The buffers used in the rotavirus assays are similar to those used in other solid-phase immunoassay systems. Animal proteins are often added to such buffers to reduce nonspecific activity. Care should be taken that the "normal" animal proteins used in rotavirus assays are free of rotavirus antibodies. Particular care should be observed in the use of proteins derived from bovine sources, since most cows contain endogenous antibodies to rotavirus proteins. Thus, blocking agents, such as neonatal calf serum, bovine serum albumin, and cows' milk, should be screened for antibodies to rotavirus proteins before they are used in rotavirus assays. The blocking assay described below is particularly suited for these measurements since it can be used to measure antibody levels in any animal species.

Commercial Assay Kits

EIA and latex agglutination kits are available commercially for the detection of group A rotavirus antigen in fecal samples. Most EIA kits are designed with polyclonal and/or monoclonal antibodies that are specific for group A rotavirus proteins, primarily VP6. At least 90 min is required to complete the test, and the results are read in a spectrophotometer. Sensitivity and specificity are generally high, averaging well over 90 and 95%, respectively. In the latex agglutination test, latex beads coated with rotavirus-specific antibody interact with rotavirus antigens in the samples. Although results can be obtained more quickly (20 min), the test is substantially less sensitive and slightly less specific than EIA in a head-to-head comparison (44).

Immunochromatography is a newer technique that is both rapid (10 min) and simple. The fecal sample, introduced at the bottom port of the device, mixes with gold particles that have an anti-rotavirus monoclonal antibody coating and is allowed to migrate along a nitrocellulose membrane for 10 min at room temperature. In the capture area, the migrating sample interacts with control (goat anti-mouse antibody) and test (anti-rotavirus polyclonal capture antibody) lines. A positive result is indicated by a red-purple line in the test area, indicating complex formation between the immunogold-labeled sample and the capture antibody. Immunochromatographic tests have performed with sensitivity, specificity, and positive and negative predictive values comparable to those of commercial EIAs (6, 44). Choosing a kit or format will depend largely on the specific needs of the laboratory, the setting in which the test is to be performed (e.g., field versus research laboratory), budgetary issues, and the availability of technical expertise and equipment.

Nucleic Acid Amplification

Rotavirus nucleic acid can also be detected in clinical samples by reverse transcription-PCR (RT-PCR) and nucleic

1. Alternate rows of microtiter plates are coated with goat anti-rotavirus Ig and an equal concentration of Ig from the serum of a goat without demonstratable anti-rotavirus anti-body.

2. The specimen is added to both wells. If a non-specific anti-immunoglobulin is present it will bind to both the goat anti-rotavirus Ig and the normal goat Ig.

3. This anti-Ig will react with the subsequent antisera leading to a reaction in both wells. If rotavirus is also present, there will be an increased reaction in the well coated with the goat anti-rotavirus Ig. If rotavirus is not present, the reaction will be equal in both wells. Since most anti-immunoglobulins are of the IgM class, the cross-reactivity can be eliminated by the pre-treatment of the specimen with a mild reducing agent.

3A. The effect of anti-Ig is reduced by the addition of normal goat serum to the specimen. If the concentration of added serum is substantially greater than that bound to the well, the anti-Ig will not bind and will be removed in the subsequent washing steps.

FIGURE 3   Cross-reactivity due to anti-immunoglobulin.

acid hybridization techniques. PCR has the greatest potential in terms of assay sensitivity and specificity; RT-PCR is estimated to be 100 to 1,000 times more sensitive than immunoassays. This technique is especially useful in identifying rotavirus nucleic acid in body fluids and environmental samples in which small quantities of virus may be present (4) and for discerning genotypes of the G and P serotypes. The principles of PCR are discussed in detail elsewhere in this manual (chapter 5).

Numerous oligonucleotide primer pairs and reaction conditions have been devised for the detection of rotavirus group-specific and species-specific genomic regions. Oligonucleotide primers derived from conserved regions of the gene encoding the group-reactive antigen VP6 can detect all available strains of group A rotavirus (48). Comparative evaluations have indicated that PCR assays involving these primers can detect rotaviruses in tissue culture and fecal samples at levels below those detectable by immunoassay methods (41). The application of this assay in clinical studies can, under certain circumstances, result in the detection of rotavirus RNA before antigens are shed in the stool in sufficient quantity to allow for immunoassay detection (43). In addition, PCR has been applied to the detection of rotavirus RNA on fomites and other environmental samples (42).

The inherent high level of sensitivity of PCR also can present a number of potential problems of which the investigator must be aware. False-positive results may occur from contamination and sample carryover. It is also theoretically possible that the assay system will not clearly differentiate between rotavirus gastroenteritis and an asymptomatic carrier state associated with the passage of low levels of rotavirus RNA. Although fecal samples can contain substances that inhibit the enzymatic reactions used in the conversion of RNA to cDNA by reverse transcription and the amplification of the cDNA by PCR, sufficiently inhibitor-free rotavirus RNA can be extracted from fecal specimens using commercial RNA extraction kits.

EIA for Determining Serotype

Two outer capsid proteins, VP4 and VP7, are the determinants of rotavirus serotype. The VP4 serotype is designated P type to indicate the sensitivity of VP4 to proteases such as trypsin. Trypsin cleavage of VP4 is necessary for rotavirus infectivity. The VP7 serotype is designated G type for the VP7 glycoprotein. Antibodies directed against VP4 and VP7 neutralize rotaviruses both in vitro and in vivo in a serotype-specific manner. Antiserum prepared against virus of one serotype tends to neutralize homotypic rotaviruses more efficiently than it neutralizes heterotypic viruses. A number of human and animal studies have shown that protection induced either by natural infection or immunization may also be serotype specific (reviewed in reference 22). As a consequence, recent epidemiological surveys have included determination of serotype in the analysis to monitor the spectrum of rotavirus strains in different populations and the emergence of new serotypes. This information is critical for developing an effective rotavirus vaccine.

Rotavirus serotypes were initially defined by cross-neutralization using hyperimmune serum against purified rotaviruses (reviewed in reference 9). Reference antisera generated from viruses with established serotype were used to type field isolates. It has been shown that this type of assay identifies VP7 serotypes to the exclusion of VP4 serotypes. This viral cross-neutralization assay is most suitable for viruses adapted to growth in tissue culture. Stool samples, anal swipes, and other clinical samples obtained directly from patients cannot be used in this assay. For these samples, EIA based on serotype-specific monoclonal antibodies to different G types is used to determine the VP7 or G serotype. Ten different VP7 serotypes have been identified from human isolates. G serotypes 1, 2, 3, and 4 are the most common serotypes associated with virulent rotavirus strains that cause diarrheal disease in humans, while other emerging serotypes, including 5, 6, 8, 9, and 10, have been isolated in different areas of the world. In recent years, some of the rarer viral serotypes have appeared more frequently in humans (16). For example, serotype 9 rotavirus has been reported to be the dominant epidemic strain in diverse populations in Asia, and serotype 8 is the dominant epidemic strain in Africa. It is not certain whether vaccines that include only serotype 1 (GSK's Rotarix [G1, P1A[8], currently in trials]) or serotypes 1 to 4 (previously licensed vaccine; Wyeth's RotaShield [G1-4] and Merck's RotaTeq [WC-3-based pentavalent bovine-human reassortments, currently in trials]) will protect vaccinated infants broadly against the strains not specifically included in the vaccine formulation (11). Therefore, it is of utmost importance that monitoring systems be in place to detect changes in rotavirus serotype and emergence of new serotypes. Commonly used VP7 serotyping monoclonal antibodies and their serotype specificity are listed in Table 1.

VP4 serotyping is substantially more difficult. Hyperimmune serum from animals immunized with purified rotavirus has low titer against VP4. It cannot be used directly to determine VP4 serotype because of interference from the predominant VP7 neutralizing antibody. Several modified methods have been devised to determine the VP4 serotype, including cross-neutralization using hyperimmune serum against reassortant viruses that have identical VP4 to the test virus but a different VP7 (15) or hyperimmune serum generated against recombinant VP4 expressed in the baculovirus system (12). Seven P types have been identified from human rotaviruses. P1A, P1B, and P2 are the most common. P1A and P1B are associated with the most virulent human rotaviruses that cause diarrhea.

Determining the VP4 serotype using monoclonal antibodies is also very difficult. Most of the anti-VP4 monoclonal antibodies that have been isolated are cross-reactive. Only a small number of monoclonal antibodies are available to detect a limited number of human and animal rotavirus P serotypes. Table 2 lists several monoclonal antibodies that have been used in EIA to determine the P types of common human rotaviruses.

An alternative to EIA-based rotavirus serotyping is rotavirus genotyping which uses RT-PCR (10) or RNA-RNA hybridization with type-specific probes (32) to compare the nucleic sequences that define VP7 or VP4 genotypes. VP7 genotype designation is identical to serotype, but VP4 genotype designation is different from serotype; the genotype is indicated in brackets. In theory, the genotype is not a direct reflection of the serotype that is defined by a specific neutralization activity. However, several of the P or G genotypes that have been identified match perfectly with the P or G serotype determined separately (examples are given in Table 2). Genotyping based on RT-PCR has been used frequently in recent epidemiological studies. A detailed discussion of rotavirus genotyping is beyond the scope of this chapter (see references 9 and 10 for more details).

Protocols for EIA

Antigen Assays

Assays to detect rotavirus antigen are performed by using the direct (Fig. 1) or indirect (Fig. 2) format. Viral antigen is most likely to be detected if fecal specimens are collected between the first and fourth day of rotavirus illness (22).

Interpretation of results. Calculate a rotavirus-specific activity by subtracting the mean activity of the specimen in wells coated with the rotavirus-negative serum from the mean activity in the wells coated with the anti-rotavirus serum. To ensure accurate quantification, specimens giving readings of greater than 1.2 optical density (OD) units should be diluted 1:10 and retested. Calculate the mean and standard deviation of the rotavirus-specific activity of the

TABLE 2 Reference viruses and a partial list of VP4 monoclonal antibodies for P serotyping

P serotype [P genotype]	Reference viruses	Monoclonal antibodies
1A[8]	Wa, Ku, YO, F45, RV-4	F45:4, 1A10
1B[4]	DS-1, RV-5, S2	RV-5:2
2[6]	ST-3, RV-3, M37	ST-3:3, HS6, HS11

negative controls. A specimen is considered positive if its mean activity is greater than 2 standard deviations above the mean activity of the negative controls. Alternatively, a specimen may be considered positive if its activity is greater than that of the weakly positive control.

If qualitative visual determinations are used, a specimen is considered positive if its color in the goat anti-rotavirus wells is more intense than its color in the normal goat immunoglobulin wells and the color of the weakly positive control in the goat anti-rotavirus wells. Note that if the β-lactamase starch-iodine system is used, a positive reaction is manifested by a decrease in color.

Antibody Assays

Binding Test for Antibody Measurement: Antiglobulin Method

To measure antibody binding, microtiter plate wells coated with purified rotavirus are contrasted with wells coated with control antigen. If purified antigen is not available, wells can be coated first with anti-rotavirus antibody and then with unpurified rotavirus. Fourfold dilutions of test samples (to a final dilution of at least 1:2,560 for serum or 1:256 for other specimens) are assayed.

Interpretation of results. For each dilution, calculate a rotavirus-specific antibody activity by subtracting the activity in wells treated with the control antigen from the activity in wells treated with the viral antigen. A dilution is considered to contain antibody if the rotavirus-specific antibody activity is equal to or greater than the rotavirus-specific antibody activity of the positive control specimen at its end point. The antibody can be more accurately quantified by extrapolating from a standard curve generated by using specimens of known specific antibody concentrations. Antibody concentrations can also be calculated from computer programs that have been developed for this purpose (35).

Measurements of IgM or IgA in serum are more accurate if excess IgG is first removed. The immunoglobulins can be separated by physicochemical or immunological methods (28).

Blocking Assay for Antibody Determination

In general, the blocking assay is used less commonly than the binding assay. The presence of antibody in a dilution is manifested by a reduction in the activity of antigen as a result of virus neutralization.

Interpretation of results. A dilution of the specimen is considered to contain antibody if it yields a value that is less than or equal to that of the positive control specimen at its end point. Alternatively, a predetermined reduction of activity, such as a fixed percentage (at least 20%) or 2 standard deviations below that in wells in which negative control serum was added, can be used to calculate the end points. If visual determinations are used, wells that have less color visibly than wells to which negative control serum has been added are considered positive for antibody.

EIA To Determine VP7 G Serotype

To prepare for the VP7 serotype EIA, hyperimmune serum against one reference rotavirus representing each of the G types should be procured. Since the conformational integrity of VP7 is dependent on binding Ca^{2+}, we recommend that all buffers used in the EIA contain Ca^{2+}. Wells are coated with hyperimmune sera against rotavirus G types 1 to 9 or with rotavirus-negative serum from the same species that

was used to produce the hyperimmune serum. A partial list of serotyping monoclonal antibodies for G types 1 to 6, 8, and 9 is shown in Table 1. The concentration of each of the monoclonal antibodies should be adjusted before use in the assay, such that comparable OD readings to those of the reference virus are achieved. If serotyping monoclonal antibodies are used to coat the wells initially, hyperimmune serum against rotavirus may be used as the detector antibody.

Interpretation of results. The serotype of a test virus is determined if OD of virus from one serotype monoclonal antibody is greater than or equal to two times the OD from antibodies of other serotypes (positive OD/negative OD ≥ 2.0).

EIA To Determine VP4 P Serotype

The protocol for the EIA to determine the VP4 serotype is similar to that for the VP7 serotyping EIA described above, except that VP4 serotyping antibodies (listed in Table 2) are used. In addition, it has been shown that the sensitivity of VP4 serotyping increases if the hyperimmune serum used to coat the plates matches the G type of the test virus. Thus, G typing should precede P typing. Sensitivity of VP4 serotyping is compromised if the fecal samples are repeatedly frozen and thawed.

NOROVIRUS

It is estimated that ingestion of contaminated food accounts for about 76 million cases of gastroenteritis and leads to hospitalization in over 300,000 cases each year in the United States (30). Of the known pathogens, viruses as a group are thought to account for at least two-thirds of these illnesses, with the largest number of cases (23 million estimated) attributable to noroviruses. Although food-borne gastroenteritis is not associated significantly with mortality, its economic impact may be considerable since ill individuals may require medical attention or days off from school or work owing to symptoms which include vomiting and/or watery diarrhea that can lead to dehydration, abdominal cramps, low-grade fever, myalgia, and headache. While the symptoms usually resolve within 1 to 3 days, virus may be shed in feces for up to 2 weeks afterward.

Norovirus, a genus of the family *Caliciviridae*, comprises a genetically diverse but related group of small, nonenveloped, plus-strand RNA viruses. In the literature prior to 2002, they were more commonly referred to as Norwalk-like viruses (after the outbreak in Norwalk, Ohio, that led to the discovery of these agents) and small round structured viruses (after their ultrastructural features).

Immunological methods have played a key role in the detection and study of the human caliciviruses, beginning with the discovery of Norwalk virus in 1972 by Albert Kapikian and coworkers (23). For this seminal work, immunoelectron microscopy (IEM) was applied to fecal extracts from a patient with a secondary case in the 1968 outbreak of gastroenteritis at a school in Norwalk, Ohio, and resulted in the visualization of the 27-nm viral agent thereafter known as Norwalk virus. Subsequently, IEM was instrumental in determining the biophysical characteristics of Norwalk virus, tracking the course of viral shedding in ill individuals, and identifying other viruses that infect the gastrointestinal tract and liver. Solid-phase immunoassays were also developed, but their widespread use was curtailed by virtue of their dependence on limited supplies of native viral antigen.

Standard virological techniques were not readily applicable to the study of Norwalk virus and other related human

caliciviruses, given that these viruses could not be propagated in cell culture or studied in a laboratory animal model (7). (The very recent description of a mouse model that supports infection by a mouse norovirus holds promise for future studies [45].) In the early 1990s, reports of cloning the Norwalk virus genome (17, 18, 29) opened new avenues of investigation and presented fresh opportunities to develop reliable diagnostic tests. Knowledge of the viral genomic sequence enabled the application of RT-PCR to detect viral nucleic acid in a variety of samples (summarized in reference 40). Data acquired over the years have allowed the classification of the noroviruses into four genogroups (GI, GII, GIII, and GIV) that can be divided into 20 or more genetic clusters. Human infections are most commonly caused by GI and GII noroviruses, representing 15 or more genotypes (reviewed in reference 13).

Expression of Norwalk virus capsid sequence in the baculovirus system was another important milestone, since it yielded large numbers of noninfectious virus-like particles (VLPs) that were easily purified from cell culture supernatant fluids (19) and had antigenic features comparable to those of wild-type virus. Subsequently, VLPs of other noroviruses have been produced (listed in reference 5). The VLPs have been used directly as antigens in EIAs to measure antibody response and as immunogens to develop serological reagents that can be used to detect viral antigen in clinical samples (reviewed in reference 20).

EIA To Detect Antigen

For antigen detetion EIAs, highly purified norovirus VLPs were used initially to immunize laboratory animals to produce polyclonal antibodies. The antibodies from one animal species (e.g., mouse) were then used to coat the EIA plate and serve as capture antibody, while the antibodies from a second animal species (e.g., rabbit) were used as the detector antibody in a sandwich EIA format. In general, the rabbit polyclonal antibodies showed high specificity for the genetic subgroup of the immunizing VLPs. More recently, mouse monoclonal antibodies that are reactive with a wider variety of noroviruses (GI and GII) have been identified. Two commercial EIAs for the detection of norovirus antigen in fecal samples, using these more broadly reactive monoclonal antibodies, have been marketed in Europe and Asia but are not currently available in the United States.

It is not clear whether these EIAs are sensitive enough to be recommended as a screening test for norovirus infection. A study from the United Kingdom (36) compared the Dako IDEIA assay and EM with RT-PCR detection of noroviurses. Compared with RT-PCR, the sensitivity and specificity of the EIA were 55.5 and 98.3%, respectively, versus 23.9 and 99.2%, respectively, for EM. To facilitate identification of the cause of a norovirus-like outbreak, six or more samples from an outbreak needed to be tested to improve the sensitivity and specificity of the EIA to 71.4 and 100%, respectively. Although these investigators suggest that this EIA may be used as a preliminary screening tool, they recommend using RT-PCR to examine samples from outbreaks that test negative by EIA and to further characterize the viral strains identified by EIA.

In a separate study, the Dako IDEIA NLV assay from the United Kingdom was compared to the Denko SRSV (II)-AD assay from Japan (5). The Dako kit demonstrated low sensitivity overall (less than 30% for six genogroup II subgroups) and high specificity (100%). The Denko kit, by contrast, had higher sensitivity, achieving a sensitivity of greater than 70% for 10 of the 14 subgroups, but lower specificity (69%). In addition, the Dako kit could distinguish between GI and GII noroviruses while the Denko kit exhibited nonspecific cross-reactivity of GI and GII noroviruses, as well as sapoviruses. As a result, these investigators were unable to recommend either of these EIA-based kits as practical alternatives to RT-PCR for the detection of noroviruses.

EIA To Detect Antibody

In contrast to EIAs that detect norovirus antigen, which tend to be more highly strain specific (estimated >95% identity in the RNA polymerase region), EIAs developed for detection of norovirus antibody have the distinct feature of being more broadly reactive, such that the presence of antibody does not necessarily indicate the individual has been infected with the specific virus represented by the VLP in the assay. It has been estimated that 70% identity to the test strain in the region of the RNA polymerase is sufficient to cause the antibody detection EIA to be positive. Although antibody to a heterologous strain of norovirus can be detected by this type of assay, homologous or more genetically closely related strains display more frequent and vigorous responses (reviewed in reference 20).

An EIA designed to measure salivary antibodies to Norwalk virus and a related outbreak strain has been reported (31). Wells of microtiter plates were coated with recombinant Norwalk virus antigen and blocked. Saliva samples were then added, and IgG- or IgA-specific antibodies were detected by a colorimetric reaction. Use of this approach to determine the cause of an outbreak has some clear advantages, including the ability to quickly and noninvasively acquire the saliva from affected individuals. It is not possible, however, to make the diagnosis on the basis of a single sample, since many people have anti-Norwalk virus salivary IgA and IgG. Two samples are required, one on day 4 (or as early in the infection as possible) and the other on about day 14, and a fourfold increase in antibody titer between the samples must be demonstrated. Compared to the antigen detection EIA tested previously by Richards et al. (36) (see above), a slightly higher sensitivity (78%) and nearly equivalent specificity (95 to 100%) were achieved. Potential applications of this test include its use in studies of epidemic and endemic infection, as well as host immune response, particularly in groups of individuals for whom it may be difficult to obtain adequate clinical material for testing.

Nucleic Acid Detection

Since the cloning of the Norwalk virus genome, methods to detect norovirus nucleic acid in clinical samples by using RT-PCR have been developed and used widely to diagnose norovirus infection. Amplicons derived by these methods can be verified by hybridization with specific probes or sequencing. Although highly sensitive, RT-PCR has been difficult to standardize for widespread use for a number of reasons (40).

First, by nature of the infection, detection of norovirus nucleic acid is performed with stool samples which may contain inhibitors to RT-PCR. Although methods to minimize the presence of these compounds have been developed, they require additional time to perform, necessitate extra handling of the sample (which may reduce the amount of antigen/nucleic acid available in the final sample), and add to the cost of the test. In addition, these methods are not standardized and vary from laboratory to laboratory (40). Assaying other materials, such as prepared food or raw shellfish through which infection may be transmitted, may require different methods to extract the virus or its nucleic acid from these matrices (27).

Second, significant sequence diversity among the multitude of norovirus strains has made it difficult to design primers that detect all strains of norovirus. As the sequences of more norovirus strain genomes have been elucidated, the ability to select primers that are more broadly reactive and useful for detecting currently circulating strains has improved. In general, primers capable of identifying a wider range of noroviruses are based on a conserved area of open reading frame 1 (ORF1) that encodes the viral RNA polymerase. Primers targeting sequences of the 2C helicase, the 5′ end of the capsid, or ORF3 tend to be more strain specific.

Third, the RT-PCR methods used most extensively to date are neither the simplest nor the fastest. Contamination of the sample is always a concern in carrying out highly sensitive tests that require multiple steps and sample manipulation. In addition, verifying the specificity of the amplicon necessitates additional analysis, including probe hybridization and variations of this technique, as well as sequencing the product.

Recent efforts have attempted to address some of these problems. A promising strategy has been the application of real-time RT-PCR, a quantitative test that permits both amplification of viral nucleic acid and detection of virus-specific amplicons, using intercalating dyes or fluorescent probes or primers. Two fluorescence techniques, in single-tube formats, are increasingly studied to detect noroviruses in clinical samples, water, and shellfish: SYBR green dye incorporation into amplicons (1, 37, 38) and the TaqMan fluorogenic detection system (14, 21).

The TaqMan assay uses virus-specific primer sets and fluorogenic probes that identify GI and GII sequences (14). The fluorogenic probes are labeled with a fluorescent reporter and quencher dye. After the probe hybridizes with the norovirus target sequence, the 5′-3′ nuclease activity of *Taq* polymerase cleaves the TaqMan probe during amplification, thus separating the quencher dye from the reporter. The increase in fluorescence intensity of the reporter is proportional to the starting copy number of the target nucleic acid and enables the quantitation of norovirus RNA when compared to a standard curve. Besides the high sensitivity of this test, other benefits of this one-tube method include the potential to screen large numbers of samples expeditiously, lower chance of sample contamination, and no need to confirm the validity of the product by additional tests. For this approach to yield reliable results, however, the probe must bind to the amplicon of interest, which presents a challenge to probe designers, given the great diversity in sequence among noroviruses. Kageyama et al. (21) sought to minimize the potential probe-binding problem by amplifying with degenerate primers (one set for genogroup I and a second set for genogroup II) a highly conserved region of the norovirus genome that spanned the junction between ORF1 and ORF2.

The strategy involving SYBR green detection, rather than TaqMan probes, has the advantage that the fluorescent dye is incorporated into amplicons and does not rely on a probe binding to a norovirus sequence that may not be sufficiently complementary. Richards et al. (37) recently were able to detect noroviruses from five genetic clusters of genogroup I and eight genetic clusters of genogroup II, which represents most of the known circulating strains of human noroviruses. They designed two sets of degenerate primers (for genogroups I and II, respectively) based on sequences from the RNA-dependent RNA polymerase region for use in a one-step, hot-start real-time RT-PCR. The highly degenerate primers necessitated increasing the time for denaturation, annealing, and extension, as well as low temperatures for optimal annealing and extension, compared

to standard RT-PCR. SYBR green is also known to intercalate into primer-dimers, as well as the amplicons of interest. To ensure proper interpretation of their test results, the authors imposed a 6-s optical read step at 77°C (after the normal 60°C extension step) for each PCR cycle to fully melt primer-dimers and other undesired products that had lower melting temperatures than the norovirus amplicon, thereby reducing the fluorescence from the nonspecific products.

Developing the optimal molecular detection assay for the highly diverse noroviruses continues to be a challenge that is being pursued by scientists throughout the world. For the present, in the United States, diagnostic testing for noroviruses is limited largely to public health and research laboratories. The Centers for Disease Control and Prevention has provided primers and reagents to state and local laboratories to facilitate their efforts in investigating outbreaks of gastroenteritis (3). The Centers for Disease Control and Prevention also maintains CaliciNet, a database of norovirus sequences from outbreaks, to facilitate the study of relationships between outbreaks and to gain more insight into the norovirus strains in circulation.

Arboviruses

ROBERT S. LANCIOTTI AND JOHN T. ROEHRIG

85

The arthropod-borne viruses (arboviruses) represent a diverse amalgam of more than 500 animal viruses that are grouped together because of their ability to replicate in both vertebrates and arthropods. While more than 150 arboviruses are known to cause human illness or infection, the list of the most medically important viruses is considerably shorter (Table 1) (8, 17, 27). Because of the vast number of agents that potentially should be considered in a differential diagnosis, the use of epidemiologic, ecologic, and clinical data to guide the choice and interpretation of clinical laboratory diagnostic tests is essential. Most arboviruses are transmitted seasonally in specific geographic locations or ecological habitats. The patient's history of travel, activities, and potential exposures to arthropods or habitats associated with arbovirus transmission provides vital data for selection of appropriate antigens and relevant diagnostic approaches. Knowledge of the patient's immunizations against yellow fever (YF), Japanese encephalitis (JE), or tick-borne encephalitis (TBE) viruses is also important for the proper interpretation of serological results. Although the laboratory diagnosis of arboviral infections still relies chiefly on serology, other approaches that directly detect viral antigen or genomic material and not antibodies are now routine.

METHODS

Antibody Detection

IgM ELISA

Assays that detect virus-elicited immunoglobulin M (IgM) are useful because they detect antibodies produced within days of a primary viral infection. IgM antibody capture enzyme-linked immunosorbent assay (MAC-ELISA) is the preferred approach to IgM detection because it is simple, sensitive, and applicable to serum and cerebrospinal fluid (CSF) samples. False-positive reactions due to rheumatoid factor also are minimized (2, 22). While most ELISAs are based on a 96-well microplate format, assays are being developed and adapted to microsphere-based systems. These new systems require very small volumes of test specimens and permit antigen multiplexing, resulting in a considerable savings of time and money (30, 31).

IgM from serum or CSF is first captured onto the solid phase with μ-chain-specific antispecies antibody. IgM

antibodies of all reactivities are thus concentrated, but during an acute infection, IgM antibodies directed at the etiologic agent are the principal circulating species. Virus antigen is next added, and if virus-specific IgM is present, viral antigen is bound to the plate. A variety of antigen sources such as virus-infected mouse brain, lysed cells, cell culture supernatant, or recombinant antigen can be employed. The bound antigen can be detected by a variety of means; however, the most practical approach is to use an enzyme-labeled antiviral monoclonal antibody. Since the reactivity of the patient's IgM with the test antigen in part defines the specificity of the assay, broadly reactive labeled antibodies can be used as detectors for most of the medically important arboviruses, e.g., monoclonal antibodies reactive against flavivirus group (6B6C-1), alphavirus group (2A2C-3), and California serogroup (10G5.4) (Table 2) (7).

Approximately 75% of patients with flavivirus encephalitis (e.g., JE or St. Louis encephalitis [SLE]) have detectable IgM in serum or CSF in the first 4 days of illness, and nearly 100% of samples are reactive by 7 days. Similar levels of sensitivity have been reported for patients with LaCrosse (LAC) encephalitis or alphavirus encephalitis and in patients with dengue (DEN) or YF. For patients with central nervous system (CNS) infections, greater sensitivity and specificity are obtained by also testing CSF.

The specificity of the MAC-ELISA is similar to that of the complement fixation (CF) test, and heterologous antibodies to related viruses may interfere with interpretation, particularly in patients with previous related infections. To improve diagnostic specificity, ratios of absorbances to related viruses can be calculated, yielding indices that are better discriminators than the individual absorbances alone. For example, antibodies to DEN and JE viruses cross-react in hemagglutination inhibition (HI) tests and ELISAs, but patients with the respective infections can be identified by calculating ratios of ELISA absorbances to the two viruses. Similarly, ratios of absorbances in IgM and IgG capture tests have a high predictive value in discriminating recent from previous infections with these viruses (5).

Although levels of IgM antibodies generally decline after 2 to 4 weeks and are absent after 90 to 120 days, IgM persists for a year or more after infection in some patients. This phenomenon has been reported for patients with JE, SLE, West Nile (WN) encephalitis, Murray Valley encephalitis (MVE), LAC encephalitis, and Sindbis and Ross River (RR) virus

TABLE 1 Characteristics of selected medically important arbovirus disease

Disease	Viral agent	Arthropod vector or source	Clinical syndrome(s)	Geographic distribution	Risk factor(s)	Case-fatality ratio (%)
EEE	Alphavirus	Mosquito	CNS infection	Eastern United States, Central and South America	Advanced age	30
JE	Flavivirus	Mosquito	CNS infection	Asian rice-growing areas	Exposure to rural areas	15–30
LAC encephalitis	Bunyavirus	Mosquito	CNS infection	East-central United States (children)	Males > females; agricultural occupations	<1
Rocio encephalitis	Flavivirus	Mosquito	CNS infection	Sao Paulo state, Brazil	Males > females; agricultural occupations	5
SLE	Flavivirus	Mosquito	CNS infection	North, Central, and South America	Advanced age	7
TBE	Flavivirus	Tick	CNS infection	Europe, Asia	Forest exposure	1–10
Powassan encephalitis	Flavivirus	Tick, mosquito	CNS infection	Canada, United States, Russia, China	Forest exposure	10
WEE	Alphavirus	Mosquito	CNS infection	Western United States, South America, Canada, Mexico	Males > females; extremes of age	5
CTF	Coltivirus	Tick	Febrile grippe	Rocky Mountain states, South Dakota, California, western Canada	Exposure to areas >5,000 ft (ca. 1,500 m) in elevation	<1
DEN	Flavivirus	Mosquito	Febrile grippe and rash; hemorrhagic fever	Tropical locations worldwide	Urban, peridomestic exposure	5
WN fever	Flavivirus	Mosquito	Febrile grippe and rash; encephalitis	United States, Africa, Europe, Asia	Advanced age	<1
Oropouche fever	Bunyavirus	Midge	Febrile grippe	Central and South America	Agricultural occupation	<1
Phlebotomus fever	Phlebovirus	Phlebotomine fly	Febrile grippe	Europe, Africa, Asia	Peridomestic exposure	<1
Chikungunya	Alphavirus	Mosquito	Febrile polyarthropathy and rash; rarely hemorrhagic fever	Africa, Asia	Urban, peridomestic exposure	<1
Mayaro fever	Alphavirus	Mosquito	Febrile polyarthropathy and rash	Central, South America	Males > females; forest exposure	<1
RR arthropathy	Alphavirus	Mosquito	Febrile polyarthropathy and rash	Australia, Pacific	Females > males	<1
Sindbis virus fever	Alphavirus	Mosquito	Febrile polyarthropathy and rash	Africa, Europe, Asia	Woodland exposure	<1
Crimean-Congo hemorrhagic fever	Nairovirus	Tick, infected blood	Hemorrhagic fever	Africa, Europe, Asia	Animal husbandry; agricultural and medical occupations	10–50
Rift Valley fever	Phlebovirus	Mosquito, infected blood	Febrile grippe; hemorrhagic fever	Africa, Middle East	Animal husbandry; butchering	<1
YF	Flavivirus	Mosquito	Febrile grippe; hemorrhagic fever	South America, West and Central Africa	Forest or rural exposure	15

TABLE 2 Selected arbovirus monoclonal antibodies for serologic and antigen detection assays[a]

Antibody[b]	Prepared against:	Reactivity	Use
6B6C-1	SLE virus (MSI-7)	Flavivirus group	As HRP[c] conjugate in antigen capture and IgM capture ELISAs
4G2	DEN virus 2 (New Guinea C)	Flavivirus group	Viral identification by IF or ELISA; ELISA capture antibody
6B4A-10	JE virus (Nakayama)	JE-SLE-WN-MVE complex	Capture antibody in antigen capture ELISA
JE314H52	JE virus (Nakayama)	JE virus specific	Viral identification by IF or ELISA
6B5A-2	SLE virus (MSI-7)	SLE virus specific	Viral identification by IF and neutralization
4A4C-4	SLE virus (MSI-7)	SLE virus specific	Capture antibody in antigen capture ELISA
4B6C-2	MVE virus (original)	MVE virus specific	Viral identification by IF or ELISA
D2-1F-3	DEN virus 1 (Hawaii)	DEN virus 1 specific	Viral identification by IF or ELISA
3H5-1-21	DEN virus 2 (New Guinea C)	DEN virus 2 specific	Viral identification by IF or ELISA
D6-8A1-12	DEN virus 3 (H87)	DEN virus 3 specific	Viral identification by IF or ELISA
1H10-6-7	DEN virus 4 (H-241)	DEN virus 4 specific	Viral identification by IF or ELISA
5E-3	YF virus (17D)	YF virus specific	Capture antibody in antigen capture ELISA
117	YF virus (Asibi)	YF wild-type virus specific	Viral identification by IF
864	YF virus (17D)	YF vaccine virus specific	Identification of vaccine strains by IF
4D9	TBE virus	Tick-borne flavivirus complex	Viral identification by IF or ELISA
H5.46	WN virus	WN virus specific	Viral identification by IF or ELISA
2A2C-3	WEE virus (McMillan)	Alphavirus group	As HRP conjugate in antigen and IgM capture ELISAs
2A3D-5	WEE virus (McMillan)	WEE complex	Capture antibody for WEE and HJ antigen capture ELISA
2B1C-6	WEE virus (McMillan)	WEE virus specific	Viral identification by IF or ELISA; as HRP conjugate in antigen capture ELISA
1B5C-3	EEE virus (NJ 60)	EEE North American virus specific	Viral identification by IF or ELISA; as HRP conjugate in antigen capture ELISA
1C1J-4	EEE virus (BeAn 5122)	EEE South American virus specific	Viral identification by IF or ELISA
1B1C-4	EEE virus (BeAn 5122)	EEE complex specific	Viral identification by IF or ELISA
2D4-1	Highlands J virus (B230)	Highlands J virus specific	Viral identification by IF or ELISA; as HRP conjugate in antigen capture ELISA
1A2B-10	VEE virus (E2 peptide)	VEE complex	Viral identification by IF or ELISA
5B4D-6	VEE virus (TC-83)	TC-83 (vaccine) specific	Viral identification by IF or ELISA
1A3A-5	VEE virus (IC)	Epizootic VEE virus	Viral identification by IF or ELISA
1A1B-9	VEE virus (IE)	Enzootic VEE virus	Viral identification by IF or ELISA
807-18	LAC virus (original)	LAC virus specific	Viral identification by HI, neutralization, or ELISA
10G5.4	LAC virus (original)	California serogroup reactive	Viral identification by ELISA

[a]Adapted from reference 19.
[b]Antibodies and/or conjugates are available from the Centers for Disease Control and Prevention.
[c]HRP, horseradish peroxidase.

polyarthropathy, and it is common in patients with YF or after YF vaccination. This observation is of diagnostic importance, because in areas where the diseases are endemic, IgM from infection during a previous transmission season could be mistaken as evidence of recent infection. For this reason, demonstration of IgM in a single serum sample alone does not necessarily indicate a recent infection. Virus-specific IgM in CSF has been detected 50 to 180 days after onset of acute JE, indicating continuing intrathecal production of antibody and the possibility of persistent CNS infection. However, these appear to be unusual cases, and in most circumstances, detection of arbovirus-specific IgM in CSF is a reliable indication of recent infection.

A practical problem in implementing the MAC-ELISA is the unavailability of positive-control sera containing IgM for all the antigens of interest. Although reactive human sera for many of the common arbovirus infections are available from the Centers for Disease Control and Prevention and other laboratories, human positive-control sera for less prevalent infections are unavailable. These laboratories can provide testing panels of serum for quality control of test performance. Unlike the HI, CF, and neutralization tests described below, in which mouse immune fluids can be used as controls, the MAC-ELISA incorporates a species-specific capture antibody and requires reactive human samples. MAC-ELISAs for agents of arbovirus encephalitis are offered by commercial reference laboratories, and a kit for TBE diagnosis is available in Europe. Commercial dot blot kits for DEN and JE are available in Asia, but their sensitivity and specificity require further characterization.

MAC-ELISAs also have been developed to detect eastern equine encephalitis (EEE), western equine encephalitis (WEE), and Venezuelan equine encephalitis (VEE) virus antibodies in horses; EEE, SLE, WEE, and WN virus antibodies in birds; and JE virus antibody in pigs. The test formats are identical to the procedure described above for human sera, except that commercially available anti-horse, anti-chicken, and anti-pig IgM, respectively, replaces the anti-human capture antibody. Horses immunized with inactive EEE, WEE, and VEE vaccines produce HI and neutralizing antibodies that cannot be readily distinguished from naturally acquired antibodies; however, IgM antibodies to

the viruses are usually detectable only after natural infection. The MAC-ELISA is sensitive when serum samples are obtained within 1 week of the onset of illness, and it is now the procedure of choice in the laboratory diagnosis of arbovirus encephalitis in horses.

Sparrows and other passerine birds are the principal amplifying hosts for SLE, WN, and WEE viruses. Serologic surveillance of wild birds and sentinel chickens is a means by which state and local health agencies monitor the risk of epidemic arbovirus transmission. Likewise, in certain areas of Asia, seroconversions in pigs are monitored in JE surveillance programs. IgM antibodies to SLE and WEE viruses in sparrows rise and fall to undetectable levels within 2 weeks of infection, and the MAC-ELISA (using commercially available anti-chicken IgM) is useful only in monitoring recent infections among sparrows. HI and/or neutralizing antibodies are still valuable indicators of more remote infections.

IgG ELISA

IgG ELISA has replaced the HI test for the diagnosis of some infections because the procedure is less cumbersome and titration curves for the two procedures are similar. Various indirect procedures to measure the levels of IgG antibodies to arboviruses differ chiefly in the procedures for antigen preparation and methods for their attachment to the solid phase. Conventional mouse brain antigens extracted with sucrose and acetone generally do not have adequate potency as antigens unless they are first captured and concentrated onto the solid phase with antibody (mouse monoclonal or polyclonal ascitic fluid) (6). Dot ELISAs, in which antigens are adsorbed to nitrocellulose or other membranes, also have been used successfully. The sensitivities of IgG ELISAs generally are similar to or greater than those of HI tests, and their specificities correspondingly are equal or lower.

IF Test

Indirect immunofluorescence (IF) tests for IgG and IgM antibodies are described in chapter 48. The procedures for arbovirus diagnosis generally use virus-infected Vero or other cells fixed onto slides in monovalent or polyvalent preparations. Commercially available spot slides with SLE, WEE, EEE, and LAC virus-infected cells make it possible to screen a serum sample simultaneously against the principal arbovirus agents of encephalitis in the United States. A similar polyvalent slide is available to screen patients with suspected viral hemorrhagic fever for antibodies against Crimean-Congo and Rift Valley fever (RVF) viruses, two strains of Ebola virus, and Lassa and Marburg viruses in a single CRE$_2$LM (derived from the names of the viruses) slide. Virus-specific IgM and IgG antibodies in CSF also can be measured by IF, although the titers generally are lower than in serum. With all indirect tests for IgM, the confounding effects of IgM rheumatoid factors should be controlled.

Indirect IF, HI, and neutralization tests have similar sensitivities, but IF is less sensitive than ELISA. The indirect IF test for antibodies to most arboviruses is as specific as or less specific than the HI test. Indirect IF cannot be relied upon to distinguish infections among the flaviviruses, among the alphaviruses, or among viruses in bunyavirus serogroups. However, the broad reactivity of IF can be exploited in screening tests and in epidemiologic studies.

HI and CF Tests

Classical serodiagnosis of arbovirus infections relied on the HI and CF tests. These technically demanding assays rely on the availability of goose or other erthrocytes and have largely been abandoned in favor of the more readily standardizable IgM and IgG ELISAs exept in the largest diagnostic reference laboratories (1). The major advantage of both the HI and the CF test is that species-specific positive-control reagents are not necessary. Consequently, more readily available, experimentally derived antiviral antibodies from mice, rabbits, or goats can be used in these tests.

HI antibodies are long-lived, and for this reason HI has often been used as a screening test, especially in serosurveys. After infection, HI antibodies rise within the first week, peak by the third week, and decline to low levels that may persist for years or decades. HI antibodies arising from a primary infection are relatively specific; however, with second and repeated flavivirus infections (superinfection), such as with DEN, YF, or JE virus, the antibody response broadens and heterologous reactions preclude differentiation of the most recent infection from previous infections. Patients with repeated exposures to flaviviruses routinely develop heterologous antibodies to agents to which they have never been exposed. Often, these heterologous reactions have titers that are equal to or higher than those of the presumed homologous reaction. More specific assays, described below, are required to differentiate these cross-reactions.

The CF test provides a level of specificity intermediate between those of HI and neutralization tests (1). CF antibody levels usually are late to rise, and in some patients they are not detectable until 6 weeks after infection. In up to one-third of proven SLE patients, no CF antibodies can be detected. Because of its insensitivity, the CF test should not be used alone as a diagnostic procedure. The test remains useful for viruses that do not hemagglutinate, such as Colorado tick fever (CTF) virus. The kinetics of the rise and fall (half-life of 2 years) of CF antibody levels can be exploited to identify infections that have occurred relatively recently, in the period after which IgM antibodies have disappeared. The test also is relatively specific in differentiating natural from vaccine-induced immunity to YF virus. Immunized patients generally do not produce detectable CF antibodies to YF virus unless they have had previous flavivirus infections.

Neutralization Test

The serum neutralization test is the most virus-specific test for serologic diagnosis and is used to confirm other serologic testing results (1). The serum dilution-plaque reduction neutralization test performed in cell culture is the standard method; however, animal, especially mouse, protection tests follow the same principle. Dilutions of heat-inactivated serum are added to equal volumes of a viral preparation, known to contain a predetermined viral input dose from previous infectivity titrations. The resulting mixtures of serum, beginning at a 1:10 final dilution, and virus (100 plaques for 35-mm-diameter wells and 25 plaques for 16-mm-diameter wells) are incubated either overnight at 4°C or for 1 h at 37°C for viral neutralization to proceed. The resulting mixtures are used to inoculate confluent cell monolayers and overlaid with a nutrient semisolid or solid medium (methylcellulose, agarose, gum tragacanth, or agar can be used); after a suitable interval (e.g., 2 to 7 days, depending on the virus), when plaques have formed, a vital stain is added to differentiate infected nonviable cells, which appear as unstained plaques, from the uninfected stained monolayer. Neutral red in agar or as a liquid solution is conventionally used, but when removable semisolid overlays are used, a permanent record of the test can be made by fixing

the monolayer and staining it with amido black or crystal violet.

Numerous variations of the procedure have been described, including (i) the use of DEAE-dextran or other cationic polymers to reduce electrostatic charges on agar that interfere with virus-cell interactions and (ii) the addition of complement or normal human or animal serum to serum-virus mixtures to increase the sensitivity of neutralization.

The last serum dilution that significantly reduces the input dose of virus is the end point (80 to 90% reduction of the plaque count in the virus control). End points in animal protection assays are calculated by the Reed-Muench or Karber method, and six animals per serum dilution should be the minimum number used.

For viruses that do not produce cytopathic effects, fluorescent focus reduction assays or their equivalent, using enzyme-labeled conjugates, can be used to measure viral neutralization. Similarly, the in situ ELISA technique described above can be applied to automate large-scale tests if 96-well cell culture panels are used.

Neutralizing-antibody levels generally rise within days of the onset of illness, peak in the second week, and decline slowly to moderate or low levels, where they persist for years and often a lifetime. The sensitivity of the test is high, usually equal to that of HI or IF tests, but, most importantly, no other approach is as virus specific.

An alternative approach to measuring the neutralizing power of a serum is the constant serum-varying virus dilution test, resulting in a log neutralization index. This procedure has fallen into disuse because it is somewhat less specific than the serum dilution method and large quantities of serum are needed.

Antigen Detection

Certain arboviruses produce a viremia of sufficient magnitude and duration that the viruses can be isolated from blood during the acute phase of illness, e.g., 0 to 5 days after onset. Epidemiologically, this is significant because during the period of viremia, the viruses may be transmitted from person to person by biting vectors. Examples of these viruses include the agents of YF, DEN, chikungunya, sandfly, RR, and Oropouche fevers. The viremia in CTF is unique because it can extend for weeks or months and infection has been transmitted by transfusion.

While VEE virus can be recovered from the throat of one-fourth of patients, person-to-person spread has not been conclusively proven. SLE virus and certain hantaviruses can be detected in urine (see below). Many encephalitogenic arboviruses can be recovered from CSF obtained during the acute phase of illness, and, rarely, SLE, JE, WEE, and EEE viruses have been recovered from blood. The virus of TBE commonly contaminates milk of infected sheep, cows, and goats, but its occurrence in human milk has not been reported.

Antigen Capture ELISA

Antigen capture ELISA has been used to directly detect antigens of YF, DEN, sandfly fever, Rift Valley fever, Sindbis, and chikungunya viruses directly in blood. In some cases, viral antigens complexed with antibody must first be dissociated by use of a reducing agent, e.g., dithiothreitol. Generally, an overnight incubation of antigen maximizes sensitivity, which approaches 10^3 PFU/0.1 ml. The sensitivity of antigen capture ELISA for YF virus is similar to that of viral isolation from cell cultures, mosquitoes, or mice and is accomplished 3 to 7 days more quickly.

Antigen capture ELISA also has proved useful in epidemiologic surveillance of arbovirus infection rates in vector mosquitoes. A single infected mosquito in a pool can be detected rapidly and cheaply by the direct detection of antigen, allowing greater flexibility and time to implement emergency vector control measures. This approach has been applied to SLE, WN, EEE, and LAC viruses (28). The SLE and EEE virus tests have been converted to a commercial dipstick format. Other arbovirus antigens have been detected directly in sandflies and ticks.

Immunohistochemical Staining

Certain arbovirus infections can be rapidly diagnosed by direct detection of virus-infected cells by IF or other histochemical techniques (see chapter 45 for a general discussion of these procedures). The various causes of potentially fatal viral hemorrhagic fever, including DEN virus, cannot be reliably differentiated on a clinical basis, and immunohistochemical examination of liver tissues is a means by which a specific diagnosis can be reached. When liver biopsy specimens from patients with suspected YF are available, ordinary histopathological examination should be supplemented with more specific immunohistochemical techniques such as indirect IF. Similarly, IF and immunoperoxidase staining of brain biopsy or autopsy specimens have been helpful in differentiating arbovirus infections such as WEE, EEE, and LAC virus infections from other causes of encephalitis.

In disseminated infections such as YF and DEN, viral antigen has been demonstrated in various sites, including myocardium and kidney (YF) and bone marrow, spleen, lymph nodes, and dermal mononuclear cells (DEN) (3).

The CTF virus is unusual because it infects erythrocyte precursors and infected erythrocytes can be detected in peripheral blood for the life of the infected cells. Examination of peripheral blood smears by IF is the most rapid approach to diagnosis and is more sensitive than serology. For patients with RR virus polyarthropathy, IF viral antigen has been found in monocytes and macrophages of synovial exudates, and it has been possible to rapidly identify infected patients by examining fluid from inflamed joints. Peripheral blood mononuclear cells are a principal replicative site for DEN virus and other flaviviruses. DEN and JE virus-infected mononuclear cells have been detected in peripheral blood by IF, and JE virus-infected cells have been found in CSF, making a specific diagnosis possible within hours of a diagnostic lumbar puncture. SLE virus-infected cells have been detected by IF in urinary sediment of some patients, and free viral particles were visualized by electron microscopy; however, virus was not recovered from urine. Patients with suspected viruria had urinary incontinence and other symptoms possibly associated with myelitis.

IF is the simplest approach to identifying viral isolates recovered from clinical samples. The source of the isolate, the rapidity and characteristics of viral growth in cell culture, and mortality patterns and average survival time in mice may provide clues to its identity; e.g., alphaviruses kill suckling mice and produce plaques in cell culture within 1 to 5 days. The basic approach to viral identification is to prepare spot slides with an infected cell culture suspension. After being dried, the slides are fixed in acetone and stained by the indirect method with a series of mouse ascitic grouping fluids, containing antibodies to various groups of arboviruses (National Institutes of Health grouping fluids) or broadly cross-reactive monoclonal antibodies (Table 2). A positive reaction to a single grouping fluid is followed by further IF and neutralization tests with monospecific ascitic

fluids or monoclonal antibodies until the virus is identified (4, 20, 21, 23, 24). Inoculated cell cultures that do not show cytopathic effects still should be tested by the aforementioned method because arboviruses may not be lytic in every cell line. Alternatively, frozen brain sections of intracerebrally inoculated suckling mice or squashes of intrathoracically inoculated mosquitoes can be stained by the same procedure. Morphologic characteristics of the isolate should be confirmed by electron microscopy, but definitive antigenic classification requires the production of a homologous antibody (immune mouse ascitic fluid) and cross-serologic tests, especially cross-neutralization tests, with antigenically related agents.

In situ ELISA combines the sensitivity of cell culture systems for viral isolation with the rapidity of ELISA to identify the amplified isolates. Virus in clinical specimens is amplified briefly by growth in cell culture in 96-well panels; after fixation, the resulting amplified cell-associated antigens are detected directly by ELISA in the same vessel. Infected cell cultures can be identified within 24 to 72 h after inoculation, depending on the titer of the inoculum and viral growth characteristics. The approach is especially useful for mass screening, such as for inhibitory effects of candidate antiviral drugs and for viruses that do not produce cytopathic effects. If a long-working-distance objective is available, the monolayer also can be examined microscopically for infected foci.

Detection of Viral Genomic Sequences

In Situ Hybridization

A general outline of the procedure for in situ hybridization is given in chapter 46. In situ hybridization has been used to identify genomic sequences of LAC virus and other bunyaviruses, SIN virus, and DEN virus in mosquitoes; bluetongue virus in sandflies; and DEN and YF virus genomic sequences in formalin-fixed, paraffin-embedded liver tissue (18).

The principal advantage of in situ hybridization over immunohistochemical detection of viral proteins is the greater stability of viral RNA than of viral protein antigens in fixed, embedded specimens. Paraffin-embedded liver samples that had been stored at ambient temperatures for 23 years still had detectable viral RNA when viral antigens were undetectable by immunohistochemical stains. Non-isotope-labeled probes, such as biotin, have been used for the detection of DEN virus in human tissues.

NAATs for the Detection of Arboviruses

A variety of nucleic acid amplification platforms have been successfully utilized for the detection of arboviruses, including standard reverse transcriptase PCR (RT-PCR) (with agarose gel analysis), real-time RT-PCR using fluorescent probes, and nucleic acid sequence-based amplification (NASBA). Each of these technologies will be described below; however, several important issues common to each approach will be presented first. In general, the sensitivity of any of the nucleic acid amplification tests (NAATs) in identifying arboviruses has been shown to be equal to or greater than that of the most sensitive viral isolation procedures (either in cultured cells or in neonatal mice) while providing equal specificity in identifying specific viruses. The dynamics of in vivo viral replication and tissue tropisms must be carefully considered so that the utility of a NAAT to a particular arbovirus can be properly applied and interpreted. For example, the encephalitic flaviviruses (i.e., WN, SLE, and JE viruses) demonstrate a short viremia which is low or absent at the time of clinical presentation of CNS symptoms. With

these viruses, the detection of virus in serum by NAAT (or any method) is typically unproductive and a negative result is not informative. Detection of virus in CSF obtained from meningitis or encephalitis patients is often better. In one study of WN encephalitis patients, virus was detected by a real-time RT-PCR in 14% of acute-phase serum specimens and 57% of CSF specimens (14). In contrast, the DEN viruses often achieve a much higher viremia of longer duration which can be detected by virus isolation or NAAT methods; as a result, NAATs are a good choice for detecting and serotyping the DEN viruses. In general, the alphaviruses demonstrate replication kinetics similar to those of the flaviviruses and are not commonly detected in acute-phase serum and/or CSF specimens, although detection is generally greater than with the flaviviruses. In contrast, NAATs have been highly successful in detecting arboviruses from tissues obtained from fatal human cases when the appropriate tissue target is known and assayed (i.e., brain tissue for WN virus, LAC or EEE virus cases, liver tissue from YF cases, etc.).

The use of NAATs for the detection of arboviruses in surveillance protocols is highly successful, in particular the testing of field-collected mosquitoes. In this application, NAATs have often demonstrated superior sensitivity compared to virus isolation or antigen detection assays. With the addition of automation, these NAAT approaches have been used to test hundreds of mosquito specimens in a single day (26). NAATs have also been successfully utilized in environmental surveillance by detecting arboviruses from tissues obtained from field-collected vertebrate hosts. Detection of WN virus in field-collected dead birds and detection of EEE virus from fatal equine cases are typical applications of this technology.

RNA Extraction and Purification

Most arboviruses have a single-stranded RNA genome, and as a result the sensitivity and specificity of all amplification strategies depend upon the efficient extraction and purification of the target RNA template. In the past, RNA extraction protocols were developed primarily in-house and suffered from inconsistency due to RNA degradation during purification; however, a variety of highly efficient RNA extraction and purification protocols which allow for more rapid, consistent, and high-volume sample processing are now commercially available. Most of these utilize a chaotropic lysis buffer for efficient solubilization and stabilization of RNA from a variety of sources, followed by binding to silica, subsequent washing, and then elution in a low-salt solution. This approach also has been automated, and hundreds of samples can be processed within a single day. The use of a chaotropic lysis buffer has also enabled the efficient extraction of intact RNA from a variety of sources, including serum or plasma, whole blood, CSF, tissues, and homogenized ticks or mosquitoes. The last are particularly useful for environmental surveillance of arboviruses.

Testing Algorithms and Interpretation

Sound testing algorithms for NAATs are necessary to ensure that results have a high degree of confidence. The most desirable testing algorithm is one in which the amplification assays are complemented by another virus detection assay, such as an alternate NAAT, virus isolation, antigen capture ELISA, or direct IF assay. At a minimum, NAAT-positive results should be confirmed by retesting using the same technology with an additional primer set. NAAT assays must also incorporate the appropriate controls to ensure against

false-positive or false-negative results. At a minimum, clinical samples should be tested in duplicate. Positive controls included in each assay should contain various levels of target RNA (high, medium, low, etc.) to evaluate the sensitivity of each test in comparison with previous tests. An internal positive control also can be very useful when specimens that may contain inhibitors of RT-PCR (i.e., blood, mosquito lysates, etc.) are tested. In all amplification-based technologies, it is essential that proper laboratory procedures be followed that prevent cross contamination of nascent samples with amplified DNA (amplicon) from previous tests, resulting in the generation of false-positive results. In general, there should be complete physical separation of pre- and postamplification laboratory space and equipment. Of particular importance is the use of several no-template (negative) controls spaced randomly throughout the assay to monitor for amplicon contamination.

RT-PCR

Standard RT-PCR-based assays (compared to the real-time assays described below) to detect arbovirus genomic sequences have been developed for a number of agents (9). These assays use either virus-specific primers or consensus primers that are designed to amplify genetically related viruses. These "first-generation" assays typically involve RT-PCR amplification followed by agarose gel electrophoresis with DNA visualization by staining with ethidium bromide to characterize the amplified DNA by molecular weight. Obtaining a DNA fragment of the predicted size is considered by some to be diagnostic. However, note that in some instances nonspecific amplification can generate DNA products with mobility on agarose gels similar or identical to that of the predicted fragment, which would lead to a false-positive interpretation of results. Greater specificity can be achieved by using sequence-specific approaches for detecting and confirming the identity of the amplified DNA, including hybridization with virus-specific probes (e.g., Southern blot, dot blot, or microtiter plate hybridization), PCR amplification with additional primers internal to the original primers (nested or seminested PCR), restriction endonuclease digestion of the DNA product, or nucleic acid sequence analysis. When consensus primers are utilized, a sequence-specific detection method such as one of those described above must be employed to specifically identify the resulting DNA, since by the design of the assay all related viruses would all be amplified. Consensus RT-PCR assays have been described for alphaviruses, flaviviruses, and the California and Bunyamwera serogroup bunyaviruses (10, 13, 19, 25). Virus-specific assays include assays for the DEN viruses; the YF, JE, WEE, EEE, SLE, MVE, Powassan, TBE, and WN viruses; the California serogroup viruses; and the RR and Ockelbo and CTF viruses.

Real-Time 5′-Exonuclease Fluorogenic Assays (TaqMan)

TaqMan RT-PCR assays combine RT-PCR amplification with fluorescently labeled virus-specific probes able to detect amplified DNA during the amplification reaction. These assays offer numerous advantages over standard RT-PCR, namely, increased sensitivity and specificity, quantitation of initial target RNA, high throughput, and rapid turnaround of results. The increased specificity of the TaqMan assay compared to that of standard RT-PCR is due to the use of the virus-specific internal probe during the amplification. The hybridization of this probe to the target sequence is detectable by the increase in fluorescence in real time. This sequence-specific detection obviates the need for any postamplification characterization of the amplified DNA. As a result, amplified DNA is not manipulated in the laboratory as occurs with standard RT-PCR, thus greatly reducing the likelihood of amplicon contamination. Real-time fluorogenic assays also offer the advantage of the ability to detect multiple targets at the same time in the same amplification reaction (multiplexing). This can be accomplished by using multiple oligonucleotide probes (up to four in some instruments) each labeled with fluorescent reporter dyes with discrete emission spectra. Several TaqMan assays for the detection of arboviruses have been described, including assays for WN, SLE, TBE, DEN, EEE, WEE, and LAC viruses (11, 14, 16, 29).

NASBA

Another amplification technology which has successfully been used for the detection and identification of arboviruses is NASBA. This approach shows some similarities to RT-PCR at the initial stages. However, there are several significant differences; namely, the reaction is isothermic (41°C); the enzymes utilized are RT, RNase H, and T7 RNA polymerase; and the final amplification product is single-stranded RNA. Amplified RNA can be detected in a sequence-specific manner either by utilizing an electrochemiluminescence probe detection format or by using a fluorescently labeled molecular beacon probe in real time. These approaches have been successfully employed for the detection of a number of arboviruses, including WN, SLE, EEE, WEE, LAC, and DEN viruses (11, 15, 32).

SELECTION AND SEQUENCE OF TESTS

The laboratory diagnosis of an arbovirus infection presents a unique set of problems because of the large number of arbovirus agents that must be considered in a differential diagnosis. The approach is simplified by first considering the viruses according to the clinical illness they produce, e.g., viruses that produce principally CNS infection, hemorrhagic fever, polyarthritis, or nonspecific febrile illnesses with or without a rash (Table 1). The geographic distribution of certain arboviruses may be restricted to certain countries or regions, and the choice of antigens to be included in a diagnostic battery can be reduced further by including only those that are relevant to the patient's history of travel and exposure. If the patient gives a history of exposure to a specific vector, the choice of antigens can be narrowed further; e.g., if the patient reports an attached tick or tick exposure, antigens of tick-borne viruses should be emphasized.

When brain or liver specimens are available from patients with encephalitis or hemorrhagic fever, respectively, the tissues should be submitted for viral isolation and detection of viral genome or antigens. The tissue should be divided, and portions should be fixed in buffered formalin for histochemical staining and frozen in liquid N_2 on dry ice or in a mechanical freezer at −70°C for viral isolation or molecular detection. If sufficient quantities are available, tissues in 10% (wt/vol) suspensions should be used to inoculate cell cultures and to intracerebrally inoculate suckling mice for viral isolation. While areas of the cerebral cortex have served as good sources of virus and antigen for many arboviruses, recent experience with WN virus suggested that more virus and antigen can be obtained from the brain stem and spinal cord. This observation is supported by the flaccid paralysis demonstrated by WN virus-infected patients.

Although a probable diagnosis sometimes can be made serologically from a single serum specimen, paired sera

should always be used when possible. In patients with a CNS infection, an accompanying CSF sample should be requested routinely. The MAC-ELISA is more sensitive when CSF samples are tested, and IgM can often be demonstrated in CSF slightly earlier than in acute-phase serum. MAC-ELISA is now the serologic test of first choice in the laboratory diagnosis of arbovirus infections because of its sensitivity and the possibility that a presumptive diagnosis can be made in an early stage of infection.

The conventional sequence of serologic testing, which is still a valid and sensitive approach, is to test paired sera to quantify a change in antibody titer. Often, an elevated titer in an acute-phase serum sample is sufficient information upon which to make a presumptive diagnosis. If heterologous reactions are present, the sera are tested subsequently by neutralization to better elucidate the cause of infection.

INTERPRETATION OF RESULTS

Serologic test results should be interpreted in the context of the clinical and epidemiologic features of the case. Heterologous antibodies from previous infections or from immunizations (namely, to YF) may interfere with the correct interpretation of a result, especially if serum specimens are tested by a single screening assay. For example, anti-SLE virus antibody may be present in people who previously were infected with DEN virus during travel or residence in tropical countries of South or Central America or Asia. Unless changes in antibody titer or specific IgM antibody levels are demonstrable or more specific tests are done, it may be difficult to differentiate these reactions. Epidemiologically and clinically, fourfold changes in serum antibody titer or the presence of virus-specific IgM in CSF confirms a recent infection.

Until the introduction of WN virus into the United States, the incidence of arbovirus infections had been low and the diseases occurred in certain geographic locations or episodically. Seroprevalence remains low, except in areas where WN virus outbreaks have been documented or where LAC virus is transmitted in an endemic pattern. Therefore, the discovery of specific arbovirus antibodies in a single serum specimen of an ill patient is likely to be associated with a recent infection. The recent introduction of WN virus into the United States has also complicated the serodiagnosis of SLE virus infections in regions where these viruses may cocirculate (12). Seroprevalence to EEE virus is the lowest among all the domestic arboviruses, and the positive predictive value of a single seroreactive serum sample for other arboviruses depends on the clinical and epidemiological circumstances of the case. For example, the majority of SLE virus infections are asymptomatic or result in mild symptoms of headache and fever. The probability of SLE in seroreactive patients without frank signs of CNS infection normally is low, but in an epidemic, seroreactions in patients with less distinctive symptoms, such as acute fever and headache, may have a high predictive value.

The interpretation of ELISA results is not standardized, and the significance of raw absorbance values has been determined by methods established in individual laboratories. Thorough evaluations of the operating characteristics of arbovirus ELISAs have been hampered by the large number of agents for which assays must be established and the scarcity of positive human specimens for rare infections. A frequently used standard for a positive absorbance value is 3 standard errors above the mean absorbance of a sample of known negative sera. An alternative approach is to calculate the ratio of the sample absorbances with test (positive) and control (negative) antibodies (positive-to-negative ratio). With the diagnosis of RR and JE virus infections, a binding index, in which the sample absorbance is expressed in units in relation to the absorbance of a known positive sample, has also been used.

The isolation and identification of an arbovirus or its antigen or viral genomic sequences in a clinical sample generally are specific evidence of a recent infection. With few exceptions, arboviruses cause acute self-limited infections without persistence or latency. Certain flavivirus infections, however, cause subacute or persistent CNS infection. A progressive degenerative infection of the brain stem and cervical spinal cord leading to paralysis and atrophy of the shoulder girdle and upper arm after infection with viruses of the tick-borne flavivirus complex has been described, and in a small proportion of patients with JE, clearance from the CNS is delayed for several months after the onset of acute illness. Experimental infection of monkeys with WN virus, another flavivirus, also results in persistent CNS infection. IgM antibodies to YF virus remain detectable in a large proportion of patients for years or decades following infection or immunization, leading to the suspicion that this flavivirus persists in some individuals. Infections with certain viruses of the *Bunyaviridae* family also are followed by persistent silent infections in animals, of which the clearest examples are the lifelong infections of rodents with Hantaan, Seoul, and Prospect Hill viruses and other hantaviruses. There is no evidence, however, of persistent bunyavirus infections in humans.

CONCLUSIONS

Arbovirus infections in the wealthy countries of the world are usually rare events. As a result, funding for research on arboviruses had fallen dramatically, resulting in only small advances and improvements in the diagnosis of arboviral infections. Two events which have shifted these priorities have occurred in recent years. One is the renewed emphasis on preparedness for bioterrorist events. Three of these arboviruses (VEE, EEE, and WEE viruses) have been classified as possible biological threats. This designation has renewed interest in rapid and sensitive diagnosis of alphaviruses. The second event was the introduction of WN virus into the Western Hemisphere for the first time, reminding us of the ease with which new and emerging infections can travel great distances. As mentioned above, the introduction of a second mosquito-borne flaviviral encephalitis virus into the United States resets the diagnostic algorithms. It will be imperative for the diagnostic virologist to keep close watch for new, faster, and more sensitive diagnostic methods which will undoubtedly result from this new level of recognition of this group of viral pathogens.

Hantavirus Infections

BRIAN HJELLE AND STEPHEN A. YOUNG

86

The genus *Hantavirus* is composed of plus-strand RNA viruses within the family *Bunyaviridae* (22, 23). The members of the genus *Hantavirus* have a tripartite single-stranded RNA genome, an enveloped virion containing two viral transmembrane glycoproteins, and a helical nucleocapsid. The individual hantaviruses each cause persistent infections of one or a small number of closely related rodent species that serve as the primary natural reservoir(s). The genomic RNA segments are named according to their size: the mRNA from the large segment, L, encodes an RNA-dependent RNA polymerase and endonuclease (200 kDa); the mRNA from the middle (M) segment encodes the precursor (GPC) for the two glycoproteins, G1 (72 kDa) and G2 (56 kDa); and the mRNA from the small (S) genomic segment encodes the nucleocapsid protein (50 kDa).

OLD WORLD HANTAVIRUSES

The genus is named for the prototypical virus species, Hantaan virus (HTNV). The disease caused by Hantaan virus, now called hemorrhagic fever with renal syndrome (HFRS), came to the attention of western medicine during the Korean war, when soldiers presented with symptoms of fever, hemorrhage, hypotension, and renal failure (6). The rodent associated with Korean hemorrhagic fever was identified when Lee and his coworkers showed that human convalescent-phase sera react with antigen in the lungs of a particular species of field mice, *Apodemus agrarius* (18). Because the mice were captured in the Hantaan river basin of Korea, the prototype virus was called Hantaan virus. Serial propagation of Hantaan virus in *A. agrarius* resulted in the first continuous source of viral antigen for laboratory testing, but the virus was later adapted to cell culture. The isolation of HTNV was followed shortly thereafter by the isolation of two other common causes of milder forms of HFRS: the European Puumala virus (PUUV) followed by the commensal rat-borne Seoul virus (SEOV), which, despite its worldwide distribution, causes disease almost exclusively in Eastern Asia (22).

Over the ensuing few years, investigators from several continents isolated additional viruses that antigenically, morphologically and genetically resembled the pathogenic strains but were known solely from their presence among field rodents. The identification of those distinctive molecular and morphologic features enabled investigators to recognize that a number of different isolates collectively could be grouped under a single genus of the family *Bunyaviridae* (23). Since then, investigators have recognized that hantaviruses fall into three major clades (groups of viruses sharing a common ancestor), based on their serologic, genetic, and epidemiologic features (22). All of the viral groups except for the shrew-borne Thottapalayam virus are carried by rodents of the family *Muridae*, but members of each clade are carried by rodents of a different subfamily: *Sigmodontinae*, *Murinae*, and *Arvicolinae*. These three groups include the New World clade, which encompasses all of the viruses that have been linked to hantavirus cardiopulmonary syndrome (HCPS or HPS) and which is associated with rodents of the subfamily *Sigmodontinae*; the Old World clade, including HTNV, which is carried by rodents of the subfamily *Murinae*; and the clade carried by voles of the subfamily *Arvicolinae*, which are indigenous to both the Old World and New World.

NEW WORLD HANTAVIRUSES

Serological surveys in the United States revealed the presence of HTNV or related virus enzootic in domestic rats as well as several autochthonous rodent species (27). Several viruses were isolated that were serologically distinct from HTNV but grouped with Seoul virus. In the early 1980s, the prototypical indigenous North American hantavirus, Prospect Hill virus (PHV), was isolated from the lung tissue of a vole, *Microtus pennsylvanicus* (P. W. Lee, H. L. Amyx, D. C. Gajdusek, R. T. Yanagihara, D. Goldgaber, and C. J. Gibbs, Jr., Letter, *Lancet* **ii:** 1405, 1982). During the 1980s, investigators detected numerous patients from the United States with evidence of past exposure to one or another hantavirus through serological surveys of healthy blood donors, but the results were difficult to interpret with the information that was available at that time (27). Attempts to identify autochthonous cases of HFRS in the New World went largely unrewarded, although a few cases caused by SEOV were eventually detected among residents of inner-city Baltimore and possible cases were also identified in coastal Brazil.

Clinicians and medical investigators reported a cluster of cases of an unexplained and frequently fatal acute illness in the southwestern United States in the spring of 1993 (20). The disease, HCPS, evolves in three stages: the prodromal, cardiorespiratory, and convalescent phases (19). Patients in the prodromal phase of HCPS most frequently report symptoms of fever, chills, myalgias, nausea and vomiting. The prodromal

phase, which usually lasts 3 to 6 days, is followed by a pulmonary phase during which the patient experiences shortness of breath and cough. Laboratory findings either at presentation or during disease progression include elevated lactate dehydrogenase and aspartate aminotransferase levels in serum, metabolic acidosis, prolonged partial thromboplastin time, hemoconcentration, leukocytosis with a specific pattern of atypical lymphocytes (immunoblasts), and highly immature granulocytes, often including myelocytes or promyelocytes in the peripheral smear (16, 19). Many patients with HCPS require intubation and mechanical ventilation to treat progressive hypoxemia due to noncardiogenic pulmonary edema. During the intubation, providers sometimes must remove impressive amounts of a flaxen proteinaceous fluid by endotracheal suctioning, as much as 1 liter per h. A significant number of patients have unmanageable hypotension that results in death.

In the midst of the original outbreak in 1993, after extensive local efforts to identify a pathogen were unsuccessful, the Centers for Disease Control and Prevention (CDC) in Atlanta tested serum samples from HCPS patients for specific antibodies against known hantaviruses, using an immunoglobulin M (IgM) capture enzyme immunoassay (EIA) and an IgG EIA. The antigen source for these assays consisted of lysates of Vero E6 cells that had been infected with HTNV, SEOV, Puumala, or Prospect Hill viruses. The low-titer and rather mixed patterns of reactivity to these four viral antigens suggested that the patients had become infected with a previously unrecognized hantavirus (20). This initial impression was confirmed when the cDNA of a newly recognized hantavirus, now called Sin Nombre virus (SNV), was amplified from the tissues of several patients by reverse transcription-PCR (RT-PCR) with consensus primers (10, 20).

Armed with genetic and serologic evidence that a new hantavirus was circulating in the Four Corners region of the United States, investigators conducted intensive trapping in the vicinity of case households in an attempt to identify a rodent reservoir for SNV. The most frequently captured rodent was *Peromyscus maniculatus* (the deer mouse), and deer mice were the most frequently serologically positive rodent captured during the initial investigation (20). The nucleotide sequence of the amplimer obtained from the lung tissue of a deer mouse captured at a case-patient's residence was nearly identical to that of the amplimer obtained from the tissues of the patient obtained at necropsy, lending further support to the hypothesis that the patient had contracted the virus from a deer mouse. This suspicion was abundantly confirmed through further investigation (13). It was not for another 5 to 6 months that virologists at CDC and the U.S. Army Medical Research Institute of Infectious Diseases first isolated SNV from the tissues of wild infected deer mice by serial passages in laboratory *P. maniculatus* and/or by direct inoculation of Vero E6 cells.

Originally, because the primary focus of the disease was the lung, the disease was termed hantavirus pulmonary syndrome (HPS). More recently, as investigators came to realize that most deaths due to SNV infection occur from declining cardiac output rather than from noncardiogenic pulmonary edema, many publications have referred to the syndrome as hantavirus cardiopulmonary syndrome (HCPS).

Several cases of HCPS that occurred outside the range of *P. maniculatus* have been investigated, leading to the recognition of three other etiologic agents in North America. These investigations revealed four known or presumed cases of HCPS due to Bayou virus that occurred in Louisiana and eastern Texas (8, 24). Investigators later determined that the predominant carrier rodent for Bayou hantavirus is the rice rat *Oryzomys palustris* (24; N. Torrez-Martinez and B. Hjelle, Letter, *Lancet* **346**:780–781, 1995). In another case, a patient from Dade County, Fla., contracted HCPS, and while the pathogen was never conclusively identified at the molecular level, the presence of a novel SNV-like agent called Black Creek Canal virus (BCCV) in nearby cotton rats (*Sigmodon hispidus*) led investigators to conclude that BCCV was the etiologic agent (15). Two hantavirus infections that were both traced to exposures in Shelter Island, N.Y., in the mid-1990s led to fatal cases of HCPS in patients from Rhode Island and New York. The etiologic virus, now called New York virus (NYV or sometimes NY-1V), is a distinctive SNV-like pathogen that is carried by island populations of white-footed mice, *P. leucopus* (11; J. W. Song, L. J. Baek, D. J. Gajdusek, R. Yanagihara, I. Gavrilovskaya, B. J. Luft, E. R. Mackow, and B. Hjelle, Letter, *Lancet* **344**:1637, 1994).

The four species of rodents that carry the viruses that are implicated in causing HCPS in the United States have a host range that encompasses the contiguous United States and a large part of Canada and Mexico. As of 1 September 2004, 49 cases of HCPS had been confirmed in Canada, with most cases occurring in the three westernmost provinces (H. Artsob, personal communication). Although most Central American countries and Mexico have reported no cases, Panama has recognized endemic cases of hantavirus infection since 2000, with a collective total of 64 cases as of November 2004 (25; J. M. Pascale, personal communication). The etiologic agent, Choclo virus, is distinct from known North and South American hantaviruses, and the associated disease is unusually mild, causing relatively little cardiac depression and an overall case fatality ratio of 15%.

The proposed existence of hantaviruses indigenous to South America was confirmed by the description of Rio Mamoré virus in pygmy rice rats (*Oligoryzomys microtis*) in early 1996 (B. Hjelle, N. Torrez-Martinez, and F. T. Koster, Letter, *Lancet* **347**:57, 1996). Subsequent surveillance for HCPS-like diseases in South America resulted in the identification of both HCPS epidemics and sporadic cases. HCPS has been detected in Argentina, Bolivia, Brazil, Chile, Paraguay, and Uruguay. One prototypical etiologic agent of HCPS, Andes virus, is phylogenetically rather more closely related to Bayou virus and BCCV than it is to SNV, and it causes a form of HCPS with increased renal involvement, similar to that described for Bayou virus and BCCV. At the molecular level, Andes virus is closely allied to and may be synonymous with forms with designations such as Oran, Bermejo, Castelo dos Sonhos, Araraquara, Lechiguanas, and Juquitiba viruses. Andes virus is the only hantavirus for which person-to-person transmission of HCPS has been described, with the first examples occurring during an outbreak in Argentina in 1996 (21). Additional subsequent examples of interpersonal transmission of Andes virus have certainly occurred but as of yet have not been reported in the peer-reviewed literature; at present it appears that sexual contacts may be at substantially increased risk of disease relative to nonsexual contacts (M. Ferres, personal communication). However, the great majority of cases in South America are sporadic cases associated with exposure to infected rodents. Collectively approximately 600 cases have been recorded in Argentina, 400 have been recorded in Chile, 350 have been recorded in Brazil, and 20 have been recorded in each of Uruguay and Bolivia since HCPS was first recognized in South America.

In 1997, investigators reported 23 laboratory-confirmed cases of a rather less severe form of HCPS in Paraguay that were linked to Laguna Negra virus, a Rio Mamoré-like virus carried by the vesper mouse (*Calomys laucha*). Serological

testing of the population during this outbreak revealed a high hantavirus antibody prevalence in the indigenous population. Although the indigenous Indians constituted a majority of the antibody-positive population, the population with Mennonite ancestry constituted the majority of confirmed HCPS cases (26). It is thought that all or nearly all of the approximately 75 cases of HCPS occurring in Paraguay were caused by Laguna Negra virus, which is closely allied to the *Oligoryzomys*-borne Rio Mamoré virus. A list of pathogenic New World hantaviruses and their primary rodent vector, disease, and geographic distribution is presented in Table 1.

CLINICAL INDICATIONS

The CDC established clinical and postmortem screening criteria for HCPS in persons with respiratory disease of unknown origin: (i) a febrile illness (>101°F [>38.3°C]) occurring in a previously healthy person, characterized by an unexplained adult respiratory distress syndrome; (ii) bilateral interstitial pulmonary infiltrates developing within 1 week of hospitalization with respiratory compromise requiring supplemental oxygen; or (iii) an unexplained respiratory illness resulting in death in conjunction with an autopsy examination demonstrating noncardiogenic pulmonary edema without an identifiable cause of death. For the diagnosis of HCPS to be confirmed, one or more of the following diagnostic markers must be positive: (i) presence of hantavirus-specific IgM or rising titers of IgG, (ii) presence of hantavirus RNA by RT-PCR, and (iii) positive immunohistochemistry for hantavirus antigen.

In practice, HCPS in its more fulminant forms presents in a very stereotypical manner, with a constellation of clinical abnormalities that has scant overlap with other disease entities (19). The clinical diagnosis of HCPS during the prodromal phase of illness is more problematic, because the clinical characteristics are so nonspecific that it is difficult to make a diagnosis on initial presentation. Other conditions that can mimic HCPS depend on the geographic region. In North America those conditions might include influenza or community-acquired pneumonia in many areas and septicemic plague in the southwestern United States, but in Latin America such conditions as dengue fever or leptospirosis may present with symptoms similar to early HCPS. Laboratory findings that may help confirm hantavirus infection progressing to hypoxemia/pulmonary edema are (i) low albumin levels in serum (<3.5 g/dl) or a decreasing albumin level in serum, (ii) thrombocytopenia (<150,000 platelets/μl) or a decreasing platelet count, and (iii) presence of circulating immunoblasts (16). While unfortunately it is uncommon for HCPS to be suspected during the prodromal phase of illness, serological tests or RT-PCR for viral RNA with peripheral blood mononuclear cell (PBMC) or blood clot RNA as the template are generally positive in all but the smallest fraction of very earliest cases (9, 12).

SPECIMENS

The specimen requirement for serological testing is blood drawn into a serum collection tube (red top) that contains no additive but is silicone coated. For ideal diagnostic purposes, the sample should be drawn at or immediately following admission, a second specimen should be drawn just before the samples are shipped for testing, and a third should be drawn 3 weeks after the first sample. For autopsy samples, heart blood should be collected in a red-top tube. The blood should be centrifuged, and the serum should be aliquoted. The aliquot used for testing can be stored at 4°C for 24 h but should be frozen at −70°C if more than 24 h will elapse before testing can be performed. The sample may be shipped either frozen or on ice pack, and such samples are not considered to be "etiologic agents" for purposes of shipment even if the patient is already known to have HCPS.

CDC HANTAVIRUS EIA

Reagents

The CDC supplies state and public health laboratories with reagents needed to perform anti-SNV IgG and IgM EIA assays (5). The IgG EIA antigen is affinity-purified SNV nucleocapsid fusion protein expressed in *Escherichia coli*, and control antigen is affinity-purified protein expressed from the vector in which the SNV nucleoprotein gene was inserted in the opposite orientation and the fusion was expressed in *E. coli* (7). The IgM EIA antigen is a gamma-irradiated lysate prepared from SNV-infected Vero E6 cells in serum diluent, and the control antigen is a gamma-irradiated lysate prepared

TABLE 1 Pathogenic New World hantaviruses and their suspected rodent hosts

Virus	Rodent host	Disease	Geographic distribution
Sin Nombre virus	*Peromyscus maniculatus*	HCPS	United States except Gulf Coast, Canada except far north
New York virus	*Peromyscus leucopus*	HCPS	Shelter Island, Long Island, N.Y. (*P. leucopus* is more widespread, but through most of its range it is a minor carrier of SNV)
Bayou virus	*Oryzomus palustris*	HCPS	Southern United States
Black Creek Canal virus	*Sigmodon hispidus* (eastern form)	HCPS	Florida
Andes virus (including variant forms such as Oran, Juquitiba, Araraquara, Pergamino Lechiguanas, Hu39641, and Bermejo viruses)	*Oligoryzomys longicaudatus* (*Oligoryzomys chacoensis* for Bermejo virus)	HCPS	Argentina, Brazil, and Chile
Laguna Negra virus	*Calomys laucha*	HCPS	Paraguay and Bolivia
Choclo virus	*Oligoryzomys fulvescens*	HCPS	Panama

from uninfected Vero E6 cells in the serum diluent. Additional reagents required for these assays include human sera positive for SNV IgG and IgM, human sera negative for SNV, and hyperimmune mouse ascitic fluid containing antibodies directed against the SNV nucleocapsid antigen (17).

IgM Test Procedure

The IgM EIA is an immune capture procedure in which specific and nonspecific human IgM is first captured using an anti-human mu chain. The wells of microtiter plates are precoated overnight with the anti-human mu chain antibody. The coated plates may be prepared weekly. The titer of each serum sample is determined in duplicate in fourfold dilutions starting at 1:100 and ending at 1:6,400. The bound anti-mu antibody captures IgM antibodies of all specificities. The plate is then washed, SNV-infected cell lysate is added to rows A through D, and lysates from the uninfected cells are added to rows E through H. The antigen binds any plate-bound anti-hantavirus-specific IgM. Bound antigen is detected in a three-step process. The first step involves incubation with an anti-SNV nucleocapsid hyperimmune mouse ascitic fluid, which sandwiches N antigen that was captured by the IgM. The second detection reagent is a horseradish peroxidase-conjugated anti-mouse IgG (heavy and light chains), and the final reagent is 2,2-azinobis (3-ethylbenzthiazolinesulfonic acid) (ABTS)–peroxide substrate. The optical density (OD) of the color reaction is read spectrophometrically.

Interpretation of IgM Test Results

Quality control measures used in each run are an IgM-positive sample run in duplicate and an IgM-negative sample run in duplicate, along with up to four samples in duplicate. The results are interpreted by subtracting the OD value of each serum dilution well without SNV antigen from the OD value of the corresponding serum dilution well that contains SNV antigen. A dilution is considered to be positive if the corrected OD value is greater than 0.1. The test is reported as positive if any dilution above 1:100 is positive. A sample that is positive only at the 1:100 dilution is not reported as positive, but the test is repeated. Quality assurance for acceptable test variation can be judged by summing the OD values of the controls in each assay and monitoring the summation over time for fluctuations in the signals.

The sensitivity and specificity of this assay are high but must be viewed with caution. There is no "gold standard" to which any HCPS serological assay can be compared. As of September 2004, the CDC listed a cumulative total of only 379 cases in the United States (http://www.cdc.gov/ncidod/diseases/hanta/hps/noframes/caseinfo.htm). Therefore, the total number of positive samples is limited, meaning that only tests with excellent specificity will have acceptable predictive value when positive. Samples collected early in the course of illness have occasionally had specific IgM that was missed by EIA, but fortunately many or most such samples can be detected by a strip immunoblot assay (SIA). Few non-HCPS patient samples have been positive for anti-SNV IgM; therefore, the specificity appears to be close to 100% and the sensitivity appears to be in the upper 90% range.

IgG Test Procedure

The IgG test is also performed in a microtiter format but is different in that the antigen preparation, the affinity-purified nucleoprotein fusion expressed in *E. coli*, is itself used to coat rows A through D. Rows E through H are coated with affinity-purified control fusion antigen expressed in *E. coli*. The

dilution scheme used for the IgG assay is identical to the IgM assay, and horseradish peroxidase-conjugated mouse anti-human IgG (heavy and light chain) is used for detection.

Interpretation of IgG Test Results

The OD value of the serum dilutions with antigen is corrected by subtracting the OD obtained from the no-antigen control well with the corresponding dilution of serum. The serum dilution is considered positive for anti-hantavirus IgG if the corrected OD value is greater than 0.2. In the IgG assay, any dilution with an OD over 0.2 is interpreted as a positive result. The sensitivity of this assay is close to 100% in samples collected late in the course of illness but is about 60% in samples collected very early in the disease process. The specificity is high, but precise numbers are not available.

COMMERCIAL HANTAVIRUS EIA

Hantavirus IgM EIA and hantavirus IgG EIA are also available commercially from Focus Diagnostics (Los Angeles, Calif.) as research use only (RUO) kits. Information regarding these kits can be obtained at the Focus Diagnostics web site (http://www.focustechnologies.com/focus/0-home/index.asp).

Reagents

Hantavirus N antigens are coated onto 12 eight-well polystyrene microwells. The antigen is a cocktail of baculovirus-expressed recombinant N proteins, derived from HNTV, SEOV, PUUV, Dobrava virus, and SNV.

Procedure for Anti-Hantavirus IgM Test

Each specimen or control serum is diluted 1:101 in IgM sample diluent. The sample diluent contains anti-human IgG and binds IgG in the samples. After incubation, the IgM conjugate is added to all of the wells, followed by substrate reagent. After 10 min, the reaction is stopped by the addition of 100 µl of stop reagent. The OD of each well is measured at 450 nm.

Procedure for Anti-Hantavirus IgG Test

Samples (100 µl) of each specimen as well as the control samples and calibrator are diluted 1:2 in sample diluent, after microwell pretreatment. The remainder of the procedure is identical to the IgM procedure.

Test Interpretation and Quality Control

The index value for all samples and controls is calculated by dividing the OD of each sample or control by the mean OD value of the cutoff calibrators. The index values of the controls should be as follows: high-positive control OD, >3.0; low-positive control OD, 1.5 to 3.0; negative control OD, <0.8. The index values of the samples are interpreted as follows: a positive sample has an index value of >1.10, a negative sample has an index value of <0.9, and samples with equivocal results have index values of ≥0.90 to ≤1.10.

SIA

Reagents

SIA is performed at the Genetics and Cytometry Division of TriCore Reference Laboratories (Albuquerque, N.M.). It is a descendent of the first specific test for anti-SNV antibodies (Western blot), developed during the 1993 outbreak of HCPS in the Four Corners region of the United States (34). The test was refined to increase its specificity over tests that used intact viral antigen preparations after epitope-mapping studies using

serum samples from SNV HCPS case-patients were incorporated into its design. The original Western blot assay used in the epitope-mapping studies was soon replaced by the first (Chiron) SIA, which used purified recombinant viral antigens that are attached to a membrane via vacuum rather than by electrophoresis (27). The Chiron SIA was supplanted by a version of the SIA that detected and distinguished anti-hantavirus antibodies of both IgG and IgM class. To make SIA test strips, investigators apply each of several antigens and control materials in separate lanes to the membrane by using a vacuum manifold, and the membrane is then cut into 1.6-mm wide strips lengthwise using a paper shredder. Affinity-purified full-length SNV N protein from *E. coli* is used to coat one band, while another band is coated with an *E. coli*-derived phage MS2 coat protein fused to an immunodominant 31-amino-acid epitope of the SNV G1 antigen. Two other bands consisting of high and low concentrations of human serum IgM or IgG are also coated onto the membrane to serve as controls to demonstrate the proper functions of the anti-human IgM and IgG antibody conjugates, respectively, as well as for the proper function of the substrates and developer solutions.

Test Procedure

The patient's serum is first diluted 1:200 into a blocking reagent that contains a 5% lysate of *E. coli* cells in which an empty pET vector (Novagen) has been induced. The mixture is incubated for 1 h or more to allow the preadsorption of any antibody that recognizes *E. coli* protein(s). Investigators apply N antigen (typically 2.4 µg/membrane), G1 fusion antigen (typically 3 µg/membrane), and the serum equivalent of 0.3 and 0.05 µl of human IgG or IgM onto each membrane before the membrane is shredded into about 40 strips for storage at 4°C. Each assay strip is a section of nitrocellulose containing, from top to bottom, Coomassie brilliant blue for strip orientation, "high-intensity" (3+) human IgM or IgG preparation, RecN T7 His$_6$ fusion protein, MS2-G1 His$_6$ fusion protein, and "low-intensity" (1+) human IgM or IgG preparation. In addition to the strip for the sample, a weak-IgM SNV-positive human serum sample and a negative human serum sample are assayed in each run. The blot is added to the serum/blocking reagent after the 1- to 4-h preadsorption interval and rocked in the reagent for 4 h or overnight at room temperature. The strips are incubated with alkaline phosphatase-conjugated goat anti-human IgG or alkaline phosphatase-conjugated goat anti-human IgM and then placed in substrate buffer with alkaline phosphatase substrate, leading to color deposition over the bands. The investigator stops the reaction with an excess of water.

Test Interpretation

The investigator considers the intensity of the color of each reactive band in the positive-control serum blot to determine whether an unknown sample is positive or negative. The criteria used in a positive test for acute HCPS are a positive IgM reaction to the nucleocapsid antigen with or without a positive IgM G1 glycoprotein and the IgG positive for both N and G1.

This assay has been used to evaluate sera from well over 200 patients who were acutely ill with HCPS. With one exception, which was also negative in the CDC EIA, the IgM assay has always been positive for the nucleoprotein fusion, including the Florida case where the hantavirus was BCCV. The IgG assay is positive in about 95% of cases. In fewer than 0.1% of cases, the IgM assay gives a false-positive result, but such false reactions typically are easily identified by considering a combination of clinical history or the (generally unchanging) results of serial SIAs, performed using serum samples collected over 2 days or more.

MOLECULAR BIOLOGY-BASED DIAGNOSIS OF HANTAVIRUS INFECTION

Two molecular biology-based diagnostic methods, both based on RT-PCR, are in common use: nested RT-PCR for detection and/or sequencing and TaqMan quantitative RT-PCR (qRT-PCR) for detection and/or quantitation of hantavirus genomes. Neither method is approved by the U.S. Food and Drug Administration, and neither method is in use in any commercial or government laboratory except for confirmatory or investigational usage. An almost unlimited number of different potential variants of both methods are available, for example involving many different published primer combinations. A representative procedure for each method is described below.

Nested RT-PCR

Because the concentration of hantavirus RNA in any particular sample can be quite low, one cannot reliably detect hantavirus genomes without conducting a second round of nested PCR (12). To conduct second-round PCR, the investigator uses primers that are internal to those used in the first round. The high abundance of inner-round PCR product lends itself to downstream manipulations of the amplimer such as cloning or sequencing.

Because the S genome is the most abundant, we recommend using primers in the S genome for routine diagnostic work. The existence of a second open reading frame is useful diagnostically because its consistent presence in SNV imposes an additional constraint on sequence variability in that part of the genome. Because SNV can vary by nearly 20% in nucleotide sequence across geographic space while encoding virtually identical proteins, it is sometimes advantageous to choose primers spanned by the S genome's overlapping open reading frames to help ensure that the template will be adequately complementary to the primers.

Reagents

To control temperatures during the RT and amplification reactions, use a Peltier-based or equivalent 96-well thermal cycler such as the ABI model 9700 GeneAmp unit. The protocol calls for four SNV-specific primers (two for the outer RT-PCR and two for the inner PCR), four nucleoside triphosphates (20 mM each; Pharmacia), 5×RT-PCR buffer (Boehringer Mannheim) for the outer reaction, 10×PCR buffer II (with 15 mM MgCl$_2$) for the inner reaction, 0.2-ml thin-walled snap-cap test tubes for PCR (Fisher), β-mercaptoethanol (Sigma), avian myeloblastosis virus reverse transcriptase (Boehringer Mannheim), and AmpliTaq (Roche) (12). Before storage, the following primers are diluted in aliquots to 100 µM and stored frozen:

Har S 167+: 5′ AGC ACA TTA CAG AGC AGA CGG GC (outer RT-PCR)

Har S 190+: 5′ AGC TGT GTC TGC ATT GGA GA (inner PCR)

Har S 401−: 5′ TAG AAT GTA GAG TCC GAT GGA (inner PCR)

Har S 423−: 5′ GGA TAA TCG GTA ATG CAA AAC T (outer RT-PCR)

All manipulations of all reagents should be carried out exclusively with plugged pipette tips. Great caution must be

taken to separate pre-PCR from nesting from post-PCR steps, including use of separate pipetters, pipette tips, and bench spaces or hoods.

Test Procedure

The most commonly used nested RT-PCR protocols are those using one-tube systems for the first-step (outer) RT and PCR procedures. The term "one-tube" indicates that all of the reagents needed for both the RT and amplification reactions are placed into the same tube initially and the tube is neither transferred nor opened until it is time to perform the nesting reaction. There is some loss of sensitivity, negligible for most diagnostic applications, relative to separately preparing a cDNA reverse transcript and later utilizing that cDNA for PCR, but because a one-tube system does not require that low-abundance cDNA templates be manipulated, it also greatly reduces the chances of PCR contamination.

RNA preparations should be made from human serum or plasma by using kits designed to prepare RNA from substances with a low abundance of nucleic acids, such as the Qiagen viral RNA miniprep kit. When using tissues or cultured cells as the source of viral RNA, the investigator should use kits intended for samples containing significant amounts of RNA, such as the Qiagen RNeasy kit or the BioChemika Ultra RNA isolation kit (Sigma), as recommended by the manufacturer. The equivalent of about 5 to 25 µl of plasma should be used for each RT-PCR. If one is using RNA prepared from tissues, PBMC, or cultured cell lysates, one should use 0.1 to 0.5 µg of RNA per RT-PCR. The final concentration of RNA should be adjusted so that those quantities can be delivered in 5 µl. At minimum, a positive-control RNA, a negative-control RNA and a negative-control water sample are subjected to RT-PCR.

The investigator prepares for the assay by preparing a cocktail or master mix of reagents in advance, using a sufficient volume to conduct two or three more assays than are needed, to compensate for mechanical losses due to pipetting. The reagents are added to the master mix in the following order: water to take the final volume of each tube to 50 µl, 5× Boehringer RT buffer, 3.5 µl of 25 mM MgCl$_2$, 0.5 µl of β-mercaptoethanol, 0.5 µl of 20 mM each deoxynucleoside triphosphate mix, 0.25 µl of 100 µM each outer primer, 5 U of reverse transcriptase, and 2.5 U of AmpliTaq polymerase. The investigator then adds 45 µl of master mix to each 200-µl thin-walled PCR tube, followed by 5 µl of RNA. After brief trituration of the contents with the pipette the PCR tube is placed into the thermal cycler that is programmed to expose the sample to an RT step (1 h at 42°C) followed by 30 cycles at 95°C (10 s), 55°C (10 s), and 72°C (15 s), followed by a single extension step of 72°C for 10 min and then reduction to "soak" temperature at 4°C until the sample can be processed for the nesting step.

For the nesting reaction, the investigator prepares a cocktail as above but containing enough water to bring the final volume to 50 µl, 10× PCR buffer II (Roche), 0.5 µl of 20 mM deoxynucleoside triphosphate mix, 0.25 µl of each 100 µM inner primer, and 0.5 µl of AmpliTaq polymerase per tube, with enough volume to prepare two or three extra tubes. After returning all of the stock buffers, enzymes, and reagents to the freezers, the investigator distributes 48 µl of the cocktail into each 0.2-ml snap-cap thin-walled PCR tube and then transfers 2 µl of the outer product into the new tube. The reaction is allowed to proceed through amplification as described in the previous step, except that no RT step is included. The outer product is stored at 4°C until the assay has come to a satisfactory ending, in case there is a failure of the nesting reaction.

After the second round of amplification, the investigator adds 5 µl of 10× loading buffer to each tube, runs the entirety of each 50-µl PCR product on a 1.5% submarine agarose gel for 1.5 h at 100 V in Tris acetate-EDTA (TAE) buffer, and stains the gel with ethidium bromide to visualize the PCR product under UV light. Using the S-genomic primers listed above, the investigator should expect a 211-bp PCR product to arise from positive samples. In many cases the product of nested RT-PCR is of sufficient abundance that it can be subjected to sequencing or cloning.

Interpretation of Test Results

Viral RNA is present in samples from patients with SNV infection only during the acute phases of infection, specifically the prodrome phases and early in the cardiorespiratory phase. In later phases of illness, viral RNA becomes increasingly less abundant until it is undetectable, usually within 7–12 days after hospitalization. With serum samples as the source of RNA, an investigator using nested PCR can detect viral genetic material in about 70% of acute-phase samples. The fraction of positive samples approaches 100% when one uses PBMC RNA templates collected within 1 to 5 days of hospitalization, and similar sensitivities are encountered when using lung or kidney samples collected at necropsy (10, 12). A smaller fraction of serum samples are positive when Andes virus is the etiologic agent.

Because RT-PCR assays are positive only transiently in the course of SNV infection, RT-PCR and qRT-PCR will probably remain relegated to secondary or confirmatory assays relative to serologic assays. They are of use primarily for molecular epidemiology, such as identification of the emergence of new virus genotypes or serotypes in a region (nested RT-PCR) or for studies of pathogenesis (qRT-PCR) (see below).

TaqMan Quantitative RT-PCR

Compared to nested RT-PCR, qRT-PCR has somewhat diminished sensitivity, at about 3,000 to 5,000 RNA copies/µl of blood compared to ~2 to 5 copies/µl, but despite this limitation the sensitivity of qRT-PCR in detection of viral genomes in patient samples is more modestly reduced at 50 to 60% compared with ~70% for nested RT-PCR.

qRT-PCR (TaqMan) assays are conducted with instruments such as the ABI model 7000 sequence detection system. One-tube systems are not available or are not reliable. While it is possible to conduct qRT-PCR assays by using random hexamer primers, for hantavirus assays one must appose the positive effects of hexamers (priming of the reverse transcriptase enzyme) against their negative effects (inhibition of the subsequent PCR amplification). There is no concentration at which hexamers can be added that isolate the positive effects at the expense of the negative effects. Furthermore, in some cases the primers used in PCR are less efficient in priming the RT step than in priming the *Taq* polymerase; for that reason, it is recommended that primers used in the RT step should lie external to those used in PCR (2).

Primers with melting temperatures well suited for qRT-PCR can be predicted by using programs such as PrimerExpress (ABI). Two systems for qRT-PCR have been promulgated in the real-time RT-PCR literature: those that detect the increase in abundance of a product that is detected through intercalation of a dye, SYBR green, and those that detect the production of a product by virtue of the associated degradation of a probe that lies between the primers on an amplimer (TaqMan). This chapter discusses only the latter method, since it has performed with reasonable sensitivity and specificity in the detection of SNV RNA in our laboratory and we have not similarly evaluated intercalating dyes (1–3).

To use TaqMan RT-PCR, one begins by producing a cDNA product without further amplification using RT, and then continues by conducting PCR in the presence of an excessive amount of a single-stranded DNA oligodeoxynucleotide probe that lies internal to the primers used for PCR The probe, labeled with both fluor and quencher moieties, competes for hybridization to one strand of the amplimer, but in the course of PCR it is increasingly degraded as the concentration of amplimer increases. The probe is degraded because, as *Taq* polymerase encounters it in hybridization to a strand of the amplimer, it uses an endonuclease activity to break the probe into shorter fragments, thus liberating the reporter fluor from the quencher. The sequence detection system instrument continuously (in real time) interrogates each tube by using light and simultaneously monitors the intensity of light of the wavelength emitted in response by the fluor. After the intensity of the emission wavelength exceeds a predetermined threshold level, the sample is called positive for hantavirus RNA and the number of amplification cycles required to reach that threshold level is recorded. The positive reaction is always scored during the phase of exponential amplification, which helps ensure that the inverse log-linear relationship between the threshold cycle value (minimum number of cycles needed to score the sample as positive) and the input copy number remains close.

An investigator can establish a parallel standard curve using a template molecule of known concentration and thus determine the absolute quantity of S segment RNA in a sample. While it is possible to determine the absolute number of copies of hantavirus RNA in a sample and express that number relative to the quantity of total RNA in the assay tube or the volume of serum used, such a determination is beyond the scope of this chapter and is not necessary to render a diagnosis of hantavirus infection.

Procedure for the TaqMan Assay

The investigator uses the two-step TaqMan Gold RT-PCR protocol as recommended by the manufacturer (ABI), subjecting each sample to triplicate testing. For the RT, 5 μl of template RNA derived from a 140-μl plasma sample is mixed with the S-segment coordinate-167 sense primer 5′ AGCACATTACA-GAGCAGACGGGC in a volume of 100 μl at 25°C for 10 min, 48°C for 30 min, and 95°C for 5 min. Then 5 μl of cDNA is removed for subsequent PCR. The S-segment primers used for the PCR step are the coordinate-179 sense primer 5′ GCA-GACGGGCAGCTGTG and the coordinate-245 antisense primer 5′ AGATCAGCCAGTTCCCGCT. The fluorescent probe, labeled with fluor FAM and quencher TAMRA (Perkin-Elmer Applied Biosystems) is a positive-sense oligonucleotide at coordinate 198 of the S genome, 5′ (FAM) TGCATTGGA-GACCAAACTCGGAGAACTT (TAMRA) 3′. All oligonucleotides are used at a final concentration of 200 nM. After an initial step in which the reaction is heated for 10 min at 95°C, PCR is conducted through 40 repetitions of 95°C for 10 s, 50°C for 10 s, and 72°C for 30 s. A standard curve containing dilutions ranging from 50 to 5×10^7 copies of template can be used optionally on each 96-well plate, should exact quantitation be desired. If not, a single low-copy-number template representing 5 or 50 copies of template can be used as the positive control and a no-RNA sample and an uninfected-human-serum RNA preparation control can be used as the negative control sample.

Filoviruses and Arenaviruses

JAMES E. STRONG, ALLEN GROLLA, PETER B. JAHRLING,
AND HEINZ FELDMANN

87

Emerging viral infections have recently captured the interest and concern of the general public. This concern stems in part from the revelation that exotic viral disease agents, such as the viral hemorrhagic fever (VHF) viruses, are significant human pathogens with the potential for introduction into populations of the industrialized world either through international travel or through potential bioterrorism (4, 13). It is feared that the highly virulent nature of some of these infections, coupled with a potential for aerogenic transmission to a susceptible population and with inadequate diagnostic and therapeutic strategies, could result in a major epidemic.

The VHF-causing filoviruses and arenaviruses have been a particular focus of discussion, given their high lethality and, in the case of Ebola virus (EBOV) and Lassa virus (LAS), previously demonstrated introductions into countries where they are not endemic. They are classified as biosafety level 4 (BSL-4) and have been deemed to be category A bioterrorism agents (http://www.bt.cdc.gov/Agent/Agentlist.asp). Although exotic to many parts of the world, filoviruses and arenaviruses are important public health problems in parts of Africa and South America. Patients with these infections frequently present with similar, nonspecific clinical signs resembling malaria, typhoid, and pharyngitis. Early diagnosis is critical to timely implementation of specialized patient isolation and clinical management procedures and limited therapeutic intervention with, for example, hyperimmune globulin (South American arenaviruses) and ribavirin (arenaviruses).

The need for sensitive, specific viral diagnostics and for having procedures in place to handle such agents is essential for the correct identification and containment of outbreaks of VHFs. Travel histories have historically been important in deciphering etiologies. Events occurring since 11 September 2001, including the anthrax scare, have raised the possibility of potential bioterrorism including utilizing these VHFs in countries where they are not endemic. Outbreak management in rural African or South American hospitals, in cases of natural epidemics, has its own challenges. Clinicians here must always keep a high index of suspicion and rely on the clinical and epidemiological information available to set in motion a train of events including the cautious collection of appropriate samples for sophisticated virologic investigations. The World Health Organization (http://who.int/csr/don/en/) and several other organizations, such as ProMed, provide up-to-date information on outbreaks including those from VHFs. The mobilization of adequate logistics to permit the collection, transport, and processing of clinical specimens and other laboratory samples presents numerous difficulties in remote areas of rural Africa and South America. These technical and logistic questions remain of paramount importance to the physician practicing in remote rural populations as well as to those responsible for epidemiological surveillance and public health in countries at risk.

Since the procedures for initial isolation, clinical management, and virologic diagnoses of patients with suspected arenavirus and filovirus infections are similar, these taxonomically distinct viruses are discussed together in this chapter.

VIRAL AGENTS

Arenaviridae

The family *Arenaviridae* comprises at least 23 viral species within the single genus *Arenavirus* (Table 1). All arenaviruses share a unique morphology when observed in thin section by electron microscopy (EM). They are round to pleomorphic and range in size from 50 to 300 nm (mean, 110 to 130 nm) (Fig. 1A). The genome consists of two single-stranded, negative-sense RNA segments, designated large (L) and small (S). Each segment encodes two different proteins in two nonoverlapping reading frames of opposite polarities (ambisense coding strategy) separated by an intergenic noncoding region with the potential to form hairpin structures. The L segment encodes the viral RNA-dependent RNA polymerase (L) and the zinc binding protein (Z); the S segment encodes the nucleoprotein (NP) and the glycoprotein precursor that is posttranslationally cleaved into GP-1 and GP-2 (5, 32).

Both serology and phylogenetic analyses divide the arenaviruses into two complexes. The first group includes the Old World complex with *Lymphocytic choriomeningitis virus* (LCMV) and the Lassa viruses, including a number of apparently benign LAS-like strains from Mozambique, Zimbabwe, and the Central African Republic. All of these have been isolated from rodents of the family Muridae (Table 1). The second group includes the Tacaribe or New World complex with the four South American VHF-causing arenaviruses *Junin* (Argentine HF) (JUN), *Machupo* (Bolivian HF) (MAC), *Guanarito* (Venezuelan HF) (GTO) and *Sabia*

TABLE 1 Characteristics of arenaviruses

Classification	Acronym	Geographic distribution	Reservoir species	Human disease	Year discovered
New World					
Junin	JUN	Argentina	*Calomys musculinus*	Argentinian hemorrhagic fever	1958
Machupo	MAC	Bolivia	*Calomys callosus, C. laucha*	Bolivian hemorrhagic fever	1963
Sabia	SAB	Brazil	?	Brazilian hemorrhagic fever	1993
Guanarito	GTO	Venezuela	*Sigmodon alstoni, Zygodontomys brevicauda*	Venezuelan hemorrhagic fever	1989
Tacaribe	TCR	Trinidad	*Artibeus* spp. (bats)	Unknown	1956
Cupixi	CPX	Brazil	*Oryzomys gaeldi, O. megacephalis*	Unknown	1998

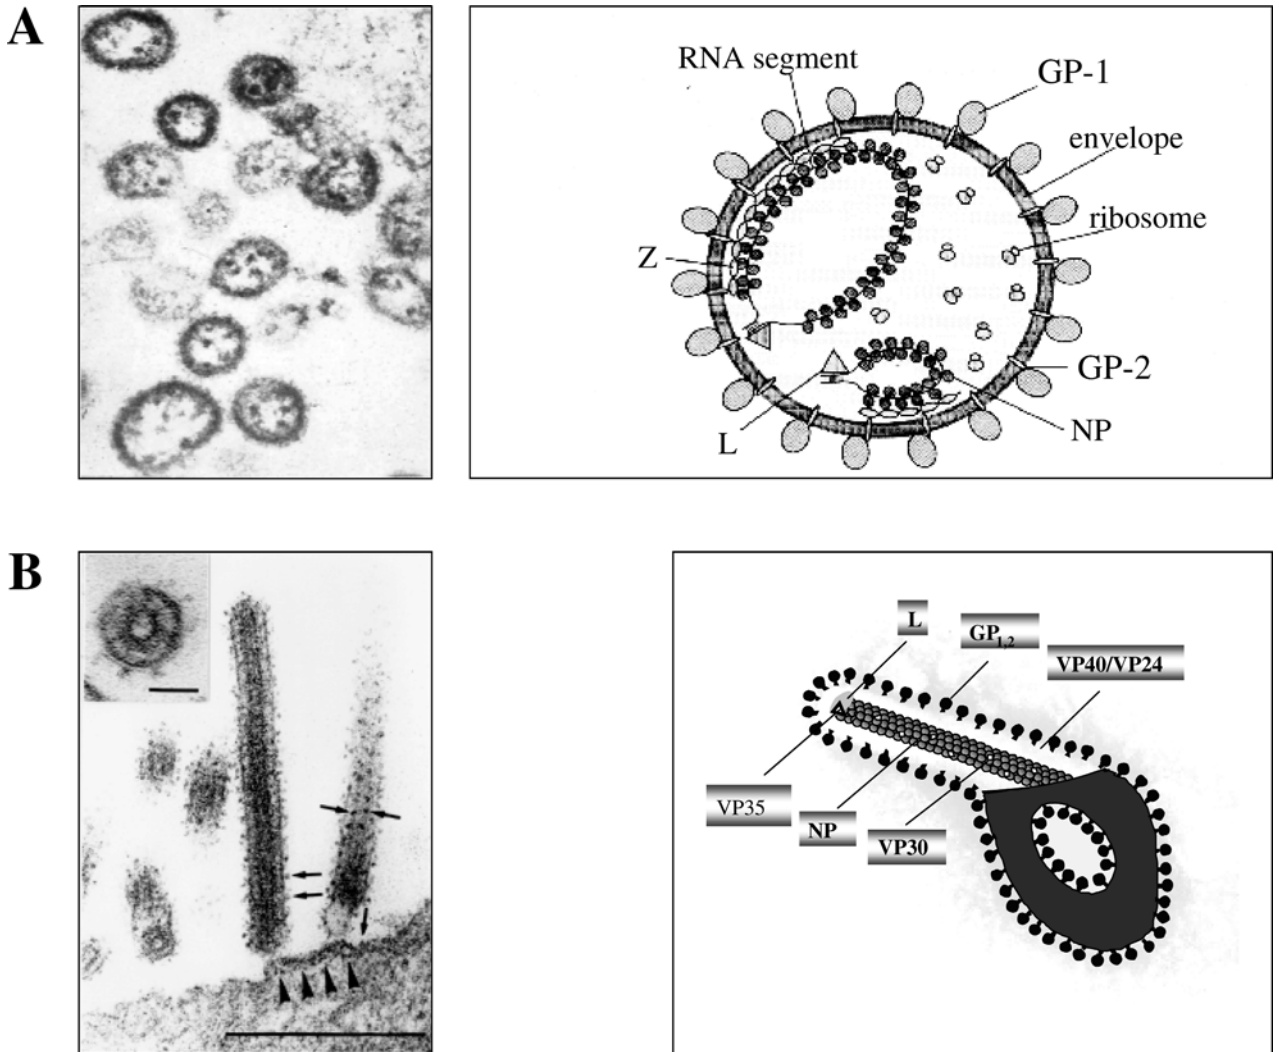
Whitewater Arroyo	WWA	New Mexico, California	*Netoma albigula*	Adult respiratory distress syndrome	1996
Tamiami	TAM	United States	*Sigmodon hispidus*	Unknown	1970
Bear Canyon	BCN	California	*Peromyscus californicus*	Unknown	2002
Pichinde	PIC	Colombia	*Oryzomys albigularis*	Unknown	1967
Pirital	PIR	Venezuela	*Sigmodon alstoni*	Unknown	1997
Flexal	FLE	Brazil	*Oryzomys* spp.	Unknown	1975
Parana	PAR	Paraguay	*Oryzomys buccinatus*	Unknown	1965
Allpahuayo	ALL	Peru	*Oecomys bicolour, O. paricola*	Unknown	2001
Oliveros	OLV	Argentina	*Bolomys obscurus*	Unknown	1996
Latino	LAT	Bolivia	*Callomys callosus*	Unknown	1965
Pampa	PAM	Argentina	*Bolomys* spp.	Unknown	1997
Old World					
Lassa	LAS	Nigeria, Ivory Coast, Guinea, Sierra Leone	*Mastomys* spp.	Lassa fever	1969
Lymphocytic choriomeningitis	LCM	Europe, Americas	*Mus musculus, M. domesticus*	Meningitis/encephalitis and congenital defects	1933
Mopeia	MOP	Mozambique	*Praomys* spp., *Mastomys natelensis*	Unknown	1977
Mobala	MOB	Zimbawa, Central African Republic	*Praomys* spp., *Mastomys natelensis*	Unknown	1983
Ippy	Ippy	Central African Republic	*Arvicanthus* spp.	Unknown	1970


FIGURE 1 Morphology of virus particles. (A) Arenaviruses. Arenaviruses are round to pleomorphic enveloped particles with a bisegmented, single-stranded, negative-sense RNA genome. Two proteins are involved in nucleocapsid formation: RNA-dependent RNA polymerase (L) and nucleoprotein (NP). The glycoproteins (GP-1 and GP-2) form the spikes on the virion surface. The Z protein functions as the matrix protein. Ribosomes are usually incorporated during particle maturation. (B) Filoviruses. Filoviruses are filamentous enveloped particles with a nonsegmented, single-stranded, negative-sense RNA genome. Four proteins are involved in nucleocapsid formation: RNA-dependent RNA polymerase (L), nucleoprotein (NP), virion structural protein 30 (VP30), and VP35. The glycoprotein ($GP_{1,2}$) forms the spikes on the virion surface (arrows in electron micrograph). VP40 functions as the matrix protein; VP24 is membrane associated.

(Brazilian HF) (SAB) viruses. All New World complex viruses have been isolated from rodents of the family Cricetidae, or, in the case of *Tacaribe virus*, from bats (Table 1). The Old and New World complexes are distantly related; only when very high-titer antisera are used can cross-reactions be observed. The use of monoclonal antibodies with specificities for structural proteins of arenaviruses suggests that the nucleoprotein is the group-reactive determinant while the envelope glycoproteins (GP-1 and GP-2) are responsible for type specificity (6, 32).

All arenaviruses are maintained in nature by establishing chronic viremia in their reservoir host (almost exclusively rodents) and are transmitted to humans through contaminated animal excreta or occasionally bites. Person-to-person transmission (secondary infection) also occurs with LAS and less frequently with the South American VHF-causing arenaviruses (5, 32).

LAS is the etiologic agent of Lassa fever, a West African VHF (Table 1). The original outbreaks described were hospital associated, occurring first in Nigeria in 1969 and later in Liberia, Sierra Leone, and the Republic of Guinea. Different percentages (8 to 52%) of the population of this area are seropositive. LAS is now recognized to persist in endemic foci, and the true incidence of human Lassa fever is thought to be thousands to tens of thousands per year. Among hospitalized patients with Lassa fever, the mortality

rate is currently estimated to be 15 to 20%. Overall mortality, including subclinical cases identified serologically, is substantially lower, perhaps less than 1%. Arenaviruses serologically related to yet distinct from LAS have been isolated from rodents in Mozambique (Mopeia virus), Zimbabwe and the Central African Republic (Mobala virus, Ippy virus). These viruses have not been associated with naturally occurring human disease and may, in fact, elicit protective immunity against virulent LAS infection.

JUN, the causative agent of Argentine HF (AHF) (Table 1), was first isolated in 1958, although the disease had been recognized since 1943 in Argentina, where it has been associated with annual outbreaks primarily among agricultural workers. From 1958 to the present, annual fluctuations in AHF cases range from 100 to 3,500, with several hundred cases occurring in most years. Since the recent introduction of a live attenuated vaccine for JUN in Argentina, the annual incidence of disease now numbers 10 to 100 cases. The mortality rate for patients with laboratory-confirmed AHF who do not receive specific immune plasma therapy is reported to be 14 to 17%. The vesper mouse, *Calomys musculinus*, is considered the primary reservoir because it was the most commonly trapped rodent in the area of endemic infection and because persistent viremia and virus shedding via saliva have been shown both in naturally infected and laboratory-infected animals (5, 6).

MAC, the etiologic agent of Bolivian HF (BHF) (Table 1), was first isolated in 1963, although reports of sporadic outbreaks began in 1959 and a series of devastating epidemics occurred from 1962 to 1964; these involved more than 1,000 patients and had an 18% mortality rate. Another severe outbreak occurred in Cochabamba, Bolivia, in 1971 and was associated entirely with nosocomial spread from an index case apparently infected in the region of endemicity. Following a long quiescence, Machupo virus reemerged in Bolivia in 1994, in association with a small outbreak. The reservoir of MAC is the rodent *Calomys callosus,* and the infection most often affects agricultural workers during spring and summer (5, 6).

GTO was first recognized in association with an outbreak of HF thought initially to be dengue fever in Venezuela in 1989 (Table 1). During 3 years of epidemiologic surveillance, from September 1989 to December 1991, 88 cases of VHF were documented, with a fatality rate of 34%. The Venezuelan virus was first discovered in a zone in which tropical forest was removed to permit the establishment of small farms and ranches. Apparently, a local rodent species that carries the virus found the cleared areas hospitable and multiplied in proportion to the increased food supplies available in fields and houses. Since then, only sporadic cases have emerged, causing a lower percentage of deaths. All cases were in rural areas, and the cotton rat, *Sigmodon alstoni*, is the major host and natural reservoir of GTO. As with the other arenaviruses, transmission from rodents to humans is thought to relate primarily to contact with food, water, or air contaminated with rodent urine. Person-to-person transmission is uncommon (5, 6).

SAB was isolated from a patient with a fatal case of VHF thought initially to be yellow fever in Brazil in 1993 (Table 1). During characterization of this virus, a laboratory technician became infected, probably via the aerosol route; he eventually recovered. This virus once again infected a virologist in 1994. The emergence of both GTO and SAB and the initial confusion with other viral fevers including dengue and yellow fever illustrate the importance of developing specific, definitive diagnostic tools for these agents (5, 6).

Filoviridae

Marburg virus (MARV) and EBOV are classified in the order *Mononegavirales*, family *Filoviridae*. The family *Filoviridae* consists of the genera *Marburgvirus* and *Ebolavirus*. The *Ebolavirus* genus is subdivided into three distinct African species, *Ivory Coast ebolavirus* (ICEBOV), *Sudan ebolavirus* (SEBOV), and *Zaire ebolavirus* (ZEBOV), and a single Asian species, *Reston ebolavirus* (REBOV). Serologically, MARV and EBOV strains are distinct. EBOV species have some epitopes in common, responsible for the serological cross-reactivity observed in broadly reactive tests (9).

Filovirus particles are bacilliform but can also appear as branched, circular, U-shaped, 6-shaped, and long filamentous forms (Fig. 1B). They have a uniform diameter of approximately 80 nm but vary greatly in length. Negatively contrasted particles, regardless of serotype or host cell, contain an electron-dense central axis (19 to 25 nm in diameter) surrounded by an outer helical layer (45 to 50 nm in diameter) with cross-striations at 5-nm intervals. This central core is formed by the ribonucleoprotein complex, which is surrounded by a lipid envelope derived from the host cell plasma membrane. Spikes of approximately 7 nm in diameter and spaced at about 5- to 10-nm intervals are seen as globular structures on the surface of virions (9, 33).

Virus particles contain a nonsegmented single-stranded negative-sense linear RNA genome that does not contain a poly(A) tail and is noninfectious. Virions are made of seven structural proteins with presumed identical functions for the different viruses. Four proteins make up the ribonucleoprotein complex (NP, virion protein 35 [VP35], VP30, and L), together with the viral RNA, while the remaining three proteins are membrane associated (glycoprotein [$GP_{1,2}$], VP40, and VP24). The single type I transmembrane glycoprotein ($GP_{1,2}$) is inserted in the envelope as a homotrimer and functions in receptor binding and fusion; VP40 has been identified and characterized as the matrix protein, but the function of VP24 is unknown. EBOV expresses a nonstructural soluble glycoprotein (sGP) as the primary gene product of the glycoprotein gene, which is efficiently secreted from infected cells; its functions remain unknown (9, 33).

MARV and the species ICEBOV, SEBOV, and ZEBOV are indigenous to Central Africa in an area approximately between the 10th parallel north and south of the equator as indicated by the locations of known outbreaks and seroepidemiologic studies (Fig. 2). The geographic range of EBOV may extend to other regions in Africa, for which adequate serosurveys are lacking. In 1994 ICEBOV was isolated in West Africa during an outbreak of HF among wild chimpanzees in the Tai Forest. Before that, the identification of REBOV suggested for the first time the presence of a filovirus in Asia that may be associated with wild nonhuman primates (8, 33). Since 1995, reports have been accumulating of EBOV infection in great apes (chimpanzees and gorillas) in Gabon and the Republic of Congo, in which 80% of the world's population of these great apes are found. It is predicted that in some regions the gorilla population is threatened by extinction. Understanding the maintenance strategy of filoviruses in nature is essential to prediction of their emergence and to their control.

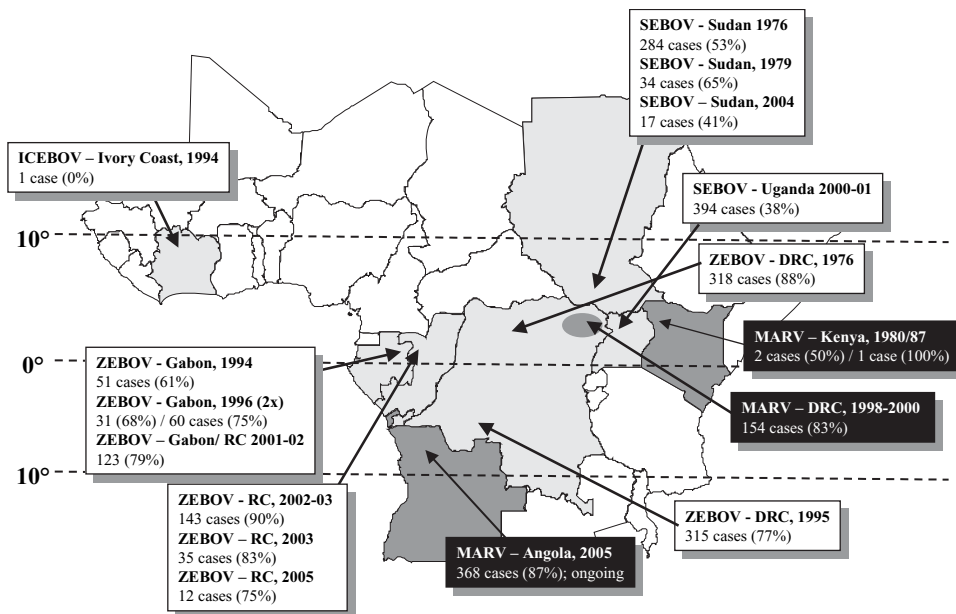
Many outbreaks have been traced to index cases, in which an infected person probably came into contact with an as yet unidentified reservoir. It is likely that monkeys do not serve as reservoir hosts since their pathogenicity is similar to our own. However, nonhuman primates may serve as the intermediate host of some outbreaks, such as has been demonstrated in the Republic of Congo. The reservoirs are


FIGURE 2 Filovirus outbreaks in Central Africa. Reported outbreaks of HF caused by MARV (dark gray) and EBOV (light gray) in the affected countries are indicated with the corresponding year, case numbers, and percentage lethality. DRC, Democratic Republic of the Congo; ICEBOV, Ivory Coast ebolavirus; RC, Republic of the Congo; SEBOV, Sudan ebolavirus; ZEBOV, Zaire ebolavirus.

likely to be other mammals, birds, or invertebrate species including mosquitoes and ticks. Bat species are currently the most favored candidate due to some epidemiologic links and experimental studies demonstrating replication of EBOV in bats. From the index case, transmission among humans is principally due to direct contact, such as among family members but also from infected patients to nurses, doctors, and other health care workers (8, 10, 33).

CLINICAL ASPECTS

Arenaviruses

Initial symptoms of the VHF-causing arenaviruses are rather nonspecific and follow an incubation period of 2 to 16 days. Patients experience an insidious or sudden onset of progressive fever (that may be biphasic), chills, malaise, generalized myalgias and arthralgias, headache, anorexia, and cough. Most patients have a severe sore throat and may have epigastric pain, vomiting, and diarrhea. Typical physical findings are not distinctive; they include nonspecific conjunctival injection, facial and truncal flushing, petechiae, purpura, ecchymoses, icterus, epistaxis, gastrointestinal and genitourinary bleeding, and lymphadenopathy. Severe illness is associated with hypotension and shock, relative bradycardia, pneumonitis, pleural and pericardial effusions, hemorrhage, encephalopathy, seizures, coma, and occasionally death.

For LAS infection, fever and myalgia develop insidiously between 3 and 16 days after exposure and increase in severity during the following week. Lassa fever patients usually come to the hospital within 5 to 7 days of onset, with sore throat, severe lower back pain, and conjunctivitis. Pneumonitis and pleural and pericardial effusions with friction rub frequently occur. A maculopapular rash may develop, but although Lassa fever is grouped with the hemorrhagic fevers, frank hemorrhage is seen only in a small proportion of the more severe cases. Death, due to sudden cardiovascular collapse as a consequence of hepatic, pulmonary, and myocardial damage, occurs in the second or third week in approximately 15 to 20% of hospitalized patients. Although few Lassa fever patients develop central nervous system (CNS) signs, tinnitus or deafness may develop as recovery begins. Lassa fever is a particularly severe disease among pregnant women, for whom mortality rates are somewhat higher. Swollen-baby syndrome describes severe Lassa fever in infants and toddlers, with anasarca, abdominal distension, and spontaneous bleeding, but pediatric disease otherwise is no different from that observed in older patients. Clinical laboratory studies are usually not helpful for Lassa fever; specific virological diagnosis is required (5, 30).

The clinical pictures for AHF (JUN) and BHF (MAC) are well characterized; for VHF caused by GTO and SAB, less information is available. However, all these infections are sufficiently similar to each other to be discussed as a single entity, South American HF. Incubation periods range from 7 to 14 days, and very few subclinical cases are thought to occur. Following a gradual onset of fever, anorexia, and malaise over several days, constitutional signs involving gastrointestinal, cardiovascular, and CNS symptoms become apparent by the time patients present to the hospital. On initial examination, AHF and BHF patients are febrile, acutely ill, and mildly hypotensive. They frequently complain of back pain, epigastric pain, headache, retro-orbital pain, photophobia, dizziness, constipation or diarrhea, and coughing. Vascular phenomena, including flushing of the face, neck, and chest, as well as bleeding from the gums, are common. Enanthema are almost invariably present; petechiae or tiny vesicles spread over erythematous palate and fauces. Neurologic involvement, ranging from mild irritability and lethargy to abnormalities in gait, tremors of the upper extremities, and, in severely ill patients, coma, delirium, and convulsions, occurs in more than half of the patients. During

the second week of illness, clinical improvement may begin, or complications may develop. The latter include extensive petechial hemorrhages, oozing from puncture wounds, melena, and hematemesis. These manifestations of capillary damage and thrombocytopenia do not result in life-threatening blood loss. However, hypotension and shock, complicated by gross hemorrhaging, may develop, often in combination with serious neurologic signs in the 15% of patients who die. Survivors begin to show improvement by the third week. Recovery is slow; weakness, fatigue, and mental difficulties may last for weeks. In contrast to Lassa fever, clinical laboratory studies are frequently useful. Total white blood cell counts usually fall to 1,000 to 2,000 cells/mm^3, although the differential remains normal. Platelet counts fall precipitously, usually to 25,000 to 100,000/mm^3, and occasionally lower. Routine clotting parameters are usually normal or slightly deranged, but in severe cases, evidence of disseminated intravascular coagulation (DIC) is apparent (6, 30, 36).

Filoviruses

MARV and EBOV infections are clinically similar. MARV HF manifests after an incubation period of 5 to 10 days, with a sudden onset of marked fever, chills, headache, and myalgia. Patients may develop a maculopapular rash, most prominent on the trunk (chest, back, or stomach) on the fifth day after onset of symptoms. Nausea, vomiting, chest pain, sore throat, abdominal pain, and diarrhea may then appear. Symptoms become increasingly severe and may include jaundice, pancreatitis, severe weight loss, delirium, shock, liver failure, massive hemorrhaging, and multiorgan dysfunction. The hemorrhaging may be the result of a combination of DIC and hepatic failure. Uveitis has occurred following MARV infection, after a 2-month asymptomatic period, and may persist for several weeks. MARV has been cultured from the anterior chamber of the eye following such infection (29, 33).

Human infections with ZEBOV, SEBOV, and ICEBOV follow similar courses and typically include incubation periods of 2 to 8 days in primary cases to slightly longer in secondary cases. Cases with longer incubation periods of 19 and 21 days have been observed. The onset of clinical symptoms is often sudden, and clinical findings depend on the stage of disease at which patients present. Early in the disease, symptoms include pharyngitis, severe headache, arthralgias or myalgias, fever, anorexia, and asthenia, followed by gastrointestinal symptoms, including abdominal pain, nausea and vomiting, and diarrhea later in the course. There may be mucous membrane involvement including conjunctivitis with effusions, odynophagia or dysphagia. Chemical hepatitis without clinical jaundice is usual, and multiple organ systems become involved. A characteristic maculopapular rash develops over the trunk. Petechiae, mucous membrane hemorrhages, and bleeding from multiple sites along the gastrointestinal tract are occasionally accompanied by uncontrollable bleeding from venipuncture sites. Although the mechanism is unclear, hiccups have been noted in fatal cases of ZEBOV in both the 1976 and the 1995 outbreaks in the Democratic Republic of Congo. Terminally ill patients often are normothermic, obtunded, anuric, tachypneic, and in shock. Late in the disease, patients often develop an expressionless hippocratic face—"the mask of death." Myocarditis and pulmonary edema also are seen in the later stages of the disease. Development of shock occurs soon before death, often 6 to 16 days after onset of illness (29, 33).

Early nonvirologic laboratory studies are nonspecific and often unavailable in an outbreak setting. These include thrombocytopenia and leukopenia with pronounced lymphopenia. After several days, neutrophilia occurs and may be associated with elevations in aspartate aminotransferase and alanine aminotransferase levels. Hyperbillirubinemia can occur. Prothrombin and partial thromboplastin times are prolonged, with the notable presence of fibrin split products, particularly in MARV disease. Platelet counts decline to 50,000 to 100,000/mm^3 during the hemorrhagic phase. Later in the clinical course, elevated blood urea nitrogen and serum creatinine levels occur in association with the onset of anuria. Also, secondary bacterial infections may occur later in the course, with associated elevation of the white blood cell counts. Metabolic acidosis with compensatory hyperventilation can develop in terminally ill patients.

COLLECTION AND PREPARATION OF CLINICAL SAMPLES

Special precautions and equipment are required for the safe handling of diagnostic specimens obtained from patients suspected of being infected with arenaviruses and filoviruses (www.who.int/entity/csr/resources/publications/biosafety/ WHO_CDS_CSR_LYO_2004_11/en [*Laboratory Biosafety Manual*], http://www.cdc.gov/od/ohs/biosfty/biosfty.htm [*Biosafety in Microbiology and Biomedical Laboratories*]). Current recommendations are that samples from such infected patients be manipulated only at the maximum biological containment level, BSL-4. In the field, personnel caring for patients and obtaining diagnostic specimens should wear disposable caps, gowns, shoe covers, surgical gloves, and masks; full-face respirators equipped with high-efficiency particulate air (HEPA) filters are preferable. Suggestions for reducing the risk of handling patient samples prior to shipment to a BSL-4 laboratory are detailed elsewhere (28; see also the websites given above). For transport of infectious material, specimens should be packaged in accordance with international regulations (International Air Transport Association [IATA] [http://www.thecompliancecenter.com/forms.htm]) and forwarded, after consultation, to a specialized national or international reference laboratory that maintains diagnostic capability for these agents. With a few exceptions, these are BSL-4 facilities; Table 2 lists laboratories that are organized in the International High Security Laboratory Network (IHSLN).

For virus isolation, serum or plasma (or, less ideally, whole blood) obtained during the acute, febrile stage of illness should be frozen on dry ice or in liquid nitrogen vapor. Storage at higher temperature may be unavoidable in some circumstances but leads to rapid loss in infectivity. Throat washings and urine specimens should also be collected and mixed with a buffered diluent containing protein (e.g., 10% fetal bovine serum or normal rabbit serum) before being frozen. Specimens collected for viral isolation are also suitable for testing by antigen capture enzyme-linked immunosorbent assay (ELISA); maintenance at −20°C for periods up to several weeks is adequate for antigen preservation. Impression smears of infected tissues may be fixed by immersion in cold acetone and stored frozen for viral antigen staining by direct immunofluorescence assay (DFA). Formaldehyde-fixed tissues and paraffin-embedded blocks are also suitable for immunohistochemical (IHC) identification of viral antigens. Blood obtained in early convalescence for serodiagnosis may be infectious despite the presence of antibodies and should be handled accordingly. Maintenance of samples at −20°C or below is sufficient to preserve antibody titers and antigenicity, but lower

temperatures are required to preserve infectivity. Citrate and oxalate should be avoided as anticoagulants because of interference with the indirect immunofluorescence assay (IFA) and nonspecific cytopathic effect in Vero and MA-104 cells used for virus isolation. Heparin seems to be the best anticoagulant for antibody and antigen detection systems, and EDTA is the best for PCR diagnostics.

LAS is frequently isolated from acute-phase sera and throat washings for several weeks following onset of clinical signs, but it is only occasionally isolated from urine. Sera obtained as late as 15 days after onset have yielded LAS. JUN is usually recoverable from serum for 3 to 10 days after onset and is often recoverable from throat washings for a similar period but is rarely recovered from urine. MAC is recovered from only one of five acute-phase sera and even less frequently from throat washings or urine. MARV and EBOV are usually recoverable from acute-phase sera; various specimens including throat washings, urine, soft tissue effusates, semen, and anterior eye fluid have yielded these viruses, even when the specimens are obtained late in convalescence (Fig. 3). LAS, MAC, JUN, MARV, and EBOV are all readily isolated from spleen, lymph nodes, liver, and kidneys obtained at autopsy but rarely, if ever, are recovered from brain or other CNS tissues. Notably, LAS is usually isolated from the placentas of infected pregnant women.

All arenaviruses and filoviruses are readily inactivated by ethyl ether, chloroform, sodium deoxycholate, and acid media (pH less than 5). β-Propiolactone and gamma irradiation (on dry ice) are both reported to inactivate viral infectivity while preserving reactivity in standard serologic and antigen detection tests. RNA extraction medium containing guanidinium isothiocyanate in general inactivates viral infectivity but has only been experimentally proven for some commercially available extraction buffers (unpublished data). It should be noted that arenaviruses and particularly filoviruses can be stable at room temperature for several hours to days. In the field, infectivity of samples may be greatly reduced, if not totally inactivated, by the addition of sodium dodecyl sulfate (SDS) and Triton-X-100 (0.1% SDS; 0.1% Triton X-100) and treatment with heat (60°C for 30 min). Treated specimens may subsequently be safely used in serologic or antigen detection assays.

DIAGNOSTIC PROCEDURES

The differential diagnosis of HF, especially in individual patients, presents considerable difficulties. Although the VHF-causing viruses are the most worrisome infectious agents in regard to public health and case patient management, bacterial, fungal, and protozoal infections must also be considered. Severe sepsis syndromes with DIC and shock diatheses caused by any infectious agents also should be included in the differential diagnosis. Complicating matters is the possibility of noninfectious entities (including acute leukemia, lupus erythematosus, thrombocytopenia of various etiologies, and hemolytic-uremic syndromes) as well as combinations of these infectious and noninfectious entities.

Laboratory diagnosis can be achieved in two ways, measurement of host-specific immune responses to the infection and detection of viral antigen and/or genomic RNA (Table 3). Because of the presence of high titers of infectious virus in blood and tissues even during early stages, antigen and nucleic acid detection plays the most important role in early detection of VHF infections caused by arenaviruses and filoviruses. Here the assays of choice would be the antigen capture ELISA and reverse transcription-PCR (RT-PCR).
FIGURE 3 Time line for diagnostic sampling. The scheme demonstrates an approximate time line for sampling and testing of EBOV-infected patients. The numbers indicate days after onset of symptoms.

With the development of more sensitive tests, such as the immunoglobulin M (IgM) capture ELISA and the direct IgG test, antibody detection has become more valuable in early diagnosis but is still considered second line for acute diagnostics (Fig. 3). Electron microscopy has been particularly useful in the diagnosis of filovirus infections in the past but can also be applied for arenaviruses. IHC on formalin-fixed material and paraffin-embedded tissues as well as DFA on impression smears of tissues can be used for viral antigen detection. Virus isolation from serum and/or other clinical material should always be attempted in tissue culture (e.g., Vero or MA-104 cells). However, most filoviruses and arenaviruses do not cause extensive cytopathic effect on primary isolation. Isolation attempts in animals frequently fail due to a lack of susceptibility of the most commonly used small-animal models and are thus less valuable.

In the following sections, the current commonly used diagnostic procedure are discussed under the headings of "Detection of Viral Antigen and Nucleic Acid" and "Detection of Virus-Specific Antibodies." Furthermore, a few additional procedures are discussed. Figure 4 presents an outline of the important steps from clinical to laboratory-confirmed diagnosis.

Detection of Viral Antigen and Nucleic Acid

Antigen Capture ELISA

The development of antigen capture ELISAs for quantitative detection of viral antigen in clinical specimens has facilitated

TABLE 3 Laboratory diagnosis

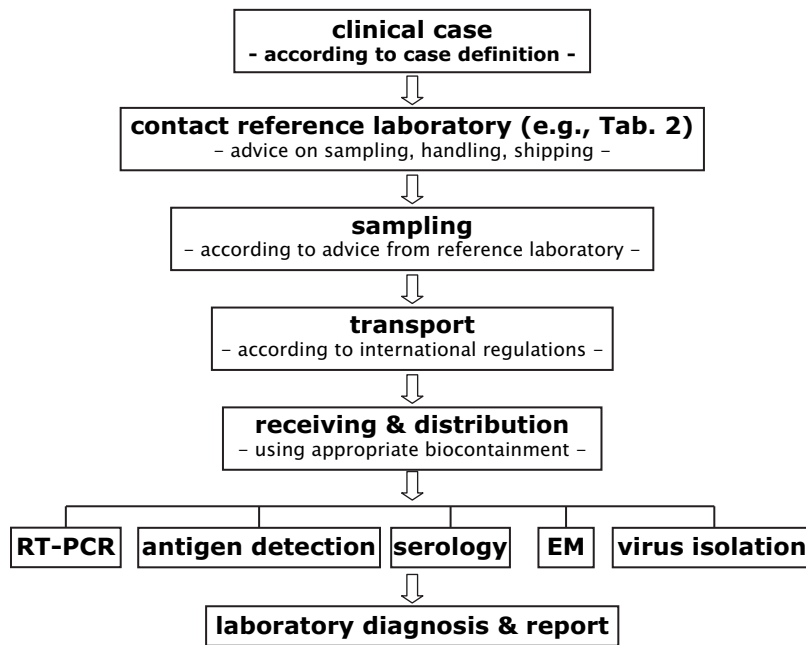
Test	Target	Source	Remarks
Detection of viral antigen/nucleic acid			
Antigen capture enzyme-linked immunosorbent assay	Viral antigen	Blood, serum, tissues	Rapid and sensitive, but requires special equipment
Reverse transcription-PCR (RT-PCR)	Viral nucleic acid	Blood, serum, tissues	Rapid and sensitive, but requires expensive and special equipment
Direct fluorescence assay (DFA)	Viral antigen	Tissues (e.g., liver)	Rapid and easy, but prone to subjective interpretation
Immunohistochemistry (IHC)	Viral antigen	Tissues (e.g., skin, liver)	Inactivated material, but requires time
Detection of virus-specific antibodies			
Enzyme-linked immunosorbent assay (ELISA)	Antiviral antibodies	Serum	Specific and sensitive, but initial response is slower than indirect immunofluorescence assay
Indirect immunofluorescence assay (IFA)	Antiviral antibodies	Serum	Simple to perform, but prone to nonspecific positives and subjective interpretation
Neutralization test (NT)	Antiviral antibodies (neutralizing activity)	Serum	Specific, but requires time
Additional diagnostic procedures			
Virus isolation	Viral particle	Blood, tissues	Virus available for studies, but requires time and biocontainment
Electron microscopy (EM)	Viral particle	Blood, tissues	Unique morphology (immunostaining possible), but insensitive and requires expensive equipment


FIGURE 4 Diagnostic flowchart. For further information, see the text.

the early detection and identification of these agents and is both sensitive and specific (3, 16, 20, 23, 26). These tests reliably detect antigens in samples inactivated by either β-propiolactone or gamma irradiation; thus, they can be conducted safely without elaborate BSL-4 facilities. The threshold sensitivities for these assays are approximately 1.3×10^2 to 3.2×10^2 PFU/ml; therefore, they are sufficiently sensitive to detect antigen in most acute-phase VHF viremias, as well as virus concentrations in late-phase throat wash and urine samples. The antigen capture ELISA developed for EBOV serves as a generic model for antigen capture ELISAs for both arenavirus and filovirus groups (20). The assay is a double-sandwich capture ELISA. Plates are coated overnight with a mixture of monoclonal antibodies and washed, and unknowns are added in fourfold dilutions. Following incubation and wash steps, polyclonal antibodies (mainly rabbit serum) against the virus to be tested are added, and the plates are incubated and washed; an anti-species antibody (e.g., anti-rabbit IgG) is then added. Color development, by the horseradish peroxidase-ABTS [2,2'-azino-di-(3-ethylbenzthiazoline sulfonate)] system, is proportional to the quantity of viral antigen captured on the plate.

A few researchers have developed and compared antigen capture ELISAs by using monoclonal versus polyclonal antibodies against various EBOV proteins. The antigen capture ELISA developed by Ksiazek et al. (20) uses a pool of five mouse monoclonal antibodies for coating. Others use NP or VP40 and/or GP-secific specific monoclonal antibodies (23, 26). Most published antigen capture ELISAs use polyclonal rabbit serum for detection. Polyclonal antisera often show higher sensitivity and avidity than do monoclonal antibodies. On the other hand, monoclonal antibodies may have the advantages of higher specificity and availability in unlimited amounts of the same quality.

In the REBOV epizootic setting, very close concordance was obtained between conventional isolation and the antigen capture ELISA techniques. The suitability of this test for use with clinical materials from human patients with ZEBOV was also validated during the 1995 Zaire outbreak. Similar formats have been devised and tested for LAS and JUN. For LAS, good correlation with viral isolation was found for serum samples collected in West Africa, provided that the infectious virus titers exceeded 1.3×10^2 PFU/ml. Substitution of monoclonal antibody of high avidity and appropriate specificities for polyclonal sera generally increases the sensitivities and specificities of these antigen capture ELISAs. However, monoclonal antibodies with broad cross-reactivities are potentially useful for the development of a general pan-arenavirus detector system.

RT-PCR

Nucleic acid detection assays based on PCR have been developed as very useful tools for rapid, definitive diagnosis of most VHF infections. The procedures for performing this assay vary and are sometimes performed through the use of commercially available kits. The process starts with an RNA purification step. Most commonly, total RNA is extracted from clinical specimens with commercially available RNA extraction kits on the basis of denaturation using a monophasic solution of guanidine thiocyanate, thus inactivating the infectious material. At this stage, the specimen can be removed from biocontainment and processed in a standard molecular diagnostic setting under BSL-2 conditions.

The RT and amplification steps are ideally performed in a one-tube system to simplify handling and avoid cross-contamination. Several commercial kits are available and perform more or less equally well in amplification. Alternate PCRs can be set up by designing primer sets against specific areas of the viral gene of interest. The presence of amplification products of the appropriate size when run on agarose gels confirms the presence of RNA from the original sample. It is strongly recommended that a positive PCR result be confirmed by determination of the amplicon DNA sequence and amplification of a second target gene. The sequence information can be used for further phylogenetic analyses.

More recently, real-time PCR methods for rapid nucleic acid detection have been developed which allow for online evaluation. The systems also can be used for quantitation, which becomes important for the evaluation of treatment protocols. Several methods are available at present to monitor the amplification process. A sequence-specific fluorogenic probe(s) can be incorporated into the amplified products and detected through 5′ nuclease action or fluorescence resonance energy transfer, or fluorescent dyes (SYBR Green I) can intercalate into the amplified double-stranded DNA nonspecifically. This method requires a further "melt curve analysis" to verify the identity of the amplified products. In general, these methods eliminate the need for agarose gels and thus limit the potential for contamination.

There are many assays available, and specific details can be obtained from the appropriate publications (see references 7, 22, 34, and 35). Assays can be set up for the detection of a group of viruses such as the Old World or New World arenaviruses or members of a genus such as *Ebolavirus* or *Marburgvirus*. Many assays target the nucleoprotein gene (thought to be the most abundant viral RNA species in infected cells) or polymerase gene (thought to be the most highly conserved genome region). For virus-specific assays, the glycoprotein gene, the most variable genome region, is preferred. Figures 5 and 6 provide examples of real-time RT-PCR analysis for filoviruses and arenaviruses based on methods developed in our laboratory (unpublished data).

Amplification of DNA is prone to several drawbacks, notably the serious potential of cross-contamination and, thus, false-positive results. Several of the conventional RT-PCR assays include a second-round amplification (nested PCR), which can increase the sensitivity and specificity of the amplification reaction but is particularly prone to template contamination due to the inherent need for opening first-round reactions, exposing the environment to amplification products prior to the last amplification step. Because of this potential, most researchers advocate the use of a second independent RT-PCR targeting a different region of the genome, an independent extraction of RNA, or a confirmatory test based on a different technique such as the antigen capture ELISA. Another potential problem with PCR-based diagnostics is the considerable genetic variability of these viruses, which must be accounted for when designing oligonucleotide primers and probes. This problem is enhanced when multiple primer-probe combinations are necessary for real-time assays and a failure of one component to properly hybridize gives a false-negative result. The use of novel agents and strains also provides a situation where PCR-based techniques may fail due to the specificity inherent in the reaction, a situation that has arisen in the past and promises to arise again.

A side-by-side comparison of standard single-round and nested RT-PCR and real-time RT-PCR (34) demonstrated that the real-time RT-PCR detection systems might be more sensitive than standard RT-PCR. The threshold for detection by standard single-round RT-PCR was approximately 10^5 genomic-sense RNA copies per ml. Nested RT-PCR assays from the Gulu Sudan EBOV outbreak demonstrated a threshold of detection of approximately 10^4 copies per ml. The one-step real-time RT-PCR method demonstrated a sensitivity of detection to the level of approximately 10^3 copies per ml. The sensitivity of PCR can be much higher than that of antigen detection (antigen capture ELISA) or virus isolation. However, it must be remembered that the volume of clinical sample which is actually tested in the RT-PCR analysis is quite small, usually between 1 and 10 μl (our

standard is approximately 3 μl of serum or blood); thus, the concentration of infectious virions in the clinical material must exceed 500/ml to expect a positive RT-PCR signal.

An RT-PCR has also been evaluated by using sera from two small series of Lassa fever patients from West Africa (35). The sensitivity by RT-PCR relative to conventional viral isolation was 82%, and the specificity was 68%. The RT-PCR assay was positive for more of the disease course than was isolation, perhaps a reflection of the early antibodies associated with acute Lassa fever. These results predict good success with detection of LAS in tissue samples obtained at autopsy, although this has not been field tested. Likewise, various strategies for RT-PCR have been devised to detect JUN and MAC RNA in clinical materials (22). RT-PCR strategies also exist for GTO but remain to be field tested. The sensitivity of the JUN RT-PCR is reported to be 1 infected cell in a population of 10^4 (22).

DFA

To process infected cells for DFA examination and presumptive identification, inoculated cell monolayers are dispersed by trypsinization, diluted in phosphate-buffered saline containing 10% calf serum, washed, and resuspended in phosphate-buffered saline to a final concentration of 10^6 cells/ml. Small drops (10 to 20 μl) of cell suspensions are placed onto circular areas of specially prepared epoxy-coated microscope slides, cleaned previously by immersion in ethanol followed by polishing to remove residual oily deposits. These "spotslides" are air dried, fixed in acetone at room temperature for 10 min, and either stained immediately or stored frozen at −70°C until used. Note that although acetone fixation greatly reduces the amount of infectious intracellular virus, spotslides prepared in this manner should still be considered infectious and handled accordingly. Spotslides are usually rendered noninfectious by gamma radiation, with no diminution in fluorescent-antigen intensity reported; this treatment is recommended if the appropriate equipment is available. Alternatively, infected cells may be biologically inactivated with β-propiolactone.

For DFA tests, specific immune globulin, prepared by ethanol or ammonium sulfate precipitation of immune sera followed by conjugation with fluorescein, is diluted to a working concentration predetermined by box titration and flooded onto the infected cells, which are incubated at room temperature in a moist chamber. After incubation, the slides are washed, dipped in water to remove salts, dried by evaporation, and mounted under coverslips. Specific viral fluorescence is characterized as intense, punctuate to granular aggregates confined to the cytoplasm of infected cells. In addition, specific MARV and EBOV fluorescence may include large, bizarrely shaped aggregates up to 10 μm across. Nonspecific fluorescence is rarely a problem in DFA procedures for these viruses.

DFA can also be applied to impression smears from biopsy or autopsy material (e.g., liver, spleen, or kidney tissue) obtained from infected individuals. A suspension of the material is prepared in PBS and applied to microscope slides that are subsequently air dried and acetone fixed. DFA also has been used successfully to detect MARV antigen on dried, citrated human blood smears and on impression smears from blood, tissues, nasal turbinates, and even urine from REBOV-infected macaques (31). In addition, the approach has been successfully applied to JUN-infected cells in peripheral blood and urinary sediment.

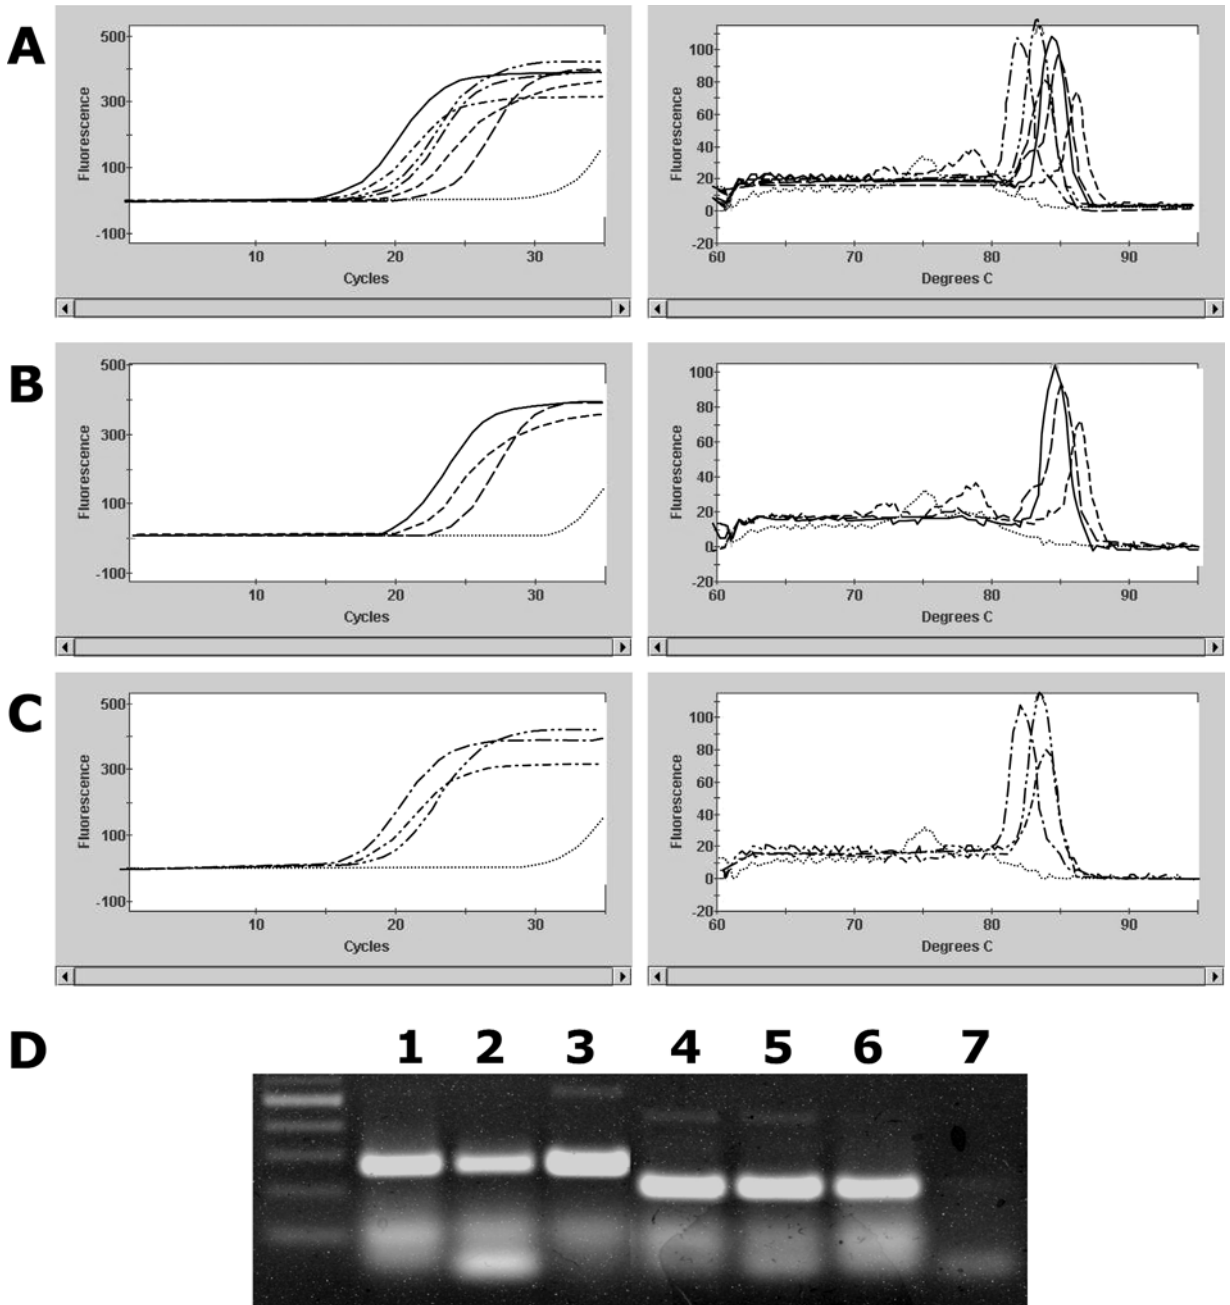
Detection of MARV, EBOV, and LAS antigens by DFA is usually considered sufficient for a definitive diagnosis.


FIGURE 5 Real-time RT-PCR detection of filoviruses. (A) Amplification curves and melting point analysis of *Zaire ebolavirus* (ZEBOV) (long dash, D-1), *Sudan ebolavirus* (SEBOV) (dash, D-2), *Ivory Coast ebolavirus* (ICEBOV) (solid, D-3), *Marburgvirus* (MARV) strain Musoke (dash dot, D-4), MARV strain Ravin (long dash dot, D-5), MARV strain Ozolin (long dash dot dot, D-6), and a control (round dot, D-7). (B and C) Separate amplification curves and melting point analyses for the EBOV species (ZEBOV, SEBOV, and ICEBOV) and MARV strains, respectively. (D) Agarose gel electrophoresis of the amplification products of the real-time filovirus RT-PCR with a 100-bp DNA ladder. Viral RNA was extracted from tissue culture supernatants by using a Qiagen viral RNA kit followed by real-time RT-PCR with a Lightcycler RNA SYBR Green I kit with 0.2 μM each primer and cycling parameters of RT reaction at 50°C for 20 min, denaturation at 94°C for 120 s, and amplification of 40 cycles at 95°C for 15 s, 50°C for 30 s, and 72°C for 30 s. Primers target the EBOV (EVSP5 [5′ ACATCTTTCTTTCTTTG GGTAAT] and EVSP3 [5′ CAGT TCTCAGC-CCATTCACCAGCTT]) and MARV (MVSP5 [5′AAAGTTGCTGAT TCCCCTTTGGA] and MVSP3 [5′ GCATGAGG GTTTTGACCTTGAAT]) glycoprotein genes and produce 273- and 223-bp amplification products, respectively. Melting-point analysis was done by heating the amplification products from 60 to 95°C at 0.2°C/s while monitoring the samples for loss of fluorescence, indicating the point at which double-stranded DNA melts and the intercalating dye loses fluorescence. The first derivative of the melting curve is shown here for ease of interpretation. The presence of peaks at appropriate melting temperatures distinguishes authentic product from nonspecific products and primer-dimers as seen for the control (round dot).
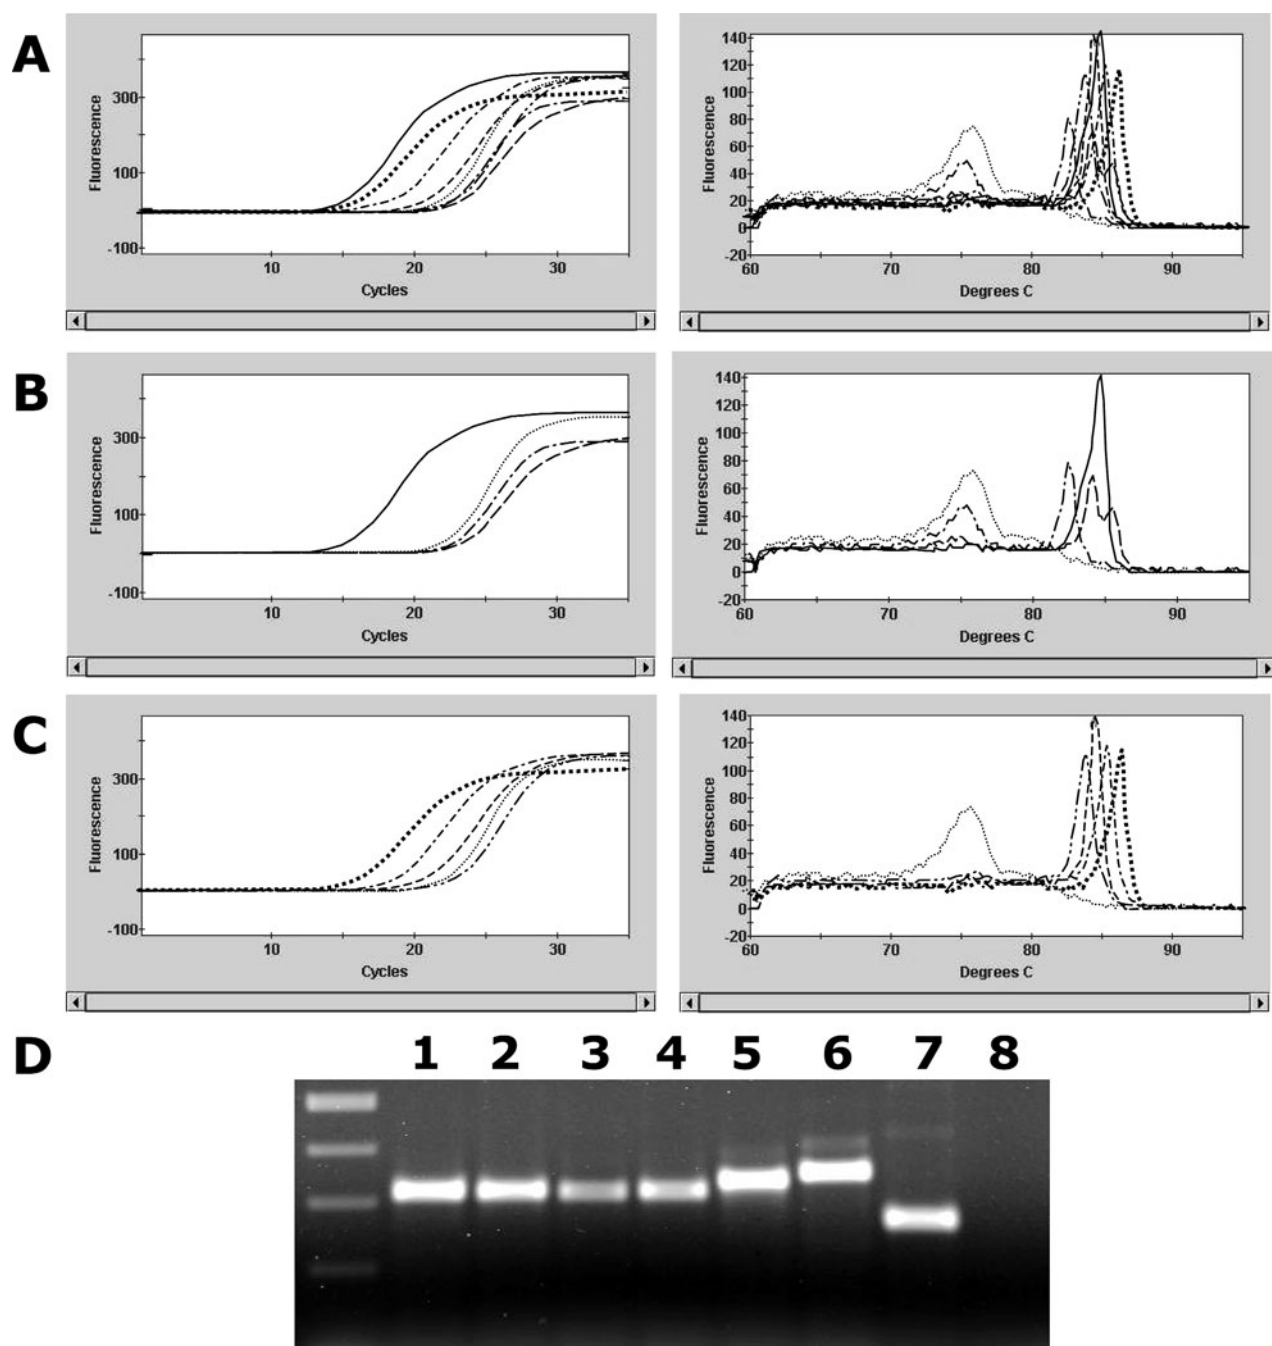

FIGURE 6   Real-time RT-PCR detection of arenaviruses. (A) Amplification curves and melting-point analysis of Machupo (MAC) (dash, D-1), Junin (JUN) (square dot, D-2), Sabia (SAB) (dash dot, D-3), Guanarito (GTO) (long dash dot dot, D-4), Lassa (LAS), strain Josiah (solid, D-5), LAS strain Pinneo (long dash, D-6), *Lymphocytic choriomeningitis* virus (LCMV) (long dash dot, D-7), and a control (round dot, D-8). (B and C) Separate amplification curves and melting point analysis for the New World complex species (MAC, JUN, GTO, and SAB) and the Old World complex species (LAS and LCMV), respectively. (D) Agarose gel electrophoresis of the amplification products of the arenavirus real-time RT-PCR with a 100-bp DNA ladder. RNA was extracted from tissue culture supernatants by using a Qiagen viral RNA kit followed by real-time RT-PCR with a Lightcycler RNA SYBR Green I kit with 0.2 μM each primer and cycling parameters of RT reaction at 50°C for 20 min, denaturation at 94°C for 120 s, and amplification of 40 cycles at 95°C for 15 s, 50°C for 30 s, and 72°C for 30 s. Primers target the NP gene for New World arenaviruses (NWA5 [5′ TTTGAAGC-CTTTCTCATCATG] and NWA3 [5′ TGGCCTTACATTGGTTC(CA)AG(AG)TC]) and the GPC gene of the Old World arenaviruses (OWA5 [5′ ACCGGGGATCCTAGGCATTT] and OWA3 [5′ ATATAATGATGACTGTTGTTCTTTGTCA]) and produce amplification products of 288 and ~250 to 345 bp, respectively. Melting-point analysis was achieved by heating the amplification products from 60 to 95°C at 0.2°C/s while monitoring the samples for loss of fluorescence, indicating the point at which double-stranded DNA melts and the intercalating dye loses fluorescence. The first derivative of the melting curve is shown here for ease of interpretation. The presence of peaks at appropriate melting temperatures distinguishes authentic product from nonspecific products and primer-dimers as seen for the mock infection (round dots).

Detection of antigen from South American arenaviruses by DFA constitutes a presumptive diagnosis since these viruses can be reliably distinguished from each other only by neutralization tests (NTs).

IHC

The development of IHC techniques for detection of filovirus and arenavirus antigens in formalin-fixed tissues has recently advanced to the point that results are far more satisfactory than for DFA examination of frozen, acetone-fixed sections. Obtaining frozen sections for diagnosis is rarely worth the biohazard incurred, especially since the threshold sensitivity for detection exceeds 6 $\log_{10}$ PFU/g. For filoviruses, paraffin blocks of tissues are sectioned and mounted on silane-coated slides. They are deparaffinized, hydrated, digested with protease, and stained for the presence of viral antigens with cocktails of monoclonal antibodies. Biotinylated anti-mouse antiserum is then added, and the reaction product is developed with a streptavidin-alkaline phosphatase system. Substitution of other chromogens can further increase sensitivity while reducing background. These techniques are expected to prove especially useful for the retrospective diagnosis of viral infections in archived tissues and paraffin blocks. However, systematic examinations of archived materials have not yet been reported.

Remarkable success was reported in application of IHC to detect viral antigens in formalin-fixed skin biopsy specimens obtained from EBOV patients (37). This tool facilitates a definitive diagnosis of patients when liquid nitrogen or dry ice is not available and simplifies submission of the samples to a reference laboratory, since fixation inactivates the virus.

Detection of Virus-Specific Antibodies

ELISA

The current method of choice for diagnostic antibody detection is ELISA (3, 11, 17, 21, 24, 27). The best-evaluated assays use infected cell lysates as antigen. Normally, for IgG detection, infected cells are treated with Triton X-100 followed by inactivation using gamma irradiation. This antigen is coated onto 96-well plates overnight. The plates are washed, and serum or plasma is applied to the wells in a serial fourfold dilution normally starting at 1:100. This is followed by washing and addition of a species-specific secondary antibody mostly coupled with horseradish peroxidase. Color development is measured by the horseradish peroxidase-ABTS system. In parallel, each sample is run against a negative control antigen (uninfected cell lysate prepared using the same method).

For IgM detection, many laboratories use a capture format (21, 27). Microtiter plates are coated with anti-human IgM, washed, and incubated with a serial fourfold dilution of the clinical specimen (serum or plasma) normally starting at 1:100. In the next step, viral antigen is applied after being prepared by sonication and gamma irradiation of infected cells. Subsequently, the antigen is detected using a polyclonal antiserum following the IgG protocol.

ELISAs have been developed using recombinant-expressed viral proteins as antigens for detection of virus-specific antibodies. These assays thereby abrogate the need for BSL-4 infections to establish antigen supplies. Stably expressing cell lines, bacterial recombinant-expressed as well as recombinant baculovirus-expressed viral proteins, have been used for the detection of EBOV and LAS antigens (1, 2, 11, 14, 17). The sensitivity and specificity of the EBOV recombinant ELISAs compared to those of the

immunofluorescence assay were 92 and 99%, respectively. Similar results were shown for the nucleocapsid of LAS expressed from a baculovirus system as well as from the recombinant bacterium-expressed LAS nucleocapsid.

IFA

IFA is currently the most simple method for documenting recent filovirus and arenavirus infections in the field. Preparation of spotslides using infected Vero or MA-104 cells is identical to the procedure described above for DFA. Uninfected cells are often admixed with the virus-infected cells to aid discrimination between specific and nonspecific fluorescence. Although monovalent spotslides are usually desired and are prepared with cells optimally infected with a single virus, polyvalent spotslides can also be prepared by mixing cells infected with different viruses selected from these or other taxonomic groups which have similar geographic distributions (19). Test sera are diluted serially, usually in twofold increments, starting at 1:4 or 1:10. Prozones may occur in low dilutions. Thus, for screening procedures, sera are commonly tested at both 1:10 and 1:80 dilutions. Infected cells (and uninfected control cells) are incubated with serum dilutions, washed, reincubated with appropriate fluorescein-conjugated anti-globulin (or specific anti-IgM or -IgG), washed, mounted, and observed. End-point determination is very subjective. Most experienced observers consider the end point to be the highest dilution producing typical cytoplasmic fluorescence clearly positive relative to uninfected cells. Although it is possible to obtain reproducible end points within individual laboratories, discrepancies in titers determined by different laboratories are common and probably relate to variations in interpretation, epi-illumination intensity, filtration systems, and fluorescein conjugates.

Previous investigations of the seroprevalence of EBOV relied on inactivated infected cells as the source of antigen for IFA, requiring the preparation of slides in BSL-4 laboratories. Others have more recently developed IFA to detect IgG based on cell lines stably expressing viral proteins such as REBOV nucleoprotein or cell lines infected with a recombinant baculovirus expressing an appropriate antigen (15). If this proves reliable in the future, antigen production would be independent on BSL-4 facilities.

Despite the simplicity of the assay, IFA, particularly for the detection of filovirus-specific immune responses, has often been not very reliable, probably because of cross-reactivities with other viruses. For example, significant proportions of human and nonhuman primate sera have been shown to react with filovirus and arenavirus antigens without an apparent history of such exposure.

NT

Neutralization tests (NT) are considered definitive for arenavirus identification but are rarely necessary since, with the exceptions of JUN, MAC, and perhaps LAS and the LAS-like viruses (Mopeia and Mobala viruses), these viruses may be readily distinguished on the basis of IFA, ELISA, or other less frequently used antibody detection tests such as immunoblot assay or radioimmunoprecipitation (not described here). NT depends on inhibition of viral replication by a specific immune serum; the format is determined in part by the availability of tools to measure infectivity or viral antigens (e.g. plaques, DFA, ELISA, or in vivo infectivity). The most generally applied NT is a plaque reduction neutralization test (PRNT) using Vero cells and the serum dilution-constant virus format. The serum dilution calculated (by probit analysis) to reduce the control number of plaques by

50% (PRNT-50) is usually taken as the end point, although in some laboratories the highest serum dilution producing 80% reduction (PRNT-80) is used. The PRNT-80 test is commonly used to distinguish JUN from MAC. For LAS, neutralizing-antibody activity is rapidly lost on dilution; for this reason, the constant serum dilution-varying virus format is preferred. The same principles apply to neutralization of MARV and EBOV, for which NTs have been notoriously imprecise. Neutralization of Old World arenaviruses is also markedly enhanced by addition of complement; thus, 10% fresh guinea pig serum is routinely added to the diluent. Plaque reduction is further enhanced by addition of either anti-immunoglobulin or protein A. PRNTs in various formats have largely replaced animal protection tests for measurement of neutralizing antibodies to these viruses.

Acute-phase sera from Lassa fever patients frequently contain both infectious virus and IFA and complement fixation antibodies. In survivors, neutralizing antibodies to LAS virus first appear very late in convalescence (6 weeks or later), long after viremia has disappeared. Neutralizing antibodies against JUN and MAC become detectable 3 to 4 weeks after onset, soon after the termination of viremia. For MARV and EBOV, as for LAS, neutralizing antibodies evolve late; while neutralizing antibodies are thought to be important in protection against reinfection, their role in resolution of acute infections is less firmly established (18).

Additional Diagnostic Procedures

Virus Isolation
The ultimate goal of diagnostic efforts should always be the isolation of the infectious agent in either tissue culture or animal models. The method of choice for isolation of pathogenic filoviruses and arenaviruses is the inoculation of appropriate cell cultures, usually Vero cells (especially clone E6), MA-104 cells, or SW-13 cells, followed by examination of inoculated cells at intervals for the presence of viral antigens by using an immunological staining method such as DFA or immunoperoxidase assays. This approach has been successfully applied to routine primary isolations from field-collected materials. Isolation of some filoviruses, such as SEBOV, by Vero cell inoculation is less reliable since several blind passages might be required. SW-13 and MA-104 cells are reported to be more sensitive and preferable for primary isolations of filoviruses. Other cell lines, including human diploid lung (MRC-5) and BHK-21 cells, have been substituted for Vero cells with reasonable success. Although MAC and JUN were historically isolated by inoculation of newborn hamsters and mice, respectively, Vero cells are approximately as sensitive and are far less cumbersome to manage in BSL-4 containment. Furthermore, Vero cells permit isolation and identification, usually within 1 to 5 days, a significant advantage over the use of animals, which can require a 7- to 20-day incubation period for illness to develop. For primary isolation of other arenaviruses, and for MARV and EBOV, animal inoculations are still used when cell cultures are not available. Guinea pigs are the species of choice for these studies, particularly for filoviruses that initially do not grow well in tissue culture. Often several passages within these animals are required to produce uniformly fatal disease.

EM
MARV and EBOV have been successfully visualized directly by EM of both heparinized blood and urine obtained during the febrile period, as well as tissue culture supernatant fluids following isolation attempts from human material (Fig. 1B).

The concentrations of virus in tissues, blood, and often urine of febrile patients are sufficiently high, and the morphology is sufficiently distinct, to permit a preliminary diagnosis of filovirus infection even when the isolate had been previously unknown, such as with REBOV. Filovirus particles and intracellular inclusions can be used in the diagnosis of suspected VHF cases since these are morphologically distinct features associated with filovirus infections and even have serotype-specific features (12). The materials are processed by immediate fixation with 0.5% glutaraldehyde followed by low-speed centrifugation. Virions are sedimented at $12,000 \times g$ for 15 min, resuspended in 1/100 original sample volumes, and placed on Formvar-carbon coated EM grids, which are then negatively stained with 1% phosphotungstic acid for 30 s and examined.

For confirmation, immune EM (IEM) techniques are used. Monoclonal or polyclonal antibodies have been successfully applied to recent filovirus isolates. These IEM techniques also work well for diagnosis of arenavirus infections, although the morphology of the virions is less striking (Fig. 1A).

For filoviruses, ultrathin sections of cell pellets prepared from peripheral blood leukocytes by Hypaque-Ficoll gradients frequently reveal clusters of virus associated with monocytes. Ultrathin sections of formalin-fixed tissues, most often liver, spleen, or kidney, have frequently revealed typical filovirus and arenavirus particles (Fig. 1). This approach is successful because infectious virus concentrations are frequently very high. Thin-section EM finds utility in retrospective examination of archived tissues.

EVALUATION AND INTERPRETATION OF RESULTS
Early laboratory diagnosis of arenavirus and filovirus infection is most desirable because of the implications for case patient management and public health interventions. Specific antiviral treatment is limited, but specific immune plasma (South American arenaviruses) and the antiviral drug ribavirin (arenaviruses) are most effective when treatment is started soon after onset.

Despite all the achievements in laboratory diagnostics in the past decades, it should be kept in mind that the diagnosis of arenavirus and filovirus infections initially has to be based on clinical assessment (Fig. 4). For this purpose, contingency plans should be developed; these are still missing in many countries, particularly developing countries. Since clinical microbiology and public health laboratories are not generally equipped for diagnosis of VHF caused by arenaviruses and filoviruses, it is necessary that samples be sent to national and/or international reference laboratories capable of performing the required assays (Table 2). In addition, many nations encounter difficulties in sample transport, which can cause substantial delays in laboratory response. Once samples are received, the laboratory response is fairly reasonable and results can be expected within 24 to 48 h.

Of the available techniques for diagnosis, antigen capture ELISA and RT-PCR are currently the most useful for making a diagnosis in an acute clinical setting. RT-PCR assays seem to be favored by many investigators because BSL-4 biocontainment is not necessary after proper inactivation and because of sensitivity, specificity, and rapidity of the technique. However, the diagnosis of index cases of outbreaks or of single imported cases should not be based solely on RT-PCR because of the problem of cross-contamination and, thus, false-positive results. Confirmation by an independent assay such as antigen capture ELISA should always

be attempted. If confirmatory techniques and biocontainment (virus isolation) are not available, RT-PCR on an independent target gene and/or independent sample should be the minimum confirmation. In such cases it might be useful to seek confirmation through another reference laboratory.

Serology can be useful for confirmation, but it should be kept in mind that negative serology is not exclusive since patients, particularly filovirus-infected individuals, often die without mounting a proper humoral immune response. Currently, IgM capture ELISA and IgG ELISA are the assays of choice for serology because of their sensitivity, specificity, and reliability. For all the arenavirus and filovirus pathogens, a rising IgM or IgG titer constitutes a strong presumptive diagnosis. However, a single positive result should be confirmed by using a follow-up sample preferentially taken a week later. Decreasing IgM and/or increasing IgG titers (fourfold) in successive paired sera are highly suggestive of a recent infection.

EM can be used as a confirmatory diagnostic procedure but is far less sensitive than any other assay. Virus isolation should be achieved, although its utility as a diagnostic procedure is restricted by time and biosafety concerns. For nonoutbreak surveillance, IHC on formalin-fixed biopsy or autopsy material is available for some of the agents (e.g., filoviruses) and has several advantages including its simplicity and specificity and the lack of any need for enhanced biocontainment.

QUALITY ASSURANCE

Since filoviruses and the VHF-causing arenaviruses have been designated category A bioterrorism agents, procedures for rapid diagnoses have been recently implemented by many countries to enable rapid, sensitive, and efficient detection of these special pathogens. PCR technologies are most widely utilized for this testing (see reference 7), but because of the restricted availability of virologic and clinical material, the evaluation and standardization of test procedures are difficult. Recently, external agencies have been designated to provide external quality assurance of the levels of PCR diagnostic proficiency of responsible laboratories in Europe and Canada through the European Network for Imported Viral Diseases (ENIVD) (25). A total of 28 laboratories from 17 countries were invited to participate in the study. For these, the cumulative fraction of positively testing results for all virus-containing samples (including filoviruses, LAS, and orthopoxviruses) ranged between 70 and 78%. If the samples contained low levels of virus, the detection rates plummeted to between 40 and 46%. Although most laboratories in this study showed reasonable abilities to detect category A agents, a small but significant fraction of laboratories demonstrated rather poor sensitivities. Thus, continued and extended quality assurance studies are required to maximize the robustness of these testing procedures.

FUTURE DEVELOPMENTS

Because of the constant threat posed by emerging infectious diseases and the limitations of existing approaches used to identify new pathogens, there is a great demand for new technological methods for VHF diagnostics. These advances include improved immunologic reagents matched with improved laboratory technologies that are more readily available, more portable, less cumbersome, and less expensive. These have ranged from automated analyzers and microarrays that facilitate the analysis of large numbers of

samples to self-contained, disposable miniaturized devices that enable immunoassays to be performed in a field setting. Together, these novel reagents and new technologies are likely to transform diagnostic medicine over the next decade and will probably have large impacts in the field of VHFs.

Outbreaks of filovirus and arenavirus infections often occur in remote, isolated communities that do not have ready access to sophisticated medical resources. This often means that cases must be managed based solely on clinical presentation and contact history, with little or no timely diagnostic support. Patients with unrelated fevers may not be recognized as infected and may risk potential exposure to a more lethal virus. The development of truly portable real-time thermocyclers and simple immunological assays for use in the field has made the provision of a field diagnostic laboratory a reasonable undertaking. Teams developed for rapid response to bioterrorism events are readily adaptable for outbreak response and can prove to be a valuable tool in managing these events.

Since it is not possible to relocate an entire laboratory to remote settings, it is necessary to bring the equipment essential to provide a safe work environment while completing the necessary testing. The initial and most important task is to protect the workers from the virus. Ideally this can be accomplished by using a portable class III biosafety cabinet, if time and logistics permit. This allows safe handling of samples until the infectious agents are inactivated or packaged appropriately for shipping. Although portable, this unit is often too large to travel as checked baggage on commercial flights and would need to be shipped cargo or by charter. Alternatively, personal protective equipment similar to that used by the isolation ward medical staff can be used to protect workers while handling infectious material. Inactivated samples can be used directly in diagnostic assays, as is the case with serological assays, or nucleic acids can be isolated for molecular biology-based assays by using a suitable commercial kit. Real-time PCR-based assays run on machines designed to be portable are well suited to these environments and can be extremely sensitive and provide results in a very short time. In addition to confirming the presence of a virus in patient samples, real-time tests provide a quantitative assay that may be of use when viral-load determination is necessary, as in trials of antivirals or other treatment regimens. Tests for other agents that may be confounding and mistaken originally as the causative agent (e.g., *Plasmodium* spp.) should also be included in the reagent inventory. Logistical issues must be addressed; these include the fact that in truly remote locations a source of reliable electrical power can be difficult to obtain. The provision of a generator with surge protection may be needed and is best obtained locally if rapid response is necessary. Ensuring that the team has all the necessary equipment and reagents can be a significant challenge. In our experience, it is possible to equip a team of two persons for rapid response to an outbreak situation by using six suitcase-sized cases with enough reagents for 500 assays.

An immunofiltration assay for the direct detection of EBOV antigen (which will most probably also be applicable for other VHF agents) in sera and other body fluids will soon be available in column format (unpublished data). These assays have a number of features that make them suitable for rapid tests that can be used in a field or outbreak setting. Refrigeration is not required for any component, nor is there any need for electrical power sources other than a battery-driven photometer. A simple protocol consisting of rehydration of the column and sequential loading of the sample followed by addition of test reagents and substrate

provides a colormetric determination in approximately 30 min. Antibody detection assays based on this system are also under development (unpublished data). This method should be applicable to most arenaviruses and filoviruses and should lend itself very well to field applications.

Rabies Virus

D. CRAIG HOOPER

88

Rabies virus, the type species of the genus *Lyssavirus* of the family *Rhabdoviridae,* order *Mononegavirales,* is the causative agent of rabies, an invariably lethal neurological disease of a wide variety of animals and humans. The virus is endemic throughout much of the world as an extensive range of variants, each associated with a particular wildlife or domestic animal host species but with the capacity to infect secondary targets, including humans. In developing countries, the major carrier of viruses causing human rabies is the dog. However, significant reservoirs of rabies viruses exist throughout much of the world in foxes, coyotes, skunks, raccoons, various bat species, and a variety of other mammals. Rabies virus can be transmitted from these natural host species to humans either directly or by intermediate animals that are not normally associated with rabies, such as cats, rabbits, etc. Moreover, transplantation of organs from rabies virus-infected individuals has led to the lethal infection of the recipients.

The rabies virion is a characteristically bullet-shaped, enveloped particle of, on average, 75 by 180 nm (26). Projections of glycoprotein (G), the primary target of neutralizing antibodies, are dispersed evenly over the surface, and a helical nucleocapsid contains a single-stranded negative-sense RNA genome encoding five proteins: the nucleoprotein (N), the phosphoprotein (NS), the polymerase (L), the matrix protein (M), and the viral glycoprotein. Since distinct rabies virus strains are endemic in different reservoir species in diverse geographical regions, antigenic or gene sequence analysis of a particular virus isolate can determine its origin and help understanding of the etiology of an infection, which is important in developing risk management strategies. Variability between different virus isolates is extensive for G protein at both sequence and antigenic levels, while N is more conserved. Thus, N-protein-specific antibodies have greater utility for the general detection of rabies virus infection by direct immunofluorescence or immunohistochemical analysis of tissue biopsies or corneal impressions. Identification of a particular virus isolate is commonly accomplished by assessing G-protein nucleic acid structure.

In the absence of treatment, progression to clinical rabies in humans is dependent upon the location and severity of the exposure, the virus strain involved, and, likely, the immune status of the host. For attacks by infected animals, historical evidence suggests that the highest mortality occurs with patients bitten on the head and face (at least 40 to 80%), with diminishing mortality as the bite site becomes more distant from the central nervous system (CNS). Generally, the initial signs of disease appear 2 to 6 weeks after exposure, but there have been occasional cases that developed a number of years after exposure. Clinical rabies becomes apparent initially in nonspecific symptoms which may include general malaise, chills, fever, headache, photophobia, anorexia, sore throat, cough, and musculoskeletal pain. In the case of a bite, there is often itching, burning, numbness, or paresthesia around the site. This prodromal period generally lasts from 2 to 10 days and precedes the acute neurologic phase in which patients manifest signs of neurological dysfunction such as anxiety, agitation, paralysis, or episodes of delirium. A variable proportion of patients exhibit the classical pathognomonic sign of rabies, hydrophobia. Disease progression is variable but usually proceeds through coma to death from respiratory arrest by approximately 30 to 60 days after infection. Survival may be prolonged somewhat by respiratory assistance, but death invariably occurs due to other complications.

Recognition of potential exposure is the most important criterion for successful postexposure prophylaxis, which entails the passive administration of rabies virus-neutralizing antibodies and immunization with a potent vaccine and must be commenced as soon as practical after exposure. Such intervention invariably fails if begun after the appearance of clinical signs of rabies. When potential exposure is due to the bite, or contact with saliva through broken skin or mucosal surfaces, of an animal that might have rabies, the decision to administer postexposure prophylaxis can be based on testing of the animal, if it is available, for the virus. If the animal cannot be located, the decision to intervene is the standard of care since, unlike their predecessors, modern vaccines are safe, efficacious, and readily administered. As a consequence of the widespread use of postexposure prophylaxis when contact with rabies virus is suspected, human mortality from rabies virus infection in the United States is primarily the result of cases where exposure was not recognized. These cases are often initially classified as encephalitis of unknown origin and only correctly identified as rabies either in the terminal stages of the disease or postmortem. In the United States, cases of cryptic rabies, where exposure was unknown, have most often been caused by virus strains associated with several different bat species, including the silver-haired and Mexican free-tailed bats. In several instances, there has been a confirmed or anecdotal reference to contact

between the victim and a bat; however, the mode of transmission, which may be by an unnoticed bite or scratch or across a mucosal surface, is unknown.

The failure to diagnose rabies can be significant, as an infected individual presents a risk of infection to others. For example, in 2004, the kidneys, liver, and a segment of the iliac artery were transplanted from a donor who had died of undiagnosed rabies, resulting in the death of all four recipients from rabies and the need to administer postexposure prophylaxis to hundreds of contacts (4, 5). Since most rabies viruses replicate largely in the CNS, rabies in animals or humans has been most often confirmed by the histological identification of Negri bodies (intraneuronal cytoplasmic inclusions of rabies virus nucleocapsid [RNP]) in the brain tissue of victims or suckling mice that had been injected with suspect brain material. However, Negri bodies are not always present in rabies virus-infected brain tissue or may be confused with other viral inclusion bodies. Thus, immunohistochemical techniques using nucleoprotein-specific antibodies have supplanted simple histology in testing of tissue specimens for evidence of rabies. Detection of rabies virus nucleoprotein in histological specimens, such as brain tissue and peripheral nerve biopsies as well as corneal imprints, using fluorescein-conjugated antibody remains the accepted method for the diagnosis of rabies virus infection.

Fluorescein isothiocyanate (FITC)-conjugated monoclonal antinucleoprotein antibodies are also the basis of the rapid fluorescent focus inhibition test (RFFIT), the in vitro neutralization test commonly used to monitor vaccine efficacy or the immune status of humans or animals that have been immunized against the virus. Enzyme-linked immunosorbent assay (ELISA) techniques can also be used for the general screening of virus-specific antigen-antibody interactions when information about neutralizing capacity is unnecessary. While epitope-specific antibodies have been used for the identification and characterization of individual rabies virus isolates, technologies based on the reverse transcriptase (RT)-dependent PCR (RT-PCR) technology are now more widely utilized for these purposes. For example, real-time quantitative RT-PCR is well suited for the detection and characterization of viral genome or mRNA in relatively small tissue samples of variable quality. The existence of cryptic rabies and proof that transmission of the disease between humans can occur by organ transplantation indicate that screening of potential donors with encephalitis of unknown origin for rabies is prudent. This can be accomplished by the analysis of tissue biopsies for either rabies virus antigens or nucleic acids and serology, as many victims of clinical rabies exhibit high serum or cerebrospinal fluid (CSF) titers of rabies virus-specific antibodies prior to their death.

TECHNOLOGY

The control of human rabies is dependent upon determination of whether the animal vector responsible for a potential exposure is rabid. Thus, animals that have bitten an individual and are known reservoirs or secondary vectors of rabies virus are routinely tested for either the presence of the virus or evidence of previous immunization against rabies. Cases of fatal human rabies, most often due to infection with bat rabies virus variants, occur when exposure has gone unnoticed. Due to the nonspecificity of the clinical signs of rabies, these cases are generally undiagnosed during the course of the disease and rabies infection is confirmed only postmortem. Although little can be done once clinical disease has become evident, the diagnosis of rabies is important for management purposes. Immunological technologies are the accepted standards for the assessment of rabies virus infection as well as antiviral-immune status. However, molecular approaches to assessing rabies virus infection are becoming increasingly popular due to their sensitivity, utility for specimens of poor quality, and specificity.

As noted in Table 1, a considerable variety of laboratory, or "fixed," rabies virus strains are available for use in the various assays. Challenge virus standard (CVS) strain 11 (CVS-11) and Evelyn-Rokitnicki-Abelseth (ERA) are commonly used for in vitro assays and may be readily produced in cultures of baby hamster kidney (BHK) cells. Viruses obtained from infected wildlife, termed "street" rabies viruses, often

TABLE 1 Selected laboratory (fixed) strains of rabies virus

Virus designation (abbreviation)	Origin
Challenge virus standard (CVS)	Thought to be derived from the original Pasteur rabies virus isolate passaged in rabbit brain and then mouse brain; a number of variants exist in different laboratories (e.g., CVS-11, passaged in cell culture; CVS-24, passaged in mouse brain)
Evelyn-Rokitnicki-Abelseth (ERA)	Derived from SAD by passage in mouse brain
Flury Low egg passage (LEP) High egg passage (HEP)	Isolated from a human with rabies by mouse brain inoculation and then passaged in chick brain and chicken embryo
Kelev	Isolated from a rabid dog by mouse brain inoculation and then passaged in chicken embryo
Louis Pasteur Virus (PAST)	Isolated from a rabid cow infected by dog bite, passaged in rabbit brain and then primary hamster kidney cell culture
Pasteur Virus (PV)	Believed to be derived from the original Pasteur rabies virus isolate passaged in rabbit brain and then cell culture
Pitman Moore (PM)	Thought to be derived from a rabbit brain-passaged isolate from the original Pasteur rabies virus, adapted to cell culture
Street Alabama-Dufferin (SAD)	Isolated from a rabid dog by mouse brain inoculation and then passaged in chicken embryo and cell culture

replicate poorly in BHK cells but can often be cultured in mouse neuroblastoma (NA) cells. Alternatively, these viruses can be expanded in the suckling (1- to 3-day-old) mouse brain. Where desired, rabies virus may be purified by zonal centrifugation in a sucrose density gradient (21).

Fluorescent-Antibody Detection of Rabies Virus Antigen

A variety of different antibody-based tests have been developed to provide specificity and improve the sensitivity of the assessment of specimens for rabies virus antigen. The direct fluorescent-antibody (DFA) test, for detection of viral antigen in brain tissue sections, impressions, or smears (brain stem and cerebellum are preferred) by use of FITC-conjugated rabies virus nucleoprotein-specific antibodies, is the minimum standard for the diagnosis of rabies virus infection in the United States (7, 24). A detailed protocol for the postmortem diagnosis of rabies in animals by DFA that includes sample preparation and details of the test procedure as well as a list of reagent suppliers can be found on the Centers for Disease Control and Prevention (CDC) website (www.cdc.gov/ncidod/dvrd/rabies). DFA testing is also used to analyze ante- and postmortem samples (neural tissue biopsy, skin biopsy, saliva, corneal impressions) from humans suspected of having died of rabies, as a firm diagnosis can have important implications for postexposure prophylaxis of the patient's contacts. Sample preparation from field specimens and clinical isolates for DFA analysis has been extensively detailed elsewhere (19).

The DFA test is more sensitive and specific than the histochemical visualization of Negri bodies in CNS tissues and can be readily applied to tissue impressions and smears, as well as to fixed and frozen material of variable quality. This allows a specific diagnosis to be made earlier in the infection, providing that appropriate samples are available. The fluorescein-conjugated N-specific monoclonal antibodies capable of detecting all known rabies virus variants that are used for DFA tests are commercially available. N-specific antibodies are employed for such general screening since N antigenic determinants are more highly conserved among rabies virus isolates than those of the G protein. However, characterization of a rabies virus variant that has infected an individual will identify the originating reservoir species, which is critical to understanding the etiology of an infection. Panels of monoclonal anti-N and anti-G antibodies have been widely used in DFA tests to differentiate rabies virus variants on the basis of their expression of unique patterns of antigenic epitopes (e.g., reference 22) (Table 2). Immunohistochemical approaches using peroxidase- and alkaline phosphatase-conjugated N-specific antibodies have also been described as being reliable for studies of formalin-fixed, paraffin-embedded tissues (e.g., see references 8 and 22).

ELISA-Based Tests for Detection of Rabies Virus Antigen

The dependence of the DFA test on fluorescence microscopy has led to the development of several ELISA-based methods for the detection and quantification of rabies virus antigens that may be more suited for use in the field. The rapid rabies enzyme immunodiagnosis (RREID) and its variants are essentially ELISAs in which rabies virus antigens are detected by a substrate reaction, the product of which, under optimal conditions, is visible to the naked eye. In RREID, plates coated with anti-N antibodies are used to trap RNP from specimen preparations, which is then detected with enzyme-conjugated anti-N antibodies and conventional ELISA methods. The use of biotinylated N-specific antibodies and peroxidase-streptavidin can reduce the requirement for labeled antibody (15). Both the sensitivity and the specificity of RREID are considered to be somewhat lower than those of the DFA test with appropriately prepared samples. However, sample quality may be less critical than for the DFA test and positive results may be visualized without microscopy in dot ELISA (10) and RREID. Moreover, ELISA-based assays are more readily amenable to quantitation of antigen content than is DFA analysis (11).

Titration of Rabies Virus by the Fluorescent Focus Assay

The presence of infectious rabies virus in a particular sample is generally confirmed by determining whether the virus replicates in the brains of 1- to 3-day-old suckling mice. However, many rabies virus variants also replicate in cultures of mouse NA cells (NA C1300). Methods for the isolation of rabies virus in cell culture and by mouse inoculation are detailed elsewhere (19). As rabies virus infection is generally nonlytic, titration of the virus is generally performed with a fluorescent focus test in which foci of virus-infected cells in culture are enumerated by use of fluorescein-conjugated

TABLE 2 Antigenic variation among diverse North American rabies virus isolates

Rabies virus isolate	Monoclonal antibody reaction pattern at antigenic sites[a]:								
	Nucleocapsid specific			Glycoprotein specific					
	NS I	N I	N III	I	II A	II B	II C	III A	III B

[a]Letters denote monoclonal antibodies of unique specificities. The absence of a letter indicates that the monoclonal antibody failed to bind nucleocapsid (NC-specific antibodies) or neutralize virus (G-specific antibodies) of the indicated isolate. Adapted from the work of Rupprecht et al. (16).

rabies antigen-specific antibodies. BHK cells [BHK-21(C-13); ATCC CCL 10] are suitable targets for fixed laboratory strains of rabies virus such as CVS and ERA, but street virus isolates often infect these cells poorly. NA cells, known to be susceptible to infection by all street virus isolates tested so far, are appropriate for both virus titration and tests of antibody neutralization when street virus isolates are employed. Briefly, 10-fold dilutions of virus are made in medium (10 μl in 90 μl) and added (90 μl) to 30 μl of BHK or NA cells in suspension (approximately 2.5×10^6 cells per ml). The mixtures are transferred to the wells of flat-bottom 96-well microtiter plates (or, alternatively, 10-μl portions are transferred to the wells of Terasaki plates) which are then incubated for 24 to 48 h at 34°C, washed once with phosphate-buffered saline, and fixed with ice-cold 80% acetone for 20 to 30 min. The acetone is then removed, the plates are dried, and the cell monolayers are stained with fluorescein-labeled antirabies virus antibodies. N-protein-specific antibodies are preferred because the antigenic structure of N is more conserved than that of G and because certain rabies virus strains express relatively low levels of G protein. The results of the assay, with each initially infecting virion being represented by a focus of fluorescent infected cells, are read with a fluorescence microscope. The rabies virus titer is then reported in focus-forming units.

Titration of Rabies Virus-Specific Neutralizing Antibody

The level of protective immunity exhibited by a vaccinated individual or animal is determined by quantifying the titer of rabies virus-neutralizing antibody. For humans vaccinated against rabies due to an occupational risk of exposure, World Health Organization (WHO) guidelines recommend that effectiveness of immunization as well as the persistence of immunity be assessed by virus neutralization at 6-month intervals and that a booster vaccination be administered if the neutralizing titer drops below 0.5 IU/ml (24). As noted above, virus titers are normally determined by enumerating foci originating from single infecting virions in vitro, visualized with fluorescein-conjugated antibodies to N. Consequently, the most widely used virus neutralization assay is the RFFIT, which is based on antibody-mediated reduction in the titer of fixed, tissue culture-adapted virus (e.g., CVS or ERA) infecting susceptible cell lines (e.g., BHK, BSR, or NA cells) (25). Through the use of appropriate target cells, the RFFIT can be employed to assess antibody neutralizing activity for fixed and street strains of rabies virus. There are many variations and adaptations of this technique in practice, and a representative microculture protocol is presented here. Sera to be tested are inactivated at 56°C for 30 min prior to their use. Test serum or antibody preparations are serially diluted (e.g., threefold starting at 1:5) in medium in the wells of a microtiter plate to give a final volume of 50 μl. Rabies virus (e.g., CVS-11) is diluted so that 30 μl contains sufficient virus to give 50 to 70% infection of 30 μl of a suspension (2.5×10^6 per ml) (note that cell monolayers are not suitable for rabies virus neutralization tests) of BHK or NA cells (e.g., 5 to 10 focus-forming units per cell) and added to the serum dilutions (and a control row of medium alone) in an equal volume, and the mixture is incubated at 37°C for 60 min. Then 30 μl of BHK or NA cell suspension (1×10^6 to 2×10^6 cells per ml) is added to each well, the contents are mixed, and the cells are cultured in 96-well flat-bottom microtiter plates (alternatively, 10-μl portions can be transferred to Terasaki plates). The plates are incubated overnight at 37°C, washed once with phosphate-buffered saline, and

then fixed and stained as described for the fluorescent focus assay above. The numbers of infected cells are read by using a fluorescence microscope. The virus-neutralizing antibody titer is defined as the highest antibody dilution which gives a 50% reduction in infected cells. A standard antirabies serum (e.g., WHO reference serum) with a virus-neutralizing titer of at least 2 IU per ml should be included in each test so that the assays can be standardized.

To take into account variables in the assay such as the percent control infection obtained and the reference serum titer, the RFFIT results may be calculated as follows.

1. Determine the average percentage of infected cells in the control (virus plus cells without serum) wells (C).
2. Determine the dilution of reference serum that causes $C/2$ percent infected cells in the wells containing virus plus cells plus reference serum dilutions. Determine the percentage of infection in wells containing the next higher dilution of serum (A) as well as the percentage of infection in wells containing the next higher concentration of serum (B). The 50% dilution point of the reference serum is calculated as: dilution of serum giving $A - \{[(C/2 - B)/(A - B)] \times$ (dilution of serum giving B – dilution of serum giving A)$\}$. This number represents the dilution of reference serum that contains 2 IU (S).
3. Calculate the 50% dilution point in the test serum, using the same formula and substituting the test values of A and B, and their respective dilutions (the result of this calculation = T).
4. The titer of the test serum can now be expressed in international units by using the following relationship: titer of test serum (IU) = $2 \times S \times (1/T)$.

The fluorescent-antibody virus neutralization (FAVN) test, based on the fluorescence principle used in the RFITT but with an endpoint titer determined by the absence of fluorescence, has also been described (6). No significant differences in specificity or sensitivity between the RFFIT and FAVN were detected in comprehensive comparisons (3, 14), and the assessment of fluorescence in both assays has been automated (14), which is highly advantageous in the screening of large numbers of serum samples.

Analysis of Rabies Virus Antigen-Specific Antibody in ELISA

ELISA or radioimmunoassay can be used for the general assessment of rabies virus-specific antibody titers, particularly when a neutralization test is either unavailable or less appropriate. For example, the majority of antibodies specific for rabies virus N protein fail to neutralize, yet are readily detectable by ELISA. Since rabies virus N protein is more highly conserved among different isolates of the virus than rabies virus G protein, and a significant segment of the humoral response to rabies virus is directed against N, detection of rabies antibodies by ELISA may have particular utility where there may be significant antigenic differences between the virus that elicited the antibody and those available in the laboratory. Another situation in which ELISA for rabies virus-specific antibodies may also be more advantageous than a neutralization test is for the screening of serum and CSF from individuals with encephalitis of undiagnosed origin. Late in the disease process, individuals infected with rabies virus often produce some rabies virus-specific antibodies. ELISA can be used to detect these antibodies regardless of whether they are neutralizing. Moreover, ELISA is more suited for automated screening than neutralization

tests. Increasing titers of rabies virus-specific antibodies in consecutive serum samples or the appearance of such antibodies in CSF is indicative of an active infection.

ELISA for rabies virus-specific antibody is straightforward (see part I of this manual, "General Methods"). Briefly, ELISA plates (e.g., Immunolon 4 [Dynatech, Chantilly, Va.]) can be readily coated with purified inactivated (β-propriolactone) virus (to detect G- and N-specific antibodies), isolated virus RNP (to detect N-specific antibodies), or recombinant-expressed G and N. As an alternative to directly coating plates with rabies antigens, plates can be sensitized with rabies antigen-specific antibodies to specifically trap the antigens from crude preparations containing the virus (e.g., infected suckling mouse brain). After incubation, bound virus-, G-, or N-specific antibodies can be detected by using secondary peroxidase- or alkaline phosphatase-conjugated antibodies and conventional methods. Commercial ELISA kits for the detection of rabies virus-specific antibodies are available.

RT-PCR for Rabies Virus mRNA

RT-PCR has been found to be a sensitive way of detecting evidence of rabies virus infection in tissue from experimentally infected animals as well as in human autopsy material, including fresh, snap-frozen, formalin-fixed, and paraffin-embedded material (e.g., see references 9, 12, 18, and 23). RNA purified from these specimens by conventional technology, or in situ, can be subjected to RT-PCR or nested RT-PCR if greater sensitivity is required. A number of different procedures for RT-PCR detection and characterization of rabies virus RNA using a variety of oligonucleotide primers and probes specific for conserved or strain-specific sequences have been developed (1, 9, 12, 13, 17, 18, 23). For general RT-PCR screening of infection, primers derived from the nucleoprotein gene sequence, such as sense 10g (5′-CTA-CAATGGATGCCGAC3′) (position 66, near the initial methionine codon of N) and antisense 304 (5′-TTGACG-AAGATCTTGCTCAT3′) (position 1533, close to the initial methionine residue of the NS protein), are appropriate for amplifying rabies virus RNA from a range of street virus isolates (19). This pair of primers will amplify a fragment of 1.4 kb. When nested PCR is desired for increased sensitivity, a second PCR can be performed with primer 113 (5′-GTAGGATGCTATATGGG3′) (genomic sequence around position 900). If the above primers fail to detect rabies virus-specific sequences and analysis of β-actin RNA reveals that a specimen is of poor quality, the RT reaction can be performed with primer RabNfor [5′-TTGT(AG)GA(TC)CAATATGAGTACAA3′] and the

PCR can be performed with primers RabNfor and RabNbat1.1 (5′-TTCCATAGCTGGTCCAGTCA3′). These primers amplify a fragment of about 200 nucleotides of RNA from a large variety of rabies virus strains, including a silver-haired bat rabies virus, and are more likely to successfully amplify partially degraded RNA. PCR amplification of viral mRNA can also be performed but has proven to be more problematic for diagnostic use with specimen material. RT-PCR analysis using strain-specific primers of sequences from the remnant Ψ pseudogene found between the G and L cistrons (18) or the N gene (13) are particularly useful in discriminating between different rabies virus isolates, as is sequence analysis of RT-PCR products (e.g., see reference 1).

Real-time, quantitative RT-PCR (Q-RT-PCR) is well suited for the analysis of samples for rabies virus genome or mRNA. In addition to its specificity and sensitivity, this technology is based upon the replication of only a relatively short stretch of RNA (120 to 150 nucleotides) and therefore has utility for a wide variety of samples of varying quality, including archived paraffin tissue sections. The quality of a sample and the success of extracting usable RNA are controlled by examining the levels of expression of a house-keeping gene, such as the gene for ribosomal protein L13a or glyceraldehyde-3-phosphate dehydrogenase (GAPDH), at the same time as rabies virus RNA. Because of the extensive variability between rabies virus strains, as in other technologies the choice of primers and probes for Q-RT-PCR is of paramount importance. The specificity is such that primer and probe sets for the N mRNA of laboratory strains of the virus, such as CVS, fail to detect similar mRNA from a street rabies virus variant derived from the silver-haired bat (Table 3). In the latter case, a unique primer-probe set was necessary. To accurately assess the level of rabies virus infection of a tissue sample as well as provide a positive control for the Q-RT-PCR, a synthetic DNA template for the PCR is advantageous. With this approach, the number of copies of the rabies virus mRNA in a sample can be determined and normalized to the quality of tissue studied as established by the level of expression of a housekeeping gene.

Rabies Vaccine Potency Tests

While the potency of a rabies vaccine may partly be inferred by assessing the level of total or neutralizing rabies virus-specific antibody elicited by vaccination, the National Institutes of Health potency test is the best means of evaluating vaccine efficacy. In this test, groups of 4- to 6-week-old outbred mice are given a range of doses of vaccine intraperitoneally and then challenged intracerebrally 14 days later

TABLE 3 Primer and probe sets for quantitative PCR of rabies N-protein mRNA

[a] Primers and probes were designed from the N mRNA sequences of CVS (NCBI accession no. AF406696) and SHBRV-18 (NCBI accession no. AY705373). FAM, carboxyfluorescein; BHQ, Black Hole Quencher.
[b] Q-RT-PCR was performed with a Bio-Rad iCycler on samples of mouse brain infected with CVS-24, CVS-N2c, CVS-F3, and a silver-haired bat rabies virus (SHBRV) isolate obtained from a human rabies case.

with 5 to 50 50% lethal doses of rabies CVS so that all unvaccinated mice die. While this is the accepted method for testing a vaccine, the extensive antigenic differences between CVS and wildlife rabies virus strains suggest that assessment of protection against diverse virus isolates may be appropriate under certain cirucumstances.

QUALITY ASSURANCE AND CONTROL

The variable spread of rabies virus into different areas of the CNS, the existence of extensive antigenic diversity in rabies virus isolates, particularly in the G protein, and methodological variability between different laboratories present significant concerns in the diagnosis of rabies virus infection. Nevertheless, all of the immunological and molecular rabies virus detection approaches have sensitivity which is limited by the nature and quality of the sample, the quality of the specialized reagents necessary, and expertise with the technology. For instance, a major concern when monoclonal antibodies are employed for DFA detection of rabies virus infection is that the antibodies utilized can detect the full range of antigenically disparate rabies virus strains. In this case, N-specific antibodies are more appropriate than those specific for G because of the more conserved antigenic structure of the former. Recommended standardized reagents and DFA methods for the detection of rabies antigen are detailed on the CDC rabies website (www.edc.gov/ncidod/dvrd/rabies) and elsewhere (17). These recommendations should be followed to minimize technical failures in the diagnosis of infection. False-positive results, which are not uncommon when immunofluorescent approaches are used, are best minimized by the use of commercially available monoclonal antibody preparations (e.g., FITC-anti-rabies monoclonal globulin [Fujirebio Diagnostics, Inc.; catalog no. 800-092]). Proper sample handling and storage are important, and positive-control tissues should always be utilized. A positive DFA reaction should be considered definitive; however, a negative DFA result only implies that the particular tissue sample does not contain virus antigen. A negative result is considered conclusive only if the studies include a complete cross section of the brainstem and cerebellum or hippocampus and have been performed with fluorescein-conjugated anti-rabies virus antibodies from two different sources. Due to the procedures involved, laboratories performing the DFA test for rabies in the United States should participate in the national rabies virus proficiency testing program, available through the Wisconsin State Laboratory of Hygiene (details may be found on their website, www.slh.wisc.edu/pt). Bench training and consultation on the basic aspects of rabies training are available in the United States through a variety of state public health laboratories and the CDC. RT-PCR using primers specific for conserved regions of rabies virus N RNA is gaining acceptance for rabies diagnosis in laboratories where the technology is available because of the sensitivity of this technique, its utility for samples that are not suitable for immunohistological approaches, and the ability to use sequence analysis of the products to identify different rabies virus strains. A duplex RT-PCR protocol using rRNA as an internal control to assess sample degradation may reduce the probability of false-negative results (20). However, similar to the importance of choosing the right antibodies for the DFA test, the selection of primers is critical. For quantitative RT-PCR, both primers and probes must be appropriate. This may limit the utility of RT-PCR technology for general screening purposes unless reagents that can detect all possible rabies virus isolates are available. Due to sensitivity of RT-PCR-based technologies, false positives can be a major concern, particularly if the work is performed in laboratories where the virus is being grown or processed. Controls to ensure that the RT-PCR reagents, laboratory supplies, and environment are not contaminated with rabies virus RNA are essential.

The assessment of rabies virus-specific neutralizing antibody titers by fluorescent focus inhibition tests like the RFFIT requires technical expertise. With variability in the quality of the cell culture, the percentage of cells infected by the assay virus in the absence of antibody, and changes in the appearance of the fluorescent signal when different assay viruses are used, individual assays give results which can be difficult to interpret and must be equilibrated by using antibody standards. The FAVN test shows particular promise in having accuracy which is similar to that of RFFIT yet requiring less expertise to read. On the other hand, ELISA-based technologies are relatively straightforward technically but cannot discriminate between neutralizing and nonneutralizing antibodies. Thus, ELISA has limited value in assessing protective immunity. However, quantitation by ELISA of rabies virus N produced in culture by cells incubated with rabies virus in the presence and absence of antiserum can be used to provide an estimate of antibody neutralizing activity, but these and similar assays in which virus replication is assessed by RT-PCR have not been generally accepted. For all of these approaches, note that antigenic disparity between the fixed assay virus and the infecting or vaccine strain that elicited the antibody may be a concern and the proper controls should always be utilized.

INTERPRETATION

Rabies continues to be an all too common disease of wildlife throughout much of the world. Reducing animal reservoirs of rabies by vaccination has proven effective in various animal species. Vaccination of potential intermediary vectors of rabies virus, such as cats, can also limit human exposure to the virus. Nevertheless, the thousands of animals submitted for testing that are found to be positive for rabies virus each year in the United States necessitate the administration of postexposure prophylaxis to human contacts at a rate of up to 40,000 times a year. These measures, which limited annual fatal human cases of rabies in the United States to an average of fewer than 6 per year in the late 1990s, are dependent upon prompt confirmation of rabies infection in a suspect animal. Routine evaluation of the levels of rabies virus-neutralizing antibody in the sera of individuals immunized against rabies because of a risk of exposure through the nature of their employment or travel to areas of the world with endemic dog rabies is also recommended.

The apparent emergence of cases of human rabies without known exposure, associated predominantly with bat-borne rabies virus strains, has led to the suggestion that rabies virus infection may be a more common cause of lethal encephalitis of unknown origin than is currently thought. The failure to correctly diagnose rabies as a cause of fatal encephalitis has recently led to the death from rabies of a number of individuals who received organ transplants contaminated with the virus. At the least, this indicates that more vigorous attempts should be made to rule out rabies virus infection as a cause of encephalitis progressing to coma. Thus, techniques for the rapid detection of rabies virus antigens, for the identification of rabies virus strains, and for the assessment of immunity to the virus continue to have considerable value. A confirmed elevation in serum

rabies virus-specific antibody titer has diagnostic value, but the appearance of rabies virus-specific antibody in CSF is more conclusive of an infection, as such antibodies are never seen in CSF following immunization. However, negative results for the presence of rabies virus-specific antibody in CSF and serum from an infected individual are not uncommon. The detection of rabies virus antigen in various histological specimens or RT-PCR detection of rabies virus-specific RNA sequences is more reliable. With proper care being taken to control for false-positive reactions, a confirmed positive result from a single sample is taken as definitive. Negative results are considered less meaningful since viral replication may be limited to sites which have not been sampled.

The U.S. Department of Health and Human Services, Public Health Service, CDC, and National Institutes of Health recommend Biosafety Level 2 practices and facilities for all activities with materials infected or potentially infected with rabies virus. Immunization is recommended for individuals whose occupations or other activities may predispose them to exposure to rabies virus. It is noteworthy in this regard that antigenic cross-reactivity between rabies virus G and human immunodeficiency virus type 1 (HIV-1) gp120 has been described, and sera from rabies-immune individuals have occasionally cross-reacted against HIV-1 gp120 in ELISA (2).

Human T-Cell Lymphotropic Virus Types 1 and 2

SUSAN B. NYLAND, THOMAS P. LOUGHRAN, AND KENNETH E. UGEN

89

VIRAL CHARACTERISTICS

The human T-cell leukemia virus type 1 (HTLV-1) is a member of the family *Retroviridae*, consisting of enveloped, single-stranded, positive-polarity RNA (two copies make the virus diploid) viruses using RNA-dependent DNA polymerase (reverse transcriptase, [RT]). It is classified as an oncovirus. Although the virus has proliferative capabilities similar to true type C oncogenic retroviruses, it does not appear to express a defined "conventional" viral oncogene, and thus it is unique within the oncovirus subfamily. HTLV-1 is transmitted by parenteral, vertical, and sexual routes, in descending order of efficiency. Its seroprevalence varies according to geographical region. Historically, regions of endemic infection have included Japan, South America, Central Africa, and the Caribbean basin, with a seropositivity range of 3 to 30%. More recently, HTLV-1 infection has become more common in the southeastern United States and in injecting drug users (IDU) worldwide. In the general U.S. population, the seropositivity level is about 0.06%, while in the southern United States, it ranges from 0.5 to 2% in the non-IDU population and around 20% in the IDU population (16). HTLV-2 has 66% homology to HTLV-1, and although it transforms cells similarly to HTLV-1 in vitro, it is less able to do so in vivo and hence is considered the less pathogenic of the two retroviruses. HTLV-2 is endemic to several Amerindian tribes, and it is estimated that 2 to 30% of some tribal populations are carriers of this retrovirus. From 3 to 18% of IDU in the United States and Europe are also infected with the virus (9, 16). Recent in vitro data relevant to HTLV and human immunodeficiency virus (HIV) seropositivity in IDU suggest that morphine/heroin exposure at levels relevant to heroin addiction enhanced HTLV infection in cells coinfected with HIV and HTLV, perhaps increasing the likelihood of disease development in coinfected IDU (17).

HTLV-1 was reported in 1980 by Bernard Poiesz and Robert Gallo as the first retrovirus shown to be pathogenic to humans (19). HTLV-1 preferentially infects CD4+ lymphocytes, with rare infections noted in dendritic cells, CD8+ T lymphocytes, and null (CD4− CD8−) T lymphocytes. HTLV-2 exhibits expanded tropism and infects macrophages in addition to all of the cell types mentioned above. In the later stages of HTLV-1 diseases, viral proteins can be detected in a variety of affected tissues; however, the virus itself has not been identified in other tissue cells. The virus is transmitted predominantly by direct contact with infected cells; therefore, whole packed blood is infectious while cell-free serum is not. HTLV-1 is extremely difficult to isolate, and cell-free clones typically exhibit titers so low that infection can be detected only by PCR techniques. This cell-dependent quality has made the virus somewhat more difficult to study than its lentiviral cousin, HIV. With the exception of the glucose transporter GLUT-1 (13), receptors used by the virus for attachment remain unconfirmed. Cell adhesion molecules may also play an important role in infection (1).

Once the virus is in the host cell, the HTLV RNA genome is reverse transcribed into proviral DNA, which is then integrated into the host DNA. When the host cell is activated, cellular transcription factors initiate the synthesis of new viral mRNA. Translation of the viral mRNA produces the 40-kDa Tax protein as well as other viral proteins. Tax focuses the cellular transcriptional machinery by dominating the interactions with cell transcription factors, such as NF-κB and cyclic AMP response element binding proteins (3). The enhancer activity induced by Tax is located in the viral long terminal repeat sequences of the proviral DNA. The long terminal repeat contains a 21-bp repeat sequence, which is a Tax response element that functions as a viral cyclic AMP response element. Thus, more viral proteins are produced and eventually processed into progeny for cell-to-cell transmission.

In addition to virus production, the promiscuous interactions of Tax with host transcription factors contribute to a constitutively activated state of the infected cell. Secreted Tax acts in a similar fashion on noninfected bystanders. Two cytokines associated with activation, interleukin 2 (IL-2) and IL-6, are abundantly present in HTLV-1-infected cell cultures (5, 7). IL-2 is considered an essential cytokine for the initiation of cell-mediated immune responses and is necessary for the proliferation of T lymphocytes. IL-6 is best known for its role in inflammatory immune responses. Thus, the constantly activated state is thought to be responsible for the diseases associated with HTLV infection.

DISEASES ASSOCIATED WITH HTLV INFECTION

As can be surmised from the description of some mechanisms of pathogenesis, the diseases associated with HTLV

798

infection have inflammatory and/or proliferative attributes. HTLV-1 and HTLV-2 diseases are usually classified as malignant or nonmalignant clinical presentations. Nonneoplastic disease states may be due to an oligoclonal proliferation of infected cells, while the proliferation of only a few infected clones is thought to lead to the development of neoplasia. It has been postulated that all HTLV infections begin with oligoclonal proliferation (4). With time and other unknown factors, a few dominant infected clones evolve; therefore, the progression of nonmalignant disease may be related to the risk of developing a malignancy.

Nonneoplastic Diseases Due to Infection with HTLV-1

HAM/TSP

HTLV-associated myelopathy/tropical spastic paraparesis (HAM/TSP) is probably the best-known nonmalignant syndrome attributed to HTLV infection. Although HAM/TSP is attributed mostly to the effects of HTLV-1 infection contracted after the onset of adulthood, spinal cord lesions from a few patients have demonstrated evidence of HTLV-2 infection (9). The lifetime risk of developing HAM/TSP in seropositive carriers is currently estimated to be 2%. HAM/TSP is characterized by a set of progressive neurological disorders that include incontinence with constipation, hyperreflexia, hypoesthesias, Babinski reflex, clonus, ataxia, and weakness of the lower extremities. Activated immune cells are thought to contribute to the inflammatory process in the central nervous system during HAM (12, 18) by direct and indirect pathways. The diagnosis of HAM/TSP is based on clinical presentation, lack of documented history of other known causes of paraparesis, and the presence of antibodies against HTLV-1 in the blood or cerebrospinal fluid. HAM patients are treated symptomatically, with danazol for incontinence and with corticosteroids and benzodiazepines.

HU

HTLV uveitis (HU) presents clinically as an intraocular inflammation in one or both eyes, accompanied by visual impairment. HU can occur with or without HAM, and the lifetime risk to HTLV-1 carriers is approximately 2.5%, somewhat higher than the risk of developing HAM. Concurrent Graves' disease may also be observed. An examination of the eye reveals iritis, retinal vasculitis with the presence of gray-white bodies, a nontransparent vitreous humor, decreased tear breakup time, and keratoconjunctivitis. The development of HU in HTLV-1 carriers is attributed to the infiltration of infected, activated T lymphocytes and their secreted cytokines. A high level of viral antigen can be found in ocular fluids, as well as relatively elevated levels of IL-6 (15). HU patients typically have a greater viral load than asymptomatic carriers. Diagnosis of uveitis is based on clinical presentation and the presence of antibodies to HTLV-1 as well as the confirmation of proviral DNA by PCR. Because uveitis can be caused by other infectious agents, infections such as syphilis, tuberculosis, toxoplasmosis, or cytomegalovirus infection need to be ruled out (14). HU responds well to topical treatment with corticosteroids.

HTLV-1-Associated ID

HTLV-1-associated infective dermatitis (ID) is manifested primarily in children who have acquired HTLV-1 by vertical transmission (11). Clinically overt symptoms include severe eczema on the head, neck, and groin, with a clear nasal discharge. The affected areas of the head include the scalp, ears, nose, and eyelid margins. Cultures of skin biopsy specimens usually demonstrate that colonization by *Staphylococcus aureus* or beta-hemolytic streptococcal species has occurred, and testing of biopsy material reveals the presence of HTLV-1 proviral DNA. Elevated $CD4^+$ and $CD8^+$ T-cell counts, found in dermal exudates as well as in peripheral blood, contribute to an increased susceptibility to bacterial infection, due to nonspecific activation of B cells via activated T-cell-secreted cytokines. The combination of apparent dermatitis with nasal discharge and antibodies to HTLV-1 is necessary for the diagnosis of ID (11). Additional symptoms may include anemia, lymphadenitis, and abnormally high serum globulin. Long-term antibiotic therapy is required for treatment of ID, since recurrence is common when antibiotics are withdrawn.

HTLV-1-Associated Sicca Syndrome

HTLV-1-associated sicca syndrome, resembling Sjögren's syndrome, can be observed in some HAM/TSP patients as well as in otherwise asymptomatic carriers. Sjögren's syndrome is an autoimmune disorder complete with the expression of anticentromere antibodies, while the antibodies expressed with sicca syndrome are to HTLV-1 (2). Clinical presentation includes dry eyes and dry mouth frequently accompanied by recurrent fever and myelopathy. Lymphocyte infiltration, as well as viral Tax, is evident in the salivary glands (2). Diagnosis is dependent on clinical presentation with detection of HTLV-1 infection. Sicca syndrome can be due to a variety of infectious agents and chemical agents; therefore, other possible causes should be ruled out. Treatment includes topical and oral steroids and artificial tears.

Nonneoplastic Diseases Due to Infection by HTLV-2

HTLV-2 infection is associated with a progressive ataxia similar to HAM/TSP in some patients (8); however, the risk of developing this symptom in HTLV-2 carriers has not been determined. The role of HTLV-2 infection in subclinical neurological sequelae and greater susceptibility to infectious disease overall has been recently reported (16). A positive history of recurrent bladder and kidney infections, minor fungal infections, and pneumonia may indicate HTLV-2 infection. Confirmation of infection is determined by the presence of antibodies and proviral DNA.

Neoplastic Diseases Due to Infection by HTLV-1

HTLV-1 infection acquired prior to the onset of adulthood carries a higher risk of neoplastic disease than does infection acquired later in life. Adult T-cell leukemia/lymphoma (ATL) appears in about 3 to 5% of HTLV-1 carriers decades after infection (6, 20). Skin lesions constitute the most common initial clinical presentation of disease and can appear as papules, nodules, infiltrated plaques, tumors, or erythroderma. A general diagnosis of ATL is made on the basis of clinical presentation, hematological examination, and presence of antibodies to HTLV-1 and by the molecular confirmation of proviral DNA. The immune system may fail to respond to HTLV-1 due to the production of defective virus particles in neoplastic cells. If so, antibody levels may be insufficient for detection. The diagnosis is completed by a determination of (i) smoldering, (ii) chronic, (iii) lymphoma, or (iv) acute ATL, based on additional criteria. These four subtypes of ATL have been designated by the Lymphoma Study Group of Japan (20).

In smoldering-type ATL, the patient has a normal to slightly elevated lymphocyte count, with about 5% abnormal lymphocytes. Serum lactate dehydrogenase (LDH) levels are

elevated to about 1.5 times the normal value. There is usually a positive history of HAM/TSP. About half of these patients will progress to acute ATL. The median survival time after diagnosis is approximately 4 years.

Lymphocytosis with 5 to 10% abnormal T cells is evident in chronic-type ATL. These consist of small cells with cerebriform nuclei and basophilic cytoplasms together with large cells containing convoluted, multilobed nuclei. The larger cells are called flower cells and are considered characteristic of ATL. From 5 to 20% of the abnormal leukocytes may consist of flower cells, which can be viewed by Giemsa staining. The serum LDH level is about twice the normal level. As with smoldering-ATL patients, about half of the chronic ATL patients will progress to acute ATL. At that time, hypercalcemia is present. Unlike patients with other ATL subtypes, chronic ATL patients may present with concomitant HAM/TSP. The median survival time after diagnosis is 3 to 4 years.

In contrast to chronic ATL, lymphocytosis is not evident during lymphoma-type ATL. Blood histology reveals 1% or fewer abnormal lymphocytes in the patient's peripheral blood. The serum LDH level is elevated. Most patients present clinically with a generalized lymphadenopathy, and approximately half have hypercalcemia. Hepatomegaly and splenomegaly may also be present, indicating extensive organ involvement. Histologically, lymphoma-type ATL may mimic Hodgkin's disease. The abnormal cells are observed as a pleiomorphic T-cell lymphoma, with a large and bilobed Reed-Sternberg-like morphology. The median survival time after diagnosis of lymphoma-type ATL is less than 1 year.

The acute-type ATL is the most common subtype of ATL. More than 10% of the peripheral blood consists of abnormal lymphocytes. Giemsa stains of blood smears reveal a pleiomorphic T-cell lymphoma similar to chronic ATL, with 5 to >70% of the abnormal cells identified as ATL flower cells. Generalized lymphadenopathy, hypercalcemia, and skin lesions are common to the clinical picture. An additional manifestation of the skin resembling a mycosis fungoides-like rash is likely to emerge. The patient may exhibit uveitis or retinitis, with a somewhat extensive involvement of the liver and spleen. Acute ATL is rapidly fatal, with a median survival of only 6 months after diagnosis.

The treatment of ATL consists of chemotherapy, alpha interferon, and zidovudine. Relapses are common, and when they occur, treatment is generally ineffective. About 9 of 10 ATL patients have ATL cells that overexpress multidrug resistance genes (10), and this is thought to contribute to the resistance of ATL to chemotherapy. The main cause of death is disease progression combined with hypercalcemia and septicemia (20).

DETECTION OF HTLV INFECTION

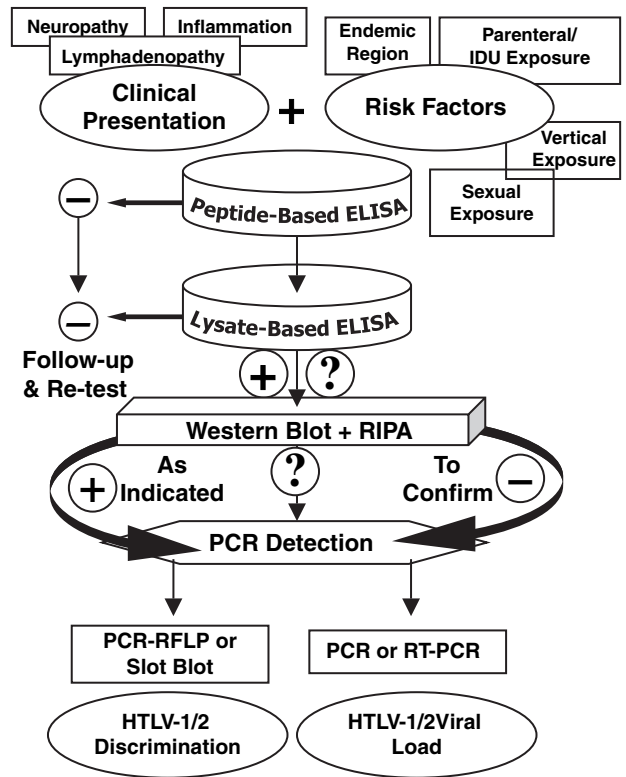
The detection of HTLV-1 and -2 relies on the presence of serum or plasma antibodies and proviral DNA. Enzyme-linked immunosorbent assays (ELISAs), Western immunoblots, and radioimmunoprecipitation assays (RIPAs) are used to confirm repeatedly reactive or inconclusive findings. In serum samples, antibodies against the core antigen proteins appear first, followed by antibodies to the viral envelope and finally by anti-Tax antibodies. Patients who have a combination of relevant symptoms and risk factors should be monitored even if their serum is nonreactive in diagnostic ELISAs, due to the previously described antibody suppression that sometimes occurs during infection. The detection process is illustrated and summarized in Fig. 1.


FIGURE 1 Flowchart for HTLV-1 and -2 detection and discrimination. For patients with combined clinical presentation and risk factors, detection of HTLV-1 and -2 infection begins with ELISA testing. When both ELISA results are negative (−), it is recommended that follow-up include documentation of other possible causes for the clinical presentation, as well as additional testing if other causes are ruled out. Repeatedly reactive (+) results must be confirmed by Western blot analysis and then analyzed by PCR if indicated. Indeterminate (?) or reactive ELISA results that are nonreactive on Western blotting should be confirmed by RIPA. Repeatedly indeterminate results can be clarified by PCR-related methods. RFLP, restriction fragment length polymorphism.

ELISA kits approved for diagnostic use in the United States are evaluated by the Food and Drug Administration Center for Biologics Evaluation and Research (FDA/CBER). According to the current CBER website, updated in March 2004 (www.fda.gov/cber/products/testkits/htm), only two approved kits are available, although other testing kits are listed elsewhere on the site. These two kits are the Abbott HTLV-1/2 ELISA (Abbott Laboratories, Diagnostics Division) and the Vironostika HTLV-1/2 MicroElisa system (marketed by Ortho at Johnson & Johnson). Abbott Laboratories recently introduced a chemiluminescent version of its diagnostic ELISA, called the Prism chLIA, which is not yet on the CBER-approved list. Briefly, recombinant HTLV-1 and -2 gag and env antigens are immobilized onto microtiter plates. A blocking agent is added to decrease nonspecific reactions. Samples containing antibodies are reacted with the immobilized antigens. The nonreactive portion of the sample is removed, while the reactive (antibody) portion remains tightly bound to the antigen. An enzyme-conjugated secondary antibody is reacted with sample and standard control antibodies and is detected colorimetrically (or with chemiluminescence if the Prism test is used). A more detailed

description of the ELISA technique is provided in chapter 3 of this volume. A positive result usually has a colorimetric value of at least 2 standard deviations greater than negative controls. Certified ELISAs involving the use of recombinant proteins or peptides are developed to reduce the number of indeterminate results or values that are between the cutoff values of the negative and positive controls. Indeterminate results can occur when the patient is undergoing seroconversion, usually very early in the infection. A retest later for such patients usually resolves this type of indeterminate finding. Certain autoimmune diseases may mimic some of the symptoms of HTLV infection, and the sera of such patients may also yield indeterminate results in the ELISA format. Patients with rheumatoid factor or antinuclear antibodies are examples of noninfected individuals who may have indeterminate results for HTLV-1 and -2 serum antibodies.

Indeterminate blood can be sent to a clinical reference laboratory. Specialty Laboratories (www.specialtylabs.com), Laboratory Corporation of America (LabCorp; www.labcorp.com), the Molecular Infectious Disease Laboratory (MIDL) division of the Genetics and IVF Institute (www.givf.com/midl), and Quest Diagnostics Laboratories (www.questdiagnostics.com) were among the reference laboratories found online with resources for confirming HTLV-1 and -2 infections. These laboratories perform several types of Western immunoblot assays with or without RIPA. The criterion for a positive Western blot assay is the detection of antibodies to a series of core antigens (gag) and envelope glycoproteins. When a sample exhibits reactivity to only one set of viral proteins or lacks reactivity to HTLV gag p24 and env proteins, it is still considered indeterminate (14). There must be no band development in order for the results to be considered seronegative.

Inconclusive ELISA and Western immunoblot findings can be further tested by RIPA, which is more sensitive to smaller amounts of serum antibody, before PCR analyses are performed. Quest Diagnostics Laboratories, LabCorp, and MIDL also have specialized facilities to perform real-time PCR analyses of genomic DNA from EDTA-treated whole blood. PCR targets typically include conserved regions of *gag* and *pol*. This technique is also useful for differentiating between HTLV-1 and HTLV-2, as well as for detecting proviral DNA in tumor tissue, exudates, and skin biopsy specimens. In addition, the use of PCR allows a determination of the viral load, which may correlate with disease progression. The following PCR-related methods of virus detection and differentiation are described in chapter 5 of this volume.

A slot blot is the combination of PCR with probe hybridization techniques. Standard primer pair sets are available for this purpose from Synthetic Genetics (San Diego, Calif.) and Roche Diagnostics. For example, genomic DNA is extracted from the sample and primer pairs for HTLV-1 and -2 *pol* genes are used to amplify a conserved region of proviral DNA. After PCR amplification, the reaction products are isolated by electrophoresis and then transferred to a nylon membrane. The subsequent hybridization with labeled HTLV-1 and -2 *pol*-specific probes to detect differently sized amplimers allows a classification of immunologically indeterminate samples (22).

Because of the genomic differences between HTLV-1 and HTLV-2, the detection of restriction fragment length polymorphisms on agarose gels after PCR amplification products have been digested is a useful alternative to the blot technique (21). The interpretation of PCR-restriction fragment length polymorphism findings is based on the comparison to the banding patterns of known standards.

The development of recombinant RT has greatly reduced the cost and uncertainty of viral-load quantification by RT-PCR. In this technique, viral RNA is reverse transcribed using RT. The resultant cDNA is then amplified by PCR and compared to amplified standards containing known amounts of target cDNA. The preferred specimen for this type of clinical test is usually EDTA-treated plasma.

Although PCR-related methods are not approved by the Food and Drug Administration and are not routinely used for screening, they have proved to be reliable and sensitive tools for the detection and discrimination of HTLV-1 and -2 from previously indeterminate samples. Thus, the ability to use or at least understand these techniques can serve to confirm and to further clarify differential diagnoses of HTLV-associated diseases.

REMARKS ON PREVENTION AND TREATMENT OF INFECTION

HTLV-1- and HTLV-2-seropositive patients should be counseled about prevention of transmission. Patients are advised to use condoms during sexual intercourse and are prohibited from donating blood or blood products. HTLV-positive female patients of childbearing age should refrain from breast-feeding. This will prevent about 90% of the incidences of vertical transmission (from 30% with breast-feeding to 3% without breast-feeding). Intimate contacts and children of patients are at risk for acquiring infection. Accordingly, testing for the corresponding virus would be appropriate for these individuals. Because of the role played by vertical transmission, parents of patients who are not suspected of acquiring the disease by parenteral or sexual routes might also prove to be seropositive. Casual household and social contacts are not at risk.

Currently, there are no antiviral drugs designed specifically for HTLV-1 or HTLV-2. Because of the differences between lentiviruses and oncoviruses, most anti-HIV drugs, including the protease and nonnucleoside RT inhibitors, are generally ineffective against the leukemia viruses. The use of zidovudine, a nucleoside analogue, in combination chemotherapy protocols appears to offer only a transient benefit to patients. Several highly conserved regions found in the genomes of both viruses make them likely candidates for successful vaccine prophylaxis (1, 14). In fact, the more genetically conserved nature of HTLV-1 and -2 compared to HIV-1 makes a vaccine against HTLV-1 and -2 more logistically feasible than is a vaccine to HIV-1. However, the development of such vaccines has been slow, and ongoing research is relatively scarce. Consequently, the treatment of HTLV-seropositive patients is directed at the amelioration of HTLV-associated disease symptoms.

Coronavirus Including Severe Acute Respiratory Syndrome (SARS)

JAMES B. MAHONY AND CHENGSHENG ZHANG

90

Coronavirus, a genus within the family *Coronaviridae*, contains a number of enveloped viruses that infect both animals and humans. Coronaviruses possess a positive-strand RNA genome, 27 to 32 kb in size, which is the largest known genome among all RNA viruses. The genomic RNA is capped and polyadenylated and comprises several genes encoding both structural and nonstructural proteins. The genome organization of coronaviruses has the characteristic order 5′-replicase, spike (S), envelope (E), membrane (M), nucleocapsid (N)-3′ (11). The G+C content ranges from a low of 32% for coronavirus HKU1 (CoV-HKU1) to a high of 41% for severe acute respiratory syndrome (SARS)-associated coronavirus (SARS-CoV). In addition to the S, E, M, and N structural proteins, the genome also encodes a chymotrypsin-like protease, replicase (polymerase), helicase, and hemagglutinin-esterase. For the replicase gene, a frameshift interrupts the protein coding regions and separates open reading frames (ORFs) 1a and 1b. Both the 5′ and the 3′ ends contain short untranslated regions. The RNA genome is translated as a polyprotein which is subsequently cleaved by the chymotrypsin-like protease activity. The S gene encodes the spike glycoprotein, which binds to the host cell receptor (ACE-2 in the case of SARS-CoV and aminopeptidase N or CD13 for HCoV-229E) and leads to membrane fusion and viral entry.

Coronaviruses have been identified in mice, rats, chickens, turkeys, swine, dogs, cats, rabbits, horses, cattle, and humans and cause a variety of severe diseases, including gastroenteritis and respiratory tract diseases. Up until 2002, there were only two known human coronaviruses (HCoVs), HCoV-OC43 and HCoV-229E. On the basis of genotypic and serological characterization, coronaviruses have been divided into three distinct groups, with HCoV-229E in group 1 and HCoV-OC43 in group 2 (11). Since 2002, three additional HCoVs have been discovered, bringing the total number of HCoVs to five. In 2002, SARS emerged from mainland China and SARS-CoV was identified as the causative agent (16). On the basis of genome analysis, SARS-CoV was originally assigned to a fourth CoV group but more recently has been recognized as a distant relative to the group 2 coronaviruses and has been considered as a group 2 subgroup (14). In 2004, a novel group 1 HCoV associated with respiratory tract infections, HCoV-NL63, was discovered in The Netherlands and its genome was sequenced (24). In 2005, the fifth HCoV, a group 2 HCoV, was discovered in patients with pneumonia in Hong Kong and its genome was sequenced (25).

HCoV-OC43 and -229E were identified in the mid-1960s as a cause of mild self-limited upper respiratory infection and were subsequently shown to cause about one-third of "common cold"-like illnesses in adults. Overall, they account for between 5 and 30% of respiratory tract infections, and outbreaks may occur at 3- to 4-year intervals (23). Like infections caused by other respiratory viruses, HCoV-OC43 and -229E infections can present with a variety of signs and symptoms ranging from a self-limiting common cold including cough, runny nose, and fever to a lower respiratory tract infection with bronchiolitis or pneumonia. HCoV-OC43 and -229E have been associated with respiratory tract infection in a variety of settings, including nosocomial infections in high-risk immunocompromised children, hospitalized elderly patients with noninfluenza severe respiratory tract infection and pneumonia, and newborns, children, and hospital staff (4, 17, 22). In one recent prospective study of 501 patients in France, HCoV-OC43 was found in 6% of patients compared with 6.1% for respiratory syncytial virus, 7.8% for influenza virus, 6.4% for rhinovirus, 1% for parainfluenzavirus 2, 2% for adenovirus, and 1% for enterovirus (22). Symptoms included fever (59%), rhinitis (37%), pharyngitis (30%), laryngitis (3%), otitis (13%), bronchitis (17%), bronchiolitis (10%), and pneumonia (7%). Like other respiratory viruses, HCoV-OC43 and -229E are spread by large-droplet infection. Of concern to infection control practitioners is a recent finding that HCoV-229E can survive for up to 3 h when dried on solid surfaces and for up to 6 days in saline solution at room temperature.

SARS first appeared as a potentially fatal cause of pneumonia in Guangdong Province of China in November 2002. The first human case was identified on 16 November, and within 6 months SARS spread to 29 countries, infecting 8,098 people and killing 774 individuals (26). The last known case in this outbreak occurred 15 July 2003 in Taiwan. This outbreak had a profound effect on public health and economies worldwide, with an estimated $100 billion lost from global economies. SARS has arguably been the most significant event in medical virology since the emergence of human immunodeficiency virus and AIDS in the early 1980s.

SARS-CoV is believed to be zoonotic in origin, having crossed into humans most likely from animal hosts in the wild-game markets in Guangdong Province. Many of the first infected individuals in November and December 2002 had contact with the live-game trade. The disease was first called

"infectious atypical pneumonia" because it caused clusters of disease in families and health care workers. The etiologic agent of SARS was identified as a new coronavirus by Peiris and coworkers at the University of Hong Kong (16), and the viral genome was fully sequenced in a record time of 3 weeks first by workers at the University of British Columbia, Vancouver, Canada (14). Genomic analysis revealed that SARS-CoV was a new coronavirus not previously found in humans. The absence of antibody in healthy humans suggested that SARS-CoV had recently emerged in the human population and that animal-to-human interspecies transmission was the most probable explanation for its emergence. Specimens collected from apparently healthy animals in the wild-game animal markets in China indicated that a number of animals, including the Himalayan palm civet cat and raccoon dogs, yielded a SARS-CoV-like virus with more than 99% nucleotide homology to human SARS-CoV. Many animal handlers with no previous history of a SARS-like illness had serum antibodies to SARS-CoV. Taken together with the fact that a number of SARS cases had an epidemiological link to wild-game animals, it is very likely that the wet markets in Guangdong provided the interface for transmission to humans. The early transmissions to humans were probably inefficient, causing little disease or human-to-human transmission. The animal SARS-CoV-like virus probably adapted in humans for efficient human-to-human transmission, and SARS-CoV emerged. There is evidence that the SARS-CoV evolved towards greater "fitness" during the SARS outbreak, since human viruses isolated late in the outbreak showed a 29-nucleotide deletion in ORF 8 that was absent from both human viruses isolated early in the outbreak and animal viruses (8). Similarly, the gene encoding the spike protein that mediates viral entry shows high rates of nonsynonymous mutations in early isolates that are absent in later isolates, probably reflecting the ongoing adaptations to the new host.

The major route of transmission in humans is droplet infection, aerosolization, and fomites. Deposition of droplets onto the respiratory epithelium probably initiates infection. Whether infection can occur through the oral or conjunctival epithelium remains unknown, but SARS-CoV has been detected in tears. Although exposure to the animal SARS-like virus may have caused asymptomatic infection, once the virus adapted to the human host, asymptomatic infection seemed to be a rare event. Despite the rapid spread of SARS worldwide, the average number of secondary infections caused by any one case is low (2.2 to 3.7) compared with influenza (5 to 25), and household transmission of SARS is relatively inefficient (6). Superspreading events in which a few infected individuals disproportionately contribute to transmission (e.g., a difficult intubation in the intensive care unit resulting in infection of a number of house staff) were characteristic of the outbreak. The factors associated with superspreading events are not well understood but may include coinfection with other viruses, host factors such as immunosuppression, and/or environmental factors.

At the beginning of the SARS outbreak, nosocomial infections played an important role. The first major outbreak in Hong Kong occurred in the Prince of Wales Hospital around 10 March 2003, resulting in 138 SARS cases, 69% of which were hospital workers. By the end of the outbreak there were 1,755 SARS cases in Hong Kong, 339 of which were workers in 16 hospitals. The attack rates for hospital workers varied widely during the outbreak. The overall attack rate for workers in the 16 hospitals in Hong Kong was 1.2%. In Canada, the first large outbreak occurred also in a community hospital, affecting 128 patients, of which 37% were hospital staff. In the

Canadian outbreak, the attack rates among nurses ranged from 10.3 to 60%, depending on which department they were serving. The number of infected staff was strongly correlated with the number of admitted SARS patients, the length and type of exposure, and the use of personal protective equipment such as gloves and masks. Later in the outbreak it was shown that personal protective equipment significantly decreased nosocomial infections and played a significant role in outbreak management. These and other studies indicated that the transmission of SARS is driven by exposure.

The natural history of SARS-CoV has been documented in several studies. The initial symptoms are unremarkable and common to all upper respiratory tract viral infections. A few days of cough and low-grade fever progresses rapidly to a full-blown pneumonia requiring hospitalization and often mechanical ventilation. Fever, malaise, lymphopenia, elevated liver enzymes, and infiltrates and consolidation on chest X ray are usually present. Quantitative PCR studies have shown that the viral load is high in the lower respiratory tract but low in the upper respiratory tract. Viral load in the upper respiratory tract and feces is low during the first 4 days and peaks at around day 10 of illness (19). This is in marked contrast to other respiratory viral infections such as influenza that peak soon after the onset of symptoms. This unusual feature of SARS-CoV infection explains its low transmissibility early in the illness and perhaps explains why outbreaks in some countries were limited to only a few cases. More importantly, it explains the poor sensitivity of early reverse transcriptase PCR (RT-PCR) tests on nasopharyngeal (NP) specimens collected early in the illness.

Although the main clinical symptoms are those of severe respiratory tract disease, the virus also infects other organs. About a quarter of SARS patients had a watery diarrhea, and virus can be cultured from the feces and urine as well as the respiratory tract. Virus can also be detected in serum, plasma, and peripheral blood leukocytes by RT-PCR; however, the viremia may be short-lived. Patients have a pronounced peripheral T-cell lymphocytopenia with reduced CD4 and CD8 cell counts, with one-third of individuals having a CD4 count of <200 cells/mm^2. Infected individuals with high viral loads in serum have a poor prognosis. Between days 10 and 15 of illness, high viral loads in NP aspirates (NPA), feces, and serum are independent predictors of adverse clinical outcome. SARS-CoV is invariably found in the lungs of individuals dying of SARS, but the viral load is usually higher in those dying earlier in the course of illness (<21 days). About one-quarter of patients with SARS require management in intensive care units, and the overall fatality rate is $\sim$11%. Disease severity and mortality are correlated with age, with the highest mortality rates (52%) for those >65 years of age and the lowest rate for the 0- to 24-year-old group. Children who acquire SARS seldom require intensive care or mechanical ventilation (10). Although SARS-CoV can be found for months in the feces of an infected individual, there is no evidence that the virus persists following resolution of the illness.

The fourth human coronavirus, HCoV-NL63, was first discovered in The Netherlands in a 7-month-old boy who presented with coryza, conjunctivitis, and fever and who had chest X-ray findings consistent with bronchiolitis (24). The virus grew in tertiary monkey kidney cells, which distinguished it from HCoV-OC43 and -229E. Sequencing of the genome indicated that the virus was not a recombinant virus but genetically distinct from all other HCoVs. After the first case, NL63 was detected in five additional children and three adults, two of whom were immunocompromised. NL63 has also been detected in 2% of prospectively studied patients

with respiratory tract infections in Brisbane, Australia. Fourchier et al. independently reported a novel group 1 HCoV with a 27,555-nucleotide genome with 34% G+C (5). This virus was first isolated in 1988 from an 8-month-old with pneumonia in monkey kidney cells and is most likely the same virus as NL63. RT-PCR assays and primers based on the first isolate were able to detect this virus in 4 of 139 specimens collected from pediatric patients with upper respiratory infections between 2000 and 2002, indicating that this virus has been circulating in The Netherlands for a number of years.

The fifth HCoV, HCoV-HKU1, was discovered in January 2004 in Hong Kong in a 71-year-old man returning from Shenzhen, China. He presented with fever and a productive cough with purulent sputum and had a chest radiograph showing patchy infiltrates. All attempts to grow a virus from NP specimens failed, but coronavirus RNA was detected in the NPA by RT-PCR using *pol* gene consensus primers (25). Quantitative PCR indicated high titers of virus (10^{-6}) present in the NPA during the first week of illness, with decreasing titers in the second week and undetectable levels of virus in the third and fourth weeks. The virus was absent from urine or stool specimens. A recombinant nucleocapsid protein-based enzyme-linked immunosorbent assay (ELISA) indicated seroconversion in the first week of infection, with both immunoglobulin M (IgM) and IgG antibody detectable. A second case was subsequently identified, a 35-year-old woman with pneumonia with unknown etiology. The recent discovery over the past 2 years of two new group 1 and 2 HCoVs from the upper respiratory tract of symptomatic patients suggests that additional as yet unidentified HCoVs may await discovery.

LABORATORY DIAGNOSIS

Infections due to HCoV-OC43 and -229E are best diagnosed by detection of viral RNA in NP specimens using a nucleic acid amplification technique such as RT-PCR. RT-PCR is more sensitive than both virus isolation and immunofluorescence staining of NP specimens. Individual coronaviruses can be detected by one of two approaches: type-specific primers can be used to amplify single HCoV types (20, 23), or consensus primers targeting conserved regions of the *pol* gene can be used to amplify all five HCoVs and the amplified RNA can be digested with specific restriction enzymes or sequenced to determine the type of HCoV present (1, 23). The diagnosis of SARS, however, presents a bigger challenge.

Isolation of SARS-CoV in cell culture followed by determination of its partial genome sequence led to the first generation of RT-PCR assays for diagnosing SARS. The first PCR assays targeted the ORF 1b *pol* gene, the first part of the genome to be sequenced. Early serological tests used SARS-CoV-infected cells and ELISAs employing crude cell lysates containing SARS-CoV antigens. Virus culture was less sensitive than RT-PCR, labor-intensive, and too slow for clinical management and required a biosafety level 3 (BSL3) laboratory. Although these tests, when used together with multiple specimens, proved useful for identifying patients at the beginning of the outbreak, they proved less satisfactory for diagnosing new cases in the first few days after onset of symptoms.

The first-generation RT-PCR assays proved more useful after the first week of illness, with only 40 to 60% of specimens testing positive in the first few days of the disease (2, 21). NP specimens had the highest positivity rates in the second week of illness, peaking at about day 10. The poor sensitivity of RT-PCR with NP specimens prompted the examination of other specimens, leading to the discovery of

virus in fecal and urine specimens. Replication of SARS-CoV in the gastrointestinal tract was confirmed by electron microscopy and RT-PCR testing of biopsy and postmortem specimens. These findings indicated that the virus rapidly disseminates from the NP to other tissues and suggested that the virus could be transmitted by the fecal route. The use of quantitative PCR assays on respiratory specimens and testing of serial specimens showed that unlike for other respiratory viral infections, the viral load and rates of positivity of SARS-CoV in the upper respiratory tract increased steadily and peaked at around day 10 after disease onset (15). Whereas viral RNA could be detected for several weeks or even months in stool specimens, virus culture was positive only during the first 2 to 3 weeks of illness. It is possible that virus replication continues for weeks but that virus is complexed with antibody and is no longer infective or transmissible. This is consistent with epidemiological findings.

In addition to being found in respiratory tract specimens, viral RNA is detected in stool, blood, cerebrospinal fluid, urine, and tears. Of these nonrespiratory specimens, stool specimens have the highest positivity rates and highest viral loads, suggesting that fecal specimens are a good alternative to respiratory tract specimens for identification of SARS patients. The low RT-PCR positivity rates for NP specimens early in the course of disease prompted examination of other approaches to increase the sensitivity of viral RNA detection. Real-time nested-PCR strategies are useful for detecting low levels of SARS-CoV in the early stage of illness, but nested PCR doubles the cost and workload and carries with it the potential for false positives due to carryover contamination. Quantitative one-step RT-PCR in a sealed reaction vessel not only reduces the chance of false positives but adds valuable viral load information. Quantitative PCR also revealed that viral loads were highest in lower respiratory tract specimens (bronchoalveolar lavage, sputum, endotracheal aspirates) and higher in NP specimens than in throat swabs (3). Fecal specimens have a high viral load at the end of the first week of illness and are the specimen of choice during the second week of disease.

Other approaches to increasing the sensitivity of PCR include testing multiple serial specimens or enhancing RNA extraction. This approach, although not comprehensively evaluated for SARS-CoV, has proven useful for detecting other microorganisms when present in low levels in clinical specimens. Targeting the nucleocapsid gene for RT-PCR should enhance the sensitivity of PCR for diagnosis, since subgenomic RNA transcripts contain nucleocapsid gene sequences following discontinuous transcription. This, however, turned out not to be the case for SARS-CoV, as RT-PCR assays targeting the nucleocapsid gene failed to be more sensitive than *pol* gene assays and subsequent studies showed that most of the viral RNA in clinical specimens was genomic RNA. The availability of nucleocapsid RT-PCR assays, however, did provide a confirmatory assay for positive specimens early in the epidemic (13). Another approach to improving sensitivity involves extraction of a larger volume of the clinical specimen and using more RNA in the PCR assay. By extracting a larger portion of NPA specimens, the sensitivity of RT-PCR was increased from about 50 to 80% for specimens collected from days 1 to 3 of disease onset while retaining 100% specificity (18). In this particular study, there was no increase in amplification inhibitors during RNA purification, but this should be controlled for by the use of an amplification control in the PCR to rule out false negatives due to PCR inhibition. Testing of serum or plasma for viral RNA was disappointing at first, but subsequent studies have shown 50 and

78% positivity rates for serum and plasma, respectively, during the first week of illness. A second study confirmed these results for plasma, with a 79% positivity rate during the first 3 days of illness (7). The demonstration of SARS-CoV RNA in peripheral leukocytes may provide another alternative for early diagnosis. Efforts aimed at optimizing RNA extraction from a larger volume of specimens such as stool or plasma should raise the sensitivity of RT-PCR for these nonrespiratory specimens for identifying SARS patients. Real-time PCR assays that provide viral loads may also be useful for identifying patients at increased risk for worse outcomes in terms of survival and requirement for intensive care and assisted ventilation. Recent studies confirmed that a high viral load in NPA specimens was associated with the need for intensive care and was an independent predictor of mortality. Thus, quantitative PCR assays may provide useful prognostic information for clinical management, including the use of antiviral therapy.

The serodiagnosis is currently the "gold standard" for confirmation of a diagnosis of SARS. The first tests were immunofluorescence assays (IFAs) using virus-infected cells spotted onto microscope slides and ELISAs using extracts from virus-infected cells to coat microtiter well plates. Both methods proved useful in diagnosing SARS, but soon after their deployment it became clear that serology had a major limitation for diagnosis. Seroconversion following infection with SARS-CoV usually occurred in weeks 2 and 3 of illness, and a few patients seroconverted as late as 28 days postinfection. Thus, serology is not useful for the early diagnosis of SARS. SARS-CoV IgM appears after IgG antibody and therefore does not assist in the serodiagnosis. IgA antibody appears about the same time as IgG and persists in serum for 1 to 2 months. IgM antibody persists for about 11 weeks and is then undetectable, whereas IgG persists for months and perhaps years. The whole-cell IFA is about 92% sensitive and 96% specific, with about 4% of serum specimens from healthy individuals giving a positive result. ELISAs using crude antigens showed sensitivity and specificity similar to those of the IFA. Early IFAs and ELISAs required the cultivation of virus in a BSL3 laboratory, and this limitation resulted in the development of serological assays utilizing recombinant proteins. Western blot (WB) assays using whole virus cell lysates show the presence of a predominant N-protein band (often a doublet or triplet around 36 to 48 kDa), a spike antibody band at 150 kDa, and less predominant antibody bands at 80, 60, 32, and 24 kDa (12). Recombinant spike and nucleocapsid proteins have quickly replaced viral lysates in ELISAs and WB and immunodot assays and provide a safe, low-cost alternative for serodiagnosis. The nucleocapsid protein has been shown to be the immunodominant protein of SARS-CoV and an excellent antigen for use in the ELISA. The recombinant N-protein ELISA has an improved sensitivity and specificity compared with those of the whole cell lysate assay and can measure IgG, IgA, and IgM class antibodies by use of specific conjugates. In one study, the N-protein ELISA had a sensitivity of 94.3% and a specificity of 95.3% when evaluated with 106 SARS patient serum samples and 149 blood donor control serum samples (24a), and in another study it performed with a sensitivity and specificity of 100%. Other laboratories have compared the use of the recombinant N protein in a WB, immunodot assay, and ELISA and found sensitivities and specificities in the same range (94 to 96% and 96 to 98%, respectively). Although the spike protein is an important viral protein and elicits neutralizing antibody, it has not been used as widely in serological tests. Further evaluations with larger numbers of serum specimens will be required to determine the true performance of these research tests.

The gold standard test for detecting SARS-CoV antibody is the neutralization (NT) test. The performance of all new serological tests should be evaluated by comparing them with the NT test. Because this test measures neutralizing antibody by reacting serum with live virus, the test can be performed only in a BSL3 laboratory and is therefore limited to only a few laboratories. For this reason, the kinetics for the appearance of NT antibody and the role of IgM and IgA class antibodies in virus NT are poorly understood. The recent development of SARS-CoV pseudotype virions and their use in NT and virus entry assays provide a novel method for assessing neutralizing antibody in SARS patients' sera that is safe (doesn't require BSL3 containment) and cost-effective (9). This assay can easily be automated for high-throughput capacity for the large-scale screening of neutralizing antibody for vaccine trials.

TESTING PROCEDURES

Specimens
For details of procedures for the collection and storage of specimens for detection of HCoVs, see *Manual of Clinical Microbiology*, 8th edition (4a).

Virus Isolation
Cell culture has proven unreliable for primary isolation of HCoV, and some strains grow in cell culture only after adaptation. HCoV-OC43 and -229E can be isolated in human embryonic lung cells (L132) or MRC-5 cells. HCoV-NL63 and HCoV-HKU1 can be isolated in tertiary monkey kidney (*Cynomolgus* monkey) or LLC-MK2 cells. Cytopathic effect may take 7 to 10 days to appear and may vary in appearance from a ground-glass refractive appearance to cell rounding and detachment, depending on the host cell. SARS-CoV can be isolated in Vero E6 cells, although this must not be attempted outside a BSL3 laboratory.

Antigen Detection
HCoV antigens can be detected in cells prepared from NP specimens by standard methods and stained with coronavirus-specific monoclonal antibodies and a fluorescence-labeled anti-mouse IgG conjugate (20).

Antibody Detection
Serum antibody to SARS-CoV can be detected by immunofluorescence staining of fixed SARS-CoV-infected Vero E6 cells. Replicate cell monolayers on glass coverslips in 1-dram shell vials are infected with SARS-CoV at a multiplicity of infection (MOI) of 1. After 24 h, the monolayers are fixed and permeabilized with cold 100% methanol and the cells are rehydrated in phosphate-buffered saline (PBS) containing 5% bovine serum albumin. Serum samples are heat inactivated at 56°C for 30 min, serial dilutions are prepared in PBS containing 0.05% Tween 20 (PBS-T) and incubated on cell monolayers for 1 h at 37°C and the cells are washed three times with PBS-T. Fluorescent anti-human IgG conjugates (either Alexa 488 from Molecular Probes, Eugene, Oreg., or fluorescein isothiocyanate from Sigma, St. Louis, Mo.) are diluted according to the manufacturer's instructions and added, and the mixtures are incubated for 1 h at room temperature. The cells are washed with PBS-T and deionized water and viewed using a fluorescence microscope. A SARS IFA antibody kit is commercially available from Euroimmune GmbH (Luebeck, Germany).

WB

SARS-CoV-infected cell lysates are generated by infecting Vero E6 cells with SARS-CoV (Tor2 or Urbani strain) at an MOI of 1 to 5 for 24 h and then lysing the cells in NP-40 lysis buffer. The lysates are heated to 65°C for 1 h, and sodium dodecyl sulfate (SDS) is added to a final concentration of 2%. (Inactivation of virus should be confirmed by cell culture inoculation.) For WB analysis, 20 μl of lysate is electrophoresed on SDS–10% polyacrylamide gels. Proteins are transblotted to nitrocellulose (Nytran from Schleicher & Schuell), and the membranes are blocked with 5% nonfat dried milk in TBS-T buffer (50 mM Tris [pH 7.6], 150 mM NaCl, containing 0.5% Tween 20) for 1 h at room temperature. A serum dilution of 1:500 in blocking buffer is incubated with the membrane for 1 h at room temperature, and the membranes are washed three times for 15 min each with TBS-T. Bound antibody is detected by enhanced chemiluminescence using goat anti-human IgG, IgM, or IgA antibody-horseradish peroxidase conjugate diluted 1:2,000 in blocking buffer (1 h, room temperature) and ECL substrate (Amersham) according to the manufacturer's instructions.

ELISA

Viral antigens, either recombinant nucleocapsid or spike protein or viral lysates, are bound to wells of Immunlon II microtiter plates by dilution of protein (0.05 to 1.0 μg/0.1 ml) in carbonate buffer (pH 9.6) and adsorption overnight at 4°C. The plates are blocked with PBS containing 5% skim milk powder. The assay is performed essentially as described by Leung et al. (12). Briefly, 100 μl of serum diluted 1:500 in PBS-T is added to the wells, and the mixture is incubated for 1 h at room temperature. The plates are washed, incubated with a 1:2,000 dilution of horseradish peroxidase-conjugated goat anti-human IgG conjugate (Sigma) for 30 min at room temperature, washed, and incubated with tetramethylbenzidine substrate for 15 min at room temperature. The plates are read in a Dynatech reader at 450 nm. Cutoffs are established as the mean plus 3 standard deviations of 20 negative sera. ELISA kits are commercially available from Beijing Genomics Institute (Beijing, China).

Nucleic Acid Detection

HCoV RNA can be detected by RT-PCR, nucleic acid sequence-based amplification (NASBA), and loop-mediated isothermal (LAMP) amplification techniques. For RT-PCR, conventional heat block or real-time assays using a one- or two-step format have been used to detect HCoV-OC43 and HCoV-229E (1, 20, 23) and SARS-CoV (2, 3, 7, 13, 15, 18). For a two-step assay, cDNA is prepared by using 5 μl of sample RNA in a 20-μl reaction volume containing Moloney murine leukemia virus RT with 50 μM random hexamer primers, and then 4 μl of the RT reaction mixture is used in a 50-μl conventional thermal cycler or 20-μl LightCycler PCR assay. Oligonucleotide primers can target either conserved or unique regions of the *nuc* or *pol* genes (Table 1). For conventional assays, the products are analyzed by agarose gel electrophoresis with ethidium bromide staining. Real-time assays in either the LightCycler or ABI 7500/7700/7900 instruments acquire the signal in "real time" during amplification using either SYBRGreen dye or Taqman or fluorescent resonance energy transfer probes and do not require post-run analysis. Forty cycles of amplification is usually sufficient to detect a single RNA copy; 50-cycle reactions do not usually add sensitivity and often make it difficult to distinguish weak positives from background. Positive and negative controls should be included in every run, and internal amplification controls (spiked RNA) are useful for detecting amplification inhibitors in specimens.

Commercially available tests have recently appeared and include the RealArt HPA CoV RT-PCR assay from Artus GmbH (Hamburg, Germany), the SARS Coronavirus NP and POL MultiCode-RTx kits from EraGen Biosciences (Madison, Wis.), and the LightCycler SARS-CoV kit from Roche Diagnostics (Branchburg, N.J.). Meaningful evaluations of these commercial assays have not yet appeared, since their true performance has not yet been determined.

QUALITY CONTROL AND INTERPRETATION

Caution must be exercised when antibody results are interpreted for diagnosis of SARS because of the late seroconversion following infection. A negative antibody result in a patient with pneumonia and an epidemiological link to a known SARS patient cannot be used to rule out SARS due to the possibility of a late seroconversion. A negative antibody result for a sample collected on or after 28 days following onset of illness can, however, rule out SARS since most SARS patients seroconvert by this time. If an in-house, recombinant protein-based ELISA is used (e.g., rN protein), performance must be determined in advance since any given recombinant protein may yield different sensitivities and specificities when used in different formats in different

[a]CB, conventional heat block assay; LC, LightCycler assay.

laboratories. Commercially available antibody assays are just now appearing and will require careful evaluation prior to their use. IgM antibody testing has not proven useful for SARS since IgM antibody may actually appear later than IgG antibody. A positive antibody test alone cannot be used to diagnose SARS due to the potential cross-reactivity of antibody to other HCoVs such as OC43 and 229E. Any positive antibody test should therefore be confirmed with an NT antibody test. A single confirmed antibody test in the absence of another positive test such as RT-PCR should also be viewed with caution since the positive predictive values of IFA and ELISA are not 100%.

A negative RT-PCR test on an NP specimen from a suspected SARS patient does not rule out SARS, since SARS-CoV is present in low levels in the upper respiratory tract in the first week of infection. Since the level of viral RNA in the NP and stool rises in the second week of illness, a follow-up NP and/or fecal specimen should be collected and tested by PCR. Negative PCR results for specimens from the upper tract could trigger sampling from the lower tract, where the titers of virus are higher, although collection of these invasive specimens is associated with an increased risk of nosocomial transmission. Detection of SARS-CoV in plasma or peripheral leukocytes should be considered, since this approach provides sensitivities of around 80% during the first week of illness. The use of multiple and serial respiratory tract and fecal specimens will improve the sensitivity of PCR for making a diagnosis, especially when a larger volume of the sample is extracted and a larger proportion of the sample RNA is used for amplification. A positive RT-PCR result should be confirmed by testing a different specimen with an independent molecular test targeting a different gene and also confirmed by an independent reference laboratory. The first commercially available PCR assays for SARS are only 65 to 75% sensitive and should not be used alone without sending parallel specimens to an experienced reference laboratory for testing. Recognizing that the first human infections were caused by a zootic virus that adapted to its new human host and that we face the continuing possibility for the introduction of new variants of animal SARS-associated viruses (which may cause milder disease with low levels of replicating virus), greater vigilance will be required to make a diagnosis of infection with SARS-associated animal coronaviruses.

Poxviruses

KEVIN L. KAREM AND INGER K. DAMON

91

Poxviruses are large double-stranded DNA viruses that have a wide range of susceptible host species. The family *Poxviridae* includes two subfamilies: *Chordopoxvirinae* and *Entomopoxvirinae*, which infect vertebrate and insect hosts, respectively, and replicate in their cytoplasm (13). The complexity of these viruses relies on the large genome which encodes most proteins required for viral replication and maturation, and their ability to modify and evade host responses to the benefit of the virus. This chapter limits discussion to the diagnostic capabilities for the subfamily *Chordopoxvirinae*, which contains viruses capable of infecting humans (Table 1). Among the *Chordopoxvirinae* are two agents that are specific for humans, variola virus (a member of the OPXs and the etiologic agent of smallpox) and molluscum contagiosum virus, a benign exanthem of the genus *Molluscipoxvirus* (7).

Within the *Chordopoxvirinae*, the genus considered most relevant to human disease is OPX. The OPXs are highly homologous, morphologically similar viruses that, with the exception of variola virus, have a broad animal host range. This genus also includes monkeypox, vaccinia, cowpox, and camelpox viruses and several other lesser known species. Other genera with species that cause any human illness are the *Yatapoxvirus* (tanapox virus and occasionally yaba monkey tumor virus [YMTV]), *Parapoxvirus* (orf, pseudocowpox; see below), and *Molluscipoxvirus* (the sole member is molluscum contagiosum virus). The poxvirus of the greatest historical significance is variola virus, the agent of smallpox and the single greatest killer of humans of all infectious diseases known. Observed since at least Egyptian times, variola major was endemic worldwide and has caused high morbidity and mortality on at least six continents (14). The eradication program of the mid to late 20th century resulted in the eradication of naturally occurring smallpox cases worldwide, with the ultimate isolation and consolidation of stocks of variola viruses in two locations worldwide (14). However, historical use of variola virus as a bioweapon and knowledge of active research into the use of variola virus as a bioweapon have heightened the awareness of the possibility that nonsanctioned stocks may exist and that rogue states or terrorists may intentionally release variola virus. Diagnostic capabilities for smallpox are therefore of utmost importance globally and have evolved significantly over the past decade.

More recent events since the eradication of smallpox have increased interest in and need for diagnostic capabilities for other OPXs. Disease caused by monkeypox was recognized in primates as early as 1958 and has been the cause of ongoing human disease in central Africa since the 1980s. Monkeypox is of increased interest since its importation into the United States in 2003 and has increased concerns of zoonotic transmission of poxviruses. The emergence of human monkeypox highlights the importance of improving and maintaining diagnostic capacities not only for variola virus but also for other poxviruses.

This chapter addresses molecular and immunological diagnostic issues for detection of viral infections associated with four genera of the *Chordopoxvirinae* that cause human disease and their public health significance (Table 1). Diagnostic methods are similar for these viruses and are addressed cumulatively. A description of specific viruses and associated diseases is presented based on genus.

GENUS OPX

Variola Virus

The primary challenge presented by smallpox for clinicians is identifying, quickly and with confidence, a disease that has been extinct for over 25 years. To facilitate the detection of variola in patients, clinical awareness has been promoted to assist a medical community that has never observed this disease except in textbooks. Humans are the only known reservoir for variola, a fact that played in favor of the eradication campaign since vaccination of a single species (humans) could facilitate extinction. Clinical illness associated with variola virus infection has been described extensively and reviewed recently (5). Airborne exposure is the mode of infection from human to human via respiratory droplets. Following exposure, upper and lower respiratory pathways are infected followed by regional lymph nodes, with subsequent viremia in most cases. The incubation period lasts from 7 to 17 days, during which the patient is not contagious. In ordinary smallpox (historically 90% of disease presentations) a prodromal stage follows, in which first symptoms appear. These symptoms include fever, malaise, head and body aches, and sometimes vomiting. Notable is a high fever, usually in the range of 101 to 104°F. During the prodromal stage patients are typically too sick to perform daily duties and are essentially incapacitated. The prodrome lasts 2 to 4 days, and during this period the patient may be contagious. Following the prodrome is the rash onset stage of

TABLE 1 Subfamily *Chordopoxvirinae*

Genus	Disease in humans	Virus	Disease (host[s])
Avipoxvirus	No	Fowlpox	Fowlpox (chickens, turkeys)
		Canarypox	Canarypox (pet bird species)
Capripoxvirus	No	Goatpox	Goatpox (goat, sheep)
		Sheeppox	Sheeppox (goat, sheep)
		Lumpy skin	Lumpy skin disease (cattle, buffalo)
Leporipoxvirus	No	Myxoma	Myxomatosis (rabbits)
Molluscipoxvirus	Yes	Molluscum	Molluscum contagiosum (humans)
OPX	Yes	Variola	Smallpox (humans)
		Monkeypox	Monkeypox (humans, monkeys, rodents)
		Vaccinia	Vaccine adverse events (humans)
		Rabbitpox	Rabbitpox (colonized rabbits)
		Buffalopox	Buffalopox (buffalo, cattle, humans)
		Cowpox	Cowpox (cattle, felines, rodents, humans)
		Taterapox	Taterapox (gerbils)
		Camelpox	Camelpox (camels)
		Ectromelia	Mousepox (mice)
		Volepox	Volepox (California voles, mice)
		Raccoonpox	Raccoonpox (North American raccoons, unknown)
		Skunkpox	Skunkpox (North American skunks, unknown)
Parapoxvirus	Yes	Orf	Orf (sheep, goats, cattle, humans)
		Pseudocow, paravaccinia	Milker's nodules (cattle, humans)
		Bovine papular stomatitis	Bovine papular stomatitis (cattle, humans)
Suipoxvirus	No	Swinepox	Swinepox (domestic swine)
Yatapoxvirus	Yes	Tanapox	Tanapox (primates, humans)
		YMTV	YMTV (primates)

illness. The rash emerges between day 7 and day 17 postexposure, on average day 10 to 12, as an exanthem consisting of small red spots on the oral mucosa, including the tongue, and shortly thereafter as an exanthem consisting of macules on the epidermis. The exanthem develops into sores that break open and spread large amounts of the virus into the mouth and throat, largely accounting for the contagious nature of the disease. The exanthem appears on the skin of the face and spreads to the arms and legs and then the feet and hands, including the soles and palms. The rash typically spreads to all parts of the body within 24 h (Fig. 1). Concurrently, the fever typically falls as the rash spreads to distal extremities. The rash develops through macular to papular to vesicular and then pustular stages. By the third to fourth day of the rash the lesions become raised bumps filled with a thick opaque fluid with a depression in the center that looks like a belly button (this is a major distinguishing characteristic of smallpox). The fever typically rises again at this time and remains high until scabs form over all of the lesions. Pustules develop soon after and become firm to the touch. During this pustule stage the patient remains contagious. After 5 or 6 days after rash onset, the pustules begin to form a crust and then to scab. Over the next 5 days scabs form over the sores while the patient remains contagious. Scabs then resolve and begin to fall off, leaving pitted scar areas over the next 6 days or so. Upon complete resolution and falling off of scabs, the patient is no longer contagious. At this stage the lesions are healed, leaving significant scarring.

Recently the use of clinical algorithms designed to differentiate smallpox from other febrile vesiculo-pustular rash illnesses has been promoted (17, 48). These algorithms use the historic classic features of ordinary smallpox described previously and contrast them with similar symptoms in other febrile vesiculo-pustular rash illnesses. A primary focus of the algorithm is the discrimination of varicella virus and other herpesvirus infections; historically, infections caused by these pathogens were most often confused with smallpox.

FIGURE 1 This photograph is of a Bangladeshi boy with smallpox, revealing the distribution of maculopapular lesions. (Source: CDC Public Health Image Library, James Hicks, 1973.)

Treatments for smallpox infection are limited and are largely supportive, using traditional methods of giving fluids and rest for viral infections. Advances in supportive care and improvements in intensive care strategies would likely enhance treatment efficacies should smallpox recur. Experimentally, several compounds are effective in vitro, such as cidofovir, but may have toxicities in vivo. Alterations in cidofovir structurally have remedied the toxicity to some degree in animal models and in vitro; however, approval of any compounds to treat poxviruses by the Food and Drug Administration remains elusive. Vaccinia immunoglobulin (VIG) is another therapy that is effective at neutralizing OPX infections and is typically used to treat adverse reactions to smallpox vaccination (see below). VIG is a polyclonal serum pool from vaccinia virus recipients that works effectively to neutralize virus in vivo and subsequently limit infection and halt adverse vaccine reactions. There are no data that currently support the use of VIG as a therapy for smallpox.

Vaccination against smallpox using the closely related live OPX vaccinia virus was used effectively to eradicate variola in the mid to late 20th century. Use of vaccinia virus was and continues to be considered prudent for protection of military and medical public health responder personnel against bioterrorism threats. Further discussion of vaccinia virus and variants is presented below.

Monkeypox Virus

Monkeypox was first recognized in primate colonies in the late 1950s to early 1960s as a disease resembling smallpox infections in humans. However, it was not until the 1970s that human disease associated with monkeypox was recognized (Fig. 2). During the eradication campaign against smallpox, human monkeypox was observed in central and western Africa. With the eradication of smallpox and with the emergence of monkeypox in central and western Africa, the World Health Organization conducted a surveillance program in the Democratic Republic of the Congo (DRC) from 1981 to 1986 that was aimed at determining the risk of

FIGURE 2 Close-up photograph of monkeypox lesions on the arm and leg of a 4-year-old female child in Liberia. (Source: CDC Public Health Image Library, 1971.)

monkeypox becoming a smallpox-like epidemic and its potential to pose a threat to the eradication program. Results indicated a high level of zoonotic infections, with a substantially lower human-to-human secondary attack rate (7.5%) than that of smallpox (60%). Ecological studies indicated an association with squirrels of the *Funisciurus* and *Heliosciurus* species. With a low secondary attack rate and primarily zoonotic transmission, the threat to the eradication of smallpox-like disease globally was considered remote. Few cases were reported until 1996, when suspected cases of monkeypox were reported from the DRC during a period of civil unrest (18). In addition to difficulties caused by civil unrest, cocirculation of chickenpox became a clinical presentation confounding to accurate diagnosis of monkeypox. Interest in monkeypox has remained high due to its clinical presentation being similar to that of smallpox, its genomic similarity to variola virus, and ongoing disease in central Africa since 1996. Awareness of the potential for monkeypox to emerge as a human disease outside of Africa occurred with the export of the virus, along with exotic animals intended for pet trade, to the United States in 2003. Importation of these African species included several suspected hosts/reservoirs of monkeypox and triggered an outbreak of monkeypox in six states in the Midwestern United States (15, 44). Outbreak investigations identified potential sources of the initial transmission from African species (Gambian rats and dormice) to native prairie dogs of North America. All subsequent human case-patients had contact with infected prairie dogs (Fig. 3). Monkeypox isolates from prairie dogs and humans were most closely related to a west African strain of monkeypox based on single-gene phylogenetics (29, 44). Differences in the severity of human disease were noted between the U.S. outbreak and a concurrent outbreak in the DRC (26). Genetic analysis of the U.S. isolate compared to a central African isolate (Zaire) reveals genomic differences (phylogenetic clades) which may hold the key to differences observed in clinical presentation, transmissibility, and virulence (29). Further analysis of strain differences may provide additional insight into the pathogenesis of monkeypox and identify targets for treatment or vaccines.

Treatment of monkeypox infection is similar to that of other OPX infections, including supportive medical care and antibiotic use to prevent secondary bacterial infection of lesion sites. Literature from the active surveillance efforts in the DRC in the 1980s demonstrated a protective benefit against disease acquisition and against disease severity (21). Prior vaccinia virus vaccination does not always prevent infection, and prevention may be related to the temporal interval since vaccination or to other unidentified host factors. During the U.S. outbreak in 2003, many confirmed case-patients were recipients of smallpox vaccine during childhood.

Vaccinia Virus

The origins of vaccinia virus remain obscure. Edward Jenner's vaccine evolved through a complex series of experiments to propagate the vaccine for use in faraway lands. Techniques used have been implicated in the development of a novel OPX with characteristics differing from those of other related viruses, such as cowpox and variola virus. Although vaccinia virus has been shown to be able to infect a wide variety of animal species, the natural reservoir and origin for vaccinia (as we know it) remains a mystery (1).

The eradication of smallpox was achieved by vaccination with vaccinia virus using intradermal inoculation resulting in a localized infection, or "take" (Fig. 4). The virus causes a

Inoculation Lesions

Disseminated Lesions
FIGURE 3 Monkeypox lesions from the 2003 U.S. outbreak, showing primary inoculation reactions (A, B, and C), examples of smallpox-like (D) and umbilicated varicella-like (E) disseminated monkeypox lesions, and morphologic appearance of disseminated lesions over time (F, G, H, and I). Panel A shows a primary inoculation reaction at the site of a prairie dog bite, panel B shows a prairie dog scratch, and panel C shows a preexisting cat scratch. Panel F shows a disseminated lesion less than 24 h after its appearance, panel G shows lesions after 6 days, panel H shows a lesion after 96 h, and panel I shows a lesion after more than 9 days. (Reproduced from reference 44 with permission.)

vesicular-pustular lesion followed by scab formation. A successful take is considered an indication of protective vaccination. However, vaccination is not without risk. Clinical disease or adverse outcomes may result from vaccination. Persons with immunosuppression or skin conditions such as eczema are at higher risk of adverse events from vaccinia virus exposure. Eczema vaccinatum, severe skin dissemination of vaccinia virus, may result from vaccination of persons with eczema or of contacts of vaccine recipients who have eczema. Progressive vaccinia, or vaccinia necrosum, may also occur in vaccine recipients. This potentially fatal illness is characterized by progressive necrosis in the area of vaccination, often with metastatic lesions. In the past, it was estimated that progressive vaccinia occurred in approximately 1 to 2 per million primary vaccinations, and it was almost always fatal before the introduction of VIG and antiviral agents. Nearly all instances have been in people with defined cell-mediated immune defects (T-cell deficiency). Progressive vaccinia was considered rare during the eradication campaign, but with concern over wide use of immunosuppressive drugs

and a larger immunocompromised population, rates may increase in today's population. Treatment of infection with vaccinia virus includes supportive care and may include antibiotics for control of secondary bacterial infections. Steroid use is contraindicated since immunosuppression and viral growth may ensue. Laboratory workers are susceptible to infection, and vaccination is recommended but not required in all facilities. Adverse events associated with vaccinia may be treated with VIG.

Cowpox Virus

Cowpox is endemic in parts of Europe and Asia, and disease associated with this zoonotic virus is typically associated with agricultural exposure. Despite its name, cowpox is not enzootic in cattle. With a host range from rodents to domestic cats, the reservoir for this virus is thought to include both European rodent species and domestic cats. Zoonotic disease has been observed in a variety of captive species in European zoos, such as cheetahs, lions, anteaters, rhinoceroses, elephants, and okapis, with transmission on occasion to animal
FIGURE 4 Major (primary) reaction—expected vaccine site reaction and progression following primary smallpox vaccination or revaccination after a prolonged period between vaccinations. Vaccinia virus vaccination results in a take under normal circumstances. A take is used as a measure of vaccine efficacy. The inoculation site becomes pustular around day 4 and then vesicular by day 7 and begins to scab around day 14. (Source: CDC [http://www.cdc.gov].)

handlers (2, 3, 41). Disease in humans is typically limited to the fingers following direct contact with infected animals, particularly cats. Redness and swelling occur, followed by papule and vesicular development in 4 to 5 days. Lesions are commonly painful, with erythema and edema at the vesicle and pustular stages. Resolution of lesions occurs from 2 to 4 weeks, with illness taking 6 to 8 weeks for complete recovery. Scarring is usually permanent. At greater risk are those with immunocompromised conditions.

Person-to-person transmission has not been reported, suggesting low infectivity for humans. Control of this disease is mainly through careful handling of infected animals and care of lesions once they appear. Management is supportive, with antibiotics to control secondary infections. Acyclovir has no activity against poxviruses. Steroids are contraindicated.

GENUS *PARAPOXVIRUS*

Parapoxviruses are structurally distinct from other *Chordopoxvirinae* and commonly cause agricultural disease of sheep, goats, and cattle that may be transmitted by direct contact to humans. Parapoxvirus commonly causes pustular skin and oral (mouth) lesions in sheep and goats that upon direct contact can be transmitted to humans and that are most often referred to as "contagious pustular dermatitis" or "orf." In cattle, the parapoxvirus-caused diseases most likely to be encountered by humans are pseudocowpox or paravaccinia (in dairy cattle, which causes milker's nodule in humans) or bovine papular stomatitis in calves and beef cattle. In humans, milker's nodule occurs as a reddened hemispheric

papule that matures to a purplish, smooth, firm nodule varying up to 2 cm in diameter; the lesions usually are not painful and can persist for about 6 weeks. Disease in livestock can have high morbidity, causing severe oral lesions and subsequent weight loss. In humans, lesions are typically limited to the fingers, hands, and arms and occur through direct contact with infected animals and transmission to existing cuts or scratches. Self-limiting illness follows, with local inflammation and the potential for secondary infections of open lesions. Lymphadenopathy and malaise are uncommon. Clinical presentation may cause difficulties if severe or prolonged lesions are observed. Large granulomatous or papillomatous lesions may be misdiagnosed as malignancies and result in inappropriate treatment, such as amputation (22).

Virions within the lesions are usually detectable by electron microscopic (EM) analysis, providing rapid and efficient diagnosis. The virus can be grown in cell culture, but this is not routinely done due to poor growth in transformed cell lines. Some molecular techniques are available, but widespread use is not yet apparent.

Interestingly, prior exposure is not thought to confer protection from subsequent exposure. Theories for reinfection with orf include heterologous but related viruses that do not provide cross-protective immunity or distinct ability to evade host immunity. The immune response to naturally occurring infection in humans has been studied, and a short-lived cell-mediated response and humoral response have been noted (53, 54). Treatment for orf infections is limited to control to prevent spread of the virus to other humans or animals. A vaccine is available for sheep but is fully virulent

高

and can cause human infections. Use of vaccine is recommended annually to prevent outbreaks in livestock and more frequently for control in affected areas.

GENUS *MOLLUSCIPOXVIRUS*

Molluscipoxvirus is a distinct genus within the *Chordopoxvirinae* that contains only one known virus, molluscum contagiosum virus (Table 1). Molluscum contagiosum virus, like variola virus, is specific for humans. Infection causes a benign skin rash illness and has no known systemic phase. In children, the rash is distributed on the face, trunk, and limbs and is transmitted by direct contact. In adults, the lesions are found in the lower abdominal and pubic region, genitalia, and inner thighs and are transmitted through sexual contact. The appearance of the rash is typically sufficient for clinical diagnosis. Virions can be observed by EM using slide preparations of lesion material. Lack of inflammation and failure to isolate virus by cell culture or other means is a hallmark of molluscum contagiosum.

Infection with molluscum contagiosum virus is benign and self-limiting. Treatment may be implemented for cosmetic reasons to ease scarring, particularly from facial lesions. Treatments have included the use of chemicals such as phenolic compounds, silver nitrate, and trichloroacetic and glacial acetic acids. Curettage and cryotherapy also have been used as a physical intervention. Trauma may induce viral clearance, presumably due to the release of immune factors that provide higher antiviral immunity.

Prevention is based on personal hygiene and improvements in living conditions. The suggestion that molluscum may contribute to or be a marker for more serious conditions has been made (40). No vaccine is available.

GENUS *YATAPOXVIRUS*

Tanapox

Tanapoxvirus was first recognized in humans in 1957 in the River Tana region of Kenya. Particular interest occurred during the smallpox eradication campaign, and descriptions of human cases were documented in Zaire (DRC) in the 1980s (10, 20). Infection occurs on the skin, with epidermal hyperplasia and little dermal involvement. A prodromal illness of fever and malaise may occur but is short in duration. Macular lesion development progresses to a nodular (raised) stage that becomes umbilicated. Lesions are large (~10 mm) and typically become ulcerated. Erythema, edema, and lymphadenopathy are commonly associated with infection. Most cases present with only one lesion, and distribution may occur anywhere on the body, with the head usually being spared.

Illnesses associated with tanapox have been reported outside of Africa, and travel to or from regions of endemicity should be considered in diagnosis of rash illness with clinical presentation consistent with yatapox (9). The virus is restricted to Africa and particularly Kenya and the DRC. Simian species are the likely reservoir, and human-to-human transmission does not occur naturally. Transmission from primates to humans is thought to occur due to overcrowding during natural disasters, such as flooding, and civil unrest. Treatment is limited to supportive care, and vaccination is not available.

YMTV

YMTV has occurred in human primate-animal handlers (46). YMTV produces epidermal histiocytomas, tumor-like

masses of histiocytic polygonal mononuclear cell infiltrates that advance to suppurative inflammatory sites. Only rare, anecdotal reports of human disease exist.

DIAGNOSTICS

Introduction to Laboratory Diagnosis

The basis for diagnosis of any poxviruses can be attributed historically to smallpox. Clinical presentation of smallpox was distinctive and usually sufficient for diagnostic recognition in order to implement public health control measures. However, in the presence of other rash illnesses, such as chickenpox and syphilis, to name a few, the diagnosis based purely on clinical presentation was often confusing. The oldest laboratory tests for poxviruses relied on visual inspection of lesion samples by light microscopy for the presence of poxviruses. More recently, EM has been utilized for the detection of poxviruses in lesion or cultured material. EM is rapid and efficient and may discriminate at the genus level for the parapoxviruses (8). Serological tests in use since the mid-1900s detect poxvirus antibodies, although discrimination among species within a genus using serology has remained difficult. Testing for serum antibodies or viral antigen has provided evidence of poxvirus exposure and has been used as a surveillance tool for the past half century. However, definitive molecular and immunology laboratory diagnostic capabilities arose only in conjunction with the eradication of smallpox in 1978. For the past several decades, poxvirus diagnosis was primarily related to vaccinia virus research as a vaccine vector and public health studies using serology and PCR testing during monkeypox outbreaks in central Africa, or isolated occurrences of cowpox, vaccinia virus-like infections, or other anecdotal poxvirus infections. Recent advances, driven by concerns of bioterrorism and a renewed vaccination campaign, have greatly improved diagnostic capabilities for a variety of poxviruses.

Physical Features of the *Poxviridae*

Poxviruses are among the largest viruses known and are brick shaped or ovoid, with an outer membrane surrounding a core that contains the double-stranded DNA genome. The genome contains 200 to 300 kb, with a G+C content of approximately 35% in OPX and yatapox virus and around 60% in parapoxviruses and molluscum virus. The size of viruses ranges from around 170 to 200 nm by 200 to 300 nm for OPXs, molluscum virus, and yatapox virus, while parapox virus is more ovoid, at 140 to 170 nm by 220 to 310 nm. The discrimination of parapoxviruses from other poxviruses is possible using EM, due to the subtle differences in physical appearance which are reviewed below.

VIRUS ISOLATION AND IDENTIFICATION

OPXs typically result in rash skin lesions that contain high levels of viral particles. During clinical disease, specimens such as rash exudates, crusts or scrapings, and vesicular fluids are suitable for growth and isolation in cell culture. Currently at the Centers for Disease Control and Prevention (CDC), identification of cytopathic effect in cell culture is followed by passage in cell culture and confirmation of viral species by PCR. Isolates are then anonymized and stored for development of diagnostic reagents, such as DNA for molecular testing and antigen for serological tests. Specimens of poxvirus rash lesions or viral cultures from such lesions are suitable for diagnosis by EM (Fig. 5). EM analysis provides
FIGURE 5 EM of vaccinia virus (A and B) and monkeypox virus (C and D) from clinical lesions collected during the 2003 U.S. outbreak. Bar equals 100 nm. (Source: CDC [vaccinia, Cynthia Goldsmith and Yasou Ichihashi; monkeypox, Cynthia Goldsmith and Christopher D. Paddock].)

the most rapid and characteristically clear distinction of poxviruses over other exanthems. Despite its utility, EM cannot distinguish between viruses within the genus OPX with any reliability. This genus includes most of the viruses of highest risk to human public health, such as variola, vaccinia, monkeypox, and cowpox viruses. Only members of the genus *Parapoxvirus* can be differentiated by EM; their distinctive morphology of a cross-hatched appearance (caused by tubule formations) and an ovoid shape (Fig. 6) allows discrimination from other poxviruses that are brick shaped
FIGURE 6 EM of parapoxvirus (orf) from a human lesion. Bar equals 100 nm. (Source: CDC [Cynthia Goldsmith and Fred A. Murphy].)

(Fig. 5). Differential diagnosis of rash illnesses associated with exanthematous viruses (e.g., varicella) other than *Poxviridae* is easily performed using EM. Tissues or rash-derived biopsy samples may also be subjected to immunohistochemistry for detection of OPX antigen.

Specimen Collection

For serological testing, serum or plasma is optimal with refrigeration of samples at a minimum and freezing of samples for storage longer than a few days prior to testing. Samples may be kept refrigerated for short periods while transporting or testing with sufficient results. For neutralization testing, heat inactivation of serum at 56°C for 20 to 30 min is recommended to avoid complement-mediated activity of the serum that may be independent of pure neutralizing capabilities.

Poxviruses will remain infective at ambient temperatures, particularly if kept dry. If specimens cannot be tested immediately, infectivity is retained during transportation at ambient temperatures by mail courier without the need for special transport medium. Vesicle fluid should be smeared on a slide and air dried. On receipt, the material can be reconstituted in buffer and used for EM, PCR, and viral isolation. Scrapings from molluscum and parapox lesions can be treated similarly. The infectivity of virus in dried crusts is retained for long periods. Virus may be extracted from such material by freeze-thawing and ultrasonic treatment. However, if the differential diagnosis includes pathogens less resistant than poxviruses, greater care should be taken and appropriate transport medium, etc., should be used.

Serology Introduction

Detection of humoral antibody responses by serology is an indirect approach to diagnosis and has been a hallmark for laboratory diagnosis of viral infections. In the absence of suitable viral samples for PCR, culture, or EM testing, serology may be the only method for diagnosing poxvirus infections. For this reason, serological tests have historically provided a standard for disease monitoring and surveillance. Characterization of the detection of humoral immune induction against smallpox provided a complement to the time line of disease progression as a measure of host response (4, 14). However, serological testing does not reliably or reproducibly provide information regarding the "type" or strain of OPX in question. This is the major limitation of serological tests to date. We review various serology methods and discuss recent advances that provide diagnostic capacity. Methods of antibody detection historically have included agar precipitation (Ouchterlony), immunofluorescence, complement fixation, hemagglutination inhibition (HI), plaque reduction neutralization testing (PRNT), and enzyme-linked immunosorbent assays (ELISAs). The most pragmatic serology tests are reviewed and include HI, PRNT, and ELISA, with methods described for PRNT and ELISA.

HI

HI exploits the fact that OPXs contain a hemagglutination protein that binds to avian or sheep red blood cells (RBCs), causing agglutination of the RBCs and forming a "shield" as compared to negative or inhibition (button or pellet) at the bottom of the well. Mixture of OPX antigen with patient serum prior to the addition of RBCs allows one to test for the presence of anti-OPX antibodies. Binding of specific antibody (if present) to the antigen prevents binding of the OPX antigen to the RBCs and subsequent agglutination of RBCs

in solution. HI has been used and is currently used for detection of virus-specific antibodies in studies for a number of viruses. For OPXs, HI has been successfully used for serological surveys of exposure to OPX, but it lacks specificity to differentiate between member species of these closely related viruses. Most often, chicken RBCs are used for agglutination, with approximately 50% of chickens having RBCs that can be agglutinated by vaccinia virus (37). HI antibody is detected 4 to 7 days after infection with OPXs. Testing of paired serum is vital to the diagnostic potential of HI tests. A rise or fall in titer is indicative of poxvirus infection. Since the advent of ELISA, the use of HI for OPX antibody detection has decreased.

PRNTs

PRNTs provide significant information regarding not only the presence of virus-specific antibodies but also their ability to neutralize viral particles in vitro. Neutralization of virus is considered to provide some evidence of a protective immune response due to prevention of viral infection of cell culture in vitro and passive transfer protection in animal models.

Virus particles form plaques in cell culture monolayers by adhering to and infecting cells and subsequently adjacent cells, forming a visible hole. The presence of anti-OPX antibodies in serum results in inhibition of plaque formation and thus plaque reduction that can be visually monitored and quantified (Fig. 7). It should be noted that a strong correlation is observed between ELISA reactivity and virus neutralization in studies of smallpox vaccination efficacy. Despite being labor-intensive and difficult to validate and transfer, the PRNT remains a vital laboratory test for determination of smallpox vaccine efficacy.

Recently, several novel neutralization tests have been developed that reduce labor and increase sensitivity and reproducibility by utilizing fluorescence or enzymatic colorimetric signals as a readout for the presence of virus. These assays may provide standardization of serum neutralization as a method for testing vaccine efficacy (11, 31). Use of gene expression as a readout prevents the need to count plaques and provides a format with potential for performing high-throughput testing in 96- or 384-well plates. The methods for performing these tests are described elsewhere and are not included here (11, 31). A traditional neutralization protocol is described below.

PRNT Method

Serum samples to be tested for neutralization should be heat inactivated to prevent complement-mediated activity of antibody. Serial twofold dilutions of test samples are prepared and incubated with an equal volume of vaccinia virus at a concentration of 100 PFU/ml and incubated at 35°C with 6% CO_2 for 3 h, with gentle rocking or vortexing every 15 min. Six-well titer plates are prepared to have confluent monolayers of adherent cells. For each well of the six-well plates, 1 ml of serum and antibody mixture is added. For every sample, duplicate wells should be used. Plates are incubated for 1 h, with rocking every 15 min, at 37°C with 6% CO_2. The inoculum is then removed from each well, 2 ml of fresh medium (2% protein) is added to each well, and plates are incubated at 35°C with 6% CO_2 for 2 days. After incubation, 1 ml of crystal violet stain solution (0.2% crystal violet, 4.5% formaldehyde, and 7.5% ethanol in phosphate-buffered saline [PBS]) is added to each well for 20 min at room temperature. Plates are then rinsed with water and allowed to air dry. Plaques are then counted and test serum
FIGURE 7 PRNT using control sera positive for plaque reduction. Sera were tested at 20-, 40-, and 80-fold dilutions. Plaque counts are the lowest in the 20-fold dilution wells (far left) and increase with higher dilutions. (Source: CDC [Poxvirus Program, Kevin L. Karem].)

wells are compared to virus-only control wells to determine the percentage of plaque reduction. Significant plaque reduction is typically considered to be equal to or greater than 50%.

ELISA

Three types of ELISA are routinely run at the CDC and represent some advances in the assays as well as analysis of the efficacy of the assays to perform during an OPX outbreak (19, 23, 47). All are indirect ELISAs and detect anti-OPX antibodies by an indirect conjugate reaction or by detection using enzyme-linked secondary antibodies against human immunoglobulin or non-species-specific immunoglobulin.

In the absence of viral samples for PCR or culture testing, active infection is difficult to determine and diagnosis is limited except for the use of serology. Efficacy of diagnosis by serology relies heavily on the collection of paired or multiple serum collections from an individual to compare the levels of antibody over time. A rise or fall in antibody levels is indicative of viral infection. More recently, the development of an OPX-specific immunoglobulin M (IgM) ELISA allowed the detection of recent exposure (or vaccination) against OPX by exploiting the biology of IgM production as a marker for acute-phase immune responses. During the monkeypox outbreak of 2003, IgM ELISA provided diagnostic support for evaluation of OPX infection, and evidence of the time line of infection correlated to illness onset. During this investigation, IgM ELISA provided 92% sensitivity in detection of cases confirmed by PCR (23). Together with epidemiology and clinical history, the IgM test may provide support of diagnosis of OPX infection even in the absence of material sufficient for viral isolation or detection (culture, EM, or PCR).

ELISA Methods

IgG ELISA. For the IgG ELISA, microtiter plates (Immulon II) are coated with 100 μl of vaccinia virus (purified vaccinia virus; Wyeth, Madison, N.J.) at 1.2×10^5 PFU/well in carbonate buffer overnight at 4°C. Plates are then blocked for 30 min at room temperature with assay diluent (PBS plus 0.05% Tween 20 [PBST], 5% skim milk, 2% bovine serum albumin, and 2% goat serum) followed by washing three times with PBST. Test samples are then added at dilutions of 1:100 for serum and incubated for 1 h at 37°C. Plates are washed and goat anti-human IgG-horseradish peroxidase conjugate (Kirkegaard & Perry [KPL], Gaithersburg, Md.) is added at a 1:2,000 dilution for 1 h at 37°C. Plates are washed, tetramethyl benzidine (TMB) one-component substrate is added, and development is allowed to proceed for 5 to 15 min. Plate reactions are stopped by addition of stop solution (KPL) and read at 450 nm on an optical density reader (Molecular Devices Corporation, Sunnyvale, Calif.). Values reported represent the average of duplicate wells of each sample. Known positive and negative sera from smallpox vaccine recipients are used as assay controls. On each day that assays are performed, cutoff values for ELISA are determined based on the mean plus 3 standard deviations of five negative control sera.

IgM ELISA. For the IgM ELISA, microtiter plates (Immulon II) are coated with 100 μl of a 1:800 dilution of goat anti-human IgM (KPL) diluted in PBS (pH 7.4) and incubated for 1 h at 37°C. Plates are then washed five times with PBST (PBS plus 0.1% Tween 20) and blocked for 30 min at room temperature with assay diluent solution (PBST, 0.5% gelatin, 2% bovine serum albumin, 5% skim milk, and 2% normal goat serum). Plates are washed and patient serum samples are added at a 1:50 dilution in assay diluent. Patient samples are incubated on the plates for 1 h at 37°C, followed by washing. Antigen (purified vaccinia virus; Wyeth) is then added at a concentration of 6.15×10^5 PFU/well (in diluent), and the plates are incubated for 1 h at 37°C. Plates are washed, and anti-OPX antiserum (concentration to be determined) is added for 1 h at 37°C. Plates are washed and conjugate (KPL) is added at 37°C for 30 min. Plates are washed and TMB one-component substrate is added for 5 to 20 min of development (KPL). Reactions are stopped by addition of stop solution (KPL) and read at 450 nm on an optical density reader. Values reported represent the average of duplicate wells of each sample. Positive and negative control sera are used as assay controls.

Molecular (Nucleic Acid) Testing

With the increasing knowledge of pox viral genomic nucleic acid sequence information, a number of methods have been developed to discriminate viruses based on nucleic acid testing. Early methods involved restriction fragment length polymorphism (RFLP) comparison of whole genomes; the preferred methods today involve PCR methodologies, as well as "chip-based" hybridization detection methods.

Single-gene PCR, followed by RFLP analysis of the amplicon, permits species identification of OPX. A number of methods have been published (30, 32, 35, 45, 49). One PCR assay targets the gene for hemagglutinin (HA) because this locus is unique for the genus OPX. Other published PCR methods target the gene for the A-type inclusion body protein (34), and another targets the gene for the B cytokine response modifier (CrmB), one of several different tumor necrosis factor receptor homologs produced by OPXs (30). In these assays, PCR is done by using primers anticipated to amplify a segment of DNA that would be present in any OPX, the amplicon is digested with an appropriate restriction endonuclease, and gel electrophoresis separation of digest fragments is used to discriminate species by comparing the fragment profiles with reference virus RFLP profiles.

Other strategies are based on the amplification of a region of nucleic acid unique for a specific species or genus of poxvirus. Such strategies have been developed for parapoxvirus and tanapox virus identification (9, 50, 51). Nucleic acid sequencing of the amplicon, regardless of whether it is predicted to be specific for one species, and its comparison to sequence databases can also provide diagnostic confirmatory information (52). The use of a multiplex format (42, 43) approach also has been described for the detection of the OPX variola virus in specimens. Another multiplex OPX assay targets the essential DNA polymerase gene (9).

Real-time PCR strategies, which can provide quantitative and qualitative information, as well as chip-based diagnostic methods have been developed for the OPXs (24, 25, 39). Most recently, such assays have demonstrated utility in detection of monkeypox during the 2003 U.S. outbreak (24, 27, 28, 38). Such assays also have been developed to specifically detect variola virus as part of bioterrorism response efforts (39). Within the United States, member laboratories of the Laboratory Response Network (a consortium of state and federal microbiology laboratories) have the capacity to test for OPXs in specimens using real-time PCR methods. Additional capacity is contained within the World Health Organization Collaborating Center for Smallpox and other Poxviruses within the Poxvirus Program of the CDC in Atlanta, Ga.

As mentioned previously, detailed nucleic acid diagnostic detection methods of poxvirus identification have been published, in addition to a recent detailed review of molecular PCR methods (32). Some commonly used methods employed by the World Health Organization reference center at the CDC include single-gene OPX HA and A-type inclusion (ATI) amplification, followed by RFLP analysis for species identification. These methods work well for clinical specimens anticipated to have large quantities of viral material, as found in rash-derived specimens. More recently, methods using real-time PCR detection also have been used. These methods are more sensitive and were used for rapid analysis of specimens during the U.S. monkeypox outbreak (28, 39).

Detailed Single-Gene PCR RFLP Methods

Perhaps the best-described locus for PCR-based detection of OPX is the HA gene. Species-generic primer amplification using EACP1 and -2 or NACP1 and -2 primers allows a positive signal to detect an Old World (Eurasian) or New World (North American) OPX species, respectively (45). Subsequent restriction digestion of the HA PCR product with TaqI or RsaI allows species-specific identification. EACP1 and -2 are used to detect the Old World OPXs vaccinia, cowpox, monkeypox, and variola viruses as well as ectromelia, camelpox, and gerbilpox viruses (not known to infect humans), via amplification of an ~950-nucleotide (nt) fragment. The methods for amplification are detailed elsewhere (45), and recent optimizations are described briefly here.

Materials (PCR for HA)

Primers: EACP1 at 250 ng/μl (forward, ATG ACA CGA TTG CCA ATA C), EACP2 at 250 ng/μl (reverse, CTA GAC TTT GTT TTC TG)

Sample nucleic acid at 50 ng per reaction

Positive controls: 5-μl volume containing 100 ng of vaccinia, variola, or monkeypox virus DNA

Negative control: nontemplate control (5 μl of H$_2$O). Other negative controls could include a cell culture lysate or non-OPX DNA (e.g., varicella virus).

PCR tubes or plate with caps and a programmable thermocycler

Add master mix (buffer, deoxynucleoside triphosphates, primer, polymerase, and H$_2$O) to each tube or well. Add test sample or control to each well, bringing the final volume to 50 μl. Cap each tube or well and place on the thermocycler. Denature the reactions for 2 min at 92°C. Perform 10 cycles as follows: 92°C for 10 s, 55°C for 30 s, and 72°C for 30 s. Then perform 20 cycles as follows: 92°C for 10 s, 55°C for 30 s, and 72°C for 35 s. Continue elongation at 72°C for 2 min, followed by a hold at 4°C. The total time for the PCR is approximately 90 min. The PCR product can be visualized by agarose gel electrophoresis.

RFLP of HA PCR Product

If a PCR product is observed by agarose gel electrophoresis, then restriction enzyme digestion will permit species determination of the OPX based on product fragments. TaqI restriction enzyme is used to digest the PCR fragment, and the resulting fragments are analyzed by agarose gel electrophoresis. Digestion with TaqI yields fragments of 452, 295, 105, and 97 nt (vaccinia virus); 303, 289, 115, 96, and 91 nt (cowpox virus); 536 and 406 nt (variola virus); and 451, 220, 105, 91, and 75 nt (monkeypox virus). NACP1 and -2 primers are used to specifically detect the New World OPXs (45) raccoonpox, volepox, and skunkpox viruses, which are not documented to be human pathogens.

PCR for A-Type Inclusion Protein

Amplification of the A-type inclusion protein is another method used to differentiate OPXs. Primer pairs ATI-low-1 and ATI-up-1 are used to amplify 1,500- to 1,700-bp fragments from vaccinia, cowpox, variola, or monkeypox virus, and amplicon identity can be confirmed with BglII or XbaI RFLP.

Materials (PCR for HA)

Primers: ATI-up used at 250 ng/μl (forward, AAT ACA AGG AGG ATC T), ATI-up used at 250 ng/μl (reverse, CTT AAC TTT TTC TTT CTC)

Sample nucleic acid at 50 ng per reaction

Positive controls: 5-μl volume containing 100 ng of vaccinia, variola, or monkeypox virus DNA

Negative control: nontemplate control (5 μl of H_2O). Other negative controls could include a cell culture lysate or non-OPX DNA (e.g., varicella virus).

PCR tubes or plate with caps and a programmable thermocycler

Add master mix (buffer, deoxynucleotide triphosphates, primer, polymerase, and H_2O) to each tube or well. Add test sample or control to each well, bringing the final volume to 50 μl. Cap each tube or well and place on the thermocycler. Denature the reactions for 2 min at 92°C. Perform 10 cycles as follows: 92°C for 10 s, 40°C for 30 s, and 72°C for 45 s. Then perform 15 cycles as follows: 92°C for 10 s, 40°C for 30 s, and 72°C for 50 s. Continue elongation at 72°C for 2 min, followed by a hold at 4°C. The total time for the PCR is approximately 90 min. The PCR product can be visualized by agarose gel electrophoresis.

RFLP of A-Type Inclusion PCR Product

If a PCR product is observed by agarose gel electrophoresis, then restriction enzyme digestion will permit species determination of the OPX based on product fragments. BglII restriction enzyme is used to digest the PCR fragment, and the resulting fragments are analyzed by agarose gel electrophoresis. Digestion with BglII yields six fragments of 470, 444, 291, 165, 154, and 72 bp for vaccinia virus; six fragments of 522, 466, 293, 165, 154, and 72 bp for cowpox virus; and six fragments of 475, 470, 180, 165, 154, and 64 bp for monkeypox virus.

An RFLP using XbaI enzyme can also be used. XbaI has also been used to discriminate vaccinia, monkeypox, variola, and cowpox virus DNA. After XbaI digestion, variola virus generates two fragments sized at 154 and 1,018 nt. Vaccinia, cowpox, and monkeypox viruses all yield five fragments after XbaI digestion. Monkeypox species can be classified into Zairian and non-Zairian isolates based on the restriction profile.

With advances in genomic sequencing and analysis, there is an increased recognition that one genetic locus may not sufficiently identify a poxvirus as a member of a particular species (6, 16, 33, 36, 52). The use of testing strategies which discriminate genus and species based on the characterization of multiple genetic loci, in concert with protein-based diagnostics, will enhance the ability to accurately identify poxviruses as members of a particular genus and species. Use of existing molecular and immune diagnostic testing has allowed detection and diagnosis of OPX infections related to vaccine adverse events as well as outbreaks of naturally occurring viruses, such as monkeypox. Continued efforts to incorporate laboratory research advances into diagnostic testing regimens are expected to facilitate more efficient and specific tests for species of viruses within the genus OPX.

Prion Diagnostics

STEPHEN DEALLER

92

INTRODUCTION

Transmissible spongiform encephalopathies (TSEs) (3, 5, 10) are a group of pathological animal conditions in which an infectious agent gives rise, after logarithmic growth in the brain, to cerebral damage but to little sign of inflammation. No antibodies are produced to the agent in the body, and TSEs were not realized to be infective until around the middle of the last century. Transmission experiments showed that they had extremely long incubation periods, often 20% of the normal life expectancy of the animal, that the infectious agent was similar in size to a virus, and that it could be filtered out using 100-nm-pore-size filters. The rapid expansion in research due to the epidemic rise of bovine spongiform encephalopathy (BSE) in the United Kingdom has widened the understanding of these TSEs, and the importance that they may have for other conditions that may be infective in similar ways (e.g., Alzheimer's disease and Parkinson's disease) has become clear.

It is now widely accepted that the infectious agent is largely proteinaceous and that the increase in infectivity during the incubation period is due to the alteration of a normal protein found in the body, the prion protein labeled PrP^c, to an abnormal (disease-associated) form called PrP^d that is not destroyed adequately by body enzymes, and that this abnormal form will cause the further alteration of PrP^c to PrP^d and build up within tissues. There is still argument as to the mode of infectivity of the agent, but it can be stated that PrP^c is required for infection to take place and that without it further infectivity is not found.

The protein infectious form is called the prion, which is resistant to irradiation, UV light, a wide range of enzymes (including powerful peptidases), antiseptic chemicals, heat, and antiviral agents. PrP^c is found throughout the animal kingdom. It has a series of well-preserved segments and two heparin binding sites, and it has retained a section normally associated with Cu^{2+} ions. It is hydrophobic in nature and tends to form into crystalloids within the tissues in which it is present. The natural forms of prion disease are shown in Table 1. Various forms and strains of prion disease are seen for different species; these vary by incubation period, brain and peripheral tissue distribution, chemical glycoform nature of the PrP^d that is produced, and different ranges of further species (usually about 50%) that may be infected by the strain experimentally.

The prion is derived from the normal (PrP^c) form of the protein, which is found throughout the body except on red cells, but to a much greater degree on various leukocytes, and brain cells. As such it may infect the body not only through the brain but also through peripheral tissues, which themselves become infectious. However, because of cellular turnover, the quantity of prions present in these tissues remains low and it is only in the brain where late in the disease PrP^d builds up to such a degree that stimulation is seen of microglia and their release of cytokine peptides along with other inflammatory intermediates. These processes result in progressive neurocytic apoptosis, leading to death of the animal.

Diagnostics for TSEs have become important following the realization that several of them may infect humans (or should be assumed to do so) and that, because of modern agricultural and medicinal techniques, large numbers of people may be put at risk (see below). Also, prophylactic agents and progress in potential methods of treatment for Creutzfeldt-Jakob disease (CJD) patients suggest that diagnostics may be necessary to permit the therapeutics to be used early in a symptomatic phase.

BSE, Variant CJD (v-CJD), and Blood Transfusion (3): the Worries that Made Rapid and Effective Diagnostics Worthwhile (2)

BSE was first diagnosed in 1987 and was quickly realized to be rapidly rising in the United Kingdom's bovine population. Epidemiology showed that the condition was spread through the feeding of infective material made from the carcass of one infected bovine to another, and this practice was stopped in the United Kingdom in 1988. Unfortunately, as cattle die generally at around 3 to 6 years due to BSE but are commonly slaughtered much earlier, most of the infected animals were eaten presymptomatically. Ultimately, it was possible to say that over a million infected cattle were present in the United Kingdom, probably at a peak around 1991, that the peak of animals dying of BSE was in 1993, that over 95% of cattle in the United Kingdom were from infected herds by 1995, and that in that country everyone had eaten, on average, approximately 50 meals made from the tissues of infected cattle by 1996. The recurrent denial by the United Kingdom's Ministry of Agriculture Fisheries and Food (MAFF) that there was any risk to humans because BSE was simply scrapie in cattle (and hence would have the same infective range among other

TABLE 1 Natural forms of prion disease

Natural TSE	Natural host(s)	Incubation period	Age of infection	World distribution
Scrapie	Sheep and goats	2 yr	<6 mo	Widespread except in Australia and New Zealand
Sporadic CJD	Humans	? >30 yr	Unknown. Familial forms seen in less than 50%.	Worldwide
GSS	Humans	30–50 yr	Familial condition	Worldwide
FFI	Humans	40 yr	Familial condition	Worldwide
Kuru	Humans	6–>40 yr	Neonate to adult	Papua New Guinea
v-CJD	Humans	?5–?40 yr	Unclear, possibly teenage or younger	United Kingdom, France, Canada, United States
BSE	Bovines (+ other animals fed BSE in error)	3–10 yr	<7 mo	United Kingdom and countries importing cattle from the United Kingdom
CWD	Deer and elk	?2–10 yr	Various points in life	United States, Canada
TME	Mink	<2 yr	<6 mo	United States, Russia, Finland

species) during this period was followed by evidence that BSE infected cats (considered immune to scrapie) and monkeys but not hamsters (common research tool for scrapie infection). The government of the United Kingdom also decided not to fund research into the field adequately; it said that if it did fund aspects including diagnostic or treatment research, then the people in that country would question the MAFF's statement that BSE was of no risk to humans and stop eating beef. However, in 1990, under pressure from the scientific society, the MAFF banned the availability in food of a progressive range of central nervous system (CNS) and lymphoid tissues that were expected to carry the highest titer of infectivity. Also, all cattle with symptoms of BSE automatically became the property of the MAFF, and therefore no tissues were available for research to any group outside the control of the government of the United Kingdom.

The incubation period of a TSE is considered to be much longer when TSE is passed from one species to another; when the dose is low or given orally, as may have been the case in BSE in human food, it was thought to be longer. Also, the incubation period rises in proportion to the normal life expectancy of the recipient animal. BSE was considered to have infected the cattle shortly after birth (within the first 7 months), and the peak incidence was at 5 years of age. Bovines have a natural life expectancy of 20 to 30 years, and humans have one of 70 years, i.e., between two and four times longer. Hence, if it was passed from other humans we might expect a human incubation period of 10 to 20 years, but because it was passed from cattle at a low dose and by mouth, this was expected to be between 20 and 40 years. As such, a peak of clinical disease in humans transferred from cattle was calculated to be 2010 to 2030.

In March 1996, v-CJD was reported for young people in the United Kingdom and was realized to be BSE in humans. The disease could be passed back to animals to produce the same tissue distribution of prion infection as seen when BSE was inoculated into them with the same type of glycosylation (see below) in the prion proteins that were extracted from humans, and from the animals with BSE; this was not true for any known form of CJD.

The initial cases of v-CJD were worrying in that it was not at all clear how the first case could appear so early without representing the beginning of a very large epidemic in the United Kingdom. It was this factor and the realization that BSE must have been exported by the United Kingdom

to countries all around the world that caused major research progress and political action. As of this writing, only 146 cases of v-CJD have been reported in the United Kingdom, the case numbers are no longer rising, and all but one are of a single PrP genotype. The reason for this is unclear. Unfortunately, there have been now two cases of v-CJD derived from blood transfusion, one of which was of a different, more common PrP genotype, and it is realized that a further epidemic of v-CJD in that genotype must be expected as a result of oral transmission of BSE.

It is because of these factors that diagnostic techniques in cattle to remove asymptomatic BSE-infected bovines from the human diet were required urgently, human diagnostic techniques were needed in that v-CJD did not have classical electroencephalogram (EEG) changes or its initial clinical symptoms, and blood testing systems were needed to avoid the transmission of v-CJD in blood and other medical practices.

CWD

Chronic wasting disease (CWD) (2, 19) was originally reported at Fort Collins, Colo., in captive mule deer in the late 1960s, but case numbers have expanded in deer and elk in the Rocky Mountains and are spreading both northward and eastward. This slow spread of what now appears to be an epidemic disease becoming endemic raises several problems in that there is no proof that the disease is not infectious to humans, and there is no clear mechanism of natural transmission. A widespread attempt has been made to monitor its growth by the testing of all slaughtered and fallen (i.e., found dead) deer and elk using a rapid testing method, and the eating of nervous tissue from these animals has been warned against by officials in specific states.

METHODS

A wide range of tests, international guidances, and local protocols are available that use basic methods (12, 14, 15, 23, 20).

Diagnostics for Prion Disease Using Transmission of the Condition to Other Animals

In the past, using transmission of prion disease to other animals was looked on as the only reliable method for diagnostics, and the minimum quantity of tissue that was found to transmit the disease to another animal of the same species by inoculation directly into the brain was said to contain

TABLE 2 Dose of infection required to transmit the disease when inoculated into various sites

Tissue into which inoculum is injected	Dose required for transmission (IU)
Brain	1
Blood	5–>10
Peritoneum	>400
Given orally	>10^4 (lower possibly in neonates)

1 infection unit (IU). The reason for this technique was that the transmission from one species to another was commonly found to require 10^4 times the quantity of tissue (the "species barrier"), and when inoculated into peripheral tissues a much larger amount might be needed; see Table 2.

When prions are inoculated into the brain a short incubation period is seen, and this still represents the most sensitive method for measuring prion infectivity. The method is unfortunately inaccurate, expensive, and ethically complex. In addition, simply because such small amounts (generally less than 3 mg) of tissue can be inoculated into mice, approximately 2 orders of magnitude of the sensitivity is lost, with a minimum of 300 IU per g required for infection to be transmitted.

Attempts were made to pass the species barrier and permit mice to be used to measure human tissue infectivity with CJD using the transgenic development of the human PrP gene in the mouse embryo. This process has proved inadequate, but progress is being made (13).

It should be noted that once a prion disease has been passed between species, the further transmission from the recipient animal to another of the same species is markedly more sensitive (i.e., the species barrier is lost or reduced). As a result, many scientific studies are carried out using human prions from CJD that have been transferred into mice. A problem with this method is that, having been transmitted between species, the range of further animals that the prion will infect changes, and the distribution of disease in the animal body also changes.

Tissue infectivity varies during the incubation period. Following peripheral inoculation of prions into the body, infectivity is found in peripheral tissues starting at a concentration that is dependent on the dose that was inoculated but dropping over a short period to a generally unmeasurable level. Following this, lymphoid tissue and reticuloendothelial tissues become infectious and rise relatively early in the incubation period to reach a plateau at a relatively low level compared with the final infectivity of brain tissue. After half the incubation period the infectivity is also found in the CNS, building up in a logarithmic manner until the death of the animal.

Quantification of infectivity in tissues may be carried out by comparing the incubation period in the animals into which a tissue inoculum has been passed with a standard range or by inoculation of a series of logarithmic dilutions of the tissue into the brains of animals, generally five for each dilution, of the same species. The cost of the large numbers of animals needed and the difficulty of carrying this out have meant that these methods are used only when disease quantity must be certain. Therefore, they are commonly used to confirm the sensitivity of other test systems.

EM

Several methods are claimed to show tubulofilamentous particles present in brain (22) that are specific to TSEs and start to appear in the tissues at around half the incubation period

of the disease. However, it now seems that they do not contain immunoreactive PrP (17) and hence probably show an early brain secondary pathological process. The buildup of PrP^d in the brain can be shown at a later point using immunogold electron microscopy (EM) staining of 65-nm sections etched in sodium periodate for 60 min, immunogold labeled to detect PrP using specific PrP monoclonal antibodies (see below), and with grids counterstained using uranyl acetate and lead citrate (11).

Scrapie-associated fibrils (SAF) can be demonstrated in brain tissue diagnosed by histopathology. This tissue is homogenized and pretreated or not with proteinase inhibitors or with dimethyl sulfoxide acting as a precipitant. SAF also can be extracted efficiently by adding a 10% solution of Sarkosyl to the homogenate and can be enriched by differential centrifugation and buffer extraction. Following centrifugation, this material can be stored at 4 or −70°C before EM is performed at a later date (9, 28; WHO Infection Control Guidelines for Transmissible Spongiform Encephalopathies, 1999 [http://www.who.int/emc-documents/tse/docs/whocdscsraph 2003.pdf]). The SAF appear under EM as long, thin, crystalloid structures that can be stained using an immunogold anti-PrP technique and are copurified with infectivity. The original hypothesis that SAF are actually the infective particles is now considered unlikely but rather that they represent the coagulation of hydrophobic PrP^d.

Histopathological Methods

Standard staining methods can be used for the demonstration of specific histopathological changes (8) in the brain, e.g., hematoxylin and eosin stains. However, tissue can be decontaminated in 96% formic acid for 1 h prior to processing in paraffin wax. A problem with this technique is that, as with BSE, where approximately 15% of cases were misdiagnosed, the spongiform changes appear late in the incubation period; although this is unlikely to be a problem with humans dying of CJD, it cannot be reliable with slaughtered animals that are killed when symptoms start. Also, the development of Congo red-stained amyloid as PrP plaques is seen in only 10% of the cases, particularly in the cerebellum in CJD, and occurs late in disease. Many samples of the brain must be taken to be sure that spongiform changes are not present, as some parts of the brain may have no changes. In CJD, spongiform change is relatively reliable in various layers of the cerebral cortex; fine vacuole-like holes appear in the neuropil as vacuoles 20 to 200 μm in diameter but become confluent at times to create larger ones, substantially distorting the cytoarchitecture. Similar vacuoles in the cytoplasm of larger cortical neurons may be seen. Cortical involvement is usually accompanied by spongiform change in the cerebellar cortex and basal ganglia. Microvacuolar change may be seen in the cerebellum. In clinical cases involving patients who die after long periods of symptomatic disease, neuronal loss may be severe and a status spongiosus appears where collapse of the cytoarchitecture appears in the cortex, leaving a distorted edge of gliotic tissues. The neurons also die in the basal ganglia, and there is a dramatic drop in granular and Purkinje cell populations. Gliosis involving astrocytes and microglia is present throughout areas associated with neuronal loss, and microglia also increase around PrP amyloid plaques. For further images and comparisons with other neurological pathology, see http://www.cjd.ed.ac.uk/path.htm; however, it should be remembered that there is a poor relationship between the course of disease and pathology distribution.

Immunostaining for PrP in brain and tonsils is of particular value in that an excess of PrP amyloid plaques would create a certain diagnosis. Ultrastructural and immunocytochemical

studies of both human and animal prion diseases have demonstrated that microglial cells are intimately involved in PrP plaque formation and may play a role in the processing of PrP into an amyloid structure (8, 10). The appearance of PrP by immunostaining in the human tonsils or those of deer is also important in that PrP is found in early clinical cases of v-CJD and CWD (24), whereas this is not true with other forms of TSE. Third-eyelid tissue biopsy in CWD is an effective and relatively simple confirmatory test (3).

EEG Changes

A gradual loss of normal EEG patterns is seen in sporadic CJD, and in 60 to 80% of cases, generalized bi- or triphasic periodic sharp wave complexes appear with a frequency of around one or two per second. With clinical signs similar to those of sporadic CJD, this would be a useful confirmation of the diagnosis. Initially, EEG changes may be unilateral, as may periodic complexes. Unfortunately, this pattern is not universally found, and many other dementia-causing illnesses may show some similar signs. The point during the clinical progression of the disease at which this periodic pattern is found may vary and indeed may not be until very late; hence, weekly EEG tests may be needed, often an unrealistic requirement. This periodic pattern appears less frequently in genetic or human growth hormone-related CJD. It is not seen in v-CJD, which even in itself may be help to separate a case of sporadic CJD from v-CJD in an older patient.

MRI Scanning

It has been noted late in the clinical period of v-CJD that a reliable, symmetrical high-intensity signal is observable in the pulvinar by high-intensity MRI scanning (4). This is not seen in other forms of human disease, although magnetic resonance imaging (MRI) sequences, only as diffusion-weighted images of the cortex, showed unequivocal pathology in CJD, and clear atrophy was only seen late in disease with a long clinical period.

Rapid Specific Diagnostic Techniques (28, 29)

Brain Samples

It was realized that cattle incubating BSE were still reaching human food supplies in Europe and that the prions would not be destroyed by cooking processes. Consequently, several technical methods were developed that would indicate PrP^d in the brain of the slaughtered animal in a manner that would permit the carcass, kept overnight, to be destroyed the next day, when the result was ready, and not reach the human diet. Several companies are now selling assessed and licensed methods for testing tissue derived from the base of the brain and obtained as a sample through the foramen magnum. Homogenized samples of around 100 mg or less are resuspended and tested using enzyme-linked immunosorbent assay systems. The company tests involved have approximately the same sensitivity and specificity, but certain types might be considered of advantage in specific conditions; see Table 3.

At the time of this writing, no testing of bovine tissue in the United States has been requested, but this is required in Canada, Europe, and Japan. Also, the Organisation International Epizoites has made it clear that the United States has a high chance of developing BSE, and therefore testing systems should be considered. All of these methods have the same problem in that they cannot ensure that the animal being slaughtered is not infected with BSE but simply does not carry enough of the PrP^d in its brain to be indicated. The tests are expected to become positive probably some time between 50 and 75% of the clinical incubation period.

Confirmation is required for all carcasses that have a positive test for BSE. This is carried out by repetition of the first test (with another method if possible) and sending of samples to the government laboratory of the individual country. In the United States, confirmation is currently being carried out by the Animal and Plant Health Inspection Service (APHIS) in Iowa (http://www.aphis.usda.gov/oa/pubs/ pub_ahbse.html).

Confirmation by Western blotting is carried out using a proteinase K-treated sample of brain tissue suspended in buffer and electrophoresed. The blotting shows a series of bands generally between 27 and 30 kDa representing three forms of the PrP^d that carry both glycosyl chains, only one of them, or none. Full confirmation must be done by inoculation of the bovine tissues into another animal, but this is now rarely used.

Specific diagnostic methods for the testing of sheep and cattle have been decided and directed at an international level (e.g., Organisation International Epizoites Laboratory Manual [http://www.oie.int/eng/normes/mmanual/A_00064.htm and http://www.oie.int/eng/normes/mmanual/A_154.htm]); methods that are commercially available for animal testing must be licensed by the Food and Drug Administration and specifically

TABLE 3 Comparison of licensed rapid brain tissue tests for PrP^d that are used commercially for the testing of asymptomatic cattle for BSE[a]

Company source of test	Speed of test	Complexity of test	Specificity	Cost	Experience in veterinary use
Enfer (Abbott, Abbott Park, Ill.)	Slow	Complex because of proteinase K step	++	Medium	Medium
Bio-Rad (Hercules, Calif.)	Slow	Complex because of proteinase K step	++	Relatively high because of equipment	Very high
Idexx (Westbrook, Maine)	Rapid	Simple because Seprion ligand used	++	Relatively low because complex equipment not needed	Medium (large amounts in CWD)
InPro (San Francisco, Calif.)	Slow	Complex	+++	Computerized equipment needed	Low
Prionics (Zurich, Switzerland)	Slow	Relatively simple because specific anti-PrP^d used	+++ because Western blot also available for confirmation	Relatively high because of antibody cost	High

[a]Data from references 20 and 29. Poor-comparison-related assessments have been carried out. All have high false-negative rates due to low levels of prions present in early stages of disease.

handled. Standard methods are also available from the European Commission in this respect. In the United States, currently the Department of Agriculture through APHIS is testing groups of cattle: nonambulatory cattle; cattle exhibiting signs of a CNS disorder; cattle exhibiting other signs that may be associated with BSE, such as emaciation or injury; and dead cattle. These groups of cattle are calculated to give a good indication as to the prevalence of BSE in the United States.

Blood Samples

No rapid technique is currently commercially available for detecting PrP[d] in blood. However, several methods are currently well advanced in development. For further information on these, contact Microsens Biotechnology (London, United Kingdom; http://www.microsens.co.uk) or BioMerieux (http://www.biomerieux-usa.com).

Urine Samples

It was realized that a PrP[d] form was in fact being excreted from much of the tissues of the body in some way because there was little local damage. The turnover of infected cells in the body and gut wall suggested that prions may be present in both urine and feces but in extremely small amounts. Complex testing systems have shown the presence of altered forms of PrP[d] in the urine (28), and this result has been confirmed by other scientists but the systems are not available commercially.

Nonspecific Diagnostic Techniques (6, 7, 16, 18, 21, 25–27)

Late in the incubation period of prion disease, the pathological processes in the brain and elsewhere cause local release of cytokines and alterations in the relative quantities of proteins in the cerebrospinal fluid (CSF) and blood. The major problem for all of these tests is that the findings may also be found in other conditions that may cause symptoms similar to those of CJD. However, they may be of use in following the progress of the patient's illness, and potentially the value of treatment.

Also, because the tests in blood and the vasovagal response test are so easily carried out, they may be used to help in diagnosis in clinically ill patients. For test types, see Table 4.

Genetic PrP Changes Associated with Prion Disease and Glycoside Changes Found in Some Clinical Strains

In humans the prion protein with 253 amino acids is encoded on the short arm of chromosome 20 from its specific gene (PRNP), and small changes in amino acids of the PrP[c] are seen between mammals. Small but specific changes are seen in familial forms of the disease, Gerstmann-Sträussler-Scheinker syndrome (GSS) and fatal familial insomnia (FFI). No changes are seen in the forms in which infection is considered to have taken place. However, the incubation period may be altered according to the structure (see the Weizmann Library [http://bioinfo.weizmann.ac.il/cards-bin/carddisp?PRNP]).

In humans there is a specific polymorphic mutation at codon 129 giving rise to either a valine or methionine at the peptide site and both a wide change in the incubation period and clinical symptoms of CJD results.

Glycosylation changes (1, 3) in the ratio of PrP[d] carrying two, one, or zero glycosyl chains have been reported for different strains of CJD, v-CJD, transmissible mink encephalopathy (TME), and scrapie. If this is required for full diagnosis or investigation of epidemic outbreaks of disease, then CJD researchers (Gambetti et al.) should be contacted at Case Western University, Cleveland, Ohio. The importance of this glycoform research data is realized as a change in some sheep scrapie, which has now been suggested to be BSE transmission to sheep.

ANALYTICAL SENSITIVITY AND SPECIFIC DIFFICULTIES CURRENTLY ENCOUNTERED WITH PRION DIAGNOSTIC ASSAYS: QUALITY CONTROL

The growth of academic groups in the field of prion research has led to a tendency for each of them to be large enough to

TABLE 4 Nonspecific tests for TSE also used to follow disease progression[a]

Change reported[b]	Tissue source	Change seen	Availability of test
14-3-3 protein (6)	CSF	Increased in CJD but not all TSEs	Neuropathology, Case Western Reserve University, or CJD Surveillance Unit, Edinburgh, Scotland
GFAP, protein S-100B, NSE, MBP (6, 24)	CSF	GFAP is more available than the others by ELISA[c]; all of these proteins are associated with brain damage and gliosis.	Neurological research groups
FABP (7)	Blood and CSF	May be increased in TSE conditions; further research required	Research groups
PrP or IFN-γ, or LR or LRP (21)	Blood	Altered in clinical conditions of TSE as a range of changes	Research groups (Proteome Sciences)
EDRF (18)	Blood	Low in scrapie and possibly other TSEs	Not commercially available. Research at Roslin Institute, Edinburgh, Scotland.
R spectra for plasma (26)	Blood	Plasma from BSE asymptomatic cattle shown to have changes in IR spectra	Roche Inc. (the test is currently unavailable)
Vasovagal reflex (25)		Loss of heart rate changes with breathing during progression of TSE	Tsens Ltd.

[b]GFAP, glial fibrillary acidic protein; NSE, neuron-specific enolase; MBP, myelin basic protein; FABP, fatty acid binding protein; IFN-γ, gamma interferon; LR, laminin receptor; LRP, LR precursor; EDRF, erythroid differentiation-related factor; IR, infrared.

[c]ELISA, enzyme-linked immunosorbent assay.

declare that their own methods are adequate. As a result, the lack of standard testing systems has been a major problem for any new quantitative or qualitative assay system. Because of the rapid growth in BSE in Europe, there has been political pressure for specific tissues to be available from international standards laboratories, but complex difficulties have given rise to a severe shortfall for many tissue samples. It has become necessary for central laboratories that hold them to limit their distribution and to question the validity of testing procedures. Also, human tissues have been exceptionally difficult for research groups to gain access to because of ethics procedures that are enforced, and as a result postmortem tissues of known dilution may be all that are available.

Currently, the Veterinary Laboratories Agency (D. E. Bunce, TSE Office, New Haw, Addlestone, Surrey, United Kingdom KT15 3NB; phone, UK-1932-357875; e-mail address, d.e.bunce@vla.maff.gsi.gov.uk) is making an attempt to have available samples of BSE- and scrapie-infected tissue. For CJD, samples might be available from the National Institute of Biological Standards and Controls (20) (NIBSC, Blanche Lane, South Mimms, Potters Bar, United Kingdom); for reagents and samples, contact the TSE Resource Centre (Institute for Animal Health, Compton, Newbury, Berkshire, United Kingdom RG20 7NN; phone, UK-1635-577294; e-mail address, tse.rc@bbsrc.ac.uk; URL, http://www.iah.bbsrc.ac.uk/tse-rc). Currently in the United States, small tissue samples can be requested from the academic research groups at the National Institutes of Health (NIH) (P. Brown) and Wyoming State University (E. Williams).

Quality control for prion testing systems is exceptionally difficult in that standard reagents containing known amounts of infectivity require complex quantitative assays. Consequently, they are expensive and infectious and must be stored under specific conditions. Currently they are used mainly for research and for the assessment of rapid diagnostic techniques. The nonspecific systems either use reagents that are commonly available through standard suppliers (e.g., Sigma), or must use reagents that are not available easily, and hence the tests are carried out only in centralized laboratories where reliable comparisons between the results of separate patient samples can be carried out (e.g., 14-3-3 protein).

Precautions for Working with Potentially Prion-Infected Material

One of the major problems with TSE diagnostics is that certain procedures should be carried out using specific methods and precautions to prevent risk of infection to any staff or cross-contamination (e.g., WHO Infection Control Guidelines for Transmissible Spongiform Encephalopathies, 1999 [http://www.who.int/emc-documents/tse/docs/whocdscsraph2003.pdf], and the Advisory Committee on Dangerous Pathogens 2002 Transmissible Spongiform Encephalopathy Agents: Safe Working and the Prevention of Infection [http://www.advisorybodies.doh.gov.uk/acdp/tseguidance/index. htm]).

Some methods require specific biohazard containment facilities and the reliable and audited use of specific policies. However, methods involving bovine tissues and the rapid techniques are not currently required in the United States except in research laboratories.

Examples of precautions are shown in Table 5. Notably, the Centers for Disease Control and Prevention (CDC) and NIH would recommend some aspects of dealing with prion-infected tissue at biosafety level 2 and some at level 3. The CDC or NIH should be contacted before laboratory testing is developed. Currently in the United States cattle are not considered infected with BSE until a test is shown to be positive. However, samples being taken for testing from symptomatic cattle and sent to APHIS should be transferred as infectious material.

DISCUSSION AND INTERPRETATION

The development of many diagnostic systems and methods has meant that many groups have difficulty knowing which would be of most value for individual patients despite the appearance of national and international guidelines (10, 14, 20, 23). In animals, the tests that are performed depend to a large degree on official direction at the time (20, 23). An attempt is made in Table 6 to list the diagnostic actions that are considered useful with clinical syndromes that fit the pattern of the individual disease. Note that some methods described earlier cannot be used clinically and are only of value in research.

TABLE 5 Precautions for working with high- and low-infectivity tissues from patients with known or suspected TSEs[a]

1. Whenever possible and where available, specimens should be examined in a laboratory or center accustomed to handling high- and low-infectivity tissues; in particular, high-infectivity tissue specimens should be examined by experienced personnel in a TSE laboratory.
2. Samples should be labeled "Biohazard."
3. Single-use protective clothing is preferred as follows:
    Liquid-repellent gowns over plastic apron
    Gloves (cut-resistant gloves are preferred for brain cutting)
    Mask
    Visor or goggles
4. Use disposable equipment wherever possible.
5. All disposable instruments that have been in contact with high-infectivity tissues should be clearly identified and disposed of by incineration.
6. Use disposable nonpermeable material to prevent contamination of the work surface. This covering and all washings, waste material, and protective clothing should be destroyed and disposed of by incineration.
7. Fixatives and waste fluids must be decontaminated by a decontamination method described in another section of the WHO advisory document or adsorbed onto materials such as sawdust and disposed of by incineration as a hazardous material.
8. Laboratories handling large numbers of samples are advised to adopt more stringent measures because of the possibility of increased residual contamination, e.g., restricted-access laboratory facilities, the use of dedicated microtomes and processing labware, and decontamination of all wastes before transport out of the facility for incineration.

[a]Data from reference 20.

TABLE 6 Value of specific tests in the diagnosis of TSEs[a]

Clinical syndrome	EEG	MRI	Brain biopsy	Tonsillar biopsy	Genetic analysis	Rapid brain sample test	Nonspecific CSF test
Sporadic CJD	+	+	May be unhelpful	−	−	−	14-3-3 test only
Familial CJD, GSS, or FFI	+++ in FFI	+	−	−	++	−	−
v-CJD	++ no specific changes	Pulvinar sign	May be unhelpful	++	+	−	14-3-3 test negative
Kuru	+	+	+	−	−	−	−
TME	−	−	+	−	−	Only positive with some test methods	−
Scrapie	−	−	+	−	+ used to decrease scrapie in flock	Only positive with some test methods	−
CWD	−	−	Confirmatory tests needed if new area of United States affected	−	−	++	−
BSE	−	−	Western blotting and animal transfer experiments to confirm rapid-test positives in United States	−	−	Currently not required by U.S. government as screening of cattle for human food	−

[a]Data from references 1, 10, 20, and 23. EEG changes are not reliable, so false-negative results may be seen in sporadic CJD but positive results are useful in diagnosis. MRI tests in human disease must always be carried out to rule out other disease. Histopathological testing of postmortem human samples, including immunological staining, should be used to confirm the diagnosis. Histopathological testing of samples from BSE, scrapie, and CWD cases may produce false-negative results without further testing (e.g., Western blot for PrP[d]). Asymptomatic infected animals may have negative rapid screening tests. Genetic analysis of v-CJD and scrapie is useful only in that some genotypes are more likely to have the disease than others but cannot be diagnostic. Symptomatic kuru is largely clinically diagnostic, and the tests suggested here are used only when a possible case is seen outside Papua New Guinea. Nonspecific vasovagal tests should be considered if available but mainly to follow the progression of the disease. EM of brain biopsy material is helpful in diagnosis, but its availability is exceedingly limited. It must be realized that certainty in ante-mortem diagnosis is commonly difficult to achieve. +, may be of value; ++, useful for diagnosis; −, not considered worthwhile.

REMARKS AND CONCLUSIONS

The change over the past 15 years from TSE being the subject of research carried out in a few laboratories to its being a major international problem with testing and assessing taking place widely shows how agricultural practices may spread an illness widely and potentially create major risks. The crushing effect of this on specific industries and hospital practices has been widespread and has been at an immense cost (considered to be over $10 billion) to mainly the European population. However, it is now realized how similar TSEs are to Alzheimer's and Parkinson's diseases. Potential diagnostics, animal models, and treatment systems may be derived from the study of TSEs, so a clear benefit may be gained for these more common afflictions.

Currently over 20 million cattle are being tested annually for BSE in Europe, and blood transfusion risks may demand that a similar number of blood donations also be tested for the foreseeable future. The development of potential clinical treatment for CJD would make the testing of large numbers of older people useful, and the gradual growth in Alzheimer's disease as the demographics of the populations grow older would mean that any test for this would become valuable. As a result, we should expect progress from commercial and academic groups despite the extreme difficulty in diagnostics and treatment.

At the time of this writing, the U.S. Department of Agriculture has not permitted the widespread testing of asymptomatic cattle for BSE in the United States and does not have CDC laboratory guidance on it. However, it should not be surprising if animal and human testing in the United States does expand.

Introduction

MICHAEL W. BASELER

93

No single disease has had such an impact on the diagnostic immunology laboratory as human immunodeficiency virus (HIV) infection and its sequelae. The laboratory evaluation of patients with HIV infection has evolved from basic flow cytometry to detailed molecular analysis of viral quasispecies and quantitation of tetramer-positive T cells. As the number of HIV infections worldwide continues to increase, the need for laboratory capabilities for the monitoring of these patients has increased as well. This need is even greater given recent advances in treatment strategies that will hopefully turn this disease into a chronic manageable illness. This section deals with the laboratory immunologic and virologic perspectives. In the chapter "Principles and Procedures of Human Immunodeficiency Virus Serodiagnosis," Dewar et al. review the current assay systems available for the serodiagnosis of HIV. These assay systems include standard enzyme-linked immunosorbent assays, the currently available rapid assay systems, and Western blot confirmatory analysis, as well as the recently Food and Drug Administration-approved home testing kits. This chapter also discusses point-of-care testing, which is critical in resource-poor settings such as developing nations, where more than 95% of all new infections are emerging.

In the chapter "General Immunologic Evaluation of Patients with Human Immunodeficiency Virus Infection," Stevens et al. discuss how to evaluate the cellular immune response in patients with HIV. Functional assays and the state of the art in immunophenotyping with flow cytometry are emphasized. Singe-platform immunophenotyping versus dual-platform immunophenotyping is also highlighted within this chapter. With the advent of better therapeutic interventions, the ability to monitor patients' immune systems over long periods becomes critical.

Along with the need to monitor cellular immune function in patients with HIV, it is equally critical to monitor viral load and drug resistance. Elbeik et al., in the chapter "Quantitation of Viremia and Determination of Drug Resistance in Patients with Human Immunodeficiency Virus Infection," outline the state-of-the-art procedures for monitoring viral load and drug resistance with time. The measurement of drug resistance is critical in managing patients with HIV in light of the multiple therapeutic modalities that are currently available.

For the more research-oriented laboratories, Hengel et al., in the chapter "Measurement of T-Cell-Specific Immunity in Patients with Human Immunodeficiency Virus Infection," discuss state-of-the-art research tools that are able to more specifically define the pathologic effects of HIV infection on T-cell-specific immunity. These advanced methods are very complementary to the more broadly characterizing methods described by Stevens et al.

The HIV epidemic has provided the standard clinical immunology laboratory with a unique opportunity and an important challenge. The close relationship between immunologic status, as determined by CD4 T-lymphocyte quantitation, and stage of disease has made immunologic monitoring an important part of the clinical management of HIV-infected patients. The combination of CD4 count and HIV RNA level provides the clinician with important information that has led to marked improvements in patient care. From determining a patient's relative risk of developing an opportunistic infection to monitoring immunologic responses to candidate vaccines, the clinical immunology lab plays a major role in the area of HIV.

Principles and Procedures of Human Immunodeficiency Virus Serodiagnosis

ROBIN DEWAR, HELENE HIGHBARGER, RICHARD DAVEY, AND JULIA METCALF

94

The first published reports of AIDS appeared in 1981, and the causative agent, human immunodeficiency virus type 1 (HIV-1), was identified in 1983 to 1984. Over the next two decades, HIV-1 infection and AIDS became one of the leading causes of illness and death worldwide. The Joint United Nations Program on HIV/AIDS (UNAIDS) reported in July 2004 that as of the end of 2003, an estimated 37.8 million people worldwide—35.7 million adults and 2.1 million children younger than 15 years—were living with HIV/AIDS. Approximately two-thirds of these people (25.0 million) live in sub-Saharan Africa; another 20% (7.4 million) live in Asia and the Pacific. More than 20 million people with HIV/AIDS have died since the first AIDS cases were identified in 1981 (41). In 2003 alone, HIV/AIDS-associated illnesses caused the deaths of approximately 2.9 million people worldwide, including an estimated 490,000 children younger than 15 years (41). In 2000, the Centers for Disease Control and Prevention (CDC) estimated that 850,000 to 950,000 U.S. residents are living with HIV infection, one-quarter of whom are unaware of their infection (16). As of the end of 2002, an estimated 385,000 people in the United States were living with AIDS and an estimated 500,000 people with AIDS in the United States had died (8). An estimated 4.8 million new HIV infections occurred worldwide during 2003, that is, about 14,000 infections each day. More than 95% of these new infections occurred in developing countries (41), while approximately 40,000 new HIV infections occur each year in the United States (7).

An important early impetus for the development and testing of serologic methods to detect HIV infection was the need to guarantee the safety of the blood supply. A quick review of the statistics above makes clear the need for the continued development of serologic methods, including point-of-care testing, that are useful especially in resource-poor settings.

ANTIBODY DETECTION ASSAYS

Screening Tests

The standard screening tests for HIV infection involve detection of HIV-specific antibodies. Early in 1985, routine testing of donated blood by a rapid solid-phase approach became available through the development, testing, and licensure of the first enzyme-linked immunosorbent assay (ELISA) kit. By 1987 a total of eight different commercial ELISAs had been licensed by the Food and Drug Administration (FDA), and the HIV-1 ELISA was rapidly established as a primary diagnostic screening tool (21). Test sites that were established nationwide in government-sponsored clinics to allow for confidential or anonymous testing of at-risk individuals were soon supplemented by wide-scale availability of these assays through other means, such as hospital-based or commercial laboratories. Since the first screening ELISAs and Western blot (immunoblot) assays came onto the market in 1985, technology has evolved to include novel assays based on a variety of immunologic principles (Table 1). The present-day assays have improved sensitivity and specificity, can better resolve indeterminate results, and help to identify infections in newborns. Some of these newer assays include augmented Western blot assays, class-specific antibody capture assays, particle agglutinations, substrate amplification procedures, tests that can differentiate antibody isotypes, rapid assays (requiring just minutes to perform), and tests that can simultaneously detect HIV-1 (including subtype O [for "other"]), HIV-2, human T-cell lymphotropic virus type 1 (HTLV-1), HTLV-2, and HIV antigen (44, 47).

Infection with HIV results in the induction of a humoral antibody response specific to viral proteins. Most exposed individuals will develop antibody against the virus within a few weeks to a few months after viral infection. There is only a single case report of a previously healthy individual who failed to produce antibodies following HIV infection. Wide-scale serologic testing of infected individuals has revealed that the major antigens against which antibodies are produced are also fairly consistent within the population, although the exact timing of appearance and the relative intensity of individual antibody responses may vary from person to person. The genome of HIV-1 is known to code for three structural polyproteins and seven regulatory proteins. The structural proteins of HIV-1 (Fig. 1) are the targets for the majority of the circulating antibodies directed against the virus and are as follows.

- Envelope (*env*) proteins: the surface glycoprotein (gp120), the transmembrane glycoprotein (gp41), and their precursor glycoprotein (gp160)
- Polymerase (*pol*) proteins: the reverse transcriptase (p66), the endonuclease-integrase (p31), and the protease (p10)
- Core (*gag*) proteins: the matrix protein (p18), the internal capsid protein (p24), the nucleocapsid protein (p7), and their precursor protein (p55)

[a]Partial listing; see also references 4 and 11.

Within a few weeks (usually between 4 and 8 weeks, although a duration as short as 8 days has been described) after exposure to the virus, infected individuals may experience a brief period of constitutional illness (fever, fatigue, myalgia, rash, gastrointestinal complaints, and, rarely, neurological symptoms) that has been likened to a mononucleosis-like viral illness. This period lasts anywhere from a few days to a few weeks and has been shown to be accompanied by a burst of active viral replication in the host, as documented by high levels of circulating virus and viral p24 antigen in plasma. With subsidence of the acute symptomatology, increasing levels of virus-specific antibody begin to appear and can be quantified by a variety of serologic detection methods (Table 1). Antibodies against p24 and against the viral envelope proteins (gp160 and gp41 in particular) are among the first detectable HIV-1-specific immunoglobulins produced during this period of acute seroconversion (Fig. 2) (1). Of note, the ELISA appears to be especially sensitive to the early detection of anti-p24 antibody, whereas certain other tests, such as the radio-immunoprecipitation assay (RIPA), may show early reactivity due to antibody directed against the higher-molecular-weight antigens, such as gp160. The ELISA is the standard screening test for HIV-1 infection. Individuals with indeterminate or positive ELISA results should undergo confirmation testing (generally by Western blotting [immunoblotting]) to determine if the reactivity is primarily directed to HIV-1 infection or secondarily directed to cross-reacting antibodies (11, 15). A commonly accepted algorithm for the sequential application of the serologic tests in the evaluation of sera from patients with potential HIV exposure is shown in Fig. 3.

ELISAs

ELISAs and enzyme immunoassays for the detection of a serologic response to HIV-1 infection were developed in a series of stages. The first generation of enzyme immunoassays that were licensed as diagnostic kits and many of those still used today are based on the use of viral lysate antigens derived from viruses that are grown in human T-lymphocyte lines. The presence of traces of host cell components, in which the virions were propagated, in these lysates may lead to false-positive results. The basis for a majority of these assay kits is a solid-phase indirect-antibody detector system (use of microtiter plate wells is most common, although polystyrene or latex beads are used by some manufacturers). The relative amounts of each of the major structural and expressed proteins of HIV-1 may differ significantly between the various commercial preparations. Both the external envelope glycoprotein (i.e., gp120 and its precursor, gp160) and the Gag-derived products (p24 and p18 antigen in particular) are generally well represented in the bound material. Using known positive and negative samples, which are run with each test as controls, a standard curve for the colorimetric
FIGURE 1 Diagrams of HIV-I virion structure (A) and the HIV-1 viral genome (B).

FIGURE 2 Hypothetical time course for the appearance of p24 antigen and HIV-1 antibodies (Ab) in serum during HIV-1 infection.

reaction is generated, and the optical density (OD) values of test samples are compared against this. A cutoff value for the lowest OD still regarded as consistent with a positive determination can be calculated on the basis of a statistical comparison of the intensity of a panel of positive control samples with that of a panel of negative sera. Whereas test sera with OD values well above the cutoff point are recorded as unequivocally positive, the scoring of samples with OD readings skirting the cutoff range can be more problematic. Sera with positive or indeterminate results should be further evaluated by a confirmatory test (Western blotting).

A significant advance in the efforts to optimize the sensitivity and specificity of existing solid-phase immunoassays came via the introduction of viral antigens produced through recombinant DNA technology and/or synthetic antigens to

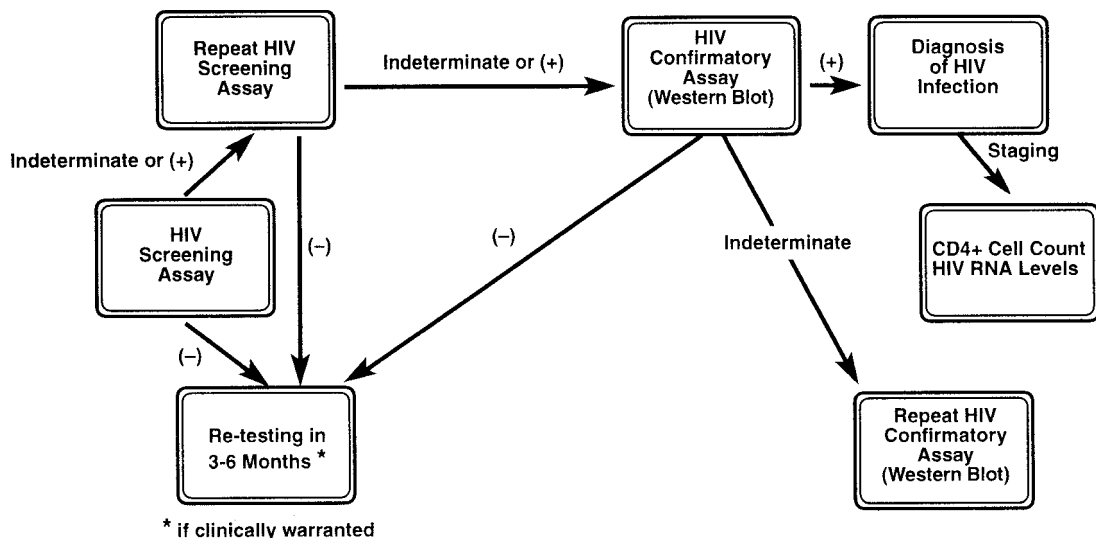
supplement or replace the crude mixtures of proteins derived from lysates. Not only can the recombinant antigens be produced with considerably more purity and in larger amounts than proteins derived from viral lysates, but also they can be bound to solid-phase surfaces with much tighter control over protein ratios and concentrations. These second-generation assays, which were introduced in the late 1980s, combine both HIV-1- and HIV-2-specific antigens. Combination assays allow screening for multiple retroviral agents simultaneously. A potential drawback of such recombinant proteins is that they may afford a more limited repertoire of antigenic sites. This appeared to have clinical significance in the failure of several of the commercial preparations used in Europe and Africa to detect infection with the subtype O strain of HIV-1 (see below). Thus, despite the use of recombinant and synthetic antigens, some of these anti-HIV ELISAs may yield a relatively poor sensitivity and/or specificity when difficult serum samples are tested. The recombinant antigens may also differ somewhat from native proteins by virtue of altered patterns of glycosylation. Nonetheless, the avidity between these antigens and anti-HIV-1 antibodies still appears to be quite high. In addition to diagnostic utility in the screening of individuals and blood products, these newer-generation immunoassays have proven especially valuable in the research setting. Immunoassays enriched in external envelope antigen such as gp160, for


FIGURE 3 Algorithm for the correct use and sequence of serologic testing in the diagnosis of HIV infection.

example, are useful in the detection of anti-envelope anti-body responses in individuals immunized with candidate anti-HIV-1 vaccines, particularly those employing either recombinant gp160 or gp120 protein as an immunogen. These assays have provided significantly enhanced sensitivity to early antibody responses over that afforded by a more conventional ELISA.

Most ELISA (see chapter 39) kits utilize enzyme-tagged anti-human immunoglobulin G (IgG) as the probe to detect the presence of bound HIV-1-specific antibody within a test well. Another refinement that may help to improve the sensitivity of existing immunoassays, leading to earlier detection of seroconversion, involves either the addition or the substitution of enzyme-labeled anti-human IgM for anti-human IgG at this stage of the assay. With some kits, care must be taken to minimize the use of heat-inactivated sera, as a higher rate of false positivity has been reported when sera are treated in this fashion prior to testing.

In the third-generation ELISA, specific recombinant antigens conjugated with enzyme are used to detect the antigen-antibody complex (antigen sandwich ELISA). Briefly, human serum or plasma is diluted in a specimen diluent and incubated with a polystyrene bead coated with recombinant HIV-1 *env* and *gag* and HIV-2 *env* proteins; specific antibody present in the sample reacts with the antigens on the coated bead. After removal of the unbound materials by washing of the bead, specific immunoglobulins bound to the solid phase are detected by incubating the bead-antigen antibody complex with a solution containing HIV-1 *env* and *gag* and HIV-2 *env* recombinant proteins labeled with horseradish peroxidase, which is then detected by incubation with *o*-phenylenediamine substrate solution. This format was developed to allow the simultaneous detection of IgG and IgM (which are present during the early stages of HIV infection) and even IgA antibodies to HIV-1 and HIV-2.

Interpretation of ELISA Results

As noted above, serum from an individual infected with HIV-1 should be positive by commercial HIV-1 ELISA within a few months of exposure. Because these assays are enriched both in Gag-derived proteins and envelope glycoproteins, antigens against which the humoral response in the host is characteristically brisk, the ELISA is usually quite sensitive for detection of early seroconversion. Given the uniformly high sensitivity of most commercial preparations, a negative ELISA reading at an appropriate interval following exposure strongly mitigates against the likelihood of infection in the majority of cases. In general, barring procedural errors in the performance of the assay, there is usually no reason to require that a screening ELISA with a negative result be immediately repeated under these circumstances. A common exception to this guideline is if the interval between testing and presumed exposure is unknown and there is the possibility that the original test was performed relatively early after a possible infection. In this situation, it may be advisable to repeat the test on a new sample within a few months of the initial assay.

Another circumstance under which repeat ELISA testing may be warranted is if the initial results showed borderline reactivity according to the internal OD standards generated within each test kit. OD readings falling slightly under (e.g., less than 1 standard deviation below) the cutoff value may simply reflect high background signals from true seronegative sera or, alternatively, could represent the initial stages of reactivity in serum from an individual undergoing incipient seroconversion. Since the immunoassay is not capable of

differentiating these two possibilities, all of the following have been used as a means of attempting to resolve this diagnostic uncertainty: repeating the test on a fresh specimen, repeating the test with the same sera but using a different commercial assay, and using a combination of these two approaches. In those situations where borderline reactivity persists despite repetitive testing, a minimal recommendation would be to repeat the ELISA within a few weeks. Failure of the OD value to rise substantially over time is suggestive that the low level of reactivity does not represent true infection. In this setting, it is prudent to perform a Western blot assay and a direct measurement of HIV RNA to help rule out an unusual serologic response to true infection.

Highly divergent strains of HIV-1 grouped provisionally as subtype O were isolated from certain patients from Cameroon and other regions of west-central Africa. Initial screening with several of the commercial ELISA kits commonly used in Europe and Africa failed to detect antibody reactivity in some of these patients (29, 36, 39). Those kits employing synthetic peptides or recombinant antigens were particularly prone to this defect. One of the nine tests, which was based on synthetic peptides, was insensitive against serum specimens from all nine infected persons, and four other tests were each unreactive against at least one of four different specimens (29). Assays based on whole-virus lysates performed better. While a retrospective study in the United States did not document any serum samples with peptide reactivity consistent with HIV-1 group O infection (33), manufacturers in the Unites States and abroad have revised their test kit antigens to enhance detection of antibodies against subtype O (3). Whether there might exist other, as-yet-uncharacterized strains of HIV-1 that could also fail to show reactivity on current commercial assays is not known.

Unlike the situation in parts of West Africa and India, documented cases of HIV-2 infection remain generally rare in the United States. The majority of cases identified to date have involved individuals who have imported the infection into this country from elsewhere, e.g., recent immigrants, U.S. servicemen and -women who were deployed overseas, or expatriates with exposure to endemic diseases (e.g., Peace Corps workers). Nonetheless, over the past 1 to 2 years, most major manufacturers of commercial ELISA kits have incorporated HIV-2 antigens in their preparations in order to enhance the sensitivity of these assays for both major types of HIV. It has now become the standard practice in blood banks to screen donated blood samples with one of the new HIV-1-HIV-2 combination ELISAs.

Cautionary Remarks

Since the ELISA was originally designed primarily as a screening assay, it was optimized to have a very high sensitivity and thus will give false-positive reactions. Because of the availability of backup or confirmatory assays to validate positive findings as well as the potentially serious consequences of undiagnosed infections, this reduction in the number of false negatives at the expense of a slightly higher rate of false positives is a reasonable trade-off. Thus, the ELISA, while an excellent test for screening, should not be used for making a diagnosis of HIV-1 infection without a positive confirmatory test. In large-scale testing of individuals with high-risk behavior for HIV-1 acquisition, most of the commercially marketed ELISA preparations have been shown to have a sensitivity of at least 99.5% and a specificity of more than 99.8%. However, the positive predictive value of the standard HIV-1 ELISA may fluctuate widely depending upon the population being screened. In an investigation

to study the sensitivity and specificity of 13 current anti-HIV-1/HIV-2 enzyme immunoassays for the detection of anti-HIV antibodies in human serum or plasma, a panel of 454 well-characterized specimens was tested. Observed sensitivities ranged from 96.9 to 100%, and observed specificities ranged from 89.9 to 100% (30). The false-positivity rate in low-risk populations is substantially higher than that in high-risk populations, an observation that must be taken into account in the interpretation of preliminary test results. In a large study by the American Red Cross of a low-risk pool of volunteer blood donors, only 13% of those individuals with a repeatedly reactive HIV-1 ELISA were confirmed to be HIV-1 infected on the basis of a confirmatory Western blot (21). Such data have obvious implications for wide-scale screening of donated blood products, for which the majority of positive ELISA reactions may be expected to be false-positive readings. In contrast, the rate of false-negative results with conventional ELISAs remains quite low, with such results generally occurring no more often than once in every 40,000 samples (43). As continued refinements in solid-phase technology lead to development of even more sensitive probes, this rate should continue to drop further.

As with any assay capable of processing large numbers of test sera at any one time, ELISA methodology is subject to a number of technical drawbacks that may diminish the significance of any single positive result. These range from procedural errors in the handling of samples, such as mislabeling of specimens, to deficiencies in the manual or automated performance of sample processing, such as well-to-well carryover during pipetting and resultant contamination of neighboring wells. A false-positive result can also be caused by inadequate washing of the specimen or incorrect dilution of the sample or of any one of the assay reagents. Usually such false-positive reactions are corrected either by repeating the assay or by testing with another manufacturer's ELISA kit. Apart from these purely technical considerations, the causes of false-positive ELISA results may be both varied and obscure. In some cases, however, certain common elements that may provide an explanation for these findings have been identified. Chief among these is the presence of cross-reactive antibodies against certain common human leukocyte antigens (HLA-DR and other class II antigens in particular) present in some patients' sera as a result of exposure to fetal leukocytes during pregnancy or by blood transfusion. These antibodies presumably recognize and bind to cellular contaminants that are present in the viral lysates used in these kits. The use of the CEM cell line to propagate virus in tissue culture has been reported to reduce or eliminate this particular cause of cross-reactivity. Newer test kits incorporate the use of recombinant or synthetic peptide antigens and offer improvements in test performance (47).

Other causes of false-positive ELISA readings that have been identified include the presence of autoreactive antibodies (e.g., antinuclear or antimitochondrial antibodies), heat inactivation of sera prior to testing, repetitive freeze-thaw cycles prior to assaying, severe hepatic disease, passive immunoglobulin administration (isolated cases of transient seroconversion have been reported for patients receiving passive IgG injections), recent exposure to certain vaccine preparations (e.g., influenza vaccine), renal transplantation, Stevens-Johnson syndrome, alcoholic hepatitis, history of multiple pregnancies, Epstein-Barr virus infections, and certain malignancies (12). The commercial ELISA cannot distinguish positive results due to antibody response to candidate HIV vaccines from those due to seroconversion as a result of HIV infection. Cross-reactivity of sera from patients with HIV-2 also occurs. In contrast, cross-reactivity in the HIV-1 ELISA generally does not occur with sera from patients with HTLV-1 infection. The causes of false-negative ELISA findings are also varied and, in addition to improper handling of reagents in individual test kits, include performance of the assay too early in the period after HIV-1 exposure (i.e., prior to seroconversion, the window period), immunosuppressive therapy, and replacement transfusion, as well as conditions that cause B-cell dysfunction and defective antibody synthesis, such as severe hypogammaglobulinemia. Powder from disposable gloves worn by technicians performing the test has been shown to absorb macromolecules such as immunoglobulins that could cause an otherwise positive sample to give a negative reaction (12).

Rapid Assays

The technical complexity and expense associated with some of the more conventional anti-HIV-1 antibody detection methods fostered a search for simplified, less costly methods of serologic screening, particularly those that could be more suitable for use under field conditions in developing nations or medically disadvantaged regions where HIV infection is endemic. These tests do not require any specialized instrumentation and are developed as a cost-effective alternative to conventional ELISA and Western blot tests. These newer tests may also offer some practical advantages in developed nations as well by providing results in a very short period, thus increasing the likelihood that patients will wait to receive their results. Some of these tests are extremely rapid (ranging from 2 to 10 min), easy to perform, stable at room temperature, and with sensitivities comparable to those of commercially available ELISAs (4, 5). Rapid and sensitive assays for HIV may also prove to be useful in organ donation centers, emergency departments, and physicians' offices. In general, tests that work on whole blood will also work on serum or plasma, but approval from the FDA requires medium-specific proof of efficacy.

SUDS HIV-1 Test

The SUDS HIV-1 test (Murex Inc., Norcross, Ga.), the first rapid test to obtain FDA approval, utilizes a microfiltration enzyme immunoassay procedure. The solid-phase capture reagent is a mixture of latex particles coated with HIV-1 p24 and gp4l synthetic peptides. The test device is a small plastic cartridge designed to filter, concentrate, and adsorb all liquid reagents added during the test, including the specimen. The test is performed at room temperature. Human serum or plasma is incubated in a sample cup with reaction diluent and the capture reagent. The mixture is transferred into the test cartridge, where the latex particles coated with antigens and any bound HIV-1 antibodies are trapped by a fiberglass filter. Following the addition of a wash reagent to remove unbound materials, an enzyme-labeled anti-human immunoglobulin is added to detect the presence of bound antibodies. Following a second incubation and washing, the substrate solution is added to develop the color reaction. A sample is considered reactive if any blue color is observed in the center circle in the bottom of the cartridge. A portion of the fiberglass filter that does not contain the capture reagent should remain white to indicate that the wash steps were performed correctly. The whole procedure takes approximately 10 min. This test is shown to have 99.9% sensitivity and 99.6% specificity. The requirement for reagent refrigeration, multiple procedural steps, and lack of an internal control make the SUDS test less well suited for point-of-care testing.

OraQuick Rapid HIV-1/2 Antibody Test

The OraQuick Rapid HIV-1/2 antibody test (OraSure Technologies, Inc., Bethlehem, Pa.) has FDA approval for the detection of antibodies to HIV-1 and HIV-2 in finger stick whole-blood and venipuncture samples. It is a qualitative immunoassay composed of a single-use test device and a single-use vial containing a premeasured amount of a buffered developer solution. The test utilizes a lateral-flow immunoassay procedure, and the plastic housing of the device holds an assay test strip that provides the matrix for the immunochromatography of the specimen and the platform for indication of the test result. The assay contains synthetic peptides representing the HIV envelope region and a goat anti-human IgG test assay control immobilized onto a nitrocellulose membrane in the test (T) zone and the control (C) zone, respectively. A finger stick whole-blood or venipuncture whole-blood specimen is collected and transferred to the vial of developer solution, followed by the insertion of the test device. The developer solution facilitates the flow of the specimen into the device and onto the test strip. As the diluted specimen flows through the device, it rehydrates the protein A colloidal gold colorimetric reagent contained in the device. As the specimen migrates up the strip, it encounters the T zone. A positive result is indicated by a reddish purple line in the T zone. The intensity of the line color is not directly proportional to the amount of antibody present in the specimen. Further up the assay strip, the sample encounters the C zone. This built-in procedural control validates that a specimen was added to the vial and that the fluid has migrated adequately through the test device. A reddish purplish line will appear in the C zone if the test was performed properly, regardless of the result in the T zone. The test must be interpreted at least 20 min but not more than 40 min after the test device was placed in the solution containing the specimen. This test is shown to have 99.6% sensitivity and 100% specificity.

Reveal Rapid HIV-1 Test

The Reveal Rapid HIV-1 antibody test (MedMira Laboratories, Halifax, Nova Scotia, Canada) is an FDA-approved, qualitative immunoassay to detect antibodies to HIV-1 in serum or plasma specimens. The test is composed of a single-use cartridge containing an immunoreactive test membrane coated with synthetic peptides corresponding to conserved regions of HIV structural proteins. This functions to capture anti-HIV-1 antibodies present in serum or plasma when a drop of specimen is added. Following the application of the sample, the membrane is washed to remove any nonspecifically bound antibodies. Captured anti-HIV-1 antibodies are visualized through a reaction with a protein A-colloidal gold conjugate, followed by a second washing step to clarify the test result. The test results must be read immediately following the second washing step. A sample is considered reactive when a distinctive red dot is produced on the test membrane, regardless of intensity. This test is shown to have 99.8% sensitivity and 99.1% specificity.

Uni-Gold Recombigen HIV Test

The Uni-Gold Recombigen HIV (Trinity Biotech PLC, Bray, County Wicklow, Ireland) is an immunochromatographic rapid test that has FDA approval for the detection of antibodies to HIV-1 in plasma, serum, and whole blood (venipuncture). The test employs genetically engineered recombinant proteins representing the immunodominant regions of the envelope proteins of HIV-1. The recombinant proteins are immobilized at the test region of a nitrocellulose strip. These proteins are also linked to colloidal gold and impregnated below the test region of the device. A narrow band of the nitrocellulose membrane is also sensitized as a control region for procedure performance. One drop of sample is added to the sample port using a pipette provided with the kit, followed by the addition of wash solution. The test must be read after 10 min of incubation. A sample is considered to be reactive if a visible pink-red band forms in the test region of the device. The control line should always appear as a pink-red line in the control region of the device to indicate that the test device is functioning properly. This test is shown to have 100% sensitivity and 99.7% specificity.

Abbott Determine HIV-1/2 Test

The Abbott Determine HIV-1/2 (Abbott Laboratories, Abbott Park, Ill.) is an immunochromatographic test for the qualitative detection of antibodies to HIV in serum, plasma, and whole blood. While this test is not approved by the FDA, it is widely employed worldwide as the rapid test of choice. Fifty microliters of sample is added to the sample pad of the test strip. If the sample is whole blood (from either venipuncture or finger stick), a drop of chase buffer must be added to the sample pad. As the sample migrates through the conjugate pad, it reconstitutes and mixes with the selenium colloidal-antigen conjugate. This mixture continues to migrate through the solid phase to the immobilized recombinant antigens and synthetic peptides in the patient window site. A sample is considered reactive if a red line forms in the patient window. For the test to be considered valid, a red line must also show up in the control window. This test is shown to have 100% sensitivity and 99.8% specificity.

Cautionary Remarks

All reactive rapid HIV test results require confirmatory testing. CDC protocols recommend that (i) either a Western blot or indirect immunofluorescence assay (IFA) be performed even if a subsequent ELISA screening test is negative, and (ii) persons with negative or indeterminate confirmatory test results receive follow-up testing 4 weeks after the initial positive rapid test result (6).

Confirmatory Tests

HIV-1 Western Blot

In low-risk populations, the frequency of false-positive ELISA readings is relatively high. All reactive ELISA samples must be tested by one of the confirmatory assays to determine the actual presence of specific anti-HIV antibodies. Among several confirmatory assays, HIV-1-specific (or HIV-2-specific) Western blotting is the most popular test in the United States and elsewhere. While the algorithm shown in Fig. 3 should be followed on samples from all individuals, it is particularly true for individuals without risk factors for HIV-1 or HIV-2 exposure, for whom the majority of positive ELISA results will be false positives. A positive Western blotting result not only confirms the presence of antibodies reactive with HIV in the infected individual but also permits identification of the specific viral components to which that individual has raised a detectable humoral response. By performing serial dilutions of the test sample, it can also be used to grade the intensity of the individual components of that response qualitatively and, in some cases, quantitatively over time.

Use of the commercially available Western blot kits requires a minimal amount of sample handling, and they can now be completed within a few hours. By comparison with
FIGURE 4 Illustration of various patterns of positive HIV-1 Western blots, showing antibody banding at the major viral proteins that can be identified using this technique. For comparison, a negative Western blot and two examples of indeterminate Western blots are also shown.

control sera as well as with internal reference standards usually provided with each kit, results can be scored visually in terms of the pattern and number of antibody bands present. Recognized viral antigens produce bands at p18, p24, p31, gp41, p51, p55, p66, gp120, and gp160 (numbers refer to apparent molecular masses, in kilodaltons). Alternatively, densitometry techniques permit quantitation of bands. Such quantitation is useful in evaluating the humoral response to candidate AIDS vaccines in noninfected seronegative recipients following primary and booster immunizations.

When used to confirm seroreactivity in a patient with presumed HIV infection, Western blotting will generally reveal variable degrees of antibody reactivity with *env, gag,* and *pol* gene products of HIV-1 (Fig. 4). The specific pattern of banding may vary from individual to individual, and the intensity may fluctuate according to both the relative amounts of specific anti-HIV-1 antibody circulating at any given time and the particular commercial preparation being used. As noted previously, most commercial Western blot preparations are especially sensitive for the detection of anti-p24 antibody, and its appearance on immunoblotting may occur relatively early in the period after exposure, occasionally serving to herald the process of seroconversion. The appearance of detectable levels of antibody against *pol* and *env* gene products may be delayed until somewhat later, although this lag period is usually sufficiently brief such that its impact on serodiagnosis is minor. Antibodies against other gene products of HIV-1, such as *nef* or other regulatory elements, are generally not detected by conventional immunoblotting techniques.

Interpretation of Western Blotting Results

Since official FDA licensure of the first commercial Western blot preparation in April 1987, a number of different manufacturers' preparations have been introduced on the market. However, the correct interpretation or scoring of a Western blotting result for HIV has not been universally

established. Even today, not all laboratories agree upon a common algorithm for the grading of immunoblot banding patterns. Occasionally this has led to some confusion in the reporting of test results, particularly when separate laboratories using different criteria have been asked to perform confirmatory assays on the same specimens.

Depending upon the rigor of the definition applied, it is generally agreed that a negative Western blotting result means that either (i) no bands are present at any location or (ii) at least no bands corresponding to the molecular weights of known viral proteins can be detected. The presence of bands at locations not corresponding to known viral antigens is a fairly common finding and is presumed to reflect contaminants within the preparation to which some degree of antibody binding occurs. The molecular weights of these so-called aberrant bands may vary from manufacturer to manufacturer and even, occasionally, from lot to lot in kits produced by the same manufacturer.

Cautionary Remarks

The definition of what should constitute a positive Western blotting result has been considerably more difficult to codify, particularly since there has been some disagreement among investigators as to whether appropriate stringency of the definition should require the presence of antibody against any two versus all three of the major viral gene products. Antibody against a protein (or proteins) from all three groups has always been accepted as unequivocal evidence of a positive finding, and the Biotech-DuPont kit was licensed with the manufacturer's recommendation that reactivity with all three gene products be present in order for a positive determination to be made. This was also the position adopted by the American Red Cross at that time. Since then, however, convincing evidence has been presented that antibody against only two of the three major groups may also be equally diagnostic of true seroreactivity to HIV-1. In 1988, for example, the Consortium for Retrovirology Serology Standardization recommended that positive scoring of a Western blot be made on the basis of the following pattern: anti-p24 or anti-p31 occurring in the presence of either anti-gp41 or anti-gp160/anti-gp120. Other groups, in contrast, suggested that the presence or absence of antibody against *pol* gene products such as p31 not be included within this definition.

While this controversy still continues to some degree today, the majority of laboratories have accepted the 1989 recommendations of the Association of State and Territorial Public Health Laboratory Directors and the CDC. According to these criteria, a Western blot can be considered positive if it contains two of the three key bands considered by the Association to be of diagnostic significance, namely, p24, gp41, and gp120/gp160.

By definition, Western blotting results that cannot be classified as either negative or positive are grouped into the category known as indeterminate findings. Bands present may correspond to the molecular weights of known HIV-1 proteins as well as to those of contaminating cellular proteins on the nitrocellulose paper. Reactivity at the p24 and/or p55 band is particularly common in Western blots falling into the indeterminate category, regardless of whether one is surveying patients whose histories might classify them as being at high or low risk for HIV-1 infection. However, the vast majority of indeterminate Western blotting results occur for patients with no other evidence of HIV-1 infection, and it is presumed that this limited antibody recognition represents reactivity by antibodies with various contaminants of the

immunoblot preparation. For example, reactivity with class I and II HLA antigens, present as cellular contaminants within the viral lysate, appears to account for a significant percentage of false-positive banding. Other causes of false-positive or indeterminate Western blotting results for HIV include the presence of antibodies to mitochondrial, nuclear, and T-cell leukocyte antigens; anticarbohydrate antibodies; globulins produced during polyclonal gammopathy; a high concentration of bilirubin in serum; and passively acquired antibodies (12). As in ELISA, some of the anti-HIV-1 subtype O specimens fail to show the complete array of HIV-1 bands and may be interpreted as indeterminate or even negative when tested using HIV-1 Western blot kits (20). Immunoblot assays utilizing recombinant-derived viral antigens or synthetic peptides corresponding to the conserved regions among different subtypes rather than viral lysates may reduce the incidence of indeterminate reactivity, although this remains to be confirmed in large-scale testing.

If clinically warranted (e.g., in the setting of a recent history of possible HIV exposure), the finding of an indeterminate Western blot pattern in the presence of a positive HIV-1 ELISA should prompt one first to repeat the Western blotting, using either the same or, if available, a fresh serum specimen. If the repeat assay result is still indeterminate, one should then consider retesting the patient within a few weeks, inasmuch as it is possible that the patient was first tested early in the process of seroconversion and that, upon serial examination, follow-up studies may reveal the full pattern of antibody reactivity. As several studies have confirmed, however, the likelihood that an indeterminate Western blotting finding represents incipient seroconversion remains low for most patients. Rather, upon serial testing, the vast majority of indeterminate findings will remain indeterminate (with either identical or different patterns of banding), revert to full seronegativity, or vacillate between the two categories. Thus, as with the ELISA, failure of the Western blot to evolve from an indeterminate to a positive test within a few months strongly mitigates against the possibility that the patient is HIV infected. Nonetheless, plagued by the anxiety generated during this period of diagnostic uncertainty, many physicians and patients understandably will opt to consult other diagnostic procedures, such as the p24 antigen capture or HIV RNA and proviral DNA assays, in an attempt to rule out more conclusively the possibility of early HIV infection.

It is particularly important to note that Western blotting is an inappropriate initial screening test for HIV infection. Among homosexual or bisexual men testing negative for HIV-1 both by ELISA and by PCR, it has been found that 20 to 30% may still show one or more bands on Western blotting. Moreover, during evaluations performed every 1 to 3 months over the course of 1 year or more, 70% of an HIV-1 ELISA-negative, PCR-negative cohort of homosexual men with an initial indeterminate Western blotting result continued to show one or more bands on serial immunoblots (13). Other studies using low-risk populations have noted similar findings. Given this high frequency of indeterminate reactivity—the overwhelming preponderance of which will be nonspecific binding—Western blotting is not appropriate for use as a primary screening tool in the population at large. Rather, its strength is as a confirmatory assay in the setting of a positive or indeterminate HIV-1 ELISA or other initial screening test result.

As mentioned above, the majority of commercial ELISA test kits in widespread use in the United States now react with antibodies against either HIV-1 or HIV-2. Given the preponderance of infection with HIV-1 in this country, a repeatedly reactive ELISA should generally first prompt use of a specific HIV-1 Western blot test as a confirmatory assay. If HIV-2 infection is suspected on epidemiologic grounds or the HIV-1 Western blot shows an atypical pattern of banding suggestive of HIV-2 cross-reactivity, then the next level of evaluation should be to perform an HIV-2 ELISA, and if the result is positive or indeterminate, to go on to HIV-2 immunoblotting. Currently, there are no HIV-2 immunoblot kits licensed by the FDA. Nonetheless, at least one company (Genelabs Diagnostics, Singapore, Singapore) manufactures a kit that is commercially available for research purposes. A positive result for HIV-2 is scored when bands are seen at *env* proteins (gp125 or gp36) and either *gag* protein (p26) or *pol* proteins (p68 or p31 or p56 or p53).

While estimates for the sensitivity and specificity of the HIV-1 Western blot test vary somewhat depending upon the manufacturer, comparative surveys have shown that most preparations afford a sensitivity of at least 96%. When the Western blot is used properly as a confirmatory test in sequence with an initial positive screening assay, the combination of these two tests should have a positive predictive value greater than 99% for both low- and high-risk populations.

IFA

IFA is performed in some laboratories for screening and/or as a substitute for conventional immunoblotting as a confirmatory assay. IFA is rapid and relatively simple to perform. However, IFA requires the use of an expensive fluorescence microscope. The assay uses immortalized human T cells that express HIV-1 antigens on their surface. The cells are fixed to the surface of an IFA glass slide with methanol-acetic acid. Fixed, uninfected T cells are provided as a control. To perform the assay, a serum or plasma specimen is diluted, and aliquots are placed in the infected and uninfected cell wells of the IFA slide and incubated in a humidified chamber for a defined period of time (Fig. 5). If HIV-1 antibodies are present in the sample, they will bind to HIV-1 viral antigens present on the infected cell surface. Unbound material is removed by aspiration and washing. Antibody to human immunoglobulin conjugated with a fluorescent dye such as fluorescein isothiocyanate is added to the infected and uninfected cell wells of the IFA slide and again incubated as described above. Unbound material is removed by aspiration and washing. A glass coverslip is mounted to the IFA slide, and the slide is viewed under a microscope with UV light. If antibodies to HIV-1 are present in the specimen, a characteristic pattern of fluorescence will become visible under UV light. The interpretation of this fluorescence is evaluated by comparing and differentiating the pattern and intensity of fluorescence in the uninfected and infected cell wells for
FIGURE 5 The principle of the IFA test. FITC, fluorescein isothiocyanate; Ab, antibody.

each sample. With use of the proper technique, background staining should be minimal. As with any of the standard antibody detection methods, proper quality control requires that serum from a known seropositive individual also be included as a positive control.

In addition to the relative ease with which it can be performed, the IFA offers the advantage of generally turning positive earlier in the course of infection than either a conventional ELISA or Western blot test. Time to development of a positive IFA result after an acute seroconversion to HIV-1 can be further reduced by substituting fluorescein isothiocyanate-labeled anti-human IgM as the developing conjugate. Most authors agree that, in clinical use, the sensitivity and specificity of the IFA are equivalent to those of Western blotting (22), although occasionally there can be some variability in appropriate scoring of samples due to inexperience with the technique. Manufacturers of a commercially available IFA (Fluorognost HIV-1 IFA; Waldheim Pharmazeutika, Vienna, Austria) estimate a sensitivity of 99.7%. IFA has also been employed for screening and confirming HIV-2 infections and to discriminate between HIV-1 and HIV-2 infections. It has been shown to be as sensitive as the ELISA in screening, and it is superior to Western blotting in discriminating HIV-1 and HIV-2 infection (27).

A sample result is considered indeterminate when fluorescence is observed in both infected and uninfected cells. Indeterminate IFA results are expected to occur with a slightly higher frequency in specimens from patients with certain autoimmune diseases (such as systemic lupus erythematosus) and certain viral infections such as hepatitis, cytomegalovirus, and Epstein Barr virus. Hyperlipemic or extremely icteric specimens and samples heavily contaminated with bacteria may show atypical background fluorescence.

Cautionary Remarks

The intensity of the fluorescence observed in the IFA does not bear a strict correlation to antibody titer. One of the limitations of the IFA in the research setting is that, unlike Western blotting, it does not permit precise delineation of specific patterns of antibody reactivity. The assay requires highly skilled, well-trained laboratory personnel to read and interpret the results. In addition, the test becomes cumbersome to perform if many samples are tested at one time.

RIPA

RIPA was first used as an alternative test to detect HIV antibodies in the mid-1980s and is still reserved as a research tool, since it involves a somewhat rigorous procedure requiring the use of radioactively labeled antigens. RIPA has the advantage of using minimally denatured antigens, provides appropriate conditions for identification of the large viral glycoproteins, and is sometimes preferred as a confirmatory assay over conventional Western blotting. However, its use is largely restricted to laboratories that have the facilities and expertise to propagate HIV-1 in continuous cell culture (9, 34).

Cautionary Remarks

Several aspects of the standard RIPA preclude its use by many clinical laboratories. The need to maintain viral stocks and active cell culture lines, the requirement for storing and handling of radioactive tracer materials, the time and technical expertise required to perform the assay properly, and the overall expense of this test have all contributed to making the RIPA substantially less attractive than Western blotting for routine use. For this reason, most assays of this type are performed in research laboratories where the skills and materials required are more readily accessible. Nonetheless, occasionally there are circumstances in which the clinician may find the RIPA helpful, such as for detecting low levels of antibody positivity or aiding in the evaluation of individuals with indeterminate Western blot results.

Line Immunoassays

The line immunoassay, a variant of the Western blot test, involves application of recombinant proteins or synthetic peptides in a band pattern on plastic-backed nitrocellulose strips and testing in a manner similar to that for the Western blot assay. In this assay, optimal concentrations of antigens can be applied, enabling easier reading and interpretation. It also eliminates or minimizes the problem of indeterminate or atypical bands that are a problem in conventional Western blotting. Antigens from HIV-1 (including group O) and HIV-2 can also be combined and added for use as a combination assay (17, 26, 46); two such kits are the RIBA HIV-1/ HIV-2 SIA (Chiron Corporation, Emeryville, Calif.) and the INNO-LIA HIV Confirmation (Innogenetics, Ghent, Belgium).

Home Test Kit

Using the FDA-approved home test kit Home Access Express Test (marketed by Home Access Health Corp., Hoffman Estates, Ill.), a person begins the testing process by reading a pretest counseling booklet about HIV and AIDS. Using a lancet, the person takes a finger stick blood sample and places it on a designated area of a test card precoded with a unique identification number. The test card is mailed in a protective envelope to a certified laboratory for testing. The results can be obtained over the telephone when the user keys in a special personal identification number.

Urine and Saliva Tests

Although difficult to collect and process, serum or plasma is regularly used for HIV antibody testing. Assays that use other body fluids such as saliva, oral mucosal transudates, and urine have recently been developed. Use of these alternate body fluids has obvious advantages: collection of these fluids is easy and less expensive and requires no invasive procedures. In addition, since these body fluids contain very low concentrations of virus, they are less biohazardous than serum. HIV antibodies are known to be present in body fluids from infected individuals and can be detected with routine screening and confirmatory tests (2, 10, 14, 45). The sensitivity and specificity of different assays for saliva samples are in the range of 97.3 to 100% and 99.4 to 100%, respectively (18, 24, 45). Since secretory IgA and IgG isotypes of antibodies are found in saliva, conjugates incorporating anti-human IgA and anti-human IgG enhance their detection. Test kits for detecting HIV-1 antibodies in urine and oral fluid have been recently approved by the FDA. The tests to detect HIV antibodies in urine (Calypte HIV-1 Urine EIA and the Cambridge Biotech HIV-1 Urine Western Blot) are marketed by Calypte/Cambridge Biomedical Corporation, Berkeley, Calif. Since neither urine test is as accurate as blood tests, they were approved as supplemental diagnostic tests but not as substitutes for the standard blood test to screen donors at blood banks. The two procedures in combination do, however, provide a full algorithm for HIV-1 antibody testing using urine only. The FDA has recently approved the use of the OraQuick Rapid HIV-1/2 antibody assay (OraSure Technologies, Inc.) as a Clinical Laboratory Improvement Amendments-waived test for the

detection of antibodies to HIV-1 in saliva samples. To perform the test, the person being tested for HIV-1 takes the device, which has an exposed absorbent pad at one end, and places the pad above the teeth and against the outer gum. The person then gently swabs completely around the outer gums, both upper and lower, one time around. The tester then takes the device and completes the assay in the same manner as if using a blood sample (see above). In a recent multicenter clinical trial, blood and saliva samples were collected from 3,750 subjects. The results of this study showed that saliva testing is a highly accurate alternative to blood testing, providing correct results in 99.97% of cases.

VIRAL ANTIGEN DETECTION ASSAYS

The major core protein of HIV-1 is p24 (Fig. 1). The assay to detect the p24 antigen has been used for many years in the prognostic staging and management of infected individuals (32) and is licensed in the United States as part of routine blood donor screening. Most commercial HIV-1 antigen capture assays are solid-phase techniques designed to provide a quantitative measure of the level of viral p24 antigen present within serum or other body fluids. Viral p24 protein circulates in the bloodstream of an infected individual during the early viremic phase prior to seroconversion and again during advanced stages of infection (Fig. 2). Failure to detect p24 antigen between seroconversion and advanced infection has been ascribed to the formation of immune complexes, which lowers the amount of free antigen. Earlier generations of the conventional p24 antigen capture assay detected only the free p24 antigen. Recent modified versions detect both bound and free antigen.

While the levels of p24 antigen in serum may vary from individual to individual, it is known that in many patients this antigen can be detected relatively early in the period after exposure to HIV-1 and will often precede the process of seroconversion by several weeks (19, 40). This rise in measurable p24 antigen level presumably correlates with the burst in viral replication, detectable by other methods such as measurements of HIV-1 RNA or plasma viremia, that has been shown to occur shortly after primary infection. p24 antigen usually drops below the threshold of detection by conventional methods, as anti-p24 antibody is formed during seroconversion and may remain undetectable during the subsequent years of asymptomatic infection. Thereafter, depending upon an individual's immune status as reflected in the dynamic equilibrium with levels of anti-p24 antibody, it may again become detectable as the infection proceeds to a more advanced stage.

Because only 20 to 30% of individuals with asymptomatic HIV-1 infection will have levels of p24 antigen in serum detectable by standard methodology, this assay compares unfavorably to either the conventional ELISA as a diagnostic tool for HIV-1 infection or the HIV-1 RNA assays for monitoring the levels of viral activity within the known infected host. Its main use today is as a routine diagnostic tool for HIV infection in blood donors who have not yet developed antibodies. It has been chosen for this role because of its ease of performance and low cost. It is estimated that somewhere between 6 and 20 HIV-1-infected donors will be eliminated from the donor pool each year as a result of routine p24 antigen testing. With regard to its role as an indicator of viral replication, it is well established that conventional antiretroviral therapy with a nucleoside analog such as zidovudine can at least temporarily reduce the serum p24 antigen level in antigenemic patients, presumably reflecting an overall inhibition of the level of viral activity within the treated patient. On the basis of these data, the p24 antigen test was used as a surrogate marker of antiviral efficacy in a number of clinical trials of antiretroviral agents.

With respect to its role in prognostic stratification, it has been shown that patients with detectable p24 antigen in serum as a group may progress more rapidly to the development of AIDS-defining illnesses than a similar group of patients lacking this serum marker (28, 35). In a 1988 study of a cohort from San Francisco, Calif., it was found that over a 3-year period, p24-antigenemic patients developed AIDS-defining conditions at a rate that was more than three times higher than that within a similar cohort of p24 antigen-negative individuals (31).

The serum p24 antigen capture assay is a solid-phase immunoassay that has been available since 1986; it is commercially marketed by several different manufacturers, including Abbott Laboratories and Coulter Corporation. While specific reagents differ among various manufacturers, the assay is generally performed as follows. Test or control sera are allowed to react with monoclonal or polyclonal anti-HIV-1 antibody (reactive to p24 antigen) bound either to the bottom of a microtiter well or used to coat polystyrene beads. After appropriate incubation and washing, the well or beads are incubated with goat or rabbit anti-HIV-1 p24 antibody which will, in turn, bind in proportionate amounts to any p24 antigen captured on the solid phase. Washing is followed by the addition of an enzyme-tagged anti-goat (or anti-rabbit) immunoglobulin that, in the presence of an appropriate substrate, will produce a colorimetric reaction whose intensity can be measured spectrophotometrically. Using dilutions of a serum with a known concentration of p24 antigen as a positive control, one can generate a standard curve of OD versus concentration, against which the absorbance values of test sera can be compared quantitatively. Most commercially available kits define their lower limits of p24 antigen detection as being in the range of 50 pg/ml, although the actual linear portion of the standard curve will often permit reliable measurements as low as 10 to 20 pg/ml. Of note, as a confirmation of the specificity of the assay, positive test sera can also be retested in the presence of human sera containing a known high concentration of anti-HIV-1 antibody. With most kits, a reduction in the test serum's OD of 50% or greater by this neutralization procedure is confirmatory of the specificity of the p24 measurement.

As mentioned, a major limitation of the overall utility of the earlier forms of the p24 antigen capture assay was that they were capable of detecting only free p24 antigen and not antigen complexed with anti-p24 antibody. A significant improvement in the sensitivity of this test was achieved through incorporation of methods to dissociate such immune complexes prior to assay. In particular, it was found that heating (37) or lowering the pH (23, 32, 42) of samples markedly increased the level of p24 antigen detectable in sera from both asymptomatic and advanced HIV-1-infected patients. One method that has been developed involves the addition of dilute hydrochloric acid to samples and subsequent neutralization with alkali (32). An alternative method involves acidification with a mild organic acid such as glycine (pH 1.85) followed by neutralization with alkaline Tris buffer (pH 8.6) (23, 42). It offers the potential advantage of being less likely to denature epitopes on p24 antigen prior to measurement. In one of these studies (42), a 300% increase in the number of p24-reactive samples and a 3- to 12-fold increase in the quantity of antigen were observed when samples were pretreated with 1.5 M glycine buffer.

COMBINATION ASSAYS

Fourth-generation assays, which allow the simultaneous detection of HIV antigen and antibody, have been recently developed. Such tests include the Enzymun-Test HIV Combi manufactured by Boehringer Mannheim (Penzberg, Germany), the VIDAS HIV DUO manufactured by bioMerieux (Marcy l'Etoile, France), and the AxSYM HIV Ag-Ab Combo manufactured by Abbott Laboratories (Abbott Diagnostika GmbH & Co. KG, Wiesbaden, Germany) (38, 44). Fourth-generation assays may permit an earlier diagnosis of HIV infection than third-generation assays through the detection of p24 antigen.

HIV Combi is an enzyme immunoassay for the simultaneous detection of HIV antigen and IgG and IgM antibodies to HIV-1 (including subtype O) and HIV-2. In the first reaction step, the sample is incubated with biotinylated and digoxigenin-labeled HIV antigens (synthetic peptides gp41 and gp36 and recombinant reverse transcriptase) and biotinylated and digoxigenin-labeled monoclonal anti-p24 antibody. After washing, *o*-phenylenediamine-conjugated antidigoxigenin antibody is added. After a final wash, HIV antigen and/or antibody is detected by the addition of diammonium 2,2'-azinobis(3-ethylbenzthiazoline-6-sulfonate) (ABTS) substrate. The minimum volume of sample required is 400 μl, and the total test time is 4 h. All of the assay steps are performed automatically by the Enzymun system (ES 300 or ES 600/700). At the end of the assay, results are automatically calculated by the Enzymun system in relation to the cutoff (0.14 × extinction of positive calibrator + 1.0 × extinction of the negative calibrator). Samples with an index value (extinction of the sample/cutoff) of >1 are considered positive.

VIDAS HIV DUO is an IFA for the simultaneous detection of p24 antigen and IgG antibodies to HIV-1 (including subtype O) and HIV-2. The first reaction step, which is for the detection of anti-HIV-1 and anti-HIV-2 IgG, is performed in the lower part of a solid phase receptacle (SPR), which is coated with synthetic peptides (gp41 and gp36). Anti-human IgG labeled with alkaline phosphatase is used as the conjugate. The second reaction, for the detection of p24, is performed in the upper part of the SPR, which is coated with monoclonal anti-p24 antibodies. During incubation, p24 is released through viral lysis and binds to the monoclonal antibodies on the SPR and also to the biotinylated anti-p24 antibodies. The antibody-antigen-antibody complex binds to alkaline phosphatase-labeled streptavidin. The final detection step is the same for both reactions. The substrate (4-methylumbelliferyl phosphate) is catalyzed by the conjugate into a fluorescent product (4-methylumbelliferone). A sample volume of 200 μl is required, and the total test time is 1.5 h. All of the assay steps are performed automatically in the VIDAS instrument. The test value is calculated by dividing the patient reference value by the reference value of the standard. A test value of >0.35 is considered positive.

AxSYM Combo is a three-step process that combines microparticle, fluorescence, and enzyme-linked immunoassay technologies in an automated, random-access system. After specimens are loaded into the instrument, AxSYM mixes serum or plasma specimens with a detergent-enriched, buffered specimen diluent formulated to disrupt HIV for optimal p24 exposure and to decrease or eliminate nonspecific or interfering reactions of undesirable plasma or serum components with the microparticles. In the second step, antibody (anti-gp41) and/or antigen (p24 core antigen) sandwiches are formed by automated addition of biotinylated

probes (biotinylated recombinant transmembrane proteins, biotinylated peptides derived from the immunodominant regions of gp41, and biotinylated monoclonal [anti-p24] antibodies) to microparticle-bound immune complexes. In the third step, biotinylated probes bound to the solid phase via sandwich formation are reacted with an antibiotin rabbit antibody complexed with alkaline phosphatase (conjugate) presented in a diluent formulated to enhance the formation of biotin-antibiotin immune complexes and to limit nonspecific binding of the conjugate. AxSYM detects the formation of antibody (anti-gp41) and antigen (p24 core protein) immune complexes by automated addition of 4-methylumbelliferyl phosphate, which is a fluorescent substrate for alkaline phosphatase. As 4-methylumbelliferyl phosphate is converted to methylumbelliferone by alkaline phosphatase, AxSYM detects and quantifies the fluorescent signal. The signal is proportional to the amount of antibody (anti-gp41) or antigen (p24 core protein) contained in the original plasma or serum sample.

The AxSYM Combo assay delivers specimen results as a ratio of the specimen signal (in rate units) to the cutoff value. Ratios of ≥1 are considered reactive and indicate the presence of anti-HIV immunoglobulin and/or p24.

QUALITY ASSURANCE PROGRAM

An overall program of quality assurance, including quality control and proficiency testing, is required to ensure the accuracy of laboratory results. Such a program consists of written policies and procedures that the laboratory has implemented to ensure that its performance is acceptable to its clients and licensing agencies.

CONCLUSIONS

Serologic assays to detect antibodies to HIV are the most widely used means of laboratory diagnosis of HIV infection (11). Most HIV testing algorithms include an ELISA as the screening component and Western blotting as the confirmatory method (25). The ELISA is used for screening because of its high sensitivity for detecting antibody, and the Western blot assay is used for confirmation because of its high specificity. Several problems related to the laboratory diagnosis of HIV infection still exist; these include the need for detection of early infection, the resolution of indeterminate results, the need for detection of infection in the newborn, and the need for less expensive confirmatory strategies. The estimated risk of transmitting HIV by transfusion of screened blood in the United States is very small, primarily because all blood donations are tested with a combination antibody test for HIV-1 and HIV-2 and are examined for the presence of p24 antigen. The use of rapid tests in point-of-care settings should have significant positive public health benefits within the United States and globally.

General Immunologic Evaluation of Patients with Human Immunodeficiency Virus Infection

RANDY A. STEVENS, RICHARD A. LEMPICKI, VEN NATARAJAN, JEANETTE HIGGINS, JOSEPH W. ADELSBERGER, AND JULIA A. METCALF

95

AIDS was first recognized in 1981 as a new clinical entity and has since become a devastating, worldwide epidemic. It is estimated that by the end of 2003, roughly 37.8 million people worldwide were living with human immunodeficiency virus (HIV) and that during 2003, approximately 14,000 new infections occurred each day (26). Since AIDS was first identified, more than 20 million people with HIV/AIDS have died, and in 2003 alone, HIV infection was responsible for the death of nearly 3 million people worldwide (26). Throughout the globe, numerous clinical trials are currently being conducted to examine preventive HIV vaccines, as well as treatments for both HIV infection and its associated infections and cancers. Because of this epidemic and the need to discover new and more effective therapies for HIV/AIDS, the clinical immunology laboratory plays a critical role in the evaluation and monitoring of patients with HIV infection.

The hallmark of HIV infection is the destruction of CD4$^+$ T lymphocytes and the concomitant destruction of the immune system. A variety of quantitative and functional immunologic abnormalities have been described to occur in individuals infected with HIV (13, 16, 17). These abnormalities affect virtually every compartment of the cellular and humoral immune systems and include (i) decreased percentage and absolute number of helper/inducer T lymphocytes (CD4$^+$ T cells), (ii) decreased proliferative responses of lymphocytes to mitogens and antigens, (iii) increased rates of peripheral T-cell turnover, (iv) decreased thymic function, (v) hypergammaglobulinemia, (vi) decreased cytotoxic lymphocyte and natural killer (NK) cell activity, and (vii) abnormalities in serum components, including elevated levels of β_2-microglobulin, neopterin, and soluble immune complexes.

When evaluating the immunologic status of individuals with HIV infection, or when developing strategies for clinical monitoring of therapeutic trials, immunologic monitoring should be conducted in a manner appropriate for the evaluation of any patient population that is suspected of having multiple defects in cell-mediated immunity. Basic testing should include immunophenotypic analysis of T-lymphocyte subpopulations (CD3$^+$, CD4$^+$, and CD8$^+$ cells) by flow cytometry, with particular attention to both the percentage and absolute number of CD4$^+$ T cells. Where appropriate, additional testing may include further phenotypic analysis of peripheral blood mononuclear cells (PBMCs), to include markers for monocytes; NK cells; B cells; T-cell activation markers, such as HLA-DR, CD38, and CD25; markers of naive and memory lymphocytes, such as CD45RO, CD45RA, CD62L, and CD27; and HIV coreceptors, such as CC-CKR5 and CXCR4. Routine assessment of immune function may include the measurement of proliferative responses of T lymphocytes to antigens and mitogens, as well as measurement of NK cell cytotoxicity and T-cell-mediated cytotoxicity. Lymphocyte turnover rates may be measured by intracellular staining for the nuclear antigen Ki67 or by ex vivo labeling of cells with the thymidine analog bromodeoxyuridine (BrdU). Most recently, techniques have been developed to study cell turnover in vivo using deuterium or BrdU to label proliferating cells. Thymic function may be assessed by the quantitation of T-cell receptor rearrangement excision circles (TRECs).

The intent of this chapter is to provide proven methods for the routine immunologic monitoring of the cellular immune status of patients with HIV infection. Since a majority of immunologic assays are performed with PBMCs, procedures for the isolation and cryopreservation of PBMCs are also discussed. The section describing each procedure is prefaced with an explanation of the rationale behind the described assay, quality control measures necessary for standardization of testing, and practical advice on pitfalls to avoid. In-depth theoretical discussions of each of the major types of monitoring procedures such as flow cytometry, lymphocyte proliferation assays (LPAs), and the quantification of TRECs are provided elsewhere in this manual.

CELL PREPARATION

When monitoring the immunologic status of patients with HIV infection, isolation of lymphoid cells is often required for performing several immunologic procedures, such as lymphocyte immunophenotyping and measurement of lymphocyte function. Lymphoid cells are most commonly obtained from peripheral whole blood, but they may also be collected from other lymph tissue, such as lymph node and tonsil. Described below is a procedure whereby PBMCs can be easily isolated from whole blood, leukapheresis packs, or lymphoid tissue preparations by use of Ficoll-Hypaque density gradient centrifugation. Alternatively, whole-blood mononuclear cells may be isolated using a Percoll gradient or by using BD Vacutainer CPT cell preparation tubes, which

are available from Becton Dickinson (http://www.bd.com/). The CPT tube combines a blood collection tube, anticoagulant, Ficoll-Hypaque density fluid, and a polyester gel, which facilitates the separation of the mononuclear cells. The advantage of the CPT tube method is that blood collection and separation occur in one tube, thereby reducing the risk of specimen contamination and reducing the time and materials needed to process the specimens. Disadvantages of CPT tubes are that recovery of PBMCs may be less than with the Ficoll method described below, and multiple CPT tubes are needed to process large volumes of blood, since each tube holds only 9 ml of blood. Once the PBMCs have been obtained, they can be further purified into various leukocyte subsets using flow cytometry cell sorting or by using immunomagnetic separation technologies that are available from Dynal, Inc. (http://www.dynal.no/) and Miltenyi Biotec (http://www.miltenyibiotec.com/).

Human peripheral blood is obtained by venipuncture into vacuum tubes or syringes containing preservative-free sodium heparin (20 U/ml of blood). Alternatively, cells obtained by leukapheresis may be used. Following phlebotomy, the heparinized blood or leukapheresis sample can be stored for up to 24 h at room temperature before further processing. PBMCs are then obtained from the whole blood or leukapheresis sample by Ficoll-Hypaque density gradient centrifugation. This procedure is accomplished by carefully layering whole blood diluted 1:2 with sterile phosphate-buffered saline (PBS) over Ficoll-Hypaque, which is commercially available from several manufacturers. After a short centrifugation at room temperature, mononuclear cells are harvested from the interface between the Ficoll-Hypaque and plasma layers. The amount of diluted whole blood layered on top of the Ficoll-Hypaque should not exceed two to three times the volume of the Ficoll-Hypaque. For small amounts of whole blood (≤5 ml), the procedure can be carried out in 15-ml conical polypropylene centrifuge tubes. Larger volumes of whole blood should be separated in 50-ml conical centrifuge tubes. The use of polystyrene or polycarbonate tubes to purify and wash the PBMCs should be avoided because of undesired cell adhesion to these types of plastics.

The separation of PBMCs by this technique is straightforward, but consistent and reproducible separations can be accomplished only through close attention to procedural detail. The end result of this procedure will be a clean population of PBMCs virtually free of erythrocyte (RBC), granulocyte, and platelet contamination. Occasionally, the PBMC layer will be contaminated with RBCs due to low mean corpuscular hemoglobin content, or contaminated with granulocytes due to degranulation of the granulocytes. This is especially true with end-stage AIDS patients or acutely ill patients. In these cases, it is not possible to remove the contaminating cells by reprocessing the sample. If RBC contamination is a problem, the cells can be removed by hypotonic or ammonium chloride lysis. It is not practical to attempt to remove contaminating granulocytes, since they do not interfere appreciably in functional assays and can be easily discriminated during phenotypic analysis using flow cytometry.

Equipment

Low-speed centrifuge
Hemacytometer or automated cell counter
50- or 15-ml sterile polypropylene conical centrifuge tubes
Disposable sterile pipettes

Reagents

1× PBS without Ca^{2+} or Mg^{2+}
Ficoll-Hypaque solution (density, 1.077 g/ml)
Cell culture medium, such as RPMI 1640 medium without L-glutamine, 2% 1 M HEPES buffer, 1% 200 mM L-glutamine, 50 μg gentamicin per ml, and 10% fetal calf serum (FCS)

Procedure

1. Bring PBS to room temperature.
2. Dilute fresh, heparinized whole blood with equal parts PBS, and place the samples into 50-ml conical tubes.
3. Add 15 ml of Ficoll-Hypaque to another 50-ml conical tube.
4. Carefully layer 30 ml of diluted blood on top of the Ficoll-Hypaque by hooking the lip of the Ficoll-Hypaque tube onto the lip of the diluted whole blood tube and gently transferring the whole blood into the Ficoll-Hypaque tube. Note: Allow the blood mixture to flow gently onto the top of the Ficoll surface without breaking the surface plane of the Ficoll. <u>Do</u> not allow the Ficoll to mix with the diluted blood. This method takes practice to master but can dramatically reduce preparation time over the alternative method of underlayering the diluted blood with Ficoll-Hypaque by using a pipette.
5. Centrifuge the samples for 10 min at $1,640 \times g$ and 20°C.
6. Remove the cloudy layer of cells at the plasma–Ficoll-Hypaque interface with a disposable sterile pipette. Avoid aspiration of the Ficoll solution located below the cell layer.
7. Resuspend cells in 50 ml of PBS, and centrifuge them for 10 min at $840 \times g$ and 20°C.
8. Wash the cell pellet twice with PBS for 10 min at $470 \times g$ and 20°C.
9. Resuspend the cells in an appropriate cell culture medium, such as RPMI 1640 medium without L-glutamine, 2% 1 M HEPES buffer, 1% 200 mM L-glutamine, 50 μg of gentamicin per ml, and 10% FCS. Perform a cell count using a hemacytometer or automated cell counter and adjust the cell concentration as needed. Cell viability should be determined either by the standard trypan blue staining method or by the flow cytometry-based propidium iodide staining method. Cells may be used immediately for experimentation, stored as pry pellets, or cryopreserved as viable cell suspensions (see cryopreservation procedure below).

IMMUNE CELL PHENOTYPING BY FLOW CYTOMETRY

HIV infection and AIDS are characterized by a significant and progressive destruction of $CD4^+$ T lymphocytes that results in a state of profound immunodeficiency and exposes the host to opportunistic pathogens and disease. In addition to the steady decline of $CD4^+$ T lymphocytes during infection, there is a concomitant increase in $CD8^+$ T lymphocytes as part of the normal immune response to viral infection. Measurement of the percentage and absolute number of $CD4^+$ T lymphocytes is the most useful laboratory test for determining the immunologic status of patients with HIV infection, making decisions regarding antiretroviral therapy, and determining when to initiate prophylaxis for opportunistic pathogens. For example, patients should be started on regimens for *Pneumocystis carinii* pneumonia prophylaxis once their absolute CD4 count is <200 cells/μl or

their CD4 level is <14% (3). Patients with CD4 counts of >200 but <250 cells/μl may be considered for treatment as well (3). Antiretroviral medications have vastly improved the morbidity and mortality of HIV-infected patients, and current treatment guidelines recommend delaying antiretroviral treatment until CD4 counts are ≤350 cells/μl (4). In addition to the prognostic value of monitoring the percentage and absolute number of CD4+ lymphocytes, these parameters have been recommended by the American College of Physicians and the Institute of Medicine as surrogate markers in the analysis of clinical trials involving HIV/AIDS patients.

Currently, there are two accepted methods for the identification and enumeration of CD4+ T cells obtained from peripheral whole blood. In 1997, the Centers for Disease Control and Prevention (CDC) issued revised guidelines for performing CD4+-T-cell determinations in persons with HIV infection (2). This method involves a dual-platform process in which the absolute CD4 cell count is calculated by multiplying together three independent measurements: the CD4 percentage, which is measured by three- or four-color flow cytometry, and the white blood cell (WBC) count and percentage of lymphocytes, which are measured by conventional hematology. In 2003, the CDC issued guidelines for performing CD4+-T-cell determinations by a single-platform technology (5). With single-platform technology, absolute cell counts are measured solely on a flow cytometer and are derived by performing standard three- or four-color flow cytometry and simultaneously counting fluorospheres, which have been added to the blood at a known concentration, thus eliminating the need for a separate hematology instrument. Two suppliers of single-platform fluorospheres are Beckman Coulter (http://www.beckman.com) and BD Biosciences (http://www.bdbiosciences.com). There are advantages and disadvantages associated with both the single- and dual-platform methodologies, so each laboratory must determine which method best suits their needs and capabilities. A major disadvantage of the dual-platform method is that errors in each of the three independent measurements (WBCs, percent lymphocytes, and percent CD4 cells) are multiplied when the absolute count is calculated. The age of blood must also be considered when deciding which method to use. For the single-platform method, blood is stable for up to 72 h after draw, whereas for the dual-platform method, flow cytometry should not be performed on blood that is more than 30 h old and hematology must be performed within the time specified by the manufacturer of the hematology instrument used (often 8 h from the time of blood

draw). This can be a major consideration when there is a need to have blood collected off-site and shipped to the testing laboratory. Compared to the single-platform method, the dual-platform method can also be quite expensive, since this method involves the purchase and maintenance of both a flow cytometer and a hematology analyzer. The major disadvantage of the single-platform method involves the need for precise pipetting, compared to the dual-platform method, because accurate results rely on the precise addition of a known number of fluorospheres to fixed volumes of blood and monoclonal antibodies (22, 24). Therefore, quality assessment becomes even more imperative with single-platform methodologies.

When performing immunophenotypic determinations by flow cytometry, peripheral whole blood is first stained with fluorescently labeled monoclonal antibodies which are specific for cell surface antigens. Next, RBCs are removed from the cell suspension by lysis and the remaining WBCs are fixed using a commercial lysing/fixing reagent. The resulting cell preparation is then suitable for analysis on a flow cytometer. Whole blood for immunophenotyping should be drawn by venipuncture into containers with either EDTA or sodium heparin anticoagulant, and the specimens should be processed as soon as possible (2, 5). If single-platform technology is used, whole blood can be stored at room temperature for up to 72 h, whereas with dual-platform technology, whole blood must be processed within 30 h.

Table 1 lists suggested three- and four-color panels of monoclonal antibodies that may be used for the basic monitoring of patients with AIDS (5). Using the panels listed in this table, one can enumerate CD4+ and CD8+ T cells and ensure the quality of the results. For each of these basic panels, lymphocytes are identified using a CD45 fluorescence and side-scatter gating strategy. Lymphocytes stain brightly for CD45 and have low light-scatter properties. When appropriate, additional testing may include further phenotypic analysis of PBMCs to include T-cell activation markers such as HLA-DR, CD25, CD38, and Ki67. One may also wish to characterize CD4+ and CD8+ T lymphocytes as naive or memory by using markers such as CD45RA, CD45RO, CD62L, and CD27. Companies that provide monoclonal antibodies for the immunophenotyping of patients include the following: Beckman Coulter, BD Biosciences, Biosource (http://www.biosource.com), Caltag (http://www.caltag.com), Dako Cytomation (http://www.dakocytomation.com), Molecular Probes (http://www.probes.com), and R & D Systems (http://www.rdlabs.com). Additional suppliers can be found at http://www.antibodyresource.com. It should be

TABLE 1 Suggested monoclonal antibody panels for lymphocyte immunophenotyping of patients with HIV infection

Panel[a]	Monoclonal antibodies	Specificity
Three color	CD3 × CD4 × CD45	CD3+ T cells and CD3+ CD4+ T cells
	CD3 × CD8 × CD45	CD3+ T cells and CD3+ CD8+ T cells
	CD3 × CD19 × CD45	CD3+ T cells and CD19+ B cells
	CD3 × CD16/56 × CD45	CD3+ T cells and NK cells
	CD27 × CD45RO × CD4	Memory and naive CD4 cells
	CD27 × CD45RO × CD8	Memory and naive CD8 cells
Four color	CD3 × CD8 × CD45 × CD4	CD3+, CD3+ CD4+, and CD3+ CD8+ T cells
	CD3 × CD16/56 × CD45 × CD19	CD3+ T cells, NK cells, and CD19+ B cells
	CD27 × CD45RO × CD3 × CD4	Memory and naive CD4 cells
	CD27 × CD45RO × CD3 × CD8	Memory and naive CD8 cells

[a]Lymphocytes are gated using CD45 and side scatter.

noted that monoclonal antibodies are supplied in various concentrations and are available in unconjugated form or conjugated to one of the following fluorochromes: fluorescein isothiocyanate (FITC), R-phycoerythrin (R-PE), BD Cy-Chrome (also known as PE-Cy5), peridinin chlorophyll protein (PerCP), PerCP-Cy 5.5, allophycocyanin (APC), and APC-Cy7. Each laboratory must determine the optimal concentration of each antibody and select the appropriate fluorochromes for its needs and applications.

Once the whole blood has been stained with the appropriate immunofluorescent antibodies, the specimens are analyzed on a flow cytometer. The two major manufacturers of clinical flow cytometers are Beckman Coulter and BD Biosciences. Prior to analysis of samples with a flow cytometer, it is imperative that the instrument be standardized and calibrated in order to provide accurate and reproducible data on a consistent basis. Detailed guidelines for the quality control and quality assurance of flow cytometric immunophenotyping in clinical laboratories have been published by the National Committee for Clinical Laboratory Standards (21). Every clinical laboratory involved in immunophenotyping of lymphocytes must develop a rigid set of protocols for the quality control and quality assurance of its flow cytometry. Such protocols should include daily calibration of the flow cytometer by using standardized immunofluorescent particles, which are available from several manufacturers. These standardized immunofluorescent particles should be used daily to verify that the optical alignment of the flow cytometer meets the manufacturer's specifications, and to calibrate the immunofluorescence and forward and right-angle light scatter properties that are appropriate for the fluorochrome-labeled cells (5). Fluorescence resolution and spectral-overlap compensation should be performed on a daily basis in accordance with National Committee for Clinical Laboratory Standards guidelines (21).

Quality control of the staining procedure is also necessary. For this purpose, laboratories should use a commercially available standardized preserved lymphocyte preparation, such as Status Flow (R & D systems), CD-Chex Plus (Streck [http://www.streck.com]), or BD Multi-Check (BD Biosciences) to serve as a positive control. The preserved lymphocytes should be stained with the same monoclonal antibodies as used in the basic immunophenotyping panel. The use of these cells will allow the clinical laboratory to determine inter- and intra-assay variation as well as provide long-term control for assay drift. The values obtained from a standardized lymphocyte panel should always fall within 2 standard deviations of a predetermined mean value for each phenotypic marker in the panel. The mean percentage of the values for any set of standardized lymphocytes should be calculated on the basis of at least 20 separate determinations made by using a completely calibrated flow cytometer. If the daily-standardized lymphocytes fall outside these specifications, then the results obtained for the patients' lymphocytes should be closely examined for accuracy and the determination should be repeated if appropriate. In addition to the use of standardized lymphocytes, fresh blood from healthy donors may be used as a positive control. However, it is not always possible to obtain fresh donors on any given day; therefore, the standardized lymphocytes offer the advantage of providing a calibrated control that can be analyzed with each set of specimens. When one is analyzing any cell population with a flow cytometer, it is important to collect between 5,000 and 10,000 cells during the analysis. The collection of this number of cells will effectively eliminate any

variability due to poor sampling numbers and provide good statistical power. Additionally, to ensure the satisfactory performance of CD4$^+$-T-cell measurements, clinical laboratories must participate in a performance evaluation program and demonstrate an acceptable level of performance (5). Performance evaluation programs for flow cytometry are offered by the DAIDS IQA Program (http://aactg.s-3.com), the College of American Pathologists Proficiency Testing Program (http://www.cap.org), and the Model Performance Evaluation Program (http://www.phppo.cdc.gov/MPEP/). If the dual-platform method is used for performing CD4$^+$-T-cell determinations, then the laboratory must also participate in a proficiency testing program for hematology, such as the College of American Pathologists program. Additionally, laboratories within the United States that perform CD4$^+$-T-cell determinations should be certified under the Clinical Laboratory Improvement Amendments (see http://www.cms.hhs.gov/clia).

In addition to reporting the percentage of positives for each of the lymphocyte populations in the standard immunophenotyping panel, one also reports the absolute number of these cells. As mentioned previously, absolute counts may be obtained with either the dual- or single-platform approach. If using the dual-platform approach to report absolute lymphocyte numbers, one must obtain a WBC and differential lymphocyte count on the patient sample. Once the percentages of lymphocytes are obtained from the differential, one can calculate the absolute number of cells in any subpopulation of lymphocytes by using the following formula: percentage of lymphocytes from differential × WBC × percentage of specific subpopulation obtained from appropriately calibrated flow cytometer = absolute number. Differential lymphocyte counts can be obtained from an automated hematology analyzer, or they can be performed by the manual method. Automated differential cell counting offers the advantage of being able to examine and count large numbers of cells (up to 10,000 lymphocytes), lending great statistical power. However, for patients who have AIDS, approximately 25 to 30% of the automated differentials may be flagged by the hematology instrument as containing unreadable cells. In these cases, an experienced hematology technician will be required to manually perform a visual evaluation of that slide. A manual differential count has the disadvantage of being a labor-intensive operation that does not offer the statistical power of the automated cell counters. However, a well-trained staff of hematology technicians can provide reliable and accurate differential cell counting from day to day and can also provide the clinicians with valuable information concerning unusual morphology of WBCs due to drug-induced changes or infection with HIV.

When using the single-platform method to provide absolute cell counts, most manufacturers of fluorospheres provide software that will automatically report calculated cell counts. If the program does not automatically calculate the values, then use the following formula: absolute cell count = (number of lymphocytes in bright CD45 region/number of fluorospheres in fluorosphere region) × (number of fluorospheres added/volume of blood added) (5).

In summary, immunophenotyping of patients with HIV infection can provide the most clinically relevant information as to the immunologic status of these patients. In light of the complex nature of the instrumentation required to perform immunophenotyping and the multiple steps necessary to prepare the cells for immunophenotyping, every laboratory must develop rigid quality assessment programs. Only through careful monitoring of immunophenotyping

will it be possible to determine the efficacy of any experimental therapy. Described below is a dual-platform procedure for staining whole blood for immune cell phenotyping by flow cytometry, using Optilyse C lysing reagent. If using an alternative lysing reagent, follow the manufacturer's instructions.

Monoclonal Antibody Staining Procedure for Flow Cytometry (Three-Color)

Equipment

Low-speed refrigerated centrifuge and carriers for 12- by 75-mm tubes
Vortex mixer
Polystyrene or polypropylene tubes (12 by 75 mm)

Reagents

Optilyse C lysing buffer
PBS
Monoclonal antibodies

Procedure

1. Collect blood into EDTA anticoagulant. Mix blood thoroughly for a minimum of 1 to 2 min. Blood collected in acid-citrate-dextrose or heparin is also acceptable for this procedure; however, if one wishes to perform hematological testing and immunophenotyping from the same tube of blood, then EDTA is the preferred anticoagulant.

2. Label tubes (polypropylene or polystyrene, 12 by 75 mm) with sample identification and monoclonal antibody name.

3. To each tube add the appropriate fluorescently labeled monoclonal antibody at the manufacturer's recommended amount.

4. Carefully add 100 µl of patient blood to the bottom of each tube. When adding blood to the tubes, avoid making air bubbles and avoid getting blood on the inner sides of the tube. Excess blood on the inner side of a tube should be removed with a cotton swab. Specimens with WBC counts of ≤3,000/µl require double volumes of blood (200 µl).

5. Gently vortex all tubes and incubate them for 15 min at room temperature, in the dark (cover tube rack with aluminum foil).

6. Add 500 µl of Optilyse C lysing solution to each tube, and then underline{immediately} vortex each tube briefly. Allow lysing solution to incubate at room temperature in the dark (cover tube rack with aluminum foil) for at least 10 min. (Cells may be incubated in the lysing solution for up to 2 h without adversely affecting the results.)

7. Add 2 ml of PBS to each tube, vortex each tube underline{immediately} after the addition of the PBS, and centrifuge each tube at 250 to $300 \times g$ for 5 min at room temperature. Resuspend the cell pellet by gently vortexing.

8. Wash the cells again with 2 ml of PBS; centrifuge at $300 \times g$ for 5 min at room temperature.

9. Resuspend the cells in 400 µl of PBS and store at 4°C in the dark until analysis is performed.

10. Perform analysis on a flow cytometer within 24 h.

LPA

HIV infection results in a severe immunodeficiency which can be characterized by a selective depletion of the helper/inducer subset of T lymphocytes (CD4$^+$). Some of the functional defects related to the loss of CD4$^+$ T cells

include decreases in in vitro lymphocyte proliferative responses to polyclonal mitogens, soluble antigens, and alloantigens. Consequently, the measurement of lymphocyte proliferative responses can be a very useful tool for determining the functional capacity of lymphocytes and for monitoring immunologic responses to therapy. During the course of HIV infection, the earliest proliferative dysfunction that appears is the inability of CD4$^+$ T cells to recognize and proliferate in response to soluble recall antigens such as tetanus toxoid (TT), diphtheria toxin, *Candida albicans*, or purified protein derivative. Response to TT is the easiest of these antigens to monitor because a majority of the population has been previously exposed to this common immunogen. As the disease state progresses, the next proliferative response that disappears is the response to class II alloantigens, expressed on donor mononuclear cells in a mixed lymphocyte culture (MLC). During end-stage disease, a decline in proliferative responses to polyclonal mitogens such as phytohemagglutinin (PHA), pokeweed mitogen (PWM), and concanavalin A (ConA) can be seen. The order of loss of responsiveness in most patients is PWM, ConA, and finally PHA. Therefore, when one is monitoring proliferation of lymphocytes from AIDS patients, a basic panel of stimuli may include TT, MLC, PWM, PHA, and ConA. While lymphocyte proliferative responses are rather easy to monitor, it is not clear if these parameters have any clinical utility over the measurement of CD4 counts.

Additional monitoring of lymphocyte proliferation may be appropriate in the setting of certain therapeutic interventions. For example, when one is monitoring a trial in which a biological response modifier such as interleukin-2 (IL-2) is being administered, it is important to measure spontaneous proliferation of freshly isolated PBMCs. This assay consists of the in vitro assessment of the proliferative state of PBMCs in the absence of mitogen or antigen, and it can be used in lieu of cell cycle analysis to determine the relative fraction of cells synthesizing DNA in vivo. Similarly, if one is monitoring an HIV vaccine trial, the purified immunogen may be used as an in vitro proliferative stimulus in order to measure HIV-specific T-lymphocyte responses evoked by the vaccine. In such assays, an irrelevant protein which has been expressed in the same system as used to manufacture the vaccine should be included as a background control. Titration of the immunogen against a positive control cell population (cells known to respond to the immunogen) will help to determine the dose of immunogen necessary to achieve maximum proliferation. If a suitable human positive control is not available, PBMCs from other species, such as chimpanzees, immunized with the immunogen may be used for dose titration. Finally, cellular immune responses to HIV type 1 (HIV-1) may be detected by measuring proliferative responses to HIV-1-associated proteins and glycoproteins such as HIV-1 p24 antigen or HIV-1 envelope glycoprotein 120.

The measurement of lymphocyte proliferation involves the in vitro culture of PBMCs in the absence or presence of a stimulus. At the end of a specified incubation period, a radiolabeled DNA precursor (usually tritiated thymidine) is added, and the amount of radioactivity incorporated into the DNA of dividing cells is measured. Although the principle of this assay is straightforward, careful consideration must be given to standardization and quality control in order to minimize significant day-to-day variability. The best positive controls for this assay are cryopreserved PBMCs from at least three healthy donors who have been preselected for a defined level of proliferative activity. The positive control cells may be obtained by leukapheresis and cryopreserved in

aliquots containing 5 million to 10 million cells. The positive control cells should be tested with each assay, and their activity may be used to monitor assay variability and to determine if the assay is working well. Each laboratory must also determine the optimal conditions for measuring proliferation. Each lot of antigen or mitogen should be titrated against normal PBMCs to achieve the correct concentration for maximum stimulation. It is also necessary to determine the optimal culture incubation times for each antigen or mitogen. Optimal polyclonal mitogen stimulation usually occurs in 2 to 4 days, while optimal antigen stimulation may take 5 to 7 days. An exception to this rule is PWM, for which the peak proliferative response is seen at day 6. Another variable, which should not be underestimated, is the choice of serum to be used in the assay medium. Not all lots of serum support cell growth equally; therefore, several lots should be tested to find one which gives low spontaneous background proliferation and supports optimal growth in the presence of mitogens or antigens. Pooled human AB serum from HIV-seronegative donors (final concentration, 15%) is recommended due to low backgrounds and high levels of stimulation.

As in all immunologic testing, quality control is an important part of the assay procedure. All pipetting devices should be calibrated to ensure accurate and consistent dilution of mitogens and antigens. All equipment, such as the incubator, cell harvester, and scintillation counter, should be calibrated periodically. All reagents and cultures must be kept sterile, since culture times range from 2 to 7 days. The use of laminar-flow hoods during all technical procedures is recommended to decrease the probability of bacterial or fungal contamination. The LPA may be performed with PBMCs that have been isolated from either heparin- or acid-citrate-dextrose-anticoagulated blood. EDTA is not a suitable anticoagulant for LPA. In order to minimize the effects of blood storage conditions on LPA, blood must be held at room temperature and PBMCs should be isolated within 30 h of venipuncture. Cells should be plated in the assay as soon as possible. Although cryopreserved PBMCs may be tested with the assay, freshly isolated PBMCs are often the best choice because cells from some HIV-infected patients do not survive cryopreservation well.

The data generated by LPAs can be expressed in various ways. Although the method of data expression is left to the discretion of each laboratory, the three most commonly used methods are net counts per minute (cpm), stimulation index, and relative proliferation index.

Net cpm = cpm of stimulated culture − cpm of unstimulated culture

Stimulation index = cpm of stimulated culture/cpm of unstimulated culture

Relative proliferation index = net cpm of patient sample/mean net cpm of a panel of at least three healthy donors that have been tested simultaneously in the assay

Equipment

96-well U-bottom microtiter plates
Humidified incubator with 5% CO_2
Cell harvester (Harvester 96 Mach 3M, Tomtec)
Scintillation fluid (Betaplate Scint, LKB Wallac)
Scintillation counter (Microbeta Trilux, LKB Wallac)
Mechanical pipettes
96-well filtermats (LKB Wallac)

Filtermat sample bags (LKB Wallac)
Heat sealer (LKB Wallac)

Reagents

Serumless medium: RPMI 1640 medium without L-glutamine, 2% 1 M HEPES buffer, 1% 200 mM L-glutamine, 50 μg of gentamicin per ml
30% human AB medium: serumless medium supplemented with 30% heat-inactivated human AB serum
[methyl-³H]thymidine, specific activity of 6.7 Ci/mmol (NEN Research Products)
Dulbecco's PBS without Ca^{2+} or Mg^{2+}, pH 7.4

Mitogen and Antigen Preparation

PHA (Murex; catalog no. HA16): Make a 1:100 dilution of stock PHA (2 mg/ml) with 30% human AB medium (final concentration, 20 μg/ml). Use 20 μl per well (final concentration, 2 μg/ml).
ConA (Sigma; catalog no. C-2010): Make a 1:2 and a 1:4 dilution of ConA stock (2 mg/ml) with 30% human AB medium (final concentrations, 1 and 0.5 mg/ml). Use 20 μl per well (final concentrations, 100 and 50 μg/ml).
MLC: Obtain PBMCs from six healthy donors by the Ficoll-Hypaque method. Cryopreserve cells from each donor in aliquots of 5×10^6 cells per ml, using a controlled-rate freezer, and irradiate them in the frozen state with 7,500 rads from a ^{137}Cs irradiator. On the day of assay, thaw one aliquot of each normal sample and pool the aliquots. Adjust the cell concentration to 10^6 cells per ml with 30% human AB medium. Use 50 μl (total of 50,000 cells) per well.
TT (Calbiochem; catalog no. 582231): Reconstitute 25 μg of TT with 2.5 ml of 30% human AB medium (final concentration, 10 μg/ml). Use 20 μl per well (final concentration, 1 μg/ml).
PWM (Sigma; catalog no. L-9379): Make a 1:80 dilution of stock PWM with 30% human AB medium. Use 20 μl per well (final dilution of 1:800).
Recombinant HIV-1 MN envelope glycoprotein 120 (catalog no. 1021; Immunodiagnostics, Inc.): Make a 1:10 and a 1:2 dilution of gp120 stock (100 μg/ml) with 30% human AB medium (final concentrations, 10 and 50 μg/ml). Use 20 μl per well (final concentrations, 1 and 5 μg/ml).
Recombinant HIV-1 NY5 p24 viral protein (Protein Sciences Corp.; catalog no. 2004): Make a 1:2 dilution of p24 stock (100 μg/ml) with 30% human AB medium (final concentration, 50 μg/ml). Use 20 μl per well (final concentration, 5 μg/ml).

Procedure

1. Isolate PBMCs by the Ficoll-Hypaque method, and adjust the concentration to 10^6 cells per ml in serumless medium.
2. Plate three control wells per patient per stimulus. Control wells contain mononuclear cells with no stimulus: 100 μl of cells (10^6/ml) in serumless medium and 100 μl of 30% human AB medium.
3. Plate three stimulated wells per patient per stimulus. Stimulus wells contain mononuclear cells and a stimulus.
    a. For PHA, ConA, TT, PWM, p24, or gp120: 100 μl of cells (10^6/ml) in serumless medium, 80 μl of 30% human AB medium, and 20 μl of appropriate mitogen or antigen.

b. For MLC: 100 μl of cells (10⁶/ml) in serumless medium, 50 μl of 30% human AB medium, and 50 μl of MLC.

4. For spontaneous blastogenesis, plate six wells per patient. Each well contains the following: 100 μl of cells (10⁶/ml) in serumless medium and 100 μl of 30% human AB medium.

5. Place 200 μl of PBS into all empty wells (this prevents fluid loss from sample wells due to evaporation).

6. Keep plates sterile and incubate them at 37°C in a humidified, 5% CO_2 incubator. Incubation times are as follows: 0 h for spontaneous blastogenesis; 3 days for PHA and ConA; 5 days for p24, gp120, and MLC; and 6 days for TT and PWM.

7. Pulse each well with 0.4 μCi of [³H]thymidine in 20 μl of serumless medium at the end of the specified incubation period.

8. Incubate the plates for an additional 4 h at 37°C in a humidified, 5% CO_2 incubator.

9. Harvest cells onto fiberglass filtermats with a cell harvester (LKB Wallac) or equivalent. Allow the filtermats to air dry. Add scintillation fluid to each filtermat, and count cells in a liquid scintillation counter for 1 min.

10. Determine the mean, standard deviation, and standard error of the mean for each triplicate. Note: Since incubation times vary with mitogen, PHA and ConA may be put on the same 96-well plate (3 days), whereas MLC, p24, and gp120 must be run on a plate with appropriate controls (5 days); TT and PWM can be put on the same plate (6 days).

EVALUATION OF CELL TURNOVER

Much debate exists over the mechanisms by which HIV-1 infection disrupts CD4 T-cell homeostasis. Numerous procedures for measuring cell turnover rates have been employed to further our understanding of T-cell dynamics during HIV-1 infection, including assessing the impact of highly active antiretroviral therapy and IL-2 immunotherapy. Some of the methods introduced in such studies include ex vivo [³H]thymidine incorporation (16), telomere terminal restriction fragment length (7), T-cell rearrangement excision circles (6), Ki67 staining (23), ex vivo and in vivo BrdU incorporation (15, 18), and in vivo incorporation of deuterated glucose or deuterated water (10, 11).

In recent years investigators have focused on more direct measures of cell turnover by directly quantitating the fraction of cycling cells. One such ex vivo method includes flow cytometric analysis of the expression of the nuclear protein Ki67 (8). Ki67 expression increases in late G_1 phase of the cell cycle and remains elevated throughout mitosis (8). Antisense experiments indicate that Ki67 expression may be important for cellular proliferation and survival (12, 16). Importantly, Ki67 is not expressed in resting cells (1), thereby making this molecule a reasonable marker of cell cycle progression. One of the main advantages of Ki67 detection is that it can be used on cryopreserved cells; however, one potential disadvantage is that cells blocked in cell cycle progression or cells in a preactivated nondividing state may be positive for Ki67. Another ex vivo method of measuring cell turnover is BrdU incorporation. BrdU is a thymidine analog taken up by cells through the nucleotide salvage pathway, converted into BrdUTP, and incorporated into DNA of dividing cells. Monoclonal antibodies are available to detect DNA-incorporated BrdU by flow cytometry. The one main disadvantage of the ex vivo BrdU labeling method

is that it must be done on freshly isolated cells. The Ki67 detection and ex vivo BrdU labeling methods provide a rapid and relatively inexpensive "snapshot" of the level of dividing cells in the blood or lymph nodes.

In vivo kinetic studies are extremely informative; however, they are significantly more expensive to conduct since they require the use of large amounts of labeling reagent, a clinical infrastructure, and long-term longitudinal follow-up (months to years) to obtain sufficient data points during the labeling and delabeling phases of the study. The main advantage of kinetic studies is that mathematical modeling can simultaneously determine the values of numerous biological parameters, including the portion of actively dividing cells, cell proliferation and death rates, the fraction of newly added cells, and the effects of cellular trafficking. The biological assumptions underlying the various models are controversial, and thus investigators partaking in such studies should consult with a mathematician. In vivo infusions of BrdU, deuterated glucose, or deuterated water are currently the methods of choice for in vivo labeling studies. Deuterated glucose is taken up by cells and converted de novo to deuterated deoxynucleoside triphosphates (dNTPs) via the pentose phosphate pathway, followed by incorporation into the DNA of dividing cells. Differences among the conclusions of a number of published papers describing in vivo labeling kinetics in patients with HIV-1 infection are mostly due to the differences in the assumptions and design of the mathematical models as opposed to the results of the raw kinetic data; i.e., there are relatively consistent findings in the raw labeling-delabeling kinetics. Despite these shortcomings, mathematical modeling is allowing for the generation of testable hypotheses that should address some of the model assumptions.

The following sections describe optimized protocols for ex vivo and in vivo BrdU incorporation, Ki67 staining, and in vivo labeling with deuterated glucose. Representative data from cross-sectional and longitudinal studies comparing these methods are presented and show that the different techniques are well correlated.

In Vivo Labeling of Lymphocytes with Deuterated Glucose

In Vivo Cell Labeling and Isolation

For the method described below, all subjects participated in an Institutional Review Board-approved clinical protocol and all subjects provided written informed consent. Deuterated glucose (Isotec, Inc., Miamisburg, Ohio, or Cambridge Isotope Laboratories, Inc., Andover, Mass.) was administered to subjects by continuous intravenous infusion over 5 days at a dose of 60 g per day. Subjects underwent a one- or two-pass lymphapheresis, and PBMCs were obtained following Ficoll-Hypaque gradient centrifugation. PBMCs were further separated by flow cytometric sorting into lymphocyte subsets by following manufacturer's recommended instructions with the monoclonal antibodies CD3 FITC, CD4 PE (BD Immunocytometry Systems, San Jose, Calif.), and CD8 Cy-Chrome (BD Biosciences Pharmingen, San Diego, Calif.). Cell sorting was performed using an amorphous forward light scatter and 90° light scatter gate and a linear gate on CD3 FITC⁺ fluorescence to identify T lymphocytes. T lymphocytes were further divided into CD4 and CD8 subsets based on amorphous gates for CD4 PE⁺ fluorescence and CD8 Cy-Chrome⁺ fluorescence. CD4 and CD8 T-cell purity was documented by flow cytometry to be >99.0%.

Genomic DNA Isolation and Hydrolysis

Genomic DNA was isolated from the 0.5 million to 4 million frozen pelleted cells using the Puregene kit (Gentra Systems, Minneapolis, Minn.) and pelleted DNA hydrated overnight with 25 μl of deionized water. In preparation for DNA hydrolysis, phosphodiesterase I (PDE I) (Worthington Biochemical Corp., Lakewood, N.J.) is reconstituted to 0.05 U/μl with PDE I storage buffer (100 mM Tris-HCl [pH 8.8], 100 mM NaCl, 15 mM MgCl$_2$, 50% glycerol) and stored at $-20°$C for no more than 3 months. The 25 μl of rehydrated genomic DNA was hydrolyzed to free deoxyribonucleosides by adding 25 μl of hydrolysis solution (30 U of DNase I [Invitrogen, Frederick, Md.], 0.1 U of reconstituted PDE I, 25 U of bacterial alkaline phosphatase [Invitrogen], 10 mM freshly added dithiothreitol, 100 mM NaCl, 40 mM Tris-HCl [pH 8.0], 20 mM MgCl$_2$) and incubating overnight at 37°C. Digestates were stored at $-20°$C until analysis. Prior to analysis, the digestate was cleaned up by reversed-phase solid-phase extraction, using an Oasis HLB (30 mg) 96-well extraction plate (Waters Corp., Milford, Mass.) prepared as follows: 1 ml of methanol was aspirated through each well under vacuum, followed by 1 ml of deionized water. To each well were pipetted 300 μl of 100 mM phosphate buffer (pH 7.0) and 50 μl of the DNA digestate. The sample solution was aspirated through the sorbent bed, followed by 0.5 ml of deionized water, and allowed to dry by aspirating air. Aspirating 0.5 ml of methanol effects elution of the deoxyribonucleosides. The eluate was collected, split into two equal volumes, and evaporated to dryness using a vacuum centrifuge (model RC10.10; Jouan, Winchester, Va.). For micro-column high-performance liquid chromatography/mass spectrometry (μHPLC/MS) analysis the residue was reconstituted in 50 μl of deionized water, followed by agitation for 1 min on a vortex mixer, and then transferred to a 96-V-shaped-well polypropylene microtiter plate and analyzed by μHPLC/MS.

Quantitation of Deuterated-dA Enrichment in Genomic DNA by HPLCEIS/MS

All μHPLC-electrospray ionization (ESI)/MS experiments were carried out using Agilent Technology 1110 series instrumentation. The μHPLC system was connected on-line to an MSD/Trap equipped with an ESI source, and with Hewlett-Packard (Palo Alto, Calif.) Vectra PC running Chemstation software for data acquisition and instrument control. Chromatography was carried out using a glass-lined stainless steel (SGE, Austin, Tex.) microanalytical column (100 mm long by 0.5 mm [internal diameter]) packed in-house with Luna C$_{18}$, 5 μM particles (Phenomenex, Torrance, Calif.). A sample volume of 1 μl was injected and eluted using a 15-μl/min mobile phase gradient beginning at 3% (vol/vol) acetonitrile and 97% 5 mM ammonium acetate, pH 5.0, for 1 min and increased linearly to 40% (vol/vol) acetonitrile over 6 min and held for 3 min, after which initial conditions were restored. EIS/MS data were acquired in positive-ion mode using the following ion source conditions: drying gas temperature, 250°C at a flow of 7 liters/min; nebulizer pressure, 15 lb/in^2; and capillary voltage, $-3,000$ V. The ion trap settings used were as follows: accumulation time, 100 ms; ion charge control target, 30,000; and scan range, m/z 248 to 258. Extracted ion chromatograms were generated for m/z 252 and 254, corresponding to the protonated molecular ions $(M + H)^+$ of deoxyadenosine (dA) and deuterated dA, respectively. Quantitation was performed using a standard calibration curve. The ratio of the peak area of deuterated dA (m/z 252) to that of the total

dA pool (m/z 252 + 254) was determined and compared to a concentration-independent calibration curve generated by mixtures of deuterated dA (Cambridge Isotope Laboratories, Inc.) and dA (Sigma, St. Louis, Mo.) of known composition from 0 to 10% enrichment.

Extraction and Processing of Serum Glucose

Glucose was extracted from 200 μl of serum by the addition of 800 μl of methanol, incubation for 1 h and centrifugation at $16,000 \times g$ for 15 min. The supernatant containing the extracted glucose was stored at $-20°$C until analysis. Glucose extracts were dried using a vacuum concentrator or dry nitrogen gas and resuspended in 200 μl of 11% aldolnitrile. The samples were transferred to 1-ml glass autosampler vials, and the solution was evaporated to dryness at 50°C under a stream of nitrogen gas. The dried sample is derivatized by adding 150 μl of 2% hydroxylamine HCl in dry pyridine (2% [wt/wt]). The vials are sealed and heated at 90°C for 1 h. The aldolnitrile penta-acetate derivative of glucose was synthesized by adding 50 μl of acetic anhydride. The vials were sealed and heated at 60°C for 1 h. The solvents in the resulting solution were evaporated under a stream of nitrogen gas at 50°C, and 100 μl of acetonitrile was added to the dry reaction mixture and vortexed for 30 s.

Technical notes: Deuterium will be incorporated into all four dNTPs through the de novo-synthesized pathway and incorporated into genomic DNA of dividing cells; however, deuterated dA is the easiest to detect. As a result of dNTPs being synthesized through pathways that do not include glucose as a precursor, only a maximum of 60% of the dA in the genomic DNA will become enriched with deuterated dA; thus, raw enrichment values must be correct by a factor of 1.67. An additional adjustment must be made for the dilution of deuterated glucose by endogenous blood glucose. This is accomplished by daily measurements of deuterated-glucose enrichment levels in serum during the infusion (see procedure below) and multiplying serum deuterated-glucose enrichment values by the average daily dilution factor.

Quantitation of Deuterated Glucose in Serum by GC/MS

Derivatized glucose samples were analyzed using an HP 5790 (Hewlett-Packard) gas chromatograph (GC) interfaced to a VG 70-250HF (VG Analytical, Ltd., Manchester, United Kingdom) mass spectrometer. One microliter of the sample was injected onto a 60-m, 0.32-mm (inside diameter), 15-μm-film DB-17ht (J & W Scientific, Folsom, Calif.) fused silica capillary column via splitless injection. Helium at a flow rate of 1 ml/min was used as the carrier gas. Injector, transfer line, and ion source temperatures were 260, 270, and 220°C, respectively. The GC oven was programmed for 140°C with a 1-min hold followed by a ramp of 15°C per min to 280°C, with a 5-min hold at 280°C. The mass spectrometer is operated in the electron ionization selected ion recording mode. It is set to monitor the fragment ions at m/z 217 and 219. Dwell times on each ion are 50 ms, with a 10-ms interchannel delay. Other MS experimental parameters are as follows: resolution, 1,000; trap current, 100 μA; electron multiplier, 2.5 to 3.0 kV; and electron energy, 70 eV. Quantitation was performed using a standard calibration curve. The ratio of the peak area of deuterated glucose (m/z 219) to that of the total glucose pool (m/z 217 + 219) was determined and compared to a concentration-independent calibration curve generated by mixtures of deuterated glucose (Cambridge Isotope Laboratories, Inc.) and glucose (Sigma) of known composition from 0 to 50% enrichment.

In Vivo BrdU Labeling of Dividing Lymphocytes

Patients and BrdU Infusion

For the method described below, HIV-infected subjects who were infused with BrdU were participants in an Institutional Review Board-approved clinical protocol, and all subjects provided written informed consent. Subjects who were pregnant or breast-feeding or receiving 5-fluorouracil were excluded from participation. While BrdU has been used in cancer patients as a marker for rates of cell turnover without any observed toxicities, it has been shown to be teratogenic in animal models. For this reason, the risk/benefit ratio precludes the infusion of BrdU in healthy volunteers. Participants in the study were counseled to practice effective contraception. BrdU (NEOMARK-BU) was supplied by NeoPharm through the National Cancer Institute and infused at a dose of 200 mg/m^2 over 30 min.

Cell Staining and Flow Cytometry

Ten milliliters of whole blood was collected into an EDTA-containing tube at various times following BrdU administration. Lymph node biopsy samples were collected from some subjects, teased to release lymphocytes and pushed through a mesh screen to obtain a single cell suspension, and then processed as for whole blood. Two 1-ml aliquots from each tube were used for three-color flow cytometric staining with monoclonal antibodies anti-BrdU FITC and anti-CD45RO PE (BD Immunocytometry Systems) crossed with either anti-CD4 PC5 or anti-CD8 PC5 (Beckman Coulter). Nonspecific antibody binding sites were blocked by adding 100 μl of 25-mg/ml immunoglobulin G (ChemiCon International, Inc., Temecula, Calif.) and incubating the mixtures for 10 min. Each cell surface-staining fluorescent antibody was added to the appropriate tube and incubated for 15 min. RBCs were lysed by incubation with 5 ml of Optilyse C lysing solution (Immunotech, Westbrook, Maine) for 10 min. Cells were washed twice with PBS and then fixed and permeabilized by incubation with 1 ml of 1% para formaldehyde plus 1% Tween 20 for 15 min at 37°C. Cells were washed with PBS and incubated with 300 μl of DNase I solution (100 U of DNase I [Roche Applied Science, Indianapolis, Ind.], PBS, 4.2 mM MgCl$_2$ [pH 5.0]) for 30 min at 37°C. The reaction was terminated by the addition of 1 ml of DNase I stopping solution (1% bovine serum albumin [BSA], 0.5% Tween 20, PBS). Cells were washed with PBS and incubated with 100 μl of 25-mg/ml mouse immunoglobulin G for 10 min. Precleared anti-BrdU was added to each tube and incubated for 30 min, followed by two washes with 3 ml of PBS. Cells were resuspended in 500 μl of PBS and analyzed on a Coulter XL flow cytometer. A total of 20,000 to 50,000 gated events were collected for most samples; a minimum of 5,000 gated events were collected when the gated cell count was low.

Technical notes: The DNA in the cells must be digested in order for the anti-BrdU antibody to bind to the incorporated BrdU in the DNA structure. The action of DNase is time, temperature, and pH dependent and should be optimized in each laboratory setting. The BrdU-negative gate is determined by using a sample of blood drawn before the infusion of BrdU. The positive staining of in vivo-labeled BrdU cells is not well separated from the BrdU-negative cells, and thus it takes a skilled, experienced operator to set the gates. This procedure has an impact on the light scatter properties of the cells, and care must be taken to exclude monocytes and granulocytes from analysis due to their autofluoresence properties. This autofluoresence may appear as positive

BrdU staining. BrdU labeling peaks at approximately day 1 after infusion with lymph node T cells and at days 3 to 5 in peripheral blood T cells.

Ex Vivo BrdU Labeling of Dividing Cells in Whole Blood

Cell Labeling

Ten milliliters of whole blood was collected into an EDTA-containing tube and 4.5 ml was aliquoted into two 15-ml tubes. Ten microliters of BrdU (Sigma) at 3 μg/ml was added to one tube of blood, with the other tube serving as a BrdU-negative control. Samples were incubated at 37°C and 5% CO$_2$ for 4 h. Cell staining and flow cytometry were performed as described in "In Vivo BrdU Labeling of Dividing Lymphocytes."

Technical notes: Comments are the same as for in vivo BrdU labeling except that the BrdU-positive cells are determined by setting the gate based on the "without BrdU" sample.

Detection of Dividing Cells by Ki67 Staining

Cell Staining

Ki67 can be detected in lymphocytes of either freshly isolated whole blood or cryopreserved PBMCs. For each sample four tubes are prepared for cell surface phenotyping and Ki67 analysis: (i) CD3 FITC/isotype PE/CD4 PE-Cy5, (ii) CD3 FITC/Ki67 PE/CD4 PE-Cy5, (iii) CD3/isotype PE/CD8 PE-Cy5, and (iv) CD3/isotype PE/CD8 PE-Cy5. CD3 FITC, isotype PE, CD4 PE-Cy5, and CD8 PE-Cy5 were purchased from BD Biosciences Pharmingen. Cell surface staining was performed by incubating the appropriate antibodies with 1 ml of whole-blood cells or 1 ml of PBMCs (one million to five million cells) for 15 min. RBCs were lysed with 5 ml of Optilyse C lysing solution (Immunotech) for 10 min. Cells were washed twice with PBS and then fixed and permeabilized by incubation with 1 ml of 1% paraformaldehyde plus 1% Tween 20 for 15 min at 37°C. Cells were washed twice in PBS, resuspended in 1 ml of Ki67 staining buffer (anti-Ki67 PE or isotype PE antibody, PBS with 1% BSA and 0.5% Tween 20), and incubated for 30 min. Cells were washed twice and resuspended in 600 μl of PBS and analyzed on a Coulter XL flow cytometer.

Technical notes: Gating for Ki67-positive cells is accomplished by setting the region on the isotype control to less than 1% positive.

Comparison of Ex Vivo and In Vivo T-Cell Labeling Methods

An important question that should be addressed before drawing conclusions based on T-cell turnover data derived from whole blood is whether blood, a compartment that only contains about 2% of the total body T cells, is representative of major body compartments harboring the majority of T cells. To evaluate this, ex vivo BrdU incorporation was measured in CD4 and CD8 T cells in paired samples of freshly drawn blood and freshly isolated lymph nodes from 14 HIV-infected subjects (Fig. 1A). There was good correlation between the proliferation rates of the T cells in the blood and lymph nodes, implying that the measures in the blood are representative of division rates in the peripheral tissue.

Ex vivo BrdU incorporation in T cells was compared to Ki67 staining in a cross-sectional study of 56 blood samples that were isolated from healthy controls and HIV-infected subjects (Fig. 1B). Significant correlations existed between

ex vivo BrdU incorporation rates and Ki67 positivity in both CD4 and CD8 T cells, although the level of Ki67 was significantly lower in CD8 cells than it was in CD4 cells. Ex vivo BrdU incorporation was also compared to Ki67 staining in a longitudinal study of three HIV-infected subjects (Fig. 1C). High within-subject correlations were seen for CD4 T cells. These results show that Ki67 and ex vivo BrdU incorporation measure similar changes in proliferation rates and thus are qualitatively comparable despite yielding different absolute numbers. The difference in absolute numbers is due to BrdU being incorporated only into those cells going through S phase, while Ki67 is expressed in cells in late G_1, S, and G_2/M phases of the cell cycle whether the cell is actively dividing or not.

Two studies showed that ex vivo BrdU incorporation and Ki67 staining correlated with in vivo BrdU labeling levels. In the first study, ex vivo BrdU incorporation levels in CD4 and CD8 T cells determined in 14 subjects just before a 30-min BrdU administration were shown to correlate with peak in vivo BrdU incorporation levels (Fig. 2A); BrdU peaks in lymph node and blood T cells around day 1 and days 3 to 5, respectively, and is in approximately equal levels in both compartments after about 1 day (15). In a second study of six subjects infused with BrdU, levels of Ki67 staining in T cells were found to correlate with the in vivo incorporation of BrdU in T cells (Fig. 2B). Ex vivo BrdU incorporation and Ki67 measures are comparable to each other and to in vivo BrdU labeling, giving confidence that these methods measure similar biological events.

Comparison of in vivo deuterated-glucose labeling and in vivo BrdU incorporation showed high correlation between these methods. Figure 3 shows the results of a double-label infusion in which a subject was given deuterated glucose for 5 days, followed by a 30-min infusion of BrdU on day 5. Samples were collected longitudinally for 16 months. Deuterated-dA enrichment in genomic DNA of CD4 cells and in vivo BrdU incorporation levels in CD4 cells were determined. Decay rates of the two labels in CD4 T cells were similar (Fig. 3A) and are highly correlated (Fig. 3B).

Summary

A number of methods have been developed to measure T-cell turnover rates in HIV-infected subjects. Protocols for two ex vivo methods, BrdU incorporation and Ki67 staining, and two in vivo methods, BrdU incorporation and deuterated-glucose labeling, are described and shown to yield data that are well correlated. The main differences in studies of cell turnover in subjects with HIV infection come in the design and interpretation of in vivo kinetic models, despite the studies yielding similar raw kinetic data. Additional creative studies are required to test the various conclusions drawn from the in vivo modeling studies.

QUANTITATION OF THYMIC FUNCTION

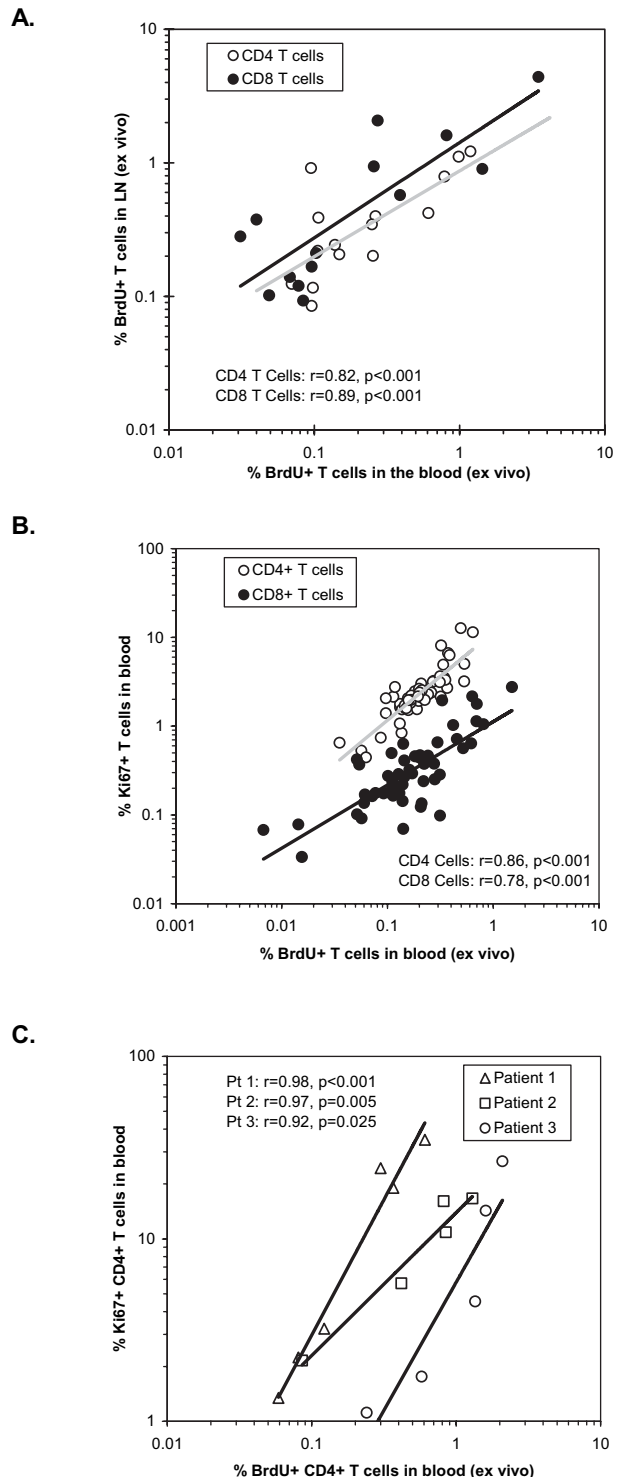
During maturation in the thymus, T cells undergo rearrangement of their T-cell receptor genes. The antigen recognition domains of the T-cell receptor are generated by site-specific somatic DNA recombination events. During the generation of a coding T-cell receptor chain chromosomal DNA, intervening DNA sequences are excised as episomal circles. These episomes, TRECs, are stable and persist in newly matured T cells; they do not replicate and are diluted out during mitosis of these cells or lost when these cells die. Quantitation of TRECs present in naive T cells is considered to be an accurate measure of thymic function.


FIGURE 1 Ex vivo methods of cell turnover are well correlated. (A) Ex vivo BrdU incorporation levels for CD4 and CD8 T cells correlated in paired samples from freshly isolated blood and lymph node suspensions from 14 subjects infected with HIV-1; (B) ex vivo BrdU incorporation correlated with Ki67 staining using the same blood samples from 56 individuals that were either healthy controls or infected with HIV; (C) ex vivo BrdU incorporation correlated with Ki67 staining in CD4 T cells from longitudinal blood samples taken once every day or two from three HIV-infected subjects.

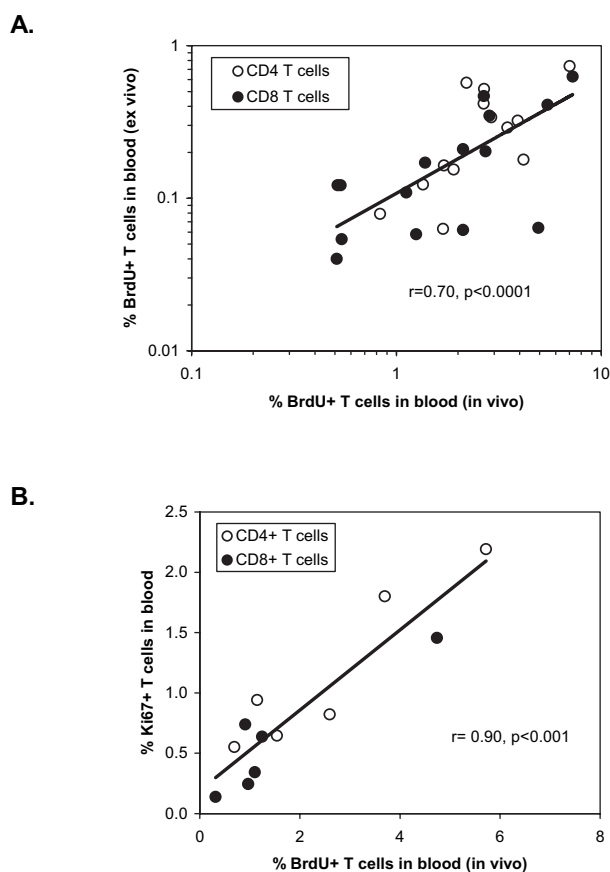

FIGURE 2 Ex vivo BrdU incorporation and Ki67 staining methods correlated with in vivo BrdU labeling. (A) Ex vivo BrdU incorporation levels in CD4 and CD8 T cells determined for 14 HIV-infected subjects just before a 30-min in vivo BrdU administration were shown to correlate with peak in vivo BrdU incorporation levels; (B) Ki67 T-cell staining levels were found to correlate with the in vivo BrdU T-cell incorporation levels in six HIV-infected subjects infused with BrdU.

The natural course of HIV-1 infection involves depletion of $CD4^+$ T cells and a continuous demand for production of $CD4^+$ T cells. Even though the thymus may shrink with age, recent data suggest that the thymus is still functionally active in adults. A desirable consequence of successful treatment of HIV infection is the restoration of thymic function. Therefore, laboratories interested in immune reconstitution during HIV treatment may find it helpful to use TRECs as a marker to assess thymic function (20).

TRECs in PBMCs and purified $CD4^+$ and $CD8^+$ cells may be quantitated by real-time PCR, based on the Taqman principle (http://www.appliedbiosystems.com/support/apptech/#rt_pcr) (9). Real-time PCR measures the amount of DNA present in the sample by PCR amplification as it occurs using a fluorescently labeled probe (Taqman probe). A probe, labeled with a fluorescent reporter dye at the 5′ end and a quencher dye at the 3′ end, is added to the PCR mixture along with the primers. The probe is designed to bind internally to PCR primers. When the probe is intact, the emission intensity of the fluorescent dye is reduced by the quencher dye. During PCR, while extending the primer, the DNA polymerase digests the probe and the fluorescent dye is

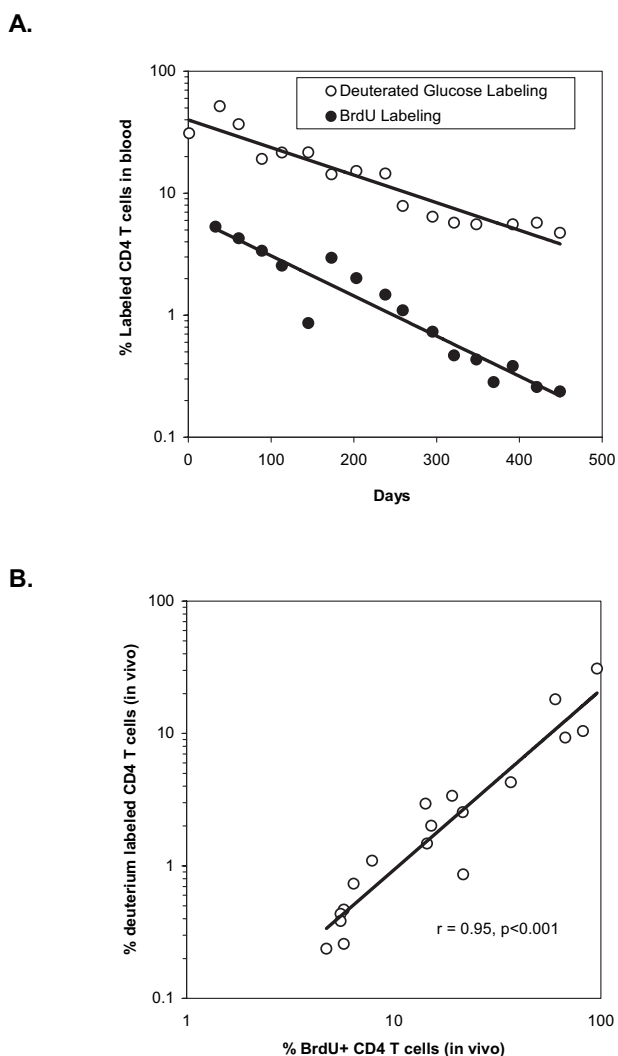

FIGURE 3 In vivo BrdU incorporation correlates with in vivo deuterated-glucose labeling in a double-labeling study. A 30-min infusion of BrdU and a 5-day continuous infusion of deuterated glucose were administered to an HIV-infected subject. (A) Samples were assayed for label incorporation and decay in CD4 T cells over a 1.5-year period; (B) in vivo BrdU incorporation and decay were highly correlated with incorporation and decay levels of deuterated glucose.

released from the quencher dye. The intensity of the fluorescence is proportional to the amount of DNA present in the sample. The cycle at which the fluorescence intensity is statistically significant at a point above the baseline value is designated as the threshold cycle. The level of TRECs in experimental samples is derived from a standard curve generated by plotting the log concentration of the standard against the threshold cycle (Fig. 4).

Equipment

Real-time PCR system (ABI Prism 7700 sequence detector)

Heat blocks at 65 and 95°C

Low-speed centrifuge

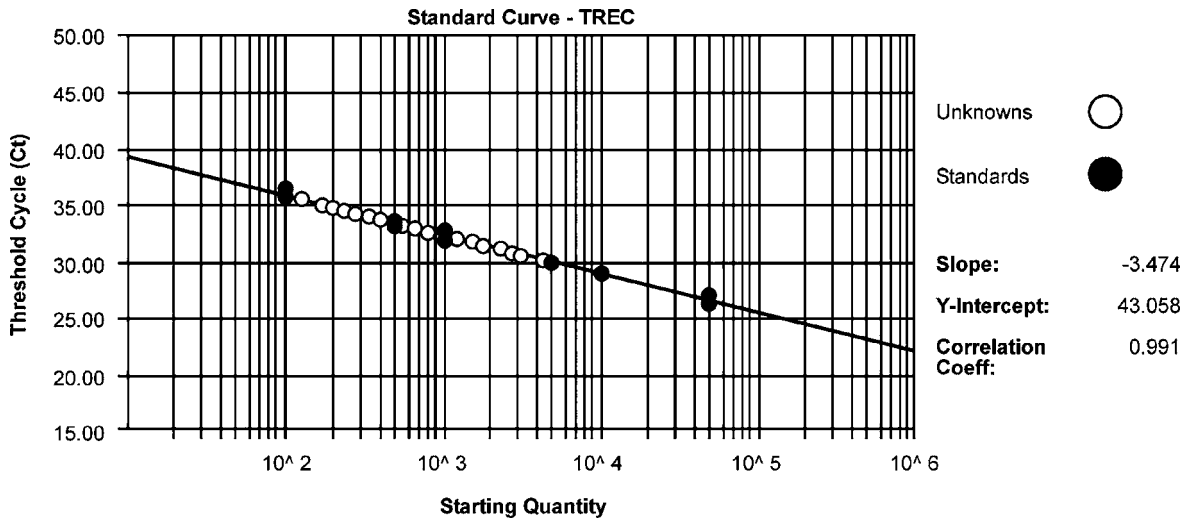
0.2-ml PCR tubes


FIGURE 4 Quantitation of TRECs in patient samples. Shown is a standard curve plotting log starting TREC copy number versus threshold cycle. The amounts of TREC in unknown samples were calculated from the standard curve by using ABI Prism 7700 software.

Reagents

Lysis buffer A: 10 mM Tris-HCl (pH 8.0), 100 mM KCl, and 2.5 mM $MgCl_2$

Lysis buffer B: 10 mM Tris-HCl (pH 8.0), 2.5 mM $MgCl_2$, 1% NP-40, and 1% Tween 20

Proteinase K (catalog no. 1964372; Roche Applied Science). Add proteinase K to a final concentration of 20 mg/ml to buffer B just before using buffer B.

Platinum Taq polymerase, 10× PCR buffer, 50 mM $MgCl_2$ (Invitrogen kit; catalog no. 10966-026), and 10 mM concentration of dNTP mixture (catalog no. 18427-013; Invitrogen).

Passive reference dye Blue 636 (Megabases Inc.)

PCR primers and probe: Primers and probe can be purchased from a number of vendors.

Reverse primer: 5′-GCCAGCTGCAGGGTTTAGG-3′

Forward primer: 5′-CACATCCCTTTCAACCAT-GCT-3′

Probe: 5′–6-carboxyfluorescein (6-FAM)–ACACCT-CTGGTTTTTGTAAAGGTGCCCACT-3′ carboxy-tetramethylrhodamine (TAMRA)

Jurkat cell line (American Type Culture Collection): Maintain in RPMI 1640 medium.

Plasmid standard: SJ plasmid that contains TREC sequence is used as a standard in PCR (19). This plasmid is diluted to 1 pg/μl (280,000 copies/μl) in water and stored as aliquots at −20°C. The plasmid is further diluted with Jurkat cell lysate for inclusions in PCR as a standard.

Lysis of patient and Jurkat cells:

(i) Suspend the cells in lysis buffer A (250 μl per million cells) and add an equal volume of lysis buffer B.

(ii) Mix equal volumes of lysis buffer A and B to use as a negative control.

(iii) Incubate at 65°C for 1.0 h in a heat block.

(iv) Incubate at 95°C for 15 min. The samples are ready to use for PCR or can be stored at 4°C. Long-term storage should be at −20°C.

PCR master mix (one reaction)

10× Platinum Taq buffer	10 μl
50 mM $MgCl_2$	7 μl
10 mM concentration each of dATP, dGTP, dTTP, and dCTP	2 μl
25 pmol of forward primer per μl	2 μl
25 pmol of reverse primer per μl	2 μl
7.5 pmol of probe per μl	2 μl
10 pmol of internal reference dye Blue 636 per μl	0.25 μl
5 U of Platinum Taq per μl	0.25 μl
water	24.5 μl

Master mix without Taq polymerase can be prepared in a large volume and stored in 1-ml aliquots at −20°C. Prior to using in PCR, thaw an aliquot and add Taq polymerase.

Procedure

1. Prepare dilutions of the plasmid (SJ) standard containing 100, 500, 1,000, 5,000, 10,000 and 50,000 copies of TREC in 50 μl of Jurkat cell lysate.

2. Add the following components to a 0.2-ml PCR tube.
   a. Master mix (50 μl)
   b. Patient sample or Jurkat cell lysate containing the standard plasmid (50 μl)

3. Set up patient samples in duplicate and the standard plasmid in triplicate. Also set up no-template controls without any input DNA by adding 50 μl of lysis buffer.

4. Using the ABI Prism 7700 software, enter the sample, standard, and no-template control information and load the plate with the corresponding tubes.

5. Perform the PCR with the following cycling conditions: 95°C for 5 min followed by 40 cycles at 95°C for 30 s and 60°C for 1 min.

6. Analyze the data with the ABI Prism 7700 (sequence detection) software and determine the TREC values in patient samples.

7. An example of TREC quantitation is shown in Fig. 4. If the sample has fewer than 100 copies of TREC per 50,000 cells, the amount of patient DNA sample added per reaction should be increased by purifying the DNA instead of using the cell lysate.

CRYOPRESERVATION AND THAWING OF PBMCs

The cryopreservation of PBMCs plays a significant role in the modern clinical research laboratory. For evaluating the cellular functions and immunophenotypes of patients, particularly during longitudinal studies, in which it is not possible to use fresh cells, cells from each time point can be cryopreserved and then assayed in batch at the completion of the study. The use of cryopreserved cells in this manner can significantly reduce the cost of performing assays and help to minimize assay variability. However, cryopreservation of patient samples can also affect the functions of some cells. The exact effect of cryopreservation on the tests of interest should be determined ahead of time. Another use of cryopreservation is to provide a consistent source of positive control donor cells for use in the standardization of LPAs, NK cell assays, and immunophenotyping of cells.

There are two basic methods for the cryopreservation of WBCs. In the first method, WBCs are mixed with medium containing serum and a cryoprotectant, such as dimethyl sulfoxide (DMSO). The cells are then immediately placed in a slow-freeze container (such as the "Mr. Frosty" Freezing Container, available from Nalgene [http://nalgenelab.nalgenunc.com/default.asp]), and stored in a −70°C freezer for 4 to 24 h. Upon freezing, the cells are transferred to a −135°C vapor-phase liquid-nitrogen freezer for long-term storage. Because of the variable rate of cooling that is inherent with this process, some laboratories may not achieve maximal cell recovery and cell viability with this method. The best method for cryopreserving WBCs is the controlled-rate method described below (25). Briefly, this method uses a controlled-rate freezing apparatus (such as a Cryomed Freezer, available from Thermo Electron Corp. [http://thermo.com/]) to gradually cool the cells at a controlled rate. Once the cells reach −90°C, they are transferred to vapor-phase liquid nitrogen for storage. The major advantage of using a controlled-rate freezing apparatus is that the device is programmed to compensate for the release of latent heat that occurs during the crystallization process, thereby improving cell viability. This method should consistently yields cell recoveries of >80% and cell viabilities of >85%. Cells frozen in this manner can be stored for years in liquid nitrogen and remain viable, although some functional activities may be compromised.

Several important factors must be considered when attempting to cryopreserve cells. The cryoprotectant DMSO must be added to the cells very slowly to allow the DMSO to penetrate the cells. The final concentration of DMSO should not exceed 7.5%. The cell-freezing medium should contain a final concentration of 10% FCS as an added protectant. Once the DMSO has been added, the cells should be kept at 4°C prior to freezing in order to avoid DMSO toxicity. After all samples are prepared for freezing, they must be immediately transferred to the controlled-rate freezer. After freezing, the cells must be quickly transferred to vapor-phase liquid nitrogen to minimize warming of the cells.

To recover the best possible functional activity of cryopreserved cells, a precise thawing method such as the one outlined below must be used. It is generally recognized that cryopreserved cells are initially more sensitive to mechanical stress than are fresh cells. Therefore, care must be taken to avoid rigorous pipetting and centrifuging of the cells during the thawing procedure. The most critical step in the procedure involves the dilution of DMSO from the cell suspension. A careful dropwise dilution of the DMSO with warm medium containing 20% serum is necessary to allow for

osmotic equilibrium of the cells. The cells should then be washed to completely remove the DMSO. Careful handling of these cells should result in maximum immunologic activity.

Since the freeze-thaw process may cause physiological and morphological changes to some cells, one should always assess the viability of cryopreserved PBMCs before using them in immunologic assays. Cell viability can easily be determined by the standard trypan blue dye exclusion method. Alternatively, one can use flow cytometry to simultaneously measure apoptosis and cell viability (14). In this method, cells are stained in combination with annexin V and propidium iodide. Non-apoptotic cells are negative for both annexin V and propidium iodide, apoptotic cells are positive for annexin V and negative for propidium iodide, and necrotic cells are positive for both propidium iodide and annexin V. To assess the validity of the cryopreservation procedure, PBMCs should be obtained from a healthy donor each day and included as a control each time patient specimens are frozen. Cell viability and recovery should be determined for each control. The viability of frozen cells obtained from healthy individuals should exceed 90%, and cell recovery should exceed 80%. If these parameters are not met, then all phases of the cryopreservation process should be evaluated for error.

Equipment

Low-speed centrifuge
37°C water bath
Controlled-rate freezing system (Thermo Electron Corp.)
Liquid-nitrogen freezer
2-ml polypropylene cryovials
15-ml round-bottom plastic tubes

Reagents

Freezing medium (RPMI 1640 plus 20% FCS, RPMI 1640 plus 15% DMSO, or RPMI 1640 plus 10% FCS plus 7.5% DMSO)
Thawing medium (RPMI 1640 plus 20% FCS)

Procedure for Preparing PBMCs for Cryopreservation

1. Separate PBMCs from heparinized peripheral blood by the Ficoll-Hypaque method.
2. Resuspend PBMCs in room temperature RPMI 1640 plus 20% FCS in half the desired final freezing volume (usually 0.5 ml).
3. Add dropwise an equal volume (0.5 ml) of 4°C RPMI 1640 plus 15% DMSO, giving a final freezing solution of RPMI 1640 plus 10% FCS plus 7.5% DMSO.
4. Transfer the cell suspension to a sterile cryovial and place it in a cryovial rack that is on ice in order to maintain vials at 4°C.
5. Prepare one control cryovial to regulate the controlled-rate freezer, using the same volume and concentrations as for the final freezing solution (usually 1 ml of complete RPMI 1640 plus 10% FCS plus 7.5% DMSO). Place the freezer thermocouple probe inside this cryovial.
6. Transfer cryovials immediately to the controlled-rate freezer and freeze them as follows.

Cryopreservation Procedure

The controlled-rate freezer should be precooled to a starting temperature of 4°C. Once the sample vials have been placed into the freezing chamber, the sample temperature and chamber temperature must be allowed to equilibrate to 4°C.

After equilibration, the freezing procedure must follow a defined set of rate kinetics. From the starting temperature of 4°C, the samples should be cooled to −4°C at a rate of −1°C/min. To compensate for the heat of fusion released during the crystallization process, the samples must then be supercooled to −42°C and allowed to warm to −9°C. From this point, the samples must be cooled to −35°C at a rate of −1°C/min and then cooled to −90°C at a rate of −5°C/min. After the samples have reached −90°C, they should be immediately transferred to vapor-phase liquid-nitrogen storage.

Procedure for Thawing Cryopreserved PBMCs

1. Remove cells from the freezer and immediately thaw them by gently shaking the vial in a 37°C water bath.

2. Remove the vial from the water bath just before the last ice crystal has melted.

3. Gently transfer the cell suspension to a 15-ml round-bottom plastic tube at room temperature.

4. Immediately add 2 drops of RPMI 1640 plus 20% FCS which is 1/20 the original volume (1 ml) to the cell suspension and mix gently (to start diluting DMSO).

5. Repeat the addition, doubling the number of drops each time, until the DMSO concentration is 3%. (For an initial volume of 1.0 ml, this occurs after five additions, when the total volume is 2.5 ml.)

6. Add 7.5 ml of medium to achieve a final 1:10 dilution of the sample.

7. Centrifuge the cell suspension for 10 min at no more than $200 \times g$.

8. Pour off the supernatant. Resuspend the cells gently in the appropriate medium; count and measure the viability of the cells.

Notes: (i) Do not thaw more than three vials at one time. (ii) Do not mix, vortex, or pipette the cells vigorously, since cells that have been frozen are initially more sensitive to mechanical stress than are fresh cells. (iii) Viability is usually >90%.

Quantitation of Viremia and Determination of Drug Resistance in Patients with Human Immunodeficiency Virus Infection

TAREK ELBEIK, HELENE HIGHBARGER, ROBIN DEWAR, VEN NATARAJAN, HIROMI IMAMICHI, AND TOMOZUMI IMAMICHI

96

In the current environment of human immunodeficiency virus type 1 (HIV-1) treatments under highly active antiretroviral therapy (HAART), not only an increase in the number of CD4$^+$ T lymphocytes but also a decrease in the level of plasma viremia (7, 13, 20, 41, 44) is expected; thus, it is essential to be able to quickly and accurately assess viral load. Several methods for quantitation of HIV-1 RNA in human plasma are outlined here. These are the Bayer Corporation Quantiplex HIV-1 RNA assay (branched-DNA [bDNA] assay), the Amplicor Roche Monitor assay, and the internally controlled virion PCR (ICVPCR). Although the different procedures may show good correlation and agreement, there is variability between assays not only within one subtype but also in the ability to quantify different HIV-1 subtypes. With some geographic regions experiencing an increased mixture of subtypes, intra-assay variability makes it preferable that patients be tested with the same assay throughout treatment (6, 31, 35).

Although the use of HAART has resulted in a decrease in virus replication in plasma to less than 50 copies/ml for prolonged periods in many patients with HIV-1 infection (27, 29), many lines of evidence have demonstrated that complete suppression of viral replication may not be possible with current HAART regimens (8, 12, 16, 21, 23, 28, 40, 48, 54, 55, 56). The persistence of low levels of ongoing viral replication may eventually lead to resistance. Continuous low-level viral replication, noncompliance issues, and gradual deterioration of the immune system have all contributed to the emergence of drug-resistant HIV-1 (32). HIV drug resistance presents another challenge for clinicians (5).

Until recently, the accepted approach to treating infected individuals with drug-resistant HIV-1 was thorough treatment history and viral load data. While initial resistance assays measured replication of the patient's viral isolate in culture with the presence of drug, these assays were highly labor-intensive, poorly reproducible, prone to variability, and insensitive; they required at least a month for results; and they were very expensive (36). Nonetheless, the demand for HIV-1 drug resistance assays increased as the numbers of patients failing HAART increased. As a result, commercially available HIV-1 resistance assays, incorporating innovative molecular technologies to overcome the handicaps of the earlier assays, have been introduced to address the needs of the treating clinician and the infected individual. We outline several commercially available resistance tests as well as a cloning-microculturing technique for measuring drug resistance.

HIV-1 RNA ASSAYS

Sample Collection and Processing

The HIV-1 RNA assays are performed on stored ($-70°C$) acid-citrate-dextrose- or EDTA-treated plasma. These anticoagulants show the least interference with amplification and detection (15). Plasma separation is achieved by centrifugation of whole blood at $500 \times g$ for 15 min.

HIV-1 RNA Quantitation Using bDNA

HIV-1 RNA is quantitated in plasma by bDNA signal amplification-based hybridization using the Quantiplex HIV-RNA assay kit in conjunction with the Quantiplex System 340 instrument according to the manufacturer's instructions (Bayer Corporation, Norwood, Mass. [formerly Chiron Diagnostics, Emeryville, Calif.]). These instructions are outlined below (Fig. 1). Virus is concentrated from 1-ml plasma specimens by centrifugation in a bench top microcentrifuge (Heraeus centrifuge model 17RS, rotor 3753) at $23,500 \times g$ for 1 h. The virus pellet is resuspended in a buffer containing proteinase K, capture probes, lithium laurel sulfate, and target probes complementary to the HIV *pol* gene and incubated at 63°C for 2 h. The extract is then spun, vortexed, transferred to microwells coated with capture probe, and placed in the automated Quantiplex 340 instrument. The RNA-probe complex is captured onto the surface of the microwell during a 63°C overnight incubation (16 to 18 h) via hybridization of the solid-phase capture probe with a subset of the target probes. The next day the wells are washed automatically and preamplifier molecules (added manually) are hybridized to the immobilized target-probe complex during a 30-min 63°C incubation, followed by another wash and 30-min 63°C hybridization of the bDNA amplifier molecules to the immobilized preamplifier complex. After another wash, multiple copies of alkaline phosphatase-labeled probes hybridize to each bDNA molecule during a 45-min 63°C incubation. The complex is then washed a final time and incubated for 30 min at 37°C with a chemiluminescent substrate (dioxetane), after which light emission is measured and analyzed by the Quantiplex System 340 and 340 Data Management System. The light emission is directly proportional to the amount of HIV RNA present in the plasma specimen. The concentration of RNA in each specimen is expressed as HIV-1 RNA copies per milliliter, determined from a standard curve, using β-propiolactone-treated virus in six known concentrations
FIGURE 1 Principle of the bDNA assay.

with a dynamic range of 50 to 500,000 RNA copies per ml of plasma. The bDNA assay is capable of detecting all HIV-1 subtypes, including subtype O.

Amplicor Roche Monitor Assay

The Roche Monitor assay is an in vitro nucleic acid amplification test for the quantitation of HIV-1 virus RNA present in most bodily fluids, including plasma, serum, and breast milk. The kit is supplied by Roche Diagnostic Systems, Indianapolis, Ind. The test can be used with either the standard or ultrasensitive specimen processing procedure. When the standard specimen processing procedure is used, the test can quantitate HIV-1 RNA over the range of 400 to 750,000 copies/ml. When the ultrasensitive specimen processing procedure is used, the test can quantitate HIV-1 RNA over the range of 50 to 75,000 copies per ml. There are two plates per kit, and 10 patient samples can be assayed per plate in addition to a positive and negative control. Before this assay can be purchased from Roche Diagnostic Systems, two things are required by Roche—first, that someone be trained in the use of the assay by a Roche Diagnostic Systems representative and, second, that the laboratory successfully perform a qualification assay set for certification.

The standard Roche Monitor assay procedure requires 200 μl of plasma, while the ultrasensitive assay procedure requires 500 μl of plasma. RNA is extracted by using guanidium thiocyanate and isopropanol. The use of an internal quantitation standard (IQS) monitors the efficiency of extraction and amplification and eliminates the need for a standard curve. The IQS RNA transcript has the same *gag* primer binding sites for SK-462 and SK-431 as the HIV-1 virus target RNA and the same size and base composition as the HIV-1 virus target but possesses a non-HIV-1 probe region. The amplification efficiency is monitored internally in each sample since the amplification efficiency of the IQS will be equivalent to that of the HIV-1 target RNA. The IQS is noncompetitive and does not interfere with the amplification of the HIV-1 RNA; it yields a quantitative value over a 4-log dynamic range (45).

To minimize the possibility of cross-contamination of samples with amplicon, target DNA, or target RNA, the assay process is performed in four physically distinct locations with the flow being one way. The areas are reagent preparation, sample preparation, amplification, and detection-analysis. In addition, the use of uridine instead of thymidine in the amplification reaction has allowed the use of

uracil-N-glycosylase (42) to help minimize the possibility of uridine-containing amplicon carryover from specimens previously amplified. The following procedure describes the use of the quantitative HIV-1 RNA Amplicor Roche Monitor assay, including reagent preparation, processing of whole-blood specimens, amplification, and detection-analysis by enzyme-linked immunosorbent assay.

Reagent Preparation

1. Add 100 μl of manganese solution containing pink dye to one tube of master mix. The master mix and manganese solution are provided in single-use vials, sufficient for 12 tests, and up to three runs can be done simultaneously with one positive and negative control.

2. Pipette 50 μl of working master mix to each PCR tube. Amplification must begin within 4 h of preparation of the working master mix.

3. Prepare 70% ethanol using diethylpyrocarbonate-treated water, and aliquot 100% isopropanol.

4. For each batch of 12 samples, prepare the working lysis reagent by adding the indicated volume (varies by lot) of HIV quantitation standard RNA (QS RNA) to one bottle of the lysis reagent. Vortex well.

Standard Assay Specimen Preparation

1. Dispense 600 μl of working lysis reagent into each 1.5-ml Sarstedt screw-cap conical tube.

2. Thaw plasma specimens at room temperature. Vortex each sample for 5 s, and then add 200 μl of plasma or control to each labeled tube containing the working lysis reagent.

3. Vortex for 5 s and incubate the tubes for 10 min at room temperature.

4. Add 800 μl of 100% isopropanol to each tube. Re-cap the tubes, and mix contents thoroughly by inverting the tubes 5 to 10 times and vortexing for 5 s.

5. Centrifuge samples at $16,000 \times g$ with the Heraeus centrifuge for 15 min at room temperature. Remove the samples from the rotor immediately, and proceed. Do not let the samples sit following centrifugation, or you will lose the pellets.

6. Beginning with the control tubes, carefully draw off the supernatant without disturbing the pellet by using a fine-tip disposable pipette. The pellet may not be obviously visible or at best will appear translucent. If the pellet is disturbed, you may repeat the centrifugation.

7. Add 1.0 ml of 70% ethanol to each tube, vortex for 5 s, and repeat steps 5 and 6.

8. Add 400 μl of specimen diluent to each pellet, and vortex vigorously for 10 s to resuspend the pellet, which contains the extracted RNA. RNAs should be amplified or frozen immediately. For short-term storage, −20°C is adequate; however, for long periods, −80°C is preferred.

9. Pipette 50 μl of the RNA prepared from controls and patient specimens into the appropriate MicroAmp tubes.

Ultrasensitive Assay Specimen Preparation

1. Thaw plasma specimens at room temperature, and then add 500 μl of each patient specimen to the appropriately labeled 1.5-ml Sarstedt screw-cap conical tube.

2. For each negative and positive control, add 500 μl of normal human plasma to each appropriately labeled tube.

3. Centrifuge specimen and control tubes containing normal human plasma at 23,600 × g at 2 to 8°C for 60 min.

4. Remove as much liquid as possible without disturbing the pellet. Withdraw the supernatant slowly, allowing the liquid to drain completely off the sides of the tube. *Do not use vacuum aspiration.*

5. Dispense 600 μl of ultrasensitive assay working lysis reagent into each tube.

6. For each negative and positive control, add 12.5 μl of HIV-1 (−) C, HIV-1 L (+) C, and HIV-1 H (+) C to the appropriately labeled tubes.

7. Cap and vortex each sample for 5 s following addition of lysis reagent.

8. Incubate the tubes for 10 min at room temperature.

9. Add 600 μl of 100% isopropanol to each tube. Re-cap the tubes, and mix contents thoroughly by inverting 5 to 10 times and vortexing for 5 s.

10. Centrifuge samples at 16,000 × g with the Heraeus centrifuge for 15 min at room temperature.

11. Beginning with the control tubes, carefully draw off the supernatant without disturbing the pellet by using a fine-tip disposable pipette. The pellet may not be obviously visible or at best will appear translucent. If the pellet is disturbed, you may repeat the centrifugation.

12. Add 1.0 ml of 70% ethanol to each tube, vortex for 5 s, and repeat steps 10 and 11.

13. Add 100 μl of specimen diluent to each pellet, and vortex vigorously for 10 s to resuspend the pellet, which contains the extracted RNA.

14. Pipette 50 μl of the RNA prepared from controls and patient specimens into the appropriate MicroAmp tubes, and move to the amplification and detection area.

PCR Amplification

1. Place the MicroAmp reaction tray in a Perkin-Elmer thermocycler (model 9600), and run the following program.

Hold:	2 min at 50°C
Hold:	30 min at 60°C
Cycle (4 cycles):	10 s at 95°C, 10 s at 55°C, and 10 s at 72°C
Cycle (26 cycles):	10 s at 90°C, 10 s at 60°C, and 10 s at 72°C
Hold:	15 min at 72°C

2. After amplification, immediately pipette 100 μl of the Monitor denaturation solution to each PCR tube, and mix by pipetting up and down five times. The denatured amplification reaction products should be held for no more than 2 h at room temperature before proceeding to detection. If detection of the amplicon cannot be performed within 2 h, store the denatured amplification reaction products at 4°C. Under these conditions the denatured amplicon is stable for up to 1 week.

Detection and Analysis

1. Remove the appropriate number of both target and QS microwell strips, and place them into a microwell frame.

2. Pipette 100 μl of HIV Monitor hybridization solution into each well of the microwell plate (MWP). Rows A to F of the HIV Monitor MWP are coated with the HIV-specific oligonucleotide probe; rows G and H are coated with the QS-specific oligonucleotide probe.

3. Add 25 μl of denatured amplification reaction product from the first row of the amplification tray into the first row of HIV wells. Mix by pipetting up and down five times, and then transfer 25 μl to the next row of wells. Repeat this procedure four more times, so as to generate five fivefold dilutions (neat, 1:5, 1:25, 1:125, 1:625, and 1:3,125) in rows A through F. Remove and discard 25 μl from row F after mixing.

4. Add 25 μl of the same amplicon from the first row of the amplification tray into the first row of the IQS wells (row G). Mix by pipetting up and down five times, and then transfer 25 μl of this dilution to the next row (row H) of wells (1:25). Remove and discard 25 μl from row H after mixing. Incubate for 1 h at 37°C.

5. Wash each MWP five times with working wash solution.

6. Add 100 μl of avidin-horseradish peroxidase conjugate to each well, and incubate for 15 min at 37°C. Wash the MWP as described in step 5.

7. Add 100 μl of working substrate to each well.

8. Allow color to develop for 10 min at room temperature (20 to 25°C) in the dark (lab drawer).

9. Add 100 μl of stop solution to each well.

10. Start the data capture and analysis program using either an Excel or Lotus spreadsheet supplied for this purpose by Roche Molecular Systems. Measure the optical density (OD) at 450 nm on the plate reader.

11. The actual HIV copy number per milliliter of sample is calculated in the following manner. First determine the OD value and sample amplicon dilution that yields an OD value next above a 0.2-OD cutoff. Also determine the OD value and QS amplicon dilution that yields an OD value next above a 0.3-OD cutoff. Subtract a standard empirically determined background OD value of 0.07 from each of the assay OD values, and multiply each of the resulting OD values by their respective dilution factor. Divide the resulting calculated sample value by the value calculated for the QS internal standard. This value represents the efficiency of the amplification of the sample relative to the input QS. This value is multiplied by the number of initial input QS RNA copies, and the result is the total HIV-1 RNA copies in 25 μl of starting plasma. This value (copies per PCR) is multiplied by 40 (if performing a standard assay) or by 4 (if performing an ultrasensitive assay) to get the number of PCR copies per milliliter of plasma. The Roche Amplicor Monitor assay has a 4-log dynamic range and detects from 400 to 750,000 HIV RNA copies per ml with the standard sample preparation procedure and from 50 to 75,000 HIV RNA copies per ml with the ultrasensitive sample preparation procedure. Roche Amplicor version 1.5 is currently marketed outside of the United States for the detection of non-B subtypes of HIV-1.

QUANTITATION OF HIV-1 RNA BY INTERNALLY CONTROLLED PCR

PCR has been used to quantitate levels of RNA and DNA from a variety of samples. With clinical specimens, the presence of inhibitors of PCR and small variations in amplification efficiency between different samples make it difficult to accurately estimate the amount of the specific sequence present in the starting material (3, 10). To avoid these problems, an internally controlled competitive PCR procedure can be used (25). In this method, various known amounts of an internal standard that shares the same primers as the target RNA but that contains either a deletion or an insertion are added to equal aliquots of the sample containing the unknown target sequence. The internal standard and the target sequence compete equally for primer binding and amplification in the PCR. Variables such as the efficiency of amplification and the number of cycles will have the same effect on both templates. Equal amounts of products will be formed when the initial concentrations of the templates are equal. Experimentally, the ratio of products formed can be determined, and the equivalence point can be calculated. This method has been successfully employed to quantify the amount of HIV-1 RNAs in clinical samples (9, 52). This method, however, does not control for the variable loss of RNA during purification steps. It has been estimated that, on average, 36% of the RNA sample can be lost due to the extraction procedures used (44).

An alternative method for measuring the HIV-1 RNA in patients' plasma or sera uses an infectious mutant virus as an internal control (49). The mutant virus, VX-46, has a 25-bp insert in a conserved region between the primer binding and major splice donor sites. To utilize this virus as an internal control, different dilutions of this virus are added to aliquots of the plasma or serum sample to be measured, and RNA is isolated and reverse transcribed to cDNA. PCR is performed with primers selected to include the sequences on either side of the insert contained in the externally added virus. The DNA product from the control virus is 25 bp longer than that from the virus present in plasma. The amount of viral RNA present in a plasma sample is calculated after the PCR-amplified products are separated by gel electrophoresis. This ICVPCR assay eliminates errors introduced by variable recovery during the RNA purification step, and thus the accuracy of the assay is enhanced. This method can also be applied to other DNA or RNA viruses.

Oligodeoxyribonucleotide Primer and Probe Sequences

Primer designation	Sequence 5′ → 3′
ICVPCR-9 (reverse transcription-primer)	TCCCTGCTTGCCCATACTA
ICVPCR-16 (+strand)	ATCTCTCGACGCAGGACT
ICVPCR-17 (−strand)	GCTCTCGCACCCATCTCT
ICVPCR-18 (probe)	ACTAGCGGAGGCTAGAAGGA

RNA Isolation and cDNA Synthesis

Sample (200 μl) is mixed with 400 μl of 6.0 M guanidium thiocyanate, 60 μl of 2.0 M sodium acetate (pH 4.0), and 600 μl of phenol-chloroform-isoamyl alcohol (25:24:1). The samples are mixed after each addition, incubated on ice for 20 min, and centrifuged at room temperature for 20 min. The aqueous phase is aspirated and mixed with 10 μg of carrier RNA (Sigma Chemical Co., St. Louis, Mo.) and precipitated with an equal volume of isopropanol. Prepare guanidium thiocyanate in 42 mM sodium citrate buffer,

pH 4.0, containing 0.83% sodium lauroylsarcosine and 0.2 mM β-mercaptoethanol.

RNA recovered by centrifugation is washed with cold 70% ethanol and dissolved in 8 μl of water and is used for cDNA synthesis in a 20-μl reaction mixture with a cDNA cycle kit obtained from Invitrogen Corporation (San Diego, Calif.) using ICVPCR-9 as the primer for reverse transcription.

PCR Amplification

cDNA (5 μl) is used in a reaction mixture containing 10 mM Tris-HCl (pH 8.3), 50 mM KCl, 1.5 mM MgCl$_2$, 0.001% gelatin, 0.2 mM deoxynucleoside triphosphates (dNTPs), 25 pmol each of primers ICVPCR-16 and -17, and 2.5 U of AmpliTaq DNA polymerase (Perkin-Elmer) in a final volume of 50 μl. Amplification is carried out in a Perkin-Elmer thermocycler (model 9600) with the following PCR cycle program: 1 cycle at 94°C for 60 s, 55°C for 10 s, and 72°C for 30 s; 30 cycles at 94°C for 15 s, 55°C for 30 s, and 72°C for 60 s; and a final incubation at 72°C for 10 min.

Analysis of the PCR Product by Liquid Hybridization

Liquid hybridization is carried out as described in reference 17a, with oligonucleotide ICVPCR-18 as a probe. Hybridized PCR products are analyzed on 10% polyacrylamide gels. The amount of radioactivity present in each band is quantitated with a Bio-Image analyzer (37). We use Fuji Medical Systems (Stamford, Conn.) BAS1000.

Estimation of RNA Present in a VX-46 Virus Preparation

The amount of RNA in a VX-46 virus preparation is estimated using a competitor plasmid (pA1) containing the pNL4.3 nucleotide sequences (GenBank accession no. M19921) from positions 501 to 1448. cDNA from VX-46 virus is PCR amplified in the presence of different amounts of plasmid pA1. The PCR product is hybridized with ICVPCR-18 labeled at the 5′ end with ^{32}P and then is separated in an acrylamide gel. The primers selected should generate 123- and 148-bp DNA PCR products from the wild-type and mutant viral sequences, respectively. The amounts of radioactivity in the specific bands are determined, and the ratios between the amounts of radioactivity present in wild-type and mutant DNA bands are plotted against the amount of input wild-type competitor plasmid DNA. The copy number of the mutant viral RNA is calculated from the plot for the ratio of 1 between the amount of radioactivity present in wild-type and mutant DNA bands.

ICVPCR To Determine the Level of HIV-1 RNA in Plasma

By using this standardized VX-46 virus as the competitor during the RNA isolation, the amount of HIV-1 viral RNA in patients' plasma can be estimated. Aliquots (100 μl) of serial dilutions of the mutant virus, VX-46, that span the estimated range are added to 100 μl of patient plasma or serum. Commonly, about four dilutions are sufficient to determine the equivalence point between the mutant and sample viral RNAs in PCR. If the equivalence point cannot be determined by these dilutions, the amount of the added mutant virus is adjusted.

RNA extracted from the samples containing patient serum and the added mutant virus is used for cDNA synthesis and for PCR, and the PCR products are analyzed as described above. The amount of radioactivity present in each band is estimated, and the ratio of radioactivity present in mutant
FIGURE 2 ICVPCR for the estimation of HIV-1 RNA in patient plasma. (A, B, and C) Different dilutions of mutant virus (VX-46) containing 0 pg (lane 1), 30 pg (lane 2), 3 pg (lane 3), 0.3 pg (lane 4), and 0.03 pg (lane 5) of p24 antigen were added to 100 μl aliquots of patients' plasma. RNA isolation, cDNA synthesis, and PCR were carried out as described in the text. The sizes of DNA products from the mutant (148) and wild type (123) are shown on the right. Each panel is for plasma from one of three different patients. (D) Estimation of HIV-1 RNA in patients' plasma. Patient 1 (triangles) had 10,000 copies, patient 2 (squares) had 7,600 copies, and patient 3 (circles) had 16,000 copies of RNA in 100 μl of plasma.

DNA bands to that in the wild-type (patient) DNA bands is plotted against the input mutant viral RNA. The amount of viral RNA present in the patient sample is calculated from the plot for the ratio of 1 between the amount of radioactivity present in patient and mutant DNA bands (Fig. 2).

The mutant virion can play the roles of both a control for the RNA extraction procedure and a source of competitive RNA template in the PCR. Any inhibitors present in the sample that will affect the cDNA synthesis and/or PCR will affect equally the product formed from the RNA present in the sample as well as the mutant viral RNA, thereby increasing the accuracy of the PCR quantitation. This method also could provide a guide for determining if an inhibitor of reverse transcriptase PCR (RT-PCR) is present in the sample, thus suggesting the use of a procedure to remove the inhibitor.

RESISTANCE TESTING

Technologies Used for HIV-1 Genotypic and Phenotypic Resistance Assays

Resistance assays are divided into two groups—genotypic and phenotypic—and are directed toward the analysis of the protease (*pro*) and the RT (*rt*) genes. However, several research groups are utilizing these assays to evaluate mutations within the group specific antigen (*gag*) gene and correlation to drug resistance (13, 19, 24, 47, 57).

The genotypic assays provide sequencing information that can be used to identify known resistance codons. The phenotypic assay, a function-based system, derives resistance data from the expression of the patient's viral isolate in the presence of drug in vitro. Also included under phenotypic assays is the virtual phenotype (extrapolates a phenotypic result through comparison of the genotype to matched genotype-phenotype resistance profiles) and replication capacity

(a component of viral fitness). Finally, online services available to analyze HIV-1 sequences for genotypic drug resistance are addressed.

Genotypic Resistance

There are currently three commercially available systems that are in use: GeneSeq (ViroLogic, South San Francisco, Calif.), TRUGENE (Bayer HealthCare LLC, Tarrytown, N.Y.) (38), and ViroSeq (Celera Diagnostics, Alameda, Calif.) (11). GeneSeq is a service provided by ViroLogic and is not available in a kit format, while TRUGENE and ViroSeq are obtainable in a kit format and available for setup in clinical and research laboratories.

TRUGENE and ViroSeq involve similar technical steps that require a highly adept group of technologists for successful operation. TRUGENE and ViroSeq are approved for use on HIV-1 subtype B; however, several groups demonstrate reduced performance, by 25 to 50%, on non-B subtypes, including failed RT-PCR or partial bidirectional sequences (2, 18, 22, 35, 43). In comparative studies, ViroSeq performs better than TRUGENE on non-B subtypes (2, 22); however, use of prototype primers improves the performance of TRUGENE (35).

GeneSeq HIV

ViroLogic offers the in-house HIV-1 genotypic drug resistance assay GeneSeq HIV. A patient plasma sample with ≥500 copies of HIV-1 RNA/ml is submitted to ViroLogic or one of the approved laboratories for in-house testing. GeneSeq HIV utilizes dideoxy sequencing technology (see "ViroSeq" below), and the resulting patient genotype is analyzed with ViroLogic's algorithm to determine the patient HIV-1 drug resistance profile. The subtype is also reported; however, there are no peer-reviewed publications on the performance characteristics of GeneSeq HIV on non-B subtypes. Additional

information on GeneSeq HIV can be obtained from the ViroLogic website (http://www.virologic.com).

TRUGENE

TRUGENE has been cleared by the Food and Drug Administration for in vitro diagnostic use with the OpenGene DNA sequencing system. TRUGENE provides all components required to genotype the HIV-1 *pro* and *rt* genes for drug resistance, including those for RT-PCR and sequencing of a total of 30 genotyping reactions (four clinical samples and one positive and one negative control per reaction plate, or a total of 23 clinical samples and seven controls when run in batch). It does not, however, contain reagents necessary for HIV-1 RNA extraction and purification, which must be purchased separately. It is recommended to process six samples in one batch (four clinical samples and one positive and one negative control) for each RT-PCR set. The lower limit of detection for TRUGENE is 1,000 copies of HIV-1 RNA per ml and has been approved for diagnostic sensitivity only to HIV-1 subtype B.

Long-Read Tower and MicroGene Clipper sequencers, computer, Gel Toaster gel units, disposable MicroCel acrylamide gel cassettes, and sequencing software are purchased separately from Bayer HealthCare LLC. All other hardware (thermal cyclers and microcentrifuges) and disposables (reaction tubes, 96-well plates, aerosolized tips, etc.) are purchased by the operator. Bayer HealthCare LLC does not provide an HIV-1 RNA extraction kit; however, various extraction methods produce HIV-1 RNA samples compatible with the TRUGENE HIV-1 genotyping kit (see "Extraction and Purification of HIV-1 RNA" below).

Three physically defined areas are recommended for this procedure: area 1, RNA preparation; area 2, reagent preparation; and area 3, sequencing and detection. A unidirectional flow from area 1 to area 2 to area 3 is required; i.e., one cannot backtrack from area 3 to area 2 or area 1 in the same day.

All technical procedures require strict adherence to techniques for working with RNA: aerosolized tips; cleaning down of all surfaces with 10% bleach followed by 70% ethanol, and frequent use of clean, powder-free gloves and lab coats; and ensuring that all disposables and reagents are RNase free. The negative control is a Tris-HCl buffered solution containing wheat germ tRNA. The positive control contains noninfectious HIV-1$_{BH10S}$ transcripts diluted in a negative control. While RNA is extracted and purified from the clinical plasma samples using any one of the recommended techniques (see below), neither positive nor negative controls are subjected to RNA extraction.

Extraction and purification of HIV-1 RNA.

Purified HIV-1 RNA from plasma with a viral load of ≥1,000 copies of HIV-1 RNA per ml can be obtained by the following approved extraction procedures using the Qiagen QIAamp Viral RNA minikit, Qiagen Ultra HIV-1 RNA extraction method, Roche Amplicor HIV-1 Monitor test, Roche Amplicor HIV-1 Monitor with ultrasensitive specimen preparation, or Organon-Teknika NASBA NucliSens HIV-1 QT nucleic acid solution reagents.

Adaptations of each method, if needed, are listed in the Bayer HealthCare LLC TRUGENE package insert, and limits of recovery for each extraction method are listed in the corresponding manufacturer product package insert. The extracted HIV-1 RNA should be immediately placed on wet ice and either used the same day or frozen at −70°C for future use (i.e., for next-day setup).

RT-PCR amplification. A two-step single-tube RT-PCR is used to amplify a 1.3-kb sequence of the *pro* and *rt* regions (*pro* codon 1 through *rt* codon 333). Master mix I (primers and deoxynucleotides) for six samples is prepared in a 0.5-ml sterile RNase-free tube on wet ice (42.0 μl of RT-PCR primers, 10.5 μl of dNTP solution, 7.0 μl of dithiothreitol [DTT] solution, and 3.5 μl of RNase inhibitor), vortexed for 5 s, and microcentrifuged for 5 s. Aliquots (9.0 μl) of master mix I are dispensed into six 0.2-ml individual (not strip) prelabeled thin-wall PCR tubes and stored on wet ice. Master mix II (enzymes and buffer) is similarly prepared in a 0.5-ml sterile RNase-free tube on wet ice (70 μl of RT-PCR buffer, 3.5 μl of RNase inhibitor, 7.0 μl of reverse transcriptase enzyme, and 17.5 μl of DNA polymerase), vortexed for 7 to 10 s, and microcentrifuged for 7 to 10 s. Master mix II is held in wet ice but must be used within 15 min. Both master mixes I and II, as well as the samples and controls, are transferred, on wet ice, to a dead-air box in area 3, and the thermal cycler is prewarmed to 90°C. While maintaining the thin-walled PCR tubes containing master mix I on wet ice, 17.0 μl of each sample, including both positive and negative controls, is added to its corresponding tube and simultaneously mixed using the pipette. The tubes are capped and transferred to the thermal cycler, and cycling is commenced at 90°C for 2 min, followed by 50°C for 60 min. After 5 min at 50°C, the tubes are uncapped, 14.0 μl of master mix II is added, and the tubes are re-capped. Program the thermal cycler prior to setting up the RT reaction as follows.

One cycle of:	90°C for 2 min (tubes paced in thermal cycler), 50°C for 60 min (add master mix II after 5 min at 50°C), and 94°C for 2 min
20 cycles of:	94°C for 30 s, 57°C for 30 s, and 68°C for 2 min
17 cycles of:	94°C for 30 s, 60°C for 30 s, and 68°C for 2.5 min
One cycle of:	68°C for 7 min and hold at 4°C (for a maximum of 24 h, or similarly in the fridge at 2 to 8°C for 24 h)

Sequencing reaction (CLIP). Four sets of primers—two sets within *pro* (protease and P2 primer pairs) and two sets within *rt* (RT-beginning and RT-end)—are used for the sequencing reaction. Each primer set generates a bidirectional sequence of the identical region, thus allowing for cross-checking during sequence analysis.

A 96-well sequencing tray (or 96-well plate containing 0.2-ml thin-walled 12-well strip tubes) is used for a total of six samples (four primer sets per sample, with a total of 16 reactions per sample). Bayer HealthCare LLC recommends that the positive and negative controls be included in each run. The sequencing tray is labeled vertically (plate orientation with columns of 12 wells and rows of 8 wells) with the reaction primers' designations so that the first 4 wells of row 1 are for protease and the remaining four wells (wells 5 to 8) of row 1 are for RT-beginning. The first four wells of row 2 are for RT-middle, and the remaining four wells (wells 5 to 8) of row 2 are for P2. Hence, each sample (or control) tested will occupy two rows of 16 wells. Using a 100-μl repeat pipettor, 7 μl of CLIP terminator mix (A, C, G, and T; columns 1 and 5, 2 and 6, 3 and 7, and 4 and 8, respectively) is added to the respective well for each primer.

CLIP master mix is prepared with 474 μl of DNase-free water, 120 μl of CLIP buffer, and 22.5 μl of CLIP enzyme; gently vortexed for 7 to 10 s; and placed on ice. An aliquot

of 95 μl of CLIP master mix is transferred to each of six 0.5-ml microcentrifuge tubes. Tubes containing the CLIP master mix and the plate containing CLIP terminator mix are held on ice in area 3.

An aliquot of 5 μl of RT-PCR product from the samples or the negative or positive control is transferred to the corresponding tube containing CLIP master mix. Each tube is vortexed for 5 s, microcentrifuged for 5 s, and transferred to ice. An aliquot of 5 μl from each tube is transferred to the appropriate well in the 96-well plate, capped, and placed in a preheated thermal cycler set at 94°C. The cycling conditions are as follows.

One cycle of:	94°C for 5 min
30 cycles of:	94°C for 20 s, 56°C for 20 s, and 70°C for 1.5 min
One cycle of:	70°C for 5 min
4°C hold	

All reactions are terminated with the addition of 14 μl of stop loading dye to each well of the 96-well plate. The plate is vortexed gently for 7 to 10 s to ensure proper mixing. The plate is either placed on ice prior to electrophoresis or stored overnight at 2 to 8°C.

Electrophoresis and data analysis. Acrylamide gels are prepared using kit products. One SureFill cartridge (containing a 6% acrylamide gel) is brought to room temperature. During this time the Long-Read Tower power is turned on, including the computer workstation. From the GeneObjects software, select "Create New Run." In the "Preference" menu, set the following parameters: heterozygosity to partial (20%), peak distance at 7 to 10, automatic basecalling and automatic save assay, and save run. In "Run Information," set the appropriate database and then the Long-Read Tower, and select "Connect." In "Sequencer Control," select the following parameters: gel temperature, 60°C; gel voltage, 2,000 V; laser power, 50%; run clock (sampling interval), 0.5 s; and run clock (run duration), 50 min.

Press "Go" and select "Prerun." Insert splash guard into the bottom of the fill fixture unit. Attach the SureFill 6% sequencing gel cartridge to the Gel Toaster polymerization unit, making sure that there are no air bubbles in the connection tube. Insert the Softplug comb into the MicroCel 500 cassette, secure with clips provided, and place a strip of Scotch tape (not shiny tape, as it will prevent polymerization) across the plate, just below the comb, to prevent acrylamide from seeping onto the glass plate. The assembled cassette is placed in the Gel Toaster polymerization unit, and the cassette is filled with acrylamide. The Gel Toaster polymerization unit is turned on for 3 min to photopolymerize the acrylamide, after which the Softplug comb and the Scotch tape are removed. Make sure there are no bubbles in the gel; generate a new gel if bubbles are detected. The cassette is placed in the Long-Read Tower with 1× Tris-borate-EDTA in the upper and lower chambers. The gel is prerun for 5 to 10 min, but no longer than 10 min, prior to loading the samples. The prerun is completed when the "Run" and "Prerun" lights on the Long-Read Tower are illuminated.

During prerun, the samples (one sample or control of 16 reactions per gel) are denatured in the 96-well plate using a thermal cycler for 1 min at 85 to 95°C and immediately transferred to wet ice. Immediately prior to loading samples, the residual urea and air bubbles are removed from the MicroCel wells by flushing with 1× Tris-borate-EDTA using a transfer pipette or a syringe. A 1.5-μl aliquot of each denatured sample is transferred to the MicroCel wells using an

eight-cylinder expandable multichannel pipettor. The reaction aliquots are added in the same manner as with the plate format; the first eight reaction aliquots include protease and RT-beginning of sample 1, row 1, the second eight reaction aliquots include RT-middle and P2 of sample 1, row 2, and so on. The condensation cover is placed on the upper buffer chamber, the door is closed, and pressing "Go" commences the sequencer and data collection.

Upon completion of the sequencing run, the data are assessed for quality. Acceptable data include strong signal, low background, and even peaks. Differences in nucleotide sequence of the sample are compared to the reference sequence of HIV-1$_{LAV-1}$. The final sequence result is based upon RT-beginning, RT-middle, and either protease or P2 but not both (the better signal generated by either protease or P2 should be used). The software translates all known mutations identified from the sample to the corresponding drug resistance profile. Novel mutations are also identified. Additional information is available at http://www.trugene.com.

ViroSeq

ViroSeq has been cleared by the Food and Drug Administration for in vitro diagnostic use with ViroSeq HIV-1 Genotyping System Software version 2.6 on the following platform: ABI Prism 377 DNA sequencer (no longer manufactured), ABI Prism 3100 genetic analyzer, ABI Prism 3100-*Avant* genetic analyzer, or ABI Prism 3700 DNA analyzer.

ViroSeq consists of four modules, including the sample preparation module, RT-PCR module, sequencing module, and 8E5 control module, for a total of 48 genotyping reactions. This translates into 46 clinical samples, one negative control, and one positive control if the entire kit is used in one go; otherwise, split into separate batches (up to four), each requiring one positive and one negative control. To optimize work flow and operating efficiency, it is recommended that operators configure test batches in multiples of 12.

The lower limit of detection for ViroSeq is 2,000 copies of HIV-1 RNA per ml, is intended for use on samples with a viral load between 2,000 and 750,000 copies/ml, and has been approved for diagnostic sensitivity only to HIV-1 subtype B. The entire HIV-1 *pro* region from codons 1 to 99 and two-thirds of *rt* from codons 1 to 335 are genotyped.

ViroSeq kits are purchased from Abbott Diagnostics, while platforms and sequencing software, as well as certain disposables and specialty reagents (96-well plates, polymer, BigDye Terminator version 1.1 sequencing standard, and Hi-Di formamide), are purchased directly from Applied Biosystems or through Abbott. The assay should be performed in three physically defined areas as described above.

Procedure. ViroSeq is based on six major processes: sample preparation, reverse transcription, PCR, sequencing, sequence detection, and software analysis. All technical procedures require strict adherence to techniques for working with RNA—aerosolized tips, cleaning down of all surfaces with 10% bleach followed by 70% ethanol, and frequent use of clean gloves and lab coats; all disposables and reagents must be RNase free. The negative control is human plasma free of HIV-1 RNA and nonreactive for antibodies to HIV-1 and -2, hepatitis C virus, human T-cell lymphotropic virus type 1, and HBsAG. The positive control contains in vitro-cultured defective HIV-1$_{8E5}$ diluted in negative control to a concentration between 50,000 and 100,000 copies of HIV-1 RNA/ml. Negative and positive controls and clinical samples are processed in the identical manner, from RNA extraction to sequencing reactions.

Sample preparation (extraction and purification of HIV-1 RNA). Purified HIV-1 RNA from patient EDTA-treated plasma with a viral load of ≥2,000 copies of HIV-1 RNA per ml is generated using the HIV sample prep module provided. Plasma samples are thawed at room temperature, mixed thoroughly using a vortex, and pulse-centrifuged for 3 to 5 s. A 500-μl aliquot of patient plasma is transferred to a 1.5-ml Sarstedt microcentrifuge tube. The positive control includes a 50-μl kit positive control mixed with a 450-μl kit negative control, and the negative control includes a 500-μl kit negative control. Using a black indelible marker, place an orientation mark on one side of the tube, and place the tube in the rotor so that the orientation mark faces outward (this is where the subsequent pellet will align). Centrifuge at 21,000 to 25,000 × g at 2 to 8°C for 1 h. During centrifugation, prepare 70% ethanol (maintain at 4°C), and thaw the viral lysis buffer and RNA diluent at room temperature. Briefly vortex the thawed viral lysis buffer and RNA diluent; store the RNA diluent on wet ice. Upon completion of centrifugation, aspirate the clarified plasma with a fine-tip transfer pipette opposite the orientation mark; avoid disturbing the viral pellet. Add 600 μl of viral lysis buffer to the pellet, vortex for 3 to 5 s, pulse-centrifuge for 1 to 2 s, and incubate at room temperature for 10 min, followed by the addition of 600 μl of isopropanol. Vortex the tube for 3 to 5 s, and, with the orientation mark facing outward, centrifuge at 12,500 to 15,000 × g for 15 min. Remove the supernatant using a fine-tip transfer pipette opposite the orientation mark. Aspiration must be performed in one motion without any backflow that would otherwise dislodge the pellet. Add 1 ml of 70% ethanol, vortex for 3 to 5 s, and, with the orientation mark facing outward, centrifuge at 12,500 to 15,000 × g for 5 min. Aspirate the ethanol using a fine-tip transfer pipette (opposite the orientation mark). Pulse-spin the tube at 2000 × g (orientation mark facing outward) for 1 to 2 s to collect residual ethanol at the bottom of the tube, and remove the residual ethanol with a new fine-tip transfer pipette (opposite the orientation mark). Air dry the pellet, with the cap removed, for 1 to 5 min to ensure that all residual ethanol is removed; otherwise, the traces will inhibit RT-PCR. Based upon the sample's viral load, resuspend the RNA pellet in 50 μl of RNA diluent if the viral load is unknown or less than 15,000 copies of HIV-1 RNA per ml, or in 100 μl of RNA diluent if the viral load is greater than 15,000 copies of HIV-1 RNA per ml. The positive control and negative control are resuspended in 50 μl of RNA diluent. Vortex for 10 s, and then pulse-centrifuge at 2,000 × g for 1 to 2 s. Hold on ice for immediate continuation to reserve transcription, or transfer to −65 to −80°C for storage.

RT-PCR amplification. A two-step one-tube RT-PCR is used to amplify a 1.8-kb sequence of *pro* and *rt* (*pro* codon 1 through *rt* codon 333). Only GeneAmp 9600 or 9700 thermal cyclers are recommended by the manufacturer. The HIV RT mix and DTT solution are thawed at room temperature, vortexed, and transferred to ice. The RNase inhibitor and murine leukemia virus RT are held in a −20°C cooler. RT master mix for one sample (one reaction) is prepared in an RNase-DNase-free 1.5-ml microcentrifuge tube on ice. Aliquots of 8 μl of HIV RT mix, 1 μl of RNase inhibitor, 1 μl of murine leukemia virus RT, and 0.4 μl of DTT are combined, vortexed for 2 to 3 s, and pulse-centrifuged at 2,000 × g for 1 to 2 s. The RT master mix must be kept at room temperature prior to being added to the reaction tubes; however, it must not be kept at room temperature for more than 30 min. Always prepare additional volumes for one or two extra reactions.

Add 10 μl of purified RNA to a thin-walled 200-μl MicroAmp reaction tube, and transfer directly to the thermal cycler for one cycle of 65°C for 30 s to relax the RNA secondary structure and increase RT binding sites. Only after the second cycle of 45°C for 5 min are the tubes removed and 10 μl of RT master mix is added to each sample, the reaction tubes are capped, and then they are returned to the thermal cycler. Program the thermal cycler prior to setting up the RT reaction as follows.

One cycle of :	65°C for 30 s (to relax RNA secondary structure)
One cycle of:	42°C for 5 min (cools for optimum enzyme activity)
One cycle to:	Manually pause the thermal cycler for the maximum permitted time of 10 min. Remove tubes and add 10 μl of RT master mix to each reaction and return to thermal cycler. This step must be completed within 10 min
One cycle of:	42°C for 60 min (reverse transcription)
One cycle of:	99°C for 5 min (inactivates murine leukemia virus RT)
Hold:	4°C (at least 10 min, but no greater than 18 h, until proceeding to the PCR step)

The reserve transcription product can be used immediately for PCR or stored at −15 to −25°C but for no longer than 2 weeks.

PCR master mix for one sample (one reaction) is prepared in an RNase-DNase-free 1.5-ml microcentrifuge tube on ice (29.5 μl of HIV PCR mix, 0.5 μl of AmpliTaq Gold DNA polymerase, and 1 μl of AmpErase UNG), vortexed for 3 to 5 s, and pulse-centrifuged at 2,000 × g for 1 to 2 s. Always prepare an additional volume for one extra reaction. An aliquot of 30 μl of PCR master mix is added to the RT reaction tube, and the tube is capped and pulse-centrifuged at 2,000 × g for 5 to 10 s. Thermal cycler conditions are as follows.

One cycle of:	50°C for 10 min
One cycle of:	93°C for 12 min
40 cycles of:	93°C for 20 s, 64°C for 45 s, and 66°C for 3 min
One cycle of:	72°C for 10 min
Hold:	4°C for up to, but no longer than, 24 h (if the PCR product cannot be sequenced within 24 h, store at −15 to −25°C)

The PCR product is purified using a YM-100 microconcentrator, supplied with the kit, as follows. Insert the YM-100 spin column, reservoir facing up, into the YM 1.5-ml collection tube. Add 300 μl of sterile, deionized water to the reservoir, followed by the addition of the entire 50-μl PCR product. Cap the YM-100 microconcentrator, and centrifuge in a fixed-angle rotor at 450 to 550 × g for 15 min. Following centrifugation, remove the cap, add 35 μl of sterile, deionized water to the reservoir, and transfer the YM-100 microconcentrator to a new 1.5-ml collection tube with the reservoir facing down. Centrifuge in a fixed-angle rotor at 450 to 550 × g for 5 min. The purified PCR product (35 to 60 μl) in the 1.5-ml collection tube is either used immediately or stored at −15 to −25°C, but for no longer than 2 weeks.

Prior to the sequencing reaction, the purified PCR product is quantified by agarose gel electrophoresis. A 1.0% agarose gel containing 0.5 μg of ethidium bromide per ml is

used. An aliquot of 5 µl of PCR product and 5 µl of agarose gel loading buffer is mixed in a microcentrifuge tube, vortexed, and pulse-centrifuged at $2,000 \times g$ for 1 to 2 s, and the entire 10 µl is loaded onto the gel. Two aliquots, one of 3 µl and the other of 6 µl, of DNA mass ladder solution (with 5 µl of loading buffer) are loaded into the exterior flanking wells of the gel. The products are resolved at 10 V per cm until the bromophenol blue has migrated 5 cm into the gel. The image is recorded by photography under UV illumination. A dilution scheme is called for, based on the intensity of the PCR product compared to the mass ladder, as follows:

If the mass of the 1.8 kbp product band is:	**Then:**
Greater than 100 ng	1:10 dilution with double-distilled water
60 to 100 ng	1:4 dilution with double-distilled water
40 to 60 ng	1:2 dilution with double-distilled water
20 to 40 ng	Bring to 60 µl with double-distilled water
Less than 20 ng	Not suitable for sequencing

Once adjusted to the correct concentration, the diluted sample is vortexed for 3 to 5 s and pulse-centrifuged at $2,000 \times g$ for 1 to 2 s; the sample is now ready for sequencing.

Sequencing reaction. Seven primers, four forward and three reverse, provide double coverage of the entire region spanning *pro* codon 1 to *rt* codon 320.

Once the product has been adjusted to the appropriate concentration, the sequencing reaction is prepared. Use the MicroAmp optical 96-well reaction plate (provided with the kit) or MicroAmp reaction tubes or MicroAmp eight-strip reaction tubes in a MicroAmp tray. For the MicroAmp optical 96-well reaction plate, label the first seven rows (from top to bottom) with the letter corresponding to the primer: A, B, C, D, F, G, or H. Label the columns across 1 to 12. In the last row, label columns 1 through 7 with A, B, C, D, F, G, and H, respectively. Thaw the HIV sequence master mix (A, B, C, D, F, G, and H) tubes at room temperature. Add 12 µl of each HIV SEQ mix to the row corresponding to the HIV SEQ letter (i.e., HIV SEQ mix A to row A, HIV SEQ mix B to row B, etc.). For the last row, add each HIV SEQ mix to each corresponding well (A through H). Next, add 8 µl of the clinical sample PCR product to each of the seven wells in its designated column. The wells are capped with the MicroAmp optical 96-well reaction plate cover and centrifuged at low speed for 5 to 10 s. The plate is transferred to a GeneAmp 9600 or 9700 thermal cycler with the following setup: 25 cycles of 96°C for 10 s, 50°C for 5 s, and 60°C for 4 min and hold at 4°C. Sequenced samples may be stored for no more than 3 days at -15 to -25°C.

Three methods are recommended to purify the sequence reaction, including isopropanol (similar to the procedure used by Roche Amplicor HIV-1 Monitor to precipitate the HIV-1 RNA), ethanol-sodium acetate, and the CENTRI•SEP 96 plate. This section deals with purification by the CENTRI•SEP 96 plate.

Equilibrate the CENTRI•SEP 96 plate to room temperature for 2 h. Remove the lower adhesive foil sealing, place the plate on a MicroAmp optical 96-well reaction plate embedded in a 96-well base, remove the upper adhesive foil sealing, and tape the plates and base together. Without letting the plate dry, immediately transfer it to a swinging rotor and centrifuge

at $700 \times g$ for 2 min to pack the columns. Replace the MicroAmp optical 96-well reaction plate with a Princeton 96-well collection plate, place the CENTRI•SEP 96 plate on top of the Princeton 96-well collection plate, and tape the plate to the 96-well base. Using a multichannel pipettor, transfer the entire sequence reaction volume of approximately 20 µl from each well to the corresponding wells on the CENTRI•SEP 96 plate, being sure to maintain the exact orientation. Immediately transfer to a swinging rotor and centrifuge at $700 \times g$ for 2 min. Transfer the Princeton 96-well collection plate containing the purified sequence reaction product (approximately 20 µl) to a Speed-Vac and dry. The desiccated product can be kept by sealing the plate with ThermaSeal and storing at -15 to -25°C in the dark, but samples need to be analyzed within 1 week.

Automated sequence detection. The HIV-1 genotyping system can be run on a multitude of automated sequence detection platforms, including the ABI Prism 3100 genetic analyzer, ABI Prism 3100-*Avant* genetic analyzer, and ABI Prism 3700 DNA analyzer. The ABI Prism 377 DNA sequencer, an acrylamide gel-based system, is also approved for use but is no longer manufactured; details on use of this platform have been previously described (17).

To perform the analysis on an ABI Prism 3100 genetic analyzer, power on the platform and the computer workstation. Ensure a constant green light status (located next to the on/off button) on the platform before proceeding; the green light must not be blinking. To prepare for sequence collection, select "Start > Applied Biosystems > 3100 Data Collection." A window will pop up with plate record identifiers and an impression for both plates. At this point the ABI Prism 3100 genetic analyzer will require final preparation for loading. Reagents required include POP-6 polymer, a 50-cm 16-capillary array, and 10× genetic analysis buffer with EDTA, diluted to 1× with deionized water. Inspect the level of POP-6 polymer in the ABI Prism 3100 genetic analyzer and add as needed (polymer must be changed every 7 days). Ensure that both the anode and cathode reservoirs are filled to the "fill line" with freshly prepared 1× genetic analysis buffer with EDTA. Water reservoirs must be filled to the fill line with deionized water. Inspect the channels in the polymer block for bubbles, and expel by pushing down on the syringe. Once the ABI Prism 3100 genetic analyzer is prepared, the "Collection Software, v.1.1" is activated on the computer workstation as follows. In "Preferences," select "Data Analysis and Extraction," and then make the following selections: select "Enable AutoAnalysis" On, clear "Extract to Sequence Collector," select "By Run," and then specify the format for the sample file name prefix: "Sample Name," "Well Position," or "<none>." End by selecting "OK." To continue, select "Plate View" and then "New," and under the "Tools Bar," select "Plate Editor." In the plate editor dialog box, name the plate (do not use space bar in naming plate), specify the application and the plate type, select "OK" to complete the application, and close the plate editor dialog box. Under "Application," select "Sequencing," and under "Plate Type," select "96-well," and then select "Finish." At this point the plate editor spreadsheet opens which allows naming of each sample. A specific naming convention is used and should be adhered to: it is patient identification, underscore, and primer; for example, patient 41/288_A to patient 41/288_H.

The following settings are set for each sample in the spreadsheet (note: when the appropriate setting is selected for the first sample, select the column heading to highlight the entire column and from the "Edit" menu select the "Fill Down" command): Dye Set, E; Mobility File, DT3100POP6{BD}v2.mob;

Comments, enter your comments; BioLIMS Project, N/A; Project Name, 3100-Project; Run Module 1, StdSeq50_POP6-DefaultModule; and Analysis Mode 1, BC-3100POP-6SR_SeqOffFtOff.saz.

To prepare the samples for analysis, bring those stored at −15 to −25°C to room temperature; otherwise proceed directly with those samples that have just been desiccated. In the Princeton 96-well collection plate, resuspend each dried sample by adding 20 μl of Hi-Di formamide, and then vortex for 10 to 15 s. Centrifuge the Princeton 96-well collection plate at $2,000 \times g$ for 20 to 30 s. Heat denaturing is not required, and the plate is now ready to load onto the ABI Prism 3100 genetic analyzer. Attach the ABI Prism 3100 genetic analyzer 96-well septa to the plate, and insert the plate in the "snap" on the ABI Prism 3100 genetic analyzer retainer and base. Load the framed plate onto the ABI Prism 3100 genetic analyzer, orienting the plate so that the A1 well is in the upper right corner, and verify that the plate position indicator is yellow. From the "Pending Plate Records" table, select the entered plate name in "Plate Record," and then select the corresponding plate on the position indicator (either A or B); the position indicator will turn from yellow to green and the plate name under "Pending Plate Record" will automatically transfer to either the A or B row under "Linked Plate Records." The plate is now linked to the plate record. Select the "Run View" tab to view the run schedule, and select each run to verify that the appropriate wells have been highlighted; if a well is not highlighted, it will not be analyzed. To start the run, click the green "Run Instrument Button" (green arrow). The software will automatically check the available space in the database and drive D and will advise accordingly; if the database or drive D is full, make more space and then click "Run Instrument." Once the instrument is running, select the "Status View" tab to confirm the electric current parameters. Should there be no indication of current, the most likely cause is a bubble in the polymer. Cancel the run, clear the bubble from the polymer, and restart the instrument.

When the run is complete, Sequence Analysis Software version 3.7 is launched and all the files (completed sequences from the run) are transferred from the run folder to the Sample Manager. The following settings are selected for each sample: Basecaller, Basecaller_3100SR; Spacing: Defined by Instrument; Basecaller Setting, HIV580; Peak 1 Location, Set by software, Start Point, Set by software; DyeSet/Primer, DT3100POP6{BD}v2.0; and Factura Setting, none (this function is not used with the ViroSeq assay).

Select the "A" (analyze) check box for each sample, clear the "P" (print) and "F" (Factura) columns, and then click "Start." Confirm analysis by checking the column A status color. If it is green, then the sample was analyzed; however, if it is red, then the sample was not analyzed (review the settings and reanalyze the data).

After proper sequence analysis, the data are ready to be used by HIV-1 Genotyping System Software version 2.6. This software incorporates and aligns all seven primer sequences of a sample into a single project with one consensus sequence. The sample consensus sequence is then compared to a reference sequence of HIV-1$_{HXB-2}$. The software performs automatic basecalling, and several options are selected to review the data. Manual editing is performed at "positions of interest," which include all resistance mutations found in the sample. The user resolves mixed-base positions in the same manner. Once editing is complete, a genotyping report is generated that contains a list of all the known resistance mutations found in *pro* and *rt* (compared with the Los Alamos National Laboratories reference database) as well as a separate list of all novel mutations. Additional information is available at http://www.celeradiagnostics.com.

Phenotypic Resistance

There are two commercially available phenotypic assays, the Antivirogram assay (Virco, Mechelen, Belgium) and the PhenoSense HIV assay (ViroLogic); however, the patient plasma sample is sent to the manufacturer or to a recommended reference laboratory (access websites below for information) for testing.

Phenotypic assays are not available in a kit format because of their technical complexity. The technically challenging aspect is derived, in part, from generating a viral construct of a vector containing the patient's viral *pro* and *rt* insert. Viral constructs are necessary, because it is generally quite difficult to directly isolate and propagate patient-derived plasma virus, except from those infected individuals with progressive disease and high viral loads (14, 39). Therefore, complicated manual and robotic procedures that rely upon strict quality control and monitoring are required for the successful outcome of each analysis.

Comparative analysis demonstrates that Antivirogram and PhenoSense HIV generate essentially concordant results on matched clinical samples (53). However, similar to genotypic assays, Antivirogram performance is less efficient, by approximately 25%, with certain non-B subtypes (33); to date there are no peer-reviewed publications for PhenoSense HIV on non-B subtype performance.

Antivirogram

The Antivirogram assay is available for the quantitative measurement of HIV-1 phenotypic resistance from patient plasma samples. Briefly, purified HIV-1 RNA is derived from patient plasma by concentration of virus through high-speed centrifugation, viral lysis, and nucleic acid purification. The patient's HIV-1 *rt* and *pro* region is amplified as one continuous 2.2-kbp fragment by nested RT-PCR. The PCR-amplified fragment is cotransfected into MT-4 cells (CD4$^+$ T-lymphocyte cell line) with a provirus-deleted plasmid pGEMT3ΔPRT (HXB2 viral backbone, of which the majority of *pro* and *rt* has been deleted). Chimeric virus is generated through homologous recombination, harvested after 7 to 8 days in culture, and titrated. Drug susceptibility is determined using a highly sensitive reporter-based assay system that specifically measures ongoing viral replication at the single-cell level. Resistance is reported as the 50% inhibitory concentration (IC$_{50}$) of the patient's chimeric virus compared with the control, recombinant HIV-1$_{IIIB/LAI}$. Generally, patient plasma samples with a viral load as low as 500 copies of HIV-1 RNA per ml can be analyzed; however, the highest sensitivity is obtained in plasma samples with a viral load of ≥1,000 copies of HIV-1 RNA per ml. The assay generally takes 18 laboratory working days to generate results (30). Additional information is available at http://www.vircolab.com/index.jhtml?product=none.

PhenoSense HIV

The PhenoSense HIV assay is available for phenotypic evaluation of patient plasma samples (51). Virus is concentrated from patient plasma by high-speed centrifugation, the virus pellet is lysed and viral RNA is purified using standard procedures. A 1.5-kbp fragment from the patient's HIV-1 RNA encompassing the entire *pro* (amino acids 1 to 99) coding region and a large portion of the *rt* (amino acids 1 to 305) coding region is amplified by RT-PCR. Using conventional molecular cloning procedures, the amplified 1.5-kbp fragments are inserted into a modified infectious, replication-defective

molecular clone, HIV_{NL4-3}, to generate resistance test vectors (RTVs). RTVs contain a luciferase expression cassette inserted in a deleted region of the envelope gene. RTVs are prepared as libraries (or pools) containing many different variants of the 1.5-kbp patient insert, thus preserving the heterogeneity of the patient's quasispecies. The replication-defective patient's RTV DNA is cotransfected with amphotropic murine leukemia virus envelope expression vector DNA into human embryonic kidney 293 cells. The amphotropic murine leukemia virus envelope expression vector provides envelope proteins in *trans* to support the assembly of infectious pseudotyped HIV-1 particles. This methodology allows for only a single replication cycle format and thus avoids in vitro selection of virus populations through multiple rounds of replication.

To evaluate susceptibility to protease inhibitors, transfected cells are propagated in the presence of serial dilutions of protease inhibitors, and progeny virus is harvested and used to infect fresh 293 target cells in the absence of drugs. To evaluate susceptibility to RT inhibitors, virus is harvested from transfected cells propagated in the absence of drugs and used to infect 293 target cells in the presence of serial dilutions of RT inhibitors. Infection is measured by quantitating luciferase expression in target cells 48 to 72 h after virus inoculation. The percent inhibition of luciferase activity (i.e., infection) at each drug concentration is determined by dividing the luciferase activity produced in the presence of drug by the luciferase activity produced in the absence of drug. The IC_{50} is extrapolated from the data by plotting percent inhibition versus drug concentration. The fold change in patient HIV-1 drug susceptibility is determined by comparing the patient virus IC_{50} with the IC_{50} for a drug-susceptible reference virus that is run in parallel. Additionally, ViroLogic has ascertained the biological cutoff of drug susceptibility for several wild-type viruses with a variety of drugs and, by utilizing the natural variation of wild-type drug susceptibility, has calculated a more accurate fold change over baseline susceptibility to determine the clinical cutoff (resistance) for patient viral isolates (50). The performance characteristics of the assay have been validated for HIV-1 group M, subtype B. Patient plasma samples with viral loads of ≥500 copies of HIV-1 RNA per ml can be evaluated, and the assay reproducibly detects ≥2.5-fold changes in susceptibility.

The assay is performed in ViroLogic's licensed clinical reference laboratory, and results are reported within 2 weeks from the date of sample receipt. The replication capacity may also be evaluated as part of PhenoSense HIV (see "Replication Capacity" below). Additional information is available at http://www.virologic.com.

PhenoSense GT

ViroLogic offers a comprehensive analysis package, PhenoSense GT, whereby the same patient plasma sample is assayed for phenotypic and genotypic drug resistance, HIV-1 subtype (from sequence analysis), and replication capacity (a component of viral fitness); phenotypic analysis is performed on the sample and is not derived from a database as described below for Virco's *Virtual*Phenotype. The sample is tested by PhenoSense HIV (see above) and GeneSeq HIV (see above) for phenotypic and genotypic resistance, respectively, and replication capacity is tested as described below. Additional information is available at http://www.virologic.com.

Virtual Phenotype

Virtual phenotype refers to the procedure whereby the phenotype is extrapolated from the genotype using shared sequence data. This is achieved from large databases containing data correlating the genotype to the phenotype from patient samples. Hence, these databases allow the entry of genotypic sequence data, which are compared with sequence data of phenotyped samples, and a virtual phenotype is then constructed based upon the best available match. However, the association may not be 100% across the sequence; the level of correlation is indicated on a virtual-phenotype report. A virtual phenotype can be interpreted as long as the genotypic sequence is continuous. Although this is a less expensive means of obtaining a phenotype, it still remains a "virtual" interpretation, because it is an extrapolation of data with the best possible fit and thus may not represent the exact phenotypic characteristics of that patient's isolate.

To generate a *Virtual*Phenotype, the HIV-1 plasma isolate is submitted to Virco and genotyped utilizing their in-house procedure, VircoGEN II, which makes use of dideoxy sequencing technology, similar to that described for ViroSeq (see above). Briefly, amplification of the target sequence is accomplished by nested PCR, generating a 2.2-kbp product encompassing the *pro* and *rt* coding sequences. Sequencing primers, developed by Virco, allow for sequence analysis of the entire *pro* gene and up to codon 400 of the *rt* gene. The sequence is then analyzed against databanks to generate the *Virtual*Phenotype report. Additional information is available at http://www.vircolab.com/index.jhtml?product=none.

Replication Capacity

Replication capacity (ViroLogic) (4) is an outcome of PhenoSense HIV where the pseudotyped patient HIV-1 particle replication is expressed as a percentage of pseudotyped wild-type HIV-1 particle replication (see "PhenoSense HIV" above). Knowledge of replication capacity can be used to aid in treatment assessment (4). ViroLogic offers the replication capacity assay as part of the PhenoSense HIV and PhenoSense GT products. Additional information is available from http://www.virologic.com.

Online Services

Online options are available to the testing laboratory and clinician for the evaluation of HIV-1 drug resistance. Specifically, once a sequence has been derived from a clinical sample, the user may elect to either submit the sequence online for a third party to analyze and generate reports or directly analyze the sequence online. VircoNET (Virco) and Virodec-HIV (F. Hoffmann-La Roche Ltd., Basel, Switzerland) are examples of these services.

The benefits of using online services vary depending on the product options available. From the clinical laboratory director's standpoint, these online services permit utilization of any available technology to generate the sequence data for genotypic resistance analysis. For example, the laboratory may elect to use ViroSeq or TRUGENE to generate the sequence or may consider other options, such as a potentially less costly homebrew assay, with the appropriate quality assurance and quality control programs. Ultimately, cost model analysis may be used to determine the most cost-effective package.

From the perspective of the clinician or researcher, data can be analyzed using up-to-date algorithms and with different reference stains (see "Virodec-HIV" below).

VircoNET

The HIV-1 sequence (obtained by either TRUGENE, ViroSeq, or homebrew) is submitted to Virco's online service to VircoNET to obtain a *Virtual*Phenotype. A result is provided within 2 working days. Additional information is available at http://www.vircogen.com.index.jhtml?product=none.

Virodec-HIV

Virodec-HIV (F. Hoffmann-La Roche Ltd.) is a browser-based service for analysis of complex data, utilizing the IDNS (Integrated Database Network System) technology. While its backbone structure includes database and web functionalities, customized disease-specific modules are offered to customers for complex diseases such as HIV. Virodec-HIV allows the user to enter disease-relevant and virus sequence data from HIV-1 *rt* and *pro*, as well as *gag* and envelope (*env*) genes, for resistance analysis and a patient report; a charge is levied for the service, and various pricing models are available to suit the needs of the user.

The platform can function online through access with the Internet and a web browser, or it can be stand-alone, or within an intranet infrastructure, with upgrades and updates accessible through connection with the Internet. To maintain security, data are encrypted for transmission. Numerous algorithms can be incorporated for analyzing data and generating drug resistance reports. The service is provided with the Stanford algorithm; however, the user can incorporate additional algorithms. The drug resistance report includes a list of HIV-1 antiretroviral drugs, their corresponding generic names, mutations detected, score and range, and interpretation of result. Planned upgrades of the service allow this information to be uploaded into the accompanying patient data management form, which also includes the clinical condition and treatment regimen of the patient. Multiple chronological entries for the same patient provide the option of a longitudinal data record that is presented in both numeric and graphic format.

The Virodec-HIV service can be made available online to permit network communications to other users using a secure pass code system. Databases can be generated for this purpose to allow other investigators to access and share and compare information; however, only the database creator can alter or add information. The data are shared only by authorized access.

From the clinician and researcher standpoint, Virodec-HIV provides options to custom analyze data, to recognize genetic profiles of both B and non-B subtype clinical isolates (using the clade finder in the Virodec program), to reanalyze data as technology advances by using up-to-date reference strains and algorithms, to consolidate clinical information, and to share data with other team members for, as an example, consultations or manuscript preparation.

For the realization of the Virodec product line, F. Hoffmann-La Roche Ltd. collaborates closely with SmartGene GmbH, Zug, Switzerland, and integrates the SmartGene IDNS technology in its offering.

Procedure. Sequence data may be generated using one of the commercial assays (ViroSeq or TRUGENE, for example) or one of several available homebrew assays.

To access the software, turn on the computer workstation and, using name and password, log into the "Specimen Management" window. Enter patient identification, date of birth, sample date, sample label, laboratory label, sample specimen, and comments. Select the "Application" tab to access the three applications, including "Reference Sequences" (blue box), "Sample Sequences" (red box), and "Clipboard(s)" (gray box).

The "Reference Sequences" function contains HIV reference sequences (B and non-B subtypes) that are used for alignment with the clinical specimen sequence for determination of mutations, which could be resistance relevant. The reference sequences are continually kept up-to-date by Virodec support staff. The user cannot edit the reference database;

however, the user may elect to generate a customized reference database, which in turn can be edited only by the user.

The "Sample Sequences" function is where the patient sample sequence and additional disease-relevant data are entered, generating a database that can be shared with other authorized users. Entered sequences and sample data sets are also accessed in this section and can be reanalyzed as needed.

The "Clipboard(s)" function permits the user to input and analyze data from different samples sequenced over a period of time. This allows for longitudinal analysis of same or related patient samples (i.e., source and recipient patients) or samples from patients on the same regimen, as well as contamination check for samples run in the same or successive batches; the flexibility of the system allows for numerous analyses.

Sequence analysis. Using the "Sample Sequences" function, select "Add Record in Virodec HIV Samples" tab. A proofreading window opens where the sequence can be either uploaded or copy pasted. The Virodec proofreading module automatically executes alignment and orientation of the sequence. Uploading the electropherogram assists in detecting and correcting ambiguities and aids in verification of the sequence. The consensus sequence is selected and compared against the patient sequence; *rt*, *pro*, *gag*, and *env* are included in the consensus sequence. The software identifies codons conferring resistance and can be executed using either the manual or automated system. Virodec accounts for insertions and deletions. The sequence can also be subtyped (select "Subtype Analysis" tab), and can be compared to other isolates with similar sequences (select "Search Sequence Similarity in a Sample Database" in "Sample Sequences" function). A drug resistance report is generated utilizing the preferred algorithm available on Virodec.

Patient management. Soon-to-be-available features of the Virodec software will allow the patient genotypic report to be incorporated into the "Patient Data Management" screen that includes numerous options to record disease states, clinical conditions, and treatment regimen. Integration of these data allows for a graphic display of results and permits the user to generate longitudinal records for each patient. Additional information is available at http://www.virodec.com.

Cloning and Microculturing Technique

As described above, both commercially phenotypic assays are now available in a kit format. In the assays, HIV protease and RT genes are inserted into replication-defective molecular clones to generate chimeric clones (see above). However, the produced recombinant chimeric clones occasionally possess a low level of replication competence due to lack of mutations in the *gag* (p7/p1/p6) cleavage site (57). To obtain accurate drug resistance profiles, it is often necessary to construct chimeric clones containing mutations in the *gag* cleavage site with high replication competence. From this point of view, a modified molecular clone, pNL4.3PFB (Fig. 3), has been designed to obtain the chimeric recombinant viruses containing mutations in the cleavage sites (34).

PCR Amplification

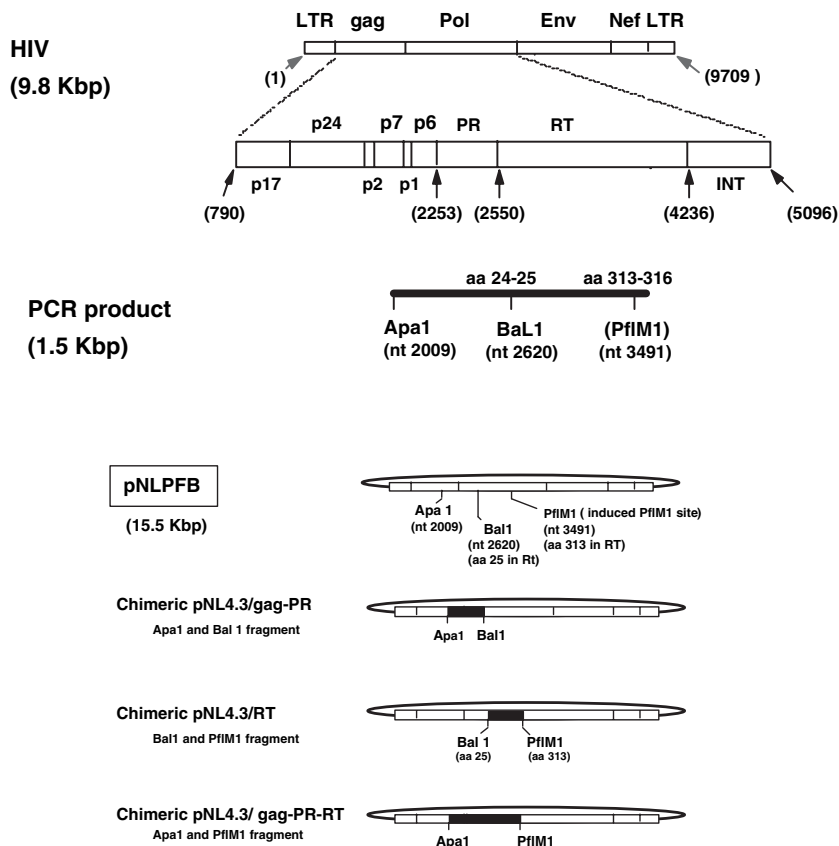
A 1,685-bp fragment of the HIV-1 genome containing the *gag* (p7/p1/p6) regions, the protease gene, and part of the RT gene is amplified by PCR as described above with the following primer pairs: forward primer (nucleotides [nt] 1881 to 1904) 5′-GAAGCAATGAGCCAAGTAACAAAT-3′


FIGURE 3 Structure of chimeric HIV. The PCR-amplified products are digested with restriction enzymes depending on the drug to be tested. To investigate drug resistance to protease inhibitor, RT inhibitor, or a combination of protease inhibitor and RT inhibitor, the products are digested with *Apa*1 plus *Bal*1, *Bal*1 plus *Pfl*M1, or *Apa*1 plus *Pfl*M1. The digested products are ligated into pNLPFB backbone. LTR, long terminal repeat; aa, amino acid; PR, protease.

and reverse primer (nt 3543 to 3566) 5′-GATATGTC-CATTGGCCTTGCCCCT-3′. A nested PCR is then carried out with the following primer pairs: forward primer (nt 1965 to 1988) 5′-TTCAATTGTGGCAAAGAAGGGCA-3′ and reverse primer (nt 3482 to 3505) 5′-ATAATACACTC-CATGTACTGGTTC-3′. The reaction mixtures (50 μl) containing 1× Expand High Fidelity buffer, oligonucleotide pairs (400 nM), dNTPs (200 nM), and 1.75 U of Expand High Fidelity PCR System enzyme mix, are subjected to 25 cycles of 95°C for 30 s, 55°C for 30 s, and 72°C for 2 min, with the final extension at 72°C for 7 min. The PCR products are purified with the QIAquick spin PCR purification kit (Qiagen).

Cloning and Sequencing

The purified PCR products are ligated into the pCRII vector (Invitrogen), and the ligation products are used to transform *Escherichia coli* TOP10F competent cells (Invitrogen). Positive colonies are identified and the presence of a 1.6-kbp insert is confirmed by restriction enzyme digestion with *Eco*RI. Plasmid DNAs containing the PCR fragments are purified with the S.N.A.P. Miniprep kit (Invitrogen). Sequencing reactions are performed with the BigDye Terminator Cycle Sequence kit (Applied Biosystems, Foster City, Calif.), and the reaction products are resolved by electrophoresis on 6.0%

polyacrylamide gels and analyzed with an Applied Biosystems 377 automated sequencing system. The nucleotide sequences of the *gag* (p7/p1/p6) regions, the protease gene, and the RT gene are translated and aligned with the Sequence Navigator (Applied Biosystems). Changes in the RT regions are compared with the HIV-1 clade B consensus sequence as a reference (46).

Construction of Molecular Chimeric Clones

The plasmid (pNL4.3PFB is available through the National Institute of Allergy and Infectious Diseases) contains one *Bal*1 site at nt 2622 and one *Pfl*M1 site at nt 3492 in the *rt* gene (Fig. 3). These two restriction enzyme sites are then utilized to construct a series of chimeric infectious clones of HIV-1. To obtain virus-containing *gag-pro-rt*, the clones are digested with *Apa*1 and *Pfl*M1. The fragments from *Apa*1 and *Pfl*M1 digestion are used to replace the corresponding fragment of pNL4.3PFB (Fig. 3). DNA sequencing is used to ascertain that each of the chimeric NLPFB and mutated NL4.3PFB variants possesses the intended mutations.

Transfections, Infections, and Generation of Viral Stocks

Transfections are performed with TranSit LT1 (Panvera) as previously described (26, 34, 57). Briefly, 3.5×10^5 RD

cells in 35-mm culture dishes are used for each transfection with 2 μg of the molecular clones in 5 ml of EMEM-10. After 24 h of transfection, 10^6 fresh MT-2 cells are added to the dishes and incubated at 37°C for another 24 h. The MT-4 cells thus infected are collected, washed, and cultured at 37°C for 3 days in 5 ml of RPMI-10. Cell-free culture supernatants are obtained and stored at −80°C until used as viral stocks. Nucleotide sequencing of the stocks is performed to confirm that each stock has the intended mutation(s) in the *rt* gene. The 50% tissue culture infectious dose ($TCID_{50}$) of each stock is determined as previously described (34, 57). Cultures of MT-4 cells and serial fourfold dilutions of the appropriate recombinant HIV stock are set up in triplicate. The tissue culture plates are incubated at 37°C for 7 days, after which culture supernatants are collected and p24 antigen assays are performed (p24 antigen capture kit; Beckman Coulter, Miami, Fla.). Using a cutoff value for p24 of <50 pg/ml, $TCID_{50}$s are calculated for each stock by the Spearman-Karber method (1).

Drug Resistance Assays

MT-4 cells (4×10^6) are incubated with 2,500 $TCID_{50}$s of HIV-1 for 2 h at 37°C, washed twice, and resuspended at a density of 0.2×10^6 cells/ml in RPMI-10. An aliquot of the suspension (0.2 ml) is added to each well of a 96-well flat-bottom plate in the presence or absence of various concentrations of anti-HIV-1 drugs, such as protease inhibitors or RT inhibitors, for 7 days at 37°C. HIV replication is monitored by measurement of p24 amount in culture supernatant with the p24 antigen capture kit (Beckman Coulter). Each assay is performed in quadruplicate. Sensitivities are reported as the concentrations of the drugs that inhibited p24 production by 50% (34).

Measurement of T-Cell-Specific Immunity in Patients with Human Immunodeficiency Virus Infection

RICHARD L. HENGEL, TOMOZUMI IMAMICHI, AND STEPHEN A. MIGUELES

97

BACKGROUND

Despite more than 20 years of intensive research, the precise mechanism of human immunodeficiency virus (HIV) pathogenesis remains unknown. Nowhere is this shortcoming more frustrating than in the field of HIV vaccine development, where empirical rather than rational vaccines continue to be necessary until we have a better understanding of how HIV causes disease. Until then, intensive research must continue, building on what is already known.

Most people with untreated HIV infection develop clinical immunodeficiency. For those without access to treatment, the median time to life-threatening opportunistic infection or malignancy averages about 10 years (13). For those fortunate enough to have access to treatment, new anti-HIV drugs can prevent this eventuality, perhaps indefinitely. However, even these individuals may suffer subtle immunodeficiency before meeting current criteria to start treatment. Clinically, such immunodeficiency can manifest by an increased susceptibility to diseases like thrush or tuberculosis.

Fortunately, while we do not yet know how HIV causes disease, we do have significant insights into correlates of the disease and, in particular, how HIV disease correlates with heightened levels of HIV replication, CD4$^+$-T-cell depletion, immune activation, and cellular turnover. Earlier in the HIV epidemic, similar correlations with disease and functional assays of immune function included impaired responses to immunization, and functional measures of T-cell responsiveness to recall antigen (9). More recently, more sophisticated assays of T-cell function have been developed, mostly owing to improvements in multiparameter flow cytometry and to improvements in T-cell isolation techniques. These new assays promise to further help refine insights into HIV pathogenesis by dissecting the intricate interactions of antigen-specific cell function from immune activation and CD4$^+$-T-cell lymphopenia. Many of these assays are now capable of more specifically measuring the human immune response directly, and many may soon be ready for clinical application. Examples could include helping physicians decide about the need for revaccination or the need for prophylaxis for latent tuberculosis infection in developed countries where widespread treatment is not yet feasible.

While the ultimate mechanism of HIV pathogenesis remains elusive, one fortunate consequence of two decades of HIV research has been the development and optimization of new tools to investigate the human immune response, both in health and in disease. In this chapter we outline both old and new tools used in evaluating patients with HIV disease. Some of these are used in clinical settings, some in the research setting. However, it seems only a matter of time before most or all of the research tools ultimately make their way into clinical use.

TCR REPERTOIRE ANALYSIS

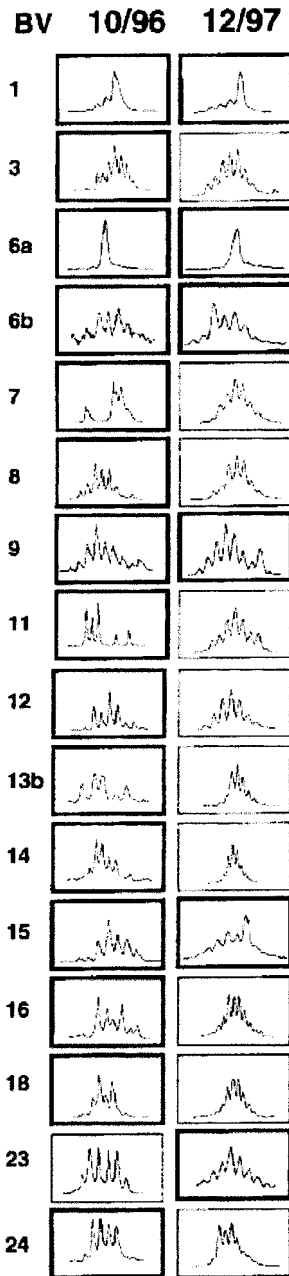
An individual's T-cell repertoire is determined when T cells traffic through the thymus. A T-cell receptor (TCR) that binds with too much or too little avidity for a self-peptide presented within a self-major histocompatibility complex molecule will cause the death of that T cell. Only T-cell clones with just the right amount of binding affinity will survive to populate the peripheral circulation and make up an individual's T-cell repertoire. Theoretically, an individual's T-cell repertoire is capable of responding to all the different antigenic epitopes on earth. Such immense diversity is possible not through germ line genetic diversity alone, but through the miracle of genetic recombination, additional genetic diversity is generated within the T cell itself (4). This occurs when clusters of gene segments responsible for encoding the subunits that make up the TCR undergo combinatorial joining prior to T-cell repertoire determination. Because this random combinatorial joining generates random and different gene lengths for any given T-cell clone, measuring the diversity of these gene lengths can therefore indirectly measure T-cell clonal diversity. In this section we outline the so-called Vβ spectratyping analysis (also known as the "immunoscope" technique), which measures gene length diversity within the CDR3 region of the Vβ gene cluster (12). Overall T-cell clonal diversity is then measured by enumerating the relative frequency of clones having the same CDR3 gene length. The greater the number of CDR3 gene lengths found, the greater the T-cell clonal diversity within the T-cell repertoire. Applications of this technique are shown in Fig. 1 and 2. In Fig. 1, CD4 T-cell clonal diversity increases over time following treatment of late-stage HIV infection. Rather than comparing T-cell clonal diversity over time, Fig. 2 shows how clonal diversity varies for the same individual at a single time point, comparing CD4 T-cell subsets, in this case comparing clonal diversity within central memory to effector memory CD4 T cells.


FIGURE 1 As recently reported by Gea-Banacloche et al., PBMCs were separated into CD4$^+$ T-cell fractions and then compared at two different time points for the same HIV-infected individual starting treatment for HIV infection. Such an analysis is typical of how the CDR3 sizing assay is applied to HIV-infected patients. The Vβ family is indicated along the y axis, while CDR3 sizing analysis is indicated along the x axis (each peak corresponding to the relative frequency of PCR products of the same size). Abnormal patterns are identified by bolded boxes around the frequency distribution graphs. Comparisons between the early and late time periods indicate an improvement in the Vβ repertoire (i.e., less skewing), presumably because of this individual's HIV treatment regimen (5).

Equipment

PCR hood with UV light
PCR GeneAmp 9700 (PE Applied Biosystems)
High-speed centrifuge
RNEasy kit (Qiagen)
Vortex machine
GeneScan 500 XL TAMRA (PE Applied Biosystems)
Heat block

Materials and Reagents

RNase-free tubes
Diethyl pyrocarbonate (DEPC) water
Pipettors and pipette tips
Trizol
Isopropanol
Ethanol
Chloroform
β-Mercaptoethanol
DEPC water
25 mM MgCl$_2$
Fam Cβ
Deoxynucleoside triphosphate (dNTP) mixture
AmpliTaq Gold
RNAlater (Ambion)
RNase OUT RNase inhibitor

Procedure

Step 1: Extraction and Quantitation of RNA

RNA extractions should be performed in a PCR hood, making sure to run the UV light for sufficient time before beginning in order to avoid any cross-contamination. Two methods, chemical (phenol) and nonchemical (column), are available to isolate RNA from cells.

A. Phenol method
  1. Using the Trizol reagent (*not* Trizol LS—the LS is intended for liquid samples, whereas the reagent can be applied directly to the cell pellet), add 1 ml to each sample, making sure to keep them on ice until the Trizol is added.
  2. Resuspend the pellet by repeat pipetting until no clumps of cells are visible.
  3. Incubate the tubes at room temperature for 5 min to ensure complete lysis of the cells.
  4. Add 200 μl of chloroform to each tube and shake them vigorously for 30 60 s, and then let stand for 10 to 15 min, ensuring that the supernatant is relatively cleared.
  5. Spin samples at 4°C at maximum speed for 15 min.
  6. Remove the supernatant (should be around 600 μl) to a clean RNase-free tube, making sure not to pick up any protein or organic material.
  7. Add 3 μl of microcarrier to each sample and flick well to mix (do not vortex), then add 1 volume (usually around 600 μl) of isopropanol to the tubes, mix by inverting or flicking, and incubate at room temperature for 10 min.
  8. Centrifuge samples at 4°C and at maximum speed for 20 to 30 min, placing the notches on the lids to the outside to orient the tubes so that the pellet is

CD45RA-62L-

Vβ18 Vβ20 Vβ21 Vβ23 Vβ24

CD45RA-62L+

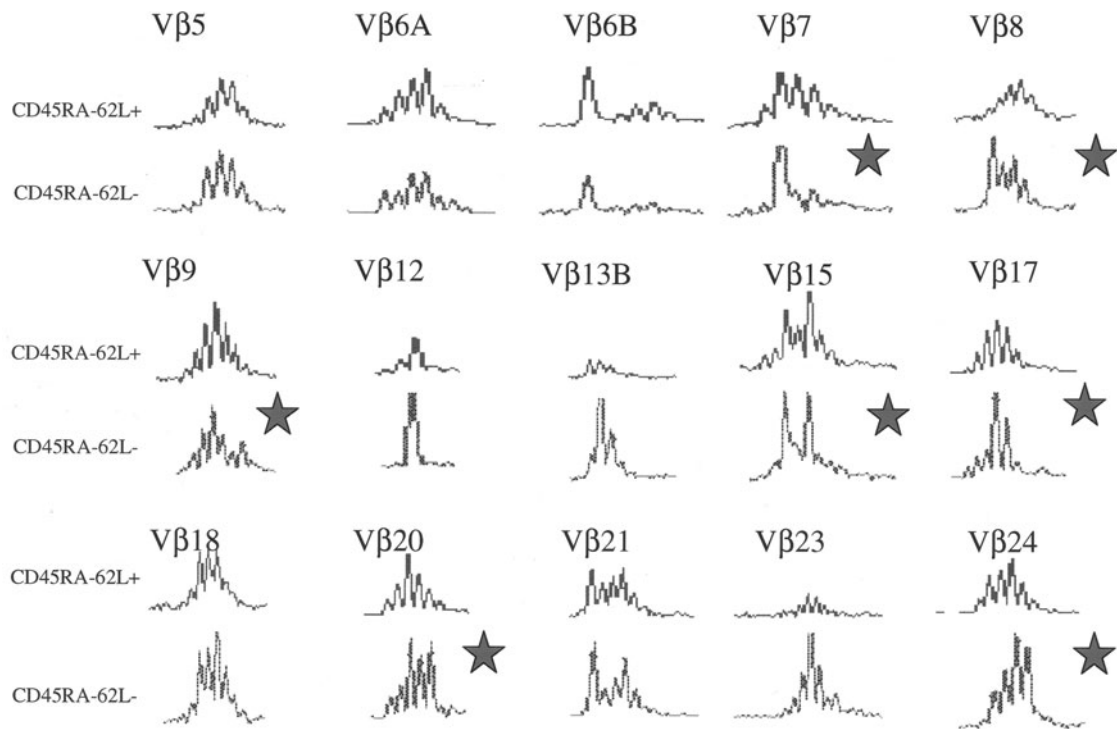
CD45RA-62L-


FIGURE 2 PBMCs from an HIV-seronegative individual were separated into CD4$^+$ CD45RA$^-$ and then into CD62L$^+$ and CD62L$^-$ fractions using magnetic beads to determine whether T-cell repertoire differences observed in later-stage HIV-seropositive individuals might be because these individuals have decreased ratios of central to effector memory (as well as naive to memory) CD4$^+$ T cells accompanying their advancing HIV infection. CDR3 gene length analysis was performed on the separated subsets, and while abnormal patterns were found among both subsets, further exaggeration was found among CD62L$^-$ effector memory subsets (as indicated with adjacent stars), suggesting some support for the hypothesis that a decreased Vβ repertoire in late-stage HIV infection may be due to a combination of a relative decrease in naive and central memory and a reciprocal increase in effector memory CD4$^+$ T cells.

easily found (it will be translucent and have a gel-like consistency).

9. Remove most of the isopropanol, being careful not to discard the pellet.
10. Wash twice with chilled 70% ethanol, mixing each time by inversion and spinning at 4°C and full speed for 5 min. (The pellet will whiten and become more rigid so that all of the liquid can be removed after the second wash.)
11. Uncap tubes and dry for 3 to 5 min in a desiccator, being careful to minimize the exposure of the pellets to air outside of the hood.
12. Pellets can be stored at −70°C until needed.
13. Working in a hood, add 10 μl of DEPC water to each pellet.
14. Dissolve the pellets by placing the tubes in a 70°C heating block for 3 to 5 min, flicking them every minute.
15. After the pellets are dissolved, immediately place tubes on ice.
16. Make appropriate dilutions in DEPC water for the spectrophotometer nucleotide-RNA program that is used, and measure the samples (usually about 1 μg/μl with the optical density at 260 to 280 nm at about 1.8 to 2.0).

B. Column method. The nonchemical method extracts RNA using the RNEasy kit (Qiagen) with QIAShredder spin column (Qiagen).
1. Add 600 μl of RNAlater (Ambion) onto a pellet of 5 million to 10 million cells in a 1.5-ml RNase-free tube. Samples can be stored at −80°C without resuspension.
2. If samples are frozen, thaw the pellet for about 10 min at 37 to 42°C in a prewarmed heat block to ensure that there are no crystals. Vortex well, and pipette up and down to ensure a monosuspension of cells.
3. Add 600 μl of phosphate-buffered saline (PBS) to sample, mix well, and spin for 5 min at maximum speed at 4°C.
4. Draw off the supernatant as completely as possible without losing any cells.
5. Add RTL with β-mercaptoethanol and follow protocol from the kit.
6. Elute RNA from spin column in 20 μl of kit-provided water into an RNase-free tube preloaded with 1 μl of RNase OUT RNase inhibitor (kit provided).
7. Take optical density in Tris-EDTA (TE) at 260 and 280 nm.

Step 2: First-strand synthesis (Reverse Transcription)

Take 3.5 to 5 μg of the RNA sample for use in the Superscript first-strand synthesis system for reverse transcription-PCR (Invitrogen). The protocol can be followed exactly as it is written in the kit instructions. If the RNA concentration is low, the first-strand synthesis is performed in twice the usual volume: e.g., 20 μl rather than 10 μl. Each reaction to set up cDNA synthesis is performed in a Sarstedt screw-cap 1.5-ml microcentrifuge tube.

Step 3: PCR Amplification of the Vβ Subfamilies (2, 3)

All primers (Table 1) should be aliquoted for single use only and not repeatedly freeze-thawed.

1. Remove all primers and reagents from the freezer to thaw. After being pulse-vortexed and spun down, all tubes should be kept on ice.

2. With the rack of tubes in a cold block, add 5 μl of each V β primer (5 μM) in sequential order to the tubes for each sample. For these purposes, Vβ 1 to Vβ 24 are used. Vβ 6A is substituted for Vβ 10, and Vβ 13B is substituted for Vβ 19. Equal amounts of Vβ 6.1, 6.2, and 6.3 primers are mixed and used as Vβ 6. Equal amounts of Vβ 12.1 and 12.2 are mixed to use as Vβ 12.

Vβ 20	TGCCCCAGACTCTCTCAGCCTCCA
Vβ 21	GGAGTAGACTCCACTCTCAAG
Vβ 22	GATCCGGTCCACAAAGCTGG
Vβ 23	ATTCTGAACTGAACATGAGCTCCT
Vβ 24	GACATCCGCTCACCAGGCCTG

[a]Concentration of each reconstituted Vβ primer is 5 μM in TE. Concentrations of Fam-labeled Cβ, unlabeled Cβ, Tet-labeled Cα, and unlabeled Cα primers are 100 μM in TE.

3. On ice or a cold block, prepare a master mix for each cDNA sample that will be used, making enough for 27 tubes each.

DEPC water	943 μl
10× PCR buffer for TaqGold (Applied Biosystems, Roche)	135 μl
25 mM MgCl₂ (Applied Biosystems, Roche)	81 μl
10 mM dNTP mixture (Roche Applied Science)	27 μl
cDNA (3.5 to 5.0 μg)	15 μl
AmpliTaq Gold (Applied Biosystems, Roche)	7 μl

4. Vortex and spin down the mix after adding the Taq, and then add 45 μl to each tube, making sure not to cross-contaminate the primers.

5. Place the tubes in a PE Applied Biosystems GeneAmp PCR system 9700 and run the reaction for 40 cycles using the following program.

Hold:	10 min at 95°C
Cycle (40 cycles):	25 s at 94°C, 45 s at 60°C, and 45 s at 72°C
Hold	5 min at 72°C

6. In order to label the products, a "runoff" reaction must be set up and run for seven cycles. One master mix can be made for every sample. The following is the mix for 27 tubes (one sample) and can be multiplied to accommodate more samples.

DEPC water	154.0 μl
10× PCR buffer	27.5 μl
25 mM MgCl₂	33.0 μl
10 mM dNTP mixture	5.5 μl
Fam Cβ (10 μM)	2.75 μl
AmpliTaq Gold	1.0 μl

7. Add 8 μl of the runoff mix to each tube of a new tray of empty tubes, and transfer 2 μl of product obtained during the first 40 cycles to the appropriate corresponding new tube.

Step 4: Gel Loading Preparation

1. In order to load labeled PCR product, a molecular size marker (GeneScan 500 XL TAMRA; PE Applied Biosystems) needs to be added in loading dye. The following is a master mixture of loading dye.

Deionized formide (Sigma)	75 μl
TAM 500	15 μl
Loading dye	15 μl

2. Add 3.5 μl of the master mix to the PCR tube.
3. Add 2.5 μl of PCR product.
4. Denature and quench immediately before loading the gel. This involves incubation at 90°C for 2 min followed by 4°C.
5. Run 1.5 μl of loading sample on a 6% DNA sequencing gel. The gel size is 36 cm, with 2-mm spacers. Run for 3 h. The plate should be scanned and prerun for 10 to 20 min using 1× Tris-borate-EDTA buffer. Urea should be blown out of the wells before loading the samples (there is no need to skip lanes as is done with the sequencing gels). Before beginning data collection, set up and save sample

sheet within GeneScan analysis and be sure to select the "settings" within "GeneScan Collection."

Step 5: Cα Relative Quantitation of Vβ Subfamilies

1. Follow steps 1 to 3 above, using the following master mix:

DEPC water	938 μl
10× PCR buffer	135 μl
25 mM MgCl$_2$	81 μl
10 mM dNTP mixture	27 μl
Fam Cβ primer (100 μM)	7 μl
3′ Tet Cα (100 μM).	7 μl
5′ unlabeled Cα (100 μM).	7 μl
cDNA (2.5 to 5.0 μg)	6 μl
AmpliTaq Gold.	7 μl

2. Follow the same steps as above, only run the sample for 25 to 27 cycles. This ensures that the PCRs will not go to saturation and that amounts of product will be proportional to the individual amounts of starting template.

3. In a fresh tray of tubes, add 18 μl of the 20% EDTA-blue dextran in formamide mixture to each tube. Two microliters of each reaction product can be directly added to the corresponding tubes of loading mix.

4. Follow the denaturation and loading steps above.

Quality Control and Quality Assurance

1. Adequate cell numbers to yield an adequate amount of total RNA are critical to generating reliable and reproducible results. Obtain ~10^7 cells to yield 5 μg of total RNA (3 μg minimum). Monitor T-cell purity and ensure that it exceeds 95%.

2. Vortex samples well for consistent results.

3. Use dry heat blocks rather than water baths to avoid RNase contamination.

4. Do not use powdered gloves.

5. Use only RNase-DNase-free screw-cap tubes and micropipette tips.

6. Aliquot all primers for single use (do not refreeze-thaw).

7. Use cold blocks to keep reaction tubes cold while setting up the PCR.

8. After 40 PCR cycles, run 5 μl of PCR mix in a 1% agarose gel to confirm PCR product reaction. The expected molecular size of the PCR product is ~300 bp.

Interpretation

1. Decreases in CDR3 gene length diversity can be associated with the relative loss of a diverse number of antigen-specific T-cell clones (polyclonal contraction), the relative gain of a limited number of antigen-specific T-cell clones (oligoclonal expansion), or both phenomena at the same time. Therefore, while Vβ spectratyping analysis provides insight into the breadth of the T-cell repertoire, it does not address how such a limited (or "skewed") repertoire might have come about in the first place.

2. Similarly, while CDR3 gene length diversity should correlate with gene sequence diversity, direct sequencing of the genes is necessary to absolutely confirm this correlation.

3. While limited repertoires are often obvious by visual inspection of the pattern of CDR3 length distributions, subtle differences are often found. Distinguishing whether these subtle differences are significant can be challenging. Several groups have attempted to apply statistical techniques to

quantifying differences between samples, but caution should be exercised when visual inspection alone does not convey obvious differences in comparator CDR3 length distribution patterns (5).

INTRACELLULAR CYTOKINE ANALYSIS

The ability of T cells to rapidly secrete cytokines following stimulation by their cognate antigen is an important hallmark of the memory T-cell response. This response can help enumerate the frequency of antigen-specific T cells in the peripheral blood. Application of this technique is shown in Color Plate 12, where the frequency of cytomegalovirus (CMV)-specific and purified protein derivative (PPD)-specific CD4 T cells, as defined by gamma interferon (IFN-γ), interleutin 2 (IL-2), or tumor necrosis factor alpha (TNF-α) production, is enumerated for one individual at a single time point. In this section we outline two popular methods to detect cytokine-secreting antigen-specific T cells using multiparameter flow cytometry. One method uses whole blood, which is more convenient and perhaps more physiological than other methods (15). The second method uses peripheral blood mononuclear cells (PBMCs). It is capable of using cells from a variety of clinical samples and may have less background noise than other methods (14). As both methods only enumerate antigen-specific cells that are capable of rapidly secreting cytokines (and certainly only those expressing the cytokines measured), antigen-specific T cells not having these characteristics are not enumerated using these assays.

Whole-Blood Method

Equipment

Centrifuge
Three- or four-color flow cytometer
Vortex mixer
Incubator (5% CO$_2$ at 37°C)
37°C water bath

Materials and Reagents

15-ml conical polypropylene tubes
12- by 75-mm polystyrene tubes
Pipettor and pipette tips
Micropipettor and micropipette tips
FACSLyse *or equivalent*
FACSPerm 2 *or equivalent*
Brefeldin A
Dimethyl sulfoxide (DMSO)
Paraformaldehyde (PFA)
PBS (without Ca^{2+} or Mg^{2+})
Staphylococcus enterotoxin B (SEB)

Procedure

Step 1: Material and Reagent Preparation

1. Brefeldin A (catalog no. B-7651; Sigma-Aldrich, St. Louis, Mo.) is supplied as a powder and when dissolved in DMSO (catalog no. D8779; Sigma-Aldrich) can be frozen in small aliquots (e.g., 60 μl) at a concentration of 10 mg/ml for up to 1 year. Just prior to use, dilute a thawed aliquot 1:50 using PBS (or medium) to make up a 1-μg/μl

working solution (e.g., add 50 μl of thawed aliquot to 2.5 ml of PBS). Store at 4°C for use the same day. Do not refreeze.

2. Prepare 4% PFA solution in a fume hood by adding 40 g of crystalline PFA (catalog no.150146; ICN Biomedicals, Inc., Aurora, Ohio), 13.4 g of $Na_2HPO_4\cdot 7H_2O$ (molecular weight [MW], 268) and 6.9 g of $NaH_2PO_4\cdot H_2O$ (MW, 138) to 900 ml of distilled H_2O in a measuring cylinder, then placing the cylinder on a hotplate/stirrer, heating to 60 to 70°C, and stirring moderately. In solution, the PFA will become clear (do not overheat or spill solution, which is a potential carcinogen). After cooling, add enough distilled H_2O to total 1,000 ml. Adjust to pH 7.0. Aliquot into 5- to 15-ml tubes and freeze at −20°C (good for at least 3 months). Prior to use, thaw and prepare 1% solution by diluting with PBS (good for 2 weeks at 4°C).

3. Prepare FACSLyse and FACSPerm 2 solutions (catalog no. 349202 and 340973; Becton Dickinson Immunocytometry Systems, San Jose, Calif.) according to the manufacturer's recommendations. Both are supplied premixed as 10× solutions and use deionized water as diluent (*do not* use PBS or other buffers).

4. Prepare intracellular cytokine staining wash buffer using PBS with 0.5% (wt/vol) bovine serum albumin (BSA) and 0.5% (wt/vol) sodium azide (NaN_3). Store at 4°C for up to 2 weeks.

5. Purified SEB is supplied as a lyophilized powder (catalog no. BT-202; Toxin Technology, Sarasota, Fla.) and is dissolved in pure water and then stored at a working concentration of 1 mg/ml at 4°C for up to 3 months.

6. Peptides or antigens are supplied from various vendors or researchers, either as lyophilized powders or as solutions, and are usually resuspended in solution and then frozen in small aliquots for later use. Specifics depend on the antigen and supplier.

Step 2: Antigenic Stimulation

1. Label 15-ml polypropylene tubes (activated lymphocytes are less likely to adhere to polypropylene than polystyrene) for each stimulation condition desired. Include both positive and negative control conditions.

2. Use only well-mixed sodium heparin-anticoagulated whole blood which has been stored at room temperature for less than 12 h (blood should be used as soon as possible). Other anticoagulants (e.g., EDTA, acid-citrate-dextrose, and lithium heparin) are not suitable, as they may interfere with cytokine secretion by chelating cations. Reject samples which are obviously hemolyzed or have been exposed to extremes of heat or cold.

3. The amount of blood needed per stimulation condition is determined by how many flow cytometry tubes will be analyzed per stimulation condition, how many cells are present in whole blood, and the cell number target for flow cytometry acquisition (e.g., 10,000 $CD4^+$-T-cell events). Blood volumes are typically 0.5 to 2 ml per stimulation condition.

4. Add CD28 and CD49d (catalog no. 347690; Becton Dickinson Immunocytometry Systems) at a final concentration of 10 μl/ml of whole blood in each of the 5-ml stimulation tubes (CD28 and CD49d are used for costimulation and alone do not trigger cytokine secretion from T cells).

5. Add the appropriate concentration of stimulating peptide, antigen, or superantigen/mitogen to each of the labeled stimulation tubes (these should be pretitrated for optimal responses, but final concentrations of antigen preparations are often ~10 μg per ml of blood). To negative control tubes

add 10 μl of RPMI 1640, and to positive control tubes add 10 μg of SEB per ml of blood (i.e., 10 μl of 1-μg/μl working solution per ml of blood).

6. Aliquot the appropriate amount of blood into each 15-ml tube.

7. Incubate between 6 and 24 h at 37°C and 5% CO_2. Incubation times can be adjusted depending on the antigen(s) used or scheduling issues, but once chosen, incubation times must remain constant for relevant comparisons (6).

8. Four hours prior to completion of the incubation (i.e., after 2 to 20 h of incubation), add brefeldin A for a final concentration of 10 μg per ml of whole blood.

Step 3: Cell Preparation for Flow Cytometric Analysis

1. Label 12- by 75-mm polystyrene tubes (include compensation control tubes).

2. Add monoclonal antibody (MAb)-fluorochrome conjugates to stain the desired cell surface epitope (e.g., CD3 or CD4) for analysis in each flow cytometry tube (7, 8).

3. After vortexing each 15-ml stimulation tube on high for 10 s, remove the desired amount of blood and add it to the corresponding flow cytometry tube(s). Usually either 100 or 200 μl of stimulated blood is added to each flow cytometry tube. If more blood is needed (e.g., for individuals with few $CD4^+$ T cells in late-stage HIV disease), prepare additional parallel tubes (rather than additional blood per tube). In this case, cells from such parallel tubes can be recombined after processing but prior to acquisition on the flow cytometer (some researchers add EDTA at a final concentration of 2 mM just prior to this step to help decrease the number of adherent activated cells from the sides of tubes).

4. Remove blood splattered on the sides of tubes with cotton swabs wetted with deionized water (unstained blood can spuriously alter cell frequencies).

5. Vortex gently and incubate at room temperature for 15 min in the dark.

6. Add 2 ml of 1× FACSLyse (3 ml for tubes with 200 μl of blood) to the blood-MAb mixture. Vortex gently and incubate at room temperature for 10 min in the dark.

7. Centrifuge at $400 \times g$ for 5 min. Remove supernatant without disturbing the cell pellet.

8. Add 500 μl of 1× FACSPerm. Vortex gently and incubate at room temperature for 10 min in the dark. Add 2 ml of wash buffer and centrifuge at $500 \times g$ for 5 min. Remove supernatant without disturbing the cell pellet.

9. Add MAb for each intracellular epitope of interest to the appropriate flow cytometry tubes (e.g., IFN-γ, TNF-α, or IL-2). Vortex gently and incubate at room temperature for 30 min in the dark. Add 2 ml of wash buffer and centrifuge at $500 \times g$ for 5 min. Remove supernatant without disturbing the cell pellet.

10. Add 200 μl of 1% PFA working solution to pellet and vortex. Analyze on the flow cytometer or store at 4°C with wax and foil covers for analysis up to 24 h later.

Quality Control and Quality Assurance

1. Volumes of blood and not cell numbers determine volumes of MAb-fluorochrome conjugates.

2. Pretiter fluorochrome-antibody conjugates to determine optimal antibody concentration.

3. Particular care and practice in removing supernatants are necessary to avoid losing cells. This is particularly true when cells are permeabilized, as their densities decrease and

they are suspended in supernatants with higher protein concentrations. Under these conditions, many investigators prefer decanting to aspirating the pellet. When decanting, do not tip twice.

4. Remove blood splatters from the tube walls with deionized water on cotton tip swabs to prevent this unstained blood from subsequently being enumerated during analysis.

5. The standard staining volume of whole blood is 100 μl but a maximum of 200 μl per tube if the patient is lymphopenic or if large numbers of cells are needed to acquire the target number of >50 positive events.

Interpretation

Blood volume is determined by the needs of each experiment. For example, an experiment to determine IFN-γ, IL-2, and TNF-α expression from activated (CD69$^+$) CD3$^+$ CD4$^+$ T cells on a four-color flow cytometer would require three flow cytometry tubes. Alternatively, when using newer multiparameter (i.e., six- or nine-color) flow cytometers, the same experiment can be performed using a single tube. Beyond the convenience of not having to separate whole blood, and having fewer steps than other methods, another possible reason to choose the whole-blood method is that autologous plasma proteins and innate immune cells may be important contributors to the acquired cellular immune response, thus theoretically making this method more physiological than others.

Saponin-Based Method

Equipment

The equipment is the same as for the whole-blood method.

Materials and Reagents

5-ml V-bottom tubes

4-ml V-bottom tubes (catalog no. 57.477; Sarstedt, Newton, N.C.).

Corning U-bottom tissue culture tubes

15-ml conical polypropylene tubes

Pipettor and pipette tips

Micropipettor and micropipette tips

Brefeldin A (Sigma)

PFA

DNase I (20,000 U, 50 to 375 U/μl; Invitrogen, Cambridge, United Kingdom)

RPMI 1640

PBS

Saponin (Sigma)

Nonfat dried milk

BSA

Autologous Epstein-Barr virus (EBV)-transformed cell lines (lymphoblastoid B-cell lines [EBV-LCL])

Vaccinia virus constructs (e.g., vTFnef and vVK1) for option 1 (see below)

Procedure

Step 1: Reagent Preparation

1. Brefeldin A (10 mg/ml in DMSO) and PFA (4% at pH 7.0) are prepared as outlined for the whole-blood method, except that PFA is not diluted in PBS prior to use and is used at 4% after thawing.

2. Complete medium (CM) is prepared using RPMI 1640 with 10% fetal calf serum and 2% glutamine. Store at 4°C for 1 week.

3. DNase is supplied at between 50 and 375 IU/μl (Invitrogen) and used in aliquots between 1.5 and 4 μl per tube, depending on needs.

4. Intracellular cytokine staining wash buffer is prepared using sterile PBS with 0.1% (wt/vol) BSA and 0.1% (wt/vol) NaN$_3$. Store at 4°C for up to 2 weeks.

5. Cell culture freezing medium-DMSO (catalog no. 11101-011; Gibco) may be used to cryopreserve stimulated cells for future use.

6. For blocking and staining procedure:

a. PBS-S solution is prepared using PBS with 0.2% saponin.

b. PBS-S–5% milk solution is prepared using PBS-S with 5% nonfat dried milk. Store at 4°C for 2 to 6 months.

c. PBS-BSA is prepared using 0.1% BSA.

7. Peptides and antigens are supplied from various vendors or researchers, either as lyophilized powders or as solutions, and are usually resuspended in solution and then frozen in small aliquots for later use. Specifics depend on the antigen and supplier.

Step 2: PBMC Isolation

1. Isolate PBMCs by the Ficoll-Hypaque method, washing cells twice with Hanks' balanced salt solution with Ca^{2+} and Mg^{2+} or RPMI 1640. Count cells during the washing.

2. Resuspend PBMCs in CM and leave at room temperature.

3. If frozen PBMCs are to be used, results are improved by incubating them overnight in CM at a concentration of approximately 10^6/ml.

4. Plate PBMCs at $4 \times 10^6/2$ ml in a U-bottom tissue culture tube, using prewarmed medium.

Step 3: Antigenic Stimulation of CD4$^+$ T Cells

1. Add anti-CD28 to a final concentration of 1 μg/ml.

2. Add antigen (e.g., p24 or p55). It is very important to try proteins from different manufacturers initially, as there may be significant differences in the results. Typically $\approx$10 μg/ml is used.

Step 4: Antigenic Stimulation of CD8$^+$ T Cells

1. Option 1: EBV-transformed vaccinia virus-infected stimulator cells (5). In this case, a large diversity of HIV antigens will be presented.

a. Autologous EBV-LCL are infected overnight with the desired vaccinia virus constructs (e.g., vTFnef and vVK1) for an optimal duration of 12 to 16 h prior to being mixed with effectors.

b. Aliquot 2.5×10^6 EBV-transformed B cells for each target cell type to be prepared in 15-ml conical tubes.

c. Centrifuge at $400 \times g$ for 10 min.

d. Aspirate the supernatant and leave the cell pellet.

e. Add 150 μl of CM containing 2.5×10^6 to 10×10^6 (each virus has to be titrated to find out which infection ratio is best) PFU of the desired recombinant vaccinia virus.

f. Vortex gently.

g. Incubate in the 15-ml conical tubes with loosened caps in a 5% CO$_2$ incubator at 37°C for 90 min. Vortex gently at 30 and 60 min.

h. Wash twice with 10 ml of CM, centrifuging each time at $400 \times g$ for 10 min.

i. Resuspend in 1.25 ml of RPMI 1640 medium with 20% fetal bovine serum and transfer to a culture flask.

j. Incubate overnight (16 h) at 37°C in a 5% CO_2 atmosphere.

k. On the following day, add 200 μl of the vaccinia virus-infected EBV-LCL to the 2 ml of effector PBMCs in the U-bottom tubes, for a final PBMC/EBV-LCL ratio of 10:1. The results are usually consistent within ratios of 1:1 to 100:1.

2. Option 2: peptide pulsing (11). In this case, the EBV-LCL, instead of being infected with HIV-vaccinia virus constructs, are incubated for 1 h with the peptides of interest at 37°C in the U-bottom stimulation tubes. Effector PBMCs are then added with the peptide-pulsed EBV-LCL. The peptides (typically previously synthesized fragments from different HIV proteins) will occupy the groove of the HLA class I molecules on the EBV-LCL and in this fashion will be presented to the PBMCs.

3. Option 3: Direct peptide pulsing, for a final peptide concentration of 1 to 10 μM or approximately 2 to 10 μg of peptide/10^6 cells/ml.

4. Option 4: Polyclonal stimulation followed by electronic gating on cellular subsets of interest.

Step 5: Cell Incubation

1. Cap tubes and spin at $400 \times g$ for 5 min.
2. Incubate in 5% CO_2 at 37°C for 2 h.
3. Warm up brefeldin A at 37°C for 5 min, and vortex until dissolved (5 to 10 min). Dilute 1:50 in CM and vortex.
4. Add 100 μl of the brefeldin solution/tube (final concentration, 10 μg/ml). Mix gently without disrupting the pellet.
5. Incubate for 4 to 8 h in 5% CO_2 at 37°C. Depending on the cytokine that is going to be determined, different incubation times will be needed. Six hours total (4 h after adding brefeldin) gives adequate results for IL-2, TNF-α, and IFN-γ, but it is too short for IL-10 and IL-16 (these two may need 24 h).

Step 6: Cell Fixation (Adapted from Reference 14)

1. Add approximately 500 U of DNase to each tube. Gently vortex. Incubate for 5 min at 37°C. (This step is needed only when the stimulus used is polyclonal, e.g., phorbol esters plus calcium ionophore or soluble MAbs targeting the TCR-CD3 complex, as the intense cellular activation originates significant cell death with release of DNA.)
2. Remove cells with a pipette.
3. Place cells in a 4-ml V-bottom tube.
4. Place 4% PFA in a 37°C water bath to warm. Cool centrifuge to 4°C.
5. Spin down ($400 \times g$ for 10 min) and aspirate supernatant.
6. Break up the pellet by knocking the tubes against a white "pincushion" test tube rack.
7. Resuspend with 1 ml of cold PBS. Spin down ($400 \times g$ for 10 min).
8. Remove PFA from water bath and set on counter at room temperature.
9. Remove PBS from the tubes by aspiration.

Note: At this point, the cells have been washed twice and have not been fixed yet. If separate surface staining is required, it may be performed here. Most surface antibodies

will work on fixed cells, but occasionally they will not. Staining with HLA tetrameric complexes is suboptimal on fixed cells, so it is mandatory to perform surface staining with tetramers at this point. Regarding tetramer use, staining at 4°C for 30 min typically provides good results, with bright fluorescence of tetramer-labeled cells, although each tetramer should be tried at 4°C, room temperature, and 37°C for 15 to 60 min to optimize the signal-to-noise ratio. The higher the temperature, the less time used for staining. All conditions should work, but depending on the HLA-peptide combination, one temperature may be better than the other (17). The tetramer staining is performed as a MAb staining: the tetramer is added to PBS–0.1% BSA, typically 1:5 to 1:50 (1 to 10 μl of tetramer in 50 μl of PBS-BSA). Other MAbs can be added to the solution so a "master mix" for surface staining is prepared. The cell pellet to be stained is resuspended in the tetramer solution (or master mix) and incubated for 20 to 30 min (see above regarding need for different temperature-time combinations). After the surface staining, continue the protocol as follows.

10. Break up the pellet by knocking the tube.
11. Add 0.5 ml of 4% PFA to each tube. Incubate for 5 min.
12. Vortex each tube for ≈3 to 5 s three or four times over the 5 min of incubation (essential to avoid clumping).
13. After 5 min, add 2 ml of ice-cold 0.1% BSA–PBS azide.
14. Cap tubes and vortex to mix.
15. Centrifuge at ≈$1,200 \times g$ (3,000 rpm) for 5 min. Remove supernatant by aspiration.

At this point, the cells have been fixed. If desired, it is possible to proceed to permeabilization and intracellular staining immediately. Alternatively, the fixed cells may be frozen in DMSO for future use. Fixed and frozen cells stored at −80°C are equivalent to freshly analyzed cells for at least a year. Therefore, if desired, resuspend each tube in 1 ml of cell culture freezing medium-DMSO. Aliquot each tube or tube equivalent into one cryovial and freeze at −80°C.

Step 7: Cell Permeabilization, Blocking, and Intracellular Staining

1. If not freezing the cells for future use, proceed directly to step 6. If cells were cryopreserved, thaw frozen cells and continue to step 2.
2. Transfer to 4-ml V-bottom tubes.
3. Add 1 ml of PBS-BSA.
4. Spin down at $1,200 \times g$ (~3,000 rpm) for 5 min at 4°C.
5. Aspirate supernatant. Watch for pellet.
6. Add 50 μl of PBS-S–5% milk per each ≈1×10^6 to 2×10^6 cells, 50 μl minimum in order to permeabilize and block the fixed cells. Excess protein minimizes nonspecific binding to permeabilized cells.
7. Leave for 1 h or overnight on ice in the cold room.
8. For intracellular staining, make a master mix with your MAbs of choice in PBS-S–5% milk. The mixture of antibodies should be spun down at maximum speed for 10 min to decrease background. (It must be emphasized that each staining protocol has to be optimized according to the reagents used. We have had excellent results with the following mix for four-color staining to study IFN-γ-producing CD8 T cells: CD3 fluorescein isothiocyanate, 10 μl; CD8 PerCP, 10 μl; CD69 phycoerythrin [Beckon Dickinson], 20 μl; IFN-γ allophycocyanin [Pharmingen], 2.5 μl; and

PBS-S–5% milk, 7.5 μl. Staining was done in a 50-μl total volume per sample.)

9. Aliquot cells into 4-ml V-bottom tubes, ≈2 × 10⁶ to 10 × 10⁶ cells/tube. Use PBS-S to resuspend for aliquoting.

10. Spin down samples. Aspirate supernatant, avoiding the pellet.

11. Add diluted MAb (after centrifuging the master mix) to cells in a 50-μl volume, resuspending the cells in the process.

12. Incubate for 30 min at 4°C.

13. Add 1 ml of PBS-S to each tube and vortex.

14. Spin down samples. Aspirate supernatant, avoiding the cell pellet.

15. Break up the pellet by knocking tube.

16. Add 1 ml of PBS-S to each tube and vortex.

17. Spin down samples. Aspirate supernatant, again avoiding the pellet.

18. Repeat above starting with step 8, if staining with secondary MAbs. If finished, resuspend in 150 to 300 μl of PBS-BSA for flow cytometric analysis.

Quality Control and Quality Assurance

1. Results obtained with cryopreserved PBMCs that have been rested overnight are comparable to results obtained with rested fresh PBMCs. Using PBMCs immediately post-Ficoll gives significantly lower frequencies of antigen-specific T cells.

2. MAbs should be titered out before use for optimal signal-to-noise ratios.

3. MAb master mixes that will be used for intracellular staining should be diluted in PBS-S–5% milk and centrifuged prior to being mixed with cells in an effort to minimize nonspecific background staining.

4. HLA class I tetrameric complexes can be combined in a master mix containing a CD8 MAb and others for surface labeling of stimulated cells prior to fixation and intracellular staining.

5. We have successfully stained up to 15 × 10⁷ PBMCs with a single aliquot of tetramer before aliquoting the cells into other tubes for staining of other markers or prior to fixation, permeabilization, and intracellular cytokine staining.

6. Be careful to minimize light exposure of all fluorochrome-conjugated reagents during the preparation of the master mixes, at the time of staining, upon completion of staining, and in handling during the analysis.

Interpretation

This sensitive, highly quantitative, and highly reproducible method affords one the ability to study the frequencies of cytokine-secreting antigen-specific T cells using a technique characterized by very low background. The major drawbacks relate to the inconveniences of isolating PBMCs by leukapheresis and sodium diatrizoate density centrifugation. However, once PBMCs are available, one has the capability to examine multiple parameters of individual cell subsets and make conclusions about frequency, phenotype, and function. Compared with older techniques, such as limiting-dilution analysis, considerably higher frequencies of antigen-specific T cells have been measured in this manner. Although this has not been established, the methods outlined herein are probably superior to ELISPOT assays, which are limited by spatial constraints and numbers of antigen-presenting cells (APC) and typically yield results that are 10 to 100 times lower than the magnitudes detected by intracellular cytokine analysis.

DETECTION OF ANTIGEN-SPECIFIC T CELLS USING HLA TETRAMERS

HLA tetramer technology revolutionized the investigation of antigen-specific T-cell clones (1). Unlike other assays and technologies, HLA tetramers can enumerate T-cell clones regardless of their functional behavior, such as proliferation, killing, or cytokine production. An example of the application of this technique is shown in Color Plate 13, where tetramer staining is combined with cell surface immunophenotype markers to better characterize these antigen-specific cells in one HIV-infected individual at one time point. The technology can also be coupled with assays measuring these functional responses, such as the intracellular cytokine production, saponin-based method, as outlined above, or the lymphocyte proliferation assays (LPAs), outlined later in this chapter. Combined analysis of antigen-specific T-cell responses using these assays allows the teasing apart of complex T-cell immunological responses, as may occur in HIV-infected patients. In this section we outline the basic method for staining with HLA class I tetramers.

Technology
The technology is the same as for intracellular cytokine production, saponin-based method.

Materials and Reagents
Same as for intracellular cytokine production, saponin-based method
HLA tetramers

Procedure

Step 1: Prepare Cells

1. PBMCs: <100 × 10⁶ cells in 50 to 100 μl (10⁶ cells/100 μl)

2. Whole blood: 200 μl

Note: Following stimulation with peptides or polyclonal activators (e.g., phorbol esters plus calcium ionophore or soluble MAbs directed against subunits of the TCR-CD3 complex), cells can be washed, resuspended in medium at a concentration of 10⁶/ml, and rested for 1 h at 37°C to preserve the fluorescence intensity of tetramer staining.

Step 2: Prepare HLA Class I Tetramers

1. Use 5 to 10 μl per test. See "Saponin-Based Method, Procedure, Step 6 (Cell Fixation)," item 9 note.

2. MAbs directed against CD8 subunits and other surface markers may be included in a master mix.

3. Centrifuge at 16,000 × g for 20 min at 4°C to decrease nonspecific staining.

Note: Minimize exposure of this reagent to light during storage or incubation.

4. Incubate cells with tetramer at 4°C (or room temperature) for 30 min. See "Saponin-Based Method, Procedure, Step 6 (Cell Fixation)," item 9 note.

5. Wash with PBS twice, aspirating the supernatant after each wash.

6. Cells may be analyzed immediately or fixed, permeabilized, and stained for intracellular cytokines and other proteins per standard protocols.

7. If cells are not going to be analyzed immediately following step 5, store at 4°C in the dark and analyze within 24 to 48 h.
FIGURE 3 PBMCs were separated into CD4$^+$ T cells using magnetic beads and then labeled with CFSE to track cell division over 5 days following stimulation with either medium control or phyto-hemagglutinin (PHA), as indicated in the two dot plots. Arbitrary cell number is indicated on the y axis, while CFSE fluorescence intensity (measured in FL-1 on the flow cytometer) is shown on the x axis. A single CFSE bright peak (0) is shown under the medium control conditions, indicating that no cell division has occurred (the dim peak is from non-CFSE-labeled irradiated PBMCs that were added into these and parallel tubes for presentation of other antigens in the experiment). Conversely, the PHA-stimulated condition shows four cell (1 to 4) divisions beyond the peak of undivided cells (0), in addition to the dim peak of unlabeled irradiated PBMCs.

Quality Control and Quality Assurance

Quality control and quality assurance are the same as for intracellular cytokine production, saponin-based method.

Interpretation

While HLA tetramer technology is a very powerful tool to investigate immunological responses in the setting of HIV infection, its major drawback reflects its high degree of specificity. In other words, when enumerating an antigen-specific T-cell clone, only T cells specific for a particular epitope loaded onto a particular HLA molecule are enumerated. Given that T-cell responses to any given pathogen may include dozens (if not hundreds) of antigenic epitopes, and HLA haplotypes can vary significantly between individuals, HLA tetramer technology is highly inductive, making interindividual comparisons difficult.

LYMPHOCYTE PROLIFERATION

The ability of lymphocytes to expand exponentially after encountering their cognate antigen is a critical attribute that allows the acquired immune response to contain otherwise lethal pathogenic challenges. For decades, immunologists have measured this response using the LPA. This assay, coupled with limiting-dilution analysis, was one of the first methods used to quantitate antigen-specific T-cells. However, because the assay does not enumerate cells with low proliferative potential, quantitation of antigen-specific T-cell precursor frequencies has been supplanted by flow cytometric techniques, such as HLA tetramer and intracellular cytokine expression assays. Nevertheless, the ability to measure proliferation in response to cognate antigen(s) remains an important functional characteristic of antigen-specific T cells.

The standard LPA uses tritiated-thymidine pulse-labeling of cellular DNA within PBMCs at the peak of proliferation in tissue culture as a surrogate measure of the precursor frequency of antigen-specific cells. Cells dividing during the period of pulse-labeling (usually 6 h) incorporate the

tritiated thymidine in the daughter DNA strands. Subsequently, cells are harvested, and quantitation of radioactivity measured from each tissue culture well correlates with the magnitude of cellular expansion during the period of labeling. This assay is outlined in chapter 95.

In this section, we outline another popular method to measure lymphocyte proliferation using a membrane-tracking fluorescent dye that spontaneously and irreversibly binds to cells (10). Once labeled, the fluorescent dye is divided equally among any subsequent daughter cells. This decay of fluorescence per generation of daughter cells is conveniently resolved using the log scale of one of the fluorescence detectors of a multiparameter flow cytometer (see Fig. 3). Simultaneous measurement of T-cell surface immunophenotype, using the other fluorescence detectors on the flow cytometer, allows determination of which T-cell subsets are proliferating, as shown in Fig. 4.

5- and 6-Carboxyfluorescein Diacetate Succinimidyl Ester (CFSE) Cell Division Assay

Equipment

Centrifuge
Three- or four-color flow cytometer
Vortex mixer
Incubator (5% CO_2 at 37°C)
37°C water bath

Materials and Reagents

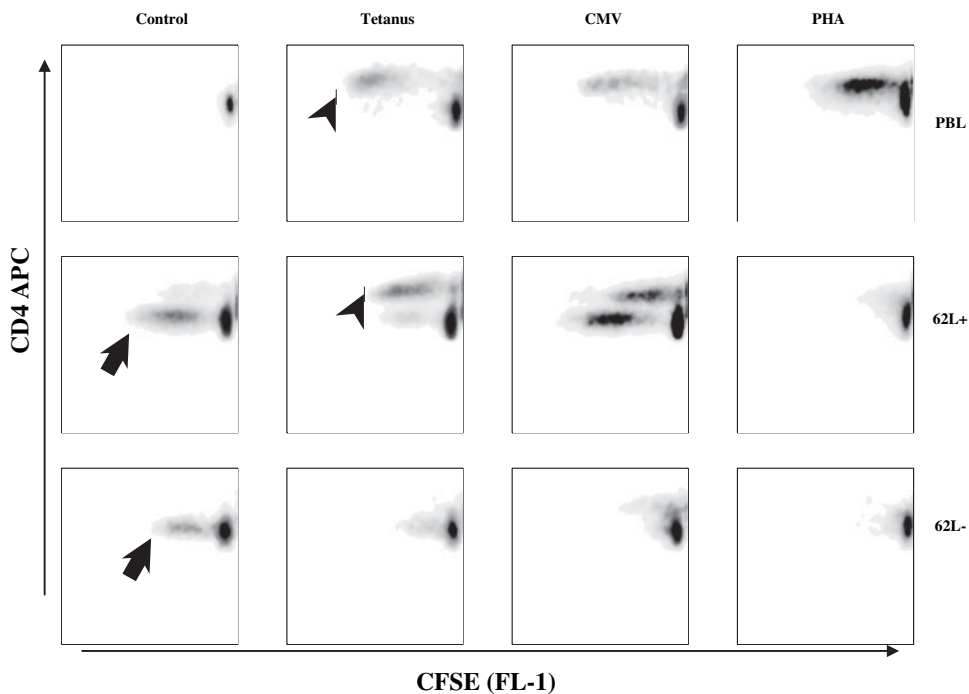
15- and 50-ml conical polypropylene tubes
12- by 75-mm polystyrene tubes
Pipettor and pipette tips
Micropipettor and micropipette tips
1× PBS (without Ca^{2+} or Mg^{2+})
RPMI 1640


FIGURE 4 PBMCs were either set aside, irradiated, or separated into CD4$^+$ CD62L$^+$ or CD4$^+$ CD62L$^-$ T cells. PBMCs (unirradiated) and separated CD4$^+$ T-cell subsets were then stimulated with medium control, tetanus toxoid, CMV, or phytohemagglutinin (PHA) (as shown across the top of all dot plots) for 2 days in the presence of irradiated PBMCs as APC. Cells were then harvested and labeled with CFSE and placed back into medium for an additional 6 days. Cells were harvested again and then labeled with MAb for surface markers (CD3 and CD4) and analyzed on a flow cytometer to track cell division. The arrowheads identify tetanus toxoid-specific cell division (bright for CD4) found in PBMCs that corresponded to division found in CD4$^+$ CD62L$^+$ T cells but not CD4$^+$ CD62L$^-$ T cells, while the arrows identify homeostatic cell division (dim for CD4) that is mostly confined to CD4$^+$ CD62L$^+$ T cells. Proliferation measured by CFSE cell division was confirmed with standard tritiated-thymidine LPA results at 5 days (results not shown). Separated PHA stimulations do not show proliferation, likely as these cells lost CFSE signal (death or >8 divisions) by day 8 of stimulation.

Human AB serum

L-Glutamine (200 mM solution)

HEPES (1 M solution)

Gentamicin

DNase I (20,000 U, 50 to 375 U/μl; Invitrogen, Cambridge, United Kingdom)

EDTA

CFSE

Antibody-fluorochrome conjugates for immunophenotyping

Antigen, peptides, or mitogens for cell stimulation

Procedure

Step 1: Reagent Preparation

1. Prepare wash buffer as PBS with 0.1% (wt/vol) BSA. Store at 4°C for up to 2 weeks.

2. Prepare culture medium as RPMI 1640, 10% (vol/vol) human AB serum (heat inactivated for 30 min at 55°C), 2 mM L-glutamine, 10 mM HEPES, and 50 μg of gentamicin per ml. Sterile filter through a 0.22-μm-pore-size polyethersulfone filter and store for up to 2 weeks at 4°C.

3. CFSE (catalog no. C1157; Molecular Probes, Eugene, Oreg.) is supplied as 25 mg of lyophilized powder (MW, 557). Dissolve 25 mg in DMSO to a final concentration of 5 mM (i.e., 2.785 mg/ml) and freeze in 50-μl aliquots at −80°C under desiccating conditions for up to 1 year.

4. DNase is supplied at between 50 and 375 IU/μl (Invitrogen) and used in aliquots between 1.5 and 4 ml per tube, depending on needs.

Step 2: Cell Labeling

1. Isolate cells of interest using density gradient centrifugation (see chapter 95).

2. Wash cells once in room temperature PBS.

3. Count and aliquot 15×10^6 to 30×10^6 cells into 15-ml conical polypropylene tubes for CFSE labeling.

4. Pellet and resuspend in 1 ml of PBS per 15-ml conical tube.

5. Prepare CFSE by thawing one vial of stock 5 mM CFSE in a 37°C water bath, diluting 4,000 times by first adding 50 μl of stock solution to 50 ml of room temperature PBS and then adding 12.5 ml of this solution to 37.5 ml of PBS (it is wise to optimize the assay to your particular cells and antigens by first testing several different CFSE concentrations). Shield from light prior to cell labeling.

6. Mix an equal volume of cell suspension with diluted CFSE solution (i.e., at 1:1). Vortex immediately and periodically (e.g., 10 times, each lasting for a few seconds) during 7 min of incubation at room temperature.

7. Quench cell staining reaction by adding 2 ml of 4°C heat-inactivated human AB serum. Vortex immediately and let sit for 1 min (the high protein content of the medium binds excess CFSE in this and subsequent wash steps).

8. Wash cells two additional times in culture medium containing heat-inactivated human AB serum.

9. Plate cells in U-bottomed plates (e.g., 1-ml-deep 96-well tissue culture plates, catalog no. P9626-S; PGC Scientifics, Frederick, Md.) in one-half the desired final tissue culture volume at twice the desired final concentration (e.g., 0.5 ml of suspension containing 4×10^6-cells/ml).

10. If using $CD4^+$ T cells previously isolated by either fluorescence-activated cell sorting or magnetic bead separation, consider adding irradiated autologous monocytes or PBMCs as APC. These should be added in one-quarter the desired final tissue culture volume at four times the desired final concentration. Ideally, the APC concentration should be previously determined in an APC titration (dose-response curve) experiment. Typically, irradiated PBMCs are plated at a final concentration of ~0.5×10^6 cells/ml.

11. Add antigen or peptide (or mitogen) to each tissue culture well in the appropriate remaining volume (i.e., in one-half the desired final tissue culture volume at twice the desired final concentration if using irradiated APC or in one-half the desired final tissue culture volume at twice the desired final concentration if not using irradiated APC).

12. Incubate the cells at 37°C and 5% CO_2 for the appropriate duration (between 5 and 8 days, usually 6 days). However, time course experiments will help determine the optimal harvest day for your particular antigens and cells.

13. On the day of harvest, add approximately 500 U of DNase to each tube. Gently vortex. Incubate for 5 min at 37°C. (This step is needed after prolonged cellular activation and turnover result in significant cell death with release of DNA.)

14. Label surface and intracellular epitopes using the saponin-based intracellular cytokine detection method outlined above (many investigators insist that dead-cell exclusion methods be used, in which case labeling with propridium iodide, 7-amino-actinomycin D (7-AAD), or TOPRO-3 to subsequently exclude positively labeled dead cells should be done prior to cell permeabilization [16]).

Step 3: Cell Analysis

1. If a dead-cell exclusion dye is used, then exclude these cells from subsequent analysis. Propridium iodide can be used to exclude brightly staining cells from FL-2 and still use another fluorochrome in the same channel, but compensation between FL-2 and FL-1 can be difficult depending on CFSE fluorescence intensity (see below). 7-AAD and TOPRO-3 can exclude positively staining dead cells from FL-3 and FL-4, respectively, but use of these agents precludes use of another fluorochrome in the same channels. Ultimately, the choice of a dead-cell exclusion dye is dependent on the particular applications, and a single approach is impossible to recommend.

2. When using CFSE, compensation between FL-2 and FL-1 can be difficult in the extreme (e.g., FL-2–FL-1 can be upwards of 90%). Make certain to have the appropriate compensation controls (i.e., single-color control tubes with CFSE, FL-2, FL-3, and FL-4 reagents). Difficulties in compensation

can be addressed by either avoiding FL-2 altogether, using a bright FL-2 fluorochrome, decreasing the photomultiplier tube voltage in FL-1, or decreasing the CFSE labeling concentration to 5 mM or less (leading to diminished sensitivity for later cell divisions).

Quality Control and Quality Assurance

1. Wash buffer should be kept on wet ice to keep it cold for use in the quenching step.

2. Always pretiter MAb concentrations prior to routine use to determine the minimal amount of antibody necessary for saturation and maximal fluorescence intensity.

3. Always pretiter antigens used in stimulation experiments for maximal optimal response at the minimal antigen concentration on the day of interest.

4. Always perform a time course experiment to determine the optimal cell harvest time for the cells and antigens used in the particular application.

5. Make certain to pretitrate out the optimal CFSE staining concentration prior to use in your particular application.

Interpretation

Using membrane dye dilution methods to track cell division on a multiparameter flow cytometer is an extremely powerful tool to investigate which cells within PBMCs respond to antigen, how they differentiate over time, and what their surface immunophenotype is as they go through successive rounds of cell division. However, it is always important to remember that the technique does not analyze cells that disappear from the culture system, thus increasing representation of cells that remain. Thus, care should be taken in making conclusions about cells that did not proliferate in an assay that only measures cells that did proliferate after about 6 days in tissue culture.

The Primary Immunodeficiency Diseases

HOWARD M. LEDERMAN

98

Patients with primary immunodeficiency diseases most often are recognized because of their increased susceptibility to infection (chronic or recurrent infections without other explanation, infection with an organism of low virulence, or infection of unusual severity). However, these patients may also present with autoimmune or inflammatory disorders (e.g., hemolytic anemia, inflammatory bowel disease, vasculitis, or systemic lupus erythematosus) or with part of a syndrome complex (Table 1).

SYMPTOMS OFTEN CAN GUIDE THE LABORATORY EVALUATION

The type of pathogen and the location of the infection may give valuable insight into the nature of the immunologic defect. For example, individuals with antibody deficiencies are unusually susceptible to encapsulated bacteria and enteroviruses, which cause infections along mucosal surfaces. Individuals with defects in cell-mediated immunity can have problems with almost any microorganism, including opportunistic pathogens. Individuals with complement deficiencies most often present with bacteremia, septic arthritis, and meningitis, caused by encapsulated bacteria. And finally, phagocytic disorders are characterized by bacterial and fungal infections of the skin and abscesses in the reticuloendothelial system (lymph nodes, spleen, and liver).

Autoimmune and inflammatory diseases are more commonly seen in particular primary immunodeficiency diseases, most notably common variable immunodeficiency, selective immunoglobulin A (IgA) deficiency, chronic mucocutaneous candidiasis, and deficiencies of early components of the classical complement pathway (C1 to C4).

When immunodeficiency is part of a constellation of signs and symptoms in a syndrome complex, the diagnosis of immunodeficiency may be made before there are any clinical manifestations of that deficiency. For instance, children with DiGeorge syndrome are most often first identified because of the neonatal presentation of congenital heart disease and/or hypocalcemic tetany. This should lead to T-lymphocyte evaluation prior to the onset of opportunistic infections. Similarly, a diagnosis of Wiskott-Aldrich syndrome can often be made in young boys with eczema and thrombocytopenia even prior to the onset of infections.

LABORATORY EVALUATION

Although immune system dysfunction can be suspected by the clinician after careful review of the history and physical exam, specific diagnoses are rarely evident without the use of the laboratory. However, the types of infections and other symptoms should help to focus the laboratory workup on specific compartments of the immune system (Table 2).

TABLE 1   Examples of immunodeficiency syndromes

Syndrome	Usual clinical presentation(s)	Immunologic abnormality
DiGeorge syndrome	Congenital heart disease, hypoparathyroidism, abnormal facies	Thymic hypoplasia
Wiskott-Aldrich syndrome	Thrombocytopenia, eczema	Variable B- and T-lymphocyte dysfunction
Ataxia-telangiectasia	Ataxia, telangiectasia	Variable B- and T-lymphocyte dysfunction
Ivemark syndrome	Congenital heart disease, bilateral three-lobed lungs	Asplenia
Polyendocrinopathy syndrome	Endocrine organ dysfunction	Chronic mucocutaneous candidiasis

TABLE 2 Patterns of illness associated with primary immunodeficiency

Disorder	Illnesses	
	Infection	Other
Antibody	Sinopulmonary (pyogenic bacteria) Gastrointestinal (enterovirus, giardiasis)	Autoimmune disease (autoantibodies, inflammatory bowel disease)
Cell-mediated immunity	Pneumonia (pyogenic bacteria, *Pneumocystis jerovici*, and viruses) Gastrointestinal (viruses) Skin, mucous membranes (fungi)	
Complement	Sepsis and other blood-borne infections (streptococci, pneumococci, and neisseriae)	Autoimmune disease (systemic lupus erythematosus, glomerulonephritis)
Phagocytosis	Skin, reticuloendothelial system, abscesses (*Staphylococcus*, enteric bacteria, fungi, and mycobacteria)	

Screening tests that should be performed for almost all patients include a complete blood count with differential and quantitative measurement of serum immunoglobulins. Other tests should be guided by the clinical features of the patient (Table 3). Finally, whenever primary immunodeficiency is suspected, consideration must also be given to secondary causes of immunodeficiency, including human immunodeficiency virus infection, therapy with anti-inflammatory medications (e.g., corticosteroids), and other underlying illnesses (e.g., lymphoreticular neoplasms and viral infections, such as infectious mononucleosis). Details about the selection and performance of specific laboratory tests are discussed in the following chapters, organized by immunologic compartment: antibody, cell-mediated immunity (severe combined immunodeficiency), complement, and phagocytes.

TABLE 3 Screening tests for primary immunodeficiency

Suspected abnormality	Diagnostic test(s)
Antibody	Quantitative immunoglobulins (IgG, IgA, and IgM) Antibody response to immunization
Cell-mediated immunity	Lymphocyte count T-lymphocyte enumeration (CD4 and CD8) HIV[a] serology Delayed-type-hypersensitivity tests
Complement	Total hemolytic complement
Phagocytosis	Neutrophil count Nitroblue tetrazolium dye test or equivalent

[a]HIV, human immunodeficiency virus.

Approach to the Diagnosis of Severe Combined Immunodeficiency

CHAIM M. ROIFMAN

99

Severe combined immunodeficiency (SCID) includes a genetically heterogeneous group of disorders that present with a distinct clinical and immunological phenotype. The phenotype is related to the profound T-cell defect which is common to all types of SCID. Central to the adaptive immune system, T cells protect the host from intracellular pathogens by mediating cytolytic activity and releasing Th1 cytokines. In addition, through release of soluble mediations such as interleukin 4 (IL-4) and IL-10 and interactions with antigen-presenting cells and B cells, T cells regulate the production of antibody against protein antigens (3). Consequently, severe defects in T-cell function result in a combined cellular and humoral immunodeficiency leading to increased susceptibility to viral, fungal, and microbial infections in infancy (21). SCID is caused by a variety of genetic aberrations in genes which appear to be critical for the normal development and expansion of the T-cell repertoire, or in genes whose products are responsible for effective elimination of metabolites which are toxic to T-cell precursors (Table 1 and Fig. 1).

In addition to T-cell deficiency, some aberrations, such as mutations in IL-2 receptor (IL-2R) gamma and its downstream signaling partner JAK-3, prevent the normal development of NK cells. Other forms of SCID, such as recombination-activating gene (RAG) deficiency, may block the maturation of B cells as well as T cells. Nevertheless, a profound selective deficiency in the T-cell lineage such as in CD3δ deficiency is sufficient to produce a full phenotype of SCID with extreme susceptibility to microbes of even low pathogenicity (Table 1).

MOLECULAR BASIS OF SCID

T⁻ B⁻ SCID

RAG Deficiency

Patients who lack circulating T lymphocytes as well as B lymphocytes are most frequently found to have mutations in one of the RAGs RAG1 and RAG2 (35). The corresponding enzymes play a critical role in the complex process of assembling the V(D) and J segments which together form the variable parts of immunoglobulin and T-cell receptor (TCR) protein chains. In the absence of effective recombination, the development of a full repertoire of T cells or B cells is greatly limited, hence the reduced number of circulating T cells and B cells in patients with abnormal RAG1 or RAG2 activity.

Missense mutations limiting, but not completely abolishing, the function of RAG1 or RAG2 were implicated as a cause of Omenn's syndrome, which is characterized by erythroderma, lymphadenopathy, hepatosplenomegaly, eosinophilia, and high immunoglobulin E levels (9, 22, 40, 41, 43).

ARTEMIS Deficiency

An essentially identical phenotype of complete absence of circulating T cells and B cells results from mutations which render the ARTEMIS enzyme inactive (19). Similar to the case with RAG1 or RAG2, partial activity of ARTEMIS may result in an Omenn's syndrome phenotype (11).

ADA Deficiency

Markedly reduced T-cell and B-cell numbers are also typical of adenosine deaminase (ADA) deficiency. This enzyme mediates conversion of adenosine into inosine and of deoxyadenosine into deoxyinosine (14). In ADA deficiency the injury to early lymphocyte precursors is caused by the intracellular accumulation of deoxyadenosine and its phosphorylated metabolites. Partial enzymatic deficiency of ADA may result in a delayed and/or milder clinical presentation (24).

Reticular Dysgenesis

Reticular dysgenesis, an exceedingly rare type of SCID, is caused by a defect in early lymphoid and myeloid precursors (10). Patients present with profound neutropenia and lymphopenia. The thymus gland is barely detectable by ultrasound and appears to be completely dysplastic when assessed by histology and immunohistochemistry.

T⁻ B⁺ (NK⁻) SCID

XL-SCID

The most common type of SCID is inherited as an X-linked trait. This disease is caused by a mutation in the gene that encodes the IL-2R common gamma chain (γc) located at Xq12-13.1 (20). Together with the IL-2Rα and -β chains, the γc forms the high-affinity receptor for IL-2, which is required for clonal expansion of T cells. The γc chain is also an essential partner to other receptors, including those for IL-4, IL-7, IL-9, IL-15, and IL-21. The typical immunotype of XL-SCID is an absence of circulating T cells and NK cells and normal numbers of B cells. This can be easily explained by a lack of

TABLE 1 Genetic and immunological features of SCID[a]

Phenotype and disease	Genetic features (gene/inheritance)	Circulating white blood cells				Thymus

activity of IL-7R and IL-15R, respectively. Rarely, atypical cases of XL-SCID may have near normal to normal numbers of circulating T cells and NK cells (Table 1) (26, 37).

JAK-3 Deficiency

Phenotypically identical to XL-SCID but inherited in an autosomal recessive fashion are cases of SCID caused by mutations in the JAK-3 gene, which is located at chromosome 19 (16, 34). This tyrosine kinase mediates signal transduction stemming from the γc chain and IL-2R (23, 33).

T⁻ B⁺ (NK⁺)

IL-7Rα Deficiency

IL-7R is essential for the development of T cells in humans (25). It is therefore not surprising that mutations in this receptor result in the absence of circulating T cells with preserved development of B and NK cells (27, 32). IL-7R consists of two subunits, the γc chain and IL-7Rα, which is specific for IL-7R. The receptor is expressed very early in lymphoid precursor cells, including some CD34⁺ stem cells, hence the block of T-cell development at an early stage (double negative) and the resultant small and dysplastic thymus (Fig. 1 and Table 1).

CD3δ Deficiency

CD3δ subunits are the signaling molecules of the TCR. While deficiencies of CD3γ result in mild to moderate cellular deficiency (1), mutations in CD3δ cause a complete arrest in the transition from double-negative to double-positive thymocytes (7). Patients would therefore have no circulating

αβ TCR- or γδ TCR-positive cells. B-cell and NK-cell numbers are normal. The thymus in these patients appears normal in size, but it contains mainly immature double-negative thymocytes and lacks Hassall's corpuscles (30). A similar phenotype has been recently identified in a case with complete CD3ε deficiency (8).

CD45 Deficiency

CD45 deficiency results in a similar phenotype, including a complete lack of circulating T cells with normal B cells and NK cells. The CD45 protein is a phosphatase that modulates TCR/CD3 signaling (15, 39).

IL-2Rα (CD25) Deficiency

IL-2Rα deficiency in humans is fascinating. It results in inefficient negative selection in the thymus that leads to expansion of autoreactive clones which infiltrate multiple tissues (29). Indeed, the thymus in such patients is densely populated with thymocytes. However, Hassall's corpuscles and corticomedullary distinctions are lacking. The number of circulating T cells is reduced, but B-cell and NK-cell numbers are normal (29, 36).

PNP Deficiency

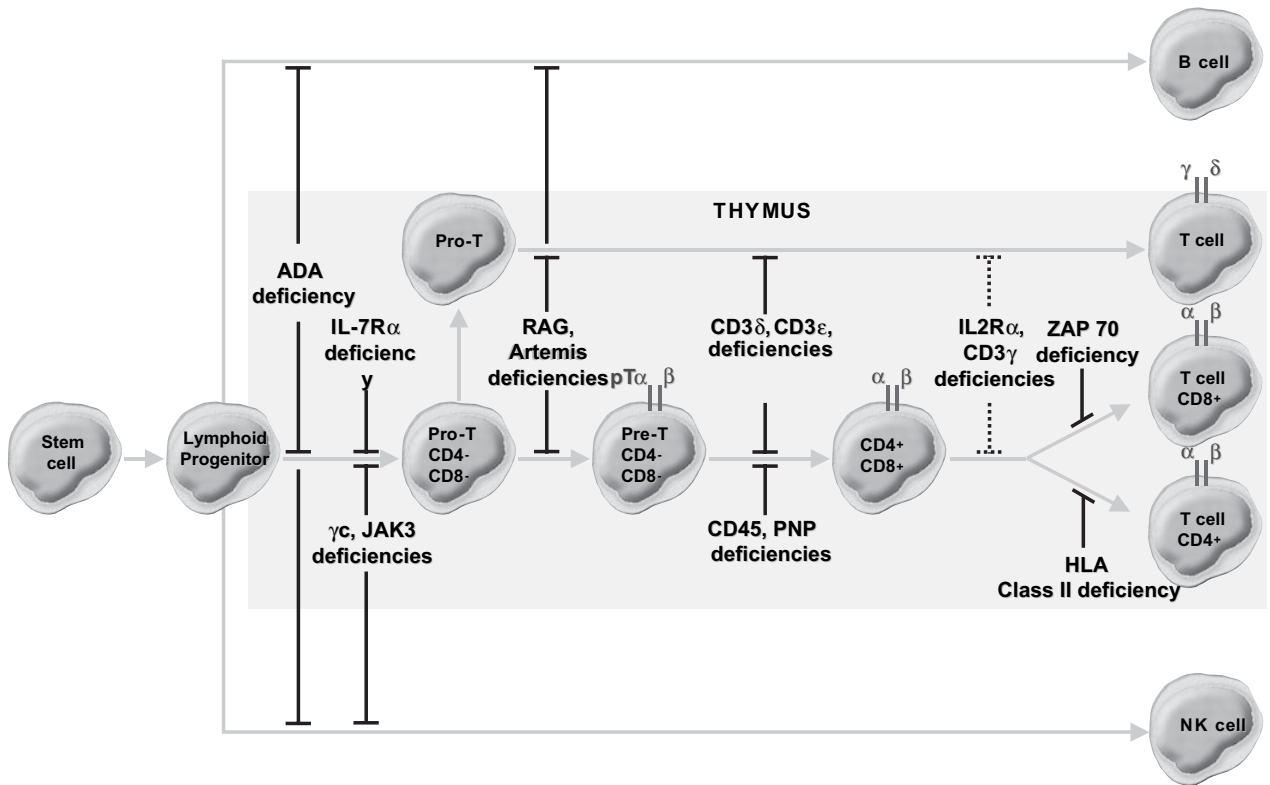
Purine nucleoside phosphorylase (PNP) deficiency, similar to ADA deficiency, results in an accumulation of toxic phosphorylated metabolites. These block ribonucleotide reductase, which is essential for DNA synthesis. Along the purine metabolism pathway, PNP converts guanosine into guanine and deoxyguanosine into deoxyguanine (6). Accumulating deoxyguanosine metabolites are selectively toxic to T-cell


FIGURE 1   Simplified scheme of the block in T-cell, NK-cell, and B-cell development caused by aberrations in genes which cause SCID. The symbol "⊥" represents complete block, while the symbol "⫶" represents partial block. Stem cells which originate in the bone marrow mature into putative lymphoid progenitor cells which either populate the thymus gland and become T-lineage precursors or develop into NK or B cells. The TCR complex consists of the α and β or γ and δ variant chains, paired as mutually exclusive heterodimers in association with the invariant chains CD3 γ, δ, ε, and ζ. After rearrangements of the δ and then γ genes, some thymocytes develop into a distinct population of γδ TCR⁺ T cells. Precursors of the αβ T-cell lineage undergo three major stages of maturation, defined by the expression of CD4 and CD8. The earliest precursors are designated double negative, expressing neither CD4 nor CD8. They progress to a stage of dual expression of CD4 and CD8 (double positive) before committing to the expression of either CD4 or CD8 alone (single positive) and leaving the thymus. A rearrangement of TCRβ occurs at the double-negative stage and precedes the rearrangement of TCRα. Transition from the double-negative stage to CD4⁺ CD8⁺ double positivity requires the surface expression of TCRβ and precursor TCRα (pTα) forming the pre-TCR, whereas the maturation from double-positive to single-positive CD4 or CD8 cells is dependent on the surface expression of the αβ TCR complex.

precursors. Patients with PNP deficiency present with progressive T-cell lymphopenia and eventually a SCID phenotype within the first few years of life (6, 13).

CHH

Patients with cartilage-hair hypoplasia (CHH) may, rarely, present with a SCID phenotype. Typically, these patients have metaphyseal dysplasia, fine hair, and immunodeficiency. Mutations in the RNA component of MRP have been identified in these patients (28). Most patients with CHH have a milder phenotype with moderate T-cell dysfunction and, infrequently, humoral deficiency.

T⁺ B⁺ (NK⁺)

ZAP-70 Deficiency

Patients with ZAP-70 deficiency present clinically with a typical SCID phenotype, yet unusually, these patients have normal numbers of circulating T cells, B cells, and NK cells (31). Flow

cytometry analysis reveals a complete or near complete absence of circulating CD8⁺ T cells (31). Circulating CD4⁺ cells, although normal in number, fail to respond to mitogens. ZAP-70 is an intracellular protein tyrosine kinase which is required for T-cell activation following ligation of the TCR. The deficiency underscores the critical role of ZAP-70 in the maturation of CD8⁺ T cells in the thymus and in the clonal expansion (mitogenic and antigenic responses) of peripheral lymphocytes (2, 12).

HLA Class II Deficiency

Patients with HLA class II deficiency can present with a SCID phenotype, although frequently patients may present later than 1 year of age and survive beyond infancy with only antimicrobial treatment. The immunological basis for the deficiency lies with the inability of T cells to recognize antigens in the context of self-HLA class II molecules expressed by antigen-presenting cells (17). In addition, development of CD4⁺ T cells is hampered by the lack of expression of major

histocompatibility complex class II molecules on thymic epithelial cells, hence the reduction in circulating CD4$^+$ T cells in these patients.

The disease is caused by mutations not in the genes which encode HLA class II molecules but, rather, in genes that encode transcription factors which control HLA class II gene expression (Table 1) (17, 18, 38, 42).

Cytokine Deficiencies (IL-2 Deficiency)

IL-2 deficiency is a functional defect of T cells which are unable to produce normal levels of endogenous IL-2. Defective production of IL-4, IL-5, and gamma interferon has also been observed. The exact pathogenesis and molecular defect remain unknown. Exogenous IL-2 can reverse the defect in vitro and to some extent in vivo (4, 5).

CLINICAL MANIFESTATIONS OF SCID

All forms of SCID present in a remarkably similar manner. Patients with typical cases are referred to tertiary-care centers between the ages of 4 to 12 months because of recurrent and persistent viral, bacterial, and fungal infections as well as failure to thrive (Table 2). Most commonly, patients suffer from chronic protracted diarrhea and interstitial pneumonitis. Viruses such as rotavirus and adenovirus readily grow in their stool cultures. Bronchial secretions or lung biopsy specimens frequently harbor *Pneumocystis carinii*, parainfluenza virus, or cytomegalovirus. Persistent oral thrush which responds poorly to topical anti-fungal medications is also a common feature. Other frequent clinical manifestations include increased liver enzymes and disseminated cytomegalovirus. Lack of palpable lymph nodes and a small to undetectable thymus shadow, as evaluated by radiography or ultrasound, are also very common in SCID.

Skin rashes may also be prominent in SCID. A maculopapular rash has been recognized in ZAP-70 deficiency, and it may be a manifestation of graft-versus-host disease due to maternal engraftment. Although maternally derived T cells are frequently found in SCID patients with profound lymphopenia, clinical symptoms of graft-versus-host disease are less common.

Some forms of SCID may present with additional typical features. Severe universal erythroderma and alopecia, which is associated with lymphadenopathy, hepatosplenomegaly, and eosinophilia, are typical of Omenn's syndrome and are likely caused by expanded autoreactive T-cell clones (Table 2).

Hepatic dysfunction and neurological manifestations, including cortical atrophy and cognitive abnormalities, are detected in ADA deficiency, while ataxia is common in PNP deficiency.

Skeletal abnormalities such as metaphyseal dysplasia causing short limb dwarfism are typical of CHH and may also be associated with Omenn's syndrome. Cupping and flaring of the ribs are seen in ADA deficiency. Hematological disorders such as hemolytic anemia are common in PNP deficiency, while profound neutropenia is a hallmark of reticular dysgenesis.

DIAGNOSTIC EVALUATION OF SCID

The most basic and informative laboratory test which can be used as a screen for SCID at all health care levels is a complete white blood cell count. Lymphopenia is observed in most cases of SCID, and counts of fewer than 2,000 lymphocytes/μl should prompt further investigation. Neutropenia in addition to lymphopenia should raise the possibility of reticular dysgenesis, while hemolytic anemia might point to PNP deficiency (Fig. 2).

However, a significant proportion of SCID patients have normal or near normal number of circulating lymphocytes (Omenn's syndrome, major histocompatibility complex class II deficiency, and ZAP-70 deficiency). Flow cytometry analysis will help decipher these cases and will aid in pinpointing the molecular defect by providing insight into the number of B cells and NK cells. It is therefore recommended that all infants with a putative diagnosis of SCID have their lymphocyte subsets analyzed. The markers to be tested include CD3, CD2, CD4, and CD8 for T cells; CD19 or CD20 for B cells; and CD16 or CD56 for NK cells. HLA class II should also be tested. In most cases this analysis should be sufficient to define which gene defect should be analyzed (Fig. 2)

Evaluation of T-cell function in vitro is helpful when flow cytometry is normal or inconclusive. Mitogenic responses to phytohemagglutinin and anti-CD3 antibody in the presence or absence of exogenous IL-2 can help in the diagnosis of atypical cases of XL-SCID, multiple cytokine deficiency, or Omenn's syndrome. Assessment of the T-cell repertoire can identify oligoclonality in Omenn's syndrome. This can be performed by determination of the relative expression of various Vβ families using PCR or flow cytometry (Fig. 2).

In cases where the diagnosis of SCID is suspected from the clinical presentation but cannot be ascertained using standard investigations, a thymus biopsy can be helpful. The lack of Hassall's corpuscles and the loss of corticomedullary distinction are indicative of a primary immunodeficiency. In contrast, depletion of thymocytes in the presence of normal Hassall's corpuscles suggests changes secondary to stress or treatment with corticosteroids. Analysis of a thymus biopsy not only helps in distinguishing primary from secondary immunodeficiency but also can help identify novel genetic aberrations leading to SCID, as demonstrated in the discoveries of ZAP-70 deficiency, CD3δ deficiency, and IL-2Rα deficiency.

In cases of extreme lymphopenia, ADA and PNP enzymatic activity in red cells can establish the diagnosis of these conditions.

Finally, since the genes responsible for many forms of SCID have already been identified, it is important to perform mutation analysis. In addition to providing definitive diagnosis, it

TABLE 2 Clinical presentation of SCID

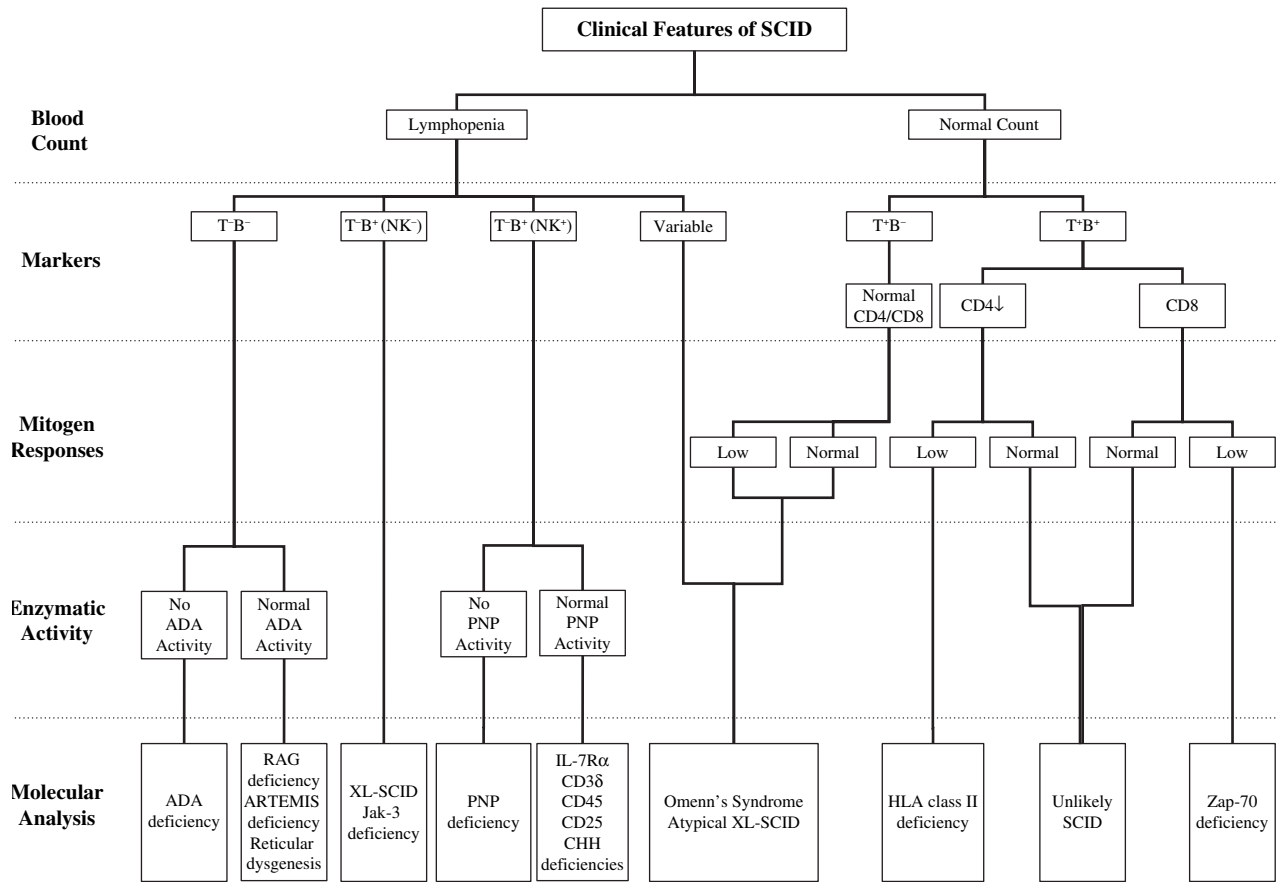
Feature	Patients
Common nonspecific	
Pneumonitis	All
Chronic protracted diarrhea	All
Failure to thrive	All
Oral thrush	All
Family history (consanguinity)	All
Early presentation (4–12 mo)	Typical cases
Specific	
Erythroderma	Omenn's syndrome
Lymphadenopathy	Omenn's, CD25 deficiency
Hepatosplenomegaly	Omenn's, CD25 deficiency
Short limbs	CHH, Omenn's syndrome
Neurological disorders and hepatic dysfunction	ADA deficiency
Gait abnormalities	PNP deficiency


FIGURE 2 Step-by-step laboratory evaluation of patients who present within the first year of life with typical manifestations of SCID (see Table 2) and after secondary causes, such as human immunodeficiency virus infection and medications, have been excluded.

allows for appropriate genetic counseling and future consideration of prenatal diagnosis and gene therapy.

Investigation of Signal Transduction Defects

MELISSA E. ELDER

100

Several forms of severe combined immunodeficiency syndrome (SCID) and other inherited T- and B-cell defects have been shown to result from mutations in signaling molecules required to transduce antigen receptor-binding events to intracellular biochemical pathways. Activation of these signaling pathways synergistically results in transcription of specific genes encoding lymphocyte functions such as cytolysis, cytokine secretion, isotype switching, cell differentiation, and proliferation. In the following discussion, antigen-receptor signal transduction pathways for both T cells and B cells are reviewed and methods to evaluate these pathways in children with inherited immune deficiencies are described.

T-CELL SIGNAL TRANSDUCTION PATHWAY

The T-cell receptor (TCR) is a multisubunit complex consisting of a disulfide-linked α/β heterodimer noncovalently associated with the CD3γ, -δ, and -ϵ chains and a $\zeta\zeta$ homodimer (22, 24, 33). The polymorphic α/β chains are responsible for recognition of peptide bound to a self-major histocompatibility complex molecule; these chains lack signaling capability. In contrast, the ζ and CD3 proteins contain conserved immunoreceptor tyrosine-based activation motifs (ITAMs) within their extensive cytoplasmic domains that are able to transduce extracellular antigen-binding events to intracellular signaling pathways through associations with cytoplasmic protein tyrosine kinases (PTKs) (22, 24, 33). PTKs known to associate with ITAMs include the Src family kinases Lck and Fyn and the Syk family kinases ZAP-70 and Syk (22, 33). Activation of Lck and ZAP-70 is absolutely required for normal TCR signaling, lymphocyte development, and differentiation (5, 9, 18, 22, 24, 33). PTK activation is a rapid and critical event that leads to phosphorylation of numerous downstream molecules, including phospholipase C-γ1, the adaptor molecules LAT (linker of activated T cells) and SLP-76 (Src homology 2 domain-containing leukocyte protein of 76 kDa), and the Tec family of PTKs (22, 24, 25, 27, 34). These tyrosine phosphorylation reactions are required for mobilization of intracellular free calcium ($[Ca^{2+}]_i$) and activation of the Ras, mitogen-activated protein kinase (MAPK), and phosphatidylinositol-3 kinase pathways, and they culminate in T-cell activation and initiation of T-cell-specific responses (22, 25).

One of the best-characterized PTKs is Lck, which is associated with the cytoplasmic domains of CD4 and CD8 (5, 33).

Lck substrates include the ITAMs of ζ and CD3, as well as ZAP-70 (22, 24, 33). Recruitment of ZAP-70 to the TCR and its subsequent phosphorylation and activation largely by Lck are essential for all downstream signaling events (5, 9, 18, 22, 24). Activated ZAP-70 phosphorylates the adaptor molecules SLP-76 and LAT, thereby triggering distal pathways that bring about T-cell activation (22, 25, 33). Syk is a related PTK family member with structural homology to ZAP-70. Although essential for normal B-cell receptor (BCR) signaling, Syk is not essential for normal TCR signaling unless ZAP-70 is deficient.

The hematopoietic lineage-specific leukocyte common antigen, CD45, is a transmembrane protein tyrosine phosphatase that dephosphorylates Src family PTKs and is a positive regulator of Lck in TCR signal transduction (11, 22). CD45 is critical to both TCR and BCR signal transduction, and its deficiency results in SCID in humans characterized by few peripheral T cells but normal B-cell numbers (13, 29).

ZAP-70 Deficiency

ZAP-70 deficiency was the first described TCR-associated PTK defect in humans (2, 5, 9). It is a rare form of autosomal recessive SCID characterized by normal numbers of CD3$^+$ T cells, abundant nonfunctional CD4$^+$ T cells, and an absence of CD8$^+$ T cells in the circulation. Most affected patients have mutations within the kinase domain of ZAP-70 that abrogate both protein expression and enzymatic function; however, mutations in other protein domains have been identified (2, 5, 9, 10, 16, 20, 31). The presence of peripheral CD4$^+$ T cells in ZAP-70-deficient patients contrasts with their absence in ZAP-70 knockout mice, which are blocked at the CD4$^+$ CD8$^+$ stage of thymocyte differentiation (18).

The diagnosis of ZAP-70 deficiency is suggested by a clinical phenotype of SCID with normal numbers of CD3$^+$ T cells and absent CD8$^+$ T cells in the peripheral blood. Moreover, markedly defective T-cell proliferation in response to TCR-mediated stimuli (mitogens and alloantigen) in vitro is observed, in contrast to preserved proliferation in response to phorbol myristic acetate (PMA) plus ionomycin (10). Markedly defective cytoplasmic protein tyrosine phosphorylation and $[Ca^{2+}]_i$ mobilization after TCR stimulation are seen (10). However, immunoblot analysis of ZAP-70 protein and DNA sequencing are required to confirm inheritance of two mutant ZAP-70 alleles in

patients with SCID characterized by a paucity of circulating CD8$^+$ T cells.

CD3 Deficiency

T-cell signaling abnormalities that are not associated with mutations in PTKs have also been identified in patients with SCID and primary T-cell immune deficiencies. These include abnormal cell surface expression of the TCR resulting from defects in the CD3 subunits ε, γ, and δ (6–8, 28). A diagnosis of CD3ε or -γ deficiency may be suggested by flow cytometry (fluorescence-activated cell sorter [FACS] analysis), since affected children have decreased numbers of peripheral T cells that weakly express TCRα/β and CD3. Mutations in CD3γ result in defective T-cell immunity, but affected patients do not require hematopoietic stem cell transplantation (1). The phenotype of CD3ε deficiency appears to be dependent on the level of residual CD3ε expression: an absence of CD3ε causes T$^-$ B$^+$ NK$^+$ SCID, while partial CD3ε expression results in decreased T-cell numbers but only mild immune deficiency (1, 7, 28). In contrast, defective CD3δ expression results in SCID characterized by complete arrest of thymocyte development prior to development of CD4$^+$CD8$^+$ thymocytes (7). Like for other forms of SCID or T-cell immune deficiency, gene sequencing is required to confirm CD3 deficiency.

CD45 Deficiency

The hematopoietic lineage-specific protein tyrosine phosphatase, CD45, is a positive regulator of Src family PTKs involved in T- and B-cell antigen-receptor signaling, and Lck in particular (11, 22). Mutations that result in the absence of CD45 expression on leukocytes are associated with the development of T$^-$ B$^+$ NK$^-$ SCID (3, 13, 30). NK cells and CD3$^+$ T cells expressing an α/β TCR are markedly reduced in the peripheral blood of affected infants (3, 13, 30). In contrast, γ/δ T cells develop normally. Despite elevated numbers of circulating B cells, serum immunoglobulin levels decrease with age and antibody responses are defective.

Defects of the IL-2 Signaling Pathway

Mutations in the γ chain (γc) common to the receptors for interleukin 2 (IL-2), IL-4, IL-7, IL-9, IL-15, and IL-21 are found in boys with X-linked recessive SCID (SCID-X1) (3, 19, 26). Although not involved in antigen-receptor signaling, the γc molecule is essential for the intracellular transmission of cytokine signals and is required for T-cell development (21, 26). The absence of γc-containing cytokine receptor complexes results in early arrest of T- and NK-cell development and production of immature B cells that exhibit defective isotype switching (3, 19, 26). Approximately 45% of SCID cases in the United States are due to mutations in γc (3, 26).

Most SCID-X1 T cells fail to express CD132 (γc) as determined by flow cytometry. However, because most SCID-X1 families have unique mutations, sequencing of the coding regions of the *IL2RG* gene should be performed in order to confirm deleterious mutations (3, 26). Sequencing of maternal DNA can also be informative, but many boys with SCID-X1 have spontaneously arising mutations without evidence of an inherited mutant maternal X chromosome either by DNA sequencing or by nonrandom pattern of X chromosome inactivation (3, 8).

Females, as well as some males, with the typical SCID-X1 phenotype do not have mutations in γc. These patients instead have autosomal recessive SCID due to mutations in

the cytoplasmic tyrosine kinase JAK3 (3, 8, 14, 21). JAK3 activation is required for transduction of ligand-binding signals from γc-containing cytokine receptors, and its deficiency results in T$^-$ B$^+$ NK$^-$ SCID indistinguishable from SCID-X1 (3, 14, 21). In contrast, mutations in the α chain of the IL-7 receptor (IL-7Rα) arrest human thymocyte development at the CD4$^-$ CD8$^-$ stage but do not affect NK-cell development (3, 21). The T$^-$ B$^+$ NK$^+$ phenotype of IL-7Rα-deficient SCID emphasizes the critical and nonredundant role of IL-7 in T-cell development, differentiation, and survival (21). Most JAK3 and IL-7Rα mutations abolish mRNA or protein expression, and molecular methods are required to confirm these diagnoses (3, 21).

B-CELL SIGNAL TRANSDUCTION PATHWAY

The BCR is composed of a membrane immunoglobulin molecule noncovalently associated with a disulfide-linked heterodimer of immunoglobulin α and β chains (CD79) (12, 33). Similar to CD3, CD79 functions to transduce extracellular binding events to intracellular signaling pathways through binding of nonreceptor-associated PTKs, culminating in specific B-cell responses such as antibody production, isotype switching, cellular differentiation, and proliferation (12, 27, 33). Additional components of the BCR signaling complex include CD72, CD5, CD21/CD19/CD81, and the negatively regulated immunoreceptor tyrosine-based inhibitory motif-containing coreceptors FcγRIIb and CD22 (12, 33).

Similar to T-cell signaling, ligand engagement of the BCR is associated with rapid activation of Syk; the Src family PTKs Lyn, Fyn, Blk, and Lck; and the Tec family PTK Bruton's tyrosine kinase (Btk) (12, 33). Similar to TCR signal transduction, PTK activation results in phosphorylation of downstream cytoplasmic signaling molecules, which include phospholipase C-γ2, BLNK (B-cell linker protein), and Vav1 (12, 23, 27, 33). Phosphorylation of these downstream substrates results in [Ca^{2+}]$_i$ flux and activation of the Ras, MAPK, phosphatidylinositol-3 kinase, and NF-κB pathways, which are required for B-cell activation, development, and induction of B-cell effector functions (12, 27, 33).

Syk binds ITAMs within CD79 via its tandem Src homology 2 domains and is absolutely required for normal B-cell function (12, 27, 33). Btk is activated in response to BCR stimulation and is expressed in early B-lineage cells, but not in terminally differentiated plasma cells. Mutations in Btk result in abnormal B-cell differentiation and development of X-linked agammaglobulinemia (XLA) in humans (3, 32). BLNK (SLP-65) is an adaptor molecule similar to SLP-76 and LAT in T cells that is required for NF-κB activation and B-cell survival (29). Mutations in BLNK result in arrest of B-cell development and absence of B cells in the peripheral blood in affected humans (17, 23, 29).

XLA

In boys with XLA, mutations in Btk result in a nearly complete block in development at an early pre-B-cell stage (3, 32). Residual B-cell development can occur, but usually <2% B cells are detected in the peripheral blood. These B cells are unable to respond to BCR engagement. A diagnosis of XLA is suggested by the absence of peripheral B cells, but confirmation of diagnosis requires sequencing of the coding portions of the *XLA* gene. Immunoblot or FACS analysis of Btk expression is difficult when peripheral blood mononuclear cells (PBMC) are used, since the number of B cells is insufficient for protein assays. However, analysis of

Btk protein expression using bone marrow-derived pre-B cells or Epstein-Barr virus (EBV)-transformed lymphoblastoid lines is possible. Unfortunately, generation of EBV-transformed lines from Btk-deficient bone marrow is technically difficult and often unsuccessful.

BLNK Deficiency

Similar to XLA, mutations in BLNK result in an absence of peripheral B cells (3, 17, 23, 29). This diagnosis should be considered in females without detectable B cells or in boys with few B cells who do not have mutations in Btk. BLNK protein expression can be evaluated on marrow-derived EBV-transformed pre-B-cell lines, but DNA sequence analysis is required to make a diagnosis of BLNK deficiency.

METHODS

Flow Cytometry

FACS analysis for cell surface expression of the TCR or BCR, CD40L, CD69, and cytokine or coreceptor molecules is discussed in chapters 18 and 19 of this volume. Since CD69 expression is dependent on activation of the Ras/MAPK pathway, the absence of CD69 on stimulated T or B cells may suggest a proximal signal transduction defect (10). Moreover, intracellular cytokine expression using FACS analysis may be useful in characterizing the scope of T-cell defects.

TCL and BCL

Because insufficient numbers of lymphocytes are available from children with primary immune deficiencies, generation of cultured cell lines is useful as a source of DNA and RNA for molecular studies. T-cell lines (TCL) may be generated using human T-cell lymphotropic virus type 1 (HTLV-1) or herpesvirus saimiri (HVS) transformation, while B-cell lines (BCL) are generally produced by EBV transformation. Unfortunately, HTLV-1 and EBV may affect cell signaling (14); alterations in cellular function appear to be less problematic when HVS is used (4).

Lymphocyte Proliferative Assays

T-cell proliferation in response to PMA plus ionomycin in vitro may be used to screen for proximal signaling defects in patients with SCID or T-cell immune deficiencies in whom SCID-X1, enzyme abnormalities (such as adenosine deaminase deficiency), or defects in recombination (RAG-1/RAG-2 deficiency or Omenn syndrome) have been eliminated.

1. Suspend PBMC or peripheral blood T cells that have been positively selected using CD3$^+$ magnetic beads (Miltenyi Biotec, Auburn, Calif.) in complete RPMI medium (RPMI 1640 plus 10% fetal calf serum, 100 μg of penicillin per ml, 100 U of streptomycin per ml, and 2 mM L-glutamine) at a concentration of 10^6 cells/ml.

2. Incubate 10^5 cells in 200 μl of complete RPMI medium at 37°C for 72 h in flat-bottomed 96-well plates with 50 ng of anti-CD3 monoclonal antibody (MAb) (Caltag Laboratories, Burlingame, Calif.) per ml or 0.5 ng of PMA (Sigma-Aldrich, St. Louis, Mo.) per ml plus 1 μM ionomycin (Calbiochem, San Diego, Calif.).

3. Pulse wells with 0.96 μCi of [^{3}H]thymidine per well for 6 h, harvest, and count in a scintillation counter.

[Ca^{2+}]$_i$ Flux

If T-cell or B-cell proliferation in response to antigen receptor-mediated stimulation is not seen, measurements of [Ca^{2+}]$_i$ mobilization may be indicated in order to localize a putative signaling defect. [Ca^{2+}]$_i$ flux assays may be done either by fluorimetry or by FACS analysis. Fluorimetric methods require more cells but do not require concomitant cell staining with potentially stimulatory MAbs. This assay is best done using fresh PBMC, but bone marrow-derived lymphocytes, BCL, or TCL rested overnight in medium without IL-2 or mitogen may also be used.

1. Rest TCL in complete RPMI medium for 16 to 24 h before analysis.

2. Suspend PBMC or bone marrow-derived lymphocytes (preferably enriched for T or B cells via magnetic bead selection) or TCL or BCL at 2×10^7 cells/ml in complete RPMI medium and load with 3 μM Indo-1 (Molecular Probes Invitrogen, Eugene, Oreg.) for 20 min at 37°C. Dilute cell suspension to 2×10^6 cells/ml with complete RPMI medium and incubate for 20 min at 37°C.

3. Wash cells three times in calcium buffer (Hanks balanced salt solution plus 1% bovine serum albumin, 1 mM CaCl$_2$, and 0.5 mM MgCl$_2$), resuspend at 5×10^6 cells/ml in calcium buffer, and keep on ice until use.

4. Warm 400 μl of cell suspension at 37°C for 2 min in a cuvette before analysis. Measure absorbance at an excitation wavelength of 355 nm and emission wavelengths of 400 and 500 nm using a fluorescence spectrophotometer (Hitachi High Technologies America, San Jose, Calif.). Maximal fluorescence is determined after cell lysis with 5 μl of 10% Triton X-100 detergent; minimal fluorescence is determined after addition of 50 μl of 1 M Tris base and 15 μl of 0.4 M EGTA.

5. Recordings are made before and after cells are stimulated by the addition of TCR or BCR cross-linkers. For T-cell analysis, add 2 μl of biotinylated anti-CD3 MAb (BD Pharmingen, San Diego, Calif.) plus 5 μg of streptavidin (Sigma-Aldrich) per ml; immunoglobulin M (IgM) MAb to TCR may be used instead if available. For B-cell analysis, add 10 to 40 μg of anti-IgM F(ab′)$_2$ antibody (Southern Biotechnology Associates, Birmingham, Ala.) per ml. To ensure proper loading of Indo-1, add 1 μl of 1 mM ionomycin to nonresponding cell suspensions after 5 min.

Protein Tyrosine Phosphorylation Assay

Analysis of tyrosine phosphoproteins is indicated if a defect in proximal antigen receptor signaling is suggested by defective lymphocyte proliferation or [Ca^{2+}]$_i$ mobilization in response to TCR stimulation. This method may also be used to evaluate BCR signaling in children with primary B-cell immune deficiencies, especially in patients of either sex who have severe hypogammaglobulinemia but normal numbers of peripheral B cells. Males without circulating B cells likely have XLA; methods to detect XLA are described in chapter 101 of this volume. However, rare patients without peripheral B cells have mutations in signaling molecules, such as BLNK, as described previously.

1. Incubate 100 μl of 2×10^6 TCL or CD3-enriched PBMC for 20 min on ice with 2 μl each of biotinylated anti-CD3 MAb plus biotinylated anti-CD4 MAb or phosphate-buffered saline alone. Wash cells, resuspend in 100 μl of phosphate-buffered saline, and cross-link with 5 μg of avidin per ml for 4 min at 37°C. For analysis of B-cell signaling events, 100 μl of 2×10^6 EBV-transformed BCL, CD2-depleted PBMC, or CD19-enriched PBMC or bone marrow cells may be stimulated with 10 to 40 μg of anti-IgM F(ab′)$_2$ antibody per ml.

2. Lyse cells in 45 μl of Nonidet P-40 (NP-40) buffer (1% NP-40 plus 10 mM Tris) [pH 7.6], 150 mM NaCl, 0.5 mM

EDTA, 10 mM NaF, 1 mM phenylmethylsulfonyl fluoride, 1 μg of pepstatin A per ml, 10 μg of leupeptin per ml, 1 μg of aprotinin per ml, and 1 mM Na$_3$VO$_4$) for 30 min at 4°C. Centrifuge cells at 12,000 × g at 4°C for 10 min, collect supernatants, and mix with 15 μl of 4× sample buffer dye (2% sodium dodecyl sulfate [SDS], 5% 2-mercaptoethanol, 250 mM Tris, 10% glycerol, and 1 mg of bromophenol blue per ml, pH 6.8). Boil at 90°C for 5 min prior to separation by SDS–12% polyacrylamide gel electrophoresis under reducing conditions.

3. Electrophoretically transfer separated protein bands to Immobilon-P membranes (Millipore Corporation, Billerica, Mass.), block in blotting buffer (Tris-buffered saline plus 0.1% Tween) plus 3% bovine serum albumin, and incubate at room temperature for 1 h in blotting buffer with 4G10 (antiphosphotyrosine MAb; Upstate Biotechnology, Waltham, Mass.).

4. Wash filters three times in blotting buffer, and incubate with horseradish peroxidase-conjugated goat anti-mouse MAb (Southern Biotechnology Associates) for 1 h at room temperature. Phosphoproteins are assayed using an enhanced chemiluminescence detection system (ECL; Amersham Biosciences, Piscataway, N.J.).

Immunoblot Analysis

If abnormal protein tyrosine phosphorylation is demonstrated, the expression of specific PTKs known to be involved in T- or B-cell signal transduction may be evaluated by immunoblotting using PBMC, T- or B-cell-enriched PBMC or cultured lines, or marrow-derived lymphocytes. For analysis of specific PTKs or other signaling proteins, separate PBMC, TCL, or BCL extracts by SDS-polyacrylamide gel electrophoresis as described above and analyze for protein expression using the enhanced chemiluminescence system.

IL-2 Production

Distal TCR signal transduction events, as well as the IL-2 pathway, may be analyzed by measurement of IL-2 production in response to TCR-mediated stimuli. Abnormal IL-2 production may lead to evaluation of other molecules that are beyond the scope of this chapter. Analysis of IL-2 production is performed as follows. Stimulate 2 × 10^5 PBMC in complete RPMI medium with 50 ng of anti-CD3 per ml plus 0.5 to 5 μg of anti-CD28 MAb (BD Biosciences) per ml or 0.5 ng of PMA per ml plus 1 mM ionomycin at 37°C for 24 h in flat-bottomed 96-well plates. Collect supernatants and quantitate IL-2 levels using standardized immunoassay kits (BioSource International, Camarillo, Calif.).

ANALYTICAL SENSITIVITY AND SPECIFICITY, QUALITY CONTROL AND ASSURANCE, DATA ANALYSIS, PITFALLS, AND TROUBLESHOOTING

In vitro T-cell proliferative studies are useful in the screening of immunodeficient patients for proximal signal transduction defects. Restoration of T-cell proliferation by PMA and ionomycin indicates a possible defect in a TCR-associated PTK; lack of stimulation by these second messengers suggests a defect in a T-cell signaling event distal to activation of Ras and [Ca^{2+}]$_i$ flux, respectively. Results of proliferative assays for patients must be compared to those for healthy individuals of similar age. Immunoblot and kinase assays may be informative in documenting PTK defects, but they

may be adversely affected by viability and quantity of cells available for study and specificity of antibodies used. Protease inhibitors and sodium orthovanadate must be included in the protein lysis buffer in order to control inadvertent protein degradation and phosphatase activity. Therefore, protein techniques require controls in order to assess the quality of the results. [Ca^{2+}]$_i$ assays may be affected by temperature and improper loading of the calcium-sensitive dye; nonresponding cells should be incubated with ionomycin to ensure that cells were properly loaded. Finally, TCL and BCL may be the only source of patient cells; therefore, analysis of signal transduction defects using transformed lines may be complicated by the effects of HTLV-1 and EBV, and possibly HVS, on lymphocyte signaling pathways.

INTERPRETATION

The described methods are valuable both to screen and to diagnose signaling defects in patients with inherited T- or B-cell immune deficiencies. However, inherited immune defects, other than those characterized as XLA, X-linked hyper-IgM syndrome, SCID-X1, and adenosine deaminase deficiency, are very rare, occurring in fewer than 1 in 10^6 children.

REMARKS AND CONCLUSIONS

Signaling pathways resulting in abnormal T- or B-cell activation and development of immune deficiency are the focus of much investigation at present. Although better understood, the roles of Tec family PTKs, adaptor molecules, and downstream signaling proteins in lymphocyte activation in humans remain to be well characterized. Knockouts or mutations in many signaling molecules have been evaluated in inbred-mouse models but have not been diagnosed in immunodeficient humans. This likely is due to the limited quantities of patient cells available for analysis and current management techniques that lead to fairly rapid stem cell transplantation prior to genetic diagnosis.

Primary Antibody Deficiency Diseases

MARY ELLEN CONLEY

101

Antibody deficiencies are a heterogeneous group of disorders that share an unusual susceptibility to recurrent or persistent infections with encapsulated bacteria, particularly *Streptococcus pneumoniae* and *Haemophilus influenzae*. The types of infections seen in affected patients are ones that are typical for these organisms. Young children with antibody deficiencies usually have a cough, recurrent otitis, and purulent nasal discharge (5). Adults are likely to have a cough, sinusitis, and recurrent pneumonias (7). Dramatic infections, like meningitis, cellulitis, empyema, or epiglottitis, are not uncommon and are often the findings that lead to an evaluation of the immune system. Additional types of infections or medical complications are more specific to particular antibody deficiencies. For example, approximately 50% of patients with X-linked hyper-immunoglobulin M (hyper-IgM) syndrome (CD40 ligand deficiency) have *Pneumocystis jiroveci* (formerly called *Pneumocystis carinii*) pneumonia in the first year of life (37). *Pneumocystis* pneumonia is seen in other antibody deficiencies, but it is quite rare.

Although all patients with antibody deficiencies are treated with gamma globulin replacement, a specific diagnosis permits a better understanding of potential complications, a more accurate prediction of prognosis, and more informative genetic counseling. Several of the antibody deficiencies that present in early childhood are inherited in an X-linked manner. These disorders, which include X-linked agammaglobulinemia (XLA) (Btk deficiency), X-linked hyper-IgM syndrome (CD40 ligand deficiency), ectodermal dysplasia with immunodeficiency (NEMO deficiency), X-linked severe combined immunodeficiency (cytokine common gamma chain deficiency), and X-linked lymphoproliferative syndrome (SAP deficiency), are seen almost exclusively in males. It is essential to take a detailed family history that goes back at least three generations in the maternal lineage; however, it is important to remember that only about 50% of affected males have a positive family history of disease. This is because these disorders are maintained in the population by new mutations.

In recent years several rare autosomal recessive disorders that result in antibody deficiency have been reported. These disorders, which include defects in μ heavy chain (18), CD79 (20), λ5 (part of the surrogate light chain) (21), BLNK (23), CD40 (9), activation-induced cytidine deaminase (AID) (31), uracil DNA glycolase (UNG), ICOS (12), CD19, TACI, and BAFF receptor, are more likely to occur in consanguineous or isolated populations. In taking a family history, it is useful to know if grandparents or great-grandparents came from the same small village. Most patients are homozygous for their mutations, and most mutations are relatively specific to particular geographic regions. For example, in North America AID deficiency is more common in Lumbee Indians from North Carolina and French Canadians from eastern Quebec (22).

IgA deficiency and common variable immunodeficiency (CVID) are usually considered multifactorial disorders (7). That is, they are not inherited in a simple Mendelian pattern; instead, multiple susceptibility genes and environmental factors combine to cause disease. Affected patients may have a family history of autoimmune disease or abnormalities of immunoglobulin production, but the pattern of inheritance usually does not conform to an autosomal recessive or dominant pattern. CVID should be considered a diagnosis of exclusion. Particularly in young children, it is important to rule out single gene defects of the immune system. Occasionally, adults present with delayed recognition of single gene defects that are more commonly diagnosed in childhood.

Some antibody deficiencies are part of a more broadly expressed systemic disorder or part of an immunodeficiency that affects T cells and/or NK cells as well as B cells. For example, patients with ataxia telangiectasia often have IgA, IgE, and IgG2 deficiency (25). These patients may present for medical attention with recurrent infections and mild cerebral palsy. Patients with severe combined immunodeficiency may have infections that suggest antibody deficiency, but the T-cell deficiency must be recognized to institute appropriate therapy. Defects in activation markers expressed on T cells, for example, CD40 ligand or ICOS, result in antibody deficiency, although, strictly speaking, the B-cell lineage is normal.

AN APPROACH TO EVALUATION OF PATIENTS WITH SUSPECTED ANTIBODY DEFICIENCY

The possibility of immunodeficiency should be considered in any patient who is hospitalized for a major infection requiring intravenous therapy. This does not mean that laboratory studies should be performed for every patient, but a careful family history should be taken and a record of the number

and nature of past infections should be obtained. If the infection results in admission to an intensive care unit or the history is suggestive of immunodeficiency (for example, a relative died of infection or the patient has received multiple courses of antibiotics), a complete blood count with differential, quantitative serum IgG, IgM, and IgA, and total hemolytic complement should be performed. Further evaluation depends on the type of infection seen in the patient and the index of suspicion. If the infection strongly suggests an antibody deficiency, for example, *H. influenzae* epiglottitis in an immunized patient, or if the screening evaluation demonstrates low serum IgM or IgG, titers of antibody to vaccine antigens should be obtained. It is useful to test for antibodies to both T-cell-independent antigens, like anti-blood group substances (isohemagglutinins) and antipneumococcal antibodies, and T-cell-dependent antigens, like anti-tetanus toxoid or anti-measles virus antibodies. Patients who have low serum immunoglobulins and poor titers of antibody to vaccine antigens should be analyzed for lymphocyte cell surface markers to determine the number and percentage of T cells and B cells.

Dramatic infections frequently elicit an evaluation of the immune system. Patients with repeated infections who are treated on an outpatient basis may not be evaluated for immunodeficiency for many, many years, and these patients may develop bronchiectasis before they are recognized to have an antibody deficiency. Children, particularly boys, who have had 10 or more courses of antibiotics for otitis, sinusitis, or pneumonia in a 2-year period should have serum immunoglobulins measured. The same is true for adults, males or females, who have had five or more courses of antibiotics in a 2-year period.

Most patients with antibody deficiencies have very low concentrations of serum IgG and IgA (less than 10% of normal adult values). The IgM level is more variable. If an individual has concentrations of serum immunoglobulins that fall just below the normal range, it is important to measure titers of antibody to vaccine antigens. Some patients with low normal concentrations of serum immunoglobulins make antibodies to some, but not all, pneumococcal serotypes. It is often difficult to know how to interpret these results. Most investigators feel that these patients may respond to chronic prophylactic antibiotics and good medical follow-up. For the purposes of this discussion, patients with antibody deficiencies are divided into those with defects in early B-cell development, that is, patients with less than 2% B cells in the peripheral circulation, and those with late defects in B-cell development, i.e., patients with more than 2% B cells in the blood.

DEFECTS IN EARLY B-CELL DEVELOPMENT

XLA

XLA accounts for approximately 85% of patients with defects in early B-cell development (6). Most patients with XLA develop recurrent or persistent infections in the first 4 to 8 months of life, and the majority are recognized to have immunodeficiency at less than 3 years of age (5). Almost all patients have recurrent otitis, many have pneumonias, and some have sepsis, meningitis, arthritis, or cellulitis. Pyoderma, neutropenia, and pseudomonas or staphylococcal disease may be seen at presentation but are rarely seen after gamma globulin replacement therapy is started. In addition to their susceptibility to encapsulated bacteria, patients with XLA are also vulnerable to giardia (17), mycoplasma (10), and enteroviral (19) infections, including vaccine-associated

polio. Currently, patients are treated with gamma globulin replacement and aggressive use of antibiotics.

The protein responsible for XLA, Btk, is a cytoplasmic tyrosine kinase encoded in 19 exons spread over 37 kb in the mid-portion of the long arm of the X chromosome (34). Btk is expressed in all hematopoietic cells except T cells and plasma cells, but the consequences of Btk deficiency are limited to the B-cell lineage. Cross-linking of the pre-B-cell or B-cell antigen receptor results in phosphorylation and activation of Btk. In turn, Btk phosphorylates the lipid kinase phospholipase-Cγ2; this results in a sustained calcium flux, cell proliferation, and differentiation (29). In patients with XLA, B-cell differentiation is blocked at the pro-B-cell to pre-B-cell transition, the stage at which the pre-B-cell receptor is first expressed. However, the block is leaky, and almost all patients with XLA do have a small number of pre-B-cells in the bone marrow and B cells in the peripheral circulation.

Laboratory studies for the majority of patients with XLA reveal very low concentrations of serum IgM, IgG, IgA, and IgE, but most patients do have some serum IgG and approximately 10% of patients have a serum IgG or IgM concentration that is normal or near normal (28). The IgM falls to low levels after gamma globulin therapy is started. With very rare exceptions, titers of antibody to all vaccine antigens are negative. The most consistent laboratory feature in patients with XLA is the marked reduction in the number of B cells in the peripheral circulation. The threshold for detection for B cells in most clinical laboratories is 1%. Patients who have less than 1% B cells are reported as having 0%. The mean percentage of B cells in patients with XLA is 0.1% (3), and I have not seen any patients with XLA (over 200 evaluated) who had more than 1.5% CD19$^+$ cells. The B cells that are present have a distinctive phenotype with very high intensity expression of surface IgM and variable expression of CD19 (see below). Bone marrow studies demonstrate normal numbers of CD34$^+$ CD19$^+$ surface IgM$^-$ (sIgM$^-$) pro-B cells but very few CD34$^-$ CD19$^+$ sIgM$^-$ pre-B cells (24). Because Btk is expressed in platelets and myeloid cells, as well as B-lineage cells, immunofluorescence studies which evaluate Btk in monocytes or platelets or Western blot studies are useful screening tests (11); however, the reagents to perform these tests reliably are not commercially available. Further, 10 to 15% of patients with XLA have mutations in Btk that result in normal amounts of Btk protein in these cells. Definitive diagnosis of XLA requires mutation detection. The mutations in Btk are highly variable, and no single mutation accounts for more than 3% of all mutations (4). Over 90% of mutations in Btk are single base pair substitutions or the insertion or deletion of less than 10 bp within the coding sequence or flanking splice sites. These mutations are easily detected by single-strand conformation polymorphism (SSCP) analysis.

Autosomal Recessive Agammaglobulinemia

Approximately 7 to 10% of patients with early onset of infections, profound hypogammaglobulinemia, and an absence of B cells are girls. One must assume that there is an equal number of boys with disease that is not X linked. The clinical presentation of these patients is identical to that seen in patients with XLA; however, as a group, these patients tend to have more severe complications, and they are recognized to have immunodeficiency at a younger age (less than 2 years of age).

Defects in μ heavy chain account for about one-third of the patients with autosomal recessive agammaglobulinemia (18). These patients do not have a leaky defect, and their

serum immunoglobulins are generally below the level of detection in clinical laboratories. If the laboratory reports detectable concentrations of serum immunoglobulins in these patients, it is because the laboratory has difficulty measuring very low concentrations, not because the patient is making serum immunoglobulins. Bone marrow studies show normal numbers of pro-B cells but no pre-B cells. Two types of mutations account for half of the pathological alterations in the μ heavy-chain gene. These are large deletions that remove all of the μ constant region as well as the D and J genes and a recurrent single base pair substitution at the alternative splice site in exon 4 of the constant-region gene (18). A PCR-based test for these mutations is described below.

Mutations in other components of the B-cell and pre-B-cell signaling pathway can also cause autosomal recessive agammaglobulinemia. Small numbers of patients with defects in Igα (CD79a), Igβ (CD79b), λ5, and BLNK have been seen. The clinical and laboratory findings in these patients are indistinguishable from those in patients with mutations in Btk or μ heavy chain. The bone marrow in these patients demonstrates a complete block at the pro-B-cell to pre-B-cell transition, and patients have normal numbers of pro-B cells but less than 10% of the normal number of pre-B cells. The most efficient way to make the diagnosis in patients with these rare autosomal recessive disorders is mutation detection.

Differential Diagnosis

There are patients with less than 2% circulating B cells who do not have defects in one of the genes listed above. Several groups have described patients with intrauterine growth retardation and/or microcephaly who have agammaglobulinemia and an absence of B cells (1, 30, 35). The causative defects in these patients are unknown. Some children with myelodysplasia come to medical attention because of recurrent infections and an absence of B cells. Bone marrow studies for these patients show markedly reduced numbers of pro-B cells as well as pre-B-cells (33). A small percentage of adults with late onset of recurrent infections and clinical and laboratory features consistent with CVID do not have B cells and do not have defects in one of the known genes associated with defects in early B-cell development (7). Some patients with Good's syndrome, that is, thymoma with immunodeficiency, have less than 2% B cells in the peripheral circulation. These patients also have decreased numbers of pro-B cells as well as pre-B cells.

LATE DEFECTS IN B-CELL DEVELOPMENT

X-Linked Hyper-IgM Syndrome (CD40 Ligand Deficiency)

Hyper-IgM syndrome is a term used to describe a group of disorders characterized by normal or elevated serum IgM with low concentrations of IgG and IgA and normal numbers of B cells. Approximately 60% of patients with early onset of infections and the laboratory features of hyper-IgM syndrome have defects in CD40 ligand (16), a member of the tumor necrosis factor family encoded in five exons on the long arm of the X chromosome. CD40 ligand is expressed transiently on the surface of activated T cells, particularly CD4$^+$ T cells. Its cognate receptor, CD40, is expressed on B cells, monocytes, and dendritic cells. Activated endothelial and epithelial cells may also express CD40. Stimulation of B cells through CD40 results in cell activation, short- and long-term cell proliferation, and, in the presence of cytokines, isotype switching. Cross-linking of CD40 on monocytes and dendritic cells results in cell activation and production of multiple cytokines, particularly interleukin 12. The cytokines feed back to T cells and further enhance T-cell activation.

The clinical spectrum of disease in patients with CD40 ligand deficiency is very broad. As noted above, many patients present with *Pneumocystis* pneumonia in the first year of life. Neutropenia, oral ulcers, and severe diarrhea are common in these patients. In addition to the increased susceptibility to encapsulated bacteria, patients with CD40 ligand deficiency are more vulnerable to cytomegalovirus, *Cryptococcus*, and *Cryptosporidium* infection and histoplasmosis. Carcinomas affecting the liver, pancreas, biliary tree, and associated neuroectodermal endocrine cells have been reported, particularly for patients with chronic gastrointestinal infections (13). Rare patients are relatively asymptomatic until they develop persistent anemia secondary to parvovirus B19 infection as young adults.

Flow cytometric analysis of activated T cells can be used as a screening evaluation to diagnose CD40 ligand deficiency; however, this assay has several drawbacks. T cells must be activated before analysis, and a control for T-cell activation, for example, CD69 or CD25, should be used. Some mutations in CD40 ligand permit normal cell surface expression of CD40 ligand; therefore, the presence of CD40 ligand on the cell surface does not rule out the diagnosis. Because the gene for CD40 ligand is small, mutation detection is often an easier and more definitive method of making the diagnosis of CD40 ligand deficiency.

Autosomal Recessive Hyper-IgM Syndrome

A small number of patients with mutations in CD40 have been reported (9). These patients have a clinical phenotype that is identical to that seen in patients with defects in CD40 ligand. Thus far, all of the reported patients have had mutations in CD40 that result in a failure to express CD40 on the cell surface. As a result, cell surface staining of B cells is a good first step in evaluating a patient suspected of having defects. If the index of suspicion is high, mutation detection might be appropriate even if staining for CD40 was normal. The gene for CD40 is encoded in nine exons on chromosome 20q13.2.

Two additional autosomal recessive forms of hyper-IgM syndrome have been identified. AID (31) and UNG (14) are required for normal isotype switching and somatic hypermutation. B cells activated with CD40 ligand and cytokines, in the context of the germinal center, transiently express the enzyme AID, which deaminates cytidine at target sites within the immunoglobulin variable-region genes and switch regions. The resulting uracil is then removed by UNG, leaving the site vulnerable to cleavage or mismatched repair.

Patients with defects in AID or UNG have a disease that is less severe than that seen in most patients with defects in CD40 ligand or CD40. Like all patients with antibody deficiencies, patients with defects in AID or UNG have recurrent upper and lower respiratory tract infections. Many have lymphoid hyperplasia, and patients with AID deficiency have increased incidences of autoimmune or inflammatory disorders. However, patients with AID or UNG deficiency do not have the opportunistic infections seen in patients who are deficient in CD40 and CD40 ligand, and their antibody deficiency is not as severe as that seen in patients with XLA or other defects in early B-cell development. The

genes for both AID and UNG are relatively small; the AID gene consists of five exons spanning 11 kb on chromosome 12p13, and the UNG gene consists of seven exons spanning 13 kb on chromosome 12q23. Mutation detection is the most practical way of making a definitive diagnosis.

Differential Diagnosis of Hyper-IgM Syndrome

Some adults with CVID have normal or mildly elevated concentrations of serum IgM with low concentrations of serum IgG and IgA. If these individuals did not have recurrent infections as children, it is unlikely that they have defects in the genes listed above. Males with mutations in the X chromosome encoded gene for NEMO (NF-κB essential modulator) may have elevated IgM with low IgG and IgA levels (8). These patients generally have mild ectodermal dysplasia, with sparse hair, conical incisors, and inadequate sweating. Response to encapsulated bacterial infection is particularly poor in patients with defects in NEMO, and these patients may continue to have problems with infection even after gamma globulin replacement is initiated.

CVID

CVID is a term used to describe patients with low concentrations of serum immunoglobulins, particularly IgG and IgA, poor antibody response to vaccine antigens, and no known cause of immunodeficiency (7). It should be considered a diagnosis of exclusion. Low concentrations of serum immunoglobulins may be seen after the use of certain drugs or in association with leukemia or lymphoma. As noted above, single gene defects of the immune system may have features in common with CVID. One should be particularly cautious in giving the diagnosis of CVID to a child with the onset of symptoms at less than 10 years of age, siblings who appear to have CVID, or debilitated patients with immunodeficiency.

The typical patient with CVID has the onset of disease in the second, third, or fourth decade of life. Most patients have had several pneumonias before they are recognized to have immunodeficiency. Autoimmune or inflammatory disorders, particularly autoimmune thrombocytopenia, hemolytic anemia, inflammatory bowel disease, and arthritis, are seen in 20 to 30% of patients and may precede the onset of recurrent infections. Laboratory studies in patients with CVID are quite variable. T cells may be abnormal in number or function, and there may be a reversal of the normal CD4/CD8 ratio. Proliferation in response to mitogens may be decreased. Although the majority of patients with CVID have normal numbers and percentages of B cells, approximately 10% have less than 2% CD19+ B cells.

Recent studies suggest that analysis of B-cell phenotype may be useful in identifying patients with CVID who have more severe disease. In the healthy individual, 10 to 40% of CD19+ cells express the memory marker CD27. The CD27-positive cells can be divided into IgM memory cells which express CD27, IgD, and IgM and "switch memory B cells" which express CD27 but not IgD or IgM. Patients lacking switch memory B cells tend to have lower concentrations of serum immunoglobulins and a higher incidence of lymphadenopathy and splenomegaly (2, 15, 27, 36).

METHODS

Flow Cytometry

Either whole blood or density gradient-separated mononuclear cells can be used to examine lymphocyte cell surface markers. Blood that has been anticoagulated with heparin or EDTA can be used for up to 24 h after the blood has been drawn. Most laboratories use directly labeled monoclonal antibodies to CD19 or CD20 to assess the percentage of B cells in the peripheral circulation. Either marker is satisfactory. To examine memory B cells, cells are stained with antibodies to CD19, surface IgD, and CD27. Directly labeled polyclonal goat antibodies to surface IgD are used. Isotype controls are essential. To decrease background staining, it is helpful to add unlabeled rabbit IgG. The principles of cell surface staining are the same for all staining reagents. B-cell staining in patients with possible XLA is used as an example.

Materials and Reagents

5-ml snap-top tubes (no. 352052; Falcon)

Staining buffer: phosphate-buffered saline with 0.2% sodium azide and 0.2% bovine serum albumin

Fix buffer: phosphate-buffered saline with 0.5% paraformaldehyde (make fresh at least every 2 weeks and filter before use)

Phycoerythrin (PE) CD19 (no. 349209; BD Pharmingen)

Fluorescein isothiocyanate (FITC)–goat anti-human IgM (no. 2020-02; Southern Biotech)

FITC-CD3 (no. 349201; BD Pharmingen)

Rabbit IgG (for blocking) (no. 090310; DAKO)

Isotype controls: PE-mouse IgG1 (no. 349043; BD Pharmingen), FITC-mouse IgG1 (no. 349041; BD Pharmingen), and FITC-goat IgG (no. 0109-02; Southern Biotech)

At least 3×10^6 cells from a control and the patient

Procedure

1. Resuspend cells to a concentration of $10^6/100$ μl.
2. Place 50 μl of cells from the control and the patient into each of five tubes on ice.
3. Add 50 μl of rabbit IgG to each tube. Vortex gently.
4. Add staining reagents in a volume of less than 50 μl. The reagents listed below are used neat except for the FITC–goat anti-human IgM and its isotype control (goat IgG), which are used at a 1:40 dilution. For consistent staining, always add the antibodies in the same order.

Tube 1: 40 μl of staining buffer (no stain control)
Tube 2: 20 μl each of FITC-mouse IgG1 and PE-mouse IgG1 (isotype controls for tube 4)
Tube 3: 20 μl each of FITC-goat IgG and PE-mouse IgG1 (isotype controls for tube 5)
Tube 4: 20 μl of FITC-CD3 and PE-CD19
Tube 5: 20 μl of FITC–anti-human IgM and PE-CD19

5. Vortex each tube gently and incubate for 15 min on ice in the dark.
6. Wash by adding 1 ml of staining buffer per tube and vortex gently. Then add an additional 2 ml of staining buffer.
7. Centrifuge the tubes at 1,300 rpm in a Beckman CPKR centrifuge for 3 min at 4°C.
8. Carefully aspirate the supernatant and wash again as in step 6 and centrifuge as in step 7.
9. Resuspend the pellet in 200 to 500 μl of fix buffer. Cells may be analyzed immediately or stored in the dark and cold for analysis within 4 days.

Because the number of B cells in patients with XLA is very low, low background fluorescence in the isotype control tubes is essential. Cells that are in less than optimal

condition will autofluoresce, making accurate analysis very difficult. To determine the number and phenotype of B cells in patients with suspected XLA, at least 175,000 to 300,000 events should be analyzed (Fig. 1).

Mutation Detection

A variety of techniques can be used to provide mutation detection. The size of the gene, the variability of the mutations, and the structure and GC content of a gene will influence the choice of technique. In evaluating any gene, it is important to keep in mind that not all alterations represent mutations. Some genes are highly polymorphic. Premature stop codons, frameshift mutations, and base pair substitutions within the invariant regions of the splice consensus sequences are clearly mutations. Amino acid substitutions may represent mutations; alternatively, they may represent uncommon polymorphic variants. If the amino acid substitution is not seen in 200 chromosomes from individuals of the same ethnic background as the patient, the substitution is probably a mutation. There are base pair substitutions within the coding sequence that do not change the amino acid sequence but still cause disease. Some of these base pair alterations affect splicing, while others may act as regulatory regions. Functional assays may be required to demonstrate that a base pair or amino acid substitution is the cause of disease. The advantages and disadvantages of some techniques are listed below.
FIGURE 1 Fluorescence-activated cell sorter analysis of B cells from a patient with XLA. Density gradient-separated peripheral blood mononuclear cells from a control (top panels) and a patient with XLA (bottom panels) were stained with PE-CD19 and either FITC-CD3 (left panels) or FITC–polyclonal anti-human IgM (right panels). The dot plot shows approximately 20,000 gated events from the control sample and 200,000 events from the patient sample. The control sample contains 7.3% CD19[+] cells, and the patient sample contains 0.07% CD19[+] cells. Note that the intensity of CD19 staining is homogeneous in the control sample but variable in the patient sample. Additionally, the majority of the B cells from the patient are very brightly stained for surface IgM, whereas those from the control are variable in surface IgM expression.

PCR Protocol for Mutation-Specific Assay

A simple PCR-based assay can be used to detect up to 60% of the mutations in μ heavy chain. Approximately 30 to 40% of mutations in μ heavy chain are large deletions that remove all of the coding regions for the D, J, and constant segments. Failure to amplify any part of this region suggests a deletion. Another 20 to 30% of mutations in μ heavy chain consist of a recurrent single base pair substitution found at the −1 position of the alternative splice site in exon 4. This G-to-A substitution in codon 433 results in the loss of an MspI restriction site. PCR amplification of the 3′ end of exon 4 of μ heavy chain, followed by MspI digestion and gel electrophoresis, will detect both deletions and the base pair substitution in codon 433.

Materials and Reagents

0.5-ml microcentrifuge tubes

Sterile water

DNA polymerase (Qiagen kit 201205—contains polymerase, 10× buffer, and Q buffer)

Primers at 10 mM concentration: sense primer, 5′-CAACAGGGTCACCGAGAGG-3′; antisense primer, 5′-GCACTCAGGACCAGTATC-3′

Deoxynucleoside triphosphates (dNTPs) at 1 mM (no. 27-2035-01; Amersham/Pharmacia)

DNA from controls and patients at a concentration of 100 ng/μl

MspI (no. R0106L; New England Biolabs)

Agarose (no. 15510-027; Life Technologies)

Ethidium bromide (E-1510; Sigma)

Gel electrophoresis apparatus

Procedure

1. PCR is very vulnerable to contamination. Before the assay is begun, the work area should be wiped down with 10% bleach. If possible, the PCR should not be done in a room where DNA is extracted, purified, stored, or analyzed. Some PCR machines require that the sample be overlaid with mineral oil. Know your machine!

2. Program the PCR machine to the following conditions: 95°C for 5 min, followed by 30 cycles of 95°C for 30 s, 56°C for 30 s, and 72°C for 30 s, with a final extension at 72°C for 5 min. Set the machine to hold at 95°C. Remove reagents from freezer and place on ice to thaw.

3. Roll up sleeves and put on fresh gloves.

4. Label two Eppendorf tubes for each control, each patient sample, and a negative control. One will be for the undigested DNA and the other will be for the digested DNA.

5. Place 2 μl (200 ng) of control or patient DNA into the tube for the undigested DNA. Place 2 μl of water into the negative control tube.

6. Prepare the PCR mixture for the total number of samples plus the negative control plus one extra sample (to make sure that you do not run out of reaction mixture). Keep all reagents on ice at all times. Add the following items, per sample, in the following order:

Water	23.75 μl
Q buffer	10 μl
10× buffer	5 μl
Sense primer	4 μl
Antisense primer	4 μl
dNTP	1 μl
Qiagen Taq	0.25 μl

7. Mix the above reagents well, and then distribute 48 μl into each DNA containing tube. Mix well with the DNA by pipetting up and down several times. Discard the tip between samples.

8. Place the samples in the PCR machine and begin to cycle.

9. At the end of the PCR, remove the tubes and take 25 μl from each tube and place it in the paired empty tube. This tube will be used for the digested DNA.

10. Add 1 μl of MspI along with 2.5 μl of appropriate 10× buffer (NEB2) into each tube labeled for digestion and incubate for 1 h at 37°C.

11. Run the paired samples on a 3% agarose gel.

12. Stain the gel with ethidium bromide, and examine and photograph.

If the patient sample shows no amplification product, the patient may have a deletion. However, it important to make sure that the patient DNA is intact by amplifying a segment from a different part of the genome. DNA from a normal individual will be completely digested by MspI and will demonstrate a 214-bp segment. If the patient has a base pair substitution in codon 433, the DNA will not be digested and the DNA exposed to MspI will be the same size as the undigested DNA.

SSCP

SSCP is a screening technique that is often used to analyze large genes with highly variable mutations. In SSCP assays, PCR is used to amplify a small segment of DNA. The PCR product is heat denatured to separate the two strands of DNA, and then the DNA is electrophoresed through a non-denaturing gel. A commercially available gel, MDE gel, is particularly useful for SSCP. The fact that the gel is non-denaturing allows the strands of DNA to form secondary structures which influence their migration through the gel (26, 32). Even single base pair substitutions change the secondary structure and therefore the migration. The ideal length of the PCR product for SSCP is 110 to 280 bp. For many genes, this length fits well with the size of exons plus flanking splice sites. If many samples are analyzed together, it is easier to identify subtle variations. The gel is run on a sequencing apparatus and is transferred to a filter, like a sequencing gel.

Materials and Reagents

As above for PCR-based mutation specific assay, with the following additions:

Primers specific for the reaction at 10 mM
[^{32}P]dCTP (no. BLU513H; Du Pont NEN)
MDE gel solution (no. 50620; Cambrex Bioscience)
Stop solution (no. 70724; USB)

Procedure

As above for PCR-based mutation-specific assay, with the following change: total volume is 25 μl rather than 50 μl.

1. Same as above.

2. Same as above. PCR conditions may vary depending on the reaction.

3. Same as above.

4. Label an Eppendorf tube for each control, each patient sample, and a negative control.

5. Place 1 μl (100 ng) of control or patient DNA into each tube. Place 1 μl of water into the negative control tube.

6. Prepare the PCR mixture for the total number of samples plus the negative control plus one extra sample (to make sure that you do not run out of reaction mixture). Keep all reagents on ice at all times. Add the following items, per sample, in the following order:

Water	11.25 μl
Q buffer	5 μl
10× buffer	2.5 μl
Sense primer	2 μl
Antisense primer	2 μl
dNTP	1 μl

7. After adding the dNTPs to the reaction mixture, transfer the reaction mixture and the tubes containing the template DNA to an area behind a radioactive shield and add 0.3 μl of [^{32}P]dCTP per sample and 0.25 μl of DNA polymerase per sample to the reaction mixture.

8. Mix the above reagents well, and then distribute 24 μl of reaction mixture into each DNA-containing tube. Mix well with the DNA by pipetting up and down several times. Discard the tip between samples.

9. Place the samples in the PCR machine and begin to cycle.

10. Prepare the MDE gel according to instructions. It will take 30 min for the gel to set.

11. At the end of the PCR, transfer 3 μl of PCR product to 8 μl of stop solution.

12. Denature all of the samples at 95°C for 5 min, and then leave on ice for 1 min prior to loading onto the gel.

13. The gel should be run in the cold (4°C) at 3 W for 4 h. Longer PCR products may require a longer run time.

An example of an SSCP gel is shown in Fig. 2. I have used SSCP to screen for mutations in Btk, CD40 ligand, ICOS, and AID.

Direct Sequencing

Direct sequencing is used to analyze small genes or genes that are not easily evaluated by screening techniques. Essential regions of the gene are amplified by PCR, the PCR product is gel purified, and the primers used to amplify the segment, or primers that recognize sites within the product, are used to sequence the segment on an automated sequencer. The PCR product must be quite clean, and the template-to-primer ratio must be appropriate to allow sequencing. Generally, 600 to 800 bp of sequence can be obtained from a single run. I have found that direct sequencing is more efficient than SSCP analysis to identify alterations in the exons encoding the constant region of μ heavy chain. The four exons of the μ heavy-chain constant region are too large (approximately 300 bp) to examine in a single SSCP reaction, and together the four exons are only 2.2 kb in length.

No single technique will identify all mutations. Although sequencing of cDNA may be a useful first screen, this approach often misses splice site defects and defects within regulatory regions. Direct sequencing of critical regions of the gene may miss base pair alterations within introns that create splice sites and pseudoexons. These mutations are found by sequencing cDNA. SSCP screening will miss duplications and inversions that are most easily detected by Southern blot analysis.
FIGURE 2 SSCP analysis of DNA from a patient with XLA and his family members. Exon 17 of Btk was amplified using primers that flank the coding sequence and splice sites. The PCR products were denatured in heat and then allowed to renature as they migrated through an electrophoresis gel. Lanes 1, 2, 6, and 7 contain DNA from controls. The DNA sample in lane 5 is from a patient with XLA. DNA samples from the patient's mother and sister are in lanes 3 and 4, respectively.

SUMMARY

Evaluation of patients with suspected antibody deficiency should proceed in a stepwise fashion. A detailed history of past infections, a careful family history, and a physical examination that focuses on sites typically involved in antibody deficiencies should come before any laboratory tests. The extent of the preliminary evaluation should depend on the index of suspicion. A screening evaluation may include only quantitative serum immunoglobulins and isohemagglutinins, or it may include additional tests such as titers of antibody to vaccine antigens and lymphocyte cell surface markers. For patients with defects in early B-cell development of unknown etiology, a bone marrow aspirate may be useful to document the numbers of pro-B cells and pre-B cells. A gene-specific diagnostic test should be performed if genetic counseling is desired and preliminary tests support the diagnosis.

Hereditary and Acquired Complement Deficiencies

PATRICIA C. GICLAS

102

Complement comprises an interactive system of more than 30 plasma and cell membrane-associated recognition molecules, enzymes, cofactors, control proteins, and receptors. It plays an important role in the host's response to infection by coating microbial surfaces with complement fragments that enhance uptake and killing by phagocytes. As a major effector arm of the innate immune system, complement serves as a link between many of the activities of acquired immunity and other defense mechanisms, with ties to diverse cell signal responses in an ever-increasing number of tissues.

Activation of the complement enzyme cascade produces peptide fragments that exhibit inflammatory properties, including chemotactic activity and the ability to regulate local blood flow and vascular permeability. Complement also has a host of "housekeeping" activities, such as clearance of immune complexes, effete and apoptotic cells, and cellular debris. Deficiencies or mutations in complement components, whether inherited or acquired, predispose an individual to infections, autoimmune diseases, impaired immune responses, and diverse conditions such as fetal loss, renal disease, vasculitis, allergic reactions, angioedema (AE), and age-related macular degeneration. The discussion that follows touches on examples of these and other complement-related functions that go awry when one or more of the proteins in the system is missing or functions abnormally. The reader is referred to Fig. 1 for a review of these pathways and the proteins involved.

A previous chapter published in the fifth edition of this manual (39) describes a process by which the appropriate laboratory methods can be used to determine which component(s) is deficient and whether the deficiency is hereditary or acquired. In general, starting with basic screening tests, such as CH50 and AH50 or their equivalents for total classical and alternative pathway function, will help pinpoint the pathway involved and limit the number of tests required. A test for lectin pathway (LP) function will further narrow the search. Since all three initiating pathways (classical pathway [CP], alternative pathway [AP], and LP) share the same terminal pathway, a missing component unique to any of the early steps will affect only the pathway involved, while a missing component in the terminal pathway will affect all of the others. As with other complement tests, care must be taken in specimen collection, handling, and shipping. It is strongly advised to contact the laboratory to which the specimen will be sent for instructions for specific assays. More labs are now offering genotyping for complement components, so the collection of specimens for DNA from the patient and family is recommended as well.

DEFICIENCIES OF THE CP: C1q, C1r, C1s, C2, AND C4

The CP is activated when the C1 complex ($C1qC1r_2C1s_2$) binds to an appropriate activator through the latter's interaction with C1q. Although often this may be an immune complex or aggregate of immunoglobulin G (IgG) (IgG3 > IgG1 > IgG2) or IgM, many other substances can serve as activators of the CP. Once bound, the C1 complex undergoes a relaxation of the constraint on C1r and C1s and the esterase activities of these subcomponents can then be expressed. The substrate of C1r is C1s, and the substrates of C1s are C4 and C2. The activities of these two enzymes are very rapidly controlled in normal plasma by C1-esterase inhibitor (C1-Inh).

The CP is critical for the clearance of immune complexes, and it also participates in the removal of apoptotic cells. The phenotype of C1q and other early CP component deficiencies is closely linked to diseases in which these processes are impaired, such as systemic lupus erythematosus (SLE), and rheumatologic disorders such as anaphylactoid purpura, vasculitis, and membranoproliferative glomerulonephritis (30). The incidences of SLE in patients with known C1q, C4, or C2 deficiency are roughly 90, 75, and 15%, respectively, while partial C4 deficiency (C4A) is also implicated in 15%. SLE patients with C1q or C4 deficiencies have characteristic features such as earlier age of onset, prominent photosensitivity, lower frequency of renal disease, variable antinuclear antibody titers, and a nearly equal male-to-female ratio. In addition to SLE and other immune complex diseases, CP deficiencies also lead to recurrent pyogenic infections with streptococcal, staphylococcal, and other common encapsulated bacteria but less likely *Neisseria*, and should not be overlooked in the workup for immune dysfunction. The CH50 or equivalent assays are the best screens for these deficiencies, since the absence of any one of the CP proteins will block CP activity (38).

The gene for human C1q is located on chromosome 1, at 1p34-1p36.3 (82). The protein is related to the collectin family, possessing both collagen-like and globular structure. There are six each of three different polypeptide chains in the intact 460-kDa molecule. These chains are combined to
FIGURE 1 CP, LP, and AP of the human complement system, showing the control steps and where some of the biologically active split products are produced.

form six triple-chain helices that make up the collagen-like "stalk" of the molecule, and then they branch away at a flexible hinge region into six smaller stalks ending in globular heads. The molecule has been described as a bunch of six tulips, based on electron microscopic photographs.

The primary synthesis of C1q is by cells of monocyte/ macrophage lineage, with follicular dendritic cells as a secondary site. C1q deficiency is an autosomal recessive condition, with deficient patients having little or no detectable protein or C1q function in the circulation. Mutations have been identified in the genes for each of the three chains. Almost all patients with documented C1q deficiency have developed SLE-like disease, and linkage studies demonstrate that the C1q gene is close to that for other proposed SLE susceptibility genes on chromosome 1 in humans (91).

The genes for C1r and C1s are located on chromosome 12, at 12p13, where the two genes lie in tandem (60). C1r and C1s are synthesized as single-chain proenzyme molecules that associate in a tail-to-tail fashion, with two C1r-C1s pairs in a calcium-dependent complex with each C1q. Each proenzyme is activated by cleavage of a single bond to produce two disulfide-linked peptides, the smaller of which has esterase activity. C1r has very limited trypsin-like activity, with C1r autoactivation followed by cleavage of C1s. C1s has trypsin-like activity against C4 and C2, each of which it cleaves into two fragments: C4a and C4b, and C2a and C2b.

C1r and C1s are synthesized primarily in the liver by hepatocytes, but monocytes, macrophages, epithelial and endothelial cells, and some cells of the central nervous system provide secondary synthesis sites. Deficiencies of C1r and C1s are rare and may be partial or combined. They predispose the patient to recurrent pyogenic infections as well as immune complex disease (65).

The proteins C4 and C2 are both required for formation of the C3 convertase enzyme of the CP (C4b2a). The absence of either protein leads to a complete block of CP

activity and is associated with recurrent infections and immune complex disease as described above. In spite of this, many patients with C2 deficiency remain asymptomatic for long periods, if not for life. The genes for C4 and C2, along with those for factor B (BF), are present in the major histocompatibility complex (MHC) on chromosome 6 in the group known as class III MHC genes (5).

C4 is produced primarily by hepatocytes but can also be made by many other cells. It is synthesized as a single chain that undergoes posttranslational modification to three chains that are disulfide linked. The alpha chain contains an internal thioester linkage that forms a covalent bond with nearby substances when the C4a is clipped off during activation. This bond provides a means for attachment of C4b to the nearest protein or carbohydrate group when activation occurs and results in long-lasting deposition of C4b and its breakdown fragment, C4d, on the activator.

Human C4 exists in two forms, C4A and C4B, coded for by different genes and present in equal amounts (two alleles of C4A and two of C4B) in approximately 75% of the population (104). The differences between the two forms of C4 are in a few amino acids near the thioester group and affect the ability of the C4b fragment to bind to proteins (C4A) or carbohydrate residues on cell surfaces (C4B). Standard assays for C4 do not distinguish between these forms. Variation in C4 gene number is not uncommon, and the gene number can range from none to eight or more copies, giving this protein a wide range of concentrations in the general population (103, 104). Most of the partial C4 deficiencies are without consequence, but some individuals have a total deficiency of one haplotype. C4A deficiency is increased (8 to 12%) in Caucasian lupus patients compared to control individuals (1 to 3%) due to the decreased binding of C4A to protein antigens and antibodies and consequent difficulty with immune complex clearance. An increased incidence of C4B null alleles was recently reported

for patients with Henoch-Schönlein purpura (86). Close to 100 different polymorphisms in the C4 protein make it one of the most variable proteins in the circulation.

C2 is synthesized by hepatocytes, monocytes, macrophages, fibroblasts, astroglioma cells, and alveolar type II cells. It is produced as a single-chain proenzyme that expresses its esterase activity only after it has been cleaved. This activity is very weak in the fluid phase but becomes efficient when the C2a fragment is bound to C4b on a surface. C2-deficient patients have increased susceptibility to infections, particularly streptococcal pneumonia, as well as the previously mentioned association with immune complex diseases. In Caucasian patients with rheumatologic disorders such as SLE, the incidence of C2 deficiency approaches 1/100, as opposed to the general population, where incidence is estimated to be 1/10,000 (4, 54). There are two forms of C2 deficiency. Type I deficiency, which affects over 90% of patients, results from a complete lack of synthesis, while type II C2 deficiency results from a secretion defect. The former deficiency is characterized by little or no detectable protein in the circulation, and the latter is characterized by up to 10% of normal levels and function.

DEFICIENCIES OF THE LP: MBL, FICOLINS, AND MASPs

Mannose-binding lectin (MBL) has also been known as mannose-binding protein, mannan-binding protein, or core-specific lectin. Similar in structure to C1q, it is made up of trimers of single polypeptide subunits, two to six of which combine to form oligomers. MBL is a pattern recognition lectin that binds with high affinity to the mannose, peptidoglycan, and N-acetylglucosamine residues that are found on the surfaces of bacteria, yeasts, and fungi (92). Like C1q, it is associated with several serine proteases, or MASPs (MBL-associated serine proteases), that become active when binding of the MBL occurs (62). In addition to activating complement, MBL may be able to act directly as an opsonin by interacting directly with cell surface receptors.

The gene for MBL is found on chromosome 10, at 10q11.2-q21, with another gene that encodes a truncated protein at 10q22.2-22.3 (42, 79). There is a wide range of serum concentrations of MBL, due in part to the presence of gene variants that produce different amounts of the protein. Approximately 5 to 10% of individuals studied to date are MBL deficient (16). Because complement activation by the LP is antibody and C1 independent, it is thought to play an important role in innate immunity during infancy before the adaptive immune responses are mature (93). Deficiency of MBL has been linked to an increased frequency of pyogenic infections and sepsis, particularly in neonates and young children. It has been implicated as a risk factor in ischemia-reperfusion injury, Behçets disease, cystic fibrosis, severe acute respiratory syndrome, and several other respiratory infections (14, 36, 46, 51, 52). There is a two- to threefold increase in MBL deficiency in lupus patients who tend to have more frequent and severe infections, and worse outcomes are observed in rheumatoid arthritis patients with MBL deficiency. Autoantibodies that reacted with MBL were found in a Japanese study of patients with SLE, but the significance of these antibodies was not evident from the disease characteristics of the patients (87).

The ficolins are a group of proteins that are similar to C1q and MBL, with a collagen-like region and a C-terminal fibrinogen domain that is thought to be the ligand-binding site for N-acetylglucosamine (61, 62). There are several

forms of ficolins that have been described: ficolin-L and ficolin-H are found in the circulation, while ficolin-M is a secretory protein that is found in the cytoplasm of neutrophils, monocytes, and type II alveolar epithelial cells. All forms have similar opsonizing capacities for pathogens and are associated with the MASP enzymes found with MBL. Although the ficolins were first described as opsonins in 1996, little is known of the prevalence or phenotype of ficolin deficiencies.

The four MASP proteins, MASP-1, MASP-2, MASP-3, and Map19, are encoded by two genes (81). Structurally they are similar to C1r and C1s, with a serine protease domain in the B chain. MASP-1 and MASP-3 are alternative splice products of one gene (MASP1/3) that have the same A chain but different B chains. A different gene encodes MASP-2 and Map19, the latter of which has only the first two domains of MASP-2 plus an additional four amino acids. MASP-2 is responsible for the cleavage of C4 and C2, making it analogous to C1s in function. Although there have been mutations found in the genes for the MASP proteins, the mutations in MBL that prevent the assembly of the complete complex are the major known cause of functional deficiency of these proteins (85, 93).

DEFICIENCIES OF THE CP AND LP CONTROL PROTEINS: C1-Inh AND C4BP

The active enzyme forms of C1r and C1s are regulated solely by C1-Inh, a member of the SERPIN family of serine protease inhibitors. C1-Inh also contributes to the control of other enzymes, including coagulation factors XIa, XIIa, plasmin, and plasma kallikrein. When the enzyme and inhibitor interact, the enzyme cleaves a "bait-sequence" on the inhibitor and the resulting change in conformation forms a tight complex, rendering the enzyme inactive. The complexes formed in these reactions are cleared from the circulation by cells of the reticuloendothelial system. C1-Inh deficiency can be of hereditary origin (HAE) or acquired (AAE) through clearance of inhibitor-enzyme complexes or through action of autoantibodies that react with the inhibitor and result in its inappropriate cleavage. Symptoms are similar regardless of the origin of the deficiency, so careful evaluation is required to distinguish between HAE and AAE. The kinin-like biochemical mediator(s) of AE, not yet definitively identified, could arise from defective regulation of either the complement or coagulation pathways. The argument for bradykinin is strengthened by current studies in an animal model and success with treatment of patients using a kallikrein inhibitor (20, 45).

C1-Inh is inherited in an autosomal codominant pattern in which each allele produces approximately half of the protein in the circulation, although increased catabolism often causes decreases of the normal gene product to below the predicted 50% level. To date, no patient homozygous for deficiency of C1-Inh (both alleles defective) has been reported, and the heterozygous state determines the phenotype (32). Patients with C1-Inh deficiency suffer various degrees of intermittent AE characterized by nonpainful, nonpruritic, and nonerythematous subcutaneous and submucosal swelling that spontaneously subsides within 72 h (21, 32). Swelling may arise sporadically and spontaneously, or it may be triggered by mild trauma or psychological stress. It is not accompanied by urticaria and is not responsive to antihistamines, steroids, or beta agonists. Symptoms usually begin in adolescence and range in severity from mild edema of the extremities to life-threatening laryngeal edema.

Edema of the bowel wall results in severe colicky abdominal pain, nausea, and vomiting that can be distinguished from acute abdominal syndromes by the absence of fever, peritoneal signs, and elevated white blood cell count. Angiotensin inhibitors may increase attack frequency (33). There are several new drugs being developed that may help control AE, including recombinant human C1-Inh, human C1-Inh purified by new methods, and kallikrein antagonists.

Genetic defects in C1-Inh range from single nucleotide polymorphisms that may alter the function of the protein produced to inappropriate stop codons resulting in large deletions and no protein production. Since each patient has one normal allele and one abnormal allele, he or she will have variable amounts of C1-Inh protein in the circulation, from very low to elevated, depending upon the particular mutation in the affected gene. In the majority of patients, low levels of C1-Inh are indicative of the defect, but final diagnosis of HAE should be based on the functional activity of C1-Inh protein in conjunction with decreased levels of C4, the clinical presentation, and family history. Spontaneous mutations in C1-Inh genes have been documented in about 20% of cases, so the lack of family history does not rule out the defect (12, 18, 22). The prevalence of C1-Inh deficiency is 1/10,000 in Caucasian populations. MASP-1 and MASP-2 are controlled in a 1:1 manner by C1-Inh, in the same way that C1r and C1s are controlled. The control of MASP-3 is not known at this time.

The two forms of HAE behave the same clinically. Type I HAE (80% of patients) is defined by a reduction of C1-Inh to less than half of normal antigenic and functional levels. Type II patients have normal or elevated antigenic C1-Inh levels but synthesize a dysfunctional protein with reduced or absent C1-Inh function. Recent studies have identified a third type in which the patients, all women, have clinical findings consistent with HAE but normal C1-Inh level and function (9, 11). The underlying estrogen-dependent defect has not been identified.

As in HAE, two forms of acquired AE have been described. In type I AAE, patients with B-cell lymphoproliferative diseases produce circulating anti-idiotype antibodies. The immune complexes produced by these antibodies cause a persistent activation of the CP, resulting in profound C1-Inh consumption as the enzyme-inhibitor complexes are cleared (13, 64). In this form of AAE, the C1q level is decreased, whereas in the hereditary forms it is not. In type II AAE, inactivation of C1-Inh is caused by autoantibodies to the C1-Inh protein (53). In type II AAE, the C1-Inh level can be normal by immunoassay, but the protein is dysfunctional. The autoantibody can be detected by enzyme-linked immunosorbent assay, and a cleaved form of the C1-Inh molecule can be detected by Western blotting.

The fluid-phase control of C4aC2b, the C3 convertase of the CP and LP, is accomplished through the combined effects of C4b-binding protein (C4BP) and factor I (FI). Also known as proline-rich protein, human C4BP is a member of the family known as regulators of complement activation (RCA). Characterized by multiple short consensus repeat motifs, also referred to as complement control protein (CCP) units, the RCA proteins bind C3b and C4b fragments and possess various control properties that are critical for regulation of complement activity. These small globular CCP units are typically connected in linear fashion like beads on a string. They occur in all of the RCA and many other complement proteins in various numbers.

C4BP has several isomers made up of two types of subunits: six or seven alpha chains and zero or one beta chain.

These are connected at a central joining region and radiate outward, giving the molecule a spider-like appearance (19). The alpha chains bind to C4b and accelerate the dissociation of C4bC2a to form free C2a and C4b-C4BP. C2a is unable to bind to newly formed C4b and becomes inactivated, while C4b undergoes degradation by FI (with C4BP as a cofactor) to form C4c and C4d (34). C3 convertase activity by the CP enzyme is short-lived due to the efficiency of C4BP. For this reason, activation of the CP does not produce a large amount of C3 fragments and activation often stops at this point in the cascade unless the AP is activated. In the absence of C1-Inh, it is the control of C4bC2a activity by C4BP and FI that accounts for the stability of C3 in HAE patients in spite of decreased C4 and C2 (41). The beta chain has a binding site for the anticoagulant protein S and may play a role in control of coagulation.

C4BP is synthesized in the liver by hepatocytes. The genes for the C4BP alpha and beta chains are located in the RCA gene cluster on chromosome 1, at 1q32. Circulating concentrations of C4BP vary according to genetic determinants as well as fluctuations due to consumption during disease states. Deficiencies of C4BP are very rare and would logically be associated with uncontrolled activation of C3 through the CP. The only documented case was a patient with an atypical form of Behçet's disease and AE (90).

DEFICIENCIES OF THE AP: FD, Bf, AND PROPERDIN (P)

Factor D (FD) is the smallest of the complement proteins and is the only serine protease of the system that does not require enzymatic cleavage in order to become active. Instead, its enzyme activity is a function of its conformational state, and it can flip between the active and inactive forms depending on its proximity to its substrate: C3b-bound Bf (94). Like other complement proteins, it is synthesized by cells of monocyte/macrophage lineage, but its major source of synthesis is adipose tissue (101). FD is the only initiating enzyme for the AP. It binds to and cleaves Bf only when the Bf is bound to C3b. The resulting complex, C3bBb, is the AP C3 convertase.

FD is synthesized by a gene located on chromosome 19. One family with FD deficiency has been described to date. In five generations of family members, the propositus was a 23-year-old woman who presented with meningococcemia from *Neisseria meningitidis*, three relatives had FD deficiency with no health problems, and a deceased family member had a history of meningitis in his twenties and died from pneumonia and meningitis caused by *Streptococcus pneumoniae* at age 81 (8). Complement studies for the patient and family members included C3 and C4 levels and CH50 (normal in all). The AH50 was <10% of normal in homozygous deficient individuals but was normal in all others, including those heterozygous for the deficiency. When FD was analyzed, it was found to be slightly elevated in those members who were homozygous for the wild-type FD gene, about half the normal level in those heterozygous for the mutation, and undetectable in the four patients homozygous for the mutation.

In addition to its participation in the AP of complement, FD plays a role in fatty acid metabolism, and the $C3a_{desArg}$ fragment produced by FD-mediated cleavage of C3 has been identified as the autocrine mediator of hyperapobetalipoproteinemia (57, 101). It is tempting to speculate that this involvement with lipid metabolism may be impaired or dysregulated somehow in those rare patients with partial lipodystrophy who have increased cleavage of C3 due to the

presence of autoantibodies to the C3bBb complex (C3 nephritic factors).

Bf has been known variably as glycine-rich beta glyco-protein, properdin factor B, C3 proactivator, C3 convertase, C5 convertase, and EC 3.4.21.47. The gene for Bf is in the MHC complex on chromosome 6, at 6p21.1-6p21.3, 3′ to the C2 gene (15). It is synthesized primarily in the liver, with additional protein produced by cells of monocyte/macrophage lineage, fibroblasts, endothelial cells, and alveolar type II epithelial cells. Secreted as a single polypeptide chain proenzyme, Bf is activated only when it is bound to C3b and cleaved by FD. Its activity is specific for C3 and C5, but it requires C3b as a cofactor to cleave the former and an additional C3b to cleave the latter. The hydrolyzed form of C3 known as C3•H$_2$O can serve as the first ligand for Bf binding.

Bf is an acute-phase protein and increases during inflammation. There are two polymorphic forms of Bf, BF*F and BF*S, based on their electrophoretic mobilities on immuno-electrophoresis. The amount of Bf in the circulation is higher in individuals homozygous for the former and lower in individuals homozygous for the latter, with heterozygous individuals intermediate (66). There has only been one unconfirmed report of a Bf deficiency in humans and none in animals except Bf gene knockout mice. The latter do not appear to have problems in specific-pathogen-free conditions.

P is a unique protein that acts as a stabilizer for the AP C3 convertase and makes possible the amplification loop that very efficiently cleaves C3 when the AP is activated. P is a single-chain linear molecule with no enzyme activity, but it forms head-to-tail polymers, about half of which are trimers, with dimers and tetramers making up the remainder. P binds to C3b with increasing avidity depending on the number of C3b molecules in a cluster, and its affinity increases when Bb is present (26, 27).

P is the only complement protein that is X-linked, with its gene at Xp11.3-Xp11.23 (40). The protein is synthesized by monocytes, granulocytic cells, and T cells. Three types of P deficiency have been described. Type I deficiency is associated with fulminant meningococcal infections, and the patients had little or no P detectable in the circulation (83). Partial P deficiency found in another family with neisserial septicemia was characterized by about 10% of normal levels of P in the serum (84). Several dysfunctional mutant forms of the protein have been identified that result in decreased AP function, making this type III deficiency (100). P deficiency increases the susceptibility to bacterial infections, including *Neisseria* infections. Carriers of a defective or absent P gene cannot be reliably identified from the protein's level in the circulation, and genetic typing is necessary to provide evidence of the carrier state (59).

CONTROL PROTEINS OF THE AP: CFH AND FI

The amplification, or feedback, loop of the AP makes it one of the most efficient enzyme systems in the circulation (28). As long as P can stabilize the C3 convertase (C3bBbP), C3 cleavage continues unchecked. This leads to deposits of C3 clusters on the surface of cells, where the C3bBb is bound, and greatly enhances opsonization and other inflammatory cell interactions with the C3-coated particles due to the increased avidity provided by multiple closely spaced C3 fragments for C3 receptor interaction. The two major controls of the fluid-phase activation of the AP are factor H (CFH) and FI. The former is a member of the RCA family,

described above for C4BP, and the latter is a serine protease with specificity for C3b and C4b.

CFH is synthesized as a single chain with 20 complement control protein modules. The gene for CFH is located in the RCA cluster of genes on chromosome 1, at 1q32 (48). CFH is produced primarily in the liver, but like other complement components, it can also be made by monocytes, macrophages, fibroblasts, endothelial cells, and myoblasts. There are several variant forms of CFH, referred to as FH-like or FH-related proteins, that differ in size and function from CFH. In humans, these different forms of CFH appear to represent products of alternative splicing of the CFH gene, rather than separate genes (25).

CFH has multiple binding sites that interact with C3b, heparin, chondroitin sulfate and other polyanions, bacterial surface components, DNA, and endothelial cells. Its mode of action as a control protein is to bind to C3b and displace the Bb enzyme component of the C3 convertase. If additional C3b fragments are bound to or near the convertase, the avidity of this binding is increased. Once Bb has been removed, FI can use CFH as a cofactor in cleaving C3b to form iC3b, C3d,g, and C3c, thus preventing the C3b from interacting with B to form a new convertase. The fragments iC3b and C3d,g can interact with CR3 receptors on phagocytic cells and with CR2 receptors on B cells and dendritic cells, respectively (96, 97). In addition to its function as a fluid-phase control protein, CFH has been reported to have chemotactic activity for monocytes (69, 73). It also functions as an adhesion protein for neutrophils, possibly through the RGD sequence in the fourth CCP module. CFH binds to many cell types, including endothelial cells, through its polyanion binding regions and can serve as a cell surface control protein in this capacity.

CFH deficiency involves compromise of the complement regulatory action, which can be severe in patients that lack CFH protein completely. These patients have varied presentations, including recurrent infections, membranoproliferative glomerulonephritis, SLE, and atypical hemolytic-uremic syndrome (aHUS) (6, 67, 71). Initial lab results may identify them as C3 deficient, since without functional CFH, the C3 in their circulation is diminished or absent. More subtle deficiencies stem from point mutation in the CFH gene and result in decreased ability of the CFH to control complement on cell surfaces, particularly in the kidney (aHUS) and in the eye (age-related macular degeneration [AMD]) (24, 43, 44, 58, 77, 78). In the latter case, the mutated protein has not yet been characterized functionally but the gene defect was strongly associated with the susceptibility to AMD. An acquired form of aHUS was reported for a patient with anti-CFH autoantibodies (23).

Another disease-related property of CFH is the prevalence of bacterial or viral binding surface proteins that have evolved to bind it and thus wrap the microbe in a protective coating that prevents complement activation on their surfaces. Among the microbes that use this scheme to escape complement attack are strains of *Borrelia*, *Streptococcus*, *Yersinia*, and *Neisseria* (10, 17, 49, 63, 70, 76). This method of acquiring serum resistance also includes binding of other regulatory proteins (C4BP and membrane cofactor protein [MCP]) as well as RCA-like proteins encoded by the microbial DNA and expressed on the surface.

FI, also known in the literature as C3b-inactivator and KAF (conglutinogen-activating factor), is a single-chain serine protease that cleaves two sites on the α chains of both C4b and C3b: one on either side of the thioester bond region. This stops further participation of these molecules in

complement activation and creates first iC4b or iC3b, followed by the final breakdown fragments C4c and C4d, and C3c and C3d,g. FI requires C4BP (for C4b cleavage) or CFH (for C3b cleavage) for cofactor activity in the fluid phase. On cell surfaces, the complement receptors CR1 and CR3 and MCP can fill this role as cofactors. FI is synthesized by hepatocytes, monocytes, fibroblasts, endothelial cells, myoblasts, glial cells, and Raji cells. The gene for FI is on chromosome 4, at 4q25. FI deficiency was first identified in a patient with little or no C3 in the circulation (1, 2). FI deficiencies, like those of CFH, are characterized by low or absent C3 in the circulation. FI deficiency is associated with recurrent severe pyogenic infections, vasculitis, glomerulonephritis, and aHUS (34, 37, 95).

DEFICIENCIES OF THE TERMINAL PATHWAY (LATE) COMPONENTS: C3, C5, C6, C7, C8, AND C9

Because C3 occupies the central position where the three initiating pathways merge with the terminal pathway, it is critical in the functioning of the system as a whole. C3 is an acute-phase reactant, increasing as much as twofold during inflammation. This increase may mask decreases due to activation, making it difficult to determine what is actually happening in vivo. Cleavage of C3 during complement activation produces a sequence of fragments, most of which have biological activities associated with opsonization, phagocytosis, immune adherence, effects on local vasodilation, smooth muscle contraction, and induction of mediator release, including histamine, from inflammatory cells. The absence of C3, either due to an inherited defect or an acquired condition, renders the individual highly susceptible to bacterial infections, membranoproliferative glomerulonephritis, and immune complex-mediated diseases such as lupus. The internal thioester bond in C3 is like that described earlier for C4 and leads to permanent attachment of the C3b and C3d fragments to the surface of the activating particle or molecule.

Most of the C3 in the circulation comes from hepatocytes, but many other cells can produce C3 and contribute to the local supply. The gene for human C3 is located on chromosome 19, at 19p13.3-p13.2 (102). Inheritance follows an autosomal recessive pattern in which the C3 protein is undetectable in the homozygous state and is approximately half the normal level in heterozygous individuals. The acquired forms of C3 deficiency can be profound and have been mistaken for genetic C3 deficiency on occasion. The usual causes of acquired C3 deficiency are secondary to deficiencies of FI or CFH, or the presence of autoantibodies to either of the C3 convertases, C3 or C4 nephritic factors, resulting in uncontrolled C3 cleavage in the circulation. In these cases, C3 fragments (iC3b, C3c, or C3a) can usually be detected in the circulation, and incubation of the patient's serum with normal serum or with purified C3 leads to C3 cleavage in the normal serum.

C5 is structurally similar to C3 but lacks the internal thioester bond that characterizes C3 and C4. When cleaved during activation, C5 also gives rise to similar fragments, but their activities are different from those for C3 and C4: C5b participates in the initiation and formation of the lytic complex (C5b-9) that inserts into the membrane of the target cells, and C5a is one of the most potent chemoattractants for neutrophils and other inflammatory cells. As an anaphylatoxin, C5a induces changes in vascular permeability, smooth muscle contraction, cell activation, upregulation of

adherence molecules, and release of enzymes, mediators such as histamine, and cytokines.

Like C3, C5 is produced mainly in the liver but can also be synthesized by cells in the lung, spleen, and intestine, as well as by monocytes, macrophages, and alveolar type II cells. The gene for C5 is located on the ninth chromosome, at 9q33. Homozygous deficiency of C5 is associated with severe infections, often from *N. meningitidis* or *Neisseria gonorrhoeae*. C5-deficient individuals lack bactericidal activity and are unable to mobilize their neutrophils and other inflammatory cells to respond to bacterial infections. Other presentations have included discoid lupus and Sjögren's syndrome (3, 80). Several strains of mice have spontaneously occurring C5 deficiency.

C6 and C7 are similar proteins that are encoded by genes on the fifth chromosome, at 5p12-14. Another complement gene, C9, is close to this locus as well. Unlike the previously discussed complement proteins up through C5 in the activation pathways, none of the late components (C6, C7, C8, and C9) is cleaved during activation, but all are integral proteins in the formation of the membrane attack complex (MAC) or the terminal complement complex. C6 binds to a neoepitope exposed on C5b, forming the C5b-6 complex that is rapidly expanded to C5b-6-7 by the addition of C7. The final complex formation occurs on a membrane surface when C8 binds and C9 polymerizes to form the membranolytic complement lesion, C5b-9, on the cell surface, leading to osmotic lysis of the cell.

Deficiencies of C6 and C7 are associated with recurrent severe neisserial infections as well as infections caused by other pyogenic bacteria, although there have been reports of lupus in individuals with these deficiencies as well. A number of cases of combined deficiency of C6 and C7 have been reported, as well as the influence of one gene upon the synthesis rate of the other, leading to decreased production of one of the proteins from an otherwise normal gene. Subtotal deficiencies of both proteins were accompanied in one patient by a lower-molecular-weight form of C6 that was associated with a defect in the 5′ splice donor site of intron 15 of the C6 gene. The same patient had low C7 as well, with the C7 protein containing an Arg→Ser substitution that altered the protein's isoelectric point. Patients with complete deficiency of C6 or C7 lack measurable protein and have little or no hemolytic activity in the CH50 or AH50 assays. Subtotal deficiencies of C6 or C7 are similar, although loss of hemolytic function is not complete (29).

C8 is a complex protein made up of three nonidentical polypeptide chains: a disulfide-linked α-γ pair and a noncovalently linked β chain. Each one of the chains is coded for by a separate gene and the protein is assembled intracellularly, although there is evidence from deficiencies that C8α-γ and C8β may be produced and secreted independently. The intact molecule is required for function in the lysis of the target cell (88).

The genes for the C8 subunits are located on the first (C8α and C8β at 1p32) and ninth (C8γ at 9q34.4) chromosomes. The three chains of C8 are interesting in that C8α and C8β are similar to C6, C7, and C9 in their structure, while C8γ is more closely related to the lipocalin family of proteins that bind and transport small hydrophobic ligands (56). Because C8 deficiency is due to decreased or a lack of synthesis of only part of the complex molecule (C8α chain or C8β chain), the part of the molecule that is produced is recognized by the antisera used for measuring C8 levels in serum, giving, in effect, a false-positive result. This makes it necessary to use caution in diagnosing C8 deficiency from

protein levels alone, and a functional test should be done as well. C8 deficiency, like that of other MAC proteins, is characterized by recurrent infections, most often caused by neisserial species. C8 is synthesized primarily by hepatocytes, although it can also be produced by cells of monocyte/macrophage lineage, astrocytes, oligodendrocytes, fibroblasts, and endothelial cells.

As the MAC is assembled on the cell surface, the C5 to C8 proteins are joined by C9, the final protein in the terminal complement pathway. The C9 protein unfolds to form polymers that penetrate the membrane and create perturbations that lead to osmotic lysis of the target cells. Estimates of the number of C9 molecules required to form a lytic pore range from 6 to 18 (68). C9 is produced primarily by hepatocytes and secondarily by monocytes, glial cells, fibroblasts, and other local cells at sites of inflammation. It is an acute-phase protein and is coded for by a gene at 5p13, close to the genes for C5 and C6.

Many cases of C9 deficiency have been reported, and the remarkable thing is the lack of strong association of disease phenotypes with this complement deficiency. Although there have been scattered reports of neisserial infections, most C9-deficient patients appear to be healthy. This is most likely because C9 is not absolutely required for lysis of the target cell. C9 is the most common complement component deficiency in Japan and perhaps in other Asian populations as well (35, 50, 55).

CONTROL PROTEINS OF THE TERMINAL PATHWAY: S-PROTEIN, CLUSTERIN, AND CD59

Protection of host cells from "bystander lysis" caused by insertion of fluid-phase C5b-9 (MAC) complexes is accomplished by several mechanisms. Two proteins, S-protein (vitronectin) and clusterin (SP 40,40 or apolipoprotein J), act as solubilizing factors to bind the MAC and block its hydrophobic insertion into the membranes of nearby cells. These proteins can bind to C5b-7 and C5b-8 in the fluid phase, preventing membrane interaction and C9 polymerization, although at least one C9 molecule is associated with the final SC5b-9 complexes detected in the circulation. This complex is relatively long-lived and may serve as a marker for complement activation when most other complement fragments (C3a, C5a, etc.) have been cleared from the circulation. No deficiency of either of these proteins has been identified to date.

CD59 is a membrane-bound glycoprotein that inhibits the polymerization of C9 and the lytic activity of the MAC. It is expressed on a wide variety of cell types, including erythrocytes. Because it is species specific, it is the primary cell surface protector against lysis mediated by homologous complement. CD59 is linked to the cell membrane by a glycophosphatidylinositol anchor that is variably lost from cells in patients with paroxysmal nocturnal hemoglobinuria; CD59 loss provides one of the mechanisms for hemolysis in these patients.

THERAPY FOR COMPLEMENT DEFICIENCIES

Treatment of patients with complement deficiencies has been limited to treatment of infection and autoimmunity. At this point in time the use of recombinant components for a completely deficient patient is possible, but the hurdles of economics and potential of immune responses to the recombinant proteins make this tactic unlikely to succeed. Blood

transfusion to replace C2 was tried with some success in two SLE patients and several HUS patients with CFH deficiency (6, 7). Purified plasma C1-Inh has been successful at the time of attacks, but other possible drugs are currently in the pipeline, including recombinant C1-Inh and a specific inhibitor of the bradykinin receptor BK2.

Recombinant or monoclonal antibody complement inhibitors have been used in ischemia-reperfusion injury, cardiopulmonary bypass surgery, and autoimmune disorders. Soluble CR1 acts against the C3 and C5 convertases of both the AP and CP (74, 75, 105, 106), and a humanized anti-C5 monoclonal antibody that prevents cleavage of C5 to C5a and C5b has been effective in animal models and clinical trials (31, 89, 98, 99). In paroxysmal nocturnal hemoglobinuria, however, complement inhibition by one of the C5 inhibitors led to a prompt reversal of the hemolytic process (72). Given this beginning, it seems only a matter of time until most patients with complement deficiencies can be helped by compounds that will reverse the acute symptoms as well as provide long-term prevention of the often devastating diseases associated with malfunction of this important immune pathway.

Neutropenia and Neutrophil Defects

STEVEN M. HOLLAND

103

Concern about the neutrophil status of a patient is usually raised on the basis of the frequency, severity, distribution, or specific infectious agent(s) involved in one or more episodes that are, or are thought to be, infectious. The clinical presentations of patients with neutrophil disorders usually share a few common features: gingivitis, periodontal disease, and oral ulceration. Cutaneous infections with *Staphylococcus aureus* are often recurrent and can be severe. In neutrophil disorders characterized by inadequate inflammation (neutropenia, leukocyte adhesion deficiency [LAD], Chédiak-Higashi syndrome, and specific granule deficiency), infections can extend locally and subcutaneously with little reaction until marked destruction has taken place. Clinically relevant neutrophil abnormalities fall into several broad categories: neutropenia, abnormalities of neutrophil adherence and locomotion, abnormalities of neutrophil granule formation or content, and abnormalities of killing. With the widespread use of therapies which modulate the immune system either by design (e.g., steroids and monoclonal antibodies) or incidentally (e.g., cytotoxic chemotherapy), the most common causes of immunodeficiency are iatrogenic. The recognition, characterization, identification, and cloning of disease-related genes and, in some cases, genetic correction of immune defects are moving rapidly. As specific and genetic treatments become available, making the correct diagnosis early takes on greater therapeutic importance (reviewed in reference 6).

The clinical history should include type, location, microbiology, severity, and frequency of infections; family history with specific questioning as to consanguinity; and physical examination of the oral mucosa and any lesions or scars. Complete peripheral blood count with differential and examination of the peripheral smear are necessary initial studies to determine whether the patient has a quantitative, qualitative, or combined abnormality of neutrophils.

NEUTROPENIA

The normal neutrophil count in peripheral blood is about 4,000/mm³, with a large variation among racial and ethnic groups, especially certain West Indian and African blacks and Yemeni Jews, who may have much lower neutrophil counts. Neutropenia is determined by the presence of fewer than 1,500 neutrophils/mm³. Increased risk of infections does not occur until the absolute neutrophil count (the sum of mature and band form neutrophils) falls below 1,000/mm³; risk of serious infections occurs below 500 neutrophils/mm³. Since about 90% of the body's neutrophils are kept in reserve in the bone marrow, neutropenias with impaired marrow stores are associated with greater infection risk than neutropenias with normal marrow stores. Thus, acute neutropenias associated with lack of marrow reserves, such as those induced by cancer chemotherapy, are usually associated with greater infectious complications than chronic neutropenias.

There are three basic mechanisms by which neutropenia can occur: decreased neutrophil production, increased neutrophil destruction, or abnormal neutrophil trafficking (either defective release of neutrophils from the bone marrow or an abnormal increase in the marginated or tissue pools). Recently, an autosomal dominant disorder with mild neutropenia due to neutrophil retention in the bone marrow (myelokathexis) has been molecularly characterized. The syndrome of warts, hypogammaglobulinemia, infections, and myelokathexis (WHIM) is due to mutations in the chemokine receptor CXCR4 which lead to retention of mature neutrophils on their marrow-expressed ligand stromal cell-derived factor 1 (SDF1; CXCL12). Major causes of intrinsic, acquired, and apparent neutropenia are listed in Table 1. An acquired cause of neutrophil destruction is antineutrophil antibodies. These antibodies can be detected in the clinical laboratory by either immunofluorescence or agglutination, procedures which are readily available in most laboratories.

Methods of neutrophil preparation and isolation are reviewed in chapter 31 of this volume.

Antineutrophil Antibodies

Principle

Antineutrophil antibodies may cause neutrophils to be more susceptible to complement-mediated lysis, enhance neutrophil sequestration via Fc receptors on tissue macrophages, or affect the maturation and development of myeloid precursors. Detection of these antibodies in a flow cytometer relies upon demonstration of specific binding of patient immunoglobulin G (IgG) and IgM to neutrophils (2, 3, 9). Many of these antibodies are directed against FcγRIII (CD16). Techniques which are not dependent on flow cytometry are more difficult to interpret.

TABLE 1 Causes of neutropenia[a]

Disease	Clinical features	Mechanism	Diagnosis	Treatment
Intrinsic				
Severe chronic neutropenia (Kostmann syndrome)	Neutropenia (<200 PMN/mm^3) at birth; recurrent, severe infections, autosomal dominant and recessive	Mutations in neutrophil elastase (CLA2) and GFI1	Bone marrow aspiration shows maturation defect at promyelocyte/myelocyte stage	G-CSF
Myelokathexis	Neutropenia; hypogammaglobulinemia, warts; familial cases reported	Mutations in CXCR4	Bone marrow aspiration, no evidence of peripheral destruction, abnormal marrow release on steroid challenge	G-CSF
Shwachman-Diamond syndrome	Moderate to severe neutropenia, anemia, growth retardation, exocrine pancreatic insufficiency, bone abnormalities; some patients may develop aplastic anemia or malignancy	Mutations in SDBS	Demonstration of fatty infiltration of the pancreas	G-CSF
Cyclic neutropenia (cyclic hematopoiesis)	Severe neutropenia ca. every 21 days for about 4–5 days; fever, cutaneous, oral infections; autosomal dominant, spontaneous, and acquired forms	Mutations in neutrophil elastase (ELA2)	Serial blood counts (6 wk) at least every 3 days; mutation detection	G-CSF
Benign chronic neutropenia	Infantile severe neutropenia (<200 PMN/mm^3) without serious infections; can last for years	Unknown	Bone marrow aspiration shows normal morphology and development of myeloid series	None
Chédiak-Higashi syndrome	Mild to moderate neutropenia, partial oculocutaneous albinism, recurrent cutaneous, pulmonary infections; fatal lymphoproliferative syndrome in some cases; autosomal recessive	Mutations in LYST	Demonstration of giant primary granules in peripheral blood neutrophils and in other lysosome-containing cells	Supportive; bone marrow transplantation
Reticular dysgenesis	Neonatal neutropenia, hypogammaglobulinemia, thymic abnormalities, lymphopenia; usually fatal	Unknown	Absent myeloid development in bone marrow; other lines may be normal	Supportive
Acquired				
Cytotoxic chemotherapy	Severity of neutropenia depends on dose and specific agent, commonly profound; neutropenia onset variable after treatment; fevers, oral ulcers, bacteremia (e.g., cyclophosphamide)	Reduction of dividing cells	Clinical history	Supportive; G- or GM-CSF in some cases
Drug induced				
Immune	Requires sensitization of neutrophils to antibody (e.g., β-lactams); antibodies may cross placenta	Peripheral destruction of neutrophils	Demonstration of antineutrophil antibodies	Discontinuation of drug, supportive, G-CSF in some cases
Nonimmune	Dose-related or idiopathic reaction to drug, may cause profound neutropenia (e.g., chloramphenicol or clozapine)	Suppression of bone marrow precursors	Clinical history	Supportive; G-CSF in some cases

TABLE 1 (*Continued*)

Disease	Clinical features	Mechanism	Diagnosis	Treatment
Isoimmune	Neonatal neutropenia due to maternal alloimmunization; lasts for several weeks; may be moderate to severe; predominantly cutaneous infections	Antibody-mediated peripheral destruction of neutrophils; against FcγRIII (CD16) epitopes	Clinical history, demonstration of antineutrophil antibodies	Supportive; G-CSF in some cases
Autoimmune	Antibody-mediated neutropenia during collagen vascular diseases (e.g., rheumatoid arthritis with splenomegaly, Felty syndrome; systemic lupus erythematosus)	Sequestration, peripheral destruction of neutrophils	Clinical history, demonstration of antineutrophil antibodies	Treatment of underlying disease; splenectomy in Felty syndrome; steroids in some cases; G-CSF in some cases
Splenomegaly	Mild to moderate neutropenia with moderate to massive splenomegaly due to mechanical (e.g., portal hypertension), infectious (e.g., chronic malaria), or neoplastic causes; often accompanied by anemia and thrombocytopenia	Sequestration with or without destruction of neutrophils	Clinical history and exam, normal bone marrow examination	Treatment of underlying disease; no specific therapy usually required
LGL induced	Moderate to severe acquired cyclic neutropenia; onset usually in adulthood	Clonal proliferation of T cells; probably acts on stem cells	LGL, serial blood sampling, demonstration of LGL proliferation	Treatment of underlying disease; supportive; G-CSF, steroids, or immunosuppression in some cases
Nutritional deficiency	Mild to severe neutropenia associated with vitamin B_{12}, folate, or copper deficiency; protein-energy malnutrition (marasmus)	Ineffective myelopoiesis	Clinical history, determination of specific nutrient levels	Treatment of underlying disease; supportive
AIDS	Moderate to severe neutropenia in AIDS; pyomyositis and aspergillosis seen	HIV related; treatment related (e.g., zidovudine and ganciclovir)	Demonstration of HIV infection; drug history	Discontinuation of drug if possible; G-CSF
Apparent				
Severe infections	Mild neutropenia seen early in severe infections; resolves relatively rapidly	Increase in marginated tissue neutrophil pools	Demonstration of acute infection (e.g., gram-negative sepsis)	Treatment of underlying infection
Hemodialysis	Mild to moderate neutropenia seen during hemodialysis; resolves off dialyzer	C5a-induced stiffening of neutrophils leads to transient trapping in lung	Clinical history, no evidence of acute infection	None

[a]G-CSF, granulocyte colony-stimulating factor; GM-CSF, granulocyte-macrophage colony-stimulating factor; HIV, human immunodeficiency virus; LGL, large granular lymphocyte; LYST, lysosomal transporter; PMN, polymorphonuclear leukocytes.

Specimen Collection

Patient serum, stored at −70°C, 1 ml

Pooled normal sera from several donors, stored at −70°C, 200-µl aliquots

Isolated neutrophils from three healthy donors, prepared as described above (≥10^7 neutrophils per serum sample to be assayed)

Reagents and Equipment

Phosphate-buffered saline, pH 7.2 (PBS), 1×

Bovine serum albumin (BSA), 0.22% (1 ml of 22% BSA plus 99 ml of PBS; make fresh; stable for 1 week at 4°C)

Paraformaldehyde, 4% stock solution (2 g of paraformaldehyde in 45 ml of 0.85% normal saline; warm to 70°C with dropwise addition of 1 N NaOH solution, adjust final pH to 7.2 with dropwise addition of 1 N HCl, bring volume to 50 ml, and store in the dark at 4°C) and 1% working solution (1 volume of 4% stock solution in 3 volumes of PBS; can be stored for 1 week at 4°C)

Fluorescein isothiocyanate-conjugated goat anti-human IgG and IgM, diluted 1:10 with PBS

Microcentrifuge

Flow cytometer

Procedure

1. Label triplicate pairs of microcentrifuge tubes for each serum sample to be assayed (i.e., assays for antineutrophil IgG and IgM with each of three normal donor neutrophil preparations).

2. Dilute the patient and control sera 1:1 with PBS.

3. Resuspend the healthy-donor neutrophils in PBS and sediment at $300 \times g$ for 7 min.

4. Remove and discard the supernatants and resuspend in 2 ml of 1% paraformaldehyde; allow this to stand for 5 min at room temperature.

5. Resuspend in 20 ml of PBS and sediment at $300 \times g$ for 7 min.

6. Resuspend treated cells in PBS to 3×10^7 neutrophils/ml.

7. Transfer 50 µl of each diluted serum sample to the appropriate microcentrifuge tube.

8. Add 50 µl of the neutrophil suspension to the appropriate microcentrifuge tube and incubate at 4°C for 30 min.

9. Wash twice with ice-cold 0.22% BSA, sedimenting the cells for 10 s in a microcentrifuge.

10. Remove and discard the supernatants, add 50 µl of the diluted conjugated anti-human IgG or IgM to the appropriate tube, and incubate at 4°C for 30 min.

11. Wash once with ice-cold 0.22% BSA, sedimenting the cells for 10 s in a microcentrifuge.

12. Remove and discard the supernatants; resuspend the pellets in 1 ml of PBS and transfer to tubes appropriate for analysis in the flow cytometer (usually 12 by 75 mm).

Interpretation

Patient sera are examined for a distinct shift in the peak fluorescence relative to that of the control samples run the same day. Modest and great shifts of fluorescence should be noted through both the histograms and the determinations of channel fluorescence. Increased binding of IgG or IgM over the normal control sera is considered abnormal and is reported. The report should be descriptive, including the antibody subclass implicated and the number of normal donors (out of the day's controls) to which it bound.

NEUTROPHIL DYSFUNCTION

The determination of a qualitative defect of neutrophil function is more complex than the simple determination of neutropenia, since it requires the demonstration of a dysfunctional phenotype. Methods for diagnosis of these abnormalities range from inspection of the peripheral blood smear to fluorescence-activated cell sorting (FACS). Some of these diseases simultaneously affect several limbs of neutrophil function, making prior determination of the single best diagnostic test in a given case important. The clinical history, peripheral blood neutrophil count, and inspection of the peripheral smear readily indicate the direction of further evaluation of a possible neutrophil functional abnormality.

The major classes of neutrophil defects highlight the major neutrophil functions: adhesion, chemotaxis, phagocytosis, degranulation, and killing (Table 2). General features which suggest clinically relevant neutrophil disorders include recurrent, severe infections, often requiring intravenous antibiotics, hospitalization, or surgery. Cutaneous and oral infections are common. The microbiology of specific infectious episodes may be quite informative: infections with *Burkholderia (Pseudomonas) cepacia*, *Serratia marcescens*, *Chromobacterium violaceum*, *Nocardia* species, *Aspergillus* species, or *Paecilomyces* species, or hepatic abscesses with *S. aureus*, suggest the diagnosis of chronic granulomatous disease (CGD) (8). Since patients with CGD are most susceptible to infections with catalase-producing organisms, severe infections with organisms which do not produce catalase (e.g., streptococci) would suggest abnormalities outside the superoxide-generating pathway.

Adhesion Disorders

The normal neutrophil exits the bone marrow and remains in the circulation for about 7 h before entering the tissue, the intestinal lumen, or the oral cavity. During its time in the peripheral circulation it is frequently "rolling" along and sampling the endothelium for evidence of infection or tissue damage. The low-affinity rolling of the neutrophil along the postcapillary endothelium is mediated by interacting glycoproteins on the endothelial surface (endothelial [E]-selectin and platelet [P]-selectin) and the neutrophil surface (sialyl-Lewis^x, CD15s). When the neutrophil encounters endothelium activated by chemokines or other stimuli, it adheres to specific molecules (intercellular adhesion molecules [ICAM] 1 and 2) by way of the heterodimeric leukocyte integrins (leukocyte functional antigen 1 [LFA-1] and Mac-1 or complement receptor 3 [CR3]) which contain CD18 as their common β chain. Disorders in both of these critical pathways have been described as LAD. LAD type 1 (LAD1) is due to loss of leukocyte integrin function secondary to CD18 deficiency (6); LAD2 is due to loss of neutrophil selectin binding due to loss of CD15s (3). Both diseases lead to profound impairment of the ability of neutrophils to exit the circulation to sites of infection. One of the CD18-containing molecules (CD18/CD11b, Mac-1, or CR3) also serves as the receptor for the cleaved, inactivated third component of complement (C3bi). Therefore, the absence of CD18-containing leukocyte integrins leads to the inability of neutrophils to perform complement-mediated phagocytosis as well. The cellular signal from CD18 ligation leads to adherence and movement toward the ligand. Rac2 is the G protein that tethers CD18 to cytoskeletal actin. In Rac2 deficiency, CD18 expression is intact, but adherence is reduced and the clinical presentation is like that of LAD1.

TABLE 2 Neutrophil defects[a]

Disease	Clinical features	Mechanism	Diagnosis	Treatment
Adhesion disorders				
LAD1	Neutrophilia (>15,000 PMN/mm³), delayed umbilical stump separation; recurrent, severe infections; autosomal recessive	Defective leukocyte integrin expression; neutrophils unable to exit circulation to sites of infection	FACS analysis for CD18 and the integrins it constitutes: LFA-1 (CD18/CD11a), Mac-1/CR3 (CD18/CD11b), and p150,95 (CD18/CD11c); abnormal complement-mediated phagocytosis; impaired chemotaxis	Supportive; bone marrow transplantation where possible
LAD2	Neutrophilia, short stature, abnormal facies, mental retardation, recurrent infections; autosomal recessive	Defective neutrophil selectin ligand (CD15s)	FACS analysis for sialyl-Lewis^x (CD15s) on neutrophils	Supportive
Rac2 deficiency	Neutrophilia, recurrent infections	Rac2 defect	Defective adhesion; defective chemotaxis; absence of Rac2 on immunoblot	Supportive; bone marrow transplantation probably indicated
Granule disorders				
Chédiak-Higashi syndrome	Mild to moderate neutropenia, partial oculocutaneous albinism, recurrent cutaneous or pulmonary infections, fatal lymphoproliferative syndrome in some cases; autosomal recessive	LYST defect	Demonstration of giant primary granules in peripheral blood neutrophils and in other lysosome-containing cells; delayed staphylococcal killing	Supportive; bone marrow transplantation
Specific granule deficiency	Recurrent infections, poor inflammatory response; rare; autosomal recessive	C/EBPε mutation; absence of neutrophil secondary granules and defensins	Absent secondary granules; bi- and trilobed neutrophil nuclei; absence of neutrophil lactoferrin defensins; impaired chemotaxis	Supportive; bone marrow transplantation probably indicated
Chemotactic disorders				
Actin dysfunction	Recurrent infections, poor inflammatory response; rare; autosomal recessive	Defective actin polymerization	Impaired chemotaxis and staphylococcal killing; absence of 47-kDa protein	Supportive; bone marrow transplantation
Oxidative metabolism disorders				
MPO deficiency	No clinical phenotype except in diabetics, in whom severe *Candida* infections occur; most common neutrophil abnormality; autosomal recessive	Abnormalities in MPO gene	Absence of peroxidase staining of peripheral blood neutrophils; impaired candidacidal activity	No treatment needed in most cases
CGD	Recurrent life-threatening infections with catalase-positive organisms; tissue granuloma formation; X-linked and autosomal recessive forms	Defective superoxide formation	Impaired superoxide production: abnormal NBT test, chemiluminescence, DHR oxidation, or cytochrome *c* reduction; impaired staphylococcal killing	Supportive; antibiotic and gamma interferon prophylaxis indicated; bone marrow transplantation possibly indicated

[a]PMN, polymorphonuclear leukocytes; LYST, lysosomal transport.

Diagnosis of LAD1 should be made by FACS staining for CD18 and its associated alpha chains, CD11a, CD11b, and CD11c. The functional assays below can help to suggest the diagnosis. LAD2 is rarer and clinically distinct; it can be definitively diagnosed by FACS staining for sialyl-Lewis[x] (CD15s). The diagnosis of Rac2 deficiency requires specialized research laboratory resources.

Neutrophil Adherence to Nylon Wool

Principle
Normal neutrophils adhere to several synthetic surfaces, including glass, plastic, and nylon wool, in addition to the endothelium. This adherence is impaired in LAD1 and by aspirin, ethanol, and prednisone.

Specimen collection
Heparinized blood is used, 5 ml each from the patient and three healthy subjects.

Reagents and equipment
Analytical balance

Apparatus for counting leukocytes and performing differential counts

Scrubbed nylon fiber (3 denier, 4 cm, type 200; Fenwal Labs, Morton Grove, Ill.)

Tuberculin syringes, 1 ml, without needle (three per sample)

Small collecting tubes (polypropylene preferred)

Procedure
1. Weigh out 40 mg of nylon wool/column to be used.
2. Using the plunger, pack each column with the 40 mg of nylon wool to the 0.4-ml mark on the syringe.
3. Aliquot and reserve 1 ml of blood from each sample for total leukocyte and differential counts ("precolumn" sample).
4. Place the packed syringes in a rack with their tips inside but not touching the sides or bottom of the small tubes.
5. Add 1.0 ml of heparinized blood to the column and allow it to filter by gravity for 10 min at room temperature.
6. Discard the columns.
7. Perform complete and differential leukocyte counts of the pre- and postcolumn samples.

Interpretation
The percent neutrophils adherent to the nylon wool is calculated as follows: 100% − ([cells per milliliter postcolumn/cells per milliliter precolumn] × 100) = percent cells adherent. Normally, 68% ± 7% neutrophils adhere in this assay. Adherence of a significantly lower percentage of neutrophils is suggestive of an adherence defect. Neutrophil adherence to plastic or glass requires more specialized techniques and is described elsewhere (5).

Flow Cytometric Determination of LAD
FACS analysis (chapter 31) of peripheral blood or isolated neutrophils is required for definitive diagnosis of LAD1 or LAD2. In LAD1, levels of CD18 are profoundly reduced on neutrophils and monocytes, leading to low levels of the associated molecules CD11a, CD11b, and CD11c (method given in chapter 31). Levels of CD18 expression below 0.5% of normal are seen in the "severe" phenotype and are associated with more devastating disease and earlier mortality in the absence of bone marrow transplantation. Levels of CD18 expression between 0.5 and 10% of normal are

associated with the "moderate" phenotype of LAD1 and are associated with a better rate of survival. The display of CD18/CD11 complexes, which are stored in secondary granules, is upregulated by neutrophil activation.

Demonstration of sialyl-Lewis[x] (CD15s) deficiency on neutrophils confirms the diagnosis of LAD2. These patients also have the relatively rare Bombay (Hh) blood type, another manifestation of the underlying genetic defect in fucosylation caused by mutations in the GDP-fucosyl transferase. This disease is also now named congenital disorder of glycosylation II c. Rac2 deficiency should be suspected in cases in which surface display of CD18 and CD15s is normal but adherence is impaired, as is superoxide production (7).

Granule Disorders
In the normal course of neutrophil ontogeny, the large (about 0.8 μm in diameter) azurophilic or primary granules, containing myeloperoxidase (MPO), lysozyme, β-glucuronidase, and defensins, among others, appear at the promyelocyte stage; the smaller (about 0.5 μm in diameter) specific or secondary granules, containing lactoferrin, vitamin B_{12}-binding protein, cytochrome b_{558}, and CR3, among others, appear during the myelocyte stage.

In Chédiak-Higashi syndrome, neutrophil primary granulogenesis is initially normal, but the primary granules readily fuse to each other and subsequently to some secondary granules as well, resulting in giant primary granules that are easily appreciated under the light microscope. Chédiak-Higashi syndrome is due to autosomal recessive mutations in the gene lysosomal transporter (*LYST* or *CHS1*). Neutrophils from Chédiak-Higashi syndrome patients show delayed bactericidal activity against *S. aureus*. Other clinical features include partial oculocutaneous albinism, irregular melanization of hair, peripheral neuropathy later in life, and an eventual lymphoma-like "accelerated phase" in most patients.

In specific granule deficiency, the secondary granules are rare or absent, as are secondary granule proteins, such as lactoferrin. One form of secondary (specific) granule deficiency is due to an autosomal recessive mutation in the CCAAT/enhancer binding protein C/EBPε. Since lactoferrin is present in other secretions, it appears to be a tissue-specific phenomenon. Defensins, a primary granule product, are also low to absent, because the defect is in a transcription factor important in neutrophil ontogeny and granule protein expression. Careful inspection of the peripheral smear suggests the diagnosis, as these neutrophils are larger and paler than normal. The diagnosis is confirmed by electron microscopy, showing an absence of secondary granules, or demonstration of the absence of lactoferrin in patient neutrophils by direct immunofluorescence or enzyme-linked immunosorbent assay. Methods for the detection of lactoferrin and other secondary and primary granule proteins are detailed elsewhere (4).

Chemotaxis
The neutrophil's ability to locomote up a chemoattractant gradient is chemotaxis, whereas the stimulation of shape change and random locomotion induced by a uniform concentration of a chemoattractant is chemokinesis. These properties are critical for the neutrophil response to infection. Disorders involving chemotaxis are found in only a few diseases; secondary causes of depressed chemotaxis are more common (e.g., aspirin, prednisone, and ethanol). Actin dysfunction, Chédiak-Higashi syndrome, LAD1, Rac2 deficiency,

secondary granule deficiency, and Job's syndrome (intermittently) all show decreased chemotaxis, although the mechanisms are quite disparate. In none of these disorders is the demonstration of a chemotactic defect diagnostic. The several assays of chemotaxis all require fresh neutrophils and an experienced laboratory. The sensitive techniques (Boyden chamber migration or the multiwell chamber) require highly specialized equipment, radioactivity, or both (4). In view of the complexity of the current chemotactic assays and their extremely limited diagnostic value, I recommend that for cases in which chemotactic determination appears to be appropriate, specialty reference or research laboratories be contacted. Chemotaxis assays are discussed in reference 5.

Oxidative Metabolism Disorders

The neutrophil, eosinophil, and macrophage use the NADPH oxidase enzyme complex to augment molecular oxygen by one electron yielding superoxide (O_2^-). This in turn is converted to hydrogen peroxide (H_2O_2) by superoxide dismutase. H_2O_2 is combined with halide (X^-) by MPO to produce hypohalous acid (HOX); in the neutrophil, which uses chloride for its halide, this is bleach (HOCl). Defects in the proximal portion of this pathway, at the level of the NADPH oxidase, lead to life-threatening infections in CGD; defects in the latter portion of the pathway caused by MPO deficiency are clinically quite inapparent and lead to infectious problems only when coupled to other diseases, such as diabetes mellitus.

CGD is a genetic disorder estimated to occur in about 1/250,000 persons and is characterized by severe, recurrent life-threatening infections with catalase-producing bacteria and fungi and tissue granuloma formation (8). Four separate genotypes (one X-linked, gp91^{phox}; three autosomal recessive, p22^{phox}, p47^{phox}, and p67^{phox}) can give rise to the phenotype of CGD, but there are slight differences in clinical phenotype and obvious differences in genetic transmission and associated counseling. Since all of the relevant genes have been cloned and characterized, a definitive molecular diagnosis can be made. Molecular diagnoses can be performed by reference and commercial laboratories. All patients with CGD should be referred for definitive characterization of their CGD, at least to the protein level.

Several methods are available for diagnosis of CGD. Nitroblue tetrazolium (NBT) reduction and dihydrorhodamine (DHR) oxidation are the simplest tests available and are discussed here. Chemiluminescence and staphylococcal killing are also discussed since they not only are used in the demonstration of CGD functional defects but also occasionally may help in diagnosis. Superoxide production, hydrogen peroxide production, and cytochrome *c* reduction are other techniques which bear on the integrity of oxidative metabolism covered elsewhere in this text (chapter 31).

NBT Test

Principle
Superoxide produced by neutrophils reduces NBT from a soluble yellow dye to blue-black formazan, which is readily apparent as a cytoplasmic precipitate. Neutrophils unable to produce superoxide fail to reduce NBT and are therefore free of precipitate. Because this assay is read by light microscopy, individual cells reducing or not reducing NBT can be recognized. Mothers of patients with X-linked CGD show mosaicism of peripheral blood neutrophil NBT reduction since X chromosome inactivation (lyonization) occurs randomly in hematopoietic precursors.

Interpretation
More than 95% of normal neutrophils will reduce NBT, showing orange nuclei with clumps of blue-black precipitate in the cytoplasm. In a patient with CGD, there is usually no NBT reduction. Since X chromosome inactivation is thought to be random in females, there should be two populations of neutrophils in the peripheral blood of X-linked carriers, NBT reducing (normal) and non-NBT reducing (CGD). This mosaic pattern can range anywhere from 0.001 to 97% of neutrophils, although most carriers will fall within about 20 to 80% NBT reducing. At the extremes of lyonization, these X-linked carriers are indistinguishable from CGD patients or healthy subjects, respectively. It is best to report the results as percent NBT-reducing neutrophils to avoid the confusion surrounding the terms positive and negative in this setting. The drug D-penicillamine can act as a superoxide-generating source when oxidized and therefore can cause unreliable NBT results.

The X-linked form of CGD is the most common (about 65% of cases). One can often rapidly determine whether a male patient is X-linked or autosomal recessive by analysis of the mother's blood at the time of the initial NBT test. In this way genotype can be approximated at the same time as phenotype in most cases.

There are several reports of patients with variant forms of X-linked CGD in whom a dysfunctional gp91^{phox} protein is normally expressed. These patients may have apparently normal NBT reduction. In cases in which the clinical suspicion is high, testing by DHR oxidation, quantitative superoxide generation, or bactericidal activity should be pursued.

DHR Oxidation

Principle
DHR 123 is oxidized to rhodamine 123 by H_2O_2 and O_2^-, with the emission of bright fluorescence upon stimulation by blue light (488 nm). This dye is freely able to permeate cells and can be used in whole blood to determine whether granulocytes produce H_2O_2 and O_2^-, upon stimulation with phorbol myristate acetate (PMA), a potent stimulus of NADPH oxidase activity.

This technique is simple, sensitive, and quantitative and can be performed on whole blood shipped overnight. PMA-stimulated and unstimulated samples are run simultaneously (1).

Specimen Collection
Collect 1 ml of heparin-anticoagulated peripheral blood in plastic, endotoxin-free tubes.

Reagents and Equipment

Lysis buffer (store at room temperature)

Ammonium chloride . . . . 4.15 g
Sodium bicarbonate . . . . 0.84 g
0.5 M EDTA, pH 8.0 . . . . 1 ml
Distilled water . . . . 500 ml

Suspension buffer (store at room temperature)

Hanks' balanced salt solution (HBSS)
   (without Ca^{2+}, Mg^{2+}, or phenol red) . . . . 500 ml
Albumin (human fraction V) . . . . 0.5 g
0.5 M EDTA, pH 8.0 . . . . 1 ml

Catalase stock solution (1,400 U/μl)

Catalase (C40; Sigma) . . . . 28 mg
Suspension buffer . . . . 400 μl

Store 10-μl aliquots at −70°C.

Catalase working solution: Dilute 10 μl of stock with 130 μl of suspension buffer immediately before use. Use 5 μl for each 500-μl tube (final concentration, 1,000 U/ml).
PMA stock (2 μg/μl)

PMA (P8139; Sigma) . . . . 1 mg
Dimethyl sulfoxide (DMSO) (D2650; Sigma) . . . 500 μl

Store 10-μl aliquots at −70°C.
PMA working solution (1:1000 dilution): 2 μl of PMA stock solution combined in 1,998 μl of suspension buffer immediately before use. Add 100 μl to tubes for a final concentration 400 ng/ml.
DHR stock (29 mM)

DHR 123 (catalog no. D-632; Molecular
    Probes, Eugene, Oreg.) . . . . 10 mg
DMSO . . . . 1 ml

Store 25-μl aliquots at −70°C. Add 1.8 μl of stock to each reaction tube.

Procedure

1. Add 4 ml of prewarmed, 37°C lysis buffer to polypropylene tubes.
2. Add 100 to 300 μl of whole blood to each of two tubes for each sample to be assayed, mix by inversion, and let stand for 5 min at room temperature.
3. Centrifuge at $800 \times g$ at room temperature for 5 min to pellet leukocytes.
4. Discard supernatant and blot tubes.
5. Resuspend the leukocyte pellet in 4 ml of suspension buffer and centrifuge as described above.
6. Discard supernatant, blot tubes, and resuspend in 400 μl of suspension buffer.
7. Add 5 μl of the catalase working solution.
8. Add 1.8 μl of DHR 123 stock solution and incubate for 5 min in a 37°C shaking water bath.
9. Add 100 μl of PMA working solution to one tube and 100 μl of suspension buffer to the other (unstimulated) tube.
10. Incubate for 15 min in a 37°C shaking water bath.
11. Analyze by flow cytometry, collecting forward and side scatter as well as FL2.

Interpretation

Histograms are compared for unstimulated and PMA-stimulated tubes. In normal neutrophils, PMA-stimulated DHR oxidation yields between 50- and 200-fold more mean channel fluorescence than unstimulated DHR oxidation. CGD neutrophils usually show less than 10-fold augmentation of DHR oxidation by PMA. X-linked carriers show two distinct populations of neutrophils, those which oxidize normally in the presence of PMA and those which do not. This technique is sensitive to at least 0.01% normal cells among 99.99% CGD cells and is therefore able to identify highly lyonized carriers (1). Given the general availability of FACS machines and the ease, sensitivity, and reproducibility of this assay, this test should be widely applied for the diagnosis of CGD.

Chemiluminescence

Principle

In the normal neutrophil, stimulation of the NADPH oxidase leads to the generation of H_2O_2, which couples with hypochlorite (OCL^-) to produce singlet oxygen ($^1O_2$), water, and chloride (Cl^-). Singlet oxygen is molecular oxygen with an electron lifted to a higher orbit with inversion of spin. The return of this electron to its ground state is associated with light emission which can be measured as chemiluminescence with several different reagents (5).

Specimen Collection

Isolated neutrophils, 2×10^4/ml, are used.

Reagents and Equipment

Chemiluminometer or fluorometer with only one photomultiplier tube, or beta counter that can be shifted to only one photomultiplier tube, since the coincidence sum cannot be used.
Use the ^3H channel; background is usually 25,000 to 50,000 cpm.
Glass 20-ml scintillation vials (keep in the dark) or microtiter plates
37°C incubator with rotator
Luminol stock solution (A8511; Sigma) (275 μM in DMSO stored at room temperature in the dark; the final concentration for the assay is 1 μM) or lucigenin stock solution (M8010; Sigma) (6.88 μM in distilled water stored at room temperature in the dark; the final concentration for the assay is 25 μM)
PMA stock solution (P8139; Sigma) (200 μg/ml in DMSO, aliquot and store at −70°C)
Zymosan stock solution (Z4250)

Zymosan . . . . 500 mg
PBS . . . . 50 ml

Boil for 1 h and then cool. Centrifuge at $500 \times g$ for 10 min and discard supernatant. Resuspend pellet in 10 ml of PBS and keep at 4°C in the dark.
Opsonized zymosan: On the day of use, suspend 1 part zymosan stock in 9 parts pooled human serum. Rotate for 15 min at 37°C. Centrifuge at $500 \times g$ for 10 min and discard supernatant. Resuspend to 1.25 mg/ml in $HBSS^+$ HBSS (with Ca^{2+} and Mg^{2+}).

Procedure

1. To each vial add 400 μl of opsonized zymosan or 55 μl of PMA, 20 μl of luminol solution, and $HBSS^+$ to 4.5 ml.
2. Place scintillation vials in counter in the dark for at least 20 min before adding the cells.
3. Arrange control vials:
    HBSS plus luminol
    HBSS plus luminol plus zymosan or PMA
    HBSS plus luminol plus cells
4. Record the background chemiluminescence of the vials.
5. At 1 min intervals, add 1 ml of cells to each vial sequentially, swirling each vial for 30 s before replacing the vial in the counter.

6. Count vials sequentially for 1-min periods continuously for 1 h.

7. Plot the counts per minute versus time.

Interpretation

The normal range of chemiluminescence values is 300,000 to 600,000 cpm, with peak values between 8 and 12 min. Chemiluminescence is not entirely specific for singlet oxygen, but it is a sensitive technique for detecting abnormalities in oxidative metabolism. Very low chemiluminescence is consistent with CGD. Heterozygotes can be detected as intermediate between normal subjects and CGD patients. If performed with opsonized zymosan instead of PMA, this assay can detect abnormalities of phagocytosis, such as in LAD1, in which the receptor for C3bi (CR3 or CD18/CD11b) is deficient.

The assay given here is adaptable to laboratories without highly specialized equipment. These procedures are now routinely performed in many laboratories in microtiter plates on specialized chemiluminometers. Recently, an enhancer of chemiluminescence has been marketed (Diogenes, order no. CL-202; National Diagnostics, Atlanta, Ga.) which allows ≥100-fold amplification of the chemiluminescent signal using essentially the same protocol. For experiments using B cells, cells, or cell lines which produce small amounts of superoxide, or very low numbers of neutrophils, the Diogenes system should be considered.

MPO

MPO is the enzyme that makes pus green and catalyzes the conversion of hydrogen peroxide to bleach in the neutrophil. Deficiency of MPO is the most common neutrophil disorder, occurring in about 1/2,000 persons. Despite the important role of MPO in the neutrophil, clinical disease from MPO deficiency is quite rare and has been reported mostly for diabetics with disseminated *Candida* infections. MPO is an important marker of myeloid maturation, appearing at the promyelocyte stage of development. This procedure will stain peroxidase-containing granules in neutrophils, eosinophils, and monocytes.

Specimen Collection

Cytocentrifuged neutrophils on glass slides are preferred, but peripheral blood can be used.

Reagents and Equipment

Fixative, 10% formyl ethanol

Ethanol (absolute) . . . . 90 ml
Formaldehyde (37%) . . . . 10 ml

Stain, pH 5.8 to 6.5

Ethanol (30%) . . . . 100 ml
Benzidine hydrochloride (carcinogen) . . . . 0.3 g
Zinc sulfate · 7H$_2$O (3.6%) . . . . 1.0 ml
Sodium acetate . . . . 1.0 g
Hydrogen peroxide (30%) . . . . 70 μl
Safranin O . . . . 0.2 g

Mix reagents well in the order listed. The benzidine hydrochloride may leave a slight residue, which will not dissolve. A precipitate forms on the addition of the zinc sulfate, which will dissolve with addition of the remaining reagents. Filter and store capped at room temperature. This solution is good for 6 months.

Procedure

1. Fix the slide in formyl ethanol for 60 s.

2. Rinse slide thoroughly to remove residual formyl ethanol, since this can inactivate the benzidine hydrochloride stain.

3. Place the slide in the stain for 45 s.

4. Rinse thoroughly, and allow to air dry.

Interpretation

Neutrophils show a blue cytoplasm with discrete blue granules, monocytes stain more weakly but still display discrete granules, and eosinophils stain most intensely, often tinged brown-black or green-black. Lymphocytes, basophils, and platelets do not stain. Cells from patients with MPO deficiency do not stain.

Introduction

SARBJIT SAINI

104

In 1968, immunoglobulin E (IgE) was identified as the reagin in human serum (1). This single event initiated an explosion in research that has culminated in the detection and quantitation of a number of analytes that aid in the diagnosis and management of human allergic disease. Section M covers the important topics of the allergen, in vivo and in vitro confirmatory IgE antibody testing, mediators and markers of allergic inflammation, and application of the analytical measurements to food allergy and hypereosinophilic syndromes. While accurate detection of IgE antibody in the skin is important for confirmation, it is the clinical history that drives the diagnosis of human allergic disease. The temporal association between an allergen exposure and the occurrence of an allergic symptom leads an allergist to suspect that an individual has an allergic disorder. Only after this inference has been made should confirmatory testing for IgE antibody be performed to support the working diagnosis of allergic disease.

Chapter 105, by deVore and Slater, examines assays that are used in the quantification and standardization of allergens that are glycoproteins which elicit allergic reactions in susceptible individuals. Presently, only 19 of the hundreds of allergen extracts used clinically are standardized. Chapter 105 describes (i) characterization of an allergen extract's total protein in protein nitrogen units per milliliter by the Kjeldahl method, (ii) assignment of bioequivalent allergen units using the in vivo method of intradermal dilution for 50-mm sum of erythema, and (iii) in vitro immunoassays that assess allergen potency by direct binding or inhibition of the binding of IgE from pooled allergic sera to reference allergens. Finally, research-based assays, such as basophil histamine release and basophil surface activation marker assays by flow cytometry, are discussed within the context of allergen characterization.

Chapter 106, by Damin and Peebles, examines in vivo confirmatory assays for the detection of allergen-specific IgE antibody in patients suspected of having allergic disease. The authors provide a detailed account of the rationale, reagent requirements, and procedures for prick/puncture and intradermal skin testing. In vivo provocation procedures are then discussed with a particular focus on intranasal challenge, whole-lung antigen challenge, and methacholine and histamine challenges. Chapter 106 concludes that of the in vivo diagnostic methods available, skin testing has a high degree of sensitivity and specificity for identifying the allergen specificities that cause allergic symptoms. However, caution should be exercised that the presence of a positive skin test does not necessarily indicate that a specific allergen causes symptoms specific for a certain organ system. In some cases, provocation testing may better define whether allergen exposure or nonspecific hyperreactivity is involved in the observed allergic symptoms.

Chapter 107, by Hamilton, examines the diagnostic analytes that are measured in the diagnostic allergy clinical and research laboratory to aid in the diagnosis and management of human allergic disease. Clinically used and research assays for total and allergen-specific IgE and allergen-specific IgG antibody measurements are discussed in detail. Presently, no molecular biology methods are used clinically, except for the generation of recombinant allergenic molecules that are used as reagents in antibody assays.

Chapter 108, by Schroeder and Saini, overviews mediators and markers of inflammation that are associated with immediate-type hypersensitivity reactions. More specifically, the chapter examines the design, performance, and interpretation of immunologic or flow cytometry-based assays for the measurement of mediators (histamine and leukotriene C_4), basophil cytokine secretion (interleukins 4 and 13), and basophil activation-linked surface markers (CD63, CD69, and CD203c). The performance, utility, and quality control of assays for the quantification of mast cell tryptase, eosinophil major basic protein, and eosinophil cationic protein are overviewed. Newer specimens and analytes are discussed, including the exhale condensates and nitric oxide measurements for assessing inflammation during allergic reactions.

Immediate-type hypersensitivity reactions to foods affect about 6% of children younger than 3 years. Chapter 109, by Fleischer and Wood, discusses diagnostic tests that are useful in the workup of food allergy. The diagnostic sensitivity and specificity are examined for prick/puncture and intradermal skin tests with commercially available extracts and fresh foods, atopic patch testing, elimination diets, oral food challenges, and in vitro assays for food allergen-specific IgE antibody. Since the last edition of this manual, the kilo-international unit-per-liter levels of chicken egg-, cow's milk-, soy-, wheat-, and peanut-specific IgE antibodies in serum as measured by third-generation assays have reached general acceptance as a useful predictor of the likelihood of a reaction following consumption of one of these foods.

Finally, the authors discuss the literature that indicates the lack of diagnostic utility of food-specific IgG antibodies, total serum IgE levels, basophil histamine release, and serum tryptase concentrations.

Once parasitic infections, neoplasms, drug hypersensitivity reactions, and immunodysregulatory disorders associated with secondary eosinophilia have been excluded, subtyping of hypereosinophilic syndromes can be facilitated by laboratory analyses. In chapter 110, Klion overviews the clinical features, pathogenesis, and variants of hypereosinophilic syndromes. Subtype identification is accomplished by detecting fusion tyrosine kinase using nested reverse transcriptase PCR or fluorescent in situ hybridization. Finally, this chapter discusses the controversies surrounding the diagnosis of hypereosinophilic syndrome.

Quantification and Standardization of Allergens

NICOLETTE C. deVORE AND JAY E. SLATER

105

Allergic reactions and allergic diseases are the most common human disorders of immune regulation. Diseases may include localized responses in the skin and various portions of the airway, or systemic responses characterized by extensive skin involvement, severe airway compromise, or cardiovascular collapse. Mechanisms include mast cell or basophil activation by the cross-linking of allergen-specific homocytotropic immunoglobulin E (IgE), cellular infiltration following mast cell or basophil mediator release, complement activation, the deposition of immune complexes in susceptible tissues, and the infiltration of activated T lymphocytes. The degree of impairment from allergic disease varies widely, with most reactions posing minor inconvenience but with rare episodes requiring intensive—and sometimes unsuccessful—interventions to prevent death.

While the treatment of allergic diseases often includes highly effective and specific pharmacotherapy, for many allergic disorders allergen avoidance and allergen immunotherapy remain the best and safest options. Specific allergen diagnosis—a prerequisite for effective avoidance or immunotherapy—may be achieved by controlled in vivo allergen challenge (skin testing or, less often, ocular or respiratory challenge) (see chapter 106, this volume) or by in vitro methods (such as radioallergosorbent testing [RAST], basophil histamine release, or lymphocyte stimulation). Specific allergen immunotherapy or desensitization is achieved by the graded administration of the identified allergens to achieve at least a temporary reduction in allergic response, either through receptor saturation, antibody depletion, the formation of blocking antibodies, or T-cell tolerance (currently the most favored hypothesis). Remarkably, the purity of the allergen being tested is not essential for diagnostic or therapeutic efficacy; in fact, purity has not been achieved for any commercially available allergen preparations. However, for each of these evaluations or treatments it is critical that the allergen used be correctly identified and that it be present in sufficient bioactive form to achieve the expected diagnostic or therapeutic performance. Thus, for the successful use of allergens in allergy diagnosis or immunotherapy, it is important that we be able to identify and measure the allergen being used.

Allergens are molecules that elicit allergic reactions in susceptible individuals. Typically, allergens are naturally occurring proteins or glycoproteins derived from plants or animals, but biomolecules derived from single-cell organisms (such as molds), synthetic compounds, metals, and small molecules may elicit significant allergic reactions as well. In this chapter, we limit our discussion to natural or recombinant proteins or glycoproteins used in the diagnosis and/or treatment of IgE-mediated allergic disease.

Allergen extracts are manufactured and sold worldwide for the diagnosis and treatment of IgE-mediated allergic disease. These are crude extracts of natural animal or plant source materials and are complex mixtures of natural biomaterials. Each extract contains proteins, carbohydrates, enzymes, and pigments, of which the allergens—presumably the active ingredients—may constitute only a small proportion (48).

All current U.S. allergenic products were licensed prior to the efficacy requirements that were established for biologics in 1972. The safety, efficacy, and labeling of these products were evaluated by a review panel in the 1970s, which considered all of the products available at that time and made separate recommendations for the diagnosis and therapy indications of these products (7a). Although some allergenic products were removed from the market following the panel's deliberations, most were deemed presumptively safe and effective for therapy and/or diagnosis.

Traditionally, allergen extracts have been labeled either with a designation of extraction ratio (weight per volume) or with a protein unit designation which is determined by the Kjeldahl method (protein nitrogen units per milliliter). However, there is little correlation between these two designations and biological measures of allergen potency (2, 3). In the absence of a concerted effort to maintain product consistency, lot-to-lot variations in allergen content may be considerable. Product consistency may be enhanced by the inherent nature of the raw materials; for example, pollen and pure mite extracts (34) generally have greater lot-to-lot consistency than mold, house dust, and insect extracts (28). In addition, manufacturers can increase the consistency of their products by controlled collection, storage, and processing of the raw materials; by reproducible and optimized extraction and manufacturing techniques; and by expiration dates based on real-time stability data. However, consistency can be ensured only by measuring the potency of each lot of extract and by marketing only those lots whose potency falls within an acceptable range. When such additional tests and specifications are applied to similar products from more than one manufacturer, those products are said to be standardized.

The Food and Drug Administration (FDA) allergen standardization regulation [21 CFR 680.3(e)] mandates

that when an appropriate potency test exists, manufacturers must test each lot of an allergen extract for potency prior to distribution. In practice, the FDA has provided manufacturers with a U.S. reference standard to which each new lot of allergen extract may be compared. The purpose of allergen standardization is to ensure that the extracts are well characterized in terms of allergen content and that variation between lots is minimized even among different manufacturers (49). Since standardized allergenic extracts are compared to a single, national potency standard, patients and their physicians can switch from one manufacturer's product to another with minimized risk of adverse reaction.

Currently, there are 19 standardized allergen extracts available from manufacturers in the United States (Table 1). For each of these products, there is a U.S. standard of potency to which each lot is compared prior to release for sale to the public. The potency measures and the assays used to determine these measures are specified in the approved product license applications of each manufacturer for each product.

OVERVIEW OF IN VIVO ASSESSMENTS OF ALLERGEN POTENCY

Allergen standardization in the United States comprises two important components: the selection of a reference preparation

TABLE 1 Allergenic extracts currently standardized in the United States

Allergen extract	Current lot release tests	Labeled unitage	Current standard (date placed in service)	Method(s) to establish equivalence to previous standard
Dust mites				
Dermatophagoides farinae	Competition ELISA, protein	AU/ml (equivalent to BAU/ml)	E8-Df (2000)	Competition ELISA
Dermatophagoides pteronyssinus	Competition ELISA, protein		E7-Dp (1999)	Competition ELISA
Cat (*Felis domesticus*)				
Pelt	Fel d 1 (RID), IEF, protein	BAU/ml	E3-cat pelt (1996)	RID, IEF
Hair	Fel d 1 (RID), IEF, protein	5–9.9 Fel d 1 U/ml = 5,000 BAU/ml; 10–19.9 Fel d 1 U/ml = 10,000 BAU/ml	E4-cat hair (2001); C10-cat (calibration set, 2001)	RID, IEF
Grasses				
Bermuda grass (*Cynodon dactylon*)	Competition ELISA, IEF, protein[a]	BAU/ml	E6-Ber (2004)	Competition ELISA
Red top grass (*Agrostis alba*)			E5-Rt (1999)	
June (Kentucky blue) grass (*Poa pratensis*)			E5-Jkb (1998)	
Perennial ryegrass (*Lolium perenne*)			E12-Rye (1995)	
Orchard grass (*Dactylis glomerata*)			E5-Or (1999)	
Timothy grass (*Phleum pratense*)			E8-Ti (2004)	
Meadow fescue grass (*Festuca elatior*)			E5-Mf (1999)	
Sweet vernal grass (*Anthoxanthum odoratum*)			E6-Sv (2000)	
Short ragweed (*Ambrosia artemisiifolia*)	Amb a 1 (RID)	Amb a 1 U	E15-Ras; C14-Ras (calibration set, 2004)	RID
Hymenoptera				
Yellow hornet (*Vespa* spp.)	Hyaluronidase and phospholipase activity[b]	μg of protein	V2-HB	
Wasp (*Polistes* spp.)				
Honeybee (*Apis mellifera*)				
White-faced hornet (*Vespa* spp.)				
Yellow jacket (*Vespula* spp.)				
Mixed vespid (*Vespa* + *Vespula* spp.)				

[a]The current lot release tests are the same for all grasses listed.
[b]The current lot release tests are the same for all Hymenoptera listed.

of allergenic extract and the selection of the procedures to compare manufactured products with the reference extract (37, 38, 40). In the United States, the use of a biological model of allergen standardization has permitted the assignment of bioequivalent allergen units (BAU) for most standardized allergens (38). Once a specific unitage is assigned to a reference, then all allergenic extracts from the same allergenic source can be assigned units based on the relative potency (RP) with respect to the reference, using the established quantitative in vitro potency method (41).

In theory, standardizing an allergenic extract might involve purifying each allergen in the extract and establishing with precision the importance of these allergens. However, most allergenic extracts are complex mixtures of several relevant allergens of as yet uncertain immunodominance. In addition, an individual allergen in a particular lot may be less "allergenic" due to instability or denaturation. The choice of the best potency test depends on the extract to be standardized. In the absence of data supporting the safety of potency designations based on single-allergen content, a measure of overall allergenicity may be a better predictor of safe dosing. For two allergenic extracts (short ragweed and cat hair), data have supported the use of single-allergen determinations (Amb a 1 and Fel d 1, respectively); for cat pelt and hymenopteran venoms, the presence of two allergens (Fel d 1 and albumin for cat pelt; hyaluronidase and phospholipase A2 for hymenopteran venoms) is verified for each lot; for dust mites and grass pollens, overall allergenicity is determined.

For initial overall allergenicity assessment, The Center for Biologics Evaluation and Research (CBER) has developed a method using erythema size following serial intradermal testing of highly allergic individuals. Intradermal testing was chosen over prick-puncture testing to achieve greater dosing accuracy; erythema size was chosen over wheal size to achieve greater accuracy in reaction measurements (41). This method, called $ID_{50}EAL$ (intradermal dilution for 50-mm sum of erythema determines the BAU), can be used to compare the allergenicities of extracts, regardless of source. Subsequent comparisons of extracts from the same source material are made by a variant analysis called the parallel line bioassay. Both of these methods are described in CBER's "Methods of the Allergenic Products Testing Laboratory" (1994, FDA Docket 94N-0012).

In the $ID_{50}EAL$ method, allergenic extracts are evaluated in subjects maximally reactive to the respective reference concentrates. Each subject is tested with serial threefold dilutions of the reference extract. After 15 min, the sum of the longest and midpoint orthogonal diameters of erythema (ΣE) is determined at each dilution, and the log dose producing a 50-mm ΣE response (D_{50}) is calculated (41) (Fig. 1).

Extracts that produce similar D_{50}s can be considered bioequivalent and are assigned similar units (BAU). Because the modal D_{50} of a series of extracts was 14 (a 3^{-14} or 1:4.8 million dilution), extracts with a mean D_{50} of 14 were arbitrarily assigned the value of 100,000 BAU/ml (38). Thus, the formula for the determination of potency from the D_{50} is:

$$\text{Potency} = 3^{-(14 - \text{mean } D_{50})} \times 100{,}000 \text{ BAU/ml}$$

By a similar technique and analysis, bioequivalent doses of test extracts from the same source as the reference extract can be determined by the parallel line bioassay (44). The inverse ratio of the doses of test extract required to produce identical D_{50}s to a reference extract is the RP of that extract. This analysis requires that the log dose-response curves of the test extract and the reference extract be parallel; if the two dose-response lines are not parallel, then the ratio of skin test doses for identical responses (and the RP) will vary with the dose. In this situation, which strongly suggests compositional differences between the two extracts, the distance between the two lines is different at each dose and a meaningful RP cannot be determined (36, 37) (Fig. 2).

In the original 1994 protocol, the mean D_{50} for 15 highly allergic individuals was used to determine the D_{50} for the extract. In a recent reanalysis of the statistical considerations underlying such potency studies, Rabin et al. (30) applied the following formula for the number of study subjects, n, that would be required:

$$n = 2\left(\frac{\sigma}{\delta}\right)^2 (z_{1-\alpha} + z_{1-\beta/2})^2$$

where σ is the standard deviation of the measurement, δ is the acceptable difference in D_{50}s of two equivalent products, and the z values are the critical values from the cumulative normal distribution table for a significance level α and a
FIGURE 1 Sample calculation of D_{50}. Serial threefold dilutions of test material were injected, and the ΣE responses were plotted against the negative log dilutions. The D_{50} is determined from the best-fit line by using the formula $D_{50} = (50 - \text{intercept})/\text{slope}$. The calculated D_{50} of 6.78 corresponds to a value of $3^{-(14 - 6.78)} \times 100{,}000$ BAU/ml = 35.9 BAU/ml.
FIGURE 2— Hypothetical parallel line bioassay curves. (Left) The bioassay curves are parallel, and the difference of log dilutions resulting in the same diameters is constant at all diameters. The log RP of test sample B compared to reference A is represented by the difference. (Right) The curves are not parallel, and the differences vary with the strength of the reaction. Thus, the log RP of B' compared to A cannot be calculated.

power of $1 - \beta$ (31). From this formula, n is a function of the squares of σ and δ. The value of n will depend on the particular allergen to be tested, but, for typical values of σ and δ, n will usually be larger than 15.

In Europe, the Committee for Proprietary Medicinal Products issued a Note for Guidance on Allergen Products that was revised in 1996 (http://www.emea.eu.int/pdfs/human/bwp/024396en.pdf). The European system for standardizing allergens and determining allergenic extract potency is different from the system used in the United States, as follows.

1. Manufacturers ensure batch-to-batch consistency by using an in-house standard. The in-house standard may be characterized by a number of physicochemical and immunologic assays, with demonstration of the presence of individual allergens preferred.
2. There are no external reference standards to ensure consistency among manufacturers.
3. Potency may be determined by any validated measure of in vitro IgE binding or other immunoassay. The potency of the in-house standard may also be tested by a skin test technique.
4. An in vivo method by which European products may be tested is called the Nordic technique (21). This skin test method differs from the CBER $ID_{50}EAL$ method in its use of prick skin tests, its focus on wheal size rather than erythema, its choice of study subjects, and its use of a histamine dose-response curve to determine unitage. The method very likely provides a reasonable estimate of extract potency. In theory, the comparison of the skin test reactivity of all allergens to a single standard (histamine dihydrochloride, 10 mg/ml) allows the assignment of universal unitage without the development or maintenance of specific allergen reference standards. However, the Note for Guidance does not prescribe the specifics of the skin test technique to be used, and manufacturers are free to modify it as needed as long as the test is validated. Thus, as applied in Europe, this method cannot provide a level of standardization among the different manufacturers that market products in the European Union.

$ID_{50}EAL$ Test

Study Sequence

1. Identify three or four testing sites to achieve geographic and ethnic diversity of study populations.

2. Recruit 6 to 10 subjects per tester for proficiency testing (subjects need not be atopic). In order to generate useful data, the $ID_{50}EAL$ and parallel line bioassay methods must be performed by individuals proficient in the accurate and reproducible delivery of intradermal skin test doses and the precise measurement of the skin test responses. Hence, a proficiency program has been developed to qualify personnel. This program (not described in detail here) involves puncture skin testing with histamine base (0.1 mg/ml) and intradermal testing with eight serial threefold dilutions of histamine. The tester then analyzes the data and compares the results with normative data. Thus, the proficiency program examines the tester's ability to prepare accurate dilutions, administer the skin tests with precision, and record and analyze the data properly.
3. Recruit 10 to 20 study subjects for initial allergen skin testing.
4. Skin test subjects and analyze skin test data. Analysis will include determination of σ for intradermal testing.
5. On the basis of the initial data, determine the final study size.
6. Recruit study subjects, skin test the subjects, and analyze skin test data.
7. Prepare final study report.

Selection of Subjects

Select individuals within the target age range with a history of allergic disease relevant to the allergen being tested, who have puncture sum of erythema diameter responses (ΣE) to the allergen concentrate of at least 30 mm. Exclude individuals with asthma whose peak flow is <75% of the flow predicted at the time of testing, whose skin coloring or skin condition would preclude the measurement of erythema responses, who are dermographic, or who are currently using antihistamines, tricyclic antidepressants, monoamine oxidase inhibitors, and beta-blockers.

Dilution of Allergens for Skin Testing

Starting with the undiluted or reconstituted lyophilized extract, prepare serial threefold dilutions, using sterile technique, down to a dilution of 3^{-17}. For convenience, label the dilution by the $-\log_3$ doses: undiluted extract is labeled 0, and the 3^{-17} dose is labeled 17.

Preparation of Subjects

Skin tests may be placed on the back or the glabrous skin of the volar surface of the arms, avoiding a 1-in. area above

and below the antecubital fossa and a 1-in. area above the wrist. For consistency, the back should be used for final titrations.

Injection Technique

The volume of solution to be injected is 0.05 ml. Insert the needle of a 27-gauge 0.5-ml syringe at a 30° angle, bevel down. A distinct injection bleb should be observed. Injections in which gross leakage of extract around the needle, an indistinct bleb, or a subcutaneous injection occurs should be repeated at a different site.

Measurement of Skin Tests

THIS IS A TIME-DEPENDENT ASSAY. Exactly 15 min following injection, the wheal and erythema margins are outlined with a fine, roller-tip pen with washable ink. In order to make a permanent record of the skin test reaction, transparent surgical tape is placed on the skin over the skin test outline. Lifting of the tape from the skin results in transfer of the outline to the tape. The tape is then placed in a notebook for future reference.

The size of the skin response is obtained by measuring and recording the longest diameter of erythema and the orthogonal erythema diameter measured at one-half the longest erythema diameter (Fig. 3). The sum of the longest and orthogonal erythema diameters (ΣEs) (or wheal [ΣW]) constitutes the skin response at that site. Measurements are made from the inner edge of the skin test outlines.

Skin Test Procedure

The dose-response line for each product is generated by using four serial threefold dilutions with graded erythema responses which bracket a ΣE of 50 mm and include the end point where ΣE = 0 or ΣE ~ ΣW. The skin response (ΣE) should fall within the limits of $\geq$0 to $\leq$125 mm. Each more concentrated dilution should produce a graded erythema response. The four dilutions selected should span a wide range of ΣEs (for example, from 0 to 20 mm to 80 to 125 mm) and bracket a ΣE of 50 mm.

Inject the test and reference extracts, beginning with dilution 15. The expected change in ΣE going from one dilution to the next dilution is about 20 mm. Therefore, if dilution 15 is negative, proceeding to dilution 12 would not be expected to exceed a ΣE response of 60 mm. Similarly, if dilution 12 is negative, proceed to dilution 9. Do not inject reference extract dilutions more concentrated than no. 5 unless the extract is known to be of low potency. Apply each dilution singly for each product and reference. Always include an intradermal diluent control test.
FIGURE 3 Diameters are measured from the inner margins of the penned outline. Longest (A) plus midpoint orthogonal (B) diameters and summed diameters (A + B) are recorded.

OVERVIEW OF IN VITRO ASSAYS OF ALLERGEN POTENCY

Although skin testing is an essential component of the allergen standardization program, it is not intended for routine use in the testing of manufactured lots of extracts prior to release. In vitro potency assays that accurately predict the in vivo activity of extracts have been developed (36). Once an in vivo assay has been utilized to assign unitage to a reference extract, then an appropriate surrogate in vitro assay can be used to assign units to test extracts from the same sources. These methods can be based on quantitation of the total protein content (Hymenoptera venoms), the specific allergen content within the allergenic extract (short ragweed and cat hair), or the inhibition of binding of IgE from pooled allergic sera to reference allergen (grasses and mites) (31). For the Hymenoptera venom allergens, the potency determination is also based on the content of the known principal allergens within the extract, hyaluronidase and phospholipase, which is determined by enzyme activity (Table 1).

The potency units for short ragweed extracts were originally assigned on the basis of their Amb a 1 content. Subsequent data suggested that 1 U of Amb a 1 is equivalent to 1 μg of Amb a 1, and 350 Amb a 1 U/ml is equivalent to 100,000 BAU/ml. However, the original unitage has been retained. Grass pollen extracts are labeled in BAU per milliliter, based on $ID_{50}EAL$ testing. In some cases, the assignment of potency units to standardized allergenic extracts in the United States has changed as better bioequivalence data have become available (41). Cat pelt extracts were originally standardized on the basis of their Fel d 1 content, with arbitrary unitage (AU per milliliter) tied to the Fel d 1 determinations. Subsequent $ID_{50}EAL$ testing suggested that the 100,000-AU/ml cat pelt extracts, which contained 10 to 19.9 Fel d 1 U/ml, should be relabeled as 10,000 BAU/ml (22). In addition, 20% of individuals allergic to cat were found to have antibody to non-Fel d 1 proteins (43), and the identification of a cat albumin band on isoelectric focusing (IEF) gels was added as a requirement for cat pelt extracts. Dust mite extracts were originally standardized (in AU per milliliter) on the basis of RAST inhibition assays. Subsequent $ID_{50}EAL$ testing indicated that the arbitrary unitage was statistically bioequivalent to BAU per milliliter (22, 42); in this case, the original unitage was retained (39).

TESTS FOR INDIVIDUAL ALLERGENS

Individual allergens may be measured and detected by various approaches using monospecific antisera or antibodies. Assay designs using these antisera include the radial immunodiffusion (RID) assay, crossed immunoelectrophoresis/crossed radioimmunoelectrophoresis (CIE/CRIE), and enzyme-linked immunosorbent assay (ELISA) variants (direct, two-site, and competition). Each of the assays utilizes monospecific antisera or antibodies to detect and quantify the specified allergen. The RID assay is currently applied to two standardized allergenic extracts, short ragweed and cat hair, in which the immunodominant allergens (Amb a 1 and Fel d 1, respectively) have been identified and defined. Sheep antisera are used for the RID performed at CBER/FDA, but polyclonal and monoclonal antibodies from several species have been used with success for many of these assays. Specifications for the antibodies vary with the assay system. For example, antibodies for the RID assay must form a discrete precipitin ring, the two antibodies for the

two-site ELISA must recognize different epitopes on the allergen molecule, and, in all cases, the epitope(s) recognized must be present on the allergen and reflective of its bioactivity.

Antibodies

Monospecific antisera that recognize the allergen of interest may be purchased or, alternatively, obtained by inoculating an animal with the appropriate amounts of recombinant or purified allergen. Monoclonal antibodies or recombinant antibodies (such as scFv or Fabs) can also be generated for these assays.

Sandwich ELISA

Antibody sandwich ELISAs are two- to fivefold more sensitive than ELISAs in which the antigen is bound directly to the plate (10). The capture antibody is diluted to 0.2 to 10 µg/ml in phosphate-buffered saline (PBS) and allowed to bind to 96-well polystyrene plates overnight at 4°C. The plates are washed, blocked, and washed again. A standard antigen dilution series is prepared by serial 1:3 dilutions of the antigen in blocking buffer and typically falls in the range of 0.1 to 1,000 ng/ml. A few serial dilutions of the test antigen should also be prepared so that the concentration falls in the range of 1 to 100 ng/ml. Incubate the plates for 3 to 4 h at room temperature and then wash them. Incubate in 50 µl of specific secondary antibody-enzyme conjugate. Develop the reaction in the appropriate solution, and read the results in a plate reader (Laboratory of Immunobiochemistry—Standard Operating Procedures 7, revised November 1998). To analyze these data, construct a graph using the values obtained from the standard antigen dilution and interpolate.

RID Assay

In this assay, used by CBER and most U.S. allergen manufacturers to measure the allergen content of short ragweed and cat allergen extracts, monospecific antiserum is added to an agar solution, which is allowed to solidify. Wells are then cut into the agar, and test allergen is placed in the wells. As the specific allergen diffuses out into the agar a precipitin ring forms, which delineates the equivalence zone for antigen-antibody binding. The radius of the precipitin ring can then be measured. Since the antibody concentration in the agar is constant, the antigen concentration decreases with increasing distance from the well and is proportional to the log of the concentration of the applied test allergen in comparison to the reference extract (Laboratory of Immunobiochemistry—Standard Operating Procedures 5 and 6, revised November 1993).

1. Prepare a solution consisting of 1% Noble agar (Difco) and 1% sodium azide in water. Heat in a boiling water bath until the solution is clear. Allow the temperature to equilibrate in a 55°C water bath.

2. Once the solution has cooled to 55°C, add 0.2 ml of monospecific antiserum to 2 ml of agar solution. Mix thoroughly but gently and pour onto a microscope slide that has been precoated with 0.01% Noble agar. Allow the agar to solidify at room temperature.

3. After the agar has hardened, place the slide on a sheet of graph paper that contains a template with five evenly spaced dots, approximately 1.5 mm apart. Cut wells into the agar over each dot with a gel cutter, and carefully pipette 8 µl of allergen test solutions into each well. Incubate the slides in a sealed humidified chamber at room temperature for 72 h.

4. Fix the slides by soaking them in 10% acetic acid for 2 min and then rinsing them briefly in deionized water. The diameters of the precipitin rings can be measured to the nearest 0.1 mm with a calibrating viewer (Transidyne General Corp., Ann Arbor, Mich.).

5. After the diameters of the precipitin rings are measured, the reference standard data are graphed on a semilog scale. The average ring size of the unknown can then be used to determine the amount of allergen by interpolation.

Troubleshooting the RID Assay

Before this assay is performed on an unknown, a dose-response curve should be made to determine the antiserum concentration at which the ring diameter plateaus. If multiple RID assays are going to be compared, person-to-person variability should be established by direct comparison of an identical test profile. Likely sources of person-to-person variability may include (i) pipetting errors leading to spillover of samples applied to the wells and (ii) measurement errors with the calibrating viewer.

CIE/CRIE

In CIE, allergen extract is typically separated by electrophoresis on a 1% agarose gel, and a narrow strip of gel containing the separated antigen is then transferred to a clean glass plate. The remaining area of the plate is then filled with agarose containing polyspecific antisera against the antigen. A second electrophoresis is performed at right angles to the first one (hence the name "crossed" electrophoresis). Immune complexes form precipitin arcs that can be visualized by Coomassie blue staining (45, 46).

In CRIE, the unstained CIE preparation is incubated in the presence of appropriately diluted patient sera containing specific IgE, which is detected by overnight incubation in ^{125}I-labeled anti-IgE (20).

Enzyme Activity Assays

Hymenoptera venoms contain multiple glycoprotein enzymes, the most important of which are hyaluronidase and phospholipases A1 and A2. Venom allergenic extracts are standardized by enzymatic assays, which estimate hyaluronidase and phospholipase content on the basis of their enzymatic activity. In these assays, an agar solution is prepared with the appropriate enzymatic substrate and test samples are then added to cut wells. As the enzyme present in the sample diffuses into the agar, it digests the substrate, forming clearing zones around the wells. The radius of the clear zones is then measured and calculated as the log of the concentration of the enzyme present in the sample (Laboratory of Immunobiochemistry—Standard Operating Procedures 1 and 2, revised January 1995).

TESTS OF OVERALL POTENCY

The potency of standardized allergen extracts for which the immunodominant components have not been identified with certainty may be estimated by assays for IgE-antigen binding that compare the overall IgE binding properties of test and reference extracts, using pooled allergic sera. Initially, a RAST inhibition assay was used for this purpose; CBER adopted the competition ELISA as its standard assay because of its greater precision and convenience. After the wells of the polystyrene microtiter plate are coated with the reference allergen and the wells are blocked with bovine serum albumin, a mixture of the extract to be tested and a reference serum pool is added to the wells. The greater the amount of immunoreactive allergen in the mix, the less free

IgE antibody will be available from the serum pool to bind to the immobilized allergen on the plate. The concentration of the allergens in the extract is determined by comparison to the reference allergen extract. However, since this assay does not explicitly measure a specific allergen, the allergen concentration is expressed as RP, with the reference extract assigned an arbitrary RP of 1.0. Early studies showed an excellent correlation between RP assigned by titration skin testing and RP determined by RAST inhibition assay (38); subsequent studies showed the competition ELISA to be equivalent as well (18).

Method Summary—Inhibition Immunoassays

The inhibition immunoassays for the determination of overall allergen potency share basic design features.

1. Known allergens are bound to a solid-phase support.
2. The solid support is then exposed to serum containing IgE antibodies from an allergic individual, mixed with dilutions of unknown competing allergen.
3. IgE binds to the allergens on the solid phase, forming antigen-allergen complexes. The competing (soluble) unknown allergen reduces the binding of specific IgE to the solid-phase allergen.
4. The unbound IgE is washed away. Labeled anti-IgE is allowed to bind to the antigen-IgE complexes. After a final wash, the label remaining bound to the antigen-allergen complex is related to the quantity of the IgE antibody present in the serum of the patient.
5. The results are then plotted, and the 50% binding value determined is proportional to the potency of the extract. In addition to finding the 50% binding value, the slopes of different extracts can be compared; extracts with similar slopes have similar antigen compositions. The RP may then be determined as illustrated in Fig. 2.

RAST

RAST was first described in 1967 (47). In this assay, intended to determine the presence of specific IgE in a serum sample, allergen is bound to cyanogen bromide-activated paper disks, which are then incubated with patient serum. After unbound antibody is washed away, ^{125}I-radiolabeled anti-IgE is used to detect the bound IgE. Following the approach outlined above, the RAST inhibition assay is used to establish the overall allergen content of an unknown extract.

CAP

Pharmacia introduced the CAP system as an alternative to the paper-based RAST in 1990. Instead of paper disks, a sponge cellulose material is used to bind the allergen; the secondary antibody is an anti-human IgE–β-galactosidase conjugate; and the substrate is 4-methylumbelliferyl-β-D-galactoside, cleavage of which by the β-galactosidase generates a detectable fluorogen. The CAP system has been shown to have increased sensitivity for some allergens (hymenopteran venoms [11, 15], cat [5, 7, 15], *Dermatophagoides pteronyssinus* [5, 7, 15], and *Alternaria* [5, 7]), while other studies have not shown a significant improvement in sensitivity (24, 27). This assay can be used to measure overall allergen content in a similar way to RAST.

Overview of ELISA Inhibition, or Competition ELISA

In this assay, the one used by CBER and most U.S. allergen manufacturers to determine the RP of standardized grass pollen and dust mite allergenic extracts, serial dilutions of an extract to be tested are placed in a well that has been precoated with a known amount of reference extract. Optimal concentrations of the reference extract and the detecting antibody conjugate must be determined by checkerboard titration for each new set of reagents.

The detecting antibody is a critical component of the assay. It is essential that the antibodies used reflect the broadest range of allergens considered relevant to the overall allergenicity of the allergenic extract being tested, and the antibodies should be evaluated by Western blotting or a comparable technique. IgE is biologically relevant for allergic disease, but each batch of IgE-containing sera is likely to vary in the specificity of the IgE, and—since most atopic donors are multiallergic—may well include IgE molecules that recognize irrelevant allergens as well. Such extraneous IgE will only interfere in the assay to the degree that the coating allergen contains cognate irrelevant allergens. Human sera containing IgE antibodies should be collected from as many allergic individuals as possible, with a minimum of 6, but preferably 10 to 20 (Laboratory of Immunobiochemistry—Standard Operating Procedure 13, revised October 1998). Other polyspecific antisera can also be utilized for these assays and are discussed above.

ELISA Inhibition Procedure (Laboratory of Immunobiochemistry—Standard Operating Procedure 7, revised November 1998)

1. Coat the microplate wells with 100 μl of the reference extract per well and allow binding at 4°C overnight. Wash the plates in 0.05% Tween in PBS (PBS-T).
2. Block at room temperature for 1.5 h in blocking buffer (1% bovine serum albumin in PBS-T), and wash in PBS-T.
3. Into duplicate wells, pipette 1:3 serial dilutions of the reference extract. Into the remaining wells, pipette 1:3 serial dilutions of the test extracts in duplicate.
4. Immediately add 50 μl of the detecting antibody at the appropriate concentration.
5. Incubate the plate overnight at 4°C.
6. Wash the plate with PBS-T, develop, and read results as appropriate.
7. The results are plotted with the values of the optical density along the y axis and the log of the dilution factor along the x axis. The 50% binding value that is determined is proportional to the potency of the extract; the RP is estimated by comparing the x intercepts of the test and reference extracts. The slopes of the different extracts can also be compared; extracts with identical slopes as determined by the t test are presumed to have similar antigen compositions.

Histamine Release

Basophil histamine release is an in vitro surrogate for skin testing and, as with other assays based upon interactions between allergen and specific IgE, the release of histamine from sensitized human basophils may be used to measure the allergen content of an unknown solution. Histamine release assays have been performed on heparinized whole blood (12, 26), crude leukocyte preparations (17), purified basophils (8, 13, 35), cell lines (4, 19), and rabbit leukocytes (33). The drawbacks of this assay are that histamine release assays with whole or fractionated blood require large amounts of recently drawn blood, and specialized cell lines are not readily available. In addition, basophils from 20% or more of skin test-positive patients do not release histamine in vitro (1), even in the presence of cross-linking anti-IgE. However, the same individuals' serum IgE may still be used in histamine release experiments by passively sensitizing basophils from

other donors with the heterologous IgE (16). In all variants of this assay, released histamine may be quantified by radioimmunoassay or fluorimetry (32). Although this technique and its variants have been used to assess allergen potency (9, 14, 29), it does not appear to have any advantage over other assays that depend upon specific allergen-antibody interactions.

Flow Cytometry

In the past decade, the discovery of basophil activation markers CD63, CD45, CD69, and CD203c have led to a flow cytometric approach that assesses the in vitro activation of basophils. Most commonly, basophil activation markers CD63 and CD203c are used (6). CD63 is weakly expressed on the surface of basophils in both allergic and nonallergic patients. When FcεRI-bound IgE encounters an allergen, granules containing large quantities of CD63 fuse with the plasma membrane, resulting in a large increase in CD63 on the surface of basophils. However, CD63 is expressed not only by basophils, but also by mast cells, macrophages, and platelets (23, 25). Therefore, when CD63 is used in a flow cytometric analysis, a separate antibody that recognizes IgE must also be used. CD203c is a basophil-specific marker that is not expressed on other blood leukocytes and is upregulated in the presence of IgE cross-linking in a manner similar to that of CD63. Because CD203c is a basophil-specific marker, a second antibody is not required for specificity.

IDENTITY TESTING

The identity of an allergen extract may be verified by visualizing the separated allergen proteins on the basis of their size and isoelectric points (48). The IEF assay is an important safety test in the lot release of grass pollen and cat allergen extracts. The patterns produced by the crude allergen mixtures are reproducible enough to consistently indicate the presence of known allergens, to identify possible contaminants present in the extracts, and to check lot-to-lot variation in the extracts (50). In addition, IEF is used to verify the presence of cat albumin in cat pelt extracts.

Method Summary: Identity Testing

IEF

Polyacrylamide gels (PAGplates), wicks, applicators, cellophane preserving sheets, and the Multiphor II electrophoresis unit are available from Pharmacia-LKB. No specific buffer is required for IEF, but salt concentrations of >50 mM should be avoided as they will cause band distortions.

1. Place the polyacrylamide gel (PAGplate, pH 3.5 to 9.5) on the electrophoresis unit, using the screen print as a guide. The Multiphor II unit serves to both apply the electric current to the gel and keep the gel cool during the run.

2. Soak one electrode wick with anode buffer (1 M H_3PO_4) and one with freshly made cathode buffer (1 M NaOH). Remove excess moisture with tissue paper and place the damp electrode wicks along the length of the gel, being sure to position the strips along the appropriate ends of the gel.

3. For sample application, place dry IEF/SDS sample applicator strips on the cathode end of the gel. Apply 5 to 20 μl of the sample to the applicator. If a greater volume of sample is required, then up to five applicator strips may be stacked vertically and 20 μl of the sample can be loaded per strip. (Note that for cat pelt 0.6 to 0.8 Fel d 1 U must be used, and more may be needed for cat hair extracts.) When larger proteins are being focused, the sample applicator should be placed near, but not at, the expected pI.

4. For each sample, a reference extract and a pI marker should also be run from the cathode end of the gel. To monitor progress visually, 20 μl of a 1% solution of methyl green (MP Biomedicals) in deionized water will separate into three colored bands as the gradient is established when the sample is placed just to the left of the anode. For best results, the gel should be run for 60 to 75 min with a maximum voltage of 500 V, maximum current of 50 mA, and power of 30 W. Maintain the temperature at 8 to 10°C.

5. After the gel has been run, the gel is immediately fixed for 15 to 30 min in 7.5% sulfosalicyclic acid–12.5% trichloroacetic acid, washed with destain (7% acetic acid–10% methanol), and stained for 1 to 3 h in 0.05% Coomassie brilliant blue R250 in 10% acetic acid–50% methanol. Destain over a period of 16 to 24 h with several exchanges of destain until the background is clear.

6. An image of the gel may be captured by using a densitometer (Molecular Dynamics) and saved as a TIF. Alternatively, the gel may be photographed with high-contrast film and a yellow filter. To preserve the gel, incubate it in preserving solution (10% glycerol in destain) for 1 h at room temperature. Then place the gel on a glass plate and cover with a cellophane preserving sheet that has been soaked in the preserving solution. Allow the gel and cellophane to dry for 24 to 48 h and store away from bright light.

7. The pI of the sample proteins can be determined by interpolation on a calibration curve utilizing the IEF marker that was resolved along with the sample.

In Vivo Diagnostic Allergy Testing

DEREK A. DAMIN AND R. STOKES PEEBLES, JR.

106

In recent decades, understanding of atopic diseases has increased exponentially. Pollens, fungi, animal dander, insects, and foods have been implicated in such diseases as allergic rhinitis, extrinsic asthma, atopic dermatitis, and anaphylaxis. Phenotypic association has been replaced with a profound understanding of biomolecular pathways, signaling molecules, and receptors. Despite marked advancements in the understanding of the pathophysiology of allergic disease, the simple idea of challenging subjects with antigenic material to reproduce a biological response remains fundamental in investigation.

Prick-puncture and intradermal skin testing are the most commonly used methods for the diagnosis of immediate hypersensitivity in allergic disease, while airway challenges may be used in the evaluation of rhinitis and asthma. This chapter describes the technique and utility of in vivo skin testing, intranasal allergen challenge, and specific and nonspecific lower airway challenge testing. These tools provide clinically useful information in the evaluation of the atopic patient.

SKIN TESTING

Overview

Allergen skin testing is considered to be the most convenient, least expensive, and most specific screening method in the diagnosis of allergic diseases. The first skin test recorded was in 1865, when Charles H. Blackley placed pollen grains on abraded skin (3). The prick skin test was first documented in the early 1920s, but scarification was the method of choice until the 1970s (13). Prick testing reemerged as the most common method when studies revealed increased false-positive and -negative results with scarification. During the 1980s, further studies elucidated the correlation of skin test reactivity with allergic symptoms to specific allergens. In recent years, major advancements have been made in allergen reagent standardization and national organizations have appealed for universal reporting methods to aid testing interpretation of an increasingly mobile population (see chapter 105, this volume).

Skin test positivity is an indication of individual immunoglobulin E (IgE) production. Allergen-specific IgE produced by plasma cells binds to specific receptors on the surface of mast cells and basophils. After introduction of allergen into the skin either by prick-puncture or by needle injection, the allergen may cross-link the allergen-specific IgE on the mast cell and/or basophil surface, resulting in cellular degranulation and mediator release. These mediators, including histamine, leukotrienes, and others, produce the sharply demarcated area of edema and even larger area of erythema characteristically referred to as the "wheal and flare" response. Demonstrable results are produced within minutes, and marked reactivity can be impressive.

Alternative Assessments

Serum assays allowing direct measurement of allergen-specific IgE antibodies are described in chapter 107. Skin testing is more economical per test than in vitro IgE assays, but in vitro testing should be utilized for patients with extensive dermatitis or dermatographism or for patients who cannot withhold interfering medications or refuse testing. Sensitivity for in vivo and in vitro testing varies, depending on the antigen being tested. Wood and colleagues compared predictive values of skin tests and radio allergosorbent tests (RASTs) in the diagnosis of cat allergy (33). Depending on the outcome measured, sensitivity for prick testing ranged from 79 to 97% while that of the RAST ranged from 69 to 91% (33). More comparative studies are needed for individual antigens, but sensitivity for in vivo testing is usually 10 to 25% greater than that for in vitro testing. In the diagnosis of food allergy, threshold in vitro values that have 95% positive and 90% negative predictive values have been derived (36).

An alternative to skin testing to assess the potential role of allergy in clinical symptoms is to assess basophil mediator release. This topic is reviewed extensively in chapter 108.

Clinical Indications

Allergen skin testing is indicated for the further evaluation of symptoms suspected of being mediated by allergen-specific IgE antibodies. In the evaluation of rhinitis, asthma, and conjunctivitis, aeroallergen assessment is performed with extracts of clinical relevance to the geographical area where testing is performed or symptoms are experienced. Assessment of foods is often indicated in the evaluation of eczema and systemic reactions suggestive of anaphylaxis. In the evaluation of stinging-insect hypersensitivity, purified venoms and whole-body extracts are used in the evaluation of systemic reactions to insects of the order Hymenoptera. Although much less defined, skin testing with nonirritating concentrations of medications is used when medication hypersensitivity is being assessed.

In the evaluation of aeroallergens and stinging-insect hypersensitivity, proper allergen identification is essential in accurate immunotherapy prescription and administration. Identification of food allergens is necessary for appropriate avoidance. In vivo testing is also essential in identifying medications that should be avoided or to which desensitization should be initiated.

Aeroallergen Assessment

Aeroallergen assessment is routinely performed by the prick-puncture method and has excellent positive predictive value. The use of intracutaneous or "intradermal" skin testing in aeroallergen assessment is less supported. Nelson and colleagues found a poor correlation between timothy grass intradermal positivity and symptom provocation (22, 33). However, intracutaneous testing may detect relevant sensitivity in some populations when prick-puncture testing is negative but sensitivity is strongly suggested on the basis of exposure and symptomatic history.

Food Allergy Assessment

A vast amount of information exists on the evaluation of food allergy (see chapter 109). General principles that relate to in vivo examination are discussed here. Food allergens are implicated in approximately 30 to 40% of children with eczema (28). The "gold standard" of diagnosis is the double-blind placebo-controlled food challenge (DBPCFC). However, DBPCFC is limited by the risk of systemic reaction. Prick-puncture testing, therefore, is often the initial choice for evaluation. Intradermal testing is not routinely performed in the evaluation of food allergy secondary to high false-positive and low false-negative rates compared to DBPCFC (26). Negative skin prick testing essentially rules out allergy to that food with >95% negative predictive accuracy (27). In the diagnosis of eczema in which a food is the etiologic agent, 80 to 90% is accounted for by allergies to milk, egg, wheat, soy, peanut, tree nuts, fish, and shellfish. One caveat of testing, however, is false-negative results with manufactured extracts from fruits and vegetables due to the lack of relevant antigens. Freshly prepared extracts should be used for definitive exclusion (24).

Stinging-Insect Assessment

The diagnosis and treatment of stinging-insect hypersensitivity remain controversial. For in vivo testing, intradermal injection is required for definitive diagnosis when prick-puncture testing is negative. Initially, prick-puncture testing is started at 1.0 μg/ml. If negative, the protocol proceeds with intracutaneous testing started at 0.01 μg/ml and injections are advanced in single logarithmic increases to 1.0 μg/ml. In vitro IgE assays have additional utility in the diagnosis of hymenopteran sensitivity. Ten percent of skin test-negative patients being evaluated for insect allergy will have increased serum-specific IgE antibodies detected. Currently, a combination of in vivo and in vitro testing is used for patients with a history of systemic reaction to provide maximum sensitivity for detecting at-risk individuals (10).

Medication Adverse Reaction Assessment

Skin testing can be utilized as a diagnostic tool when the adverse reaction to a medication is suspicious of an IgE-mediated mechanism. Skin testing for allergy to medications is not well defined, and more studies are needed to establish reproducible parameters for individual medications. Also, in many instances, the relevant antigen is not the parent compound and therefore not commercially available for testing.

It is important that interpreters realize that the antigenic epitope responsible for the reaction may be a metabolized product of the parent compound. Currently, the only group of medications for which the predictive values have been elucidated is beta-lactam antibiotics. If tested to the major (benzyl penicilloyl polylysine) and minor (benzylpenicillin, benzylpenilloate, and benzyl penicilloate) determinants of penicillin, negative testing confers a 97 to 99% negative predictive value. If positive, there is approximately a 60% chance of immediate reaction with subsequent exposure (31). False-negative testing is possible if major or minor determinants are tested alone. Several obstacles exist for appropriate testing. First, the only commercially available, major determinant skin test reagent (PREPEN; Bayer) has been plagued by manufacturing shortages. Second, minor determinant mixtures are generally available only at major medical centers through complex preparative methods.

If skin testing is performed for other medications, control subjects should be tested to rule out an irritant response, and the results should be interpreted cautiously, given the lack of predetermined validity. A commonly used method for testing various medications is to determine the threshold dilution titration by preparing serial dilutions of the original concentration for testing. Prick-puncture testing is performed with the original concentration along with appropriate controls. If negative, intradermal testing is performed with a 1:1,000 dilution and increased until a positive reaction develops or the original concentration is tolerated.

Procedures

Several preparatory measures are required for successful testing outcomes. All interfering medications must be discontinued in order to achieve interpretable results. It is advised that narrow-spectrum antihistamines be discontinued 24 to 72 h before testing, hydroxyzine 96 h prior to testing, broad-spectrum antihistamines 4 to 7 days before testing, and tricyclic antidepressants 7 to 14 days before testing (1, 2). Testing should not be done on areas of active dermatitis and should be done with caution in patients with dermatographism because of difficulties in interpretation. Testing can be performed on pregnant patients but is not advisable unless the information gained from testing is deemed to outweigh the risk of adverse effects on the fetus if a systemic reaction is encountered. Although prick-puncture and intradermal skin testing are exceptionally safe, rare systemic reactions have occurred. In a 5,063-subject cohort of patients in a sexually transmitted disease clinic who were being screened for penicillin allergy, mild anaphylaxis occurred in 1 patient and 11 others experienced systemic pruritus or urticaria, for an overall incidence of adverse reactions to skin tests of 1.2% (9). Therefore, a supervising physician and resuscitation materials should be on hand in case of systemic reaction. First-line treatment for a systemic reaction is 0.3 ml of 1:1,000 aqueous epinephrine for adults and 0.01 ml/kg of body weight (up to 0.3 ml) for children, administered intramuscularly (29). Other resuscitative materials should include antihistamines, corticosteroids, oxygen, and normal saline for volume replacement. Patients with life-threatening reactions should be transported to the nearest emergency department. The risk of systemic reaction is higher with intracutaneous testing. A practical approach is to use prick-puncture testing for screening and intradermal testing for confirming equivocal or negative percutaneous testing results (32).

The number of individual extracts tested is dependent on many variables, including the condition for which testing is

required, geographical area, age, and knowledge of antigen cross-reactivity. Special consideration should be given to infants and very young children. In this population, few tests are needed and relevant antigens are usually limited to constant environmental exposures, including foods, dust mites, and animal dander.

Testing sites are cleansed with 70% isopropyl alcohol and marked for identification. Using barrier precautions, allergen extracts of known composition are introduced into the skin, usually on the volar aspect of the arm or the upper back. Either site is appropriate, but the back is associated with clinically significant higher sensitivity, whereas the arm affords tourniquet application if systemic reaction is encountered (19). Individual tests should have sufficient spacing, usually 2.5 cm, and should not be placed within 5 cm of the wrist or 3 cm of the antecubital fossa. False-positive results from adjacent reactions are unlikely to be caused when there is at least 2 cm between individual test sites (19).

Controls

Positive and negative controls must be applied in the absence of interfering medications. Histamine as a positive control must be read at 15 min to achieve peak reactivity. For prick-puncture testing in the United States, a concentration of 2.7 mg of histamine phosphate per ml (1 mg/ml equivalent of histamine base) is used, whereas a 100-fold dilution is used for intradermal testing. A negative control must be performed with the same diluent used for the extracts (2).

Prick-Puncture Tests

Several devices and techniques can be used in performing the prick-puncture test. The purpose is to introduce a small quantity of allergen into the skin after interruption of the epidermal barrier. Disposable lancets on single- or multitipped devices as well as various needles can be used for the prick-puncture technique. Lancets are usually 1 mm long with a plastic rim to prevent excessive penetration. Variables involved in testing include the device being used, the angle and depth of penetration, and the force applied by the applicator. Testers should be aware of trauma associated with different devices and their influence on interpretability (20, 21). Proper application should not cause excessive trauma or bleeding at the site. Single- and multitipped devices often simultaneously place a drop of allergen extract while puncturing the skin. If such devices are not used, a drop of extract is placed on the skin and the needle or lancet is used to prick through the extract.

Intradermal Tests

Intradermal testing is usually performed on the volar aspect of the arm to allow application of a tourniquet in the event of a systemic reaction. The concentration used is usually 100- to 1,000-fold more dilute than the concentration used in the prick-puncture method. As in the previous method, the skin test site is cleansed and marked for individual allergen identification. Using a 27-gauge tuberculin needle, 0.01 to 0.05 ml of diluted extract is introduced into the skin. With the skin held taut, the needle is inserted bevel down at a 45° angle to the skin. After initial insertion, the syringe is lowered parallel to the skin and advanced only sufficiently to provide an intradermal injection. A small wheal about 3 mm in diameter is usually formed. A new needle is used for each injection.

Interpretation

Quality interpretation can depend on many variables, including skin color, testing site, skin reactivity, and reader skill. Tests should be read 15 to 20 min after application. Reporting

in a standardized manner as recommended by the American College of Allergy, Asthma and Immunology and the American Academy of Allergy, Asthma and Immunology should include the following information: subject name and date of birth, longest diameter of wheal and flare in millimeters, device used, time, date, reader, and extracts tested. A semiquantitative manner of reporting using 1+, 2+, etc., is not advised. Marked interphysician variability has been noted to occur with semiquantitative reading of prick-puncture tests, with the exception of the extreme positive result (16). If semiquantitative scores are reported, the grading system should be included in the report. The goal is to include a sufficient amount of information in the report to eliminate the need for repeat testing if interpreted by another physician or provider. A wheal diameter of 3 mm greater than that of the diluent control is considered positive and representative of the presence of IgE antibodies with prick-puncture testing. A wheal diameter of 8 mm greater than the diluent control is considered positive for intradermal testing. Accurate interpretation is enhanced when erythema is considered (32). Readers must be proficient to maximize intra- and interpatient validity. Prick-puncture testing is usually considered more specific and less sensitive than intracutaneous testing. Interpretation is dependent on clinical correlation and an understanding of testing limitations, since the presence of IgE antibodies does not always imply symptom culpability.

Reagents

Reconstitution, Stability, and Storage

A vast number of commercial extracts are available from companies that collect and purify allergens, but the number of standardized antigens available is a very small percentage (see chapter 105). Reproducible and precise extract constitution through standardization has been a major advancement in the utility of allergy skin testing. Extract standardization is important in providing test reliability and minimizing lot-to-lot variability. Concentration assignment in bioequivalence allergy units is a method of reporting potency based on a skin test bioassay reducing lot-to-lot variability. Standardized extracts exist for short ragweed, cat hair, grass pollens, dust mites, and hymenopteran venoms. Until universal standardization, many allergen extracts will continue to be supplied in weight per volume and may have significant variation in lot-to-lot concentration (17).

It is important to understand extract thermal stability, compatibility, and cross-reactivity when storing and mixing different reagents for testing or injectable immunotherapy. Allergen extract potency deteriorates with time, dilution, and increased temperature. Several studies have demonstrated extract degradation with higher temperatures, fungal and insect protease activity, and percent glycerin of diluent (11, 18). Protease activity from fungal and insect extracts can have degradative effects on other antigens. An understanding of protease degradation and unnecessary inclusion of redundant cross-reactive extracts is required when mixing extracts for injectable therapy. Glycerinated extracts protect unstable allergens from denaturation, inhibit protease degradation, and increase thermal stability. Diluted extracts need to be remixed every 2 to 3 months in buffered saline or normal saline diluent and every 6 months in 10% glycerin or human serum albumin diluent. Allergen extracts should be stored at 4°C (11).

Recombinant Allergens

Many recombinant allergens have been generated for basic and clinical investigation. Further investigation is needed for

recombinant allergens to be licensed for human use in the United States and become useful for skin testing. One problem with recombinant allergens is that allergenicity does not equal immunogenicity, and antigen epitopes may be excluded when single recombinant allergens, versus their natural counterparts, are used. They do, however, afford the opportunity of having greater purity and stability as well as improved delivery since protease degradation can be avoided. Diagnostic products may be ineffective for immunotherapy, and immunotherapy products may be ineffective for diagnosis. Diagnostic and therapeutic uses will have to be defined as each allergen is approved (30).

AIRWAY CHALLENGES

Although antigens that elicit IgE-mediated reactions can be identified in an individual by either skin or serologic testing, there may be variability in the nature and the intensity of challenged organs in that subject. For example, a dose of inhaled ragweed might cause intense immediate rhinitis symptoms in a patient who also has allergic asthma; however, even much larger doses of ragweed may cause minimal or no asthmatic symptoms. Similarly, the same subject might have a greater skin test reaction to ragweed than to timothy grass, yet small doses of inhaled timothy grass cause intense bronchoconstriction while the ragweed at even greater concentrations has no effect on pulmonary symptoms. The benefit of using organ-specific antigen challenges is that allergens that precipitate clinical symptoms can be identified. In this section, we will focus on both upper (intranasal) and lower (bronchial) airway challenges that are used to diagnose rhinitis and asthma. In addition, we will briefly mention the rationale and procedures for the bronchial methacholine and histamine challenges as diagnostic tools, since they are often used to assess the presence of asthma.

Clinical Indications

Airway challenges, either intranasal or bronchial, can be used to determine whether a single allergen may be responsible for symptoms of either rhinitis or asthma or both conditions. In general, most allergists use a combination of patient-reported rhinitis symptoms and positive skin tests to identify the most likely culprit of allergic nasal symptoms. Intranasal challenges are more often used to determine the effect of antiallergic drugs in an experimental setting. Bronchial challenge is more often used to measure airway reactivity in the diagnosis of asthma but also has been utilized to determine the effectiveness of pharmacologic agents.

Two bronchial challenge models that have been developed to mimic allergic asthma are the whole-lung and segmental antigen challenges. Segmental challenge involves installation of antigen solution through a bronchoscope into a subsegment of the lung. Since it may be performed only by those trained in bronchoscopy and is used almost exclusively for research investigation, it will not be discussed further in this chapter. Whole-lung antigen challenge can be used both as a diagnostic and as a research tool and is useful in determining relevant environmental asthmatic stimuli for a patient who cannot define exacerbating factors. In addition to its diagnostic application, whole-lung antigen challenge is also used to determine the effects of treatment methods to block allergic physiologic changes and asthmatic symptoms.

Both intranasal and whole-lung antigen challenges initiate allergic reactions and may precipitate bronchoconstriction. Therefore, these techniques should be used with caution under the supervision of a physician or similarly trained health care professional who can treat allergic emergencies. Equipment to treat such emergencies should be ready when these challenges are being performed. Several contraindications to performing either intranasal or whole-lung antigen challenge must be observed to protect the subject. Neither should be performed during asthmatic exacerbations, since such a condition might significantly worsen as a result of the challenge. Also, the results of whole-lung antigen challenge may be misinterpreted during asthma flares, as increases in nonspecific bronchial reactivity occur during exacerbations. In general, it is not recommended that whole-lung antigen challenge be performed if the forced expiratory volume in 1 s (FEV_1) is <60% of predicted values (5). Other health problems such as underlying heart disease must be considered, since whole-lung antigen challenge may result in prolonged bronchoconstriction and potentially hypoxia.

Test Procedures

Intranasal Challenge

Several methods have been developed to test the effect of antigen exposure on the nasal mucosal surface in allergic reactions. First, a specific antigen is identified by a combination of history consistent of allergic symptoms upon exposure to the antigen and positive skin testing, followed by intranasal challenge with that antigen. The two most commonly used methods of intranasal challenge include instillation of antigen into the nares either by spray pump (14) or by nebulizer (8). Symptoms of rhinorrhea and nasal congestion can be scored, the sneezes can be counted, and measurements of nasal patency may be made by rhinometry. These outcomes can be determined at various time points, including baseline before the subject starts the challenge protocol, subsequent to administration of the vehicle in which the antigen is dissolved, and after each dose of antigen. Antigen doses are usually increased at log or half-log intervals, starting at very low antigen concentrations (approximately 0.0001 allergy units for ragweed, for instance) (14). The period between the administrations of consecutive doses of antigen may vary, depending on the challenge protocol, but most frequently the interval is either 5 or 10 min. Completion of the challenge protocol may be determined by a preordained level of symptoms or physiologic changes or by administration of a defined number of individual antigen concentrations. Another outcome which may be measured during intranasal challenges is nasal secretion weight, in which paper disks are placed on the nasal mucosa, removed after a defined period, and then weighed, or alternatively the weight and/or number of paper tissues into which a subject has blown his or her nose is determined (8). Other possible end points include the number of inflammatory cells and mediators measured in the nasal secretions. Some investigators use nasal lavage with 2.5 ml of saline after antigen challenge to collect nasal secretions for determination of inflammatory parameters (14). In such cases, a nasal decongestant such as oxymetazolone may be used as a pretreatment before antigen instillation to ensure nasal patency, as this agent has been shown not to alter allergen-induced inflammation in the nose (15).

Since there is no standardized protocol for intranasal challenge and different investigators have used a wide variety of methods and doses of antigen instillation, there are few reports concerning the reproducibility of intranasal challenge. Doyle and colleagues, using a three-antigen dose protocol administered by nebulizer, found a high degree of correlation

when the challenges were performed out of the specific allergen season (8). In this study, ragweed challenge resulted in highly correlated intraindividual responses for the outcomes of sneeze count and secretion weight, while there was moderate correlation in rhinorrhea and congestion symptom scores. Some authors recommend that individuals be challenged no more frequently than once every 2 weeks to minimize the "priming effect," in which an exposure to allergen augments the response to subsequent exposure to the same allergen (14).

Whole-Lung Antigen Challenge

Skin test titration is first performed to determine the concentration of antigen that will be used. The procedure defined earlier in this chapter for a threshold dilution titration with a 10-fold dilution series is initiated. The lowest concentration of this dilution series is given intradermally, and after 15 min the wheal is measured. The concentration given intradermally is then increased at 15-min intervals until a wheal response of 10 mm is obtained. One log higher than this concentration will be used to initiate the inhaled challenge.

The choice of an apparatus to deliver aerosolized solutions is important for ensuring delivery of test doses reproducibly (25). Technical factors that may vary include the preparation and storage of test solutions, generation and inhalation of the aerosol to be delivered, and reporting methods. Factors that affect aerosol delivery from a nebulizer apparatus include output, particle size, and whether the aerosol is delivered continuously or intermittently. Additionally, there may be intrasubject variability in the lung volume at the start of the inhalation, the inspiratory volume and flow rate, and the time that each breath after aerosol inhalation is held. The solutions to be inhaled should be obtained sterile from the manufacturer or sterile filtered before use.

The particle size generated from the nebulizer is critical to ensure consistent delivery of the solution to be aerosolized. Particles of >5 μm tend to be deposited in the mouthpiece apparatus, oropharynx, and upper airway, while particles smaller than 1 μm can be lost through exhalation. The inspiratory flow rate through the nebulizer should be consistent, in the range of 0.13 ml/min, by keeping the flow through the nebulizer at 7 to 9 liters/min.

The Wright and DeVilbiss nebulizers are widely used. The Wright nebulizer generates an aerosol that is inhaled by tidal breathing for 2 min for each dose. It generates an output of 0.13 ml/min, with a particle size of 1.3 μm aerodynamic mass median diameter. With this apparatus, the speed of inhalation and the volume of aerosol inspired are not regulated, and there is no breath holding after each inhalation (25). In our experiments, we have used a DeVilbiss no. 646 nebulizer attached to a solenoid tuning circuit and compressed air source. Two milliliters of the solution to be inhaled is added to the nebulizer well. During a slow, deep inspiration, the solenoid is then activated, delivering compressed air at 10 lb/in^2 for 0.6 s to the nebulizer. An electronic metronome and breath counter is integrated with the solenoid timing device to assist the subject in performing a 3-s inhalation and a 3-s breath hold. This system delivers a mean volume of 0.051 ml of solution, with a standard error of 0.007 ml. The mass median diameter of the droplets is 1.6 μm, with a geometric deviation of 3.14 μm (25). When either the Wright or the DeVilbiss nebulizer device is regulated by a dosimeter, the reproducibility of results in the same subject is similar.

At the start of the procedure, baseline pulmonary function testing is performed and the FEV_1 is recorded. Next, the subject takes five breaths of sterile 10% phosphate-buffered saline solution used as a diluent via the nebulizer. Spirometry is performed 3 min later. If the FEV_1 decreases by more than 10%, the study should be terminated since the specificity of the antigen challenge cannot be evaluated. Five breaths of the initial antigen concentration are then inhaled, and the FEV_1 is measured 10 min later. Five breaths of half-log-increasing concentrations of antigen are inhaled at 10-min intervals until either a >20% decrease in FEV_1 or the maximum dose is achieved.

The maximal dose of antigen to be employed must be carefully considered and may vary for each antigen. High concentrations of antigen solution will cause allergic subjects with rhinitis to have asthma symptoms, even though they may have never experienced such symptoms before. If a whole-lung antigen challenge is to determine a cause-and-effect relationship between an antigen and asthma symptoms, then the use of too high a dose may give false-positive data.

After a 20% fall in FEV_1 has been observed (Fig. 1), the bronchoconstriction can be immediately reversed with a bronchodilator, or hourly pulmonary function measurements can be made to determine whether the subject experiences an asthmatic late-phase reaction. The presence of a late-phase reaction is defined as an FEV_1 measurement 4 to 8 h after the whole-lung antigen challenge that is <15% of the saline control FEV_1 measurement. Approximately 30 to 40% of subjects who have at least a 20% immediate decrease in FEV_1 with whole-lung antigen challenge experience a late-phase reaction. The physiologic mechanisms behind late-phase reactions are unclear. The three factors that are thought to contribute to the allergen-induced late-phase reaction are smooth muscle constriction, airway swelling as a result of increased vascular permeability, and increased mucus production causing airflow obstruction.

Several medications have been shown to affect either the immediate or the late-phase response or both. To avoid a confounding effect of these medications on whole-lung antigen challenge, patients should be instructed to abstain from the following medications for the times listed below based on recent American Thoracic Society (ATS) guidelines (5):

8 h, inhaled short-acting beta-agonists and inhaled cromolyn

24 h, oral beta-agonists, short-acting anticholinergic agents, and leukotriene-modifying agents

48 h, long-acting theophylline preparations, long-acting beta-agonists, long-acting anticholinergics, and inhaled nedocromil

72 h, classical antihistamines

5 days, nonsedating antihistamines

2 weeks, inhaled corticosteroids and nasal steroids

4 weeks, oral corticosteroids

Note: the ATS guidelines do not recommend routinely withholding oral or inhaled corticosteroids if needed for symptom control. However, if these agents are to be withheld to answer either a research or a clinical question, they should be discontinued for the periods listed above, as their anti-inflammatory effect may decrease bronchial responsiveness.

Methacholine and Histamine Challenges

Methacholine and histamine challenges are used to assess nonspecific bronchial reactivity (5). Although neither test is specific for asthma, both tests are commonly used in the evaluation of patients who describe asthmatic symptoms and who have not been observed during an exacerbation. The
FIGURE 1 Graph of the change of FEV_1 that occurs in an allergic asthmatic subject during a typical whole-lung challenge to which the subject is sensitive. Protein nitrogen units (PNU) are one measure of allergen quantity.

contraindications for methacholine and histamine challenges are essentially the same as for whole-lung antigen challenge.

Methacholine directly interacts with muscarinic receptors to produce smooth muscle contraction. The peak of methacholine effect occurs within 1 to 4 min after inhalation, and the duration of activity is between 1 and 2 h. There is no tachyphylaxis (decreasing response when doses are repeated) associated with methacholine challenges, although there can be diurnal variation (up to 1 to 2 doubling doses) in effecting a 20% fall in FEV_1 during challenges. Methacholine is very safe when administered properly. Rare patients will experience flushing with administration of higher concentrations, but there are no clear predictors as to who will be affected. Methacholine is stable in solution for up to 3 months and is relatively inexpensive.

Histamine has the same onset of action as methacholine, but the duration of activity, 10 to 30 min, is much shorter (34). Histamine can cause bronchoconstriction by stimulating sensory nerves that elicit vagally mediated reflex bronchoconstriction. In addition, histamine can cause airway constriction by binding to histamine receptors on bronchial smooth muscle (34). Tachyphylaxis is reported to occur with histamine challenge and can last up to 6 h. The degree of diurnal variation that occurs with histamine challenge is similar to that for methacholine. Although histamine challenge is safe when administered properly, it is associated with greater side effects, i.e., flushing, headache, and tachycardia. Histamine is stable for 1 to 3 months in solution and is also inexpensive.

Both methacholine and histamine inhalational challenges are similar to antigen challenge in that baseline pulmonary function tests are recorded and then saline challenge

is done to assess nonspecific bronchial reactivity. If the fall in FEV_1 after saline challenge is less than 10% of the baseline, the methacholine or histamine challenge can be started. The ATS has issued recommended guidelines for methacholine challenge protocol for both the 2-min tidal breathing and the five-dose dosimeter methods (5). When the 2-min tidal breathing method is employed, twofold concentration increases are recommended according to the following schedule: 0.03, 0.06, 0.125, 0.25, 0.50, 1, 2, 4, 8, and 16 mg/ml. When the five-dose dosimeter method is used, the doses of methacholine are 0.06, 0.25, 1, 4, and 16 mg/ml. A recent report revealed that when these ATS protocols were used in a study population of stable asthma patients in a crossover manner, there was no intrasubject difference between the provocative concentration that causes a drop in FEV_1 of 20% from the saline control value (PC_{20}) obtained by either method on randomized study days (35). Histamine can be administered with the same dosing schedule protocol outlined for methacholine.

Some investigators suggest that adenosine or hypertonic saline challenges might be a useful adjunct to methacholine in epidemiologic studies. This argument is based on the hypothesis that inhalation of adenosine or hypertonic saline induces the release of inflammatory mediators from mast cells and eosinophils, which in turn causes bronchoconstriction, whereas methacholine principally acts on cholinergic nerve endings to effect airway obstruction (6, 7). Currently, there are no ATS guidelines for adenosine challenges.

Data Analysis

Values for whole-lung antigen, methacholine, and histamine challenges are calculated similarly, and the major end point is usually the PC_{20} (5). Generally, the PC_{20} is expressed as a

noncumulative measurement in milligrams per milliliter. A few groups express results as the provocative dose (PD_{20}) that is usually reported as a cumulative dose, in terms of either micromoles or "breath units." The number of breath units is determined by the following formula: breath units = concentration (micrograms per milliliter) × breath number (23). The results of any of the challenges described are determined by a dose-response curve, using a semilogarithmic scale. The dose (either cumulative or noncumulative) of the challenge substance is plotted on the logarithmic abscissa, while the FEV_1 responses as a percentage of the saline control inhalation are plotted on the linear ordinate. The line of best fit for the values obtained is determined, and the PC_{20} or PD_{20} is calculated by interpolating from the final two concentrations or doses the point at which the FEV_1 is 20% decreased from that of the saline control.

Interpretation

Whole-lung allergen challenge is considered to be the definitive method to test the specificity of a particular antigen to cause bronchial reactions. False-positive reactions can occur when the antigen is given in high enough concentrations to cause asthma symptoms in allergic rhinitis patients or normal subjects who previously have never experienced asthma. The reproducibility of whole-lung allergen challenge from day to day is less than twofold in concentration and is improved if the prechallenge FEV_1 is within 10% on the two challenges.

The diagnostic sensitivity of methacholine and histamine challenges for asthma has been studied by several investigators, but the results have varied because of a lack of uniform diagnostic criteria for asthma. The concentrations for methacholine and histamine that are regarded as positive for bronchial reactivity (FEV_1 fall of >20%) are both 8 mg/ml. Two studies have reported widely accepted values for the sensitivity of methacholine and histamine challenges. Hopp et al. reported that the sensitivity of an 8-mg/ml concentration of methacholine for diagnosing asthmatic subjects was 85%, while the specificity was 95% (12). Cockcroft and his colleagues reported that the sensitivity of a PC_{20} for histamine of 8 mg/ml or less was 100%, while the specificity was 93% for the diagnosis of asthma (4). Currently, the ATS categorizes bronchial responsiveness thus (5) for the indicated PC_{20} (in milligrams per milliliter):

>16, normal bronchial responsiveness

4–16, borderline bronchial responsiveness

1–4, mild bronchial responsiveness

<1, moderate to severe bronchial responsiveness

The reproducibility of inhalational challenges is dependent not only on the technique, but also on the health of the subject. Subjects should not be studied during asthmatic exacerbations, for two reasons. First, natural allergen exposures such as animals or seasonal pollens increase nonspecific bronchial reactivity and fail to provide a clear answer. Second, an allergen reactivity priming effect may potentiate so that lower doses may result in excessive responses and diminish the safety of the procedure. Active upper respiratory tract infections can also increase nonspecific reactivity. Patients should be free of symptoms from colds, bronchitis, and sinus infections for at least 2 weeks before challenge. Persons exposed to oxidizing pollutants, smokers, and cystic fibrosis patients may also have increased reactivity based on methacholine and histamine challenges.

CONCLUSION

Challenge procedures can be extremely useful in the investigation of allergy. Skin testing has a high degree of sensitivity and specificity for determining antigens that cause allergic symptoms. However, positive skin tests do not necessarily indicate that a specific allergen causes symptoms specific for a certain organ system. Provocation testing can help define both relevant allergens that cause asthma symptoms and nonspecific bronchial hyperreactivity to pharmacologic agents. These tests have predictive profiles that make them useful diagnostic tools and can be safe when performed properly and under close supervision by experienced health care personnel.

Immunological Methods in the Diagnostic Allergy Clinical and Research Laboratory

ROBERT G. HAMILTON

107

Almost 40 years have passed since immunoglobulin E (IgE) was identified as the reagin or serum antibody that sensitizes skin and mediates immediate-type hypersensitivity reactions in humans (2, 6). Since this pivotal event, the diagnostic allergy laboratory has provided the clinician with an array of analytical measurements that aid in the diagnosis, management, and study of the epidemiology of IgE-mediated diseases. Table 1 summarizes the analytes that are currently measured in diagnostic allergy laboratories. Total and allergen-specific IgE antibodies are the primary analytes measured to support the diagnosis of human allergic disease (Table 2). Mast cell tryptase, eosinophil cationic protein, IgG antivenom, cotenine (a metabolite of nicotine and indicator of passive smoke exposure), and the levels of indoor aeroallergens in surface dust are less frequently measured to aid in allergic disease diagnosis or management. The goal of this chapter is to overview clinically used and research methods for the quantification of total and allergen-specific IgE antibodies and allergen-specific IgG antibodies. The performance of immunoassays for these analytes has continued to improve with the availability of new solid-phase matrices, conjugate labeling technology, standardized reference reagents, and data processing methods. Methods for the measurement of the other analytes listed in Table 1 are discussed elsewhere (7, 13) and are not discussed further here.

ANALYTES RELEVANT TO ALLERGIC DISEASE

Immediate-type hypersensitivity or allergic disease manifests as a spectrum of symptoms involving respiratory responses (asthma or rhinitis), skin reactions (urticaria and dermatitis), gastrointestinal symptoms, or life-threatening anaphylactic shock. These symptoms are produced as a result of the reexposure of a previously sensitized (IgE antibody-positive) individual to one or many sensitizing allergens. These allergens are ubiquitous proteins that are released from pollens of grasses, weeds, and trees or antigenic proteins released from mites, rodents, domestic animals, insects, and mold spores and present in some drugs and generally well-tolerated foods.

IgE mediates allergic reactions by binding onto high-affinity Fcε receptors on mast cells and basophils and initiating the release of vasoactive mediators following allergen binding and cell surface IgE antibody cross-linking (18). Total serum IgE has been used clinically as a diagnostic analyte, since a moderately elevated total serum IgE level reinforces the clinical diagnosis of atopic disorders, including allergic rhinitis, allergic asthma, and atopic dermatitis. Moreover, high IgE levels are commonly observed in parasite infections and are necessary in the definitive diagnosis of bronchopulmonary aspergillosis and hypergammaglobulinemia E syndrome (Table 2). Serial total serum IgE levels can confirm an expected seasonal boost in serum IgE that is commonly seen after environmental exposure to the allergen to which the patient has become sensitized. However, the wide overlap in total serum IgE levels among atopic and nonatopic individuals diminishes their general diagnostic utility. Thus, the clinician must refrain from discounting allergy when total IgE levels are low or from automatically inferring an allergic etiology when the total serum IgE is high.

Allergen-specific IgE antibody is the primary analyte used to support the definitive diagnosis of IgE-mediated allergic disease (Table 2). IgE antibody can be detected in vivo using puncture or intradermal skin tests that provoke IgE-mediated skin mast cell release and elicitation of a wheal and erythema. The skin test is extensively discussed in chapter 106 and is not further discussed here. Some generalized skin conditions, such as eczema, dermatographism, psoriasis, and urticaria, make skin testing problematic. Moreover, skin testing of children under 10 years can be difficult. There are also occasions when skin reactivity has been suppressed by prolonged use of antihistamines and other medications that cannot be stopped prior to skin testing. In all of these cases, analysis of a serum specimen for allergen-specific IgE antibody may be preferred over skin testing in the diagnostic workup of a suspected allergic patient (12, 16).

Antigen-specific IgG antibody levels in serum can sometimes serve to document exposure of an individual to a potent antigen. However, IgG antibody that is specific for allergenic substances is not generally assayed because there has been no clear clinical indication for these measurements. The exception is Hymenoptera venom hypersensitivity, where IgG antibody levels may serve as an indicator of the effectiveness of various antigen doses used to induce a specific immune response during venom immunotherapy (5) (Table 2). IgG antibody has been used to monitor venom-allergic patients when maintenance venom immunotherapy doses are first achieved (after 3 to 6 months) for comparison with pretreatment levels to assess the adequacy of the humoral immune response. The venom-specific IgG level can also serve as a baseline for future immunological monitoring

TABLE 1 Analytes measured in the diagnostic allergy laboratory

Analyte
Diagnosis
Allergen-specific IgE (individual allergen specificities and multiallergen screens)
Total serum IgE, and free serum IgE for patients on anti-IgE (omalizumab) therapy
Mast cell tryptase (alpha and beta tryptase); indicator for mast cell-mediated anaphylaxis
Management
Eosinophil cationic protein
IgG antivenom (monitoring Hymenoptera venom patients on immunotherapy)
Environmental testing
Cotinine (monitoring secondhand smoke exposure)
Indoor aeroallergen quantification
Dust mite: *Dermatophagoides pteronyssinus* group 1 allergen (Der p 1)
Dust mite: *Dermatophagoides farinae* group 1 allergen (Der f 1)
Cat: *Felis domesticus* group 1 allergen (Fel d 1)
Dog: *Canis familiaris* group 1 allergen (Can f 1)
German cockroach: *Blatella germanica* group 1 and 2 allergens (Bla g 1 and 2)
Mouse: *Mus musculus* group 1 allergen (Mus m 1)
Rat: *Rattus norvegicus* group 1 allergen (Rat n 1)
Bacterial endotoxin
Viable mold spore analysis

and at 12- to 18-month intervals to monitor the efficacy of the maintenance immunotherapy regimen. Comparison with previous levels can be useful as a periodic guide to plan modifications in venom immunotherapy, such as increasing the maintenance injection interval, changing the dose, or discontinuing some or all venoms. IgG antibody levels can be used to assist in the evaluation of clinical problems such as adverse reactions to venom injections during venom treatment or an inadvertent field sting. Finally, levels of specific IgG antibody to venom and other model antigens, such as ragweed, are used in research studies to document humoral immune responses to an antigen to which the individual has been accidentally or intentionally exposed.

TOTAL SERUM IgE

Historically, total human serum IgE has been measured by several assays, including competitive-binding liquid-phase immunoprecipitation (double-antibody or labeled-antigen) assays, competitive-binding solid-phase labeled-antigen immunoassays, noncompetitive solid-phase two-site (sandwich) immunometric (labeled-antibody) assays, and nephelometric assays. Of these assays, the two-site immunometric assay has become the most widely used clinical and research assay for the quantification of total serum IgE. The first reported noncompetitive solid-phase two-site immunometric assay used polyclonal anti-human IgE covalently bound to a solid phase (paper disks) to bind IgE from unknown and calibrated reference and control sera. Following a buffer wash, radiolabeled anti-IgE was added to detect bound IgE. The amount of radiolabeled anti-IgE bound was directly related to the IgE content in the original serum. The assay displayed excellent sensitivity (as low as 0.2 ng of IgE per ml) and precision (coefficients of variation [CV] of ≤5%), and it was minimally affected by nonspecific serum factors as a result of the washing step. Reliable commercial sources of polyclonal and monoclonal anti-IgE are now available. Clinical laboratories perform one of several Food and Drug Administration (FDA)-cleared immunometric assays, such as the Pharmacia ImmunoCAP, Diagnostic Products Corporation Immulite 2000, Bayer ADVIA Centaur, Beckman Access/2, or Behring

Nephelometer, for measuring total serum IgE. Since their performance has been extensively discussed elsewhere (13), it is not further discussed here.

Occasionally, researchers need to measure total serum IgE using an inexpensive and flexible assay that can accommodate unusual specimens other than serum. One monoclonal antibody-based noncompetitive solid-phase two-site immunoenzymetric assay (IEMA) is described here as the procedure of choice for research investigations of total serum IgE. This assay is a 1-day microtiter plate-based enzyme immunoassay (EIA) that uses monoclonal anti-human IgE adsorbed onto plastic wells to bind IgE and a different labeled monoclonal anti-human IgE to detect bound IgE (11). The use of a murine IgM monoclonal anti-human IgE Fc capture antibody and biotinylated murine IgG monoclonal anti-human IgE Fc detection antibody optimizes both assay sensitivity and specificity.

Reagents

Mouse IgM-k anti-human IgE Fc (clone HP6061; EMD Biosciences, La Jolla, Calif.) should be obtained in purified form at 2 mg/ml in phosphate-buffered saline (PBS) with no added protein. Mouse IgG2a-k anti-human IgE Fc (clone HP6029; EMD Biosciences) should be obtained in biotinylated form at 1 mg/ml in PBS containing 10 mg of bovine serum albumin (BSA) per ml. Buffers and other reagents required for the assay include PBS, PBS–0.05% Tween 20 (PBS-Tween), PBS–1% BSA, streptavidin-horseradish peroxidase (streptavidin-HRP), 1 mM 2,2'-azino-di-(3-ethylbenzthiazoline sulfonic acid) (ABTS) substrate in 70 mM citrate phosphate buffer, and 2 mM sodium azide. These buffers are prepared using endotoxin-free water and chemicals obtained from Sigma Chemical Company (St. Louis, Mo.).

Specimen Requirements

The IEMA is designed to measure the level of IgE protein in human serum. Heparinized or cation-chelated plasma may be used, although fibrin formation can reduce pipetting accuracy. This assay can also be used to measure IgE levels in tear fluid, bronchial alveolar lavage fluid, saliva, nasal washings, and peripheral blood cell culture supernatants.

TABLE 2 Clinical conditions in which serological determinations may be useful in differential diagnosis

Clinical condition	Total serum IgE	Allergen-specific IgE	Allergen-specific IgG
Atopic disorders: allergic rhinitis, allergic asthma, atopic dermatitis	Moderately elevated levels positively reinforce clinical diagnosis; however, low or normal IgE level is not incompatible with diagnosis.	Positive allergen-specific IgE antibody level supports the diagnosis of IgE-mediated atopic disorders.	In the absence of allergen immunotherapy, the level of allergen-specific IgG antibody can be low or undetectable.
Intrinsic (nonallergic) asthma	Normal or low levels suggest that IgE mechanisms play only a minor role in the pathogenesis of asthma.	Negative IgE antibody levels support the diagnosis of intrinsic asthma.	Not useful in the definitive diagnosis of intrinsic asthma
ABPA[a]	Normal serum IgE levels virtually exclude diagnosis.	Positive *Aspergillus*-specific IgE antibody is required for definitive diagnosis of ABPA.	Precipitating IgG antibodies are required for definitive diagnosis of ABPA.
Wiskott-Aldrich syndrome	Elevated levels are commonly found in patients who exhibit eczema.		
Hypergammaglobulinemia E syndrome (elevated IgE, increased susceptibility to infection and dermatitis)	Very high serum IgE levels are necessary for definitive diagnosis of hyper-IgE syndrome.		
Parasitism	Many parasitic infections produce extreme elevations in serum IgE; a very high IgE level in the absence of other explanations strongly suggests the possibility of parasitism.	The presence of parasite-specific IgE antibodies confirms the diagnosis of parasitism.	Parasite-specific IgG antibodies confirm a present or recent parasite infection.
Eosinophilia	A normal IgE level makes the diagnosis of parasitism less likely as a cause of eosinophilia; eosinophilia with normal serum IgE is a common feature of nonallergic asthma.		
Allergen immunotherapy	Same as for atopic disorders (above)	Specific IgE antibodies are not helpful in monitoring patients on immunotherapy or assessing its clinical efficacy.	Used in Hymenoptera venom immunotherapy to confirm adequate immunotherapy dosages and assess relative risk for reactions upon resting

[a]ABPA, allergic bronchopulmonary aspergillosis.

Use of specimens other than serum and plasma requires the analysis of an appropriate non-IgE-containing "negative" control to define the magnitude of the nonspecific binding produced by matrix proteins that can vary widely. The antigenic properties of IgE protein are maintained almost indefinitely when serum is stored frozen at -20 or $-70°C$. Transportation of serum specimens at ambient temperatures for more than several days is not generally recommended without packaging in insulated mailers.

IEMA Procedure

The IEMA has been designed to balance good performance with a reasonable turnaround time.

1. Plastic 96-well microtiter plates are coated for 1 h at room temperature (RT; $\sim23°C$) and then overnight at 4°C with mouse IgM monoclonal anti-human IgE Fc (clone HP6061, 100 μl/well) which has been diluted in PBS to 10 μg/ml just prior to use. Plates are covered with Parafilm between each step to minimize evaporation and dust contamination.

2. Each plate is washed once with PBS-Tween using a 12-channel handheld Corning washing system or a comparable washing device, and 0.3 ml of PBS–1% BSA is added to each well to block unreacted sites.

3. After a second wash (four times) with PBS-Tween, 0.1 ml of reference, control, or test serum is added to its respective well. The standard curve is composed of 8 to 10 twofold dilutions in duplicate of a reference serum, beginning with a concentration of 100 kIU/liter (1 IU of IgE = 2.4 ng). Test sera are initially screened undiluted in duplicate and reanalyzed at several dilutions up to 1:100 if they exceed the top point of the dose-response curve. A buffer blank is analyzed to control for nonspecific binding. Each plate is pipetted within 15 min without interruption. The plates are then incubated for 2 h at RT. Two or three dilutions of high, medium, and low IgE serum controls are analyzed in different regions of the plate to demonstrate that the assay is in control.

4. Following a PBS-Tween buffer wash (four times), biotin-conjugated mouse IgG anti-human IgE Fc (clone HP6029) is added (0.1 ml per well, 1 μg/ml in PBS–1% BSA) with a multichannel pipette and the plates are incubated for 1 h at RT.

5. The plates are washed four times with PBS-Tween buffer, streptavidin-HRP (avidin HRP; Sigma S5512) is

added with a multichannel pipette (0.1 ml per well, 1 µg/ml in PBS–1% BSA), and the plates are incubated for 1 h at RT.

6. Plates are washed four times and 0.1 ml of substrate is added. Three substrates have been successfully used in this assay: 1,3-benzenediamine (also known as o-phenlyenediamine) (free base; Sigma P2903), ABTS (Sigma A1888), and 3,3',5,5'-tetramethylbenzidine (Sigma T5525). For routine analysis of human sera, 1 mM ABTS is prepared in 70 mM citrate-phosphate buffer. Immediately prior to use, 1 µl of 30% hydrogen peroxide is added per ml of ABTS required. The substrate is immediately pipetted into the plate (0.1 ml/well) using a multichannel pipette.

7. The peroxidase enzymatic reaction is stopped by adding 0.1 ml of 2 mM sodium azide per well when the top point on the standard curve reaches an optical density of 1.5 to 2.0 (usually within 5 to 15 min). The plate is read on a microtiter plate reader at 410 nm, and optical densities of the unknown sera are interpolated from the standard curve in kilo-international units per liter traceable to the World Health Organization total serum IgE reference preparation using an interpolation program.

Standardization

The World Health Organization international reference standard for human IgE or the U.S. IgE reference serum preparation can be used as a primary standard from which secondary standard serum pools can be cross-calibrated for IgE content by the value transfer technique (e.g., 3 to 5 dilutions in 10 assays). Alternatively, commercially available precalibrated IgE standards can be used (e.g., Pharmacia). Once a secondary working standard has been reproducibly cross-calibrated, it can be used in routine assays with periodic reevaluation against the primary reference preparation to ensure quality control. Nonparallelism may be observed in the high-end range of the IEMA possibly because of an atypical nonspecific binding when sera containing >2,000 kIU/liter are used as reference sera.

Working Range, Sensitivity, Reproducibility, and Parallelism

The minimal detectable concentration and working range of the IEMA are dependent on the dilution and affinity of the capture and detection antibodies and duration of the serum, conjugate, and substrate incubations. One practical goal in assay design is to achieve a clinically useful assay working range (e.g., 1 to 200 IU/ml added) while minimizing nonspecific binding effects and reagent use. A sensitivity of 0.5 IU/ml (1.2 µg/liter) can be achieved with this total IgE IEMA. Agreement among replicates is usually excellent (CV, <5%), and an interexperimental reproducibility of <15% (CV) can be achieved. Finally, parallelism is assessed by analyzing test sera at two or more dilutions and computing an interdilutional CV following correction for serum dilution. Interdilutional CV of <15% are achievable with most test sera.

Quality Control

The total serum IgE IEMA can be quality controlled by inclusion of two or three well-studied sera within each assay. The three quality control sera should have low (<10 IU/ml), moderate (100 to 250 IU/ml), and high (>1,000 IU/ml) levels of IgE, respectively.

Because total serum IgE is a regulated analyte as defined by the amended Clinical Laboratory Improvement Act of 1988, licensed clinical laboratories providing this analytical measurement must demonstrate proficiency in an external proficiency survey such as the Diagnostic Allergy (SE) survey conducted by the College of American Pathologists. In the SE survey, five challenge sera are sent to each participating laboratory during each of three cycles per year (15 challenges per year) and each is tested for total serum IgE and allergen-specific IgE antibody. The total serum IgE levels range from <10 to >10,000 IU/ml to test the laboratory's ability to accurately measure a wide spectrum of IgE levels in serum.

Interpretation

Total serum IgE levels are age dependent. The level of IgE in cord serum is usually less than 2 IU/ml since IgE does not cross the placental barrier in significant amounts. Mean serum IgE levels progressively increase in healthy children until 10 to 15 years of age (1). Atopic infants have an earlier and steeper rise in serum IgE levels during the early years of life than do nonatopic controls. An age-dependent decline in total serum IgE typically occurs from the second to eighth decade of life. Individuals with total serum IgE levels above the upper 95% confidence limit (12, 13) (Table 2) often have atopic disorders such as allergic rhinitis, extrinsic or allergic asthma, and atopic dermatitis. However, the overlap between atopic and nonatopic populations is considerable. In one study of adults with allergic asthma, the mean serum IgE level was 1,589 ng/ml (range, 55 to 12,750 ng/ml). Only about one-half of these asthmatic patients had serum IgE levels above the upper 95% confidence limit for nonatopic individuals of the same age. In another study, high levels of serum IgE (mean, 978 kIU/liter; range, 1.3 to 65,208 kIU/liter) were observed in approximately 90% of patients with atopic dermatitis.

Modification of Total IgE IEMA for Free IgE Quantification in Serum

In 2003, omalizumab, a recombinant humanized IgG1 monoclonal anti-human IgE Fc (Xolair), was licensed for therapeutic use in the United States to treat persistent allergic asthma. Omalizumab binds circulating IgE, blocking its binding to alpha chain of FcεR1 receptors and down regulating the FcεR1 receptor number on mast cells and basophils (18). Reduced cell-bound IgE can result in a concomitant reduction in mediator release and reduced allergy symptoms. Comparison of the total and free IgE levels in serum before and 1 to 3 months after treatment can serve as one measure of an effective omalizumab dose administration (14). A modification of the total serum IEMA described above allows the quantification of the level of "free" or non-omalizumab-bound IgE in serum. In this assay, IgE is captured from serum with monoclonal anti-human IgE (clone HP6061) and detected with biotin-labeled FcεR1α. In the absence of omalizumab, working ranges of the free and total IgE IEMAs were comparable (10 to 1,000 kIU/liter), with excellent precision, reproducibility, and parallelism. Pre-omalizumab administration total and free IgE levels by IEMA are highly correlated, and in vitro reduction of free IgE (>90%) has been observed with omalizumab/IgE molar ratios of 2 to 20 (14).

ALLERGEN-SPECIFIC IgE ANTIBODY

Historically, the first-generation assay for allergen-specific IgE antibody in human serum was the radioallergosorbent test (19). In this assay, an allergen-coated solid phase (paper disks) was incubated with human serum, during which time

specific antibody of all immunoglobulin classes (if present) bound. The solid phase was then washed, and radiolabeled anti-human IgE antibody detected bound IgE. The quantity of bound radioactivity directly correlated with the quantity of specific IgE antibody in the original serum. IgE antibody results were compared to a calibrated standard reference serum, and insolubilized allergen and radiolabeled anti-IgE antibody were used in molar excess.

Clinical Allergen-Specific IgE Antibody Assays

Over the past ~40 years, there have been major improvements in the design and performance of allergen-specific IgE assays. FDA-cleared commercially available semiautomated and automated allergen-specific IgE antibody assays have been developed. An overview of these commercial IgE antibody assays is presented the sixth edition of this manual (4) and elsewhere (12, 13, 17). These assays have in common an allergen-containing reagent (typically a solid-phase allergosorbent); a panel of reference, control, and test human sera; and a labeled anti-human IgE reagent. The Pharmacia ImmunoCAP system and the Diagnostic Products Corporation Immulite 2000 have achieved the highest degree of quantification and automation. Tighter precision around the positive/negative threshold and a more rapid, robust chemistry have been achieved with automation. With automation comes the need to analyze quality control sera with IgE antibody levels across the measured dose-response curve range. The quality control sera containing different specificities of IgE antibody should be randomly sprinkled through the assay run to investigate the quality of the whole assay analysis. Daily monitoring of results from these positive control sera in the form of Levey-Jennings plots verifies that the instrument is performing all of its serum and reagent addition, incubation, washing, and data analysis steps accurately.

Analyte-Specific Reagents

In the United States, the FDA regulates the sale of in vitro diagnostic products under regulation 21 CFR 809. This includes allergen-specific IgE antibody assay reagents that are intended for human use. One component of the IgE antibody assay reagent is the allergen extract, which is often a complex protein mixture. Presently, only 19 of the hundreds of allergen specificities of clinical interest have been standardized (see chapter 105). Some allergen extracts that have been insolubilized on allergosorbents for use in allergen-specific IgE assays have not yet been cleared by the FDA. These can be provided to clinical laboratories under an "analyte-specific reagent" classification. These allergosorbents can be used by laboratories that are qualified to perform high-complexity testing; however, a disclaimer must be included in the report indicating that a measurement was performed with an analyte-specific reagent.

Research Allergen-Specific IgE Assays

Researchers sometimes have need of a versatile immunoassay to measure allergen-specific IgE antibody. A number of polymers have been used for allergen insolubilization, including carbohydrate matrices (Sephadex, agarose, and cellulose) and polystyrene test tubes and 96-well microtiter plates. Each of these polymers differs with respect to its allergen-binding capacity, nonspecific binding properties, stability, and ease of washing. The use of a solid phase with the highest allergen-binding capacity is needed when maximum sensitivity is required, or when sera from hyperimmunized patients with high levels of allergen-specific IgG antibodies are to be studied for the presence of IgE antibody. For suitably equipped clinical laboratories with adequate facilities for centrifugation, aspiration, and pipetting, one of the carbohydrate particle matrices is preferred because of its high antigen-binding capacity. Alternatively, polystyrene solid phases (plastic microtiter plates) are quite satisfactory with some allergens (e.g., purified proteins). Plastic solid phases, however, can display selectivity and variable and limited binding capacity that make them less than ideal for use in IgE antibody immunoassays involving crude mixtures with multiple protein antigens.

One research assay has been effectively used for the measurement of IgE antibody specific for crude allergen mixtures. It is a noncompetitive radioallergosorbent test that uses an agarose carbohydrate solid phase to which allergenic protein is covalently coupled to bind specific antibody. Radiolabeled anti-human IgE is then used to detect bound IgE. This assay has been described in detail in the fifth edition of this manual (11) and is not discussed further here. An alternative is the microtiter plate-based EIA for the detection of IgE antibody to a purified allergen such as Amb a 1, the group 1 allergen in short ragweed. This EIA format is described in detail below for IgG anti-Amb a 1 detection in human serum. A modification of this assay format, using more concentrated serum (neat to 1:5) and a biotin-conjugated murine anti-human IgE detection antibody (e.g., HP6061-biotin; EMD Biosciences), allows the IgG antibody assay format to detect Amb a 1-specific IgE antibody in human serum.

Specimen Requirements

The commercially available third-generation assays for allergen-specific IgE antibody and the research-based microtiter plate-based EIA are designed to measure levels of IgE antibody in human serum. While heparinized or cation-chelated plasma can be used with good results, fibrin formation may cause high interassay variation and increased levels of nonspecific binding in the assay. Serum is best stored at –20 or –80°C until used. Allowing blood samples to clot and retract overnight at 4°C before centrifugation and storage has no detectable effect on the measurement of serum IgE antibody levels.

Standardization

The National Committee on Clinical Laboratory Standards has prepared a guideline that extensively examines the issue of standardization of IgE antibody assays (17). Several approaches have been used by researchers to standardize IgE antibody-containing reference sera (3). One approach involves elution of a portion of the specific IgE bound to the allergen-solid phase followed by measurement of the quantity and proportion of IgE eluted. This approach allows standardization of reference and test sera in weight/volume terms, usually in nanograms per milliliter. Another approach involves the total depletion of specific antibody by immunoabsorption and subsequent measurement of the reduction of total IgE protein observed with a total serum IgE assay. This approach is useful only when the IgE antibodies of interest comprise a significant fraction of the total serum IgE. In both cases, it is necessary to only standardize the reference serum. The quantity of IgE antibody in the test sera may then be estimated by homologous interpolation from a standard curve that has been constructed with multiple dilutions of the reference serum that contains defined levels of IgE antibody of the same allergen specificity. This outcome allows comparison of IgE antibody results in different allergen systems, each with its own calibrated reference serum, and it facilitates interlaboratory standardization.

From a practical point of view, preparing separate calibrated IgE antibody-containing reference sera for each of the hundreds of allergen specificities of clinical importance is not possible. An alternative generic strategy for calibrating IgE antibody assays has been adopted which uses heterologous interpolation from a total serum IgE reference curve that is run in parallel with the IgE antibody assay (3, 17). This approach requires that the total serum IgE (heterologous) curve is diluted out in parallel with control and test sera analyzed in the IgE antibody portion of the assay. Parallelism ensures reproducible estimates of IgE antibody when sera are analyzed at different dilutions. With heterologous interpolation, IgE antibody from any of hundreds of different allergen specificities can be interpolated from a single total serum IgE dilution curve that is traceable to defined levels of IgE (in kilo-international units per liter) in a primary standard.

Quality Control

The most important region of the IgE antibody assay dose-response curve from a clinical point of view is the minimal detectable dose. Positive thresholds can differ according to the blank subtraction and reporting methods used (17). Therefore, each allergen-specific IgE antibody assay should contain one or more positive and negative serum controls for each allergosorbent in addition to a reference serum dilution curve. All samples should be analyzed in duplicate to identify and minimize procedural errors. Since the quality of each antibody measurement depends on parallelism between the dilution curves of the reference serum and test sera under study, 2 or 3 dilutions of IgE antibody-positive test serum should be analyzed to confirm parallelism.

Clinical laboratories performing allergen-specific IgE antibody assays are required by federal licensing requirements to participate in an external proficiency testing program. The College of American Pathologists conducts the SE survey, which sends five sera in each of three cycles per year to participating laboratories. Each serum is analyzed for total serum IgE and IgE antibody to five allergen specificities that cycle among the weeds, grasses, trees, pet epidermal, mold, occupational allergen, and food allergen groups. Results are submitted to the survey's coordinating center, and performance of a participating laboratory is examined in relation to that of its peer laboratories using the same assay. Since IgE antibody is still a nonregulated analyte, participation in a national proficiency survey is required for licensure but the individualized laboratory performance is not formally graded.

Interpretation

The presence of allergen-specific IgE antibody in serum indicates that the individual is sensitized to that allergen and has an increased probability of experiencing allergic symptoms that are associated with IgE-mediated disease. Moreover, the relative quantity of IgE antibody in serum may but does not always correlate with the risk of severity of these symptoms. The association between antibody quantity and allergic symptoms can be confounded by many variables, including antibody affinity, the presence of IgG blocking antibodies, and, most importantly, the relative biochemical sensitivity or "releasability" of the subject's IgE-laden effector cells. Thus, IgE antibody is necessary but not sufficient for expression of allergic disease. For many food, drug, and insect allergies, only about half of those individuals with IgE antibody will react clinically when challenged. IgE results must therefore be carefully integrated with other clinical information for proper diagnostic interpretation.

Quantitative results (in kilo-international units per liter) from commercial IgE antibody assays have allowed investigators to study whether the quantity of serum IgE antibody has any predictive utility in defining clinical sensitivity. Several groups have shown that the quantity of specific IgE antibody in serum to peanut, egg white, cow's milk, and fish can accurately define a patient's current clinical sensitivity as determined diagnostically with double-blind placebo-controlled food challenges. The probability distribution for a positive food challenge as a function of food-specific IgE antibody in serum using the Pharmacia CAP assay has been published for five foods (13). Using probability curves, it has been possible to define IgE thresholds for provocative testing below which there is >95% probability that the challenge will be negative. Alternatively, upper limits define IgE levels above which a positive challenge test is >95% likely, thereby avoiding the need for this cumbersome, expensive, and sometimes uncomfortable clinical procedure.

IgE antibody serology has recently become a diagnostic test complementary to the skin test for those patients who experience a systemic reaction following a hymenopteran venom sting in the face of a negative intradermal skin test. The American Academy of Allergy, Asthma and Immunology practice parameters were modified in 2003 to recommend IgE antivenom serology in cases where a positive clinical history is not confirmed by intradermal venom skin testing.

Multiallergen Screen

In cases where the clinical indication for allergic disease is weak, a single qualitative screening assay for IgE antibody to multiple allergen specificities can support the absence of allergic disease. In the multiallergen screen, a panel of up to 15 allergen specificities representing those primarily involved in aeroallergen-induced allergic disease are coupled to a single allergosorbent. The IgE antibody results from these screening assays can be highly predictive of individual IgE antibody results obtained by a panel of separate skin tests or in vitro IgE antibody tests. Screening assays provide a positive or negative result. If negative, it may be the single best test for confirming the absence of significant atopic disease in individuals who are suspected of having an intrinsic or non-IgE-mediated disease process. The negative predictive value of this single test is higher than total serum IgE or any single specific IgE antibody measurement for identifying nonatopic individuals. Such a test can minimize the need for multiple in vivo or in vitro allergen-specific IgE measurements in patients with a questionable clinical history for allergic disease.

ALLERGEN-SPECIFIC SERUM IgG ANTIBODY

The levels of specific IgG antibodies are generally low or nondetectable in an unimmunized individual who has been naturally exposed to clinically important antigens (e.g., aeroallergens from weeds, grass, and tree pollens and dust mite, mold, and animal epidermal antigens). The analytical sensitivity and specificity of an IgG antibody assay used to assess these sera therefore become important because nanogram-per-milliliter levels of specific IgG must be measured in the presence of milligram-per-milliliter levels of nonspecific IgG. In contrast, individuals who have received injections of an antigen, either by accidental exposure (e.g., bee sting or drug injection) or by active allergen immunotherapy, can produce high microgram-per-milliliter levels of specific IgG. At these levels, nonspecific binding and assay

sensitivity become less critical and assay parallelism, precision, and accuracy and human antibody standards become the focus of assay design.

An early research assay that measured antigen-specific IgG in human serum employed a reaction between a radiolabeled antigen mixture and antibody-containing serum. IgG was then selectively precipitated from other antibody isotypes in serum with a polyclonal anti-human IgG reagent. This assay, called the radioimmunoprecipitation or double-antibody assay, has remained a research tool for the measurement of IgG antibody specific to purified antigens. However, it is difficult to uniformly radioiodinate or enzyme label complex mixtures of protein antigens that vary widely in isoelectric point and molecular weight. Nonparallelism and differential plateauing (variable maximum binding) can result with the double-antibody assay when a labeled protein mixture is used, indicating that the assay will not perform in a uniform, quantitative manner with all human sera. To address this problem with complex antigen mixtures, a noncompetitive solid-phase radioimmunoassay (SPRIA) was developed based on the assay design described above for IgE antibody except that it uses staphylococcal protein A or protein G to detect bound IgG antibody. This assay is still in use today to assess Hymenoptera venom-specific IgG (8). Since there are naturally occurring IgG antibodies for carbohydrates present in the agarose solid-phase matrix that interfere in this assay, all sera analyzed in this assay are routinely preadsorbed with uncoupled agarose (10). The generic SPRIA for IgG antibody specific for complex protein mixtures has been discussed in detail in the fifth edition of this manual (11; see also references 8 and 9) and is not discussed further here.

A versatile nonisotopic monoclonal antibody-based EIA for the detection of IgG antibodies specific for purified allergens such as ragweed group 1 allergen (Amb a 1) is presented. Although a crude aqueous extract can be used as an antigen source, it contains many irrelevant proteins that readily adsorb onto plastic surfaces. In doing so, these occupy limited sites on the plastic surface that can be used to bind more relevant antigens. Because the microtiter plate well has a limited surface area for binding proteins, well-characterized purified antigens are recommended for use with the microtiter plate-based EIAs. The assay uses documented murine monoclonal antibodies that bind to the Fc regions of all four subclasses of human IgG and are purified and biotinylated or HRP conjugated (clone HP6043; EMD Biosciences Corporation). The biotinylated monoclonal anti-human IgG PAN reagent can be used with an avidin-enzyme preparation to maximize the working range of the assay while minimizing nonspecific binding.

Specimen Requirements

The antigen-specific IgG EIAs are designed to measure the level of specific IgG antibody in human serum. Heparinized or cation-chelated plasma can be used with good results, but fibrin formation may cause high interassay variation and increased levels of nonspecific binding in the assay. The serum is best stored at –20°C until used. Allowing blood samples to clot and retract overnight at 4°C before centrifugation and storage has no detectable effect on the measurement of serum IgG antibody levels. While serum is desired, plasma and other body fluids (e.g., bronchial alveolar lavage fluid, tears, and nasal secretions) can be tested if the appropriate negative controls are analyzed in the same assay to identify the level of nonspecific binding.

Assay Procedure

1. Flat-bottom 96-well microtiter plates are coated for 1 h at RT and then overnight at 4°C with purified antigen (e.g., Amb a 1 or Der p 1; 0.1 ml per well) which has been diluted in endotoxin-free PBS to a final concentration of 10 μg/ml just prior to use. Since these proteins bind by means of adsorption, caution must be exercised so as not to lose antigen on plastic tubes, pipettes, and reservoirs used for dispensing it into the microtiter plate. A variety of plastic microtiter plates (e.g., Costar or Nunc) have been successfully used as solid phases. The plates are covered with Parafilm between each step to minimize evaporation and dust contamination.

2. Each plate is washed once with PBS–0.5% Tween 20 using a 12-channel handheld Corning washing system or equivalent, and 0.3 ml of PBS–1% BSA is added to each well to block unreacted sites on the microtiter plate wells (1 h at RT).

3. After a second wash (four times) with PBS-Tween, 0.1-ml volumes of antigen-specific IgG-containing reference, control, and test sera (diluted at least 1:50 in PBS–1% BSA) are added to their respective wells. The standard curve is composed of 8 to 10 twofold dilutions in duplicate of a reference serum, beginning with a concentration of 1,000 ng of IgG antibody per ml. Test sera are initially screened at a 1:50 dilution in duplicate and reanalyzed at several dilutions up to 1:10,000 if they exceed the top point of the dose-response curve.

Soluble antigen can be added at this step to confirm assay specificity by competitive inhibition (see chapter 105). A buffer blank and a negative control serum are analyzed to control for nonspecific binding. The 1:50 negative serum control consistently produces an optical density above that of the buffer blank. The plates are incubated for 2 h at RT or overnight at 4°C. Two or three dilutions of high, medium, and low IgG anti–Amb a 1 serum controls are analyzed in different regions of the plate to ensure that the assay is in control.

4. Following a PBS-Tween buffer wash (four times), HRP-conjugated mouse anti-human IgG Fc (HP6043-HRP; EMD Biosciences Corporation) is added (0.1 ml per well, 1 μg/ml in PBS–1% BSA) with a multichannel pipette and the mixture is incubated for 1 h at RT.

5. Plates are washed four times for the last time and developed with ABTS substrate as described above for the total and free serum IgE EIAs. The enzyme reaction is stopped with the addition of 0.1 ml of 2 mM sodium azide when the top point on the standard curve reaches an A_{410} of 1.5 to 2.0 (usually in 5 to 15 min). The plate is read on a microtiter plate reader at 410 nm, and optical densities of unknown sera are interpolated from a standard curve into estimates of antibody concentration using a computer data processing program.

Standardization

Reference serum dose-response curves are plotted using optical density as the response variable and then used to interpolate test serum results. Nonspecific binding produced by the negative control serum should be subtracted from the replicate means for all points on the reference curve as well as each test serum.

Working Range, Sensitivity, Reproducibility, and Parallelism

The SPRIA and EIA are capable of measuring nanogram quantities of IgG antibody. The working range of the agarose-based

SPRIA spans from 10 to 2,000 ng of specific IgG per ml. While the theoretical sensitivity of the EIA is 1 ng of IgG per ml, the observed sensitivity typically ranges from 5 to 15 ng/ml, which is comparable to that of the SPRIA. Both the sensitivity and working range of these assays are dependent on the density of the antigen on the solid phase; the dilution and affinity of the detection antibody; the duration of the serum, conjugate, and substrate incubations; and the relative amount of specific antibody of other isotypes (e.g., IgE, IgA, and IgM) that compete for available solid-phase antigen epitopes. Parallelism between the reference and test serum dilution curves remains good over the working range of both assays, with interdilutional CV typically of <20%. The CV for within-experiment replicates averages typically 5%, and the CV for results between assays when all reagents remain constant should be 10 to 15%.

Quality Assurance

The most important region of the IgG SPRIA and EIA dose-response curves from a clinical point of view is the low portion of the working range. The minimum detectable concentration of the assay varies as a function of the negative serum subtraction and reporting methods used. Therefore, each assay should contain one or more positive and negative serum controls for each allergosorbent used in the assay, in addition to the reference serum dilution curve. All samples should be analyzed in duplicate to identify and minimize systematic (procedural) and random errors. At present, there are no external proficiency surveys for assays that monitor allergen-specific human IgG antibodies.

Interpretation

An IgG antibody measurement is commonly performed to document an exposure of an individual to an immunizing dose of antigen. In some cases, it can serve as an indicator of the effectiveness of various antigen doses used to induce a specific IgG antibody response in immunotherapy. In research applications, specific IgG antibody levels are used to quantitatively monitor the humoral immune response to an antigen to which a patient has been accidentally or intentionally exposed.

In the 1930s, allergen-specific IgG antibodies were identified as "blocking antibodies" that could block transfer of reaginic activity in the Prausnitz-Küstner reaction and basophil leukocyte histamine release assays. Presently, the only cited clinical application for IgG antibody measurements in the field of allergy is their use in the evaluation of hymenopteran venom-allergic patients who are initiating venom immunotherapy or who have been receiving maintenance injections for a number of years. In a 1992 study (5), 211 insect sting challenges were performed in 109 patients over a 4-year period to investigate the clinical significance of venom-specific IgG levels measured by the protein A SPRIA. In individuals on immunotherapy for less than 4 years, systemic symptoms occurred in only 1.6% of individuals with venom-specific IgG levels greater than 3.5 μg/ml but in 16% of individuals with levels lower than 3.5 μg/ml. The venom-specific IgG level had no predictive value for risk in patients who received therapy for more than 4 years. This study concluded that venom-specific IgG levels of <3.5 μg/ml are associated with an increased risk of allergic reactions upon a resting during the first 4 years of immunotherapy with yellow jacket or mixed vespid venoms. The observations described in other published studies of IgG antibody levels in patients receiving ragweed, grass, and dust mite immunotherapy have remained research observations that relate the antigen exposure to IgG (humoral) immune responses.

CONCLUDING THOUGHTS

In summary, the diagnostic allergy laboratory uses a number of immunoassay methods to measure IgE and IgG antibodies that aid the clinician in the diagnosis and management of individuals with allergic disease. At present, there are no molecular biology techniques explicitly used by allergy laboratories to facilitate the diagnosis of allergic disease. Recombinant-DNA technology to date has only been used in the generation of allergenic proteins that have become incorporated as reagents in some research-based microarray assays for IgE antibody (15). As more is learned about genetic polymorphisms that predispose individuals to allergic disease, molecular biology methods may also be employed in the diagnostic allergy laboratory of the future.

Assay Methods for Measurement of Mediators and Markers of Allergic Inflammation

JOHN T. SCHROEDER AND SARBJIT SAINI

108

With the discovery of immunoglobulin E (IgE) as the source of reaginic activity in serum, the release of histamine from leukocyte suspensions challenged with a specific antigen has been used as a reliable in vitro correlate of immediate hypersensitivity (5). Indeed, much of the knowledge obtained during the past 40 years concerning the detection and treatment of allergic disease has come from in vitro studies investigating the parameters, mechanisms, and pharmacologic control of the inflammatory mediators released from basophils and mast cells. Both of these cell types express the high-affinity receptor for IgE (FcεR1) and are responsible for the anaphylactic release of mediators in response to an allergen. However, basophils, by virtue of their accessibility and the fact that they are the sole source of histamine among the leukocytes in blood, continue to facilitate these studies to a greater extent than tissue-derived mast cells. Thus, an antigen (or anti-IgE antibody) that has the ability to bind and cross-link IgE-receptor complexes when simply added to a suspension of washed leukocytes in the presence of calcium is sufficient to trigger a complex cascade of signals within basophils, resulting in the release of preformed histamine and newly generated mediators.

Although histamine remains the most commonly measured mediator released following this IgE-mediated reaction, it is now well established that other mediators are also released from basophils and are important markers of allergic inflammation (see Fig. 1). The lipid mediator leukotriene C_4 (LTC4), which is derived from the metabolism of arachidonic acid, is secreted at concentrations nearly 100-fold lower (on a molar basis) than those of histamine. However, since LTC4 is some 100 to 6,000 times more potent in contracting smooth muscle than is histamine, it may be responsible for more of the symptoms of asthma and, therefore, has gained considerable attention in recent years. Clinical studies with antihistamines have not shown benefit for the treatment of asthma, but leukotriene receptor antagonists have shown efficacy, which supports the importance of LTC4 as a bronchoconstrictive agent. Cytokines represent a third class of mediators released from cells expressing FcεR1, but unlike histamine and LTC4, they are generated de novo (13). In particular, human basophils secrete high levels of interleukin-4 (IL-4) and IL-13—arguably the two most important cytokines in allergic disease given the primary role of these cytokines in regulating IgE synthesis from B cells. The importance of this response has only recently been appreciated,

with evidence that basophils in IL-4-transgenic mice are, indeed, a major source of this cytokine (9, 20). Therefore, it has been the objective of this chapter during the last two editions of this manual to focus on the laboratory procedures commonly performed for measuring the release of these inflammatory mediators, both in vitro and in biological fluids. However, rather than concentrating on those procedures that have changed little during the course of three decades, this chapter will focus on more recent approaches for measuring these mediators and will refer to previous editions when specific details are deemed necessary. In particular, this chapter will highlight the growing interest in the use of flow cytometry assays to monitor activation-linked markers (e.g., CD63, CD69, and CD203c) on basophils and the applicability of such assays as surrogate indicators of mediator release. Emphasis will also be given to those mediators that are not necessarily produced by basophils but that are commonly found in lavage fluids taken from sites of allergic inflammation. In particular, an update of the assays used for the detection of tryptase (a mast cell product) and major basic protein (MBP; a product of eosinophils) will be included in this discussion. Novel approaches regarding the potential use of exhalation condensates and measurements of nitric oxide (NO) in assessing the overall inflammation occurring during allergic reactions will be reviewed. Finally, although several technical advances have made these detection assays more applicable for clinical use, it is important that some of these methods remain time-consuming and are presently useful only in specialized clinical situations or for research purposes.

HISTAMINE

Laboratory Assays

While commercial assays for measuring histamine (see below) are becoming increasingly popular as a result of their not requiring specialized equipment, the automated fluorometric technique remains perhaps the most rapid, accurate, and sensitive way to measure histamine, particularly when there is a need for high throughput. Since the original development of this technique by Siraganian in the mid-1970s (19), it has become possible to analyze, with modern machines, as many as 45 to 60 samples per hour. The procedure is based on the extraction of histamine and its coupling

with ophthalaldehyde (OPT) at a highly alkaline pH to form a fluorescent product. Samples tested must be relatively free of protein and other interfering compounds, such as histidine. The machine achieves this extraction and coupling by first extracting histamine into *n*-butanol from a salt-saturated, alkalinized solution. In addition, before the condensation step with OPT, histamine is back extracted into an aqueous solution of diluted HCl by adding heptane. The histamine-OPT complex is stable at an acid pH, which increases the fluorescence intensity of the compound. The automated technique requires a sample volume of 0.6 to 1.0 ml and is capable of detecting histamine levels in the range of 0.5 to >100 ng/ml. Although the automated methodology for histamine measurement is preferable, similar results can be obtained manually with minor loss of sensitivity and precision. The assay is linear from 0.5 to 1,000 ng/ml. The advantage of automated fluorometry over other systems is its ability to rapidly process, with reproducibility and ease, a large quantity of samples. This is the method of choice, however, only when samples are obtained from studies using low-protein-concentration buffer systems such as that involving the in vitro release of histamine from basophil or mast cell cultures. It has also been useful for determining levels of histamine released at sites of experimental allergen challenge in the nose, lung, and skin by assaying fluids from lavages performed with normal saline. Fluorometric measurement of histamine in whole blood and in serum at concentrations greater than 10% requires extensive acid precipitation and/or dialysis to remove protein, cumbersome manipulations that lead to a loss of assay sensitivity.

The radioenzymatic assay (REA) has the advantage of detecting very low levels of histamine, with a sensitivity of approximately 10 pg/ml. Importantly, unlike the fluorometric method, the REA is not subject to interference from high protein levels, which makes it an excellent protocol for measuring plasma histamine levels. The assay involves the transfer of ^{3}H- or ^{14}C-labeled methyl groups from *S*-adenosylmethionine to histamine by using the enzyme histamine *N*-methyltransferase, which is commonly derived from crude extracts of rat kidney (Pel-Freez, Rogers, Ark.). The product, radiolabled methylhistamine, is extracted from the reaction mixture by using a solvent such as chloroform or toluene. This compound is then recovered into an aqueous solution by using NaOH saturated with NaCl. In addition to the standard curve generated with each assay, internal standards are often incorporated into the protocol by adding a trace amount of histamine (labeled with a second isotope or simply left unlabeled) to the unknown sample. The ratio of the counts obtained for the "spiked" sample to those obtained for the internal standard itself is proportional to the amount of histamine in the original sample. The REA has a narrower working range (50 pg/ml to 20 ng/ml) but is more sensitive than the fluorometric assay. The REA also has the advantage of requiring a small sample size (0.02 ml). However, since the assay is performed manually, it is relatively time-consuming and lacks the reproducibility achieved with the automated fluorometric system. Presently, one must also establish this assay in-house, since greater appeal of the enzyme-linked immunosorbent assay (ELISA) and the enzyme immunoassay (see below) have diminished the commercial availability of the REA.

The standards used in both the fluorometric assay and the REA are made from stock solutions prepared by accurately weighing an appropriate amount of histamine dihydrochloride (see Appendix). Standard solutions used for the fluorometric assay are stable at 4°C when the stock solution

is diluted in water containing 2% $HClO_4$. The standards used in the REA are prepared fresh by diluting the stock in the diluent best representing the samples to be tested but in the absence of $HClO_4$, which interferes with the histamine *N*-methyltransferase used in the assay.

Commercial Histamine Assays

An enzyme immunoassay and an ELISA are offered by Cayman Chemicals and Immuno-Biological Laboratories, respectively, for the detection of histamine in a variety of biological specimens, including culture supernatant, urine, and plasma. As the REA, these assays have the advantage of needing relatively small sample volumes (e.g., 0.050 to 0.100 ml), are less bothered by high-protein contamination than automated fluorometry, and are cost-effective for low-throughput needs. On the other hand, their use remains somewhat limited and they should be evaluated for sensitivity and specificity prior to application.

Clinical Indications for Measuring In Vitro Histamine Release from Basophils

Measuring the release of histamine from basophil leukocytes in vitro continues to serve as a valuable test for evaluating IgE-mediated reactions. In fact, the indications for the use of this method are, at this time, more extensive than those for any other test described in this chapter. Yet because the parameters involved in the histamine release assay have been extensively described in previous editions of this book, they will be only briefly mentioned here. Some of its more common uses are outlined below.

Evaluation of Allergic Status

It was noted some 40 years ago that there is good correlation between the level of histamine released from basophils in response to allergens (e.g., antigen E, or Amb a I, and Fel d1, etc.) and the severity of clinical symptoms suffered by individuals who are allergic to these allergens (7). In fact, studies show that allergen sensitivity is related to the levels of specific IgE in serum, with very low concentrations of an allergen often causing histamine release from basophils in vitro when allergen-specific IgE antibody levels are high. As a result, the release of histamine from basophils in vitro can serve as a dependable and precise indicator of the allergic status of an individual, with few false positives compared to skin-testing techniques. However, a caveat is that the presence of allergen-specific IgE is not sufficient and must be combined with the clinical history to indicate the presence of disease given the widespread prevalence of IgE specific to insect venoms, latex, and food allergens. Also, since many dilutions of an antigen can be readily tested for reactivity, the histamine release assay can be more quantitative than skin testing, which often relies on a somewhat less precise endpoint. Most important, basophil analyses can be performed safely using "crude" allergens and products not yet approved for in vivo use. However, any clinical applicability is limited to a positive assay result, since in vitro histamine release from basophils does not necessarily predict a negative skin test reaction. Due to the complexities of the assay, direct measures of specific IgE rather than histamine release are more commonly used in clinical practice (see chapter 107, this volume).

Demonstration of IgE Antibody Activity

Measuring the release of histamine from normal donor leukocyte suspensions passively sensitized with IgE is a useful technique for detecting allergen-specific antibody in the

sera (or plasma) of patients presenting with clinical symptoms (6). In fact, the histamine release assay has some advantages over the more commonly used radioallergosorbent test (RAST) in the detection of allergen-specific IgE. First, it gives a quick and precise assessment of whether serum contains biologically active IgE. The RAST, although more easily standardized, simply quantifies the amount of allergen-specific IgE that is in serum. Second, very little antigen is required to induce histamine release from passively sensitized basophils. In contrast, the RAST requires relatively large quantities of pure allergen in order to successfully couple the allergen to an insoluble matrix for subsequent binding of allergen-specific IgE. Third, the basophil histamine release assay is excellent for studies investigating, by direct analysis and after passive sensitization, whether a patient has become sensitized to an uncommon allergen for which a RAST is not available. Naturally, a disadvantage of these assays is their requirement for a fair amount of fresh leukocytes from a nonallergic subject whose cells can withstand the rigors of passive sensitization (see below) and retain responsiveness. In this respect, the histamine release assay is at a disadvantage to the RAST, which is technically far less challenging. In addition, there is the potential for serum to contain priming factors (homologous restriction factor and IL-3, etc.) that can trigger the recipient basophils in a nonspecific fashion, even though proof of this has yet to emerge.

Quality Control of Prepared Allergens

It is often desirable to check the quality of allergens, whether commercially prepared or made in-house, by testing their ability to induce histamine release from leukocytes obtained from allergic donors. This is becoming particularly useful for immunotherapy studies for which modified allergens can be evaluated for biological activity or cross-reactivity prior to testing in vivo.

Alternative for Skin Testing

In some instances, it is desirable to avoid skin testing and to use the in vitro basophil histamine release assay as an alternative approach for evaluating allergic status. However, given the prevalence of RAST, this particular indication is rarely practiced.

Test Procedures

Induction of Histamine Release from Washed Human Leukocytes: General Method

While there are presently many variations of the protocol originally described for inducing histamine release from basophils in vitro, these relate primarily to the method used for histamine analysis. Otherwise, little has changed during the past 40 years since its first description. The reader is therefore directed to previous editions of this book for specific details, as this section will emphasize only certain aspects of the assay. Also, the techniques described herein are, for the most part, used when histamine is analyzed by automated fluorometry.

Blood is drawn into a plastic syringe, preferably by using a butterfly infusion set with the needle size reflecting the desired volume required for the assay. Usually 1 ml of blood per reaction tube will provide total histamine levels of approximately 20 ng, with some variation occurring among donors. Dextran sedimentation remains the method of choice for preparing washed leukocytes for histamine release, as it requires little technical expertise and is the least

manipulative toward the cells. These issues are necessary to consider when both preparation time and retention of cell function are of greatest importance. In this instance, whole blood is immediately transferred into disposable 50-ml polypropylene centrifuge tubes (catalog no. 25330; Corning Incorporated, Corning, N.Y.) each containing 12.5 ml of dextran, 5.0 ml of 0.1 M EDTA, and 375 mg of dextrose, which allows proper mixing for up to 20 ml of blood. After sitting for 60 to 90 min at room temperature (23 to 25°C), the leukocyte-rich plasma layer is carefully removed and centrifuged and the cell pellet is washed two to three times in PIPES [piperazine-N,N'-bis(2-ethanesulfonic acid)]-albumin-glucose (PAG) buffer (see Appendix) to remove platelets. It is sometimes useful to do one or more washes in PAG containing EDTA ($\sim$4 mM), since this reagent chelates calcium and prevents platelet clumping. However, it is important that the final wash be done in the absence of EDTA, since histamine release requires calcium and residual EDTA may prevent the reaction cascade. After the final wash, the cell pellet is resuspended in PAG buffer containing 1 mM $CaCl_2$ and 1 mM $MgCl_2$ (PAGCM) to a volume sufficient to allow the addition of the required amount of cells to each reaction tube as per the protocol. Histamine release can be induced in almost any variety of test tube, but total reaction volumes usually range from 0.1 to 1.0 ml. The washed leukocytes in PAGCM and the reaction tubes are then warmed separately in a 37°C water bath before mixing with one another. The total histamine content (called "completes") is obtained by the lysis of cells in a duplicate set of reaction tubes using perchloric acid at a final concentration of 1.6%. The amount of histamine released spontaneously (usually less than 5% of the total) is determined by incubating cells in buffer alone. Reactions are allowed to proceed at 37°C for 30 to 45 min, at which time buffer is added to a 1-ml total volume, the cells are centrifuged, and the cell-free supernatants are decanted into 2-ml autoanalyzer cups (Sarstedt, Inc., Princeton, N.J.; catalog no. 73.641) and stored at 4°C in plastic racks (Elkay Products Inc., Shrewsbury, Mass.). To prevent evaporation, samples should be frozen at −20°C if histamine cannot be analyzed within 2 weeks.

Any samples requiring added protein during the reaction may require acid precipitation in order to prevent interference with histamine measurements using the automated fluorometric technique. In such instances, much of the protein can be precipitated prior to analysis by adding perchloric acid to the cell-free supernatant at a final concentration of 1.6%, incubating overnight at 4°C, and recentrifuging prior to analysis. Alternatively, histamine can be measured using either the REA or ELISA.

Inhibition of Histamine Release from Basophils

As a modification of the standard assay, the inhibition of histamine release from basophils can be useful in testing whether a patient's serum contains an antigen-neutralizing blocking antibody. This assay has been used to monitor patients receiving allergen immunotherapy, since this treatment causes an increase in allergen-specific IgG antibodies (1). However, the assay has largely been replaced by radioimmunoassays (RIAs) and REAs, which both directly measure specific IgG antibody. In brief, the protocol involves the use of a reference donor (or donors) whose basophils are known to release high levels (>70%) of histamine in response to an antigen. The patient's serum or normal (type AB) serum (at $\sim$10% final concentration) is then mixed with a dose of an antigen that will cause approximately half of the maximal histamine release from the

reference cells. After preincubating for up to 60 min at 37°C, washed leukocytes are added for an additional 45-min incubation, with the cell-free supernatants then collected for histamine analysis as described above.

Although its clinical utility is somewhat limited, the inhibition of in vitro histamine release is often used to determine the effectiveness of pharmacologic agents. This test also involves a modification of the standard release assay but differs slightly from that used in measuring IgG antibodies. In brief, washed leukocytes are mixed with PAGCM alone or with several concentrations of the drug diluted in buffer. Final drug concentrations of 10^{-4} M to 10^{-6} M are useful for initial screening. After preincubation (usually for 10 to 15 min) at 37°C, several concentrations of an antigen (or anti-IgE antibody) are added for an additional 45 min for the induction of histamine release. Once again, it is best to use stimulus concentrations that normally cause approximately half of the maximal histamine release. In addition to the usual controls (completes and blanks), it is important to include cells incubated with the drugs alone to assess any lytic effects of the drugs, as well as drugs diluted in buffer (no cells) to control for fluorescent compounds if the OPT-based assay is used.

Passive Sensitization of Basophils

The basophils isolated from some donors express sufficient numbers of unoccupied IgE FcεR1 sites to enable these cells to be passively sensitized with IgE antibody from an unrelated source. Thus, the serum or plasma of an allergic individual can be tested for antigen-reactive IgE antibodies by sensitizing the basophils of a nonallergic donor and inducing histamine release from these cells by using the antigen in question. The success of studies using this technique requires the use of nonallergic donors whose basophils normally release well in response to IgE-dependent stimulation and whose cells have naturally unoccupied IgE FcεR1 sites that can be passively sensitized with IgE antibody. Since only an estimated 1 out of 20 nonallergic individuals has basophils that meet these criteria, lactic acid is often used to remove endogenous basophil-bound IgE, thereby increasing one's ability to passively sensitize cells. In fact, the details of performing this procedure are outlined elsewhere (11) and are also described in previous editions of this chapter. As a result, it seems appropriate to note here only a few considerations, since the reader can refer to the above-mentioned references for specific information. First, these assays are best done using mixed leukocytes prepared by sedimentation and must use cells from a donor whose basophils respond to IgE-mediated stimulation. The lactic acid solution (pH 3.9) works best when fresh and can be used either at room temperature (25°C) or on ice (4°C) for up to 5 min. Cells are then immediately washed to remove unbound IgE before passive sensitization (30 min at 37°C) with an appropriate dilution of patient serum in PAG containing 10 U of heparin/ml and 4 mM EDTA. An important negative control includes acid-treated cells sensitized with an equal amount of irrelevant IgE in control serum. It is also important to leave a portion of cells untreated with acid solution in order to control for any effect this treatment may have on basophil responsiveness. After washing twice in PAG buffer, the leukocytes are tested for histamine release by using identical test conditions. The antigen-induced release of histamine by leukocytes passively sensitized with the patient's serum, but not with control serum, indicates positivity. Of course, non-passively sensitized cells should not react with the antigen, while cells subjected to all conditions of passive

sensitization should still respond to anti-IgE used as a positive control.

LIPID MEDIATORS

LTC4

The secretion of LTC4 by basophils and mast cells is also rapid, nearly paralleling the release of histamine, and is essentially complete by 30 min after activation. IL-3 has been shown to enhance the levels of LTC4 generated by basophils in response to IgE-dependent activation by nearly 100-fold, and following IL-3 priming, release of LTC4 occurs with stimulation by C5a, a secretagogue that alone does not normally cause the release of this mediator. Essentially no release of prostaglandins from basophils occurs in response to activation, indicating that cyclooxygenase enzyme activity is not prominent in these cells. However, all human mast cells studied to date do produce prostaglandin D_2 (PGD2) and lung and mucosal cells secrete levels of LTC4 nearly identical to those secreted by basophils but usually only in response to IgE-dependent stimuli.

The assays for LTC4 are, most commonly, competitive RIAs. Briefly, ^{3}H labeling is added to all sample tubes and to unlabeled LTC4 standards. This step is followed by the addition of a limiting quantity of anti-LTC4 antibody (usually polyclonal in origin) sufficient to bind all of the ^{3}H-labeled LTC4. The standards or unknowns containing LTC4 compete with radiolabeled LTC4 for antibody binding sites, and the antigen-antibody complexes formed in this reaction are then precipitated and removed by activated charcoal, thus leaving unbound ^{3}H-labeled LTC4. As the levels of sample LTC4 increase, less radioactive label is bound to the antibody, leading to higher remaining radioactivity. The levels of LTC4 are then measured by comparing the radioactivity in the unknown samples to that in the standard curve. With most RIAs, picogram quantities of LTC4 can be accurately measured with a range of <10 pg/ml to 100 ng/ml. RIAs are quite reliable for use with buffer systems. However, the signal-to-noise ratio for serum and other biological fluids (e.g., nasal and bronchial lavage and skin blister fluids) makes the measurement of LTC4 difficult and less quantitative. The ^{3}H-labeled LTC4 standards used in this assay were prepared from commercially available stock solutions (New England Nuclear Corp.).

ELISA kits that measure LTC4 using a competitive immunoassay approach are also commercially available (Assay Designs and Cayman Chemicals) and have the advantage of being free of radioactive isotopes. These assays are also generally quite sensitive (~50 pg/ml), showing only slight cross-reactivity with LTD4 and LTE4.

Clinical Indications

Evaluation of Allergic Status

LTC4 is generated from several cell types, including monocytes and eosinophils. However, the formation and secretion of this mediator from washed leukocytes can serve as an in vitro test of allergic status, since the basophil is the only cell in these preparations that responds to IgE-mediated stimulation. In practice, however, since histamine is released in parallel with LTC4 and the assays for it are less cumbersome and more reliable, histamine is more often used as an index of allergen sensitivity. Nonetheless, measurements of LTC4 in biological specimens may be useful in assessing the

inhibitory actions of the 5-lipoxygenase inhibitors, which do not affect histamine release.

Test Procedures

Washed leukocytes are prepared from peripheral blood using dextran sedimentation as described above for histamine release from basophils; LTC4 and histamine release are assessed simultaneously. However, the reactions are done in a total volume of 0.1 ml in PAGCM buffer. PAG buffer (0.2 ml) is added to all tubes at the end of the reaction, and after centrifugation, a portion of the supernatant (0.1 ml) is carefully removed for LTC4 analysis. An additional 0.5 to 0.8 ml of PAG buffer is then added to the reaction tubes, and following recentrifugation, the supernatant is obtained for histamine analysis by automated fluorometry as described above. By measuring the release of these two mediators from the same aliquot of cells, the LTC4 levels can be normalized to the amount of histamine released (i.e., picograms of LTC4 per nanograms of histamine).

CYTOKINE GENERATION BY BASOPHILS

Much effort during the past 30 years has been directed at understanding the stimuli, activation and desensitization mechanisms, and pharmacologic control of histamine release and LTC4 generation by basophils. During the past decade, there has emerged solid evidence that human basophils are the predominant source of IL-4 (and likely IL-13) among the cells circulating in blood and they appear to constitute a significant source of these cytokines among the cells infiltrating allergic lesions (10, 14). Both IL-4 and IL-13 promote IgE production from B lymphocytes and activate the endothelium for the selective adherence and transendothelial migration of eosinophils. IL-4 is also the only cytokine known to direct the conversion of Th1 lymphocytes into the Th2 phenotype, with concomitant changes in cytokine profiles. The parameters important for the generation of these cytokines in basophils indicate that both proteins, much like histamine, are important correlates of immediate hypersensitivity (15). In fact, both IL-4 and IL-13 are secreted following IgE cross-linking, and the concentration of a stimulus required for optimal release is nearly 10-fold less than that necessary for histamine release. This is particularly true for cells stimulated by anti-IgE antibody, but it is also found with activation by an antigen. IL-4 protein levels peak after 4 to 6 h of activation, with IL-13 secretion being somewhat slower, beginning at ~4 h and peaking after some 20 h of incubation (Fig. 1). The generation of both cytokines is inhibited by the addition of cycloheximide, suggesting that their production occurs de novo and that neither is stored and released during degranulation or produced minutes following stimulation, as is true for histamine and LTC4.

Clinical Indications for Measuring In Vitro Basophil IL-4 and IL-13 Secretion

At the time the previous edition of this book was published, the clinical indications for measuring IL-4 and IL-13 appeared to be the same as those described for measuring histamine release from basophils. This remains true in that these cytokines show increased sensitivity to IgE-mediated stimulation and are somewhat specific for this type of activation: IgE-independent secretagogues, including C5a and N-formyl-methionyl-leucyl phenylalanine (FMLP), which are potent stimuli for histamine release, do not normally induce IL-4 and IL-13. However, in recent studies comparing cells from allergic and nonallergic subjects, greater levels of IL-13
FIGURE 1 Diagrammatic representation of the time course for histamine, LTC4, and IL-4 and IL-13 protein release by human basophils following IgE-dependent activation. Both preformed histamine and newly generated LTC4 are released within minutes after stimulation. The generation of IL-4 and IL-13 is thought to occur de novo, with protein detectable only after 1 to 2 h for IL-4 and after 4 h for IL-13, following stimulation.

were secreted by cells of the latter group in response to specific non-IgE-dependent stimuli. For instance, it has been found that cells from allergic subjects secrete three to seven times more IL-13 following direct stimulation with IL-3 and/or nerve growth factor than cells from nonallergic subjects (18). Moreover, there is recent evidence that IL-13 is spontaneously produced in vitro from basophils of allergic subjects repeatedly exposed to allergen via nasal challenge (12). Overall, these findings suggest a novel indication for measuring basophil secretion of cytokines (particularly IL-13), since these cytokines are observed in the absence of mediator (histamine) release, and may also be indicative of underlying systemic Th2-like responses occurring as a result of allergen exposure. Nonetheless, the clinical applicability of measuring IL-4 and IL-13 remains less than that of measuring histamine, since measuring IL-4 and IL-13 is time-consuming and requires multiple assay systems.

IL-4 and IL-13 Protein: Methods of Cytokine Detection

As that of many other cytokines, the measurement of IL-4 and IL-13 protein most often employs an ELISA. Many sources of commercial kits now exist, and some assays have sensitivities of 1 pg/ml to 1 ng/ml. Alternatively, the development of in-house ELISAs is economically desirable if the appropriately matched antibody pairs for the cytokine of interest are available. With respect to IL-4 and IL-13, several companies now offer such antibody combinations for use in developing in-house assays. Since there are protocols described elsewhere in this manual that are devoted to ELISA design, specific details will not be belabored here other than to make some general comments. First, when quantifying IL-4 and IL-13 protein by ELISA (as with any protein ELISA), there are potential problems that may arise with interassay variation. This is particularly true since many assays, including commercially available kits, are supplied with standards that are likely to give different results among assays. It is important, therefore, to calibrate in-house standards against a variety of other available standards, ideally those set by World Health Organization specifications. In addition, it is important to store IL-4 and IL-13 stock solutions in working aliquots frozen at $-20°C$ or below, since protein degradation may occur at $4°C$ or with repeated freezing and thawing.

While ELISAs detect secreted protein, it has become increasingly popular to monitor cytokine generation at the single-cell level by using multicolor flow cytometry. The technique requires the inclusion of a protein transport inhibitor, such as brefeldin A or monensin, which is added to cell cultures during stimulation to prevent the secretion of cytokines from activated cells. Intracellular cytokines are subsequently detected in paraformaldehyde-fixed, detergent-permeabilized cells using fluorescence-conjugated antibodies. With the use of a two-color staining protocol, it was recently shown that basophils account for most of the IL-4 and IL-13 produced in peripheral blood mononuclear cell suspensions following in vitro stimulation with an allergen (3). While multicolor flow cytometry has significant potential as an analytical technique for monitoring cytokine generation in specific cell types, particularly those found in low frequencies, its success depends on antibodies that are compatible with fixation and permeabilization. Fixation with paraformaldehyde (4%) is usually necessary to maintain cell integrity for permeabilization with detergent (e.g., saponin, 0.1%), which allows intracellular access by fluorescence-conjugated antibodies. These procedures, however, can often affect antigenic binding sites, making cytokines unrecognizable by antibodies (particularly those monoclonal in nature) that would ordinarily detect native protein. When antibodies do stain, it is important to establish specificity by performing neutralization experiments with unlabeled antibody. In fact, there are presently many commercially available anticytokine monoclonal antibodies directly conjugated with a variety of fluorochromes that have been subjected to such testing and appear to be suitable for multicolor flow cytometry.

Preparation of Basophil Suspensions for Cytokine and/or Mediator Release

Enriched Suspensions

Basophil-enriched suspensions are prepared by density centrifugation on isotonic Percoll gradients to allow simultaneous assessment of cytokine secretion and histamine release (15). For IL-4 and IL-13 production, 5 ml of blood per reaction tube, approximately five times the amount required for histamine release, is anticoagulated with 10 mM EDTA. The plasma layer, obtained following centrifugation ($300 \times g$; 15 min; $24°C$), is aspirated without disturbing the leukocyte interface (buffy coat). The buffy coat interface is removed and transferred to a tube containing an equal volume of PAG-EDTA buffer (approximately 20 ml of buffy coat per 50 ml of whole blood). Diluted buffy coat (20 ml) is then layered onto gradients consisting of 12.5 ml of 55% isotonic Percoll (approximate density, 1.072 g/ml) underlaid with 12.5 ml of 61% isotonic Percoll ($d \approx 1.082$ g/ml), as illustrated in Fig. 2. Note that an alternative to performing this "double Percoll" approach is the simple use of the 61% Percoll solution for a "single Percoll" protocol. While this typically results in a basophil purity of less than 3%, it adequately removes excessive red cells, producing a leukocyte suspension suitable for investigating cytokine expression by flow cytometry. In any case, the gradients are centrifuged ($700 \times g$; 20 min; $24°C$). The cells banding at the 55% Percoll interface and penetrating the top half of this layer are removed and discarded. Basophils are present in the fraction consisting of the lower half of the 55% Percoll layer, the 61% interface, and the upper half of this layer. These leukocytes are immediately transferred into clean tubes containing 35 ml of PAG-EDTA buffer and centrifuged ($150 \times g$; 10 min; $24°C$). After combining and transferring the cells into 15-ml polypropylene tubes, the cells are washed twice in cold PAG (6 to 10 ml per wash). The mean percentage of basophils found in these fractions ranges from 5 to 50% (using the double Percoll approach), as determined by cell counts in Spiers-Levy chambers using alcian blue (4).

Mixed Leukocyte Preparations

Yet another alternative is simply to use washed leukocytes obtained from dextran sedimentation. In fact, the availability of ultrasensitive ELISAs allows the measurement of IgE-mediated IL-4 secretion by using the same preparation technique and number of basophils ($\sim$20,000) as those used for histamine release. Note, however, that this protocol does not allow the simultaneous analysis of the histamine released into the culture supernatant, since the entire supernatant volume is needed for the IL-4 measurement. Furthermore, it is important not to culture the total number of cells at an excessively high density ($\sim$20 × 10^6 cells/ml), which is thought to decrease somewhat the ability to detect any cytokine secreted. Rather than depending on ELISA methodology for detecting secreted protein, protocols for
FIGURE 2 Diagrammatic representation of preparation of peripheral blood basophils by discontinuous Percoll density centrifugation. Leukocyte interface cells (buffy coat) are prepared from whole blood by centrifugation. Diluted buffy-coat cell suspensions are layered onto buffered isotonic gradients consisting of two Percoll densities (d) of 1.072 and 1.082 g/ml. Following centrifugation ($700 \times g$, 20 min, at 24°C), basophils band on the 1.082-g/ml Percoll interface and range from 5 to 50% purity. v/v, vol/vol.

detecting intracellular cytokines may be more appropriate when cells prepared in this manner are used. The rationale is that any cytokine retained in the cell, and under conditions of chemical fixation, is more likely to be absorbed or metabolized by contaminating cells in crowded cell cultures.

Culture Procedure

For cytokine protein secretion from basophils, leukocytes obtained directly or from Percoll gradients are resuspended in a culture medium such as Iscove's modified Dulbecco's medium, pH 7.4, supplemented with 5% heat-inactivated (56°C for 30 min) fetal bovine serum, nonessential amino acids, and 5 μg of gentamicin per ml (C-IMDM). For simultaneous analysis of histamine release and IL-4 protein secretion, basophil-enriched suspensions are prepared on Percoll gradients, and 100,000 to 200,000 basophils, accurately enumerated by counting of alcian blue-stained cells, are added per well in a 96-well microtiter plate. The cells are added in 125 μl of C-IMDM and are brought to 37°C in a CO_2 incubator (5% CO_2), after which 125 μl of C-IMDM with or without a stimulus (e.g., a specific antigen) at 37°C is added for a 4-h incubation. The cultures are then centrifuged, and the cell-free supernatants are collected for analysis. A portion of the supernatant is obtained for histamine measurement by carefully removing the upper 25 to 50 μl of supernatant and adding this to 1 ml of PAG buffer containing 1.6% $HClO_4$. After precipitation of protein overnight at 4°C, the histamine in the samples is measured by automated fluorometry or by other methods. Histamine release is reported as a percentage of the total histamine, which is measured by taking a portion of the starting leukocyte suspension, containing a number of basophils proportional to the amount of supernatant used for analysis, for direct lysis in 1 ml of acid solution. The supernatant remaining is then collected for IL-4 protein analysis by ELISA.

As noted, the conditions necessary for IgE-dependent secretion of IL-13 are essentially the same as those important for secretion of IL-4, with the only difference being that detection of the former cytokine requires an 8- to 20-h incubation.

Thus, the protocol described above for IL-4 also applies to IL-13 secretion with the exception that longer incubation times are required.

NOVEL NON-IgE STIMULI OF BASOPHILS

Recently, there has been great interest in the role innate immunity plays in directing the course of acquired immunity, including that associated with allergic disease. At the core of this attention are the Toll-like receptors (TLRs), their expression on various immune cells (particularly antigen-presenting cells), and the cellular responses resulting from the binding of their putative ligands. For instance, basophils are now reported to express several of the 11 known TLRs, including TLR1, 2, 4, 6, 8, 9, and 10. There is also mounting evidence that specific ligands for these receptors can either augment or suppress both mediator release and cytokine secretion by these basophils (and mast cells). For example, TLR2 ligands (such as the peptidoglycan derived from the cell wall of gram-positive bacteria) will directly induce IL-4 and IL-13 from basophils and are capable of augmenting IgE-dependent secretion of all mediator classes (histamine, LTC4, and cytokines) as well as IgE-independent secretion of IL-13 (2). While the significance of these findings pertains more, at this time, to the pathogenesis of allergic disease itself, they do raise potential issues with regard to the tests described above. For instance, it is not uncommon for allergen preparations to be contaminated with microbial products (e.g., endotoxin), and such contamination may become even more of a problem as recombinant allergens are developed for use in skin testing and immunotherapy. Thus, it is reasonable to believe that products containing endotoxin could affect basophil function as well as any interpretations arising from assay results.

BASOPHIL SURFACE ACTIVATION MARKERS

Several groups have reported the use of select surface markers readily measured by flow cytometry as another means to detect basophil activation, particularly via the IgE receptor.

Specifically, CD63, CD69, and CD203c have been put forward as surface markers that are sensitive to basophil activation after exposure to an allergen (CD63 and CD203c), exposure to IL-3 (CD69), or exposure to other degranulation stimuli such as FMLP and ionophores. The use of these activation markers as part of diagnostic evaluation of the presence of allergic reaction-specific IgE, such as in the case of venom allergy, has been reported, and limited evidence suggests specificity in the pattern and degree of basophil activation. However, several questions remain as to the specificity of these markers for diagnostic testing with specific allergens. As apparent from basophil histamine release assays, a broad range of allergen doses must be utilized to allow the use of these tests across a given population. Access to sufficient blood basophils for each individual allergen to be tested must be considered, as well as the potential that nearly 1 in 20 subjects may have nonresponding basophils, which may hamper the ability to interpret the results. In addition, there is some controversy about the preferred surface marker or the use of a panel of all three markers and the potential for the kinetics for each individual marker to shift. Given the number of issues, the application of these markers as an in vitro diagnostic tool remains to be seen.

Although it is accepted that CD69 is the marker on basophils that is most sensitive to prolonged IL-3 exposure, several additional factors must be considered. The use of whole blood for assay of these surface markers is quite popular; however, the conditions used for the lysis of contaminating red cells may also deliver an activation stimulus to the basophils. Other isolation strategies such as Percoll isolation may be desirable, but negative selection procedures for highly purified basophil preparation may evoke nonspecific basophil activation due to prolonged handling of basophils. In addition, controls to monitor for false signals from other cell types that bear CD69 and CD63, such as adherent platelets, must be considered in assays. Although some studies have shown expression of activation markers in parallel with histamine release from basophils, at least one study has shown discordance between the elevation of activation marker expression and basophil histamine release in response to a polyclonal anti-IgE stimulus (8). Thus, the potential for these surface markers to become an adjunct or surrogate to other diagnostic tests such as mediator detection awaits the development of rigorous standards and procedures.

NON-BASOPHIL-SECRETED MEDIATORS AND MARKERS

Tryptase

Tryptase is a neutral protease with trypsin-like substrate specificity that is found in relatively large quantities in mast cells (~10 pg per lung mast cell and up to l35 pg per skin mast cell), where it is most commonly stored in the secretory granules as an active enzyme complexed to, and stabilized by, heparin. Although several forms have been described (I, IIβ, III, α, and transmembrane tryptase) and all are found in mast cells, only the β and, less frequently, α species are clinically relevant. Since negligible amounts are found in basophils (0.04 pg per cell), tryptase is considered to be a specific marker of mast cell activation. Although tryptase is generally accepted as a mediator of immediate hypersensitivity, its biological role is not known. However, several in vitro activities of tryptase, such as its ability to sensitize smooth muscle to histamine and to stimulate fibroblast proliferation, have suggested a direct role for this enzyme in conditions ranging from asthma to wound healing.

Clinical Indications: Assessment of In Vivo Mast Cell Activation

Unlike that of histamine release from basophils, measurement of tryptase release as a routine in vitro correlate of immediate hypersensitivity is not practical, since this requires preparation of tissue mast cells from human subjects. However, the ability to readily detect tryptase in many types of biological specimens, such as serum, bronchial lavage fluid, nasal lavage fluid, skin blister fluid, and tears, has made this enzyme a valuable marker of in vivo mast cell activation. Thus, in conjunction with histamine measurements, the detection of tryptase is useful in determining the involvement of mast cells in immediate allergic responses occurring in many different reaction sites. Like histamine, β-tryptase is released from mast cells within 15 min following in vitro degranulation and is the predominant form detected in the serum 1 to 2 h following anaphylaxis. However, since α-tryptase is spontaneously secreted from mast cells and often elevated in mastocytosis patients during mast cell burden, quantifying ratios of α and β forms in serum provides the best indication of mast cell activation (16).

Test Procedures for Detection of Tryptase

Several laboratories have developed antibodies against purified human pulmonary mast cell tryptase, enabling the specific detection of this protein in a variety of biological fluids. The measurements are most often performed by ELISA, utilizing an anti-lung tryptase antibody as the primary antibody and biotinylated secondary antibodies in a two-site immunoenzymatic assay, much like that described above for IL-4 protein measurements. Polyclonal antibodies are also useful for detecting tryptase by RIA, although nonspecific binding and protein interference are often problematic. Human lung mast cell tryptase is often used as a source of standards in both the ELISA and RIA techniques and requires extensive purification protocols. While at least one company (Promega) offers recombinant tryptase, its usefulness as a standard has not been fully determined. It is now possible to measure tryptase using the commercially available ImmunoCAP assay (Pharmacia, Uppsala, Sweden), which is designed as a sandwich immunoassay involving a cellulose-derivative solid-phase component. The assay is reported to be suitable for serum or nasal lavage specimens collected between 15 min and 3 h after mast cell activation.

PGD2

Cyclooxygenase enzyme activity is prevalent in mast cells, since the proinflammatory mediator PGD2 is released from these cells (~60 ng/10^6 cells) upon activation. In contrast, as mentioned above, basophils do not produce PGD2, making this prostanoid a specific marker of IgE-mediated mast cell activation. PGD2 is also a proinflammatory mediator, capable of causing bronchoconstriction, dilation, and increased permeability of the microvasculature. Recent studies indicate that PGD2 is an important chemoattractant, selectively recruiting cells expressing its receptor, CRTH2, including basophils and Th2 cells. Unlike assays for LTC4, PGD2 assays should be performed as quickly as possible, especially when skin mast cells are involved, since this mediator is susceptible to degradation even when stored at −20°C. PGD2 is most often measured using a competitive RIA, either a commercially available or an in-house assay.

Because of the technical problems observed, especially with high-protein-concentration fluids, some laboratories have developed gas chromatographic technology, which is considered the method of choice for detection of prostanoids in biologic fluids. The addition of tetradeuterated standards overcomes problems of differential degradation, and chromatography of samples using Sep-Pak columns removes interfering proteins and other substances in biologic matrices. PGD2 is not regularly analyzed as a mediator of allergic inflammation, since tryptase is more readily detected in the same biological specimens and is generally accepted as a more specific marker of mast cell activation (see below).

MBP and ECP

No cell type shows more striking infiltration into allergic lesions than the eosinophil. In fact, patients with mild to moderate asthma often have blood eosinophilia that correlates with the severity of disease, and activated eosinophils have been demonstrated to be present in bronchial biopsy specimens and in the lavage fluids taken from reaction sites in the lung. Eosinophils contain many granule-associated proteins that are thought to be responsible for much of the tissue destruction occurring in diseases such as asthma. In particular, both MBP and eosinophil cationic protein (ECP) account for a large portion of the protein found in the cytoplasmic granules of eosinophils, and both are released upon activation. Both are rich in arginine residues, making them very basic proteins that are highly toxic to host cells, particularly those of the tracheal epithelium. MBP is also known to activate basophils, mast cells, and neutrophils, causing mediator release from these cells, which can contribute to the overall response. MBP is found at relatively high concentrations in eosinophils, averaging nearly 5 $\mu g/10^6$ cells in normal donors. Although low levels of this protein are found in basophils (<1 $\mu g/10^6$ cells), this is thought to be an artifact, resulting from internalization of MBP by these cells.

Clinical Indications: Assessment of Eosinophil Activation

Since MBP and ECP are often detected in a variety of biological specimens, including serum, sputum, and lavage fluid collected from a variety of reaction sites, they are becoming recognized as important in vivo correlates of eosinophil activation. In fact, increased levels of these proteins in these biological specimens show a strong correlation with the severity of clinical symptoms in asthma and rhinitis, particularly as they relate to decreased airway function. In vitro studies investigating the release of MBP and ECP from highly enriched eosinophil suspensions prepared from peripheral blood have also been useful in elucidating the mechanisms of eosinophil activation.

Test Procedures for Detecting MBP and ECP

MBP is most commonly measured by competitive RIA using polyclonal anti-MBP antibody and radiolabeled MBP. The technique, therefore, is similar to the procedure outlined above for the RIA used in the measurement of LTC4 but remains specialized in that antibodies to MBP are usually made in-house. At least one company (HyTest, Oy, Finland) now offers a rabbit polyclonal antibody reportedly suitable for the detection of human pro-MBP by either ELISA or Western blotting. Serum ECP levels can now be determined using the commercially available ImmunoCAP assay (Pharmacia) much as noted for measuring tryptase. However, the success of the assay is very much dependent on specimen preparation, as collection tubes, coagulation time,

and temperature will all affect the levels measured in serum samples.

NO

Many studies show that increased levels of exhaled NO are associated with airway inflammation, particularly that transpiring in allergic disease (17). Several nitric oxide synthases (NOS) have a role in the production of NO from many substrate species found in the lung (e.g., O_2, NADPH, and L-arginine). Endothelial cell membrane-associated NOS (type III) is constitutively expressed and is primarily responsible for NO generated in response to shear stresses in the systemic and pulmonary circulation. Neuronal NOS (type I) has a role in neurotransmission and is also constitutively expressed. Thus, both the type I and III forms mediate physiologic functions. In contrast, inducible NOS (iNOS, or type II) is the form associated with inflammation, and although it is expressed in many cell types, its expression is markedly increased in the bronchial epithelia of asthmatics. Allergen challenge, in fact, will induce epithelial expression of iNOS, resulting in increased production of NO. More recently, it has been shown that IL-1, tumor necrosis factor alpha, and IL-4, when combined with gamma interferon, can upregulate iNOS expression in epithelial cell lines, suggesting a role for proinflammatory cytokines in regulating exhaled NO levels. NO is quite unstable and rapidly autooxidizes into a variety of metabolites, including nitrite (NO_2^-), nitrate (NO_3^-), peroxynitrite ($OONO^-$), and nitrothiols. These nitrogen oxides have been shown to modulate many different effects, ranging from bronchodilation to immune defense, including chemotaxis and apoptosis.

Clinical Indications: Assessment of Allergic Airway Disease

Measurements of exhaled NO are noninvasive and can be performed on children as well as adults. This convenience, along with evidence that increased levels of NO correlate with methacholine responsiveness and with sputum eosinophilia, has sparked interest in this mediator as a sensitive marker of ongoing allergic inflammation in the lower airways. Evidence shows, in fact, that exhaled NO can be used as a parameter to discriminate asthmatics from nonasthmatics and to monitor the therapeutic efficacy of certain anti-inflammatory drugs (e.g., corticosteroids) that inhibit iNOS activity and thus reduce NO levels. However, underlying viral infections, acute allograft lung rejection, and collagen diseases with lung involvement have been shown to increase levels of exhaled NO. Thus, there are some instances that warrant caution against oversimplification in interpreting levels of exhaled NO. At this time, further evaluation is required in assessing the utility of nasal NO measurements in the diagnosis of upper airway inflammation, such as that associated with allergic rhinitis.

Measurement of Exhaled NO

Exhaled NO is most commonly measured by chemiluminescence, in which sample NO is drawn into a reaction cell and reacted with ozone, resulting in the emission of light that is detected by a photomultiplier tube. Values are reported as parts per billion, with some instruments sensitive to parts per trillion. On-line and off-line measurements can be performed. For off-line measurements, specimens are collected into special receptacles (e.g., Mylar balloons and Tedlar bags), which allow the convenience of sampling at home or at sites distant from the analyzer. Patients inhale to total lung capacity, and the exhalant is then collected while

mouth pressure, expiratory resistance, and expiratory flow rate are monitored. The same parameters of fixed pressure and resistance are monitored during on-line measurements in which NO profiles are simultaneously displayed, allowing the collection of reproducible tracings. For adults, an NO plateau of 3 to 6 s should be obtained, whereas a 2-s plateau is sufficient for children of less than 12 years old. The most precise measurements are obtained when subjects inhale air from a source containing <5 ppb of NO, since surrounding NO levels may be higher than endogenous levels. Measurements should be performed before spirometry so as not to decrease the levels of exhaled NO. Other factors that lower NO levels and which need to be controlled for include smoking, the use of glucocorticoids, and bronchoconstriction. In contrast, bronchodilators increase NO levels; thus, their use should be well documented. As noted above, exhaled NO levels also increase in certain infections; thus, measurements should be postponed until recovery is evident.

QUALITY ASSURANCE

Since none of the assays described above are regulated by the Clinical Laboratory Improvement Act of 1988, interlaboratory proficiency surveys are presently not available. However, there are certain critical steps that can be taken to ensure the validity of the analytical measurements. The first deals with the tests performed to detect in vitro correlates of immediate hypersensitivity (i.e., histamine, LTC4 and IL-4 and IL-13 protein release from basophils). When the allergic status of an individual is evaluated, it is important to include controls to ensure basophil reactivity, especially when the challenging allergen does not induce the release of the mediator in question. For histamine and LTC4 release, this inclusion is most commonly achieved by stimulating basophils with anti-IgE antibody and/or with FMLP, which are both quite effective in inducing the release of these mediators from basophils obtained from most donors. For IL-4 and IL-13 protein, anti-IgE antibody alone is usually sufficient to induce the secretion of the cytokine from most donors' basophils. However, as noted above, a calcium ionophore (ionomycin or A23187) has been shown to be a potent and relatively specific stimulus for the secretion of both cytokines by basophils. The lack of reactivity with these stimuli could indicate that calcium is missing from the reaction buffer or that the temperature is not 37°C (e.g., it is above 40°C). It is also important that IL-3 pretreatment (15 min) will often enhance the IgE-mediated release of all of the above-listed mediators and may be employed when basophils show marginal release in response to an antigen alone. In contrast, false-positive histamine release may occur as a result of cell lysis due to solvents found in allergen preparations. In this instance, it is important to include controls showing that, in the absence of allergen, the solvents cause no additional release above the spontaneous release (blanks). Similarly, in studies investigating substances that inhibit mediator release, it is important to show that final concentrations of the solvent (e.g., dimethyl sulfoxide) have no effect on secretion.

There are several other factors to consider when performing assays that are used to directly measure mediators and markers of allergic inflammation. The first deals with the general use of standards for these assays. Stock solutions should always be prepared using established methodology to prevent interassay variability. It is also important to store stock solutions in small aliquots to avoid repeated freezing and thawing that may result in loss of activity. Since the type of buffer used and the amount of protein present have a profound effect in all of the assays described above, it is also extremely important that the standards be prepared in diluent identical to, or closely resembling, that found in the test samples. For example, when culture supernatants are tested for IL-4 or IL-13 protein, it is important that the standards be diluted in medium identical to that used in the cultures, since medium containing serum may produce different background levels compared to buffer containing little to no protein. Finally, data analysis for these assays is greatly facilitated by the use of computer application programs, which are often commercially available from equipment manufacturers. They are especially helpful for histamine measurements determined by automated fluorometry, in which many samples can be assayed at a given time and the data can be saved and stored for later access and rapid analysis.

SUMMARY

It is now possible to measure a number of inflammatory mediators released from cells participating in allergic disease. Measurement of the release of preformed histamine from peripheral blood basophils challenged with a specific antigen is among several tests available, and histamine release remains a valuable in vitro correlate of immediate hypersensitivity reactions. However, other mediators that have a role in allergic inflammation, such as LTC4 and IL-4, are also generated by basophils upon IgE-dependent activation, and in vitro assays have recently been developed to measure these products. These assays, combined with those available for the detection of several other mediators occurring in biological fluids, have produced data that have significantly added to our understanding of the parameters, mechanisms, and pharmacologic control of allergic inflammation.

APPENDIX

Special reagents and equipment

RFA 300 rapid flow analyzer for histamine measurement by fluorometry (Astoria-Pacific International, Clackamas, Oreg.)

Filtered reagents for fluorometry

Phosphoric acid (0.73 M)
30% NaCl
5 N NaOH
1 N NaOH containing 1 mM EDTA
0.1 N HCl
Brij-saline-EDTA: 0.17 M NaCl, 1.5 mM EDTA, 0.015% Brij 35 (Perstorp Analytical, Silver Spring, Md.)
Heptane
Butanol
OPT solution: 50 mg of OPT (Sigma, St. Louis, Mo.) recrystallized in ligroine solvent (Eastman Kodak Co., Rochester, N.Y.), 1 ml of spectranalyzed methanol (Fisher Scientific, Pittsburgh, Pa.), and 99 ml of borate buffer (0.5 M)

Histamine standards (for fluorometry)
Histamine dihydrochloride (molecular weight, 184.1)
Histamine (molecular weight, 111.0)

Make a 1-mg/ml solution of histamine.

Note that 1 mg of histamine equals 1.66 mg of histamine dihydrochloride.

Dilute the 1-mg/ml solution 1/1,000 in 2% $HClO_4$ to give a 1-μg/ml stock and store at $-20°C$ in 6-ml aliquots. Six milliliters of 1-μg/ml histamine added to 294 ml of 2% $HClO_4$ yields 20 ng/ml; 50 ml of 20-ng/ml standard added to 50 ml of 2% $HClO_4$ yields 10 ng/ml.

10× PIPES buffer, pH 7.4: 250 mM PIPES (Sigma Chemical Co.), 1.10 M NaCl, 50 mM KCl

PAG buffer: 10% 10× PIPES, 0.003% human serum albumin (Calbiochem-Behring Corp., La Jolla, Calif.), 0.1% D-glucose

PAG-EDTA buffer: PAG containing 4 mM EDTA

PAGCM buffer: PAG containing 1 mM $CaCl_2$ and 1 mM $MgCl_2$

Isotonic Percoll: 9 parts Percoll (Pharmacia, Piscataway, N.J.) plus 1 part 10× PIPES

Lactic acid buffer (pH 3.9): 90.1 mg of lactic acid (Calbiochem-Behring Corp.), 817.6 mg of NaCl, 37.28 mg of KCl, 100 ml of distilled water

Tests for Immunological Reactions to Foods

DAVID M. FLEISCHER AND ROBERT A. WOOD

109

Food allergy is defined as an adverse immunological response to food. Food allergic disorders can be divided into those that are immunoglobulin E (IgE) mediated and those that are non-IgE mediated. Disorders with acute onset of symptoms, defined typically as occurring within 2 h after ingestion, are usually mediated by IgE antibodies, while subacute and chronic food allergic disorders may be cell mediated (primarily T cell) or of mixed origin with both cell-mediated and IgE-associated mechanisms, and they usually affect the gastrointestinal tract. In Table 1, a number of IgE-, cell-, and mixed IgE- and cell-mediated disorders are listed.

The diagnosis of food allergy must first begin with a careful medical history, as the information gathered will be used to guide the best mode of diagnosis, or it could lead to dismissal of the problem by history alone. In fact, it is well documented in several studies in which double-blind, placebo-controlled food challenges (DBPCFCs) were used to diagnose food allergy that only about 40% of patient histories of suspected food-induced allergic reactions can be verified (4). In cases of acute reactions such as anaphylaxis and urticaria after the ingestion of an isolated food, the medical history has a much higher predictive value than in chronic disorders such as atopic dermatitis and allergic eosinophilic gastroenteritis (AEG) (32). The history should focus on the food(s) and quantity of food suspected of provoking the reaction, the type of symptoms attributed to food ingestion (acute versus chronic), the timing between ingestion and onset of symptoms, patterns of reactivity, the most recent reaction, and whether other associated activities play a role in inducing symptoms (e.g., exercise or alcohol ingestion). When gathering the history, one must also be aware of other foods eaten at the same time, potentially contaminated foods that may have been packaged on nondedicated lines, and hidden sources of ingredients.

Once a symptom history is established (see Table 2 for signs and symptoms of food-induced allergic reactions), the search for a food-related etiology needs to be put in context with the prevalence that food allergy is implicated as the causative factor. For example, food-allergic reactions account for about 20% of acute urticaria, <10% of chronic urticaria, and about 35% of moderate to severe atopic dermatitis in children, but food allergy is not a common cause of atopic dermatitis in adults (32). While food allergy may affect up to 5% of children with asthma and 1 to 2% of children with allergic rhinitis, it is not a common cause (<1%) of isolated upper or lower respiratory disease in either children or adults (40). Also, the prevalence of food hypersensitivities is greatest in the first few years of life, affecting about 6% of children <3 years of age and then decreasing to a steady prevalence of 1 to 2% by late childhood through adulthood (35). Furthermore, although any food could theoretically cause an allergic reaction, a small number of foods account for about 90% of verified food reactions: milk, egg, soy, wheat, peanut, tree nuts, and fish for children and peanuts, tree nuts, fish, and shellfish for adults. Finally, the physician should realize that the majority of food allergy is outgrown, usually as a child. In fact, about 85% of children lose their sensitivity to the most allergenic foods (milk, egg, soy, wheat) within the first 3 to 5 years of life (41). However, sensitivity to peanut, tree nuts, fish, and shellfish is rarely lost and thus persists into adulthood; for example, only about 20% of children achieve tolerance to peanut. Some of the tests to be discussed in this chapter not only aid in the diagnosis of food allergies, but also are useful in monitoring the natural history of patients' food allergies over time, from diagnosis to oral tolerance.

Once a thorough history has been obtained, the physical examination should focus on detecting other atopic features, which are more commonly found in patients with IgE-mediated allergic reactions. After completing the history and physical, the physician should first determine whether the patient's findings implicate a food-induced disorder based on the information gathered, and then determine whether an IgE-mediated or non-IgE-mediated mechanism is most likely responsible. Typically, the clinical presentations of allergic reactions listed in Table 2, such as urticaria, angioedema, and wheezing, have a rapid onset in IgE-mediated disorders, whereas other presentations such as vomiting, diarrhea, and bloody stools may not develop for hours to days after ingestion of the allergen in non-IgE-mediated disorders. For disorders with mixed IgE- and cell-mediated mechanisms, clinical features may be variable in onset. Once food allergy has been identified as the likely cause of symptoms, confirmation of the diagnosis and identification of the implicated food(s) can begin. There are a number of tools that aid in the diagnosis of food allergy, some of which are more commonly used, and they vary in their ability to provide an accurate diagnosis. In general, laboratory tests are more useful in delineating the specific foods responsible for IgE-mediated reactions, whereas they are of limited value in non-IgE-mediated

TABLE 1 Food allergy disorders

IgE mediated
    Gastrointestinal: oral allergy syndrome, gastrointestinal
        anaphylaxis
    Cutaneous: urticaria, angioedema, morbilloform rashes and
        flushing
    Respiratory: acute rhinoconjunctivitis, wheezing
    Generalized: anaphylactic shock

Mixed IgE and cell mediated
    Gastrointestinal: allergic eosinophilic esophagitis/AEG
    Cutaneous: atopic dermatitis
    Respiratory: asthma

Cell mediated
    Gastrointestinal: food protein-induced enterocolitis, proctocoli-
        tis, and enteropathy syndromes; celiac disease
    Cutaneous: contact dermatitis, dermatitis herpetiformis
    Respiratory: food-induced pulmonary hemosiderosis (Heiner
        syndrome)

disorders. Available studies include in vivo tests such as skin prick and intradermal testing, oral food challenges (OFCs), elimination diets, and patch testing and in vitro tests such as quantification of food-specific IgE and basophil histamine release (BHR). The utility of these and other test modalities will be discussed in detail.

IN VIVO TESTS

Skin Prick Testing

Skin prick tests (SPTs) are commonly used to screen patients with suspected IgE-mediated food reactions. While the patient is off antihistamines for an appropriate amount of time (short acting, 72 h; long acting, 7 days), a device such as a bifurcated needle, lancet, plastic probe, or the tip of a small-gauge needle is used to puncture the skin through a glycerinated food extract (1:10 or 1:20, wt/vol) into the epidermis. Positive (histamine) controls are used to show that the skin response is not blocked, and negative (saline-glycerine) controls are used to show that there is not dermatographism or other potential causes for false-positive results such as irritant and contact reactions from the diluent used to preserve allergen extracts or poor technique of the tester. Food skin testing with large panels of foods is generally not advised because there could be many irrelevant positive results, but should rather be limited to the most common food allergens and foods that are suspected of provoking symptoms gathered on history (5). If food-specific antibody is present, mast cells with the same food-specific IgE bound to their surface degranulate and release mediators that result in a local wheal-and-flare reaction within 15 to 20 min.

SPTs are generally considered positive if there is a mean wheal diameter of ≥3 mm, after subtraction of the negative control wheal. The mean diameter of the wheal is calculated by measuring the greatest diameter of the wheal and the largest diameter perpendicular to it and then averaging the sum of these diameters. When an SPT is positive, it indicates the possible association between the food tested and the patient's reactivity to that food because the positive predictive accuracies of SPTs are <50% compared to those of DBPCFCs. On the other hand, negative responses virtually exclude the possibility of an IgE-mediated reaction because

their negative predictive value exceeds 95% (32). Therefore, negative SPTs are an excellent means of excluding IgE-mediated food allergies, although they are not perfect (31), and positive SPTs are only suggestive of the presence of symptomatic allergy. However, a positive SPT may be considered diagnostic in patients who have experienced a systemic anaphylactic reaction to an isolated food (32).

Several key studies have looked at the performance characteristics of SPTs in predicting true food allergy at different wheal cutoffs compared to the outcome of DBPCFCs. Sampson (31), in a study of 87 patients (median age, 7.9 years) who all had atopic dermatitis and underwent DBPCFCs to rule out food hypersensitivities after SPTs, reported that a 3-mm wheal had a 96% sensitivity in identifying children with cow's milk allergy, 98% with egg allergy, and 90% with peanut allergy, with corresponding specificities of 51, 53, and 29%, respectively. Sporik et al. (43) showed corresponding sensitivities for a 3-mm wheal of 74% for cow's milk, 84% for egg, and 96% for peanut, with respective specificities of 79, 70, and 71% from 535 challenges in 467 children (median age, 3 years). For each food, Sporik et al. (43) were also able to identify a SPT wheal diameter at and above which negative food challenges did not occur, thus in theory reducing the need for formal food challenges if the wheal size equaled or exceeded these values: 8 mm for cow's milk, 7 mm for egg, and 8 mm for peanut in a group of children with a median age of 3 years. For children 2 years of age or younger, the SPT wheal diameter cutoffs were lower: 6 mm for cow's milk, 5 mm for egg, and 4 mm for peanut. Finally, Eigenmann and Sampson (13) reevaluated SPTs in the diagnosis of food allergy in a group of children (median age, 4.6 years) with a history of atopic dermatitis. They used as cutoffs wheal sizes at the upper 95% confidence interval for food-tolerant patients; these were 5 mm for cow's milk, 4 mm for egg, and 6 mm for peanut. The corresponding sensitivities were 89% for cow's milk,

    Feeling of "impending doom"

98% for egg, and 63% for peanut, and the specificities were 68, 61, and 71%, respectively.

When the test is appropriately performed, SPT results have been shown to be highly reproducible (31). The accuracy of SPTs does vary, however, depending on which food antigen is being studied, the quality of the food extract, and the technical skills of the tester. There are a number of other variables that have to be considered when interpreting SPTs. First, children <1 year old may have negative SPT responses but still have IgE-mediated disease, and infants <2 years old may have smaller wheals, which is presumably due to lower levels of food-specific IgE and skin reactivity. Second, skin testing on areas of the skin that have been treated frequently with topical steroids or in patients on long-term, high-dose systemic corticosteroid therapy may result in reduced wheal size. Third, histamine control wheals <5 mm in diameter may indicate the presence of antihistamines, other interfering medications, or decreased skin reactivity that results in decreased wheal size and possible false-negative test responses (32).

SPTs have several advantages: they are quick, patients can see the reaction of a positive test result on the skin, and they are relatively inexpensive compared with serologic methods for allergy investigation (each SPT on average costs less than one-half as much as measuring the food-specific IgE level in serum). They are also safe: no lethal reactions have been reported after SPTs (11). However, SPTs are often not helpful in determining if a patient who was allergic to a particular food has achieved tolerance to that food, as skin tests often remain significantly positive for years following attainment of clinical tolerance determined by OFC (40).

Intradermal Skin Testing

In 1978, Bock et al. (5) performed DBPCFCs on 76 children aged 5 months to 15 years who exhibited a wheal of 3.0 mm or greater in response to an SPT with one or more of 14 foods, regardless of whether or not they reported a history of an adverse reaction to that food. SPTs with 1:20 (wt/vol) food extracts identified all subjects who exhibited adverse reactions during their challenges. In addition, intradermal skin tests (ISTs) were performed with 1:1,000 (wt/vol) extracts. For each of the 14 foods, between 19 and 39 additional patients (mean, 26) who were negative by SPT had a 3.0 mm or greater wheal in response to intradermal testing. Using peanut as an example, 26 patients were identified by SPT, 12 of whom failed DBPCFCs, and an additional 28 patients, all of whom had negative DBPCFCs, were identified by positive intradermal tests. As a result of this study, it was shown that ISTs with food extracts had no positive advantage over SPTs, and it was concluded that the increased sensitivity of ISTs would lead to even more false-positive tests than seen with the prick technique (34). Furthermore, fatalities after intradermal testing for food allergies have been reported (32). In 1929, a 5-month-old infant died after intradermal injection of ovomucoid. Between 1964 and 1984, sufficient information was available to analyze six fatalities from skin testing. Of these six, two were children aged 10 and 11, both with asthma, who received either ISTs without prior SPTs or ISTs with food extracts (45).

FFSPTs

Fresh food skin prick tests (FFSPTs) are not commonly performed, since the indications for doing so are limited. Some commercially prepared extracts frequently lack the labile proteins that are responsible for IgE-mediated sensitivity to

many fruits and vegetables (e.g., apples, oranges, bananas, pears, melons, potato, carrots, and celery), as is seen in patients with oral allergy syndrome (OAS), because the proteins are degraded or lose allergenicity during extract preparation (23). OAS, or pollen-food allergy syndrome, is a condition in which patients develop pruritus, tingling, and angioedema, usually localized to the lips and mouth, due to certain plant proteins in fresh fruits and vegetables cross-reacting with airborne allergens, such as ragweed, birch, and mugwort pollens. Negative SPTs with commercially available extracts that contradict a convincing history of a food-induced allergic reaction should be repeated with the fresh food before conclusion that food-specific IgE is absent (13). Rosen et al. (30) also suggested that patients be tested with the food in the form that caused the reaction (e.g., raw or cooked). FFSPTs are usually done in one of two manners, depending on the type of food. In the prick-plus-prick technique, the needle or lancet device is first embedded in the fresh food and is then immediately used to prick the patient's skin, whereas foods with a harder consistency, such as peanut, are often ground first and diluted in buffered saline.

Several studies have been performed with various combinations of comparisons of FFSPTs with commercial extracts, food-specific-IgE levels, and/or food challenges. In a study by Ortolani et al. (23), 100 patients with OAS and 32 nonallergic control subjects were enrolled. Patients had FFSPTs, commercial extract SPTs, and Phadebas radioallergosorbent tests (RASTs), and 14 patients with OAS underwent open OFCs. The results showed that with FFSPTs there was better sensitivity to foods such as carrot, celery, cherry, apple, and potato, but that sensitivity was better with commercial extract SPTs for peanut, almond, banana, and pea. Rosen et al. (30) confirmed the superiority of fresh extracts in a study of 22 patients, including 9 children. Fourteen of the 22 patients presented with anaphylactic reactions, and the remaining 8 presented with OAS. For 18 of the 22 patients, the foods presumed to be the offending allergens were not limited solely to fruits or vegetables, but included fish, crustaceans, mollusks, milk, egg, peanut, and tree nuts. All of the patients demonstrated a negative response to SPTs with commercial extracts but positive responses to SPTs with natural food extracts, although no food challenges were performed to confirm that these foods were the ones that caused the symptoms. Rance et al. (27), using commercial extracts and fresh foods, compared SPT results for milk, egg, and peanut to the results obtained with labial and/or oral challenge. They found that the overall correlations between positive SPT (≥3 mm) and positive challenges with commercial extracts were 58.8 and 91.7% with fresh foods. They also observed that challenges were positive for 40.5% of subjects with negative commercial SPTs, while only 7.4% of challenges were positive for subjects with negative FFSPTs.

One must be careful, however, in extrapolating these data to the allergic population as a whole. One must also be careful when performing FFSPTs, as safety is an issue with this type of skin testing as well. Two cases of anaphylactic reactions in adults were reported after FFSPTs (11). Devenney and Falth-Magnusson (11) reported six cases of generalized reactions requiring treatment with antihistamine and/or epinephrine in six infants <6 months of age when FFSPTs were used.

Atopy Patch Testing

Atopy patch tests (APTs) have been proposed as a mode of diagnosis of non-IgE-mediated food allergy and for identification of allergens in delayed-onset clinical reactions. APTs

are performed epicutaneously, usually on a patient's back. Instead of using type IV allergens such as metals or perfumes, typical immediate-type allergens such as foods are used. A small amount of a food is placed on filter paper, which is then applied to uninvolved skin and covered by an aluminum cup. The application sites are checked after 15 to 20 min for immediate reactions and then are usually kept occluded for 48 h. Results are usually read 20 min after removal of the cups and again 24 h later for the final evaluation. Final reactions are then scored; a type of scoring system used is 1+ for erythema and slight infiltration, 2+ for erythema and papules, and 3+ for erythema and vesicles. Irritant reactions, which have been described as sharply defined, brownish erythema, blistering, and a lack of clear infiltration, are not regarded as positive (28).

Although the exact pathomechanism of the APT is not known, it has been proposed that when the allergen that is applied to the skin under occlusion and penetrates the epidermis, it is captured by IgE molecules which are bound to IgE receptors on Langerhans cells. Allergen-specific T cells are then activated, possibly by IgE-mediated antigen presentation by these Langerhans cells, and initiate an eczematous reaction, which immunocytochemically resembles that seen in atopic dermatitis. APT reactions are therefore associated with the T-lymphocyte-mediated allergen-specific immune response (44). The patch test reaction to aeroallergens seems to be specific for sensitized patients with atopic dermatitis, as it does not occur in healthy volunteers or in patients suffering from asthma or rhinitis (10).

The outcome of APTs in different studies shows large variations due to differences in patient selection and, more importantly, differences in method. At this time, there are large disparities in the type and concentrations of allergens used and in the duration of application and reading time (10). Nonspecific irritation is a common finding in standard patch testing and therefore requires a good deal of skill in differentiating it from a positive reaction (35). These facts make interpretation of studies somewhat difficult due to reliability issues, but a number of investigators have examined the use of the APTs in addition to SPTs for the diagnosis of non-IgE-mediated food allergy, primarily in patients with atopic dermatitis (20), but also in patients with allergic eosinophilic esophagitis.

Roehr et al. (28) studied 173 challenges in 98 patients with atopic dermatitis and used APTs, SPTs, and food-specific IgE levels with cow's milk, egg, soy, and wheat to see if the combination of a positive APT result plus a positive food-specific-IgE level, a positive SPT, or both would make DBPCFCs unnecessary. Patients were observed for 48 h on an inpatient basis after challenges to document late-phase reactions (>2 h postchallenge) of eczema exacerbations, which were counted as positive challenges if they occurred either alone or in combination with early reactions. Positive APT results alone correlated with high positive predictive values (PPVs) for cow's milk (95%), hen's egg (94%), and wheat (94%) compared to positive DBPCFCs, but with only a 50% PPV for soy (only four children reacted to soy). Combination of the APT with proof of specific IgE for cow's milk (≥0.35 kU of antibody [kU_A] per liter) and for egg (≥17.5 kU_A/liter) increased the PPVs to 100%, thus making DBPCFCs superfluous. Addition of SPTs to the other two tests did not further improve results. Spergel et al. (42) studied 26 patients with biopsy-proven eosinophilic esophagitis and performed both SPTs and APTs. Allergies to a total of 68 foods were identified by SPTs in 19 patients and to 67 foods by APTs in 21 patients, and specific foods were

eliminated from patients' diets on the basis of those results. Eighteen patients reported complete resolution of symptoms on the restricted diet, and six reported partial improvement. Posttreatment biopsies also showed decreased numbers of eosinophils per high-powered field, and in some patients, symptoms returned when foods that were positive on patch testing were reintroduced.

Elimination Diets

The purpose of an elimination diet is to determine whether a patient's symptoms will resolve when foods are restricted from the diet. Once certain foods are suspected of being responsible for a food-induced allergic disorder, an elimination diet is started as an attempt to support the diagnosis. If a patient's symptoms persist despite a very strict avoidance diet, it is unlikely that the food accounts for the patient's complaints (6). There are three types of elimination diets: elimination of one or more suspect foods, elimination of all but a defined group of allowed foods that are rarely antigenic (oligo-antigenic diet), and an elemental diet consisting of a hydrolyzed or amino acid-based formula (40). The type of diet chosen depends upon the clinical presentation being evaluated and the results of IgE antibody tests.

Elimination of one or more foods in the first diet type may be the obvious course of action and therapeutic in the case of an acute reaction to a food and the presence of a positive test for IgE to that food. It may also be especially helpful in evaluating infants who are on a very limited diet. In the oligo-antigenic diet, a large number of foods suspected to cause a chronic problem are removed, and the patient is given a list of allowed foods. This type of diet is useful for evaluation of chronic disorders such as atopic dermatitis in children or chronic urticaria. The foods eliminated usually are those that are common causes of food-allergic reactions. In the most extreme diet, the elemental diet, a hydrolyzed (Nutramigen, Alimentum) or amino acid-based (Neocate, EleCare) formula provides all the nutrition. The elemental diet provides the most definitive trial, but it can be difficult to undertake and maintain, especially in patients beyond infancy. This diet may be necessary when the other two diets mentioned above have failed but the suspicion for food-related illness remains high. It may also be necesssary in disorders such as AEG, which is often associated with multiple food allergies. If a patient's symptoms do not disappear on an elemental diet, then it is very unlikely that ingested substances are the problem (6, 40). The length of trial is dependent on the type of symptoms, but 1 to 6 weeks is the usual range required.

If symptoms resolve on an elimination diet, some form of food challenge is generally warranted, especially in chronic disorders such as atopic dermatitis. One must be careful when a food to which the patient is sensitized is removed from the diet during a chronic disorder because reintroduction could induce severe reactions (41). Suspect foods should not be reintroduced at home except under the direction of a physician. With gastrointestinal allergies such as AEG, endoscopy and biopsy after 6 to 8 weeks on an elimination diet showing resolution of pathology will confirm that the implicated foods were likely responsible for the disorder (32).

With any of these diets, specific information needs to be reviewed carefully to ensure adherence, as it is common for patients to make errors. For example, eliminating egg from someone's diet means reading labels for key words such as ovalbumin, lysozyme, and globulin. Contamination of the food being eliminated and hidden ingredients can be issues

that hinder strict avoidance. Organizations such as the Food Allergy and Anaphylaxis Network (http://www.foodallergy. org) may provide assistance for patients. When multiple foods are eliminated from the diet, it may be necessary to consult the aid of a nutritionist to maintain a balanced diet.

OFCs

OFCs are performed by feeding suspected foods in gradually increasing amounts over hours or days under the supervision of a physician. OFCs can be done openly, where both the physician and the patient know the food being challenged; single-blind, where only the physican knows; or double-blind, placebo-controlled, where neither patient nor physician knows the content of the challenge. Open food challenges are best performed when it is not very likely that symptoms will develop and when there is little pyschologic play that could bias results (40). The DBPCFC is considered to be the "gold standard" for the diagnosis of food allergy, and it is the least prone to bias and confounding factors (38, 40). OFCs can be used to assess any kind of adverse response to foods. When several foods are under consideration, tests for IgE are positive, and elimination resulted in resolution of symptoms, the OFCs for each food may allow expansion of the diet. For acute anaphylactic reactions in which there is no specific IgE for the suspected food found, an OFC would be indicated to safely reintroduce the food in case of a false-negative skin test or RAST. If an elimination diet did not alleviate symptoms and suspicion is still high for a food-related cause, then the OFC may be needed to resolve the issue. For those who have been previously diagnosed with an IgE-mediated food allergy, the OFC can also be used to determine whether the patients have outgrown their clinical reactivity. Finally, for non-IgE-mediated reactions, OFCs are often the only means of diagnosis (41).

To optimize challenge conditions, the suspected food should be eliminated from the diet for 1 to 2 weeks (and up to 8 to 12 weeks in some gastrointestinal disorders), potentially interfering medications should be withdrawn (antihistamines, β-agonists), symptoms of chronic diseases such as asthma and atopic dermatitis should be adequately controlled, fresh or dehydrated foods should be used, and challenge vehicles should not contain fat, which can interfere with protein absorption. The OFC should be administered in the fasting state in a graded fashion, starting with a dose that is unlikely to produce symptoms (25 to 500 mg of lyophilized food). Some physicians start with a labial food challenge as an added precaution before actual ingestion, whereby a small amount of the challenge food is placed on the lower lip for 2 min and then the patient is observed for some time; if this test is negative, then an OFC follows. In suspected IgE-mediated reactions, if there is no reaction with the starting dose, then the dose is doubled every 15 to 60 min (the interval time may need to be increased for more delayed reactions) until 8 to 10 g of dried food, 60 to 100 g of the wet food, or 100 ml of liquid has been consumed (32, 40). Once the challenge is finished, patients should generally be observed for up to 2 h. Once the patient has tolerated one of the above amounts in the challenge, then clinical reactivity has generally been ruled out, since a negative challenge has a high negative-predictive value (33). However, for blinded challenges, all negative challenges should be confirmed by an open feeding of the suspected food made in its commonly prepared state and served in normal meal-size quantities under medical supervision to exclude the rare false-negative challenge response (6).

In suspected non-IgE-mediated food allergies such as AEG and food protein-induced enterocolitis syndrome (FPIES), since there are no specific laboratory tests for these illnesses, the OFC may be the only way to identify causative foods. OFCs for FPIES may require up to 0.3 to 0.6 g of food/kg of body weight given in two doses, and patients need to be observed for 2 to 6 h for possible profuse vomiting and diarrhea (intravenous access is usually placed prior to challenge as a precaution). For AEG, patients may require several feedings over a 1- to 3-day period. In most IgE-mediated disorders, further challenges can be conducted every 1 or 2 days, or even on the same day 4 h apart for each part of the DBPCFC. Most non-IgE-mediated disorders, however, require a longer interval of 3 to 5 days between challenges (32, 40).

The decision to perform OFCs should not be taken lightly, as severe anaphylactic reactions can occur, and the challenges are time-consuming, cost-intensive, and stressful to the patient and families. To aid in making the decision of when to challenge, some information has already been presented regarding the use of SPT wheal size cutoffs and the likelihood of true allergy based upon DBPCFCs; other tools that help determine whether to challenge a patient will be mentioned when food-specific-IgE levels are discussed later in this chapter. Recent and severe anaphylaxis after an isolated ingestion with a positive test for specific IgE to the causal food is an example of a relative contraindication to challenge, as this is a convincing history and would not warrant further investigation (41). Because of the risk of anaphylaxis, the physician must be comfortable with a potential severe reaction and be prepared to treat it with emergency medications and equipment. Patients must be examined before the challenge begins, as well as frequently during the OFC for objective signs of a reaction, and challenges need to be terminated promptly when a reaction becomes apparent. As a general rule, challenges should not be done at home (41); when the skin test is negative, though, and the history of a reaction to that food is doubtful, the food may be replaced at home with a 99% expectation that the food will be tolerated (6). However, reintroduction of foods should never be done at home if there is even the slightest chance of severe symptoms developing.

As with any diagnostic test, there can be false-positive and false-negative results. From two university centers in the United States, the average false-positive rate for the DBPCFC was reported to be 0.7%, and the false-negative rate was 3.2% (33). Caffarelli and Petroccione (8) reported that 5 patients of 193 (3%) challenged by DBPCFCs had passed a DBPCFC and then reacted the next day to an open feeding of the same food at home. Occasionally, an open challenge is positive in the face of a negative blinded challenge. Several possibilities explain this phenomenon. First, the patient's threshold response may have been higher than was achieved during the blind challenge. This possibility could be tested in a blind challenge with greater amounts of food. Second, the allergenicity of the food may have been different because of the way it was prepared; this is rarely confirmed because the open consumption of the food after the blinded challenge usually eliminates the notion that cooking, digestion, and other factors may have altered the food. Third, the reaction may have been due to psychological factors (6).

IN VITRO TESTING

Quantification of Food-Specific IgE

Another way to identify food-specific IgE that is more widely available to the general practitioner is the RAST. In this type

of test, the allergen in question is bound to a solid matrix and exposed to the patient's serum. If there is specific IgE for that allergen in the patient's serum, it binds to the protein matrix. After a buffer wash to remove unbound serum proteins, bound human IgE antibodies are detected with a radio-labeled anti-human IgE Fc. Different manufacturers use various substrates, and results can be reported as classes (class 1 to 5 or 6), percentages, counts, or arbitrary units of concentration (kU_A/liter) (41).

The first-generation RAST results compared with clinically diagnosed food allergy showed false-positive rates of 3 to 40% and false-negative rates of 3 to 48%, depending largely on how the diagnosis of food hypersensitivity was made and on the antigens used in the RAST (36). Much of this disparity had to do with relying on patient history in making the diagnosis, which, as stated previously, is confirmed only about 40% of the time by DBPCFCs. Using DBPCFCs and eight common food antigens, Sampson and Albergo (36) studied 40 patients with atopic dermatitis and compared SPT and Phadebas RAST results with the challenge results. They found that the sensitivities and specificities of the SPTs and RASTs were similar if a Phadebas RAST score of 3+ or higher was considered positive. RASTs are generally considered less sensitive than SPTs, but the development of the second-generation RAST, the CAP System FEIA (Pharmacia-Upjohn Diagnostics, Uppsala, Sweden), improved the allergosorbent's overall antibody-binding capacity, which led to more rapid assay kinetics and an enhanced assay sensitivity. The Pharmacia CAP System also uses standardized allergens and is calibrated against the World Health Organization IgE standard (38) (for more quality control issues, please refer to chapter 107).

The development of the CAP System allowed better quantitation of food-specific IgE antibodies (on a scale from <0.35 kU_A/liter, or negative, to the upper limit of >100 kU_A/liter), which have been shown in key studies to be more predictive of symptomatic IgE-mediated food hypersensitivity. These studies of children provided support that certain concentrations of food-specific IgE were associated with a high likelihood of reactions, or true allergy. Because sensitivity and specificity are inherent properties of a test and predictive values reflect the inherent properties of the test plus the prevalence of disease in the population under investigation, an alternative approach used in the studies mentioned below to minimize the effect of disease prevalence has been the use of the 90 or 95% specificity values to establish diagnostic decision points (34).

In a retrospective study of 196 children and adolescents (mean age, 5.2 years) with atopic dermatitis, Sampson and Ho (38) compared the levels of food-specific IgE with the results of DBPCFCs and found that concentrations of 6 kU_A/liter or greater for egg, 32 kU_A/liter or greater for cow's milk, 15 kU_A/liter or greater for peanut, and 20 kU_A/liter or greater for codfish were 95% predictive of an allergic reaction. Therefore, a patient with a food-specific-IgE level greater than the 95% PPV could be considered reactive and an OFC would not be warranted. If, however, the level of food-specific IgE was less than the 95% PPV, a patient may be reactive but would need an OFC to confirm the diagnosis. There are caveats with this study that affect its use in the general population: first, all patients had atopic dermatitis, and these patients tend to have higher IgE levels; and second, this group of patients had a much higher prevalence of food allergy than is seen in most populations. Because of these factors, Sampson performed a prospective study of 100 children (median age, 3.8 years) not selected for atopic

dermatitis (only 61% had this disorder), with similar results, except the 95% PPV cutoff was lower for milk at 15 kU_A/liter (34).

Different results were obtained in studies of younger infants and children with different clinical histories. Garcia-Ara et al. (14) showed that an even lower concentration of food-specific IgE to milk had a high predictive capability, although their study was of a much younger patient population of 170 infants (mean age, 4.8 months) without atopic dermatitis or gastrointestinal allergy. They determined the 95% PPV cutoff to be >5 kU_A/liter but recommended 2.5 kU_A/liter or greater as the cutoff to not challenge because it still had a high probability of a positive challenge (90%) without a significant reduction in sensitivity. Finally, Osterballe and Bindslev-Jensen (24) determined the 95% PPV for egg to be 1.5 kU_A/liter in a population of 56 children with atopic dermatitis and a median age of 2.2 years, while Boyano et al. (7), in a population of 81 children under 2 years of age (43% with atopic dermatitis), determined that an OFC was unnecessary to establish the diagnosis of egg allergy if the egg-white-specific IgE was ≥0.35 kU_A/liter and the patient had a history of immediate hypersensitivity to egg.

The use of food-specific-IgE concentrations can also be helpful in monitoring allergen-specific IgE values on an annual basis as part of a routine follow-up of food-allergic patients to assess their ongoing sensitivity because they provide numerical values that can be monitored from an initial reference point. Moreover, food-specific-IgE values have been pivotal in determining other cutoff points below which patients should undergo OFCs because they might have lost their clinical reactivity. To define guidelines of when an IgE level is low enough to warrant challenges, Perry et al. (26) retrospectively reviewed the levels of food-specific IgE for five major foods at the time of open OFCs with the results of 604 challenges carried out in 391 patients. Challenges were performed when oral tolerance was suspected due to the lack of any reaction to the suspect food within the previous year and, for most patients, when the food-specific-IgE level was <0.35 kU_A/liter or approached one-fourth of the previously established 95% PPVs for milk, egg, and peanut or one-fourth of the 50 and 75% PPVs for soy and wheat, respectively. For analysis, patients were divided into two groups as follows, based on their reaction history: group 1, patients who clearly had a history of an allergic reaction or had previously failed a challenge to that food; and group 2, patients who were avoiding the suspect food solely on the basis of a positive test for food-specific IgE or who had an unclear history of reaction, such as worsening atopic dermatitis.

Perry et al. (26) found that when looking for a food-specific-IgE level at which 50% of patients would be expected to pass OFCs, which has been a reasonable and acceptable pass rate with both physicians and parents given the risk, expense, and time that each challenge entails, clear values were found for milk, egg, and peanut. The proposed cutoff level for milk-specific IgE was 2 kU_A/liter, below which 53% of patients passed their challenge, and for egg-specific IgE the cutoff was also 2 kU_A/liter, below which 60% of patients passed their challenge both with and without a clear history of reaction. For peanut, they recommended that patients with a clear history of reaction be challenged when the peanut-specific-IgE level is <2 kU_A/liter, whereas a cutoff level of 5 kU_A/liter should be used for those patients with no clear history of ingestion. Firm recommendations could not be provided for soy and wheat, a problem seen with results in other studies as well (34, 38). However, they generally recommended that if the level of wheat-specific IgE is <10 kU_A/liter

or the level of soy-specific IgE is <5 kU$_A$/liter, challenges should be considered, although higher levels may be appropriate for some patients, depending on the clinical history.

There are several important points regarding food-specific-IgE levels that need to be mentioned. The level of food-specific IgE, like the size of the SPT, does not usefully correlate with the severity or type of reaction a patient will have, but especially high concentrations are associated with a very high likelihood of reactions occurring (34). Also, it is preferable to obtain food-specific-IgE levels instead of performing SPTs in certain clinical situations: in patients with significant dermatographism for whom there could be many false-positive tests, in patients with severe skin disease and limited area for testing, in patients who cannot discontinue taking antihistamines, and in patients with intense sensitivity to certain foods for whom SPTs could be dangerous (38).

Quantification of Food-Specific IgG

Food-specific IgG or IgG4 antibodies can be measured by immunoassay. The levels of IgG subclasses other than IgG4 rise in response to long-term exposure in both symptomatic and asymptomatic conditions (1). They are generally elevated in patients with food allergy affecting the gastrointestinal tract, but their specificities typically reflect the type of foods ingested and are not indicative of food-related pathogenesis (38). Roger et al. (29) measured egg-specific IgG4 and IgE antibodies in 104 patients and found that while IgG4 levels may be high in food-allergic patients, detection of IgG4 had little diagnostic value in childhood allergy to egg as determined by OFCs. In addition, food-specific IgG4 was a frequent finding in patients who tolerated egg. Bjorksten et al. (3), studying 47 children with cow's milk allergy, found no relationship between the presence of milk-specific IgG4 antibodies and the results of OFCs, nor was there a relationship between the presence of IgG4 and IgE antibodies against milk. Finally, Morgan et al. (19) looked at the relationship among shrimp-specific IgG subclass antibodies and results of DBPCFCs in their study with 31 patients with a history of immediate adverse reactions to shrimp and 20 control subjects who were shrimp tolerant. None of the shrimp-specific IgG subclass responses was predictive of a positive response to DBPCFC, and therefore they were not diagnostic of shrimp intolerance. In summary, food-specific IgG antibodies play no role in the diagnosis of food hypersensitivity reactions.

Total IgE

IgE concentrations in serum are highly age dependent, rising gradually through childhood until they peak between ages 10 and 15 and then steadily decline throughout adulthood. Klink et al. (17) analyzed serum IgE levels in 2,657 subjects grouped into skin test-positive or skin test-negative rhinitic, asthmatic, or asymptomatic individuals. They found that although serum IgE concentrations tend to be higher in allergic children and adults than in nonallergic individuals, the range of IgE in all groups was extremely wide. There is usually a large overlap in the ranges of IgE between atopic and nonatopic populations, resulting in no single level of IgE that clearly distinguishes the different groups at a level of precision that is clinically meaningful. This large overlap greatly limits the diagnostic sensitivity of total serum IgE as a screening test for allergy (17).

There are many conditions that can be associated with greatly elevated total IgE levels, but probably the most common and the one associated with food allergy in 30% of children is atopic dermatitis. High serum IgE levels, with a mean of 978 IU/ml (range, 1.3 to 65,208), have been observed in patients with atopic dermatitis (15). Total serum IgE levels are related to the probability of an individual having detectable allergen-specific IgE. In a large adult study population, patients with total serum IgE levels in the highest quintile (>66 IU/ml) were 37 times more likely to have one or more allergen-specific IgE antibodies (25). Because of this, patients with high IgE levels, especially those with atopic dermatitis, can have many false-positive food-specific antibodies if their total IgE level is greatly elevated, thus making the diagnosis of true food allergy in these patients more difficult. In summary, total serum IgE levels are not useful diagnostic tests for food allergy.

BHR

BHR has been proposed as an in vitro correlate to in vivo allergic responses (12). BHR as a method of diagnosing food allergy was reported by Nolte (21) to correlate well with SPTs, RASTs, and open food challenges but did not correlate with histamine release from intestinal mast cells obtained by duodenal biopsy in children. Another study by Sampson comparing BHR, SPTs, and DBPCFCs, however, showed that the BHR assay was no more effective in predicting clinical sensitivity than SPTs (38).

The clinical use of BHR is complicated by several factors. It is not a widely available test, blood needs to be processed within a certain amount of time for cells to be viable, and there are no standardized methods for performing BHR. About 8 to 20% of patients in a normal population fail to show BHR upon immunological activation of their basophils (21). Increased spontaneous release of up to 35% of the total basophil histamine associated with mononuclear cell-derived production of basophil-releasing factors has been reported for patients with atopic dermatitis and food allergy documented by DBPCFC (37), although the use of whole blood now in these assays reportedly overcomes this problem of spontaneous histamine release. Also, there are functional differences between mast cells and basophils that cause the BHR tests to be a controversial means for diagnosing food allergy. BHR assays are now used primarily in research settings.

Serum Tryptase

An increased level of serum tryptase, a neutral protease found almost exclusively in mast cells, has been found to be an excellent marker of mast cell activation in anaphylactic reactions. Basophils, the only other cell type in which tryptase has been found, contain 100 to 1,000 times less tryptase than mast cells (22). Tryptase level elevations are believed to begin at 1 h after mast cell stimulation (18), and the half-life of tryptase in the circulation is approximately 2 h (22).

An increase in serum tryptase in food-induced anaphylaxis, however, is rarely seen and therefore is not a reliable marker of food-related allergic reactions. The short half-life of serum tryptase, its quick rise in relation to onset of reaction, and the required special processing in a limited number of specialty laboratories make it even less useful as a diagnostic test for food allergy. The absence of a substantial increase in mast cell tryptase in food-induced reactions suggests that other mediators from mast cells may play a more central role or that basophils, which contain significantly less tryptase, may play a more important role in these reactions. It is also possible that other cells such as

macrophages, monocytes, and endothelial cells become activated through Fcε II receptors or by cytokines and mediators released early in the allergic reaction to foods (39).

Future Directions: Specific Epitope Analysis

While it has been shown that measurement of food-specific IgE concentrations in the serum and SPT wheal diameter is helpful in determining possible patient clinical reactivity, many patients still require OFCs because their food-specific-IgE levels or wheal diameters fall below the 95% PPV diagnostic decision levels or because they may have lost their clinical reactivity. Recent technological advances have enabled investigators to map allergenic epitopes of many major food allergens, including milk, egg, and peanut, and determine specifically where a patient's IgE antibodies bind to those proteins. As a result, it was discovered that conformational and sequential (or linear) epitopes might be responsible for allergic reactions. Researchers also found that individuals who possess IgE antibodies to sequential epitopes react to the allergenic food in any form, whether extensively cooked or partially hydrolyzed, while patients with IgE antibodies to conformational epitopes appear to tolerate small amounts of the food after extensive cooking or partial hydrolysis because the tertiary structure of the allergenic protein is altered and the conformational epitopes are destroyed (35).

Additionally, in several studies of egg- and milk-allergic patients (9, 16), it was shown that certain patients with IgE antibodies to sequential epitopes have a propensity to have persistent allergy, while patients with IgE antibodies primarily to conformational epitopes tend to have clinical tolerance. Therefore, screening for antibodies to those epitopes may prove useful in identifying children who will not outgrow their allergy and thus will possibly be candidates for immunotherapy when it becomes available (9). Further analysis of epitope binding in peanut-allergic patients demonstrated that there are differences in peanut allergenic epitope recognition patterns between patients with symptomatic peanut allergy and those who are sensitized but clinically tolerant. Therefore, the addition of epitope-specific IgE determinations might prove to be a more valuable tool for diagnosing symptomatic peanut allergy than quantitative IgE antibodies to the whole protein and may be particularly useful for patients with peanut-specific-IgE levels below the diagnostic decision levels (2). It has also been demonstrated that patients with peanut allergy and IgE antibodies to many epitopes, called broad epitope diversity, tend to have more severe allergic reactions than those who have IgE binding to relatively few epitopes (35). The clinical use of epitope-specific IgE antibodies as diagnostic tools requires further research.

CONCLUSIONS

The diagnosis of immunological reactions to foods must begin with a thorough history and physical, as this provides the basis for making decisions of what testing, if any, needs to be done to confirm the history. A number of valid diagnostic tools exist for diagnosing IgE-mediated food reactions, both in vivo methods such as skin testing and food challenges and in vitro methods including measurement of food-specific-IgE concentrations in serum. Both methods of testing have their advantages and limitations, depending on the clinical situation, but for non-IgE-mediated food reactions, elimination diets and OFCs may be the only means of diagnosis for this group of disorders. Tests that have not proven helpful in food allergy diagnosis include quantification of food-specific IgG, total serum IgE levels, BHR, and serum tryptase concentrations. Tests

that need further study but show some promise include the APT, which may aid in the diagnosis of non-IgE-mediated disorders and delayed reactions to foods. The identification of epitopes to which IgE binding correlates with a high risk of clinical reactions might not only prove useful in enhancing the diagnostic value of SPTs and RASTs, but also provide a means of determining the clinical course of food allergy. Regardless of the test chosen, the DBPCFC still remains the gold standard for diagnosing food allergy. Finally, important features of the studies mentioned in this chapter for the described tests that need to be appreciated by clinicians are (i) that the data generated may be particular to the study population and test material and (ii) that the age and clinical disease of the patients are important variables. Clinicians must therefore be careful in applying the results in these published studies to their own individual clinical situations.

Diagnosis of Hypereosinophilic Syndromes

AMY D. KLION

110

HYPEREOSINOPHILIC SYNDROMES

Whereas mild to moderate eosinophilia has been reported in as many as 0.1% of North American outpatients (5) and may be due to seasonal allergies, asthma, or other common conditions, marked eosinophilia ($>1,500/mm^3$) is relatively infrequent and should always prompt a diagnostic evaluation. The differential diagnosis of marked eosinophilia is broad and includes secondary causes of eosinophilia (Table 1), such as hypersensitivity reactions, helminth infection, and neoplastic and inflammatory disorders, as well as several disorders for which eosinophilia is thought to be the primary etiology. In many cases, a thorough diagnostic evaluation will reveal a secondary cause of the eosinophilia, and appropriate treatment can be instituted. In other instances, a well-defined, single organ-restricted, primary eosinophil disorder, such as eosinophilic esophagitis, eosinophilic fasciitis, or eosinophilia cystitis, is identified. Once secondary causes and alternative diagnoses have been excluded, however, a systemic primary eosinophil disorder should be considered. The diagnostic evaluation of this small subgroup of eosinophilic patients will be the focus of this chapter.

Historical Definition

The term hypereosinophilic syndromes (HES) was first used in 1968 by Hardy and Anderson to describe three patients with marked peripheral eosinophilia, hepatosplenomegaly, and cardiac and/or pulmonary symptoms (16). Diagnostic criteria for HES were proposed in 1975 by Chusid et al. and include idiopathic hypereosinophilia ($>1,500$ eosinophils/mm^3) of >6 months' duration with signs and symptoms of eosinophil-mediated or unexplained end organ damage (7). Whereas this definition is extremely useful as a first step in identifying patients with systemic hypereosinophilic syndromes, as more sophisticated diagnostic testing becomes available and subgroups of patients with HES of known causes are described, the "idiopathic" nature of HES has been called into question. Furthermore, the availability of effective treatment for HES often leads to the resolution of eosinophilia before the requisite 6 months have elapsed. Finally, the classification of eosinophilic syndromes of unknown cause with distinctive clinical patterns, such as episodic angioedema and eosinophilia and chronic eosinophilic pneumonia, which are not excluded by this definition, remains unresolved (see below).

Clinical Features

Using Chusid's criteria, several characteristic features of HES have been described (7, 11). Although some of these, such as the male predominance (9:1), are likely due to skewing by a single HES subtype (see below), some general conclusions can be drawn.

HES typically occurs between the ages of 20 and 50, but may present in childhood or advanced age. The clinical manifestations of HES are extremely varied, ranging from nonspecific complaints, such as fatigue, myalgias, and rhinitis, to severe end organ damage, including endomyocardial fibrosis, restrictive pulmonary disease, and neuropathy (11, 42). Furthermore, some patients may remain asymptomatic for decades despite markedly elevated eosinophil counts. Although data from a number of published case series suggest that cardiac, neurologic, and dermatologic manifestations are most common (11, 42), any organ can be affected. A description of the many and varied end organ manifestations of HES is beyond the scope of this chapter but can be found in some excellent reviews (1, 42). Notably, increased susceptibility to infection is not a feature of HES; thus, a history of recurrent infection should prompt an investigation for secondary causes of eosinophilia, including malignancy and immunodeficiencies.

Pathogenesis

Bone marrow eosinophils are increased in number in all forms of HES and may reflect a primary myeloproliferative process (as in Fip1-like 1/platelet-derived growth factor alpha (F/P)-associated HES) or a response to eosinophilopoietic cytokines produced by nonmyeloid cells. Regardless of the mechanism of increased eosinophil production, increased numbers of activated eosinophils released into the peripheral blood and tissues are thought to play a primary role in the tissue damage observed in this disorder through the local release of a variety of inflammatory mediators, including cationic proteins, leukotrienes, and cytokines.

RECENT DEFINITION OF SUBTYPES

Although it has long been appreciated that HES are a heterogeneous group of disorders (11, 40), it is only recently that advances in molecular and immunologic techniques have begun to delineate the precise pathogenesis of HES in some groups of patients. Of these defined groups, the most

TABLE 1 Secondary causes of marked eosinophilia[a]

Cause
Allergic disorders
Asthma and/or atopic disease (rare)
Allergic bronchopulmonary aspergillosis
Drug hypersensitivity reactions
Infectious diseases
Helminth infection
Ectoparasite infestations (scabies and myiasis)
Protozoal infection (rarely in isosporiasis and sarcocystis)
Fungal infection (especially coccidiomycosis)
HIV infection
Neoplasms
Leukemia, lymphoma, or adenocarcinoma
Hypoadrenalism
Diseases associated with immunodysregulation
Sarcoidosis, inflammatory bowel disease, or connective tissue
disorders
Other
Cholesterol embolization, radiation exposure

[a]This list is not exhaustive.

common appear to be a clonal myeloproliferative disorder associated with the constitutive activation of platelet-derived growth factor receptor alpha (PDGFRA) (9, 15) and a lymphocytic variant characterized by the presence of a clonal population of lymphocytes (35, 39). An autosomal dominant familial form of HES mapped to chromosome 5q31-33 has also been described, although the exact nature of the molecular abnormality remains to be elucidated (24, 31). Finally, additional subgroups of HES with distinctive clinical manifestations await characterization at the molecular and immunologic levels.

Imatinib-Responsive HES

Imatinib is a tyrosine kinase inhibitor with potent activity against ABL, ARG, BCR-ABL, KIT, and PDGFRA and -B. Following the report of a clinical response to imatinib in a single patient with HES (36), several small clinical trials were initiated to explore the utility of imatinib for the treatment of HES (2, 13, 22). This led to the identification of F/P, a fusion tyrosine kinase associated with the majority of cases of imatinib-responsive HES (9, 15). Although patients with F/P-associated HES occasionally have cytogenetic abnormalities (9, 26), in the vast majority of cases the *FIP1L1-PDGFRA* fusion gene is created by a small interstitial deletion in chromosome 4, del(4)(q12q12), that is undetectable by standard cytogenetics (9, 15). The breakpoints in *FIP1L1* are variable but are typically located in a 40-kb region spanning introns 7 to 10 of *FIP1L1*. In contrast, the breakpoints in *PDGFRA* appear to be restricted to a region of exon 12 that contains the WW-like region of the juxtamembrane domain (9). Disruption of this WW-like domain has been shown to cause constitutive kinase activation in members of the PDGFR family of tyrosine kinases, including PDGFRA (17).

Clinical, hematologic, and molecular responses are rapidly achieved with imatinib treatment in the setting of the F/P mutation and appear to be sustained (23), although the long-term efficacy of this drug for the treatment of HES remains to be proven. A resistance mutation (T674I) in F/P that is homologous to the well-described T315I mutation in BCR-ABL seen in patients with imatinib-resistant chronic

myelogenous leukemia has been described for a single patient with HES who relapsed during therapy (9), further confirming the etiologic role of the fusion gene in this disorder.

Imatinib-responsive patients with HES in whom the F/P mutation cannot be demonstrated have been reported in several studies (12, 41). Clinical and hematologic responses in these patients are generally slower and incomplete and require higher doses of imatinib than responses in patients with F/P-associated disease. Although molecular abnormalities have been described for a few of these patients, the basis of the response remains uncharacterized in most instances.

Lymphocytic Variant HES

Despite isolated reports of clonal populations of T cells in patients with HES as early as 1994 (6, 8), it was not until 1999 that a distinct subgroup of patients with lymphocyte-driven HES was first described (39). Hypereosinophilia in these patients appears to occur in response to the production of eosinophilopoietic cytokines, particularly interleukin 5 (IL-5), by clonal populations of phenotypically abnormal activated T lymphocytes. Although the levels of IL-5 in the serum are often normal for patients with the lymphocytic variant, an increased production of IL-5 by stimulated peripheral blood mononuclear cells and/or phenotypically abnormal T-cell populations can be demonstrated in most patients with the lymphocytic variant of HES, consistent with this hypothesis (34, 35). Other evidence of Th2 activation in patients with this variant include elevations of immunoglobulin E (IgE) and thymus and activation-regulated chemokine (TARC) in serum (10). Cytogenetic abnormalities are occasionally present in patients with the lymphocytic variant, although no consistent pattern has been delineated (34).

Familial Eosinophilia

The occurrence of marked eosinophilia in multiple members of the same family is rare, with only a few reports in the literature to date (24). Autosomal dominant transmission appears to be the most common form of transmission. In one such family, the gene responsible for the eosinophilia has been mapped to chromosome 5q31-33 (31). Despite marked eosinophilia (2,000 to 6,000/mm³) from birth, a minority of family members with familial eosinophilia develop eosinophil-mediated end organ damage (21). This paucity of clinical manifestations is associated with a relative lack of eosinophil activation compared to that in patients with non-familial HES. Whether the sudden disease progression in a small number of these patients after a lifetime of asymptomatic eosinophilia represents a second mutation remains unknown at this time.

Other

Several other HES of unknown etiology have distinctive clinical patterns that appear to set them apart. One of the most intriguing of these is episodic angioedema and eosinophilia (Gleich's syndrome) (14). Gleich's syndrome is characterized by episodic, but pronounced, eosinophilia and angioedema. In most cases, the episodes occur monthly and last for 7 to 11 days. Cyclical increases in eosinophilopoietic cytokines, most often IL-5, can be demonstrated preceding the rise in peripheral eosinophil counts (14). Although some patients with this syndrome ultimately progress to HES and/or develop clonal populations of lymphocytes (25), the unique clinical presentation is suggestive of a common and distinct etiology for this clinical subgroup of patients.

A second, less well-defined clinical subgroup of patients presents with marked eosinophilia and clinical features highly suggestive of Churg-Strauss syndrome, including a long history of asthma, paranasal sinus abnormalities, and recurrent pulmonary infiltrates, without demonstrable vasculitis. Although some of these patients likely have occult Churg-Strauss vasculitis, in some cases biopsies of affected tissues repeatedly fail to show evidence of vasculitis, and antineutrophil cytoplasmic antibodies are undetectable in serum. The pathologic basis of end organ damage in this subgroup of patients remains to be elucidated.

Primary eosinophilic disorders affecting a single organ, such as eosinophilic gastroenteritis, eosinophilic fasciitis, and chronic eosinophilic pneumonia, may be associated with peripheral eosinophilia of >1,500/mm³. When this occurs, it can be difficult to determine whether the patient has HES with single organ involvement or a distinct primary eosinophilic disorder. A more useful classification system for these patients awaits advances in our understanding of the etiology of single-organ-restricted disease, particularly the mechanisms of eosinophil homing to specific sites, such as the gastrointestinal tract and the lungs.

IMPORTANCE OF SUBTYPES

Subtype identification has profound implications for the patient with respect to the clinical manifestations, prognosis, and treatment of HES. This is best illustrated by the differences between F/P-associated HES and the lymphocytic variant (see below).

Clinical Manifestations

Current data suggest that 10 to 20% of HES cases that meet Chusid et al.'s classic definition have F/P-associated disease (27). Most of these cases belong to a distinct clinical subgroup characterized by extreme male predominance, pathologic evidence of eosinophil-related tissue damage and tissue fibrosis, elevated serum tryptase levels, splenomegaly, anemia, thrombocytopenia, and bone marrow hypercellularity with reticulin fibrosis and increased atypical mast cells (see below) (22). Interestingly, some clinical manifestations, such as endomyocardial fibrosis, restrictive lung disease, and mucosal ulcerations, appear to occur predominantly, if not exclusively, in patients with F/P-associated disease. Leukemic transformation is rare, but it does occur in this subgroup (12, 41).

The F/P mutation has also been described for a subset of eosinophilic patients presenting with clinical features of systemic mastocytosis that are indistinguishable from those of c-*kit* mutation-driven systemic mast cell disease (27). It is extremely important to distinguish these patients from those with c-*kit* mutation-driven disease, as 816V, the most common c-*kit* mutation associated with systemic mastocytosis, is resistant to imatinib.

Interestingly, the clinical presentation of patients with symptomatic familial eosinophilia shares many features with F/P-associated HES, with the exception of male predominance. Endomyocardial fibrosis and neurologic involvement are the most common clinical manifestations, and the response to conventional therapies, including steroids, alpha interferon, and hydroxyurea, is limited. Data on the presence of the F/P mutation and/or imatinib responsiveness are not available at this time. The clinical manifestations of patients with HES and features of myeloproliferative disease, but no evidence of the F/P mutation, have not been systematically examined.

The lymphocytic variant of HES appears to be equally distributed between men and women. Although the clinical manifestations of this subgroup of patients can be extremely varied, tissue fibrosis, including endomyocardial fibrosis, is uncommon. In addition, patients with the lymphocytic variant of HES share several clinical characteristics, the most striking of which is the predominance of dermatologic manifestations, including pruritus, urticaria, angioedema, and erythroderma (34). Gastrointestinal symptoms and obstructive pulmonary disease are also extremely common. Many patients have a history of atopic disease, and elevated IgE and IgG levels are common, but not restricted, to this subgroup of patients with HES. The prevalence of this subtype of HES is unknown, since the largest series reported in the literature to date recruited patients predominantly from dermatology clinics.

Prognosis

The prognosis of HES varies considerably depending on the underlying cause and is poorest for patients with the *FIP1L1/PDGFRA* fusion (22, 41). The dismal survival rates reported in the literature (29) likely reflect the high morbidity and mortality from cardiac and neurologic complications in this subgroup. Although imatinib treatment results in dramatic improvement in most of the clinical manifestations of F/P-associated HES, cardiac involvement appears to be relatively refractory to treatment (23). A report of the reversal of cardiac abnormalities with imatinib treatment in a single patient with the F/P mutation and recent-onset cardiac involvement underscores the importance of early identification of patients with F/P-associated disease (33).

In contrast to F/P-associated HES, severe end organ damage is uncommon in the lymphocytic variant of HES (39). Despite the relatively low mortality rate for this subgroup, the morbidity, due both to the underlying disease and to secondary effects of treatment, is significant. Furthermore, progression to T-cell lymphoma appears to be most common in this subgroup of patients and should be suspected in the setting of increasing numbers of aberrant T cells and/or the development of lymphadenopathy (34, 35). Two features that appear to be associated with an increased likelihood of progression to lymphoma are the CD3⁻ CD4⁺ surface phenotype and the presence of cytogenetic abnormalities.

Therapy

Finally, and perhaps most importantly, the identification of the HES subtype has profound implications for therapy. Whereas conventional first-line therapy for HES in most patients should continue to be steroids, patients with F/P-associated HES are typically resistant to steroids and should receive targeted therapy with imatinib mesylate. Although imatinib resistance has been reported in several patients with a documented F/P fusion (9), the incidence of resistance remains extremely low. The utility of imatinib therapy in patients without the F/P mutation remains to be determined, although some patients have demonstrated a response. It should be noted that imatinib therapy is not without risk, as life-threatening complications have occurred in patients with eosinophilic cardiac disease (30, 32). Troponin levels in serum have been proposed as a pretreatment marker for the development of this complication (30).

Imatinib does not appear to be useful for treating patients with the lymphocytic variant of HES (26) and should not be used as first-line therapy for these patients. Historically, steroids have been used successfully in the majority of cases

to control clinical symptoms, and significant decreases in clonal populations in response to steroid therapy have been described (35). In patients with steroid-refractory disease or who are intolerant of the side effects of steroid treatment, a number of immunomodulatory agents with effects on Th2 cytokine production and T-cell proliferation, including alpha interferon, cyclosporine, and intravenous immunoglobulin, have been shown to have a therapeutic effect. Although stable responses have been achieved with relatively low doses of alpha interferon over prolonged periods of time, in vitro data demonstrating an inhibition of apoptosis of clonal CD3− CD4+ T cells (37) suggest that interferon monotherapy should be avoided for this subgroup of patients (34). New agents, such as antibody to IL-5, that directly target eosinophilipoietic cytokines remain to be assessed.

DIAGNOSTIC ALGORITHM

The first step in the diagnosis of HES is to exclude other disorders associated with marked peripheral eosinophilia. These include parasitic infections, drug hypersensitivity reactions, neoplasms, and immunodysregulatory disorders associated with secondary eosinophilia (Table 1). Once it is established that the patient has eosinophilia of >1,500/mm³ of unknown cause, it is important to determine if the patient has one of the identifiable subtypes of HES, as these have prognostic and therapeutic implications as discussed above (Table 2).

Exclusion of Other Disorders

It is beyond the scope of this chapter to provide a comprehensive diagnostic approach to eosinophil-associated disorders. Nevertheless, several general principles apply.

TABLE 2 Evaluation of patients with presumed HES

Test or measurement
Complete blood count with differential[a]
Bone marrow aspirate and biopsy (with staining for reticulin and tryptase)
Conventional cytogenetics
Assessment of end organ pathology
Echocardiogram
Pulmonary function tests
Skin or gastrointestinal biopsies, if indicated
Chest and abdomen computed tomography scan
Subtype differentiation: myeloproliferative disease
Examination of peripheral smear for myeloid precursors or dysplasia
Tryptase level in serum
Vitamin B_{12} level in serum
Testing for *FIP1L1/PDGFRA* fusion (by RT-PCR or FISH)
Subtype differentiation: lymphoproliferative disease
Serum immunoglobulins, including IgE
Lymphocyte phenotyping[b]
TCR and B-cell-receptor gene rearrangement analysis
TARC level in serum
Assessment of T-cell cytokine profile, if reliable assays are available

[a]This should be performed every 3 days for 1 month in the absence of steroid treatment (if possible) for patients presenting with angioedema to exclude episodic angioedema and eosinophilia.

[b]Antibodies specific for the following additional markers should be included if routine phenotyping is normal and the lymphocytic variant is suspected: CD2, CD5, CD6, CD7, CD8, CD25, CD27, CD45RO, TCRα/β, TCRγ/δ, HLA-DR, and CD95.

First, a thorough clinical history and physical examination is essential and should include a detailed travel history, medication and dietary history (including the use of dietary and herbal supplements), past medical history (including risk factors for human immunodeficiency virus [HIV] infections), and family history. It should be noted that HES occurs in countries where helminth infections are common, and some helminth infections associated with marked eosinophilia, including strongyloidiasis, occur worldwide. Second, whenever possible, all medications and supplements should be discontinued for a minimum of 1 month (or longer, depending on the half-life of the particular agent). Finally, if routine laboratory results (including HIV testing) and diagnostic testing do not lead to an alternative diagnosis, computed tomography of the chest, abdomen, and pelvis, as well as a bone marrow examination, should be performed in all patients to exclude occult malignancy before a diagnosis of HES is confirmed.

Hematologic malignancies that may present with marked eosinophilia include T-cell lymphoma, chronic myelomonocytic leukemia, and pre-B-cell acute lymphocytic leukemia. If a bone marrow aspirate is not possible due to myelofibrosis or other reasons, lymphocyte clonality should be assessed by PCR analysis of T-cell receptor (TCR) and immunoglobulin heavy chain gene usage, as the diagnosis may be obscured upon biopsy by the presence of markedly increased numbers of eosinophils and eosinophil precursors (32). Chronic eosinophilic leukemia (CEL), defined by the World Health Organization as HES with evidence of clonality on the basis of chromosome abnormalities or X-inactivation studies (4), represents a special situation for several reasons. First, although the presence of F/P is indicative of eosinophil clonality (and thus of CEL), in most cases it is not detectable by standard cytogenetic analysis. Since the clinical presentation of HES with clonal eosinophilia overlaps with other forms of HES, it seems arbitrary to call those cases for which testing for F/P is available and positive CEL and to call the rest HES. Second, F/P is the causative mutation in some, but not all, cases of HES in which clonal eosinophilia can be demonstrated (41). For the purposes of this chapter, therefore, HES with the F/P mutation is referred to as F/P-associated HES rather than CEL.

Subtype Identification

The "gold standard" for the diagnosis of F/P-associated HES is detection of the fusion tyrosine kinase by nested reverse transcription-PCR (RT-PCR) or fluorescence in situ hybridization (FISH). If these tests are not available, a number of clinical and laboratory features may be helpful in identifying the patients most likely to have imatinib-responsive HES. Notably, some clinical manifestations, such as mucosal ulcerations, appear to occur exclusively in patients with F/P-associated HES. Since patients with familial eosinophilia may present with clinical features indistinguishable from those of F/P-associated HES, it is important to elicit a family history of eosinophilia from all patients with suspected HES.

The identification of a population of phenotypically abnormal circulating lymphocytes by flow cytometry is considered the hallmark of the lymphocytic variant of HES. In the majority of cases, T-cell clonality can also be demonstrated by an analysis of TCR rearrangement patterns. Although one or both of these features may be considered sufficient to make a diagnosis of the lymphocytic variant of HES for the purposes of clinical management, it is important to recognize that neither clonality nor an abnormal surface phenotype is synonymous with an increased secretion of

eosinophilopoietic cytokines, the pathologic basis for this subtype of HES.

For patients whose primary complaint is swelling and/or weight gain, it is useful to measure eosinophil counts every 3 days for several weeks off therapy in order to identify episodic angioedema and eosinophilia. Often, the periodicity is missed because of intermittent steroid use and the measurement of eosinophil counts only when symptoms are present. Clonal T-cell populations have been described for this subgroup of patients and should be assessed by flow cytometry and TCR rearrangement analysis.

In general, IL-5 levels in serum are not useful for the differentiation between primary and secondary disorders of eosinophilia or between the various HES subtypes. Furthermore, they do not appear to predict a therapeutic response to imatinib mesylate (22), or interestingly, to anti-IL-5 antibody therapy (20).

SPECIALIZED DIAGNOSTIC TESTS

Myeloproliferative HES

The F/P fusion can be detected in peripheral blood or bone marrow mononuclear cells by using either nested RT-PCR or FISH. Although published data to date suggest that these methods have comparable sensitivities for the detection of the *FIP1L1/PDGFRA* fusion gene (41), FISH has the theoretical advantage of being able to detect cases with variant *FIP1L1* breakpoints, translocations, or alternative *PDGFRA* fusion partners that appear negative by nested RT-PCR. On the other hand, FISH is more technically challenging, and the high autofluorescence of eosinophil granules makes an exact quantification of the number of positive cells difficult. If neither of these tests is available, surrogate markers for F/P-associated HES can be used, as described below.

Nested RT-PCR for *FIP1L1/PDGFRA*

Following total RNA isolation from peripheral blood mononuclear cells by standard methods, first-strand cDNA is synthesized from 2 µg of total RNA by the use of random hexamer primers. The fusion of *FIP1L1* to *PDGFRA* is detected by nested PCR. The first PCR amplifies 2 µl of cDNA in a 50-µl reaction mix; using primers FIP1L1-F1 (5′-ACCTGGTGCTGATCTTTCTGAT) and PDGFRA-R1 (5′-TGAGAGCTTGTTTTTCACTGGA) and the following cycle conditions: 3 min at 95°C followed by 35 cycles of 95°C for 30 s, 58°C for 30 s, and 72°C for 1 min and a final extension at 72°C for 4 min. The product is then diluted 1/100, and 1 µl is used in a second PCR with primers FIP1L1-F2 (5′-AAAGAGGATACGAATGGGACTTG) and PDGFRA-R2 (5′-GGGACCGGCTTAATCCATAG) and the same cycle conditions. Multiple bands are often present upon gel electrophoresis and represent splice variants (9, 22). The EOL-1 cell line (ACC386; available from the Deutsche Sammlung von Mikroorganismen und Zellkulturen [http://www.dsmz.de]) has been shown to possess the F/P mutation (15) and is useful as a positive control. RT-PCR for a housekeeping gene, such as the glyceraldehyde-3-phosphate dehydrogenase gene, should also be performed as a control for the amount and quality of the RNA template.

FISH

Slides for FISH are prepared by standard methods. BAC clones 120K16 (mapped centromeric of *FIP1L1*), 3H20 (mapped between *FIP1L1* and *PDGFRA*), and 24O10 (mapped telomeric of *PDGFRA*), can be obtained from the RPCI11 Roswell Park Cancer Institute library (http://www.chori.org/BACPAC) for three-color labeling by nick translation. Following hybridization, interphase nuclei are examined for the presence or absence of the 3H20 signal, which is lost as a result of the interstitial deletion in cells with the *FIP1L1/PDGFRA* fusion gene (9).

One-color FISH with a probe for the cysteine-rich hydrophobic domain 2 (*CHIC2*) locus situated between *FIP1L1* and *PDGFRA* on chromosome 4q has been suggested as a surrogate for detection of the fusion gene to identify patients with the F/P fusion gene (28). Although it is less cumbersome, this method is not useful for the detection of F/P fusion genes in which there is a translocation. A two-color modification of this approach has recently been reported by the same authors (27) and appears to be comparable to the three-color strategy outlined above.

Other (Bone Marrow Features and Level of Tryptase in Serum)

In addition to the assays described above, several clinical and laboratory features are supportive of a diagnosis of F/P-positive HES (22) and may serve as surrogates if formal testing for the mutation is not available. These include male gender, elevated tryptase levels in serum, splenomegaly, clinical evidence of fibrotic end organ involvement, bone marrow features of myeloproliferative disease (including hypercellularity and reticulin fibrosis), increased and spindle-shaped bone marrow mast cells, anemia, thrombocytopenia, and elevated vitamin B_{12} levels in serum. Although none of these features is by itself diagnostic of the *FIP1L1/PDGFRA* fusion gene, the presence of an elevated tryptase level in serum and four or more of the above clinical features has correlated with the presence of the fusion gene in all of the patients evaluated at our center to date. Measurements of tryptase levels in serum are performed by several commercial laboratories. Enzyme-linked immunosorbent assay (ELISA) kits are also available from a number of sources.

Lymphoproliferative HES

The diagnosis of the lymphocytic variant of HES is based on the identification of a clonal population of phenotypically abnormal T cells in the peripheral blood by flow cytometry (see chapter 18, this volume). The sensitivity of this assay depends to a large degree on the number of antibodies used and the ability of the laboratory to detect subtle changes in the surface phenotype. Although T-cell clonality is not always present in cases with a demonstrable population of aberrant lymphocytes and is not essential for the diagnosis of the lymphocytic variant, identification of a clonal population of T cells by TCR rearrangement analysis is strongly supportive of this diagnosis. Other diagnostic tests that may be helpful in establishing the diagnosis include the measurement of TARC levels in serum and the assessment of the lymphocyte production of eosinophilopoietic cytokines.

Lymphocyte Phenotype

Although the most common aberrant phenotype of the lymphocytic variant of HES appears to be CD3− CD4+, several other surface phenotypes have been described, including CD3+ CD4− CD8− and CD2− CD3+ (39). In many cases, the aberrant population may be identifiable only by markers that are not included in routine panels (such as CD5, CD6, CD7, CD27, and CD95) or by slight alterations in staining intensity. Therefore, if the lymphocytic variant is suspected

and routine lymphocyte phenotyping is normal, surface staining for additional markers, including CD5, CD6, CD7, and CD27, should be considered. Activation markers, such as CD25 and HLA-DR, are commonly increased on the surfaces of aberrant T cells, providing additional markers.

Other (TCR Rearrangement Analysis, Measurement of TARC Levels, and Cytokine Assays)

T-cell clonality can be assessed in peripheral blood or bone marrow samples by PCR evaluation of TCR usage and has been reported to be present in approximately 75% of patients with the lymphocytic variant of HES, as defined by flow cytometry. When present, the demonstration of clonality may be helpful, although false-negative results may occur when the clonal population is very small or involves clonal deletion of TCR chain genes (35). In addition, restricted (or oligoclonal) patterns of TCR usage are common in all forms of HES, necessitating a very strict interpretation of banding results.

TARC is a CC chemokine thought to be involved in Th2-mediated immune responses. TARC levels in serum can be measured reliably by using several commercially available ELISA kits and are markedly elevated (>1,000 pg/ml) in patients with lymphocytic HES (10). TARC levels in serum are also markedly elevated in patients with cutaneous T-cell lymphoma (18), a disorder that may overlap with HES in clinical presentation, and rarely in patients with atopic dermatitis (38) or helminth infection (19). Thus, although TARC levels in serum may be a useful surrogate marker for T-cell clonality in HES, the presence of elevated levels should not replace a thorough diagnostic evaluation.

The ultimate proof of lymphocyte-driven HES is the documentation of an increased production of eosinophilopoietic cytokines by circulating lymphoctyes. Enhanced levels of IL-3, IL-5, and/or granulocyte-macrophage colony-stimulating factor have been detected by ELISA in supernatants from in vitro cultures of peripheral blood mononuclear cells or purified T cells from patients with the lymphocytic variant of HES (35, 39). Increased percentages of lymphocytes positive for eosinophilopoietic cytokines have also been demonstrated by intracellular flow cytometry in these patients. Although these assays are not routinely available in clinical laboratories at this time, they may be helpful, particularly in situations where an abnormal surface phenotype is not detected by more standard methods.

CONTROVERSIES

Several controversies currently exist surrounding the diagnosis of HES and its classification into subtypes. These include (i) the classification of patients with marked eosinophilia and no evidence of end organ damage, (ii) the distinction between HES and other organ-specific eosinophilic disorders of unknown etiology (e.g., eosinophilic gastroenteritis or chronic eosinophilic pneumonia) in patients with concomitant peripheral eosinophilia, and (iii) the diagnostic classification of patients with the *FIP1L1/PDGFRA* fusion gene (chronic eosinophilic leukemia versus myeloproliferative HES versus systemic mastocytosis with eosinophilia) (3). As the number of chemotherapeutic agents with specific molecular and immunologic targets continues to grow, the resolution of these issues will become increasingly important for the appropriate management of patients with primary eosinophilic disorders.

Introduction

WESTLEY H. REEVES

111

Systemic autoimmune diseases are often associated with the production of autoantibodies that recognize a diverse array of cytoplasmic and nuclear antigens. These autoantibodies are used as adjuncts in the diagnosis of autoimmune disease, for monitoring disease activity and severity, and for predicting the outcome of autoimmune disease. As the diagnosis of systemic autoimmune disease is not always straightforward, the widespread use of autoantibody testing has significantly improved our ability to diagnosis complex autoimmune disorders. However, autoantibody test results, particularly those based on enzyme-linked immunosorbent assays (ELISAs), must be interpreted with caution due to the occasional occurrence of false-positive results. It is important to interpret the results of autoantibody tests in light of both the clinical context and the methodology employed. In some cases, confirmatory testing, analogous to the use of Western blot to verify positive ELISA test results for HIV infection, is warranted.

Conversely, it is important to understand that positive autoantibody tests can be harbingers of autoimmune disease in otherwise healthy individuals, especially in the case of disease-specific autoantibodies, which may appear months, years, or even decades before the onset of clinical symptoms. The detection of disease-specific autoantibodies in asymptomatic individuals may permit early diagnosis and preventative treatment. Good examples are antimitochondrial antibodies in primary biliary cirrhosis, anti-Sm, RNP, Ro(SSA), and double-stranded DNA autoantibodies in systemic lupus erythematosus (SLE), and specific autoantibodies associated with rheumatoid arthritis, polymyositis, and scleroderma, all of which may appear prior to the onset of clinical manifestations. Thus, in the case of an unexpectedly positive autoantibody test, it is important to consider two possibilities: (i) that the test result is a false positive, or (ii) that the autoantibody is present, perhaps as the initial manifestation of an autoimmune disorder.

Autoantibody testing is an evolving field. Older tests, such as double immunodiffusion in gels and agglutination assays, are highly specific but less sensitive than more recent ELISA and addressable bead assays. The older tests also are frequently less amenable to automation, which has led to their rapid abandonment in favor of other tests. The past 15 years has seen a rapid shift from double immunodiffusion and agglutination assays to the ELISA format. Newer technologies are on the horizon, including fluorescence-based assays employing addressable beads, which permit screening for multiple specificities in a single assay.

The chapters in this section reflect both the evolving technology and the need for reliable confirmatory tests, which frequently are older or more labor-intensive assays that are not readily available. Bradwell et al. review the importance of a classical screening test, the fluorescent antinuclear antibody assay, in the serodiagnosis of systemic autoimmune disease. Although automated (ELISA) testing is available, it has not yet replaced the more labor-intensive fluorescence-based assay, and is unlikely to do so in the near future. In the following chapter, Reeves et al. discuss the clinical application of double immunodiffusion, radioimmunoprecipitation, and Western blotting, relatively specific immunological tests that are generally available only in specialized or referral laboratories. With the exception of Western blot and other solid-phase assays, these tests are probably too labor-intensive for general screening, but they can be invaluable in confirming the significance (or lack thereof) when a screening test yields an unexpectedly positive result. The chapter by Chan et al. deals with the mainstream autoantibody assays employing solid-phase antigens, both natural and recombinant. The newly developing technology of addressable laser bead assays for detecting autoantibodies against multiple antigens is reviewed along with future prospects for this exciting new approach.

The following four chapters deal with autoantibody testing relevant to particular diseases or syndromes. Tran and Pisetsky review the approach for detecting anti-DNA antibodies, a specificity pathognomonic for SLE. The importance of distinguishing antibodies against double-stranded DNA (disease specific) from those against single-stranded DNA (not specific) is detailed, as well as an approach to the interpretation of anti-DNA test results. Narain et al. discuss the classical rheumatoid factor assays used to screen for rheumatoid arthritis, along with newer assays for autoantibodies against citrulline-modified proteins that appear to be more specific for rheumatoid arthritis than rheumatoid factor. Schmitz covers the various antibodies associated with the antiphospholipid antibody syndrome and tests to detect and evaluate them. Finally, Wiik discusses the clinical use of antineutrophil cytoplasmic antibody testing in the diagnosis of vasculitis syndromes and the newer tests that detect autoantibodies against specific neutrophil proteins.

The identification of a wide variety of disease-specific autoantibodies over the past 30 years and the increasing sophistication of autoantibody testing have greatly facilitated the diagnosis of systemic autoimmune disease. Automation of autoantibody testing is a more recent development, raising hope that in the future, screening for these biological markers may be useful not only for confirming a clinical diagnosis, but also for establishing a diagnosis during the preclinical phase of the illness, when it may be more amenable to therapy.

Immunofluorescent Antinuclear Antibody Tests

ARTHUR R. BRADWELL, RICHARD G. HUGHES, AND ABID R. KARIM

112

BACKGROUND

Detection and identification of antinuclear autoantibodies (ANAs) are essential for the assessment of systemic and organ-specific autoimmune diseases. The initial screening test is usually done by immunofluorescence on HEp-2 cells followed by identification of individual antibodies with specific assays. Over 40 years, this test has proved remarkably robust and, with a few minor changes, it has retained its important position in most laboratories. It combines the detection of a wide range of autoantibodies with good sensitivity, reproducibility, economy, and ease of use. Such is its dominance that it is the most commonly performed autoantibody test worldwide and the most frequently performed test in clinical immunology laboratories. Competitors in the form of enzyme immunoassays (EIAs) have been available since the early 1990s, but to date they have not upset the hegemony of this enduring immunofluorescent assay (IFA). This chapter reviews the history and the method for ANA testing on HEp-2 cells and its utility in a laboratory setting. Further details can be obtained from the extensive reviews and monographs on the subject which, in particular, show details of the numerous patterns produced by the various autoantibodies on HEp-2 cells (3, 5, 13, 15, 26).

Antinuclear antibody tests have their origin in the "L.E." cell phenomenon, which was the observation that neutrophils from patients with systemic lupus erythematosus (SLE) ingested other leukocytes. This was first demonstrated in 1948 by Hargraves et al. (10) while working at the Mayo Clinic and became widely used as a diagnostic test for SLE but was rather insensitive and difficult to standardize. Lee et al. (14) then showed that the L.E. phenomenon was caused by a gamma globulin protein on the leukocytes, which was thought to be an antibody. In 1957, Holborow et al. (11) (Canadian Red Cross Memorial Hospital, Taplow, United Kingdom) used the fluorescence-labeled antibody technique, developed by Coons and Kaplan (6), to demonstrate that the sera of patients positive for L.E. cells contained antibodies that produced homogeneous nuclear fluorescence on human tissues.

It was soon apparent that different patterns occurred, and in 1961, Beck (2) (National Institute for Medical Research, London, United Kingdom) used rat liver sections to demonstrate homogeneous, speckled, and nucleolar staining of nuclei by sera from patients with a variety of different rheumatic diseases. He also showed that washing the cells in saline caused alterations in the patterns, which was the precursor of extractable nuclear antigen (ENA) tests. The use of human cell lines subsequently became popular, and the work of Tan (20) (Scripps Clinic, La Jolla, Calif.) and others with ENAs and HEp-2 cells led to a huge increase in the number of antigens and patterns recognized in the 1970s and 1980s. Widespread commercial production of HEp-2 cells and the development of national quality control schemes ensured that the test entered worldwide routine laboratory usage. While rodent tissues proved useful in their day, poor sensitivity and variable quality have been conspicuous problems (1, 8), so for the detection of ANAs they have now been replaced by HEp-2 cells in almost all laboratories.

HEp-2 cells, originally considered to originate from a human laryngeal carcinoma, are now known to have been established from a HeLa cell contamination (HEp-2 cells: CCL-23, American Type Culture Collection; depositor, A. E. Moore). This was shown by several techniques, including isoenzyme analysis and DNA fingerprinting. The cells are grown as monolayers on microscope slides. These slides provide a sensitive substrate, and their advantages over rodent tissues include the following.

1. They have increased sensitivity because of greater antigen expression.
2. Human origin ensures better specificity.
3. Cell division rates are higher, so cell cycle-dependent antibodies are easily identified.
4. The cells are grown in monolayers so that all nuclei are visible.
5. The nuclei are much larger, so complex nuclear details can be seen.
6. Antigen distribution is uniform.
7. There is no obscuring intercellular matrix.
8. They are widely available as a standardized immortal cell line.

HEp-2 cells allow recognition of over 30 different nuclear and cytoplasmic patterns that are given by upwards of 50 different autoantibodies. Some patterns, such as centromere patterns, are antigen specific, but most can be attributed to several different autoantibodies. For this

TABLE 1 HEp-2 cell patterns, autoantigens, and disease associations[a]

HEp-2 cell pattern		Antigen target(s)	Disease association(s)
Nucleus	Homogeneous	dsDNA, histones	SLE, drug-induced lupus (histones)
	Nuclear membranous	Lamins A, B1, B2, and C	Mixed chronic autoimmune disorders and chronic fatigue syndrome
	Nuclear membrane pores	gp210 and nucleoporin	PBC and polymyositis
	Nuclear matrix	hnRNP	MCTD, RA, SLE, and scleroderma
	Coarse nuclear speckles	Sm, U1-snRNP, U2-snRNP, U4/U6-snRNP	MCTD, SLE, scleroderma-polymyositis, Raynaud's phenomenon, Sjögren's syndrome, and systemic sclerosis
	Fine nuclear speckles	SSA/Ro, SSB/La, RNA Ku, polymerases I and II, Ki, and Mi-2	SLE, Sjögren's syndrome, scleroderma, myositis, and MCTD
	Few nuclear dots (1–6)	p80-coilin	PBC and chronic active hepatitis
	Multiple nuclear dots (≈10)	Sp-100, PML, and NDP53	PBC, Sjögren's syndrome, and occasionally SLE
	Homogeneous or fine speckled nuclei	Scl-70 (topoisomerase I)	Systemic sclerosis; may also be present in Raynaud's phenomenon and SLE
Nucleolus	Homogeneous	Pm-Scl	Myositis-scleroderma overlap; less frequent in systemic sclerosis and myositis
		Th/To (7-2 RNA and 8-2 RNA)	Systemic sclerosis, Raynaud's phenomenon, SLE, polymyositis and RA
	Clumpy	Fibrillarin (in snoRNP)	Systemic sclerosis
	Dense speckled	RNA helicase II	Systemic sclerosis, SLE, undifferentiated connective tissue disease, and watermelon stomach disease
	Speckled with mitotic dots	RNA polymerase I	Mainly in systemic sclerosis; also SLE, RA, and MCTD
		NOR-90/hUBF	Scleroderma, Raynaud's phenomenon, SLE, RA, and malignancies
Cell cycle related	Centromere, 40–80 discrete nuclear speckles	Centromere (CENP-A, B, C, D)	CREST
	Nuclear pleomorphic pattern (PCNA)	DNA-polymerase associated protein (cyclin)	SLE
	Mitotic spindle (pole-pole) and cytoplasmic fibers	Tubulin	Nonspecific
	1–2 perinuclear cytoplasmic dots, located at spindle poles in mitosis	Centriole/centrosome proteins	Raynaud's phenomenon, scleroderma, Sjögren's syndrome, and CREST
	Spindle poles and fibers in close proximity to poles with fine speckled nuclei	NuMA-1/MSA-1 (210 kDa)	Nonspecific; reported in SLE, Sjögren's syndrome, MCTD, and polyarthritis
	Spindle poles and fibers (pole-pole), midbody and intercellular bridge	NuMA-2, HsEg5	SLE and Sjögren's syndrome
	Cleavage furrow and midbody, staining of chromatin in metaphase and speckled nuclei in interphase	MSA-2, Unknown antigen	Systemic sclerosis and Raynaud's phenomenon
	Speckles along spindle poles. Fine, dense nuclear speckling in some interphase cells	MSA-3, unknown antigen	Unknown
	G$_2$ granular nuclei and nuclear rim. Kinetochores, cleavage furrow, and either side of the midbody	CENP-F/Na (367 kDa)	Neoplasms (breast and lung cancer)

TABLE 1 (*Continued*)

HEp-2 cell pattern		Antigen target(s)	Disease association(s)
Cytoplasmic staining	Fine speckled staining concentrated around the nucleus	Jo-1 (histyl-tRNA synthetase) and other amino-acyl-tRNA synthetases	Polymyositis, dermatomyositis, associated with interstitial pulmonary diseases
	Granular filamentous cytoplasmic staining	Mitochondrial (frequently M2, PDC E2 antigen)	PBC; less frequent in scleroderma, CREST, SLE, and Sjögren's syndrome
	Fine, dense granular to homogeneous cytoplasm, with nucleolar staining	Ribosome P phosphoproteins (PO, P1, P2), 28S rRNA, S10, Ja, L12, L5/5S	SLE (associated with neuropsychiatric symptoms)
	Fine speckled to granular cytoplasmic staining	Signal recognition particle (SRP); 54-kDa protein is major antigen	Polymyositis, dermatomyositis
	Large irregular cytoplasmic speckles	Lysosomal; antigens are poorly characterized	SLE
	Fine, uniform cytoplasmic speckles	Peroxisomal; antigens are unknown	Nonspecific
	Speckled granular staining adjacent to one part of the nucleus	Golgi complex, golgins (-67, -95, -97, -160, and -245) and macrogolgin/giantin	SLE, Sjögren's syndrome, and other rheumatic diseases
Cytoplasmic fibers	Fine fibers running the length of the cell	Actin	Chronic active hepatitis; also seen in PBC and connective tissue diseases
	Reticular pattern throughout the cytoplasm. Cytoplasmic speckles in mitosis	Cytokeratin 8, 18, and 19	Nonspecific
	Stress fibers running the length of the cells	Tropomyosin	Nonspecific
	Fine whorled fibers	Vimentin	Nonspecific
	Short fibers adjacent to nuclear and cytoplasmic membranes	Vinculin	Nonspecific
	Fine cytoplasmic filaments with cytoplasmic speckles in mitosis	Desmin	Nonspecific
	Short filaments from the cytoplasmic membrane	Cytoplasmic anchoring proteins, e.g., paxillin and zyxin	Unknown, although reported in early systemic sclerosis

[a] Abbreviations: CENP, centromere protein; CREST, syndrome of calcinosis, Raynaud's phenomenon, esophageal dismotility, sclerodactyly, and telangiectasia; MCTD, mixed connective tissue diseases/overlap syndromes; MSA, mitotic spindle apparatus; PBC, primary biliary cirrhosis; RA, rheumatoid arthritis; SLE, systemic lupus erythematosus.

reason and because patients' sera frequently contain several autoantibodies, specific tests are usually performed. Nevertheless, the broad specificity and sensitivity of HEp-2 cells are ideal for an initial screening assay (Table 1), so HEp-2 cells are unlikely to disappear from the clinical laboratory for many years to come.

TECHNOLOGY

The immunofluorescent HEp-2 test is used for several purposes:

- as a general screen to identify patients with ANAs
- to link autoantibody patterns with individual diseases for guidance on specific tests
- to help monitor patients during treatment
- to screen out patients who have negative tests

To meet this broad range of requirements, the test needs a variety of characteristics. It must be sufficiently sensitive to detect a whole range of autoantibodies, yet sufficiently specific that healthy individuals are not falsely identified as positive. Since modest levels of autoantibodies are common in elderly people, normal ranges must be carefully selected. As regards the use of HEp-2 for identifying individual autoantibodies, some patterns such as centromere are antigen specific (Table 1), but for most, specificity should be confirmed against individual proteins.

Monitoring of autoantibodies is normally achieved with specific tests such as anti-double-stranded DNA (anti-dsDNA) assays for SLE. However, the low cost and broad specificity of HEp-2 assays allow them to be used in parallel with specific tests during the management of patients.

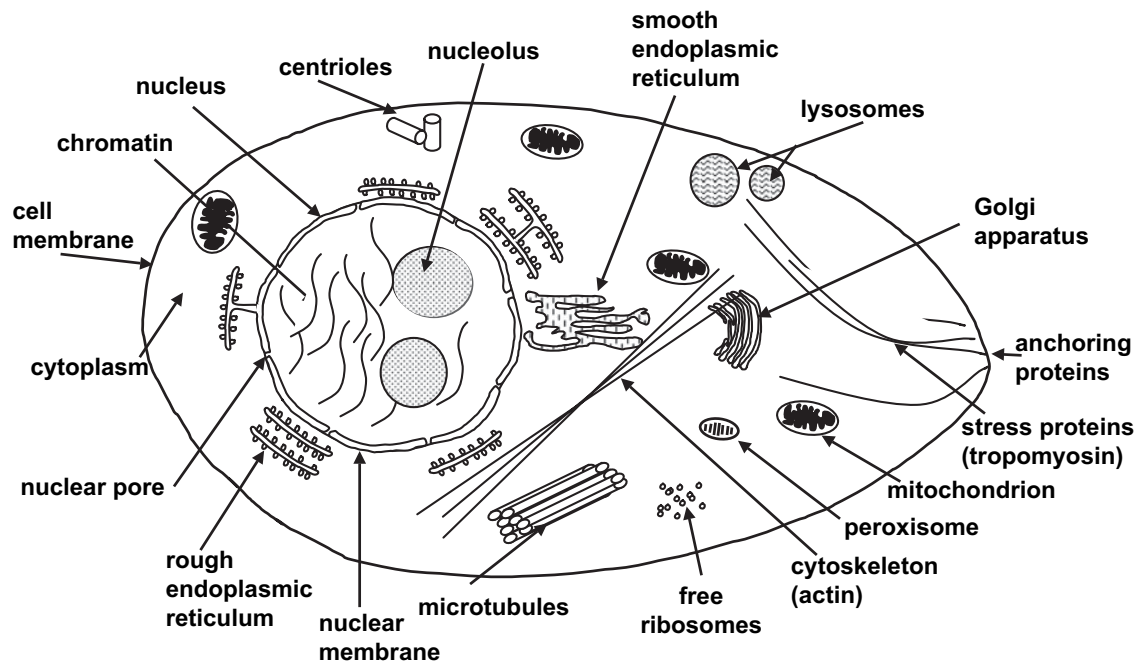
The immunofluorescence patterns seen on HEp-2 cells depend upon their stage in the cell cycle. Since most autoantibodies are directed against interphase antigens, most HEp-2 cells should be at this stage of development (Fig. 1). Autoantibodies directed against antigens in the cytoplasm of HEp-2 cells are frequently observed, and some of them are important diagnostically. They can be classified into either speckled or fibrous patterns. Autoantibodies with a speckled appearance bind to targets such as histidyl-tRNA synthetase (e.g., Jo-1), signal recognition particles, mitochondria, lysosomes, and peroxisomes. The cytoplasmic fibers are of many types, and low-titer antibodies to these proteins are found in healthy people, so disease specificity is low. Several autoantibodies produce characteristic patterns on cells that are in division. The following is a brief outline of the various phases of HEp-2 cells during their reproductive cycle and should assist in understanding of autoantibody patterns.


FIGURE 1 Diagrammatic representation of HEp-2 cell antigens during interphase.

The Cell during Interphase

In interphase, the chromosomes form a fibrillar network of chromatin, more or less uniformly distributed throughout the nucleoplasm and delimited by the nuclear membrane. Only the nucleoli are well differentiated. Cytoplasmic organelles and fibrous structures are most visible at this stage and tend to largely disappear or change their appearance during mitosis. Interphase is subdivided into three successive periods: G_1, S, and G_2 (G = gap, S = synthesis). The G_1 phase is preparatory to the biosynthesis and doubling of DNA which occur during S phase. Once the cell reaches the G_2 phase, DNA synthesis is complete and the pairs of chromatids remain joined at the centromere. In the M phase (M = mitosis), the DNA per cell drops to one-half as the cell divides. There are numerous autoantigens in the nucleus, some associated with the chromosomes such as dsDNA and histones, and many associated with ribosomes, polymerases, and nucleoli (Table 1).

The Nuclear Envelope

The nuclear envelope is the membrane that maintains the integrity of the nucleoplasm during interphase. There are three distinct layers, comprising the nuclear lamina and the inner and outer nuclear membranes. The membranes are interrupted by the nuclear pore complexes, and the outer nuclear membrane is continuous with the endoplasmic reticulum with attached ribosomes. The transcriptionally active euchromatin is found in the vicinity of the nuclear pore complexes, whereas the heterochromatin is found adjacent to the nuclear lamina, which in turn is attached to the inner nuclear membrane. Autoantibodies against lamins A, B1, B2, and C are found and are seen as linear nuclear membranous staining, while antibodies directed against the nuclear pore complexes show granular nuclear membrane staining.

The Cell during Division

Mitosis takes place during 10 to 15% of the cell cycle and is divided into four successive phases: prophase, metaphase, anaphase, and telophase.

During prophase, DNA condensation gives rise to the appearance of individual chromosomes while the nucleolar contents are distributed throughout the nucleoplasm. Meanwhile, the mitotic spindle forms around the nucleus and terminates at the polar centrioles (or centrosomes). During mid-prophase, the nuclear membrane disrupts and then disappears. The chromosomes are attached to the mitotic spindle by microtubules (tubulin) which originate from the kinetochores and attach to the chromosome centromeres. Metaphase is characterized by the localization of condensed chromosomes at the equator of the spindle apparatus through the action of microtubules. In anaphase, each pair of chromatids splits at the centromere and the chromatids migrate separately to each pole of the spindle. Microtubules disappear at the end of anaphase as the chromatids reach opposite poles of the mitotic spindle. In telophase, the nuclear membrane re-forms around each of the two daughter nuclei. The nucleoli reappear, and the chromosomes become decondensed in the newly formed nuclei.

Mitosis is followed by cytoplasmic division or cytokinesis, which proceeds at the midbody region of the dividing cell. During this process, the cytoplasmic membrane invaginates around the middle of the cell at right angles to the mitotic spindle and between the two daughter nuclei. As membrane invagination proceeds, the midbody is progressively constricted and finally disappears as the two daughter cells separate.

Important autoantibodies are found against most of the cell cycle-related structures that have been mentioned, such as the centromeres, proliferating cell nuclear antigen, mitotic spindle proteins, and centriole proteins. The pattern on HEp-2 cells is usually sufficient to identify most of these autoantibodies (Table 1).

What Is the Best Fluorescent Conjugate for the Autoantibodies?

The species of animals commonly used for the fluorescein-conjugated antibody are goat, sheep, and rabbit. Affinity-purified antibodies are preferable because they produce the

least background staining, although immunoglobulin fractions are widely used and quite satisfactory. Antibodies are conjugated with fluorescein at a fluorescein/protein molar ratio of approximately 3. This applies to all animal species, although some individual monoclonal antibodies may perform better with a higher fluorescein content.

There is considerable variation in laboratory usage for the fine specificity of the conjugated antibody. Immunoglobulin G (IgG) ANAs are undoubtedly the most important in terms of diagnosis and monitoring of rheumatic diseases and must always be measured. IgM ANAs may coexist with IgG but are usually of secondary importance, except perhaps in pediatric SLE. If IgM antibodies dominate, they indicate a milder or nonspecific disease with a better prognosis and less renal or other organ damage. IgA ANAs correlate with IgG antibodies and offer little additional information and so are generally ignored (4).

The majority of laboratories use a non-affinity-purified, fluorescein-conjugated second antibody directed against IgG, -A, and -M heavy chains (or anti-IgG heavy and light chains). This detects IgG, IgM, and IgA antibodies but with a bias towards IgG, and the results are reported without identification of the antibody class. Many laboratories use a second antibody directed against IgG heavy chains alone, thereby ignoring IgM antibodies on the basis that they are rarely of clinical importance.

Alternative Technology

ANA EIA screens, available since the early 1990s, are viable alternatives to ANA detection on HEp-2 cells. Given the subjectivity of IFA interpretation and the high number of negative samples, an EIA method for ANA screening has considerable potential. Assay conditions of EIAs are optimized for performance; however, the sensitivity of the ANA EIA screen ultimately depends on the choice of antigens, and for every antigen used the cost increases.

The antigens of choice are the major markers for the autoimmune diseases of interest, such as SLE, Sjögren's syndrome, mixed connective tissue disease, scleroderma, and the syndrome of calcinosis, Raynaud's phenomenon, esophageal dismotility, sclerodactyly, and telangiectasia. The antigens are from either purified or recombinant sources. Since the antigens on the plate are known, one can further identify the specificity of positive samples by using single EIAs (25). This approach will detect the majority of ANAs, but a proportion of ANA samples will be missed. These may be of limited clinical importance, as the specificities will be towards minor antigens that have little known significance. An alternative approach is to include nuclear and/or nucleolar extracts to supplement the specific antigens. This may increase the number of positive ANA samples detected, but a number of these will be difficult to characterize as the antigen targets may be unknown or of little clinical consequence.

In one study (13), five EIA kits were compared with HEp-2 cells for 600 patient samples and 200 blood donor samples. Overall, agreement with IFA was approximately 90% (range, 87 to 96%), the sensitivity of EIA was 90% of that of IFA (range, 70 to 96%), and the specificity was 95% (range, 81 to 98%), the figures being dependent upon the cutoff selection for sensitivity and specificity. None of the EIAs was 100% sensitive, having failed to demonstrate a few atypical as well as classical HEp-2 patterns, and some kits produced rather discordant results. Other studies comparing HEp-2 cells with EIA for ANA detection have produced similar results (7) and rather poor detection rates for antibodies against dsDNA and Sm in some EIAs (24). Also,

low-affinity autoantibodies are more readily detected in the "capacity" EIAs, so discordance between results tends to be worse at low antibody concentrations. Correlation between the results for the two techniques is, perhaps, remarkably good, considering their differences.

More recently, ANA screens have become available as multianalyte immunoassays based on multibead arrays, which can be read by use of flow cytometers. The bead arrays are interpreted with the new generation of flow cytometers, e.g., the Luminex system (Luminex Corporation) and the FACSarray (BD Biosciences). Such systems allow for the screening of samples while at the same time providing semiquantitative results on individual specificities for positive samples. Protein microarrays also have potential as multiplex platforms for ANA detection (9). The results of these are read by using fluorescence imaging systems, and they use the technology from DNA microarray analysis. Multiplex platforms are limited, like the EIA ANA screens, by their dependence on the antigens of choice present in the assay, and development difficulties are compounded by the tight performance criteria required for each individual specificity. Due to the infancy of multiplex systems, it is difficult to predict their impact on the preeminence of the HEp-2 immunofluorescent ANA screen.

ASSAY PROCEDURES

Sample Requirements

Ideally, serum samples that have been collected within the previous few hours should be used. Storage at 4°C is sufficient for samples analyzed up to a week after collection, while for longer periods (months or years) storage at $-20°C$ is preferable. Frequent thawing and freezing of the sample may lead to a decrease of antibody activity, while long-term storage may lead to lyophilization, resulting in an increase in titer. Addition of sodium azide (100 μg/ml) is recommended.

Serum dilution is an important issue. The first studies of immunofluorescence detection of ANA on rat liver sections used patients' sera diluted 1:10. With the use of HEp-2 cells, improved microscope lenses, and better-labeled second antibodies, 1:10 dilutions would produce a huge false-positive rate from normal samples, so now it is common practice to screen at a 1:80 dilution on HEp-2 cells. Since the frequency of ANAs varies with age, it can be argued that for children a 1:40 dilution would be reasonable while 1:160 might be preferable for patients >65 years of age. However, some low-titer autoantibodies may be clinically significant. One study (22) recommended that samples should be tested at both 1:40 and 1:160 dilutions and that information should be supplied to the clinicians about the numbers of healthy individuals, of the same age and sex, who have positive results at those dilutions (see quality control section below).

Materials and Reagents

Production of HEp-2 Cells

HEp-2 cells can be grown in the laboratory, but slides are normally purchased in kits that contain all the necessary reagents. For those who wish to prepare their own slides, the following is a brief description of the important steps in their preparation (12).

1. Cells are maintained in long-term storage in liquid nitrogen.

2. Short-term growth is maintained in flasks in which the cells become adherent and confluent.

3. For the production of HEp-2 slides, the cells are dissociated, checked for bacterial contamination, counted, and added to incubation flasks for rapid growth over 1 to 2 days.

4. The cells are dissociated from the flasks, separated by being passed through a fine needle, counted, and added to slide wells that have been carefully cleaned.

5. Slides are incubated for approximately 24 h in a humid CO_2 incubator at 37°C.

6. Slides are removed and drained prior to fixation. Fixation procedures vary considerably and commercial manufacturers have optimized their procedures, both to preserve the antigens and to render the membranes permeable. However, a reasonable guide would be to use a mixture of cooled (-20 to $+4$°C) acetone (80 to 90%) and methanol (10 to 20%) for 20 min. It is important to assess the fixation procedure for the preservation of antigens; in particular, sensitivity for the SS-A antigen may be affected.

7. The fixative is drained off, and the slides are dried with warm air.

8. Each slide is sealed in a foil bag with a desiccant such as silica gel and stored at 4°C.

9. For quality control, the slides are stained and checked by using a panel of sera for morphology, mitotic figures (>4 per field of view at 400× magnification), negative staining (background), weak and strong positive staining, different staining patterns, and titration characteristics of common autoantibodies.

10. Several slides are stored for long-term assessment of stability.

Fluorescent Conjugated Antibodies

The specificity and type of antibody have been discussed above, and these reagents are normally purchased. Affinity-purified, anti-human IgG (heavy and light chain) fluorescein isothiocyanate is widely used. In commercial kits, the reagent is normally supplied prediluted and matched for optimal reactivity and sensitivity with the HEp-2 cells. Undiluted antibodies must be assessed at a working dilution against a variety of different sera.

Commercial preparations tend to use derivatives of fluorescein, and for the purposes of IFA on HEp-2 cells they are amply sensitive. However, the fluorescein fluorophores are pH sensitive and susceptible to photobleaching. There are other fluorophores available that overcome these drawbacks to a certain extent. For example, the Alexa fluor dyes (Molecular Probes) give increased signals when used for immunofluorescence, although the limited benefit of detecting low concentrations of autoantibodies may not justify the associated increase in cost.

Equipment and Instrumentation

The HEp-2 cells should be observed by using an epifluorescence microscope fitted with filters appropriate for fluorescein detection. A 40× objective (dry or water immersion), along with a 10× magnification eyepiece (giving a final 400× magnification), allows easy identification of all common patterns.

Test Procedure for Immunofluorescence ANA Detection

1. Prepare phosphate-buffered saline (PBS) (pH 7.2 to 7.4) with 0.1 g of sodium azide per liter. Tween 20 (0.5 g/liter), bovine serum albumin (20 g/liter) or dilute HEp-2 medium can be added to the PBS to reduce nonspecific binding of serum globulins to the HEp-2 cells.

2. Sample dilutions:
   a. Screening. We recommend diluting samples 1:80 when screening, by adding 10 μl of serum to 790 μl of PBS buffer. See "Sample Requirements" (above) for discussion of recommended screening dilutions.
   b. Titration. Make serial dilutions of positive samples in PBS buffer (e.g., 1:80, 1:160, 1:320, etc.).

3. HEp-2 slides. Allow the slides to reach room temperature over 30 min prior to removal from their pouches. Label slides appropriately, place them in the humid chamber, and add 1 drop of each positive and negative control serum to separate wells. Add 25 μl of the diluted patients' samples to the remaining wells. Care should be taken to ensure that there is no crossover of serum samples into neighboring wells, particularly in the case of 24-well slides.

4. Incubate the slides in a humid chamber at room temperature for 30 min, ensuring that no wells dry out.

5. Remove the slides from the humid chamber and rinse thoroughly but gently with PBS. Do not squirt PBS directly onto the wells. Place the slides in a rack, immerse them in PBS, and agitate or stir for 10 min.

6. Shake off the excess PBS and blot around the wells. Immediately return the slides to the humid chamber and add a drop of fluorescein-conjugated antibody to each well. Do not leave the wells uncovered for more than 15 s, since drying out will change the results. It is important to optimize the second antibody if it is not supplied prediluted and no recommendations are provided. "Checkerboard" titrations can be used to determine the appropriate secondary-antibody concentration (19).

7. Incubate the slides for 20 min in a humid chamber at room temperature in the dark.

8. Wash again as in step 5. Counterstain as required by adding 2 or 3 drops of 1% Evans Blue per 100 ml of PBS prior to washing or immersion (not recommended if the microscopist is color-blind).

9. Remove one slide at a time from the PBS wash. Quickly dry around the wells and add a drop of mounting medium to each well (e.g., 90% glycerol in PBS, pH 8.6). {Note: chemicals should be added to the mounting medium to improve retention of fluorescence upon illumination. DABCO (1,4-diazobicyclo [2,2,2]-octane, Sigma-Aldrich Company, Ltd.), 2.5 g per 100 ml of mounting medium, is frequently used.} Carefully add a coverslip, ensuring that there are no trapped air bubbles.

10. Finished slides should be viewed as soon as possible, but they may be stored at 2 to 8°C in the dark for many days with little loss of fluorescence activity.

11. The intensity and patterns of fluorescence are assessed and recorded. A serum specimen is considered to be positive when the observed fluorescence is significant compared with that of the controls. The intensity can be expressed according to a scale of values compatible with the guidelines established for reference sera (18) as 1+ to 4+ or as negative. A semiquantitative evaluation can be obtained by performing serial dilutions of the test serum to endpoint fluorescence.

12. The procedure can be semiautomated; this saves on labor and is particularly beneficial in laboratories that have a high throughput of samples. Instruments are available which can perform dilutions and run IFAs up to the point of but not including the mounting of the coverslips. Other instruments which can perform the dilutions alone are available.

Enzyme Immunohistochemical Staining

Autoantibody patterns on HEp-2 cells can also be demonstrated by using enzyme-conjugated second antibodies.

The immunoperoxidase technique produces excellent, permanent staining. Advantages are that HEp-2 cells can be interpreted with conventional light microscopy, there is a permanent record, and the slides can be sent to different laboratories for quality control purposes. However, the technique is slightly less sensitive and the extra technical steps are time-consuming, so the procedure is not widely used.

QUALITY ASSURANCE AND QUALITY CONTROL IMPLEMENTATION

In 1980, the Arthritis Foundation in the United States, in collaboration with the Centers for Disease Control and Prevention (CDC), Atlanta, Ga., established a committee on antinuclear antibody serology with the purpose of producing a repository of ANA reference sera. Aliquots (0.5 ml) from large plasmapheresis donations of defined specificity were dispensed into borosilicate ampoules, freeze-dried, and sealed under reduced pressure. The standard requirements for establishing reference reagents, such as measurements of mean dry weight, water content, and stability, were met, and data were provided with each ampoule. The reagents were assessed before and after processing in several laboratories, and in 1982 five reference reagents were made available to laboratories as primary standards (23).

It was subsequently agreed by various international bodies that standardization of ANAs should be extended to other autoantibodies. In 1988 (21), in conjunction with the International Union of Immunological Societies and the World Health Organization, the reference sera at the CDC were expanded to 10 different specificities, and in 1997, these sera were further characterized by immunofluorescence and Western blotting (18) (Table 2). These various standards are satisfactory for the common autoantibodies and provide an important basis for HEp-2 cell usage. For rarer antibodies, appropriate sera should be exchanged to standardize interlaboratory practice.

Quality Control

Known positive and negative control sera must be tested with each group of slides. Prototype sera are available from many commercial sources and from the CDC (see above). It is important to use not only samples that produce typical patterns but also weak samples that test the sensitivity limits of each batch of slides.

Each laboratory should determine the border between positive and negative results. Approximately 200 serum samples from healthy local controls, equally distributed over age and sex, and 100 serum samples from local patients with definite SLE and other relevant diseases should be assessed.

Quality Assurance

There are several national, international, and commercial quality assurance schemes, of which two are indicated below. These schemes are widely used and cover the common autoantibodies. Samples are issued several times a year and a consensus report is produced so that individual laboratories can compare their performance with that of other participants.

A scheme for autoimmune serology is available from The College of American Pathologists, 325 Waukegan Road, Northfield, IL 60093-2750.

The United Kingdom National External Quality Assessment Schemes for Autoimmune Serology are available from the Department of Immunology, P.O. Box 894, Sheffield S5 7YT, United Kingdom.

PITFALLS AND TROUBLESHOOTING

Because HEp-2 cells for ANA tests are so widely used, laboratories have gained huge experience, and the results are generally satisfactory. The largest variation in results reported to quality control schemes relates to differences in fluorescence intensity of the samples. As shown in Table 2, even expert laboratories vary in their opinion. Samples regarded as 4 + (1:2,560) in one laboratory may be considered only 1 + (1:160) in another. Such variation is accounted for more by differences in the fluorescent conjugates and quality of microscopes (and age of the mercury vapor bulb) than differences in HEp-2 preparations. Generally, the use of a widely distributed commercial kit will ensure a high-quality substrate and give good consensus on quality control schemes. Nevertheless, individual HEp-2 batches do vary, so each batch should be assessed against a standard set of control sera. When problems are encountered it is sensible to make some simple checks, such as the production and expiration dates of the slides and conjugates and the recommended storage conditions (Table 3). The age of the bulb in the microscope should also be checked. Odd results should be reported to the manufacturer in order to

TABLE 2 Arthritis Foundation/CDC antinuclear antibody reference sera[a]

Serum	Designated specificity	IF[b] result at 1:160 or recommended Western blot dilution
AF/CDC1	Homogeneous ANA (anti-dsDNA)	2+ to 4+
AF/CDC3	Speckled-pattern ANA	2+ to 4+
AF/CDC6	Nucleolar-pattern ANA (antifibrillarin)	1+ to 3+
AF/CDC8	Centromere pattern ANA	1+ to 4+
AF/CDC2	SS-B (La) and speckled-pattern ANA	1:200
AF/CDC4	Anti-U1-snRNP	1:100
AF/CDC5	Anti-Sm (U1, U2, U5, U4/6 snRNPs)	1:2,000
AF/CDC7	SS-A (Ro)	Negative (IF +ve only)
AF/CDC9	Anti-Scl-70	1:100
AF/CDC10	Anti-Jo-1	1:100

[a]These sera are available from the Centers for Disease Control and Prevention, Atlanta, GA 30333, or CLB, Plesmanlaan 125, 1066 Cx, P.O. Box 9190, 1006 AD, Amsterdam, The Netherlands.
[b]IF, immunofluorescence; +ve, positive.

TABLE 3 Troubleshooting guide for ANA testing on HEp-2 cells

Problem	Possible reason or solution
Weak positive sera are negative or difficult to interpret	Conjugate too weak; too much Evans Blue
Excessive staining of negative cells	Conjugate too strong
Poor morphology	Slides not allowed to warm up from refrigerator or allowed to dry out during procedure
Neighboring wells positive with similar patterns	Samples splashed over several wells, particularly on 24-well slides. Ensure careful pipetting.
Mechanical damage to cells	Use care with pipettes and washing procedures and when adding coverslips
Speckles on slide and cells destroyed	Infected sample. Use new sample or heat to 65°C to destroy bacterial enzymes, filter, and reapply
Immunofluorescence fades too quickly	Use antifading agent such as DABCO
Slides stick to the microscope	Too much mounting medium
Bubbles under coverslip	Gently wash off the coverslip and carefully remount
Fluorescent film over the cells	Drying of substrate wells between reagent additions or nonspecific binding of conjugate to proteins. Add blocking agent to buffers.
Weak nucleolar staining	Samples diluted in water or glassware dirty. Use cleaner procedures and dilute samples in PBS.
Insufficient mitotic figures, cells overconfluent or too sparse	Change batch of HEp-2 cells

determine whether other users have experienced similar problems or whether the unusual results are specific to the individual laboratory.

TEST VALIDATION

The ANA immunofluorescent HEp-2 test is intended to be used for screening and titration of circulating antinuclear antibodies. The results of the test serve as an aid in the diagnosis of SLE, Sjögren's syndrome, rheumatoid arthritis, and other connective tissue disorders. The test has a class II performance standard classification from the Food and Drug Administration (FDA), requiring 510(k) submission. The submission must include performance criteria, which include precision, sensitivity, and specificity data. For a list of commercial suppliers of FDA-approved HEp-2 immunofluorescent ANA tests, either refer to the FDA website (http://www.fda.gov) or contact individual suppliers. All ANA immunofluorescent HEp-2 tests must conform to the standards already mentioned above ("Quality Assurance and Quality Control Implementation").

COST ASSESSMENT—COMMERCIAL KITS OR IN-HOUSE MANUFACTURE?

ANA tests were traditionally performed on rodent tissues that had been prepared by laboratory staff. Since animals and cryostats are readily available in most pathology laboratories, it is natural that these practices should have persisted. HEp-2 cells, in contrast, are less easily handled, and specialist knowledge is required to prepare slides in a satisfactory condition. In contrast and from a commercial point of view, HEp-2 production can be scaled up to produce batches of much larger size and better uniformity than rodent tissue sections. This has led to a proliferation of commercial suppliers of HEp-2 cells.

The actual costs of running these tests depend in some degree upon the number of tests performed. Based on a reasonable throughput, 100 or so samples per day, where 25% of the samples are positive, one would estimate about 3.5 h of labor (3 h of setup and 1/2 h of interpretation). An estimated figure would therefore be $1.90 per test (reagent cost [$1.45] + labor cost [$0.45]); notably, this does not include capital equipment investments such as microscopes, etc.

Inevitably, HEp-2 production techniques vary, and there are no standard publications or international agreement on optimal culture techniques, ideal fixatives, drying procedures, etc. Commercial HEp-2 cells therefore differ in their performance characteristics, so care should be taken when choosing a product (8). There will also be batch-to-batch variation from both in-house and commercial suppliers. It is therefore common practice to test and then reserve batches that are particularly satisfactory. This leads to minimal variation of the HEp-2 cells with time and confidence in their performance.

Much of the discussion about the quality variations has focused on preservation of the SS-A antigens. Normally, HEp-2 cells contain abundant SS-A antigen, but the antigen is destroyed by some chemical fixatives. A multicenter European study (1) clearly showed that some HEp-2 cell preparations did not contain adequate amounts of SS-A and could produce negative or confusing results with SS-A-positive sera. HEp-2 cells that contained satisfactory amounts of SS-A produced results that correlated well with very sensitive EIAs and Western blot assays. Care must therefore be exercised when preparing the cells or when selecting commercial products.

The commercial HEp-2 cells known as HEp-2000 have been genetically modified to produce extra SS-A, which allows the autoantibodies to be specifically identified by the initial screening test. However, other commercial kits containing conventionally produced HEp-2 cells express

adequate amounts of SS-A, and even use of HEp-2000 cells may miss some SS-A autoantibodies compared with EIA techniques (17).

INTERPRETATION

Autoantibodies occur in both physiological and pathological conditions. In general, high titers (>1:160) are significant disease indicators, but low or absent titers do not exclude disease. Circulating autoantibodies may be absent or not detected because of poor target antigens or unsatisfactory assay technique or even because the disease is so active that antigens released into the circulation have adsorbed all the antibodies. In contrast, low-titer antibodies may be found in healthy people, relatives of patients with autoimmune conditions, and a variety of diseases, such as chronic inflammation and cancer, which have no autoimmune basis. Autoantibodies may also appear months or years before overt manifestations of an autoimmune disorder. Autoantibodies also increase in prevalence with age, particularly in women, without necessarily being harmful. Interpretation must be made with reference to the individual's medical history, age, and existing conditions (Table 4). While ANA tests are diagnostically important, results must be interpreted in the context of the clinical information. Of equal importance are awareness of the limitations of the tests and quality control of the substrates and reagents.

Recognizing autoantibody patterns on HEp-2 cells is relatively straightforward (Fig. 2), but assessing fluorescence intensity and its clinical significance requires considerable experience. The ability to make decisions on fluorescence intensity can be gained only with practice and by regularly viewing batches of normal, or allegedly normal, sera in order to obtain the picture of a "negative" background. Interpretation of staining is partly subjective, so there may be considerable variation in the reported results from day to day and between different observers. Should discrepancies arise, particularly between past and present specimens, it is important to identify the previous sample and compare it directly with the current one. When there is doubt about a sample, the physician should be involved and the final judgment should be made in the context of the patient's clinical problems.

Reporting practices vary, but the following is a guide to commonly used protocols.

1. HEp-2 slides for ANA testing are run at the screening concentration and are scored from weak to strong positive by experienced personnel. They are reported as +/− (weak), + (positive), 2+ (strong positive), and 3+ and 4+ (very strong positive), which correspond to titrations of approximately 1:80 (+/−), 1:160 to 1:320 (+), 1:640 (2+), 1:1,280 (3+), or 1:2,560 (4+). All positive samples from new patients should be titrated. Follow-up samples are frequently titrated or skilled personnel may judge the titer from the fluorescence intensity since this approach may be clinically sufficient and is less costly.

2. All slides should be stored for a minimum of 28 days. It is good practice for results to be transcribed onto computer-generated worksheets by the person reading the slides so that mistakes are minimized. When results have been verified, with particular reference to the age, sex, and diagnosis of the patient, they are authorized for reporting. The clinical immunologist adds appropriate comments and signs the result form for dispatch. Comments should include something to the effect of "Titers of 1:80 are of limited importance for patients over 50 years of age." If a query arises, the appropriate test may be readily located by diary date, slide number, and well number and the sample can be checked.

Comments on interpretation:

1. ANA patterns are only indicative of the autoantibody, and precise determination of their specificity must be assessed by other techniques, such as immunodiffusion, immunoblotting, and EIA. Samples negative by HEp-2 can confidently be reported as such. Occasional samples will demonstrate low-titer autoantibodies by EIAs that are negative as determined by use of HEp-2 cells, but that depends upon the cutoff level of sensitivity for either assay.

2. Mixed patterns occur when patients' sera contain more than one antibody. For example, when U1-snRNP antibodies are associated with dsDNA antibodies in the serum of SLE patients, a homogeneous nuclear pattern will be observed and the chromosomal region of mitotic cells will be strongly positive. However, after serial dilution the typical speckled pattern for U1-snRNP antibodies may appear. Different serum dilutions therefore produce different fluorescence patterns, so an autoantibody titer should be assessed only by a serial dilution of the sample.

3. Mitotic figures are important for the identification of centromere antibodies and others that bind to antigens involved with cell division. The specificity of centromere antibodies can be established directly from the HEp-2 pattern after examining a few mitotic figures.

4. Unexpected or rare HEp-2 patterns can be reported to the physicians even if they do not apparently relate to the patient's stated diagnosis. The clinicians can choose to ignore the results, or it can be indicated that the autoantibodies are of no known significance. These results can be reviewed from time to time to assess their clinical and laboratory importance.

TABLE 4 Diseases associated with ANA-positive sera

Disease, condition, or group	% ANA positive
Chronic discoid lupus	5–50
Chronic infections	10–50
Dermatomyositis, polymyositis	30–40
Drug-associated SLE-like syndromes	<50
Felty's syndrome	95–100
Healthy population	<5
Healthy relatives of SLE patients	25
Juvenile arthritis	15–30
Lupoid hepatitis	95–100
Neonatal lupus syndrome	>90
Neoplastic diseases	10–30
Normal old age	<30
Polyarteritis nodosa	15–25
Pregnancy	5–10
Primary biliary cirrhosis	95–100
Rheumatoid arthritis	<95
Rheumatic fever	>5
Sjögren's syndrome	<95
SLE	95–100
Systemic sclerosis (scleroderma)	>90
Nuclear Homogeneous
Homogeneous ANA in anaphase (enlarged)
Nuclear membrane
Nuclear pores
Nuclear matrix
Coarse speckled
Fine speckled
Few nuclear dots
Multiple nuclear dots
Nucleolar clumpy
Nucleolar speckled
Nucleolar speckled with mitotic dots

FIGURE 2 Common autoantibody patterns on HEp-2 cells.
FIGURE 2 (*Continued*)

Specific immunoassays are used to analyze HEp-2-positive sera in more detail. The following is a brief description of the different methods, but details should be sought elsewhere.

1. Immunodiffusion and countercurrent immunoelectrophoresis (CIE). These are the simplest and most specific but least sensitive methods of ENA identification. An initial screening assay uses a polyvalent antigen extract that contains all common ENAs. The test is inexpensive, and negative samples (70 to 80%) are easily screened out. Positive sera are then further tested against well-characterized, monospecific antibodies by a similar procedure. A mask for sample application on CIE gels increases the sensitivity and precision of the assay.

2. Immunoblotting. The Western blot assay is an essential tool for the detailed characterization of many autoantibodies. Molecular mass markers and positive and negative controls are run together in each assay. These provide the necessary comparison bands alongside those of the patient sera. However, the assay is relatively expensive in comparison with EIAs. Furthermore, the antigens are displayed as linear polypeptides, which distorts conformational epitopes, so the results are not always accurate. For example, the international SS-A (anti-Ro) material AF/CDC7 is negative by Western blot although positive on HEp-2 cells (Table 2). This has also been observed with other antigens, such as PM-Scl (16).

3. EIAs. These are widely used for quantifying samples with antibodies against dsDNA and ENAs, and more recently, some laboratories use them when screening for ANAs. The dsDNA and ENA EIAs are very sensitive assays, and monitoring patients with quantitative measurements for autoantibodies against dsDNA and some ENAs is useful (e.g., Jo-1). In the case of anti-dsDNA autoantibodies, there is a clear relationship between disease activity and antibody titer. However, many autoantibodies do not fluctuate with disease activity, so accurate quantitation is not always necessary.

Detection of Autoantibodies against Proteins and Ribonucleoproteins by Double Immunodiffusion and Immunoprecipitation

WESTLEY H. REEVES, MINORU SATOH, ROBERT LYONS, CODY NICHOLS, AND SONALI NARAIN

113

INTRODUCTION AND BACKGROUND

Antinuclear antibodies (ANA) are markers for systemic autoimmune disease but also can be seen at low titers in healthy individuals (20). Thus, there has been considerable interest in identifying ANA subsets with greater diagnostic specificity for particular diseases. Autoantibodies specific for systemic lupus erythematosus (SLE), systemic sclerosis (SSc), polymyositis or dermatomyositis (PM/DM), and other systemic autoimmune disorders have been identified (Table 1) and are of considerable importance as diagnostic markers. The prevalence of some of the more useful autoantibody markers for various diseases is summarized in Table 2.

SLE

Several autoantibodies are produced uniquely in SLE. Anti-double-stranded DNA (anti-dsDNA) antibodies are found in ~70% of SLE patients' sera at some point during their disease and are 95% specific. Levels of anti-dsDNA antibodies may vary reciprocally with complement levels, serving as a marker of disease activity. Anti-Sm antibodies are produced by 7 to 25% of lupus patients, depending on ethnic origin, and, like anti-dsDNA, are virtually pathognomonic of SLE (12). Unlike anti-DNA antibodies, the levels of anti-Sm antibodies generally do not correlate with disease activity. Anti-nRNP antibodies, which recognize proteins associated with the Sm antigen, are not disease specific (Table 1). They are present at high levels in mixed connective tissue disease (MCTD) (12). The frequency of anti-nRNP antibodies in SLE is 20 to 40%. All but a few sera containing anti-Sm antibodies contain anti-nRNP autoantibodies as well. However, anti-nRNP antibodies frequently occur without anti-Sm.

Antiribosomal antibodies which recognize the P0, P1, and P2 antigens (Table 1) are found in about 15% of SLE patients (5). They also are highly specific for SLE. Anti-proliferating cell nuclear antigen (anti-PCNA) (2 to 5% of patients) antibodies are specific for SLE as well.

Sicca Syndrome and Sjögren's Syndrome

Anti-Ro (SS-A) and anti-La (SS-B) autoantibodies are associated with Sjögren's syndrome as well as other systemic autoimmune diseases when they are accompanied by sicca symptoms (e.g., SLE). Anti-Ro (SS-A) antibodies are found in 10 to 50% of serum samples from SLE patients and 60 to 80%

of primary Sjögren's syndrome sera (24). They recognize two antigens, one of 60 kDa (Ro60) and the other of 52 kDa (Ro52) (see below and Table 1). Anti-La (SS-B) autoantibodies are produced by 10 to 20% of SLE patients and at a somewhat higher frequency in Sjögren's syndrome. Anti-La is virtually always associated with anti-Ro, whereas anti-Ro antibodies frequently are detected in the absence of anti-La.

Congenital Complete Heart Block

Cardiac conduction abnormalities in neonates are strongly associated with maternal antibody against the Ro (especially Ro52) and La antigens (2). Screening for these autoantibodies in pregnant women with systemic autoimmune disease is important. Since these autoantibodies may be present in asymptomatic individuals, screening also is carried out in mothers of children with congenital cardiac conduction abnormalities.

SSc

A nucleolar pattern on fluorescent ANA testing is common in SSc. Nucleolar antigens recognized by SSc-specific autoantibodies include fibrillarin, the To/Th ribonucleoprotein, and RNA polymerases I and III (RNAP I/III) (10 to 20% of patients [Table 1]) (9, 15). The nucleoplasmic and nucleolar enzyme topoisomerase I (topo I) (Scl-70) also is an important marker found in ~15% of patients. Anti-topo I and RNAP I/III both are associated with a poor prognosis and with proximal scleroderma rather than just sclerodactyly. Autoantibodies against RNAP II also are present in SSc but are not disease specific. When present along with anti-topo I, antibodies against the phosphorylated form of RNAP II predict a poor outcome (17). Antifibrillarin (5 to 8% of patients) and anti-To/Th (5%) antibodies also are diagnostically useful specificities (Table 1).

PM/DM

Autoantibodies to a set of cytoplasmic antigens, many of which are aminoacyl tRNA synthetases, are diagnostic markers for PM/DM (Table 1). These antibodies are rare in the absence of myositis. The most common is anti-histidyl-tRNA synthetase (anti-Jo-1), which is produced by 20% or more of adult myositis patients (Table 1) (22). Other tRNA synthetases recognized by PM/DM sera include threonyl (anti-PL-7; 3% of patients), alanyl (anti-PL-12; 3 to 8% of patients), isoleucyl (anti-OJ; 2% of patients), glycyl (anti-EJ; 2% of patients), and

TABLE 1 Some non-DNA/chromatin autoantibodies useful in the diagnosis of systemic autoimmune disease

Disease(s)	Autoantibody	Protein component(s)	RNA component(s)
SLE	Sm	B′/B (29/28 kDa), D1/2/3 (16 kDa), E/F/G (12, 11, 10 kDa)	U1, U2, U4–U6, U5
	Ribosomal P	P0, P1, P2 (38, 19, 17 kDa)	rRNA
	PCNA	36 kDa	None
MCTD and others	RNP	70K (70 kDa), A (33 kDa), C (23 kDa)	U1
Sicca syndrome	Ro (SS-A)	Ro60 (60 kDa), Ro52 (52 kDa)	hY1, hY3, hY4, hY5
	La (SS-B)	48 kDa	8-2, 7-2, 7SL, 5S, hY1, hY3, hY4, hY5, tRNAs
SLE, MCTD, PM, SSC	Ku	Ku80 (80 kDa); Ku70 (70 kDa)	None
SLE, SSC	RNAP II	240 (IIO), 220 (IIA), 140 (IIB) kDa	None
PM/DM	Various tRNA synthetases	His (50 kDa), Thr (80 kDa), Ala (110 kDa), Ile (150 kDa), Gly (75 kDa), Leu (130 kDa), Asp (65 kDa)	Corresponding tRNAs
	SRP	72, 68, 54, 19, 14, 9 kDa	7SL
SSc	Topoisomerase I	100 kDa	None
	Fibrillarin	34 kDa	U3
	RNAP I/III	RNAP I: 190 (IA), 126 (IB) kDa; RNAP III: 155 (IIIA), 138 (IIIB) kDa	None
	To/Th	40 kDa (not readily visualized)	7-2, 8-2

asparaginyl (Table 1). For unclear reasons, only one antisynthetase autoantibody is usually detected in an individual patient. All of these autoantibodies are associated with myositis, interstitial lung disease, Raynaud's phenomenon, mechanic's hands (roughened skin over the fingertips), arthritis, and fever, a constellation known as antisynthetase autoantibody syndrome. Autoantibodies to the signal recognition particle (SRP) also are myositis specific (4% of patients) and may be a marker for severe disease.

Conclusions

Autoantibodies recognize a diverse array of nuclear and cytoplasmic antigens. Some of these autoantibodies are clinically useful markers for subsets of systemic autoimmune disease, such as SLE, SSc, or PM/DM. Others are useful because they point to organ involvement, e.g., lacrimal or salivary gland involvement with anti-Ro (SS-A) or anti-La (SS-B), though they are not disease specific. Finally, other autoantibodies are useful prognostically (e.g., anti-topo I or anti-RNAP I/III in SSc and anti-SRP in PM). Despite the importance of these autoantibodies as clinical markers, diagnostic tests for them often are less than optimal. This chapter deals with how to detect them reliably in a clinical or research setting. It is hoped that newer tests based on recombinant autoantigens will eventually take the place of some of the more technically difficult tests described below.

DID IN AGAROSE GELS (OUCHTERLONY)

Double immunodiffusion (DID) (Ouchterlony method) is a classic immunoassay to detect interactions of antigens and antibodies. Anti-Sm was the first lupus-specific autoantibody

TABLE 2 Prevalence of some non-DNA/chromatin autoantibodies by disease

Autoantibody	Prevalence in disease subset (%)			
	SLE ($n = 288$)	Sjögren's ($n = 50$)	PM/DM ($n = 30$)	Scleroderma ($n = 42$)
Sm	10	0	0	0
RNP	39	6	0	12
Ribosomal P	2	0	0	0
PCNA	0.3	0	0	0
Ro60 (SS-A)	33	58	13	12
Ro52[a]	28	36	49	15
La (SS-B)	11	28	7	0
Jo-1[b]	1	ND[c]	22	0
Alanyl tRNA synthetase[b]	0	ND	6	ND
Ku	2	0	0	2
RNAPI/III	0	0	0	21

system to be defined as a precipitin line (21). Additional precipitating autoantibodies were defined by using sera from patients with systemic rheumatic diseases, including anti-nRNP, anti-Ro (SS-A), anti-La (SS-B), anti-topo I (Scl-70), and Jo-1 (12). Antigens, such as rabbit thymus extract (RTE) or human lymphocyte extract, are added to wells punched in an agarose gel. Serum samples are placed in adjacent wells. Antigenic proteins or protein complexes in the cell extract and antibodies in the serum diffuse toward one another in the gel and form insoluble antigen-antibody complexes when the antigen-to-antibody ratio is near equivalence. Formation of insoluble immune complexes in the gel is seen as a white precipitin line.

Technology and Instrumentation

Instrumentation for the DID assay is simple, consisting of a suitable agarose gel and apparatus for punching holes in the gel, viewing the precipitin lines, and documenting the pattern photographically. The following equipment is needed: a magnetic stirrer and hot plate, a light box with black background, and a gel puncher (commercial suppliers are becoming scarce; as an alternative, a gel puncher can be made with straws or similar materials by assembling short-cut pieces with Super Glue [Fig. 1]).

The agarose gel is prepared by heating 0.6% (wt/vol) agarose in phosphate-buffered saline (PBS) with 0.02% NaN_3 and stirring the mixture on a heating plate until clear. Boiling should be avoided. A microwave oven can be used initially to shorten the heating time. A 100-mm-diameter petri dish is placed on a level surface, and 15 ml of agarose gel solution is added per plate (the amount of gel differs depending on the size of the wells and amount of extract or serum). The lid is replaced after the gel cools, and the plate is stored overnight to several weeks at 4°C in a humidified chamber or else sealed with Parafilm.

Just before use, wells are made in the agarose with a homemade gel puncher by pushing straight down gently until the bottom of the plate is reached. Pieces of gel in the wells are aspirated by use of vacuum suction and a Pasteur pipette. If the vacuum is too strong, it may damage the gel. Pieces of gel should be picked up from inside the wells by making a circular movement with the pipette. Appropriate dilutions of antigens, serum samples, and reference sera are prepared (see below) with PBS, and 40 µl is added slowly to

FIGURE 1 Homemade gel puncher for DID. A design for assembling a simple "cookie cutter" punch for agarose gels out of drinking straws is shown. (A) Arrangement of the straws. Seven straws (black) are used to punch holes in the gel, and six additional straws (white) are used as spacers and recessed so that they do not contact the agarose gel. (B) Assembled hole puncher. Straws are assembled as shown in the diagram, using Super Glue. Note the recessed spacer straws that maintain the proper distance between holes.

each well to avoid overflow. The petri dishes should be left undisturbed in a humid chamber (wet gauze or paper towels in a tightly capped plastic box work well).

Several sources of antigens can be used, including commercial extracts (e.g., RTE) and extracts of human cell lines. To prepare RTE, rabbit thymus acetone powder is stirred at a concentration of 0.2 g/ml in PBS in a flask or beaker at 4°C overnight and then centrifuged at $9,000 \times g$ for 30 min at 4°C in a microcentrifuge. The supernatant is collected, and small aliquots are frozen at −80°C until use.

K562 (human erythroleukemia) cells grown in log-phase culture (the medium is RPMI 1640 with 10% fetal bovine serum, penicillin-streptomycin, and L-glutamine) are a convenient source of human cellular proteins. They are collected by centrifugation, washed once with PBS, counted, and pelleted at $800 \times g$ for 10 min. After the PBS is aspirated, the cell pellet is frozen (−80°C) for future use. To prepare extract, 100 µl of PBS is added per 10^8 cells to either frozen cells or a freshly prepared cell pellet. The cells are sonicated on ice to disrupt them (Branson sonifier, 30% output setting 3, for 50 s). The lysate is centrifuged at $9,000 \times g$ for 30 min at 4°C (microcentrifuge). The supernatant is collected and aliquots are frozen at −80°C.

Other antigens can be used, including calf thymus acetone powder (Pel-Freez), fresh calf thymus extract, Wil-2 cell extract, human spleen extract, etc. Antibodies that can be detected with RTE, calf thymus extract, or K562 cell extract are summarized in Table 2.

Assays

Sera stored at 4°C with NaN_3 or frozen at −80 or −20°C can be used. The following materials and reagents are needed:

PBS (0.15 M NaCl–20 mM sodium phosphate, pH 7.2)

Agarose (SeaKem ME; FMC Bioproducts, Rockland, Maine [catalog no. 50010])

10% NaN_3 in distilled water

Plastic petri dish (diameter, 100 mm for four sets of seven wells)

Rabbit thymus acetone powder, calf thymus acetone powder (Pel-Freez), or cell pellet (human lymphocytes, spleen cells, K562, HeLa, or other cells)

Serum samples from patients with systemic rheumatic diseases frequently form more than one precipitin line, and the optimal dilution to form precipitin lines may vary (Fig. 2B). Even if the sample forms only one precipitin line, some sera contain autoantibodies at such a high titer that the precipitin line can be seen only with highly diluted samples. Therefore, it is essential to test serially diluted serum first to see whether precipitin lines are formed. Sera are undiluted (1:1) or diluted with PBS 1:4, 1:16, 1:64, 1:256, and 1:1,024. The diluted samples are used to identify an appropriate dilution for each precipitin line prior to comparison with reference sera. For this purpose, antigen can be placed in the center well with serially diluted serum samples set around it in clockwise order (Fig. 2B).

The precipitin lines should be sketched, and the appropriate dilution and titer for each precipitin line should be determined. At the optimal dilution, a precipitin line should form about halfway between the antigen and antibody wells. Sometimes, a dilution at which two or more precipitin lines are clearly separated may need to be used (Fig. 2C and D). It is easier to interpret the results if the precipitin lines are not too close to the antigen or serum wells.

Dilutions of the reference sera are determined as described above for the test samples. The appearance of precipitin lines

FIGURE 2 DID in agarose gels. A photograph of the assay is shown on the left, and an interpretation is diagrammed on the right. (A) Appearance of precipitin lines when properly diluted reference sera with the following specificities are used: anti-nRNP, anti-Sm (note line of partial identity with anti-nRNP), anti-Ro, anti-Jo-1, anti-ribosomal P (r-P), and anti-La. (B) Determining the optimal serum dilution. Test serum was diluted 1:1, 1:4, 1:16, 1:64, 1:256, and 1:1,024 with PBS. The optimal dilution for precipitin line 1 is 1:4; optimal dilution for line 2 is 1:64. (C and D) DID using dilutions of 1:4 (C) and 1:64 (D) of the serum shown in panel B. Precipitin line 1 is identified as anti-La (C). Precipitin line 2 is identified as anti-nRNP (D).

when properly diluted reference sera are used is illustrated in Fig. 2A. When a test sample does not form precipitin lines, it is considered negative by DID and not tested further. When the sample forms one or more precipitin lines, a second assay must be carried out. The arrangement of samples with unknown precipitin lines, reference sera, and antigens will differ depending on the situation. Examples are shown in Fig. 3. If the sample has unknown precipitin lines that need to be tested for several different specificities, the arrangements in Fig. 3A and B are convenient. If the sample forms precipitin lines with different antigens (e.g., one line with RTE and another with human lymphocyte extract), Fig. 3B may be useful. If several samples (u1 to u4) need to be tested for a single specificity, the arrangements in Fig. 3C and D can be used. If the antigen is valuable, the arrangement in

Fig. 3A or C will help to minimize the amount used. If the serum sample is limited, the arrangement in Fig. 3B will be useful. Figure 3C or D (especially the latter) should be useful when the amount of reference serum is limited.

Attention should be given to which specificities will be tested. Information from the fluorescent ANA test and/or suspected diagnosis can be used to focus attention on particular antigens for more efficient screening of unknown precipitin lines. For example, if the clinical diagnosis is SLE, a panel of lupus-related reference sera such as anti-Sm and ribosomal P should be tested initially rather than scleroderma or myositis reference sera (Table 1). Similarly, there are autoantibodies associated with certain symptoms such as Raynaud's phenomenon (anti-nRNP) or sicca (Ro/SS-A, La/SS-B) (Table 1). Consideration of the clinical diagnosis or clinical manifestations will help to identify precipitin lines more efficiently and less expensively. Similarly, the ANA pattern (e.g., nuclear or cytoplasmic) can be used to narrow the list of diagnostic possibilities, avoiding unnecessary testing. In many cases, sera positive for ANA may be screened for a set of common autoantibodies such as anti-nRNP, -Sm, -Ro, and -La. If they are negative, additional specificities can be tested on the basis of clinical information or ANA pattern. However, there are pitfalls to this approach. First, a cytoplasmic pattern may not be reported consistently by the laboratory. Second, when cytoplasmic staining is brighter than nuclear staining, ANA can be reported as negative because it is often difficult to tell whether there is coexisting (but weaker) nuclear staining.

Quality Assurance, Quality Control, and Test Validation

Normal human serum can be used as a negative control. Positive reference sera are available from the Centers for
FIGURE 3 Typical arrangements of sera and antigens for DID. (A and B) Arrangements for testing an unknown precipitin line for several specificities. Panel A illustrates the use of a single antigen; Panel B illustrates use of two different test antigens (e.g., RTE and human lymphocyte extract). (C and D) Arrangements for testing several sera for a single autoantibody specificity when reference serum is precious. Ag1 and Ag2, antigens; u1 to u4, sera with unknown specificities; a to d, reference sera.

Disease Control and Prevention (CDC) and commercially. It often is convenient to develop a set of in-house standards monospecific for individual precipitin lines. In-house reference sera should form a single strong precipitin line that fuses with the precipitin line formed by the CDC reference serum. Once good sera are found, try to obtain 20 to 30 ml or more of each in order to maintain a stock that can be used over a period of several years.

It is best to make a large amount of antigen and freeze small aliquots at −80°C. When a new lot of antigen is prepared, it must be tested for all antibody systems that normally form precipitin lines. The titer of each reference serum with each antigen should be recorded. This is the highest serum dilution at which a precipitin line can be seen clearly. It is ideal to standardize (by diluting, if necessary) the antigen with a panel of reference sera. Adjustment of the antigen concentration so that the titers are ±1 dilution will assure lot-to-lot reproducibility. Only freshly thawed antigens should be used, and they should not be refrozen.

Antigens in cell extracts can be heavily degraded. Antigens in acetone powder are more denatured than the same antigens in calf thymus extract or lymphocyte extract. Antibodies that preferentially recognize native molecules may not bind denatured antigens in acetone powder but may recognize the more native molecules in a cell extract. Although detergents such as Nonidet P-40 (NP-40) and Tween 20 extract proteins efficiently and are used to prepare extracts for other immunoassays, they cause artifacts in DID and should not be used.

The advantage of DID is its simplicity. DID is highly specific when autoantibodies produce precipitin lines that are strong and sharp and when only a single precipitin line exists. Although all specificities may not be identified on initial screening, autoantibodies to various antigens can be detected by a single test without purifying the target antigens.

A major disadvantage of DID is the difficulty in interpreting weak precipitin lines when multiple lines, especially strong and diffuse lines, coexist in the same sample. If there is only one precipitin line, the chance of misinterpretation is low. Autoantibodies that form sharp, strong precipitin lines, such as anti-nRNP and anti-La (SS-B), are easy to interpret. On the other hand, weak and faint lines, such as anti-Ro (SS-A) and anti-Ku, can be misinterpreted, especially in the presence of another strong or diffuse line. Other disadvantages include the large amounts of sera and antigens used and the fact that the reaction takes several days. Although DID is useful for many autoantibody systems, some autoantibodies, such as antifibrillarin, anti-RNA polymerases, and anti-7-2 RNP, do not produce precipitin lines and are undetectable by DID.

Although DID has been used for over 30 years to detect autoantibodies such as anti-Sm and anti-nRNP, the precise mechanism of formation of precipitin lines is not completely understood. For example, it is not known which component of the U snRNP is responsible for the precipitin lines. There is no clear explanation why the anti-nRNP precipitin line disappears when cell extract is pretreated with RNase.

Cost Assessment
Over 30 years after the initial reports, and despite the introduction of more sophisticated techniques, DID remains a standard method for detecting many clinically useful autoantibody systems because of its simplicity and reliability. However, it is labor-intensive and has gradually fallen out of common use in favor of enzyme-linked immunosorbent assays

(ELISAs) and other techniques that are more amenable to automation. Because of the difficulty in automating DID, this assay is relatively expensive. Despite its cost, the false-positive rate is significantly lower than that seen with ELISAs (S. Narain et al., unpublished data). Thus, the DID assay is highly cost-effective, since the expense (both monetary and psychological) of a false-positive test can be considerable.

Interpretation
The result is interpreted visually by examining the precipitin lines after 1, 2, 3, and 5 days. The observer should sketch the precipitin lines and judge if they fuse (identity = positive), cross (nonidentity = negative), or partially fuse (partial identity, some common part of the two antibody-antigen systems) with the lines formed by reference sera. The gels are washed carefully with PBS, avoiding bubbles, especially under the agarose gel. Afterward, PBS is added to a level 1 to 2 mm above the gel, 2 to 3 drops of 10% NaN_3 are added, and the gel can be stored at 4°C. The gel is photographed on a dark background for documentation.

Generally, the sensitivity of DID is good, and the results correlate well with more sensitive and specific methods, such as radioimmunoprecipitation (henceforth referred to as immunoprecipitation). DID remains one of the methods of choice for detecting common autoantibodies in clinical practice. In particular, commercial ELISAs for anti-Sm are unreliable, and no simple alternative to DID is available at present. The passive hemagglutination assay (11) is a good alternative but has fallen out of use.

Since the titers often are not reported and the significance of changing titers has not been emphasized, DID usually is not considered a quantitative assay. However, it can be made semiquantitative by determining the highest dilution of serum that forms a clear precipitin line.

Clear fusion of two precipitin lines is highly specific for identity. Conversely, if the precipitin lines formed by the sample and the reference serum cross, it indicates nonidentity. Partial fusion between anti-nRNP and anti-Sm precipitin lines is observed, but specificity should be verified by using monospecific anti-nRNP and anti-Sm reference sera.

Remarks and Conclusions
DID is a classic method to detect autoantibodies found in sera from patients with systemic rheumatic diseases. Positive results usually are very reliable. However, at times, false-negative or -positive results can occur due to multiple specificities, technical difficulties, or low sensitivity. Nevertheless, DID is a useful test, especially in view of the lack of good alternatives for detecting certain autoantibodies, such as anti-Sm.

IMMUNOPRECIPITATION: PROTEINS
Gel diffusion and ELISA, unlike Western blot assays (see below), allow the detection of autoantibodies to native antigenic determinants, but the composition of the antigenic particles and fine specificities of the autoantibodies cannot readily be determined. Western blotting, although useful for defining fine specificities, is of limited value for detecting antibodies against conformational epitopes. For this reason, immunoprecipitation of radiolabeled cell extracts has become an important research tool for examining autoantibody specificities. For the detection of a number of clinically important specificities, immunoprecipitation should be considered the "gold standard" against which other techniques are measured (Table 3).

TABLE 3 Gold standards for autoantibody testing (non-DNA/chromatin antigens)[a]

Autoantibody	Gold standard	Other good alternatives
Sm	R-IPP, DID	P-IPP
RNP	R-IPP, P-IPP, DID	
Ro60 (SS-A)	P-IPP	R-IPP, EIA, DID
Ro52	WB	EIA
La (SS-B)	R-IPP, DID	P-IPP, ELISA, WB
Ribosomal P	P-IPP	DID; P-peptide EIA
Ku	P-IPP	DID, EIA
Jo-1 (histidyl tRNA synthetase)	R-IPP	DID, recombinant antigen EIA
PL-7 (threonyl tRNA synthetase)	P-IPP, R-IPP	DID
SRP	P-IPP, R-IPP	
RNAP I, II, III	P-IPP	
Topoisomerase I	DID	WB, P-IPP
Fibrillarin	R-IPP	WB, P-IPP
To/Th	R-IPP	

[a] P-IPP, protein immunoprecipitation; R-IPP, RNA immunoprecipitation; WB, Western blot; EIA, enzyme immunoassay.

Technology and Instrumentation

Radiolabeled antigens are allowed to form immune complexes with autoantibodies and purified onto protein A-Sepharose beads. After the immune complexes are dissociated from the beads, the radiolabeled proteins are separated by sodium dodecyl sulfate (SDS)-polyacrylamide gel electrophoresis and detected by autoradiography (16). A similar approach can be used to analyze the nucleic acid components of small ribonucleoprotein particles (see below) (8). Required apparatus includes an electrophoresis power supply, vertical electrophoresis apparatus (e.g., models from CBS Scientific, Del Mar, Calif.), tabletop centrifuge, CO_2 incubator, cell sonicator (Branson), and microcentrifuge.

The following materials and reagents are needed:

Phenylmethylsulfonyl fluoride (PMSF) (Sigma no. P7626): 50 mM in absolute ethanol stored at $-20°C$ ($=100\times$ stock)

Aprotinin (Sigma, catalog no. A6279): 24 trypsin inhibitor units (TIU) in double-distilled H_2O ($=100\times$ stock)

Protein A-Sepharose CL4B (PAS) (Pharmacia no. 17-0780-01). Prepare the PAS as follows:

1. Add H_2O to 1.5 g of dry PAS in a 15-ml centrifuge tube and incubate with intermittent inversion for 20 to 30 min at room temperature to swell the beads.
2. Centrifuge for 1 min in a tabletop centrifuge ($800 \times g$).
3. Wash the beads three times with H_2O and centrifuge to pellet the beads.
4. To the packed beads, add an equal volume of H_2O. Add 2 M Tris-HCl (pH 8.0) to a final concentration of 20 mM (1:100). Add NaN_3 to a final concentration of 0.1%. The beads can be stored at 4°C in this buffer.

0.5 M NaCl NET/NP-40 buffer: 50 mM Tris-HCl (pH 7.5), 0.5 M NaCl, 2 mM EDTA, 0.3% NP-40

NET buffer: 50 mM Tris-HCl (pH 7.5), 0.15 M NaCl, 2 mM EDTA

3× sample buffer: mix 0.5 M Tris-HCl (pH 6.8) (6.0 ml), 1% bromophenol blue (0.6 ml), 2-mercaptoethanol (3.0 ml), 25% SDS (4.8 ml), and glycerol (6.0 ml). This mixture can be stored at $-20°C$.

Sterile Dulbecco's PBS (D-PBS): NaCl (160 g), Na_2HPO_4 (dibasic; 23 g), KCl (8 g), KH_2PO_4 (monobasic; 4 g).

Add double-distilled water (Milli-Q filtered) to 20 liters, and adjust conductivity to 15,000 to 16,000 and pH to 7.4.

D-PBS-dialyzed fetal bovine serum: 50 ml of fetal bovine serum (Gibco-BRL or HyClone) is dialyzed for 3 days at 4°C against D-PBS (500 ml). Change the D-PBS twice daily.

[35S]Methionine-cysteine (Dupont/New England Nuclear, NEG 072): upon receipt, the isotope should be snap-frozen in small aliquots sufficient for one labeling reaction and stored at $-80°C$.

Methionine- and cysteine-free RPM1 1640 (Cellgro, Fisher catalog no. 17-104-CI)

Penicillin (10,000 IU/ml)-streptomycin (10,000 μg/ml) ($=100\times$ Pen-Strep; Gibco BRL, catalog no. 15140-031)

L-Glutamine, 200 mM ($=100\times$; Gibco BRL, catalog no. 25030-081)

Fetal bovine serum (Gibco BRL, catalog no. 26140-079)

35S-labeling medium: 39 ml of methionine and cysteine-free media, 4.5 ml of D-PBS-dialyzed fetal bovine serum, 0.45 ml L-glutamine, 45 μl of Pen-Strep, 1.35 ml of regular RPMI (for 10^8 cells)

Assays

Radiolabeled cell extract is prepared from K562 cells (ATCC CCL-243). The cells are thawed 2 to 3 days before use and grown at a density of 0.5×10^6 to 1.5×10^6/ml in RPMI 1640 plus L-glutamine (1:100), penicillin-streptomycin (1:100), and 10% fetal bovine serum in 750-ml tissue culture flasks (Corning, catalog no. 430199) at 37°C in a 5% CO_2 atmosphere. Cells should be in the mid-log phase of growth and should be visually inspected before labeling. Rapidly growing cells are labeled more efficiently than slowly growing ones. *Note: K562 cells grow in small non-adherent or weakly adherent clusters when healthy. If they are not healthy, they will start to adhere to the flask and differentiate. Cells that have begun to differentiate are deficient in some antigens, such as topoisomerase I (Scl-70).*

The night before use, collect the cells by centrifugation ($600 \times g$ for 5 min in a tabletop centrifuge), resuspend them in 20 ml of sterile D-PBS, and count them. The cells should be adjusted to 10^8 cells per 45 ml of 35S-labeling medium (recipe above) in a 250-ml flask. Add 2 mCi of freshly thawed

[^{35}S]methionine-cysteine, and incubate the cells for 12 to 16 h at 37°C in a 5% CO_2 atmosphere. The following day, the cells are collected by centrifugation (1,000 rpm, 5 min). *Note: the level of RNAP II decreases after 16 h, so it is important not to label for too long.* After labeling, there should be ~1.8×10^8 cells and the medium should have turned yellow. Collect the cells in a centrifuge tube, rinse the empty flask with D-PBS, and combine. Make aliquots of 2×10^7 cells in 15-ml polypropylene centrifuge tubes. Spin the tubes at $800 \times g$ in a tabletop centrifuge (5 min) and aspirate the supernatant. Freeze tubes with their cell pellets at -70°C. *Be sure to use polypropylene centrifuge tubes (e.g., Corning no. 430052) so they will not crack when frozen.*

Immunoprecipitation is carried out with serum that has been centrifuged ($9,000 \times g$ for 5 min) to remove insoluble materials. Frozen serum samples (-20°C) should be recentrifuged before analysis. Serum samples also may be stored for 10 to 15 years at 4°C after addition of sodium azide (NaN$_3$; final concentration, 0.05%). The procedure is as follows. In a 1.5-ml microcentrifuge tube combine 40 μl of 50% PAS slurry in Tris-HCl (pH 8.0), 8 μl of human serum, and 500 μl of 0.5 M NaCl NET/NP-40. Rotate the tube end-over-end at 4°C for 1 to 2 h or at room temperature for 1 to 3 h. *Avoid vortexing the beads at any stage of the procedure.* During this incubation, prepare cell extract from radiolabeled K562 cells (see above). For a standard reaction, we use extract from 2×10^6 radiolabeled cells per sample. Add 2 ml of 0.5 M NaCl NET/NP-40 plus 1:100 (20 μl) PMSF plus 1:100 (20 μl) aprotinin to the pellet (final cell concentration, 10^7/ml). *Do not put PMSF directly on the cell pellet because the ethanol will denature the proteins.* Sonicate the cells for 1 min (duty cycle 30%, output 3). Place on ice for 1 min and then sonicate again for 1 min. Transfer the cell lysate to microcentrifuge tubes and centrifuge at $9,000 \times g$ for 30 min at 4°C. Carefully collect the lysate (avoid disturbing the small pellet). Combine all of the lysate into one tube before dispensing. Extract from 2×10^7 cells is sufficient for 12 immunoprecipitations. *Note: when using frozen cells, do not thaw the cell pellet at 37°C. Once the cells are thawed, they are disrupted and protein degradation commences. Also, avoid excessive heating of the cell suspension during sonication. The extract may become hot enough to denature proteins if not chilled on ice.*

Pellet the serum-coated PAS beads by microcentrifuging for 3 s. Aspirate the supernatant by using a drawn-out Pasteur pipette attached to a vacuum. Add 1 ml of 0.5 M NaCl NET/NP-40 and microcentrifuge for 3 s. Aspirate the supernatant. *Carefully remove any air bubbles on the surface of the samples first, since they may cause high background.* To each PAS pellet, add 150 to 160 μl of cell extract. Rotate end-over-end for 1 h at 4°C. Microcentrifuge for 3 s and aspirate the supernatant. Wash the beads three times with 1 ml of 0.5 M NaCl NET/NP-40 and then once with 1 ml of NET. Carefully aspirate the supernatant. Add 50 μl of 1× sample buffer to each pellet. Samples may be kept at -80°C for at least 1 month (keep in mind that the half-life of ^{35}S is ~60 days). To analyze, boil the samples for 3 min, pellet the beads, and load 15 to 20 μl of supernatant per lane of an SDS–12.5% polyacrylamide gel. For large proteins (>100 kDa), resolution may be enhanced by using a 10 or 8% polyacrylamide gel. It usually takes 3 to 5 h for the tracking dye to reach the bottom of the gel at a constant voltage of 100 to 130 V.

Note: if performing immunoprecipitations with antibodies that do not bind protein A (e.g., human immunoglobulin γ3 [IgG3] or mouse IgG1), it will be necessary to use protein G-Sepharose.

The proteins associated with the immunoprecipitates are analyzed by SDS-polyacrylamide gel electrophoresis and fluorography. Reagents are as follows:

25% SDS (Fisher or Bio-Rad). *Note: filter this solution and all other stock solutions through a 0.45-μm bottle top filter.*

Coomassie blue stain: Coomassie brilliant blue R-250 (Bio-Rad, catalog no. 161-0400) (5 g), methanol (1,200 ml), glacial acetic acid (400 ml); add distilled water to 4,000 ml

Destaining solution: 2 liters of glacial acetic acid, 7 liters of methanol, 11 liters of distilled water

2, 5-Diphenyloxazole (PPO) (Fisher, catalog no. D144-100), 20% (wt/vol) in dimethyl sulfoxide (DMSO). *Note: PPO is carcinogenic.*

Glycerol

BioMax MR film (Eastman Kodak, catalog no. 870-1302)

30% acrylamide–0.8% bisacrylamide stock: 30% (wt/vol) acrylamide (Fisher, catalog no. BP170-500) plus 0.8% bisacrylamide (Bio-Rad, catalog no. 160-0201) (wt/vol) in water (ratio, 37.5:1); filter through a 0.45-μm bottle top filter.

5× Tris-glycine (for running buffer): 120 g of Tris base plus 576 g of glycine; add distilled water to 4 liters (no need to adjust pH; can be stored at room temperature).

The procedure for preparing gels is as follows. *Note: precast minigels may be substituted for homemade ones. They can be purchased from Bio-Rad or other vendors. If casting your own gels, keep in mind that acrylamide is a neurotoxin and suspected carcinogen.* Gel plates, spacers, and rubber gaskets are washed thoroughly with detergent and water (e.g., PCC-54, Pierce, Rockford, Ill.), rinsed carefully, and wiped dry with ethanol. Gel plates should be assembled and clamped together, starting at the bottom and working your way up the sides.

A 12.5% resolving gel is made by combining distilled water (15.6 ml), 2 M Tris HCl (pH 8.8) (7.5 ml), 30% acrylamide–0.8% bisacrylamide (16.6 ml), and 25% SDS (160 μl). *Immediately before use (wearing gloves)* add 10% ammonium persulfate (200 μl) and TEMED (N, N, N', N'-tetra methylenediamine) (20 μl; Bio-Rad) to start polymerization. Mix gently, avoiding bubbles. Carefully pour between the glass gel plates, again avoiding bubbles. Using a Pipetteman, gently layer 70% ethanol above the resolving gel (~3- to 5-mm-thick layer) to exclude air from the gel as it polymerizes. The gel should polymerize in about 1 h. Pour off the ethanol, and rinse the top of the gel with water. Use a filter paper strip to carefully remove water droplets between the plates. *It is critical to use fresh ammonium persulfate and TEMED for polymerizing the gel. Both reagents should be stored at 4°C. Prepare 10% ammonium persulfate fresh. Do not use TEMED older than 1 year.*

Stacking gel is made by combining distilled water (12.2 ml), 0.5 M Tris HCl (pH 6.8) (5 ml), 30% acrylamide–0.8% bisacrylamide (2.6 ml), and 25% SDS (80 μl). *Immediately before use (wearing gloves)* add 10% ammonium persulfate (100 μl) and TEMED (20 μl) to start polymerization. Mix gently, avoiding bubbles. Carefully pour between the glass gel plates up to the top, avoiding bubbles. Carefully insert the comb at the top of the gel. Clamp the top. *This prevents gel bits from adhering to the wells after the comb is removed.* Stacking gel should polymerize in about 45 min at room temperature.

The gel is run as follows.

1. Make 1 liter of running buffer: 200 ml of 5× Tris-glycine plus distilled water to make 1,000 ml; add 4 ml of 25% SDS and mix well.

2. Boil samples, including molecular weight standards, for 3 min in a water bath immediately before loading the gel.

3. Carefully remove the comb and bottom spacer from the SDS-polyacrylamide gel.

4. Clamp the gel to the gel apparatus and add running buffer to the top and bottom chambers to cover the top and bottom of the gel.

5. Remove bubbles from the bottom of the gel, using a syringe with a bent (90°) 18-gauge needle.

6. Gently wash out wells with running buffer, using a Hamilton syringe.

7. Add 20 μl (or desired volume) of boiled sample per well.

8. Attach leads to the electrodes of the gel apparatus (proteins treated with SDS are negatively charged and will migrate toward the cathode).

9. Attach to power supply and run at 100 V until the blue tracking dye reaches the resolving gel. At this time, the voltage may be increased to 120 V.

10. Run the gel until the blue tracking dye reaches the bottom of the gel (do not run the dye off the gel).

11. Turn off the power, remove the electrodes, and unclamp the gel from the gel apparatus. Carefully pry the plates apart, leaving the gel adherent to one of the plates. Using a pizza cutter, cut off the stacking gel and diagonally cut off a small piece of the gel from the upper right-hand corner to aid in orienting the gel.

12. Stain the gel for 20 min with Coomassie blue solution. Destain and fix the gel with several changes of destaining solution.

After staining and fixation, the gel is fluorographed as follows.

1. Place the gel in a Tupperware (polyethylene or polypropylene but not polystyrene) container and remove as much of the destaining solution as possible. Immerse the gel in 100 to 200 ml of DMSO, cover the container, and rotate gently on a shaker for 30 min. Discard DMSO.

2. Transfer to 100 to 200 ml of fresh DMSO, cover, and rotate for 30 min. After use, this DMSO solution is removed and can be saved for use as the first DMSO wash for another gel.

3. Add 100 to 200 ml of 20% (wt/vol) PPO in DMSO, cover, and rotate gently for 60 min. Save the DMSO-PPO mixture. It can be reused for several gels, although the effectiveness gradually diminishes. The solution can be "recharged" by adding additional PPO. *Note: PPO is a carcinogen, and DMSO can penetrate standard laboratory gloves. Wear heavy rubber gloves (e.g., Playtex) and handle DMSO-PPO solution carefully.*

4. Wash the gel with several changes of water to rehydrate (at least 30 min, until the smell of DMSO is no longer apparent). The PPO will precipitate in the gel. Add glycerol to the final wash to a concentration of ~3%. Remove the gel, which will have turned white and opaque, place on 3MM paper (Whatman) and dry with a vacuum gel dryer. Wash out the tray with ethanol to remove traces of PPO (which is insoluble in water). We use a Bio-Rad gel dryer (model 583) at 60°C with the timer set to 3 h. After 1.5 h, the gel is removed. Vent the gel dryer, and remove the gel and attached 3MM paper.

5. Tape dried gels to a used piece of X-ray film. If it is sticky, dust the gel lightly with talc to prevent sticking. Place this in a cassette and (in the darkroom) place in direct contact with BioMax MR film. *This film is coated on one side, and the coated side must contact the gel.* Expose the gel to film in the cassette for 3 days or more at −70°C before developing.

Quality Assurance, Quality Control, and Test Validation

It is important to include a sample of normal human serum as a negative control. Whenever possible, it is advisable to use a known positive control serum (reference serum). Expression of individual antigens may vary, depending on the cell line used.

Molecular weight standards (Sigma, catalog no. SDS-7 [low molecular weight] or SDS-6H [high molecular weight]) are analyzed in an adjacent lane of the gel and detected by Coomassie blue staining. Migration of molecular weight standards and immunoglobulin heavy and light chains (~50 and 25 kDa, respectively) can be examined to assess the quality of separation. By using reference or prototype sera and normal human serum, the technical adequacy of the gel can be assessed. Multiple weak bands with normal human serum may indicate problems with washing.

Immunoprecipitation is a highly sensitive and specific technique for detecting a variety of autoantibodies. However, clinical application of this approach is greatly limited because it is labor-intensive and technically demanding and requires the use of radioisotopes. Nevertheless, the immunoprecipitation technique is extremely useful for validating other assays, such as ELISAs.

Cost Assessment

The protein immunoprecipitation technique is demanding and labor-intensive. However, these drawbacks are offset by the considerable information on multiple autoantibody systems gained from a single assay.

Interpretation

The major autoantibodies that can be evaluated by these techniques are summarized below.

Anti-Sm and Anti-nRNP

Anti-Sm and anti-nRNP antibodies recognize different subsets of the protein components of the U1 snRNP particle. This is an RNA-protein complex consisting of proteins U1-70K (70 kDa), A (33 kDa), B′/B (29 and 28 kDa, respectively), C (23 kDa), D1/2/3 (16 kDa), E (12 kDa), F (11 kDa), and G (10 kDa). The proteins are associated with a single U1 small nuclear RNA molecule (12). Proteins B′/B, D, E, F, and G assemble into a stable Sm core particle, which is reactive with anti-Sm, but not anti-nRNP, antibodies. The Sm core particle is a component of several additional snRNPs, each with a unique uridine-rich (U) RNA species as well as unique proteins. These include the U2, U4/U6, and U5 snRNPs, as well as other less abundant U snRNPs (12). Anti-Sm, but not anti-nRNP, antibodies immunoprecipitate the unique 200- to 205-kDa proteins of the U5 snRNP, which are associated with the Sm core particle (Fig. 4). Although autoantibodies specific for these proteins have been reported, they are unusual. Thus, immunoprecipitation of the U5 200- to 205-kDa doublet by a serum that immunoprecipitates the A to G proteins provides evidence for the presence of anti-Sm autoantibodies, a diagnostic marker for SLE (12). Anti-nRNP antibodies are not disease specific and are of limited utility in diagnosing SLE or in predicting its course. Different fine specificities of anti-nRNP and anti-Sm antibodies can be distinguished if immunoprecipitation is carried out after the U1 snRNP is dissociated into its components by use of $MgCl_2$ or RNase (18, 19).
FIGURE 4 Protein immunoprecipitation for analyzing SLE sera. Sera were tested according to the protocol in the text, and immunoprecipitated proteins were resolved on a 12.5% gel. Sera containing the following autoantibodies were tested: anti-nRNP (RNP), anti-Sm, anti-ribosomal P (r-P), anti-PCNA, anti-Ki, anti-Ro60, anti-La (SS-B), anti-Ku, anti-Ku plus anti-DNA-PK$_{cs}$ (Ku-DNAPK) anti-Su, anti-RNAP II, anti-RNA helicase A (RHA), and normal human serum (NHS). Positions of molecular weight standards are shown on the left (in kilodaltons). Protein components of the antigens are indicated (dots).

Anti-Ro (SS-A) and Anti-La (SS-B)

Sera containing anti-Ro (SS-A) autoantibodies may recognize two proteins: a 60-kDa protein (Ro60) that binds to the stem of four small RNAs designated hY1, hY3, hY4, and hY5 (3) and a 52-kDa protein (Ro52) (12) reactive with many, but not all, anti-Ro (SS-A) sera. It is controversial whether or not Ro52 interacts with Ro60 or the Y RNAs. Anti-Ro52 autoantibodies can immunoprecipitate the protein (12), but they are not reliably detected by that means, and many sera immunoprecipitate Ro60 but not Ro52. Anti-Ro60 autoantibodies are readily detected by protein immunoprecipitation (Fig. 4).

La (SS-B) antigen is a 47-kDa protein associated transiently with the precursors of several small RNAs synthesized by RNAP III (12). It can be detected readily by protein immunoprecipitation (Fig. 4), but the band often is distorted because it migrates near the immunoglobulin heavy chain ("heavy chain artifact"). Anti-La (SS-B) autoantibodies are virtually always associated with anti-Ro (SS-A) (24).

Anti-ribosomal P

Anti-ribosomal P antibodies recognize three proteins of ~38, 19, and 17 kDa (P0, P1, and P2) that are components of the large (60S) ribosomal subunit (Fig. 4). These autoantibodies recognize mainly a conserved epitope contained on the

C-terminal 22 amino acids of P0, P1, and P2 (4). Antibodies to the ribosomal P0, P1, and P2 antigens are highly specific for the diagnosis of SLE (12). Anti-P antibodies have been linked with neuropsychiatric lupus, especially psychosis, and their levels may be useful in predicting a relapse of lupus psychosis (12). Despite controversy regarding their relevance to neuropsychiatric lupus, the specificity for SLE is widely accepted. Immunoprecipitation is probably the standard test for this specificity, but DID, ELISA, and immunoblotting also are reliable (1, 23). There appear to be some sera that are positive by ELISA but negative by immunoprecipitation, however.

Anti-PCNA

PCNA is a 36-kDa protein recognized by autoantibodies found in about 2 to 5% of SLE sera (12). These antibodies, though unusual, are highly specific for SLE (6, 10). Immunoprecipitation is probably the most reliable way to detect these autoantibodies (Fig. 4), but DID also is suitable.

Anti-Ku

Ku antigen is a heterodimer of ~80- and 70-kDa subunits (p80 and p70, respectively) that binds to termini of dsDNA (12). These proteins associate with an ~460-kDa DNA-dependent protein kinase (DNA-PK catalytic subunit [DNA-PK$_{cs}$]). Autoantibodies are produced against both of

the Ku subunits as well as DNA-PK$_{cs}$. A subset of autoantibodies recognizes epitopes formed by the assembly of these proteins into a particle, which can be detected only by techniques that preserve the quaternary structure of the Ku/DNA-PK antigen. Immunoprecipitation is the gold standard for detecting autoantibodies against Ku/DNA-PK (Fig. 4 and Table 3). Antibodies that recognize specifically the DNA-PK$_{cs}$ protein must be detected following dissociation from Ku, e.g., by exposure to 0.5 to 1.5 M NaCl. Autoantibodies against Ku antigen are found in several diseases, including PM-SSc overlap syndrome, SLE, MCTD, and SSc.

Anti-tRNA Synthetases

Autoantibodies against aminoacyl tRNA synthetases are diagnostic markers for PM/DM and the antisynthetase autoantibody syndrome (see above). The most common is anti-histidyl-tRNA synthetase (anti-Jo-1), but many others have been reported, including threonyl (anti-PL-7), alanyl (anti-PL-12), isoleucyl (anti-OJ), glycyl (anti-EJ), and asparaginyl (anti-KS) tRNA synthetases. The antisynthetase autoantibodies immunoprecipitate proteins of characteristic molecular weights (Table 1) as well as the corresponding tRNA molecule (7, 22). Both the proteins and the tRNAs have distinctive mobilities on electrophoresis (Fig. 5). Recombinant antigen-based ELISAs,
FIGURE 5 Protein immunoprecipitation for analyzing myositis (PM/DM) sera. Sera were tested according to the protocol in the text, and immunoprecipitated proteins were resolved on an SDS–8% polyacrylamide gel. Sera containing the following autoantibodies were tested: anti-histidyl tRNA synthetase (Jo-1, 50 kDa), anti-alanyl tRNA synthetase (PL-12, 110 kDa), anti-glycyl tRNA synthetase (EJ, 75 kDa), anti-threonyl tRNA synthetase (PL-7, 80 kDa), anti-isoleucyl tRNA synthetase (OJ, 150 kDa and multiprotein complex), and anti-signal recognition particle (SRP, 54-kDa protein and multiprotein complex). Protein components of the antigens are indicated (dots).
FIGURE 6 Protein immunoprecipitation for analyzing scleroderma sera. Sera were tested according to the protocol in the text, and immunoprecipitated proteins were resolved on an SDS–8% polyacrylamide gel. Sera containing the following autoantibodies were tested: anti-RNAP I, II, and III (RNAP I/II/III); anti-RNAP I and III (RNAP I/III); anti-RNAP II, unphosphorylated and phosphorylated forms (RNAP IIA/O); anti-RNAP II, phosphorylated form (RNAP IIO); anti-topo I (100 kDa); antifibrillarin (34 kDa); and anti-NOR90 (doublet ~95 kDa). Protein components of the antigens are indicated (dots).

DID (histidyl, threonyl), and Western blotting (e.g., glycyl) also may be useful.

Anti-SRP

Autoantibodies against SRP are myositis specific and recognize an RNA-protein complex consisting of a single molecule of 7SL RNA and proteins of 72, 68, 54, 19, 14, and 9 kDa (13). The major antigenic determinants are located on the 54-kDa protein. Immunoprecipitation is the only technique at present for detecting anti-SRP (Fig. 5).

Anti-topo I (Scl-70)

Autoantibodies against topo I are highly associated with diffuse scleroderma and portend a poor outcome (15). The antigen is a 100-kDa nuclear protein that is not RNA associated. Although the autoantibodies are reliably detected by DID using calf thymus extract, Western blotting or immunoprecipitation (Fig. 6) is also helpful.

Antifibrillarin (U3 RNP)

Fibrillarin is a 34-kDa nucleolar protein associated with the U3 small nucleolar RNA species. Autoantibodies to this protein are highly specific for scleroderma and produce a nucleolar immunofluorescence pattern on ANA testing (15). Screening can be carried out by immunofluorescence ("clumpy" anti-nucleolar staining). Immunoprecipitation

acrylamide gel fragments. Prerun the gel at 400 to 500 V for 15 to 30 min. The plates should become warm but not so hot that you cannot touch them. After prerunning the gel, clean out the wells again. Carefully load the samples, and run the gel at 400 to 500 V constant voltage until the bromphenol blue tracking dye is about two-thirds of the way to the bottom of the plates. After electrophoresis, fix the gel on one of the glass plates for 20 to 30 min in 5% glacial acetic acid–water. Carefully transfer onto 3MM paper (place paper on top of the gel and glass plate and flip over). Dry gel under vacuum and then expose to XAR5 film (Eastman Kodak; overnight exposure at −80°C using intensifier screens).

Quality Assurance, Quality Control, and Test Validation

See "Immunoprecipitation: Proteins" (above).

Cost Assessment

See "Immunoprecipitation: Proteins" (above).

Interpretation

Anti-Sm and anti-nRNP sera immunoprecipitate distinctive subsets of small RNAs, as shown by analysis of the ^{32}P-labeled RNAs (8). Both anti-nRNP and anti-Sm sera immunoprecipitate U1 RNA, whereas the U2, U4, U5, and U6 small RNAs are immunoprecipitated only by anti-Sm, providing a useful means for unequivocally distinguishing the two specificities. Anti-Ro60 antibodies can be detected by immunoprecipitation of the hY1, hY3, hY4, and hY5 RNAs. Anti-La (SS-B) autoantibodies also can be detected by immunoprecipitation of 5S, 7SL, 7-2, 8-2, tRNA, and other small RNAs.

Detection of Autoantibodies by Using Immobilized Natural and Recombinant Autoantigens

EDWARD K. L. CHAN, RUFUS W. BURLINGAME, AND MARVIN J. FRITZLER

114

Autoantibodies directed against intracellular antigens are characteristic features of a number of human autoimmune diseases and certain malignancies (5, 12, 50–52). Studies in systemic rheumatic diseases have provided strong evidence that autoantibodies are maintained by antigen-driven responses (42, 52, 56) and that autoantibodies can be reporters from the immune system revealing the identity of antigens involved in the disease pathogenesis (51). Historically, autoantibody detection and analysis have relied on a number of different technologies, such as hemagglutination and particle aggregation, immunodiffusion (ID), indirect immunofluorescence (IIF), complement fixation, counterimmunoelectrophoresis (CIE), Western and dot blotting, immunoprecipitation (IP), enzyme-linked immunosorbent assay (ELISA), and functional assays that demonstrate inhibition of the catalytic or other functional activity of the antigen of interest. These conventional technologies have limitations because they tend to be labor-intensive and time-consuming, are limited in throughput, are semiquantitative, and are not adaptable to leading-edge research. ID has been used for more than 50 years and is still used in clinical laboratories because it is inexpensive and specific, but it lacks sensitivity and can take up to 48 h before precipitin lines are interpretable. Western blot is costly and time-consuming, and not all autoantibodies are detected by this technique. For example, in the SS-A/Ro system it has been observed that IP techniques are required to identify some sera that contain antibodies reacting only with the "native" SS-A/Ro particle (2). IP protocols that use extracts from [^{35}S]methionine-labeled cells are not suitable for the detection of all autoantibodies, such as antibodies to the 52-kDa SS-A/Ro protein (6). ELISA techniques have rapidly advanced, but highly specific, sensitive, and reliable assays that use highly purified or recombinant proteins can be expensive and are limited by intermanufacturer and interlaboratory variation (53). Some laboratories continue to use CIE for the detection of certain autoantibodies, such as SS-A/Ro, because this technique was found to be the most reliable method for the detection of these autoantibodies (33, 35). However, ID and CIE generally favor high-titer sera and often cannot discriminate multiple autoantibody responses that are characteristic of sera from patients with systemic rheumatic disease.

Despite the advantages of IP, CIE, and ELISA, IIF remains the least expensive and, perhaps, the screening assay of choice for many autoantibodies (1, 60). HEp-2 cells are currently the most commonly used cell substrate in diagnostic autoantibody tests for systemic rheumatic diseases. However, the use of IIF on HEp-2 cells to detect autoantibodies can be limited by a lack of specificity and sensitivity when the antigen in question is of low abundance, or when epitopes are hidden or lost through cell fixation. These factors have resulted in variability of commercial HEp-2 cell substrates (17). In addition to variation in kits produced by various manufacturers, significant lot-to-lot variation in kits from single manufacturers has also been noted, and variations in different batches from the same manufacturer have also been observed. Another limitation of current IIF substrates is that there is significant variation in the sensitivity of different commercially available substrates to detect different antibodies. This limitation can be compounded by sera that contain multiple autoantibodies, for which it is necessary to use other techniques to definitively identify as many autoantibodies as possible in a single serum sample.

Human sera contain autoantibodies that are notably heterogeneous with respect to antigen and epitope specificity and polyclonality of the B-cell response that leads to their formation. For example, it is not uncommon to see sera that show a complex pattern of IIF staining that might include reactivity with the nuclear envelope, mitochondrial antibodies, and homogeneous staining of interphase nuclei. Further analyses of these sera with a variety of techniques confirm that there is reactivity with a variety of antigens, which might include chromatin, SS-A/Ro, pyruvate dehydrogenase complex (PDC; also called M2 antigen), nuclear pore complex antigens (39), and p97/valosin-containing protein (VCP) (36). Of interest, autoantibodies directed to the last autoantigen VCP are not associated with a distinctive IIF staining pattern and are not detected by Western blotting when denaturing agents are utilized (37). Complex sera like those referenced here point to the need for multiplexed autoantigen arrays to provide an accurate picture of the autoantibody profile of any patient.

With the use of expression cloning and autoantibodies as probes to screen λ phage cDNA libraries, the identities of many autoantigens have been determined and validated. A logical strategy is to take advantage of the availability of recombinant autoantigens, generated from the cDNA in *Escherichia coli* or other appropriate expression systems, as substrates for immunoassays such as ELISA and multiplex

assays. This chapter focuses on the methodology in purification of recombinant autoantigens used in the authors' laboratories and recent advances in multiplex immunoassays that are suitable for autoantibody detection.

ANTIGEN TECHNOLOGY

A rapid expansion of new technologies developed by basic and applied immunology is making a significant impact on a broad spectrum of biomedical investigation (13, 43). The identification of biomarkers of disease onset, progression, and response to therapy is now made possible with the application of a variety of reagents in a number of novel platforms (7, 20, 23, 57). Polyclonal, monoclonal, and single-component antibodies have become valuable tools in basic research and diagnostic technologies, and more recently they have become a very successful approach for therapeutics in oncology, a broad spectrum of systemic rheumatic diseases, a variety of autoimmune conditions, and cell and organ transplantation. Accompanying these developments has been the appearance of a broad spectrum of DNA, RNA, and protein arrays. Protein arrays in particular are gaining acceptance as an approach to multiplexed detection of autoantibodies in biological fluids and the detection of changes in cell physiology after various physiological triggers and therapeutic interventions (43). To capitalize on these advances, there has been a need for the parallel development of new technology platforms to produce and utilize the arrays in clinical settings. These have included new adaptations of the fluorescence-activated cell sorter, which is now a standard device in most clinical immunology centers (55). In addition, devices that produce protein arrays by binding analytes of interest on solid-phase substrates have become a necessary technology of research-intensive institutions. Some of these emerging technologies include addressable laser beads, microfluidics and laboratory-on-a-chip platforms, and nanotechnology (13, 22, 54, 58, 61).

Purification of Natural and Recombinant Autoantigens

One requirement in the development of a successful immunoassay for the detection of autoantibodies is that the antigen must be recognized efficiently. Many recombinant autoantigens generated in *E. coli* can be used successfully for functional as well as immunological assays. In the analysis of systemic rheumatic diseases, recombinant human SS-B/La antigen is an excellent example, since most human anti-SS-B/La-positive sera recognize multiple epitopes, most of which are readily expressed in recombinant forms. However, some recombinant autoantigens are found to be not suitable at all. For example, SmD1 antigen generated in *E. coli* is not suitable for ELISA, while the same antigen expressed from a baculovirus system is (40). Recombinant antigens derived from the *E. coli* expression system that are not suitable for the detection of autoantibodies may lack posttranslational modifications required directly or indirectly for the reactivity of the epitope(s). There is a subgroup of autoantigens derived from *E. coli* expression systems that are not completely nonreactive but are clearly not optimal as substrates for autoantibody detection. A member of this subgroup includes the 60-kDa SS-A/Ro antigen. Only a low percentage of anti-SS-A/Ro-positive sera are reactive to the recombinant protein generated from *E. coli* compared to the native affinity-purified bovine 60-kDa protein. It is not clear why the native preparation is more immunoreactive than the one derived from *E. coli*, but probable explanations are that the native

antigen has a conformation, a posttranslational modification, or a cofactor that the protein made in *E. coli* lacks. Another instance where a cloned antigen does not have as much reactivity as the native proteins is U1 RNP. In this case, the increased reactivity with the native antigen is caused by antibodies in patients with mixed connective tissue disease that only react with the quaternary structure found in the RNA-multiprotein complex but not in the individual components.

Use of Natural Autoantigens

There remain many reasons that autoantigens are purified from natural rather than recombinant sources. Historical uses and costs are some of the issues that lead to the use of bovine chromatin preparations as substrates for the detection of antichromatin antibodies. Classical biochemical purification is still used for the purification of large quantities of different chromatin fractions as well as subunits that are useful for detecting a clinically relevant subset of antibodies (3). Additionally, it has been demonstrated that some diagnostically important antibodies react with epitopes present on the native histone-DNA complex found in chromatin. These epitopes are absent in purified histones and DNA (4). The antigen tissue transglutaminase, recognized by sera from people with celiac disease, is easily isolated by biochemical techniques from red blood cells and other tissue sources. To obtain native autoantigens that are in relatively low abundance in animal tissue, affinity column purification using well-defined human autoantibodies coupled to solid-phase matrices is routinely used. Because it is possible to obtain the large quantities of tissue that are needed at a relatively low cost, bovine spleen and thymus are often the starting material for native antigens. Examples in this category include all of the extractable nuclear antigens, such as Sm, RNP, 60-kDa SS-A/Ro, SS-B/La, Scl-70, and Jo-1.

Use of Peptide Antigens

Patients with autoimmune diseases make a wide spectrum of autoantibodies to specific antigens, and some of these antibodies will react with peptides from the antigen. Usually, the peptides are not as reactive as the whole protein in immunoassays, and thus they are not clinically useful. However, in a few instances, antibodies against peptides have been shown to be at least as clinically useful as antibodies against the corresponding native protein. In particular, the C-terminal 22 amino acids of ribosomal P proteins are the immunodominant peptide in certain patients with systemic lupus erythematosus (SLE) (9), as is a dimethylated peptide from SmD3 antigen (32). Citrullinated peptides derived from filaggrin and other sources are very reactive with sera from patients with rheumatoid arthritis (RA) (45).

Construction of Recombinant Proteins

The strategy in the design of recombinant constructs is beyond the scope of this chapter; however, some key aspects related to the production of recombinant autoantigens are discussed briefly below. The construction of recombinant proteins to be used in the detection of autoantibodies should take into consideration the suitability of the construct design and the ease of purification of resulting proteins. Earlier attempts in the production of recombinant proteins were faced with lengthy biochemical purification protocols to remove unwanted *E. coli* proteins. More importantly, most of these protocols have to be adjusted for each individual recombinant protein with distinct biochemical characteristics. Currently it is preferable to design recombinant proteins with an affinity tag that can be utilized for subsequent purification using

a one-step solid-phase affinity chromatography protocol that can be shared among most recombinant proteins largely independent of their biochemical properties. The preferred affinity tag should be short, like the six-histidine tag that can be attached to the N terminus or C terminus of the recombinant protein using vectors such as pET28 (Novagen/EMD Biosciences, Inc., San Diego, Calif.) or pDEST17 (Invitrogen, Carlsbad, Calif.). The glutathione S-transferase (GST) fusion proteins, although used by many investigators for the expression of autoantigens, may not be suitable for general use, since anti-GST antibodies have been reported in some patients with autoimmune hepatitis (24).

In most designed recombinant autoantigens, full-length constructs are preferred so as to ensure that all the epitopes are well represented. When the autoantigen is a large protein, such as the Golgi complex protein giantin, which has a molecular mass of ~350 kDa, it is technically difficult to produce the complete protein in *E. coli* or even in a mammalian expression system. Thus, overlapping fragments of giantin that can be used alone or as a mixture for the detection of autoantibodies were produced (38).

Purification of Recombinant Proteins

As discussed above, the purification of recombinant proteins depends on the strategy and requirements. It is beyond the scope of this chapter to discuss purification of different types of recombinant proteins, and thus the following discussion represents two key modifications or improvements in overcoming problems encountered during the production of six-histidine-tagged recombinant proteins for use in the detection of autoantibodies. The first concern is the purity of the preparation to ensure that there are no false-positive results caused by antibodies that bind to *E. coli* protein contaminants. A modification of the established purification protocol for six-histidine-tagged proteins has been used to achieve a higher degree of purity by repeating the affinity purification step (41). Preliminary studies showed that twice-purified recombinant proteins had lower background reactivity with normal human sera than once-purified preparations. This two-time affinity purification protocol has been used in several studies (38, 62). In brief, six-histidine-tagged recombinant proteins are purified from *E. coli* lysates under denaturing conditions as described in the Qiagen manual *The QIAexpressionist* (41) and are eluted from a nickel affinity column using buffer E (8 M urea, 100 mM NaH$_2$PO$_4$, and 10 mM Tris Cl, pH 4.5). Fractions are pooled, the pH is adjusted to 8.0 with 1 N NaOH, and the nickel column is regenerated by washing in 2 volumes of buffer A (6 M guanidine hydrochloride, 100 mM NaH$_2$PO$_4$, and 10 mM TrisCl, pH 8.0). The second purification simply utilizes the pooled fraction and the regenerated affinity column identical to that in the first purification.

Use of Rosetta Bacteria for the Production of Large Recombinant Proteins

The second improvement addresses the low yield of recombinant protein in *E. coli*, especially when the recombinant protein to be produced has a high molecular mass. Most recombinant autoantigens up to ~70 kDa have been successfully produced in standard *E. coli* strain BL21(DE3) or JM109(DE3). Examples include SS-B/La and SS-A/Ro proteins of 52 and 60 kDa. Problems are often encountered when proteins of ~100 kDa or higher are generated in these *E. coli* strains. Figure 1 illustrates the problem encountered when the Golgi autoantigen p115 (115 kDa) was expressed in JM109(DE3) and the major products were only about
FIGURE 1 Enhanced expression of recombinant proteins is illustrated by the effect on the bacterial host. A construct, pET-p115, was transformed into either bacterial strain JM109(DE3) or Rosetta(DE3), and recombinant proteins were produced with the transformed bacteria using the same culture medium (2YT) and conditions. To cultured bacteria was added 1 mM isopropyl-β-D-thiogalactopyranoside (IPTG) at time zero, and cells were harvested as pellets after 1 or 2 h, solubilized in gel sample buffer, and analyzed by sodium dodecyl sulfate-polyacrylamide gel electrophoresis using a 5% acrylamide gel. Proteins were detected by Coomassie brilliant blue G-250 stain. Note that the recombinant JM109(DE3) culture generated major products of ~60 kDa (arrowhead) plus other lower-molecular-mass products, whereas the Rosetta culture yielded major products (arrow) corresponding to the native protein.

60 kDa. Similarly low-molecular-mass products were obtained with the BL21(DE3) bacteria. However, the expression was improved significantly using a new strain known as Rosetta(DE3), and a protein band corresponding to 115 kDa was generated (Fig. 1). Rosetta host strains from Novagen/EMD Biosciences, Inc., are *E. coli* BL21 derivatives engineered to increase the expression of eukaryotic proteins that contain codons rarely used in *E. coli*. These strains contain tRNA genes for AGG, AGA, AUA, CUA, CCC, and GGA in a chloramphenicol-resistant plasmid and thus provide for "universal" translation which is otherwise limited by the codon usage of *E. coli*. Our experience is that the use of the Rosetta cells has made a significant positive impact on the production of recombinant human autoantigens in *E. coli*.

ADVANCES IN ASSAYS

Newer autoantibody assay systems include cells transfected with cDNAs of antigens of interest (16, 25, 26), "LINE" assays (34), solid-phase antigen arrays (46), and addressable laser bead arrays (ALBA) where relevant native or recombinant antigens are bound to a solid-phase matrix or to laser-reactive beads. These new advances are only the beginning of a rapid succession of newer technologies such as

microfluidics, lab-on-a-chip platforms, and nanotechnology (58). Comparison of performance and costs of some of these technologies to those of conventional assays suggest that they are reliable, highly sensitive, and cost-effective. Clinical analyses suggest that gains in accuracy and repeatability obtained in these new technologies may be clouded by a need to reevaluate current paradigms of the diagnostic and prognostic specificity of autoantibodies. One of the challenges of adapting new technologies will be to differentiate natural autoantibodies from those that are related to pathogenesis. Each assay has limitations in terms of determining the sensitivity, specificity, and positive predictive value for the detection of autoantibodies. The balance of this chapter focuses on addressable laser bead technology and recent experience with it in a clinical laboratory setting with addressable laser bead immunoassays (ALBIA).

ALBA and ALBIA

ALBA represent an application of array and flow technologies that has already entered the market and has demonstrated flexibility in a variety of genomic, proteomic, and immunoassay applications (8). Although there are several applications of this technology, much experience has been centered on the Luminex 100 platform (Luminex Corp., Austin, Tex.), which incorporates laser-based flow technology that can analyze reactants in a microtiter plate format. A key component of this technology is the ability to differentiate up to 100 classes of microspheres based on various amounts of laser-reactive dyes embedded in each class, called 100 different colors for simplicity. This platform has been developed to measure antibodies in biological fluids (18, 44), screen supernatants for monoclonal antibodies of interest (21, 47), quantitate cytokines in cell extracts and biological fluids (27), detect bacterial pathogens, perform HLA typing, detect single nucleotide polymorphisms, track cell signaling responses, and monitor gene expression. The robust application of numerous technologies in this platform suggests that a future use may be to profile patients in a variety of diagnostic and therapeutic settings (8).

ALBA and ALBIA that utilized the Luminex (Labmap) platform in research and clinical laboratory settings have been evaluated in a number of studies. In practice, an antigen of interest is chemically coupled to a specific colored microsphere. Other antigens are coupled to microspheres of different colors. After the coupling and stabilizing reactions, the antigen-coupled spheres are combined into a single microtiter well to provide a single assay that has the ability to detect multiple antibodies in a single specimen. The test samples (sera or other biological fluids) and a fluorochrome-coupled secondary antibody are added to the wells, and after an incubation time, they are analyzed. The principles of the assay are similar to those of flow cytometry with one laser identifying the specific antigen-coupled bead passing through the path and a second laser determining the presence and quantity of secondary antibody bound to the bead. The data are displayed in a number of formats but are expressed as a quantitative analysis of multiple analytes and the relative amount of antibody bound to the antigen. We have found the development of our in-house assays to be easier, more efficient, and more economical than earlier technologies such as Western blotting, IP, or ELISA. Research applications have included the development of assays to detect monoclonal antibodies and autoantibodies directed to a number of autoantigens, including early endosome antigen 1 (48, 49), GW182 (10, 11), translocated promoter region (39), and VCP (36).

TABLE 1 Reactivity of sera from 100 PBC patients in ALBIA

Antigen	% Reactivity		
	PBC (n = 100)	IBD[a] (n = 50)	Healthy (n = 100)
Chromatin	12	2	2
SLA	0	0	0
M2/PDC	72	0	0
LKM	0	0	0
p97/VCP	18	0	0

[a] IBD, inflammatory bowel disease.

In addition, a research kit used to detect antibodies to liver kidney microsomal antigen (LKM), M2 (PDC), soluble liver antigen (SLA), and chromatin (QUANTA Plex liver panel; INOVA Diagnostics Inc., San Diego, Calif.) was evaluated in the setting of autoimmune liver diseases. In a separate ALBIA, beads that were coupled to p97/VCP were also prepared (36). In a study of 25 sera from primary biliary cirrhosis (PBC) patients, 19 (76%) reacted with the M2 (PDC) antigen, 5 (20%) reacted with VCP, 2 (8%) reacted with chromatin, and none reacted with LKM or SLA (Table 1). Only one serum sample reacted with chromatin in the inflammatory bowel disease control group. In the same PBC cohort, 84% had a positive antimitochondrial antibody test as measured by IIF on rodent liver substrates. The apparent lack of sensitivity of the ALBIA is likely due to antimitochondrial antibody directed to other mitochondrial autoantigens that were not included in the ALBIA PDC antigen source (15, 28).

In a clinical service laboratory setting an autoantigen panel (QUANTA Plex; INOVA Diagnostics, Inc.) based on ALBIA was evaluated and compared to the routine diagnostic protocol, which analyzed 870 sequential unselected sera received over a 6-month period (13). In this study, the sera were submitted primarily by clinicians who were considering a diagnosis of systemic rheumatic disease. The conventional serological algorithm used IIF on HEp-2 cell substrates (HEp-2000; ImmunoConcepts, Inc.) to screen all sera. Antibodies to SS-A/Ro can be detected in this IIF assay because this substrate includes cells that are transfected with, and overexpress, the 60-kDa SS-A/Ro autoantigen (14, 25). Sera that were found to be positive in this IIF assay were then evaluated by ID for antibodies to Sm, U1-RNP, SS-A/Ro, SS-B/La, Scl-70 (topoisomerase I), and other saline-soluble autoantigens. Antibodies to double-stranded DNA (dsDNA) were detected by IIF on *Crithidia luciliae* substrate (ImmunoConcepts). This comparison showed that ALBIA agreed with the conventional test result 92% of the time. An exception was a lack of high correlation of anti-dsDNA measured by the *Crithidia* assay and the ALBIA. Because of this, anti-DNA is no longer included in this profile.

When the results of the ALBIA were compared to those of the conventional assay, it was noted that, on average, 25% of sera exhibited a positive result that was not detected by conventional autoantibody testing. The accuracy and validity of the ALBIA result could be confirmed by other techniques, such as IP and immunoblotting. This observed increased sensitivity of ALBIA was studied in various serological cohorts. The results of one such study are shown in Table 2; in that study were included 30 highly characterized sera that were previously shown to react with ribosomal P in at least one commercial ELISA (Euroimmun, Pharmacia,

MBL) (30, 31). Comparison of the data show excellent agreement of ALBIA with the ELISAs, including those that utilize the C22 terminal ribosomal P peptide (31).

Unselected sera from various disease cohorts were also studied to determine if the frequency of autoantibodies as detected by the ALBIA was consistent with the published frequency of autoantibodies (Table 3). This study showed that the frequency of various autoantibodies in SLE, systemic sclerosis (SSc), Sjögren's syndrome (SjS), and RA was in keeping with published reports. Interesting exceptions included antibodies to Scl-70 (topoisomerase I), which were found in 8% of sera from SLE patients, and antibodies to

TABLE 3 Frequency of autoantibodies detected by INOVA QUANTA Plex assay in cohorts of patients with systemic rheumatic diseases, those with multiple sclerosis, and controls[a]

Antigen	SLE (n = 200)	SSc (n = 100)	SjS (n = 100)	RA (n = 200)	IBD (n = 50)	MS (n = 100)	Healthy (n = 50)
Chromatin	60	20	20	8	2	4	0
dsDNA	48	0	0	2	0	0	0
U1 RNP	24	10	0	4	0	8	0
Sm	18	4[b]	0	0	0	1	0
Scl-70	6	24	0	0	0	4	0
SS-A/Ro	34	24	35	0	0	5	0
SS-B/La	8	5	20	2	0	10	0
Jo-1	0	3	15	0	0	4	0
Rib-P	16	2	0	0.5	0	5	0

[a] Abbreviations: IBD, inflammatory bowel disease; MS, multiple sclerosis.
[b] Low positive.

TABLE 4 Advantages, challenges, and opportunities relating to new array technologies

Advantages	Challenges and opportunities
Multiple autoantibodies detected in single assay	New clinical correlations and paradigms based on autoantibody and epitope profiling
Personnel costs	Costs of maintenance contracts and budgeting for laser replacement
Rapid test performance and automated test reporting	Medical centers not equipped or configured to accept digital reports can jeopardize rapid turnaround times.
Small sample volumes	Adoption of new technologies that do not require conventional venipuncture
High correlation with other immunoassays, particularly ELISA	Low correlation with ID
Ease of establishing new assays	Research and development required to provide broader spectrum of autoantigens (nucleolar, paraneoplastic, phospholipids)
Equipment and technology can be used for variety of relevant assays: cytokine, SNP, HLA, gene activation, cell activation, drug discovery	Emergence of other microarray and nanotechnology platforms will complicate standardization.

Jo-1 (histidyl-tRNA synthetase), which were found in 15% of sera from SjS patients and 4% of sera from SSc patients. It was noted that the reactivity of sera from SLE patients with Scl-70 was in the borderline region of positivity. Similar observations were made with anti-Sm, which was found in 5% of sera from SSc patients, but all of these demonstrated a measurement of mean fluorescence units that was just above the cutoff. Follow-up testing of these sera found that none bound the SmD3 peptide, which is highly specific for SLE (29, 32). The observation that some sera from SLE patients bind Scl-70 is interesting in light of other reports that anti-Scl-70 antibodies were found in sera from SLE patients (19). Likewise, the finding of anti-Jo-1 antibodies in sera from SjS and SSc patients was surprising but may be related to more recent observations that sera with anti-Jo-1 antibodies are occasionally found to contain antibodies to the 52-kDa SS-A/Ro autoantigen (59). Of note, none of the sera from healthy or inflammatory bowel disease controls were positive for any of the antigens used in the INOVA QUANTA Plex ALBIA.

Early studies of ALBIA kits are showing a high level (>90%) of agreement with antinuclear antibody and conventional ELISA techniques. For example, in a study of 37 sera from SjS patients that compared a conventional ELISA to an ALBIA kit (Athena Multi-Lyte ANA Test System), a 99% concordance between the two assays was found (18).

Taken together, there are advantages and challenges that come with the adoption of the ALBA platform to detect autoantibodies (Table 4). The capacity of one assay to analyze and detect a complex array of autoantibodies in a single small serum sample (>10 μl) with speed and precision is a significant advantage. There are now several ALBIA kits on the market that detect eight or more autoantibodies relevant to systemic rheumatic diseases. In some kits, the secondary antibody is added but no subsequent washing of beads is required. In addition, test reports can be automatically generated through standard database management software. These factors combine to generate test results very rapidly, since analysis of multiple antibodies in a single well typically takes less than 2 min. In our laboratory, the turnaround time from receipt of the serum sample to generation of the laboratory report using the conventional technologies was 4 to 5 days. By comparison, the turnaround time using ALBIA is 1 to 2 days. This marked improvement is predicated on a laboratory algorithm that tests samples daily, as opposed to batch runs of ~90 sera. Last, although we have not performed detailed cost analyses, there is little additional cost because the throughput has been effectively doubled and this throughput was managed with the same staff complement as with the conventional protocols. In fact, the staff now has more time for quality assurance and research projects that were formerly delegated to other staff. The tradeoff for these apparent cost savings is countered by more expensive maintenance contracts, upgrades to software, and a budget allocation for replacement of lasers.

A major challenge and opportunity in the adoption of multiplexed autoantibody analyses is the breadth of autoantibody profiles provided in the laboratory reports. This increased amount of information presents a significant challenge to clinicians who are accustomed to dealing with one or two autoantibody results for any given patient. It is likely that with autoantibody profiling, a new wave of clinical studies and clinical correlations based on more complete autoantibody profiles will emerge. The clinical picture may be enhanced by extending the breadth of this technology to epitope mapping and epitope spreading as an approach to monitoring disease progression or remission. Last, history has taught us that standardization of the new multiplexed platforms will be the most significant challenge. The utilization of international reference sera for standardization of secondary antibodies to establish controls and cutoff values will be very important. At present, because the ALBA equipment and hardware are based primarily on the Luminex platform and accompanying software, diversity of this hardware is not a significant issue.

Detection of Anti-DNA Antibodies

TRINH T. TRAN AND DAVID S. PISETSKY

115

Antibodies to DNA (anti-DNA) are prototypic autoantibodies found prominently in the sera of patients with systemic lupus erythematosus (SLE). This generalized autoimmune disease is characterized by multisystem involvement in association with abundant autoantibody production. Of these autoantibodies, those directed to components of the cell nucleus (antinuclear antibodies, or ANA) occur almost invariably in patients, with anti-DNA as a major ANA specificity, serving as a serological marker of diagnostic and prognostic significance. As established by the American College of Rheumatology, anti-DNA also represents a criterion in the classification of patients for SLE. The close association of anti-DNA with SLE has suggested that anti-DNA antibodies can signal critical events in SLE pathogenesis as well as guide patient evaluation in the clinical setting (10, 22).

As a macromolecule with a nonrepeating structure, DNA presents a potentially large array of antigenic determinants related to its sequence, conformation, and backbone structure. In its simplest form, however, DNA can be categorized antigenically as single-stranded DNA (ssDNA) or double-stranded DNA (dsDNA); dsDNA is also sometimes denoted native DNA. For this categorization, natural DNA of mammalian or bacterial origin serves as the antigen. While DNAs from various species likely differ in antigenic structure, anti-DNA antibodies in SLE sera appear to bind epitopes expressed widely on DNA, independent of its origin (15). Other antigenic forms of DNA can be prepared by using synthetic or cloned DNA, but these antigens have not produced assays that are either more sensitive or more specific than those using natural DNA.

In addition to reactivity to antigenic sites on DNA, anti-DNA antibodies can be differentiated in terms of their isotype, avidity, and pathogenicity. In general, anti-DNA immunoglobulin G (IgG) is linked more closely to disease than IgM antibodies. Indeed, IgM anti-DNA antibodies can appear in the sera of even healthy individuals, where they are designated natural autoantibodies (4, 9). Among IgG antibodies, anti-dsDNA antibodies are more specific to SLE than anti-ssDNA antibodies. Anti-ssDNA, which occurs more frequently in SLE patients than anti-dsDNA, nevertheless occurs in the sera of patients with other autoimmune and inflammatory diseases as well as in healthy subjects (6). Many antibodies cross-react with both dsDNA and ssDNA, however, making these distinctions operational. In patients

with SLE, anti-dsDNA is present in approximately 40% of patients, whereas anti-ssDNA is present in approximately 70% of patients at some point.

Although expressed pathologically, anti-DNA antibodies nevertheless differ in their ability to mediate inflammation and tissue damage, in particular glomerulonephritis. Antibodies promoting nephritis are denoted as pathogenic or nephritogenic. Since nephritis in SLE results at least in part from immune complex deposition, pathogenic antibodies likely display properties that allow the formation of complexes that deposit in the kidney. These properties include avidity, fine specificity, and the ability to fix complement (18, 21). Assays of anti-DNA based on these properties have not been developed, although ultimately, the assessment of pathogenicity involves the transfer of disease by antibodies in an animal model. Such an assessment is useful only in the research setting.

While the precise properties conferring pathogenicity are not well defined, for many patients the presence of high-avidity anti-dsDNA antibodies of the IgG isotype correlates well with the disease activity of lupus nephritis. Furthermore, the levels of these antibodies frequently vary significantly over time, with levels rising as nephritis intensifies and falling with effective therapy. These correlations are not invariable, however, and nephritis can occur in the absence of anti-DNA levels. This finding suggests that antibodies binding antigens other than DNA are pathogenic or that the assay used for anti-DNA determination misses the relevant antibody population (18). In this regard, anti-DNA levels may not correlate with other clinical manifestations of SLE or overall disease activity.

In the clinical setting, testing of anti-DNA antibodies has two distinct purposes. The first is diagnosis. For the evaluation of patients with complex, multisystem disease, anti-DNA assays are commonly performed in conjunction with testing for other ANA to assess the likelihood of SLE. Depending on the assay used, ANA positivity, while essentially ubiquitous in SLE and a criterion for classification, occurs in many other conditions, including rheumatoid arthritis and Sjögren's syndrome. Anti-DNA thus provides a more specific marker of diagnosis, and along with anti-Sm, another ANA linked to SLE, points to the diagnosis (7, 16). Since anti-DNA occurs in only some patients and since the levels vary strikingly, its use diagnostically has limitations. In this regard, anti-DNA expression can occur years prior to

clinical manifestations, suggesting that for some patients, this specificity may have predictive value as well (1, 2).

The second purpose of anti-DNA testing relates to disease activity. Since anti-DNA antibodies appear to be a major cause of SLE renal disease, the correlations between levels of these antibodies and nephritis are the clearest and most demonstrable by the use of various assay approaches (25). For some patients, anti-DNA testing has less value as an activity marker, in which case testing of complement levels (a measure of complement consumption during immune complex deposition) can provide adjunctive information. Clinically, for each patient, it is useful to establish the best serological or laboratory correlate of disease activity and not to rely exclusively on any one test. Since the "gold standard" for active lupus remains elusive, there is inherent uncertainty in this assessment (23).

While the role of anti-DNA in immune complex renal disease may underlie the correlation with disease activity, anti-DNA antibodies may have other functions that contribute to this association. As shown in studies of the human and murine systems, DNA–anti-DNA immune complexes have immunomodulatory effects and can promote B-cell activation and the production of cytokines such as interferon (19, 27). This action may be related to the ability of immune complexes to deliver DNA to internal sites in cells, where it can stimulate Toll-like receptor 9 (5, 17). Since the DNA in the complexes is needed for immune activity, an assay of antibodies alone may not reveal the potential for immune stimulation. In this regard, antibodies to DNA are a subset of antibodies to nucleosomes, the form of DNA in the nucleus, with many of these antibodies potentially able to stimulate the immune system as long as the nucleic acid component is present in the complex. This feature of anti-DNA function could suggest the basis of a more general correlation of anti-DNA with SLE in terms of both diagnosis and activity.

Despite their lower frequency in patient sera, anti-dsDNA antibodies are more specific for SLE than anti-ssDNA antibodies. Most clinical laboratories now perform tests that specifically detect anti-dsDNA antibodies, although anti-ssDNA can provide useful information for assessing disease activity; anti-ssDNA assays are also easier to perform. Currently, the methods available for anti-DNA include the radioimmunoassay (RIA), the *Crithidia luciliae* immunofluorescence (CLIF) assay, and the enzyme-linked immunosorbent assay (ELISA). Their advantages and disadvantages are discussed below (14, 16).

TECHNOLOGY

Farr Assay

The most commonly used RIA for anti-DNA measurement is the Farr assay. In this assay, a radiolabeled source of dsDNA is incubated with serum to form immune complexes, which are precipitated from solution with ammonium sulfate at 50% saturation. The quantity of anti-dsDNA antibodies is represented as the amount of radioactivity in the precipitate. A circular bacteriophage DNA or a circular plasmid DNA is used to ensure double strandedness.

The Farr assay measures high-affinity anti-DNA antibodies which do not dissociate under the high salt conditions of ammonium sulfate saturation. Given the properties of the antibodies detected, the Farr assay is specific for SLE. The results are reproducible, with high titer values in combination with other features of SLE signifying diagnosis;

moreover; the titers measured in the Farr assay can correlate with disease activity. The Farr assay, however, does not discriminate between IgM and IgG anti-dsDNA antibodies and may also detect immune complexes with proteins other than antibodies. The assay is currently used infrequently because of the cumbersome nature and risks associated with radioactivity.

Other RIA approaches are available. Thus, the precipitation of bound radioactive DNA can be accomplished by using polyethylene glycol rather than ammonium sulfate to bring down immune complexes. Alternatively, the complexes can be separated from free radioactive DNA by filtration on nitrocellulose. In this variation of the assay, the immune complexes are soluble, with binding of antibody to the filter as the basis for the physical separation of the complexes.

CLIF Assay

The *Crithidia luciliae* immunofluorescence (CLIF) assay measures the binding of antibodies to the kinetoplast of the hemoflagellate *C. luciliae*. This kinetoplast contains a piece of circular dsDNA that is not associated with histone proteins. For assay purposes, the parasite is fixed to a microscope slide and incubated with serum, and a fluorescently labeled secondary anti-Ig reagent is added. There is no contamination by ssDNA in this assay, leading to its high specificity. Different anti-dsDNA antibody isotypes can be detected by using separate anti-Ig reagents. Although this assay has a sensitivity similar to that of the Farr assay, quantitation is more difficult and the titers correlate less closely with disease activity for lupus nephritis.

ELISA

An ELISA measures the binding of antibodies to an antigen adhered to a surface, with bound antibodies measured colorimetrically from the product of the enzyme of the anti-Ig conjugate. For this assay, a plastic microtiter plate is coated with purified dsDNA, often from calf thymus, and serum dilutions are then added to the wells. Anti-dsDNA antibodies in the serum are detected by the use of an enzyme-labeled anti-Ig reagent followed by the addition of a substrate for color development. This technique is easy to perform and allows testing of many samples at one time.

In general, an ELISA is more sensitive than the Farr or CLIF assay since it detects both high- and low-avidity antibodies. Since the specificity of the anti-Ig conjugate can be varied, different isotypes can also be readily measured. In contrast to the case of the Farr or CLIF assay, the DNA source for an ELISA is more likely to be contaminated by ssDNA. This assay can also be limited by nonspecific binding of immune complexes or other immunoglobulins to the plates. In addition, the interaction of dsDNA with the plastic surface may not be reproducibly uniform, leading to the use of binding agents such as positively charged proteins to increase DNA adherence. A modification of this assay can also involve the use of biotinylated DNA to bind streptavidin-coated plates to provide more sensitive and reproducible measurements and reduce nonspecific binding (13).

Other Assays

Some other, older techniques that have been used by clinical laboratories in the past for the detection of anti-DNA antibodies include immunodiffusion, hemagglutination, and complement fixation. These are now surpassed by the assays described above.

Newer tests have been developed and described in the literature. These include the fluorometric PicoGreen assay and microarrays (3, 12). These tests have been used for research purposes only and have not been characterized sufficiently to allow their general use in clinical laboratories. The following are brief descriptions of these techniques.

Fluorometric PicoGreen Assay

The flurometric PicoGreen assay is similar to the Farr assay in principle but has the advantage of not using radiolabeled DNA. For this assay, a source of dsDNA is added to serum. After ammonium sulfate precipitation, the DNA bound in the immune complexes is detected by means of a fluorescent dye, PicoGreen, which binds specifically to dsDNA and allows the detection of DNA in the nanogram-to-picogram range. Nonspecific binding of other DNA binding proteins may lead to false-positive results for anti-DNA antibodies. The sensitivity and specificity of this assay for SLE have not been defined (3).

Microarrays

The new technology of microarrays allows the detection of several antibodies in a single experiment. In the array format, nucleic acids or protein antigens are immobilized as microspots in rows or columns on a solid chip, which is then exposed to serum. Antibodies binding to their immobilized counterparts are detected by fluorescence, radioactive labeling, chemiluminescence, mass spectrometry, or electrochemical methods.

Placing autoantigens in different concentrations on a single array allows the measurement of multiple autoantibodies from a minimal amount of serum in a single test. The titer can be defined as the lowest antigen concentration at which a product can be detected. Alternatively, titer determination can be achieved by incubation of a fixed antigen concentration with a series of serum dilutions. While both approaches should yield similar results, the determination of the titer will depend on the array format, the spot size, the amount of the antigen immobilized within the spots, and the detection system.

Parallel detection and quantification of several autoimmune diseases can be performed with the microarray assay. In addition, microarrays enable the identification of the specificity as well as the isotype and require only small amounts of samples. Microarrays will likely be a valuable technique in the future, given their flexibility and adaptability to a wide range of autoimmune diseases (12).

Measurement of Avidity and Isotype

Although high-avidity anti-dsDNA antibodies of certain IgG isotypes are both pathologic and pathogenic, clinical assessments of anti-DNA avidities and isotypes have not been done routinely. For research purposes, usual measurements of avidity have been performed by competitive inhibition in binding assays (28). More recently, surface plasmon resonance (or the BIAcore assay) has enabled a more precise detection and calculation of the antibody-antigen affinity and kinetics. In this assay, the purified dsDNA is immobilized on a streptavidin-coated sensor chip. Samples containing different concentrations of purified IgG are then flowed over the chip at a defined flow rate. The interaction between the antibody and the DNA is measured in real time and is shown by a sensorgram, from which the affinity can be derived as the ratio between the association and the dissociation rate constants (20, 24).

Assay Selection

The ELISA is now the most widely used technique for detecting anti-dsDNA antibodies. Very few clinical laboratories are still performing the Farr assay or the CLIF assay. As the number of commercially available ELISA kits for measuring anti-dsDNA has increased, most clinical laboratories would consider cost and efficiency in selection. It is important to choose an assay that has the highest sensitivity and specificity. Often, the benefit of having a sensitive assay is offset by a low specificity, and some laboratories may use a combination of two or three techniques to increase the diagnostic value of the test result. For example, a positive result by an ELISA can be confirmed by a more specific test for SLE such as the Farr RIA or CLIF assay. The application of other tests should be done in consultation with a clinician and should reflect the needs for patient evaluation (11).

The Medical Devices Agency performs critical evaluations of in vitro diagnostic kits on behalf of the UK Department of Health. The reports provided by the Medical Devices Agency can assist with decisions regarding the choice of commercially available kits to meet laboratory requirements. These reports are accessible at www.medical-devices.gov.uk. For use in clinical laboratories in the United States, these kits must be FDA approved, and the list of approved kits can be found at the research section of www.FDA.gov.

METHODOLOGY

Anti-DNA assays are currently available as kits from several manufacturers. Some details of these assays, however, are proprietary. Detailed descriptions of the procedures can be obtained from the manufacturer. Presented here are short outlines for the Farr, CLIF, and ELISA assays as adapted from kits. While information from kits from Inova Diagnostics, Inc. (www.inovadx.com) has been used in this discussion, the principles are general. Reference to these kits does not imply any preference or superiority.

Farr Assay

An anti-DNA kit is available from Inova Diagnostics, Inc.

Materials

Radioactive iodinated DNA (^{125}I-dsDNA) (recombinant dsDNA is preferable to avoid contamination with ssDNA)

Anti-DNA calibrators prepared from a World Health Organization standard anti-dsDNA pool

Ammonium sulfate precipitating solution

Anti-DNA controls

Patient serum

Plain 12- by 75-mm polypropylene tubes

All materials are stored at 2 to 8°C.

Procedure

1. Pipette 25 μl of each calibrator, control, and patient serum sample into duplicate tubes.
2. Add 200 μl of ^{125}I-DNA and mix.
3. Incubate samples at 37°C for 2 h.
4. Add 1.0 ml of cold ammonium sulfate precipitating solution.
5. Centrifuge at $2,000 \times g$ for 15 min in the cold.
6. Decant the supernatant.

7. Count in a gamma counter.

8. Determine anti-DNA concentrations from the calibration curve.

CLIF Assay

The Nova Lite dsDNA kit available from Inova Diagnostics, Inc., is an indirect immunofluorescent antibody test employing the hemoflagellate *C. luciliae* as a substrate.

Materials

The following reagents are included in the kit.

C. luciliae slides (dsDNA)

Goat anti-human IgG conjugated with fluorescein isothiocyanate

dsDNA-positive serum

Immunofluorescence assay system negative control

Procedure

1. Prepare 1× phosphate-buffered saline (PBS).

2. Dilute serum samples in PBS, with 1:10 as the initial dilution.

3. For titration, prepare serial dilutions of all positive samples with PBS (1:20, 1:40, 1:80, ...).

4. Place substrate slides in a moist chamber, and add 1 drop (30 to 50 μl) of positive and negative controls and diluted patient sample to wells.

5. Incubate slides for 30 min.

6. Wash with PBS.

7. Add fluorescent conjugate and incubate the slide for an additional 30 min.

8. Examine under a fluorescence microscope.

Quality Control

dsDNA-positive and immunofluorescence assay system–negative controls should be run on every slide to ensure proper assay performance.

Results

The specific staining of the kinetoplast can be visualized using a fluorescence microscope with a 495-nm exciter and 515-nm barrier filter. A sample is considered positive if specific kinetoplast staining or kinetoplast-plus-nuclear staining is more intense than that of the negative control. Staining of other structures such as the flagellum, body, or nucleus without kinetoplast staining is considered negative. All positive samples should be titrated to the endpoint. Since the results are obtained from titrations, there are potential errors that propagate from inaccurate dilutions. In addition, the range of the assay is more limited since the smallest difference in values is twofold.

ELISA

Materials

The following materials are included in the kit.

Polystyrene microtiter plates coated with a purified calf thymus dsDNA antigen (pretreated with S1 nuclease enzyme to remove single-stranded regions)

Positive and negative controls

Anti-dsDNA calibrator containing antibodies to dsDNA

Horseradish peroxidase (HRP)–goat anti-human IgG conjugate

Tetramethyl benzidine dihydrochloride chromogen

HRP stop solution

Procedure

1. Prepare a 1:100 dilution of each patient sample.

2. Add 100 μl of the prediluted anti-dsDNA calibrator, anti-dsDNA positive and negative controls, and diluted patient samples to the wells.

3. Incubate for 30 min at room temperature.

4. Wash three times.

5. Add HRP-IgG conjugate to each well; incubate wells at room temperature for 30 min.

6. Wash.

7. Add tetramethyl benzidine dihydrochloride chromogen and incubate in the dark.

8. Add HRP stop solution.

9. Read the absorbance (optical density [OD]) of each well on a plate reader at 450 nm within 1 h of stopping the reaction.

Quality Control

The anti-dsDNA ELISA calibrator and anti-dsDNA positive and negative controls should be run with every batch of samples, with calculated positive control and negative control values (international units per milliliter or WHO units per milliliter) falling within the range specified for the lot number. In addition, the absorbance of the dsDNA positive control must be greater than the absorbance of the calibrator, which must be greater than the absorbance of the dsDNA negative control. The positive control must have an absorbance of >1.0, and the negative control's absorbance should not be over 0.2. The dsDNA ELISA calibrator absorbance must be more than twice that of the negative control or over 0.25. The assay must be repeated if the quality control criteria are not met.

Calculation of Results

Sample value (units)

$$= \frac{\text{sample OD} \times \text{dsDNA calibrator (units)}}{\text{dsDNA ELISA calibrator OD}}$$

Results

As a solid-phase assay, the ELISA likely detects a broader array of anti-DNA specificities, including lower-avidity species, than a fluid-phase assay, especially the Farr assay. Furthermore, depending on the antigen preparation and the type of microtiter plate used, reproducibility can be variable. As a result, some ELISAs involve the use of a positively charged protein such as protamine sulfate or methylated bovine serum albumin to promote more consistent binding of the DNA. The impact of such an agent on the array of anti-DNA specificities detected is not known.

Fluorometric Anti-DNA Assay

Materials

The following reagents are needed for this assay.

Patient serum

Positive and negative anti-DNA controls

Purified calf thymus dsDNA

PicoGreen (purchased from Molecular Probes, Inc., Eugene, Oreg.) diluted 1:200 in TEN buffer (10 mM Tris, 1 mM EDTA, 100 mM NaCl [pH 8.8])

100% saturated ammonium sulfate solution

Black 96-well microtiter plates (Costar, Corning, N.Y.)

Procedure

1. Mix serum diluted 1:20 with a solution of dsDNA (1:1) in 100 μl in a microtiter plate.

2. Incubate for 1 h.

3. Add 100 μl of 100% ammonium sulfate solution and incubate for 1 h at 4°C.

4. Centrifuge for 10 min at $3,000 \times g$ and wash four times with 50% ammonium sulfate.

5. Dissolve precipitate in 100 μl of TEN buffer.

6. Add 100 μl of PicoGreen.

7. Measure fluorescence by using a microplate fluorescence reader (excitation wavelength of 485 nm and emission wavelength of 535 nm).

8. Calculate the DNA concentration by using a standard curve of dsDNA.

Quality Control

This assay has been successfully performed with sera from murine models of SLE. There is less experience with human samples. Since PicoGreen binds only dsDNA, it is important that the DNA used as the antigen as well as the standard DNA used for calibration is highly purified and lacks significant contamination with ssDNA. Digestion with S1 nuclease can be used to ensure the purity of the dsDNA used. Standard positive and negative sera can be used to assess the assay performance and to ensure appropriate quantitative assessments.

QUALITY CONTROL AND TEST VALIDATION

Currently, assays for anti-DNA involve kits that have been extensively tested by their respective manufacturers and approved for diagnostic use. Many clinical laboratories routinely verify their tests by using a panel of well-defined sera for which patient diagnoses are well verified and previous test results are known. As new tests are introduced or laboratories implement new technology, validation is important. Given the range of anti-DNA antibody specificities and avidities, differences in test performance will often occur. Thus, a patient whose serum showed anti-DNA positivity with one assay may be negative in another, and vice versa. Clinicians must therefore be informed of any changes in the testing and back-up assays provided, especially for patients for whom anti-DNA testing is important for management.

COST ASSESSMENT

Measurements of anti-DNA levels are indicated for the evaluation of patients for whom the diagnosis of SLE is considered. Depending on considerations of cost and patient convenience, this test can be performed concurrently with an ANA test or after a positive ANA test is obtained. In this regard, some patients will have a positive anti-DNA test in the absence of a positive ANA test, but the significance of this result is unclear.

Anti-DNA tests can also be performed as a part of routine patient management to assess disease activity, especially nephritis. For those patients whose anti-DNA levels have been correlated with disease activity, more frequent testing may be indicated to predict flare-ups. For those patients with manifestations of SLE other than nephritis or for whom correlations with anti-DNA have not been observed, repeat testing has less value. The predictive value of anti-DNA testing has been a source of investigation and controversy, with some studies even showing that a fall, rather than a rise, in the anti-DNA level predates renal disease activity (8). Pending studies to more fully validate the marker function of anti-DNA for selective use in patients are indicated to avoid confusion and to promote more cost-effective utilization.

INTERPRETATION

Each laboratory should develop its own normal range based on its techniques, controls, equipment, and patient population. Depending on the technique used, the result of anti-dsDNA measurements can be reported as being negative, equivocal, or positive, with results of quantitative assays provided as titers or numerical values. A positive result usually indicates the presence of anti-dsDNA antibodies and supports the diagnosis of SLE. In contrast, a negative anti-dsDNA result does not exclude the diagnosis of SLE since only some patients with SLE express this specificity and since levels vary with disease activity. Samples with equivocal results should be retested with the same technique at another time or with another technique to define the antibody status.

For diagnostic purposes, a positive test result for the CLIF assay or Farr assay may be more useful than that obtained by ELISA. Studies have suggested that the relative specificities of these tests for SLE differ, although interpretation of these data is dependent on the patient and control populations selected for analysis. In general, the CLIF assay appears to be more specific for SLE (7, 16, 26). Data on newer assays such as microarrays are not yet available.

For patients with SLE and glomerulonephritis, the changes in anti-dsDNA levels over time can provide valuable information on both disease activity and the response to treatment. Since anti-dsDNA antibodies are associated with renal disease in many patients, a rise in anti-dsDNA antibody levels may predict an exacerbation or relapse (25). This pattern may not always occur in SLE patients, with the frequency of testing also affecting the apparent fluctuation of the response and the relationship to disease activity.

In the clinical setting, the interpretation of the results needs to be individualized based on the history of the patient and preceding serological events. In this regard, some SLE patients may show persistent elevations of anti-dsDNA levels but nevertheless lack evidence of active renal disease. These patients may produce nonpathogenic antibodies or lack antigens to form immune complexes (18). The predictive value of anti-dsDNA antibodies is increased when used in combination with supportive evidence of a high likelihood of SLE based on patient history, physical examination, and other laboratory tests such as complement levels.

Since the sensitivity and specificity for diagnosing SLE increase with the detection of more than one specific autoantibody, microarrays and other multiplex assays will likely play an increasing role in patient evaluation. Pending the refinement of such approaches, the ELISA will likely remain the preferable assay used for the purpose of disease activity monitoring.

Autoantibody Testing in Rheumatoid Arthritis

SONALI NARAIN, MEGHAVI KOSBOTH, AND PAULETTE HAHN

116

Rheumatoid arthritis (RA) is a chronic, systemic, inflammatory disorder thought to affect 0.5 to 1% of the global population, predominantly women, although most studies have been carried out in North America and northern Europe. Clinical and pathogenic effects characterized by chronic inflammation and synovial proliferation result in destruction of joints, with subsequent disability and increased morbidity. Extra-articular manifestations of RA may involve most organ systems. Pulmonary, ocular, and cardiovascular involvement is common. Thus, the complications of RA are not limited to the joints and "classic" extra-articular sites. Early diagnosis of RA may help avoid these complications, resulting in decreased disability, morbidity, and mortality.

RA is thought to result from multiple poorly defined factors, including both genetic and environmental risk factors as well as age, gender, and ethnicity. Environmental associations may include hormonal effects, smoking, infections, diet, and socioeconomic factors (4). There tends to be a bimodal age distribution in the development of RA. The peak of disease onset is in the fifth decade of life.

Twin and family studies suggest an association of RA with both HLA and non-HLA genetic factors. An association with HLA-DR4 has been recognized for more than 20 years, and more recent data suggest a stronger association with particular DR4 alleles, such as DRB1*0401, DRB1*0404, DRB1*0405, and DRB1*0408. The presence of the "shared epitope" confers an even higher relative risk of the disease and is associated with a higher likelihood of developing erosive disease requiring more aggressive therapy (139).

Infectious factors in the development of RA have been proposed. It may be that infection serves as an environmental trigger in a genetically susceptible individual. Viral infections and increased titers of antibody against Epstein-Barr virus and other viruses have been found in patients with RA, yet a causal relationship remains to be established (79). Recently there has been a proposed association of elevated immunoglobulin M (IgM) and IgA antibodies to *Proteus mirabilis* and IgM to *Escherichia coli* with rheumatoid factor (RF) positivity. It may be that genetically susceptible patients with chronic clinical or subclinical infections may have onset of synovitis. The mechanism is not known.

In 1987 the American College of Rheumatology established criteria for the diagnosis of RA (8, 69). Although the criteria are useful to diagnose established RA, they are of limited utility for recognizing early disease. With new developments in the therapy of RA and evidence that therapy is most effective when started early in the disease process, it becomes increasingly important to develop criteria that will permit the accurate diagnosis of disease prior to the onset of radiographic changes. The challenge will be to distinguish early RA from other inflammatory arthritides, such as spondyloarthropathies or infectious arthritis.

RF

RF is an antibody directed against the Fc portion of human IgG. RF-IgG immune complexes can deposit in tissues, activate the classical complement pathway, and lead to tissue damage (78, 110, 145). Although RF may be IgG, IgM, IgA, or IgE, IgM RF is the species most commonly measured in clinical assays. It was initially described by Waaler (138) in 1940, when he noted that sera from some RA patients caused agglutination of sheep erythrocytes coated with rabbit antibodies. Subsequently, IgM RF was used as a diagnostic test for RA (30). The sensitivity of RF in the diagnosis of RA is 75%. However, chronic infections, such as bacterial endocarditis, may cause the production of RF (74, 142). Recently, Newkirk et al. suggested an association between RF-positive RA and anti-*P. mirabilis* IgM and IgA antibodies and anti-*E. coli* IgM antibodies in patients with recent onset of synovitis (80). However, although an attractive hypothesis, it remains unclear that infections are involved in the pathogenesis of RA.

RF-positive patients tend to have more severe disease, with extra-articular involvement (nodulosis, ulcers, vasculitis, and neuropathy) and increased mortality (37, 50, 119, 126). In addition, there is some evidence to suggest that when RA is successfully treated, the RF titer tends to fall and that loss of RF positivity confers improved prognosis (86, 92). The presence of RF in the blood is one of the diagnostic criteria used for RA. However, it is important to keep in mind that its specificity for the disease is low. RF can be seen in infections such as tuberculosis, leprosy, osteomyelitis, syphilis, bacterial endocarditis, infectious mononucleosis, and hepatitis C (66). In addition, RF is found in many patients with other systemic autoimmune diseases, such as primary Sjögren's syndrome, systemic lupus erythematosus, vasculitis, and idiopathic pulmonary fibrosis. Some patients with B-cell malignancies, such as Waldenström's macroglobulinemia, non-Hodgkin's

TABLE 1 Comparison of features of RF assays

Assay	Antigen	Equipment expense	Automation	Reagent expense	Interlaboratory precision	Result	Interferences	Class detected	Sensitivity
Sheep cell agglutination	Rabbit IgG	Low	No	Low	Low	Titer or IU[a]	C1q, anti-rabbit IgG, anti-sheep erythrocytes	IgM	Low

Nephelometry	Human or other IgG	High	Yes	Moderate	High	IU	Fibrin? Cryoglobulins? Other immune complexes if assay is polymer enhanced	IgM	High
ELISA	Variable	Moderate to high	Variable	Moderate	Moderate	IU	Nonspecific plastic binders, heterophilic anti-immunoglobulins	IgM, IgA, IgG (with modification)	High

[a]U, International Units.

lymphoma, or chronic lymphocytic leukemia, have monoclonal gammopathies with RF activity. However, RF can be present in the absence of disease states. It has been suggested that smoking is associated with chronically elevated RF in the absence of rheumatic disease, and the presence of RF and antibodies to nuclear antigens is associated with cardiovascular disease even in patients without RA (3, 49, 114).

Antigenic Specificity of RF

The antigen detected by RF is the Fc portion of the IgG molecule. There is some evidence that the recognition of human isotype IgG3 by RF is different from recognition of other IgG subclasses (92). Many RFs bind in domain C_v2 or C_v3 of IgG and often require both for binding, suggesting the presence of a conformational epitope requiring both domains for successful binding (15, 98). X-ray crystallography of the C_v2-C_v3 binding site indicates that up to half of the RFs bind conformational determinants on the Fc surface, while some IgM RF Fab fragments bind antigen unusually at the edge of the usual antigen binding via linear polypeptide determinants scattered in the C_v2 and C_v3 regions (22, 105, 107, 143).

Genetic studies of RF revealed that many monoclonal RFs are encoded by a limited number of germ line genes that are preferentially expressed in early development (101). However, RF produced in the synovial tissue of patients with RA is different. Synovial tissue RF is produced by genes encoding immunoglobulin V region that have undergone genetic mutation, while monoclonal RFs from patients with B-cell malignancies are derived from V-region genes similar to unmutated germ line genes (87, 88). This somatic mutation and evidence of class switch from IgM to IgG and other Ig subfamilies suggest that RF production in RA patients is a T-cell-driven process (60).

Assays for RF

The presence of RF can be detected by a variety of techniques (Table 1), such as agglutination of IgG-sensitized sheep erythrocytes, bentonite or latex particles coated with human IgG, radioimmunoassay, indirect immunofluoresence, enzyme-linked immunoadsorbent assay (ELISA), and laser nephelometry (54, 61, 63, 85, 93, 138). The antigen source for most RF assays is usually gamma globulin pools from humans, rabbits, or cattle (18). IgG fractions from various species differ in their abilities to be bound by RF, resulting in variability of reported results. Rabbit IgG is most commonly used as the antigen source due to its lower sensitivity but higher specificity compared to those of human IgG.

Agglutination Assays

Agglutination methods have been used for many years to detect RF. The classical Waaler-Rose test uses sheep erythrocytes coated with rabbit IgG. If RF is present, the erythrocytes agglutinate (96, 138). This technique is most sensitive for IgM RF since IgM antibodies are more efficient in agglutination reactions. Commercial reagents use stabilized preparations of sensitized sheep cells to allow adequate shelf life. The latex agglutination and bentonite flocculation methods employ particles coated nonspecifically with human or rabbit gamma globulin. When mixed with serum samples containing RF, they agglutinate or flocculate. The agglutination assays described originally were performed in test tubes with agglutination prompted by temperature-controlled incubation and centrifugation of cells or particles. Semiquantitative analysis to determine the antibody content

of a serum involves doubling dilutions of the serum and determination of an endpoint (the last doubling dilution at which agglutination can be visualized). The reciprocal of this dilution is known as the antibody titer. Results are typically expressed as titers or international units. Interlaboratory coefficient of variation has been reported as 30 to 50% based on a U.S. College of Pathologists voluntary survey. The latex agglutination test is sensitive, but it can result in a fairly high number of false positives (77). Nonspecific agglutination of latex particles by sera from healthy individuals is not uncommon (9). A potential drawback to the manual and visual agglutination techniques is that they are dependent on the skill and consistency of the technologist performing the assay and require a subjective determination of final titer.

ELISA

ELISA is used to determine RF by measuring the amount of immunoglobulin that binds to target antigen (IgG or its fragments) adsorbed to a solid phase, usually a polystyrene microtiter plate (1, 48, 82). This method can determine the immunoglobulin class of the antibody by using class-specific antibodies as reagents for human immunoglobulin binding. Microwells are coated with purified antigen (human IgG) followed by blocking of the unreacted sites to reduce nonspecific binding. Controls, calibrators, and patient serum samples are incubated in the antigen-coated wells, allowing RF present in the patient's serum to bind, forming antigen-antibody complexes. Unbound serum proteins are removed by washing the microwells. Enzyme-conjugated anti-human IgM (or IgG for IgG RF) is added to the wells. The enzyme conjugate binds to the antigen-antibody complex, and excess conjugate is washed away. Addition of specific substrate begins a hydrolytic reaction with the bound enzyme conjugate, causing color development. The intensity of the color change is proportional to the amount of IgM (or IgG) RF antibody bound to the wells, which is read using a spectrophotometer. The net absorbance is calculated by subtracting the absorbance value of the specimen blank from the value for the coated microwell. A calibration standard assayed with each plate is used to calculate IgM (or IgG) RF activity. The results are expressed in international units per milliliter. The use of IgG from different species would yield different results (35). Another pitfall may be nonspecific binding of patient sera to the plastic wells. This is overcome by subtracting the optical density from wells that are blocked but not coated with antigen.

Radioimmunoassay

Radioimmunoassays for RF were used in the past but are no longer in widespread use due to the problems of dealing with radioactivity.

Nephelometry

Laser and rate nephelometry have recently been adapted for the determination of RF activity in serum. In this method, mixing antigen and antibody under antibody excess conditions results in the formation of antigen-antibody complexes whose concentration is determined by light dispersion. When a beam of light is passed through tubes containing a fixed amount of antibody and variable concentrations of antigen, the concentration of immune complexes formed in the tube determines the extent of light scatter. The amount of light scattered is measured at angles varying from 0 to 90°. Since the antibody concentration remains constant, the light scattered is proportional to the concentration of antigen

in the mixture. Target antigen is heat-aggregated or chemically cross-linked human IgG. In latex-enhanced models, human or rabbit IgG is used to coat latex particles as in agglutination assays, with the nephelometer providing more automated and objective quantification of agglutination. Individual nephelometric assay kits come with complete instructions, which are dependent on instrumentation and software particular to the nephelometer and should be followed accordingly. Intralaboratory coefficient of variation of nephelometric methods has been reported to be fairly low, at 2% (84, 94). The nephelometric technique is considered superior because of its ability to detect changes in absolute levels at earlier stages and its low interassay coefficient of variation, 11% (93). In general, there is greater precision with ELISA and nephelometric assays, allowing greater confidence in interpreting a low-positive result.

Quality Assurance/Quality Control Implementation

Nephelometric assays and ELISAs use calibrators measured against standard sera established by the World Health Organization (6) or the Centers for Disease Control and Prevention (112) to promote uniformity in IgM RF quantification (55, 111). However, the World Health Organization standard does not contain IgG or IgA standard and therefore cannot be used for IgG or IgA RF (122). Quality control for nephelometric and ELISA values should include the multirule Shewart chart/Westgard rules for accepting or rejecting an assay (141). Control sera should be run with each assay and ideally should detect one negative serum and at least two positive sera: one at a low positive cutoff and the other at a high positive cutoff. Agglutination assays dependent on dilution titers should calculate the between-run geometric mean and standard deviation of quality control specimens (111) and use the Westgard rules to accept or reject a given run. Alternatively, the given value plus or minus one tube dilution may be an acceptable quality control. RF assays that report quantitative results such as titers or units need quantitative quality control measures for controls as well. Each lot of reagents should be evaluated to ensure equivalent results with previous reagents. It is advisable to evaluate plasma or serum without RF activity, since different reagent lots vary in their likelihood of having false-positive results in the presence of fibrin or fibrinogen (FBG).

The percentage of positive results found in normal sera within a given laboratory should be monitored and compared to a normal reference population periodically. Standardization between methods is often suboptimal; therefore, results in a given laboratory should be verified with a reference method and/or proficiency surveys to ensure reliable results.

Factors That Interfere with RF Measurements

Several factors can interfere with the measurement of RF. Agglutination and nephelometric assays can give false-positive results if a patient's serum has highly elevated levels of C1q, which binds and cross-links IgG (15, 16). This becomes important in inflammatory disorders since C1q is an acute-phase reactant. This can be avoided by heating the serum to 56°C for 15 to 30 min, since C1q is heat labile. Other approaches to complement inhibition can be employed, such as adding polyvinyl sulfonate to the reaction mixture (16, 22). The presence of fibrin or FBG in plasma or incompletely clotted serum can interfere with or induce agglutination or aggregation in nephelometric and agglutination assays, leading to false-positive or false-negative results. Nephelometric techniques that use polyethylene glycol or

similar polymers to accelerate immune complex formation may give false-positive results from polymer-enhanced delayed aggregation of fibrin, lipoproteins, cryoglobulins, or other immune complexes (128, 140). This can be avoided by subtracting background light scatter with specimens that are allowed to react for an equivalent amount of time as the nephelometric measurement but in the absence of aggregated IgG target antigen or by eliminating the use of polymer. Since RFs are frequently enriched in cryoprecipitates, they may be lost if the cryoprecipitate separates from the remainder of the serum or if the cryoprecipitate in cooled serum is not dissolved prior to assay, rendering a false-negative or diminished level of RF (98). Histidine-rich glycoprotein, a plasma protein, inhibits formation and enhances solubilization of insoluble immune complexes formed by RF, presumably due to competitive binding to the IgG (33). Some small molecules, such as aspartame, have been described as inhibitors of RF activity (87); due to its rapid metabolism, however, aspartame concentrations in serum are not likely to be high enough to influence RF detection in humans.

ELISA and sandwich immunoassays for measurement of RF may yield false results due to the presence of heterophilic anti-immunoglobulin antibodies. These are naturally occurring antibodies reacting with immunoglobulins from other species. They can react with intact IgG or F(ab) or F(ab')$_2$ fragments of IgG from one or more species. About 15% of the heterophile antibodies recognize the Fc portion of IgG and can be considered analytically true-positive versus the other 85%, which recognize the F(ab')$_2$ fragments and are not RF. Their detection would be considered a false-positive result. These antibodies were present at low titers in up to 40% of sera from a healthy population when using sandwich assays based on monoclonal murine antibodies (17). Interference by heterophile antibodies may be eliminated by using rabbit F(ab) or F(ab')$_2$ fragments (38).

RF can interfere with other immunoassays (62), especially those depending on the binding of two antibodies for detecting an antigen. Recent studies have reported a false-positive elevation of serum troponin in patients with seropositive RA (23, 52, 53) and sera from patients with systemic lupus erythematosus can give false-positive reactions in cytokine assays due to the presence of RF (148). In general, RFs are more likely to bind rabbit IgG than goat or mouse IgG, so this interference may be less frequent in assays employing murine monoclonal antibodies.

Measurement of RF Isotypes

The measurement of RF isotypes is challenging due to various confounders. RF activity within immunoglobulin subtypes is typically quantified by sandwich radioimmunoassays or enzyme immunoassays. The solid-phase antigen is usually IgG or purified Fc (component a) and the source of RF antibody is diluted serum (component b), detected by labeled or unlabeled appropriate subclass-specific detection antibodies (component c). If molecule c is unlabeled, an additional labeled antibody (component d) that reacts with antibodies of the detection antibody species is used. Since components a to d are all IgG molecules or immunoglobulin fragments, they can potentially be bound by RF. For this reason, measurement of RF may require modifications. Designers of an assay must verify that the detecting antibody components (components c and d) do not react directly with the target antigen (component a). They must also ensure that the RF being measured (component b) does not lead to false results because of RF recognition of antigenic determinants on the detecting antibody components (components

c and d). Various pairs of antigen and detecting antibodies or their fragments may be employed to ensure specificity of assay results. For example, intact rabbit IgG or the Fc fragment can be used as the target antigen (a), with F(ab')$_2$ fragments of anti-human IgG as the detection antibody (c). If RFs reacting specifically with human IgG are to be measured, then the detecting antibody (c) can be F(ab')$_2$ fragments of antibodies to the Fd region [heavy-chain region of the F(ab) fragment] of the IgG, so that the IgG in the RF (b) can be measured without cross-reactions of c with anti-a or b with anti-c. Papain digestion of serum has been advocated to allow accurate quantification of IgG RF (56). Another potential problem with measuring IgG RF is that it can self-associate (70), since both antigen and antibody are IgG. In addition, non-RF serum IgG may bind IgM or IgA RF and give falsely elevated titers of IgG RF.

In general, all RF isotypes occur together in the same patient and the titers of the different isotypes correlate with each other. Some studies suggest that agglutination assays may detect IgA RF in addition to IgM RF (28, 123). Recent studies suggest that IgA may have a role in predicting disease outcome, especially in combination with anti-cyclin citrullinated peptide (anti-CCP) antibodies (11, 65). When agglutination assays are compared with isotype-specific RF assays, they are found to perform similarly in predicting the long-term course of RA (113). However, all RF isotypes have been reported for subjects who do not develop RA, and smoking is associated with a higher positivity rate for IgG RF and IgA RF in patients without evidence of arthritis (49).

Clinical Interpretation

RFs are marker antibodies for RA, and among the seven American College of Rheumatology criteria, RF is the only serologic test (8). It does not establish the diagnosis of RA but serves a factor contributing to the diagnosis. Elderly individuals, especially females, may have low titers of RF in the absence of RA (19, 67); thus, clinical interpretation should consider the patient's age and gender. A positive RF test has a sensitivity of 60 to 80% in RA and a specificity of 75 to 93% in a clinical rheumatic disease population (Table 2) (144). The concentration of serum RF may change over time, and in patients with RA, RF levels may correlate with the degree of inflammation and disease activity. Fluctuations in RF activity can be measured sufficiently precisely only by using nephelometry or ELISA rather than agglutination titers (40, 84, 93). Measurements of disease activity such as erythrocyte sedimentation rate (ESR) and C-reactive protein (CRP) are also very useful when used together with RF in the evaluation of patients with inflammatory arthritis (63). Subjects without RA are more likely than RA patients to have transient serum RFs that do not persist on long-term follow-up (36). Substantial variations in RF titer with reversal of seropositivity and seronegativity have been observed. Most patients are RF positive within 6 months of onset of symptoms, but the RF test may turn positive a year or more before the onset of disease (44). The functional avidity of RF changes over time (97). Persistently high levels of RF have been shown to be associated with more severe radiographic joint destruction over a 3-year follow-up period (83). Patients with monoclonal gammopathies due to B-cell malignancies may have serum RF activity. Those with mixed cryoglobulinemia have serum RF that precipitates in the cryoglobulin. Conversely, in patients with Sjögren's syndrome, loss of RF activity has been a marker suggestive of the development of lymphoma. According to Bayes' theorem, the clinical utility of

TABLE 2 Comparison of the sensitivities and specificities of RF isotypes and anti-CCP combinations

Reference	Anti-CCP + IgM RF		Anti-CCP + IgA RF	
	Sensitivity (%)	Specificity (%)	Sensitivity (%)	Specificity (%)

34	90	81		

a diagnostic test depends substantially on the pretest probability of having the disease, and this is true for RF detection (102, 103).

ANTIBODIES TO CCPs

The relatively low specificity of RF and the fact that high concentrations of IgM RF are detected not only in RA but also in other conditions with polyclonal stimuli to B cells (39) create a need for improved laboratory markers with a higher disease-related specificity and sensitivity. A variety of antibodies, not very specific to RA, are seen in the sera of patients with RA, such as anti-RA-33, anticalpastatin, anti-collagen type II, anti-glucose-6-phosphate isomerase, antifibronectin, anti-neutrophil cytoplasmic antibodies, and antinuclear antibody, while other antibodies demonstrate a high specificity, such as anti-BiP, anti-Sa, and anti-citrullinated protein antibodies (APF, AKA, antifilaggrin, and anti-CCP) (135).

Anti-perinuclear factor (APF) antibodies, first described in 1964, showed an acceptable sensitivity and a much higher specificity than RF (42). In 1979, another group of RA-specific antibodies, antikeratin antibodies (AKA), was shown to have a specificity comparable to that of APF (43), and could be demonstrated to precede the onset of RA (59). These tests, however, were never implemented in routine practice, as they were inconvenient, laborious, and difficult to standardize. It was later discovered that APF and AKA target the antigen identified as the epithelial protein filaggrin (filament-aggregating protein), yielding a high specificity (99%) in patients with RA, with the sensitivity and specificity depending on the method of filaggrin purification

and the difficulty in obtaining antigen preparations with reproducible citrulline content (39).

Importance of Protein Citrullination

In 1998, Schellekens et al. (99) showed that citrulline is a major constituent of the antigenic determinants recognized by antibodies frequently found in sera from patients with RA. This family of autoantibodies includes the APF, AKA, antifilaggrin antibodies, anti-CCP antibodies, and anti-Sa antibodies. All recognize epitopes containing citrulline. Citrulline is a nonstandard amino acid that is not incorporated into proteins during translation (131). However, it is generated by posttranslational modification (deimination, citrullination) of protein-bound arginine by peptidylarginine deiminase (PAD) enzymes (Fig. 1), first described in 1977 (95).

Four related isoforms of PAD exist in mammals and other vertebrates (137). All isoforms can citrullinate most proteins with accessible arginine residues in vitro, although certain proteins are citrullinated more rapidly than others by individual PADs (137). Amino acids flanking the arginine residue influence its susceptibility to citrullination. PAD2 is the most widely expressed type of PAD, with its expression regulated at the transcriptional and the translational level. Two natural substrates for PAD2 are known: myelin basic protein in the central nervous system and vimentin in skeletal muscle and macrophages. Macrophages express PAD2, but the cytosolic Ca^{2+} concentration is too low for enzyme activity (132). Human PAD5 is a homolog of mouse and rat PAD4 and is mainly expressed in granulocytes and monocytes, detectable in a variety of tissues. It is the only isoform residing in the cell nucleus.
FIGURE 1 Citrullination (deimination) of peptidylarginine to peptidylcitrulline by PAD.

FBG, one of the targets of citrullination, is a glycoprotein found in blood plasma at concentrations of ~3 mg/ml, increasing to >7 mg/ml during inflammation. FBG or fibrin deposits in the inflamed joints may play an important role in RA (106). Deimination of FBG is mediated by PAD (108). The production of antibodies to deiminated FBG in humans may be a specific marker for RA, as antibodies to deiminated human FBG appear before the onset of joint symptoms, indicating that these antibodies may be of predictive value (108, 131).

Vimentin is citrullinated in dying human macrophages (132), which are abundant in the rheumatoid synovium. The Sa antigen, recently identified as citrullinated vimentin (130), has also been detected in rheumatoid pannus (26). Granulocytes, present in the inflamed synovium (especially the synovial fluid), have a life span of only about 3 days. They die in large numbers at inflammatory sites, triggering histone citrullination. The three proteins considered to be candidate autoantigens in RA are citrullinated fibrin, citrullinated histone, and citrullinated vimentin (134).

Oxygen metabolism is in disequilibrium in inflamed rheumatoid synovium, leading to hypoxia and synovial microinfarctions. Plaques of extravascular fibrin can be found at these sites. The inflamed synovium also contains many PAD2-expressing macrophages and sometimes PAD4-containing granulocytes. During cell death, the loss of the integrity of the plasma membrane causes an influx of calcium from the extracellular space and subsequent activation of intracellular PAD (134). Alternately, when cells are dying, as in RA synovium, due to oxidative stress, intracellular PAD enzymes might leak out and become activated in the presence of extracellular Ca^{2+}, inducing the citrullination of extracellular proteins such as fibrin (131). The calcium influx in the dying macrophages has also been hypothesized to lead to the production of citrullinated vimentin in the inflamed synovium (132).

The subclass distribution of anti-CCP antibodies (predominantly IgG1) (21, 136) is consistent with a T-cell-dependent antibody response and HLA involvement, and the antibodies are thought to be produced by local plasma cells (71). Anti-CCP-producing B cells have also been detected in the synovial fluid of RA patients (133). The initial events leading to their production are unknown, though it is believed that in principle any stress leading to death of PAD-expressing cells may suffice to initiate abnormal protein citrullination. In a susceptible individual (125) and in the appropriate environment (73) the citrullinated proteins may stimulate an immune response.

Two explanations have been offered for the high specificity of autoantibodies against citrullinated antigens for RA. First, there may be an RA-specific overexpression of citrullinated antigens in the synovium, leading to an immune response. This is supported by studies showing genetic polymorphisms of the PAD4 gene (108) and the association of a PAD4 haplotype with susceptibility to RA. This could lead to increased PAD4 enzyme expression, increased protein citrullination, and a higher chance of developing anti-CCP antibodies (108, 125). Second, the presence of citrullinated proteins is perhaps a common phenomenon in any inflamed (synovial) tissue but RA patients show an abnormal humoral response to them. This possibility is supported by studies that show the presence of citrullinated proteins in the synovium in RA patients and in deposits of extravascular fibrin (21, 72). Furthermore, citrullinated proteins have also been detected not only in RA patients but also in individuals with osteoarthritis or reactive arthritis (104, 134).

Assays for Antibodies to Citrullinated Proteins

The citrulline moiety is so important for antigenicity that essentially every citrullinated peptide or protein is recognized by autoantibodies in sera from RA patients, albeit with different sensitivities and specificities (124). The oxygen group of peptidylcitrulline is specifically recognized by autoantibodies in RA (99). The CCPs have a three-dimensional design optimally structured for recognition of the antigenic group by the heterogeneous population of RA autoantibodies. Using a single CCP as antigen in an ELISA, the sensitivity was ~68%, with a specificity of more than ~97% (118, 124). To improve the anti-CCP test, peptides from libraries of citrullinated peptides were tested with RA sera to select the most reactive species (24, 41, 117). Selected cyclic peptides have been synthesized and utilized for a second-generation anti-CCP assay, distributed worldwide as the CCP2 test (136).

Studies have compared the sensitivities and specificities of the commercially available second-generation anti-CCP antibody tests. The CCP2 ELISA provides the best combination of sensitivity and specificity for detecting RA, with little difference among various assays (27, 31, 34). The anti-CCP test has a sensitivity comparable to that of the IgM RF test but a much higher specificity (Table 3).

At present, there are five distributors of CCP2 ELISA kits: Euro-Diagnostica, Arnhem, The Netherlands (Immunoscan RA); Axis-Shield Diagnostics Ltd., Dundee, United Kingdom (Diastat Anti-CCP); Inova Diagnostics Inc., San Diego, Calif. (QUANTA Lite CCP IgG ELISA); EUROIMMUN Medizinische Labordiagnostika AG, Lübeck, Germany; and Pharmacia Diagnostics AB, Uppsala, Sweden (ELIA CCP). The ELIA CCP is a fully automated testing system for CCP antibodies that is somewhat easier to use and gives reliable results: a sensitivity of 80% and a specificity of 97% (39). At this time, only ELIA anti-CCP and QUANTA Lite CCP IgG ELISA are approved by the Food and Drug Administration.

Further research has led to the development of the third-generation anti-CCP antibody test (CCP3) that has shown comparable specificity to but increased sensitivity over previous anti-CCP assays. Two linear peptides, CCP3A (67% sensitivity) and CCP3B (55% sensitivity), are used (G.J. Pruijn et al., unpublished data). Though the CCP3B peptide has lower sensitivity, it reacts with sera from RA patients nonreactive in the CCP2 assay, leading to the conclusion that a combination of peptides (CCP2-CCP3) is required for optimal sensitivity.

Additionally, a new semiquantitative ELISA kit (INOVA Diagnostics) more sensitive than the CCP2 ELISA (QUANTA Lite CCP IgG ELISA; INOVA) has been developed, with a sensitivity of 74%, versus 69% for the old kit, and a specificity of 96%, versus 98% for the old kit, with agreement between the two assays of 96%. The new assay has an interassay variability of 2.9% and an intra-assay coefficient of variation ranging between 3.4 and 5.5% (R.W. Burlingame et al., unpublished data). However, this kit is not yet available commercially.

Quality Assurance/Quality Control Implementation

The test is performed on serum or citrated plasma specimens. Samples must be stored for a maximum of 48 h at 4 to 8°C but can be frozen at −20°C for prolonged storage. Repeat freeze-thaw cycles should be avoided. Frozen specimens must be thawed and mixed well prior to testing. Preservatives such as sodium azide at 0.1% will not affect sample results. Adequate maintenance and calibration of the plate reader should be performed according to the manufacturer's

[a]Although there is consensus among different studies about the specificity of anti-CCP, there is considerable variation in the diagnostic sensitivity. This variation can be attributed to the different serum dilutions tested or, more probably, to the different cutoff values (12). Furthermore, the observed differences in the sensitivity and specificity most likely are the consequence of the patient selection for the different cohorts used.

instructions. The ELISA kits are accompanied by detailed instructions and include calibrators and negative and positive control samples. Positive and negative controls should be run in all assays. Additional quality controls for ELISA values should include reference to National Committee for Clinical Laboratory Standards (NCCLS) document C24-A or the usual multirule Shewart chart/Westgard rules for accepting or rejecting an assay. The commercially available anti-CCP ELISAs have low analytical error. The dilution test, if performed in accordance with the NCCLS, shows a high grade of analytical reliability (109). Interassay and intra-assay coefficients of variation for different manufacturers' anti-CCP tests are comparable, ranging between 2.6 and 13.6% (interassay) and 3 and 17% (intra-assay).

Calculations and interpretation of test results are described by each manufacturer, and hence the cutoff values vary depending upon the kit used for the assay. The cutoff values established by the manufacturer are based on specific populations and may not necessarily reflect the literature. Reference ranges and appropriate cutoff points should all be evaluated for the specific populations serviced by the user. Overall, the anti-CCP has good discriminative ability. If a patient with RA and a control were to be selected at random, the RA patient would be 10 times more likely to have a higher anti-CCP antibody concentration (12).

Anti-CCP Test in Early RA

About 35 to 40% of RF-negative RA patients are positive for anti-CCP (116, 124). The diagnostic advantage of anti-CCP for RF-negative patients is even more convincing in early disease; RA patients with disease duration of less than 1 year who were CCP positive tested negative for IgG RF, IgM RF, and IgA RF (116).

The anti-CCP test predicts which patients with early arthritis would receive a clinical diagnosis of RA with a sensitivity of 55.4% and specificity of 96.7% (45). An evaluation of anti-CCP and RF behavior in RA patients in relation to the duration of the disease showed that in patients with early arthritis (diagnosis <1 year before the study), the correlation with anti-CCP was highly significant (14). A number of studies suggest that anti-CCP and IgA RF are the best predictors of future development of RA, especially in ambiguous cases or RF-negative RA (2, 81, 89, 90, 115). Additionally, anti-CCP antibodies are useful in predicting the development of RA in patients with undifferentiated arthritis (120).

Progression of RA

Preliminary studies have demonstrated that anti-CCP antibodies also have prognostic significance, as patients with antibodies develop significantly more severe radiographic damage (58, 75, 121). Anti-CCP is associated with a higher probability of radiographic signs of joint damage, while RF is associated with higher functional disability (11). Anti-CCP also is a good predictor of disease activity (116) and is better than RF in predicting disease activity over 3 years after the onset of RA (51). ESR, CRP, DAS28, and physician's global assessment were consistently higher in the anti-CCP-positive group than in the anti-CCP-negative group.

Visser et al. (129) assessed a clinical prediction model in early RA patients for three arthritis outcomes: self-limiting, persistent nonerosive, and persistent erosive arthritis. Anti-CCP was more strongly associated with erosive arthritis and severe joint destruction than RF. Anti-CCP antibodies predicted progression of the Larsen score over 2 years better than RF, and the presence of both antibodies (anti-CCP and RF) did not increase the predictive ability

(29, 127). Longitudinal studies to assess the utility of anti-CCP antibody in predicting the outcome of very early synovitis (≤3 months' duration) also show that anti-CCP antibodies are one of the significant independent predictors of persistence (91).

Fluctuation of Anti-CCP Levels

Anti-CCP antibody levels can change substantially in RA patients (7); most show elevated levels at the first visit, followed by a decrease in the majority of cases and fluctuation over time. Moreover, the change in anti-CCP levels parallels disease activity (severity of arthritis and deterioration of laboratory parameters such as ESR and CRP) (11, 46, 58, 124). A decline in anti-CCP levels in RA patients receiving therapy with other disease-modifying antirheumatic drugs has been reported (76). Though an earlier study reported that anti-CCP antibody levels decrease following infliximab (tumor necrosis factor alpha) therapy in RA patients, recent studies have indicated that its levels are relatively stable and not modulated by therapeutic interventions (5, 20, 25). It also has been hypothesized that the fluctuation in the anti-CCP levels may simply reflect the natural history of the autoantibody production over a course of time and that the level may peak early in the disease process, irrespective of therapeutic interventions, before declining and reaching baseline (76).

Combined Use of Anti-CCP and RF

Earlier studies have reported that if both RF and anti-CCP antibodies are required to be present, sensitivity decreases without a substantial increase in specificity relative to that of anti-CCP alone. However, more recent studies suggest that by evaluating the presence of either autoantibody (RF or anti-CCP), sensitivity for RA is increased without substantially altering the specificity (34, 64). These data are summarized in Table 2.

Genetic Associations of Anti-CCP Antibody

The HLA-DRB1 locus is associated with RA, especially in individuals with compound heterozygosity for shared-epitope genes (47). In addition, HLA-DRB1*0401, DRB1*1001, DQB1*0302, and DQB1*0501 are associated with the presence of anti-CCP antibodies and with more severe disease and a higher rate of joint damage (120). Studies combining the serologic (RF, anti-CCP antibodies) and genetic (SE, defined as DRB1*0404 and DRB1*0401) factors suggest that the presence of both SE and anti-CCP antibodies is strongly predictive of risk for future development of RA (11, 13). The results do not support the notion that the SE is a direct risk factor for the production of anti-CCP antibodies, but rather suggest synergy between the SE and the presence of anti-CCP (or RF).

In a study of early RA, a significant association between anti-CCP antibodies and expression of DRB1*0404 or DRB1*0101 was reported (32), suggesting that SE-positive individuals may have more sustained T- and B-cell responses to citrullinated antigens than noncarriers. These data support the hypothesis that in individuals carrying one or two SE genes, a T-cell-dependent immune response to citrullinated peptides may contribute to the pathogenesis of RA. An alternative explanation is that HLA antigens do not predispose to the autoimmune disease per se but rather fail to provide protection (13). A recent report presented numerous single nucleotide polymorphisms in PAD4, several of which are strongly associated with RA (108). Carriers of the susceptible haplotype had antibodies against citrullinated proteins significantly more often than noncarriers (108).

Association of Anti-CCP Antibodies with Other Conditions

Anti-CCP antibodies can be detected in patients with juvenile idiopathic arthritis, but generally at low levels and less commonly than in adults with RA (10). In patients with juvenile idiopathic arthritis, the presence of anti-CCP antibodies does not correlate statistically with the presence of RF, except in patients with RF-positive polyarthritis (68). Anti-CCP antibodies also help to differentiate hepatitis C virus-related arthropathy from RA (5). Anti-CCP antibody levels are not elevated in nonarthritic patients with chronic hepatitis C virus. Anti-CCP may be positive in patients with psoriatic arthritis (PsA), and its presence in PsA patients is associated with more severe disease. The association of the prevalence of anti-CCP with radiographic erosions in PsA suggests some phenotypic overlap of PsA with RA (57). The mechanism is unclear, although it is possible that the antibodies, by sustaining the inflammatory response, are directly involved in joint damage.

Laboratory Testing for Antibodies Associated with Antiphospholipid Antibody Syndrome

JOHN L. SCHMITZ

117

Testing for the presence of antiphospholipid antibodies (aPL) is typically performed for patients with vascular thrombosis and/or recurrent fetal morbidity—clinical features of aPL syndrome (APS), a disease of autoimmune nature. aPL are a heterogeneous group of antibodies that are present not only in patients with APS but also in patients in other disease states, recipients of certain drugs, and some healthy individuals. Various characteristics such as target antigen, isotype, and titer distinguish presumed pathogenic from nonpathogenic aPL. Adding to the complexity of this antibody system is the fact that several distinct types of assays are used to detect their presence and a variety of both home brew and kit-based enzyme-linked immunosorbent assay (ELISA) systems are in use, which have contributed significant variability in test performance, results, and interpretation. Nonetheless, detection of aPL is considered clinically useful. Of the several types of aPL described, lupus anticoagulant (LA) antibodies and anticardiolipin antibodies (aCL) are the types most clearly associated with APS, the latter being the focus of this chapter.

BACKGROUND ON aPL

The earliest described aPL were attributed not to an autoimmune disease but rather to an infectious disease, syphilis. The Wasserman test, a complement fixation assay that detected nontreponemal antibody, employed extracts from the livers of syphilitic newborns (73) that provided the phospholipid cardiolipin as the antigen. Subsequently cardiolipin was identified as the antigenic component of the serologic tests for syphilis (54). The Venereal Disease Research Laboratory (VDRL) and rapid plasma reagin tests were then developed, both employing purified cardiolipin combined with cholesterol and lecithin as the antigen. In the early 1980s investigators recognized an association between systemic lupus erythematosus (SLE) patients and LA-mediated thrombosis which was mediated by antibodies to phospholipids (55). A number of SLE patients also had a biological false-positive serologic test for syphilis, thus indicating a possible similarity between these two phenomena. Limitations of the LA and VDRL tests led to the development of the more sensitive radioimmunoassay (RIA) (35) for detection of aPL using cardiolipin as the test antigen. The RIA was subsequently modified to an ELISA format (28), the most common technique employed for the direct detection of aPL. The recognition of APS and the association with aPL

has led to diagnostic application of this test, a disease classification system dependent upon detection of these antibodies, and international efforts at assay standardization.

APS

Classification of patients with APS considers both clinical and laboratory criteria (Table 1). Vascular thrombosis and/or pregnancy complications in conjunction with a persistent presence of moderate to high levels of anticardiolipin immunoglobulin M (IgM) or IgG antibodies or LA antibodies establishes a definite diagnosis (74). The syndrome is classified as primary APS when not associated with another disease and accounts for over 50% of cases (12). Secondary APS is most frequently diagnosed in patients with SLE, lupus-like syndromes, Sjögren's syndrome, rheumatoid arthritis, systemic sclerosis, systemic vasculitis, and dermatomyositis (12).

Virtually any organ system can be affected in APS; however, the frequency of specific manifestations may vary with gender, age, type of associated aPL, and the presence of SLE. Recurrence is common in APS. The most frequent features associated with APS are venous thrombosis, thrombocytopenia, livedo reticularis, stroke, superficial thrombophlebitis, pulmonary embolism, fetal loss, transient ischemic attack, and hemolytic anemia (12, 40). In addition to the cerebrovascular system, manifestations are described to occur in the pulmonary, cardiovascular, renal, ocular, cutaneous, endocrine, gastrointestinal, and hematologic systems. APS in the background of SLE does not have a distinctly different array of clinical or laboratory manifestations. A small fraction of cases (<1%) may exhibit catastrophic APS resulting from widespread thrombosis in multiple organ systems leading to organ failure and a mortality rate of near 50% (4).

Fetal morbidity associated with APS typically occurs after 10 weeks of gestation (20, 40). Criteria for APS-associated fetal morbidity include three or more losses prior to the 10th week of gestation, one or more losses after the 10th week, or one or more premature deliveries at or before the 34th week because of preeclampsia, eclampsia, or placental insufficiency with the exclusion of other causes.

ANTIBODIES ASSOCIATED WITH APS

aPL are a heterogeneous group of antibodies in terms of target antigen and isotype (61). The first category of aPL,

TABLE 1 Summary of the criteria for classification of APS[a]

Clinical criteria

1. Vascular thrombosis, including one or more episodes of arterial, venous, or small-vessel thrombosis in any tissue or organ
2. Pregnancy morbidity, including one or more fetal deaths beyond the 10th week of gestation; one or more premature births of a morphologically normal neonate at or before the 34th week of gestation because of severe preeclampsia, eclampsia, or placental insufficiency; three or more consecutive spontaneous abortions before the 10th week of gestation with the exclusion of parental anatomic, hormonal, and chromosomal causes

Laboratory criteria

1. Detection of aCL of IgG and/or IgM isotype at medium or high titer on two or more occasions at least 6 weeks apart as measured by a β2GPI-dependent assay
2. Detection of LA or two or more occasions at least 6 weeks apart following established guidelines[b]

[a]This table is adapted from reference 74. Definite APS is present when at least one clinical criterion and one laboratory criterion are present.
[b]These guidelines can be found in reference 9.

LA antibodies, are detected with certain phospholipid-dependent coagulation assays. These may be the sole aPL found in APS patients or may be found in association with a second category of aPL that are detected with ELISAs. Included in this second group of aPL are those that bind directly to the phospholipid molecule (infection associated but not APS associated), those that bind to phospholipid-serum protein complexes, and those that bind directly to serum protein cofactors in the absence of phospholipid. The last two types of ELISA-detected aPL can both be found in patients with APS with or without LA. The aCL assay is the most common ELISA-based aPL assay in use to date, although other assays employing different antigens are being evaluated and in some cases used clinically (see below).

LAs

LAs are antibodies that are prothrombotic in vivo but display anticoagulant properties in vitro (i.e., they prolong certain coagulation tests). The antibodies detected in these LA assays are directed to serum proteins, including beta 2-glycoprotein I (β2GPI) and prothrombin (2, 65). Compared to other aPL tests, the LA test is considered less sensitive but more specific for APS (21, 50). However, there are patients with APS who exhibit only LA (55). The advantages of LA assays relative to aCL assays include increased specificity and a resulting higher predictive value (21, 27). A consensus approach has been developed for detection of LA (8) that defines the characteristics of APS-associated LA as (i) prolonging phospholipid-dependent clotting time assays (including activated partial thromboplastin time, dilute prothrombin time, dilute Russell's viper venom time, and Kaolin clotting time); (ii) not correctable by addition of normal plasma at a 1:1 ratio; (iii) phospholipid dependence confirmed by correction upon addition of phospholipids; and (iv) not due to inhibitors. Testing for LA is not addressed further in this chapter.

PHOSPHOLIPID-BINDING ANTIBODIES DETECTED WITH THE aCL ELISA

Antibodies associated with APS that are detected in aCL ELISAs were originally thought to bind to the phospholipid molecule. However, it was determined that binding was dependent upon the serum proteins. The protein identified

as mediating this effect was β2GPI (26, 46). Not all aCL-reactive sera require β2GPI for binding. In particular, patients with certain infections were shown to have cofactor-independent aCL. aCL have been found in patients with a variety of infectious diseases, including human immunodeficiency virus (1, 14, 17, 43), malaria (22, 66), leprosy (18, 32), hepatitis C virus (39), and human T-cell lymphotropic virus type 1 (23, 75), although their reported prevalences vary (41). These infection-associated aPL do not require serum cofactors to enhance binding and are not usually associated with thrombotic events (61). Infection-associated aPL are more commonly of the IgM isotype, have less avid binding, and are generally transient, declining with resolution of infection. Although not typical, some patients with infections do have detectable cofactor-specific antibodies. Both prothrombin and β2GPI antibodies have been detected in patients with several infectious diseases (41).

AUTOIMMUNE aPL

An appreciation of the presence of aPL in SLE patients, and their association with thrombosis, led to the development of an RIA for detection of aCL antibodies (35) and subsequently an ELISA-based format (28). aCL associated with APS are most frequently IgG antibodies and of moderate to high levels in the blood (28, 34, 51). In contrast to aCL detected in patients with infections, the autoimmune aCL are typically cofactor (β2GPI) dependent. β2GPI enhancement of aCL binding is the result of the negatively charged phospholipids promoting higher density coating of the ELISA plate by β2GPI. The higher density of β2GPI enhances detection of these typically low-avidity antibodies. The use of "high binding" ELISA plates can replace the need for phospholipid in promoting high-density coating of plates (62).

aCL may consist of one or more isotypes of antibody. Various combinations of IgG, IgM, and IgA aPL may be present in an individual with APS. IgG antibodies are the most prevalent and clinically relevant isotype (12, 28, 40, 48), although IgM and IgA isotypes have been associated with APS. The prevalence of aCL-specific isotypes may vary by ethnicity (15, 48). A small fraction of patients have solely IgM aCL (12). While these have been shown to be associated with APS in some cases, as discussed above, IgM isotype aCL are often associated with infection. IgA aCL have

a variable prevalence in various patient groups (63); however, studies indicate that IgA aCL are the predominant isotype in African-American APS patients (15). Like other aCL isotypes, IgA aCL appear to be cofactor dependent in their binding to phospholipids, but further studies are needed to establish a clear clinical association, as studies are conflicting (63).

COFACTOR-SPECIFIC AND OTHER TESTS FOR aPL

Alternative tests have been developed to enhance the specificity of aPL testing due to concerns with the specificity of the aCL test and the recognition that aCL binding is actually cofactor targeted. Some of these alternate tests are in use, while for others further study is necessary to determine their utility. The best known and most used of these is the test for β2GPI-specific antibodies (70). This test utilizes purified β2GPI and is performed as a standard ELISA with high-binding ELISA plates to facilitate greater binding of antigen to the plate, which is a requirement for detection of characteristically low-affinity aPL antibodies (62). β2GPI-binding antibodies may consist of IgG, IgM, or IgA isotypes. Positive results in this test are associated with several manifestations of APS (13, 38, 44, 52). In addition, this may be the only positive test for certain APS patients (50).

Another ELISA-based alternative to aCL testing is the APhL test (APL Diagnostics, Louisville, Ky.), which employs a mixture of negatively charged phospholipids designed to enhance specificity for APS. Published studies indicate that this test is as sensitive for APS as the aCL assays but with improved specificity (16, 47). The improved specificity of this test was demonstrated by comparison with several aCL tests, a β2GPI test, and a flow cytometry-based test (57). The sensitivities of all tests were 90% or greater. The specificities, however, varied extensively, from 37 to 100%, with the APhL test giving the best specificity.

Several other test systems for aPL have been reported in the literature. Other anionic phospholipid antibody specificities may be found in patients, including antibodies to phosphatidylserine, phosphatidylethanolamine, and phosphatidylinositol (10). In addition, other cofactor-specific assays have been developed, including prothrombin (3, 7) and protein-C and protein-S (53) tests. None of these tests are considered first-line assays for APS at this time, however.

ASSAYS FOR DETECTION OF aPL

Home brew as well as a variety of commercially available ELISA-based aCL assays are in use (29). Commercially available kits include tests for IgG, IgM, and IgA aCL that can be reported qualitatively or quantitatively. A significant effort has been put into the characterization of these tests due to the recognition of significant variability between commercial and home brew tests as well as between laboratories. International consensus conferences have focused on optimizing performance of these tests. Proficiency testing surveys are available from such organizations as the College of American Pathologists.

Quantitative aCL assays typically report results in IgG aPL (GPL) and IgM aPL (MPL) units, which are equivalent to the activity of 1 μg of standard antibody preparation. Negative and low, moderate, and high positive ranges have been defined for these units (36). However, the cutoffs for a positive result vary by manufacturer. As discussed below, cutoff levels should be validated in each laboratory performing aPL testing.

STANDARDIZATION OF aPL TESTING

Appreciation of the utility of aCL and the resultant availability of a variety of commercially available ELISA kits as well as home brew tests has proven problematic as evidenced by publications that have documented significant variability between different commercially available kits and home brew tests (5, 19, 24, 25, 58, 76). Wong et al. (76) reported an assessment of intra- and interassay variability in nine laboratories employing one home brew and eight commercial and IgG aCL assays. The mean intra-assay variability (coefficient of variation [CV]) on three samples ranged from 3.6 to 32.4%, and the mean interassay variability ranged from 8.8 to 18.6%. Six of nine labs had an interassay CV of <20%. Qualitative agreement (positive versus negative) was suboptimal. Summary data from a proficiency testing program (24) demonstrated that 90% or greater consensus was achieved in only 42% of cases during a 1-year period. In an evaluation of 10 commercial tests and one home brew test using 62 sera, the rate of positive results varied by kit from 18 to 64% (5). Based on clinical criteria, the sensitivities of the kits ranged from 65 to 90% and specificities ranged from 33 to 77%.

Because of the importance of these tests and the significant variation in performance, international workshops have been held to evaluate aCL testing parameters (33, 36, 37, 57). The first of these workshops established methods and units of measure and identified standards for aCL testing (36). GPL and MPL units were established that were equivalent to 1 μg of affinity-purified antibody per ml. In the second workshop, improvements in between-laboratory agreement were determined to be better if a semiquantitative aCL measure (reported as negative, low positive, moderate, and high positive) was used (33).

Several groups have identified and published what are felt to be important aspects of aPL testing and have recommended specific consensus guidelines for the use and performance of aPL tests (31, 67, 77). The guidelines that provide the most extensive recommendations suggest the following minimally acceptable practices for aPL testing (77): test for IgG with or without IgM; serum is the preferred sample; and controls and calibrators should be run with the goal of achieving an interassay CV of <20%. Other guidelines (67) urge running samples in duplicate, in-house cutoff determination based on 50 to 100 healthy age- and sex-matched controls, percentile-based cutoffs, and the use of external controls.

As with aCL tests, β2GPI testing appears to be susceptible to significant variability (60). Several factors may affect the performance of β2GPI tests, including the source of β2GPI, the type of ELISA tray, blocking buffer, sample integrity, secondary-antibody used, and lack of standards, as well as variability in cutoff levels used (6).

INDICATIONS FOR aPL TESTING

Indications for aPL testing have been discussed by Greaves (30) and Triplett (68). Although sensitive, aPL is not indicated as a screening test for APS due to its low specificity. As discussed previously, aPL can be found in a variety of conditions not associated with thrombosis or pregnancy morbidity as well as in apparently healthy individuals. Derksen and de Groot (20) suggest that aPL testing is indicated in patients with SLE and/or the clinical criteria associated with APS. Because pathological aPL are persistently detected, positive results should be confirmed by repeat testing after 6 weeks.

aPL testing may also be indicated in other clinical situations. For example, the presence of aPL may, in part,

influence decisions regarding oral contraception or use of estrogen (13a). The accurate and precise determination of aPL is important not only diagnostically but also because it may guide therapeutic decisions such as prophylaxis (1a) or duration of therapy (44a).

Given the variety of tests available, which should be performed? Though not all studies are consistent, the consensus is that LA and IgG aCL tests are sufficient for most cases of APS (49). Additional testing for IgA aCL may be warranted in patients with negative IgG and IgM aCL tests, as IgA may be the sole isotype present in some instances and in certain ethnic groups. Testing for IgG, IgM, and IgA β2GPI-specific antibodies (56) has been recommended because of their greater specificity. In addition, they may be the sole aPL present in some patients (59). Multiple tests for aPL should be used since no one is sufficiently sensitive to identify all patients. Alternative phospholipids and/or cofactor antibodies may be detected in patients with APS.

INTERPRETATION OF RESULTS

The interpretation of aPL tests should take into consideration patient characteristics such as age, drugs, infection, and the presence of autoimmune disease as well as the isotype and titer of the aPL. The aCL test is sensitive and as such may be positive for individuals with no history of thromboses or adverse pregnancy outcomes. Surveys of healthy blood donors demonstrated positivity rates for IgM and IgG aCL of 9.4 and 6.5%, respectively (71). However, this rate may vary depending upon the cutoff level used (42), and the tests are often negative upon repetition (71). The prevalence of aPL may be increased in the elderly (71). aPL may be present in patients with autoimmune diseases (11, 64), patients taking certain drugs (45, 69), and patients with a variety of infectious diseases as discussed previously.

aCL antibodies are found in more than 80 to 90% of patients with APS (55). In general, the higher the antibody level, the more likely that the clinical event(s) is due to APS (28, 40). An incidental- or low-titer aCL test usually has no clinical significance (20). β2GPI-specific antibodies may be present with aCL or may be the sole antibody found in 2 to 10% of APS patients (59). Occasional patients with APS do not have aCL, LA, or β2GPI antibodies. In these cases testing for reactivity to other phospholipids may identify the presence of an aPL (see above). Clinically significant aCL are also persistent (i.e., detected on two separate occasions), a characteristic that is addressed in the APS classification scheme.

REAGENTS

A detailed method for a home brew aCL ELISA test can be found in the previous version of this chapter (29). Commercially available aCL kits are available from the following companies:

1. The Binding Site
   San Diego, CA 92121
2. DL Diagnostika
   Hamburg, Germany
3. Corgenix
   Denver, CO 80234
4. Diamedix
   Miami, FL 33127
5. DiaSorin
   Stillwater, MN 55082
6. Hemagen-Virgo
   Columbia, MD 21045
7. Hycor Biomedical
   Garden Grove, CA 92841
8. IMMCO Diagnostics
   Buffalo, NY 14228
9. Immuno Concepts
   Sacramento, CA 95827
10. INOVA Diagnostics, Inc.
    San Diego, CA 92131
11. Louisville APL Diagnostics
    Louisville, KY 40202
12. MBL International
    Woburn, MA 01801
13. Pharmacia Diagnostics
    Uppsala, Sweden
14. TheraTest
    Lombard, IL 60148
15. Trinity Biotech
    Berkeley Heights, NJ 07922
16. Wampole
    Princeton, NJ 08540

Antineutrophil Cytoplasm Antibodies (ANCAs) and Strategy for Diagnosing ANCA-Associated Vasculitides

ALLAN WIIK

118

BACKGROUND

The initial organ involved in vasculitis, and therefore the type of vasculitis, may vary extensively. Hence, the physician who initially sees a patient may be a generalist or any one of a great number of subspecialists. For the nephrologist, dermatologist, and rheumatologist in a secondary- or tertiary-care center, the level of awareness of systemic vasculitis may be high because such conditions are not uncommonly seen, but for primary-care doctors and specialists, these diseases are rare and may easily be misdiagnosed or may be left undiagnosed. Since this chapter concentrates on vasculitides which are associated with presence of antineutrophil cytoplasm antibodies (ANCAs), it focuses only on idiopathic small-vessel vasculitides (SVV), but it will also mention some of the clinical conditions where other types of neutrophil-specific autoantibodies (NSA) are commonly produced.

The diagnosis of a primary vasculitic condition must rest on sound clinical judgment of more or less characteristic constellations of symptoms and features, with some being indicative of vasculitis and others reflecting just a general inflammatory condition (arthralgias, fever, fatigue, loss of appetite, hypersedimentation, etc.). It is of paramount importance to put emphasis on the latter signs so that the systemic nature of the vasculitic condition can be recognized and so that the clinician can start looking for involvement of those organs most commonly affected by vasculitis, like the kidneys, the lungs, and the upper airways. The clinical spectrum of manifestations must generally be supported by defined histopathological findings in biopsy specimens from affected organs to provide a histologic "gold standard" for diagnosis. Unfortunately, this does not always work, as many biopsy specimens, e.g., nasal biopsy specimens, are frequently dominated by nonspecific inflammation.

In patients with focal necrotizing SVV involving venules, capillaries, and/or arterioles, neutrophilic granulocytes are assumed to be instrumental in causing the vessel damage and inducing ANCA production. It is thus not unexpected that ANCAs may occur in patients with SVV, but the very pronounced B-cell reactivity toward only one of two azurophil granule components, proteinase 3 (PR3) or myeloperoxidase (MPO), is unique for SVV and quite different from the B-cell reactivities for other neutrophil-dominated inflammatory conditions, e.g., rheumatoid synovitis, ulcerative colitis, chronic hepatitis, and primary sclerosing cholangitis (8), in which NSA are less strongly expressed and target very

different neutrophil antigens. Already at the first visit the doctor thus needs to set a tentative diagnosis so that the order for autoantibody tests is as rational as possible and the results of laboratory tests, including ANCA screening, can be put into a proper diagnostic context in order to avoid incorrect interpretation of the results. Also, laboratories should take care that clinically significant levels of PR3-ANCA and MPO-ANCA combined with NSA detected by indirect immunofluorescence (IIF) are reported in a different way than NSA seen only by IIF or by a whole-cell enzyme-linked immunosorbent assay (ELISA). This being said, strongly positive results for NSA by IIF combined with clearly positive results for PR3- or MPO-ANCAs obtained by using clinically validated assay techniques strongly support a diagnosis of necrotizing SVV, such as Wegener's granulomatosis (WG), microscopic polyangiitis (MPA), or Churg-Strauss syndrome (CSS), or the clinically limited forms of any of these, e.g., "renal limited" focal necrotizing glomerulonephritis or "upper airway-limited" WG (4).

Although this chapter focuses on the methodologies used to detect ANCAs, it also stresses important aspects of setting clinically validated assay cutoff values, controlling laboratory performance quality, knowing frequent pitfalls, and how to exercise troubleshooting. It also mentions possibilities for reporting laboratory data with due consideration toward differential diagnostics, potential clinical utility, and interpretation. The narrow definition of ANCAs includes only antibodies to cytoplasmic constituents of neutrophils and monocytes, but today most groups in the world call all autoantibodies to these cells ANCAs, although the cellular targets are mostly unknown. This chapter will try to make a case for naming autoantibodies to neutrophils which are detectable only by IIF "NSA" to avoid clinical misinterpretation, false diagnosis, and wrong therapy.

MAIN CLINICAL INDICATIONS FOR ANCA TESTING

ANCA testing is mainly indicated for patients with a tentative or a definite diagnosis of primary SVV, i.e., SVV in the absence of a recognized immunoinflammatory rheumatic disease, chronic infection, drug-related condition, or malignancy. In the nomenclature for primary vasculitides, several names were previously used for a single disease or one name was used for separate conditions. This inconsistency has

tentatively been dealt with by an expert-driven proposal to use a simple, nonoverlapping nomenclature for vasculitides with accompanying short definitions (5) as a common means of scientific communication and nosologic standardization. According to this nomenclature, ANCA testing is mainly indicated for patients with suspected primary SVV, such as WG, MPA, CSS, and oligotypic forms of these conditions. In all other types of primary vasculitides, ANCAs sensu strictu are not commonly found.

Classical cytoplasmic ANCAs (C-ANCAs) (Fig. 1) prevail in patients with WG (70 to 85% of the patients, depending on the population studied), whereas perinuclear ANCAs (P-ANCAs) (Fig. 2) prevail in patients with MPA, CSS, and renal-limited SVV (60 to 80% of the patients, depending on the population studied). A positive IIF result for NSA needs to be substantiated by a positive result for PR3-ANCA or MPO-ANCA to support the diagnosis of ANCA-associated vasculitis (AAV). If true ANCAs (ELISA-positive, IIF-positive ANCAs) are found in a patient with arterial involvement and with features of polyarteritis nodosa (e.g., radiological artery aneurysms) or giant-cell arteritis (e.g., temporal artery inflammation), AAV is highly likely to coexist (2). A careful clinical search for SVV in such patients is mandatory since therapy for vasculitis in small or large arteries (mainly corticosteroids) is different from that for necrotizing SVV, in which both corticosteroids and immunosuppressive treatment are most frequently necessary. According to the Chapel Hill consensus proposal, the SVV diagnosis then becomes the main diagnosis (5). If ANCAs are found in a patient with seemingly skin-limited vasculitis, a systemic SVV should be suspected and looked for, especially if constitutional signs of disease and inflammation are present. The same is true if a patient has had long-standing purulent or hemorrhagic rhinitis, otitis, or laryngitis.

ANCAs directed toward neutrophil elastase (EL) and MPO (and sometimes other azurophil granule constituents) commonly develop in patients who develop signs of arthritis, skin exanthem, or vasculitis during prolonged drug treatment, e.g., with tetracyclines, propylthiouracil, penicillamine, quinidine, hydralazine, and other drugs. A small number of P-ANCA- and EL-ANCA-positive patients may have primary SVV that has not been provoked by drugs, but such patients are rare. In patients with an established diagnosis of SVV, it is generally advised that the level of the particular ANCA harbored by the patient be monitored for several reasons: (i) the level of ANCA is commonly higher in a patient with signs of active vasculitis than in a patient in remission;
FIGURE 2 Typical P-ANCA pattern seen on ethanol-fixed neutrophils by MPO-ANCA-containing sera, here stained for IgG.

(ii) in more than half of WG patients, a steep rise in the PR3-ANCA level over a short time heralds disease exacerbation or extension; (iii) patients who become ANCA negative during a clinical remission get clearly fewer exacerbations of the disease than patients who remain positive, despite a lack of overt disease activity, most probably due to persistent presence of smoldering disease; and (iv) patients who are getting an infection may have symptoms like those of patients who have an exacerbation, but ANCA levels generally do not rise during infections. There may be exceptions to this notion, since infections with *Staphylococcus aureus* have been found to cause exacerbations in some patients with WG. In the clinical follow-up of patients with AAV, intervals between ANCA tests can be determined only on clinical grounds, such as if the patient has shown a tendency to get frequent disease exacerbations, or if critical-organ damage has already been inflicted by the disease (e.g., decreased renal or lung function). It can also be taken into consideration whether the patient has shown successful response to previous remission-inducing treatment or has shown little response to conventional therapies. It is highly recommended that ANCA levels in AAV patients be judged by very experienced vasculitis specialists. A high persistent level of PR3-ANCA or MPO-ANCA usually does not herald disease exacerbation or reflect active disease, whereas a sudden rise is a clear warning sign.

ANCA ANTIGENS

The two main antigens targeted by vasculitis-associated ANCAs are PR3 and MPO, both being enzymes located in the azurophil granules of neutrophils and in homologous granules of monocytes. PR3 is a single-chain, 229-amino-acid serine protease with four disulfide bridges and two potential glycosylation sites. It migrates as a triple band around 29 kDa in sodium dodecyl sulfate-polyacrylamide gel electrophoresis. This apparent heterogeneity is due to the existence of differently glycosylated subspecies. PR3 is most likely identical to neutrophil proteinase 4, myeloblastin, and azurophil granule protein 7 mentioned in earlier literature, and it is partly homologous to neutrophil EL and cathepsin G as well as to the antimicrobial proteins heparin-binding protein/bacterial-permeability-increasing protein (BPI) and azurocidin, which

FIGURE 1 Typical C-ANCA pattern seen on ethanol-fixed neutrophils and monocytes by PR3-ANCA-containing sera, here stained for IgG.

are not enzymes. PR3-ANCA mainly recognizes conformational epitopes on PR3, but linear epitopes have also been described.

MPO, the second major ANCA antigen, is important for defense against microorganisms, its main function being the catalysis of the production of hypochloric acid, which is an important microbicidal agent in the phagolysosome. The concurrent production of highly reactive oxygen radicals can cause oxidative changes both in the cells themselves and in surrounding tissues. MPO is a heterodimer consisting of two light chains and two heavy chains. It contains two heme groups and has at least four potential glycosylation sites. The molecule is very cationic, with a pI of >11 and a molecular mass of about 140 kDa. MPO-ANCA associated with SVV mainly recognizes conformational epitopes.

When IIF is used with ethanol-fixed leukocytes, PR3-ANCA produces a granular cytoplasmic staining pattern (C-ANCA) (Fig. 1), whereas MPO-ANCA typically gives rise to an artifactual perinuclear or nuclear staining pattern (P-ANCA) due to the redistribution of MPO onto the polymorphonuclear leukocyte (PMN) nucleus and even neighboring cell nuclei after ethanol fixation (Fig. 2) (see below). Many groups have produced recombinant PR3 in the hope of eliminating the need for repeated purification of PR3 from normal neutrophils and to obtain pure PR3 preparations in sufficient amounts. However, only a few of these recombinants have been found to be useful for routine ANCA testing. To acquire full enzymatic activity and have the optimal conformation for ANCA reactivity, recombinant PR3 needs to have both the signal peptide and the proenzyme dipeptide cleaved off, processes which take place in myeloid precursor cells when PR3 leaves the endoplasmic reticulum and enters into the azurophil granules (12). Also, pure MPO has been prepared by recombinant synthesis technology and has been successfully used for MPO-ANCA determination.

METHODS USED TO DETECT ANCA

IIF

Human leukocytes were introduced as a convenient substrate for autoantibody demonstration soon after the IIF technique had been described as a screening method in serology (see chapter 112, this volume). In the mid-1960s autoantibodies that appeared to specifically recognize nuclear components of neutrophils were found by this technique in the sera of patients with rheumatoid arthritis, and a technique was developed to easily identify these so-called "granulocyte-specific" antinuclear antibodies (ANAs). The same technique was later adopted as a sensitive and reliable method for the detection of ANCAs (14), and its use has led to comparable recognition of C-ANCAs and P-ANCAs in multicenter studies of patients with primary vasculitides (3).

Slide Preparation

A 10-ml volume of blood is drawn into a syringe, and the blood is immediately transferred to a conical flask for defibrination with 10 glass beads (10 mm in diameter). Just after the clot has formed, the defibrinated blood is transferred into a polypropylene tube and thoroughly mixed with 250 IU of heparin. Aliquots of 2 ml are layered onto 5-ml dextran–sodium diatrizoate gradients (50 ml of 32.8% sodium diatrizoate [Nycomed] and 100 ml of 6% dextran T500 in distilled H_2O [Pharmacia]) in 10-ml polypropylene tubes, and these are left at room temperature for 45 min for

sedimentation of erythrocytes. The leukocyte-containing plasma layers are combined in a l0-ml tube.

The cells are pelleted at $200 \times g$ for 10 min and are resuspended in 1% human serum albumin in phosphate-buffered saline (PBS [pH 7.4]; 8.0 g of NaCl, 200 mg of KCl, 1.44 g of $Na_2HPO_4 \cdot 2H_2O$, 200 mg of KH_2PO_4, and distilled H_2O to 1,000 ml) and centrifuged again as described above to wash away plasma constituents. The cells are then resuspended in human serum albumin plus PBS and are pelleted by centrifugation at $200 \times g$. The last centrifugation is best done in a conical tube, so that the cells are concentrated in a small space in the bottom to allow removal of practically all washing medium, leaving only 150 to 200 μl of fluid over the pellet. The cells are then resuspended by tapping the tube, and a fine-tipped Pasteur pipette that has been drawn over a gas flame is used as a capillary pipette to deposit 1-mm-diameter droplets on carefully defatted objective slides. These droplets must be smeared immediately with a ground-edged glass slide. Deposition of leukocytes on the slides may also be done by cytocentrifugation of a leukocyte suspension onto glass slides. After air drying, the slides are fixed in cold (4°C) 99% ethanol for 5 min, a selected area is encircled with a glass marker, and the slides are ready for use as a substrate for the IIF technique. If not used directly, the slides should be wrapped in an airtight container and stored at –20°C for use within a week.

Staining

Negative control serum, C-ANCA- and P-ANCA-positive control sera, and patient sera diluted in PBS to the agreed cutoff dilution (usually 1:20 to 1:40) are added as a drop on the encircled smear area, the controls on the first three slides. Some laboratories will use the fourth slide for a sensitivity control, i.e., a weakly positive IIF reaction that needs to be detectable in each routine run. Incubation at room temperature for 30 min takes place in a humid chamber, and the smears are washed in PBS and left totally immersed in PBS for 10 min. The washing procedure is repeated, and the excess PBS around the circle is removed, leaving a minute drop of PBS in the circle to avoid drying of the specimen. A fluorescein isothiocyanate-labeled immunoglobulin G (IgG) fraction of antiserum to human Fcγ chains is added at an appropriate dilution (usually 1:25 to 1:100) and left for incubation in the humid chamber as described above, and the washing steps are then repeated. After removal of the surrounding PBS, a 2:1 glycerol-PBS mixture is then applied to each smear and a cover glass is mounted. The preparations are now ready for fluorescence microscopy, which is best done in an epi-illumination microscope at a magnification of × 400 with an objective having a high numerical aperture to allow optimal excitation of the fluorochrome.

Annotations

It is important to avoid leukocyte activation during isolation and washing of the cells, and diligent handling of the cells is therefore mandatory. Each step must be followed immediately by the next step to avoid activation artifacts and leakage of antigens out of the cells until the slides have been fixed in ethanol. Do not use paraformaldehyde fixation even in combination with a permeabilizing agent (ethanol or acetone), since such fixation destroys the reactivities of many antigens and the fixation procedure often gives unpredictable results from batch to batch of cell preparations. Extra hands must help with the smearing of the cells to avoid drying of the small suspension droplet on the slide.

Use fluorescein isothiocyanate conjugates with a low mean fluorescein/protein molar ratio, around 2.5, since higher ratios will cause nonspecific staining of neutrophils and eosinophils. *Whole buffy coat must be used to ensure the presence of a satisfactory concentration of lymphocytes on the final slides, since these cells serve as important controls for both C-ANCAs and P-ANCAs (see below).* ANCA levels may be estimated by twofold titration or reactivity judged from the strength of the fluorescence staining (weak, intermediate, or strong).

Interpretation and Controls for Non-Organ-Specific Autoantibodies

A granular cytoplasmic fluorescence which is more intense in the vicinity of the nucleus than in the periphery of the neutrophils is characteristic for C-ANCA. Monocytes are more uniformly stained in the cytoplasm (Fig. 1). Lymphocytes and eosinophils should show no fluorescence. If non-organ-specific anticytoplasmic antibodies (such as anti-Jo-1 or anti-ribosomal ribonucleoprotein antibodies) are present, it may be difficult to demonstrate C-ANCAs on leukocytes. Titration of such samples on the buffy coat substrate by using isolated human lymphocytes from the same donor as a separate control substrate may help provide a solution to the problem if a clearly higher titer of ANCAs is found. HEp-2 cells are less well suited for such titer comparisons, although HEp-2 cells may be excellent for demonstration of some anticytoplasmic antibodies (6). The C-ANCA pattern is most commonly produced by autoantibodies to PR3. C-ANCA-positive sera should be further tested by ELISA for two reasons: PR3-ANCA is are very narrowly linked to WG and to, in a minority of patients, other types of SVV, whereas C-ANCAs that are not directed to PR3 may be seen in patients with infection-related vasculitis (directed to BPI) or patients without vasculitis. In addition, in rare cases MPO-ANCA may give a classical C-ANCA pattern (9).

P-ANCAs related to SVV are seen as a perinuclear or a nuclear fluorescence on neutrophils and monocytes (Fig. 2). This staining pattern is an artifact caused by the ethanol fixation, which partially dissolves the lipid membranes of the cells, making the various intracellular compartments accessible to the autoantibodies. Cationic proteins of the cytoplasm, however, can now freely redistribute onto the anionically charged nucleus of the same cell or a closely adjacent cell (Fig. 3), and antibodies attaching to the adjacent cell nuclei will show an ANA-like pattern. Since neutrophils contain a number of cationic components (e.g., MPO, EL, cathepsin G, lysozyme, azurocidin, and lactoferrin), autoantibodies to each of these will mostly be seen as P-ANCA or atypical ANCA reactivity.

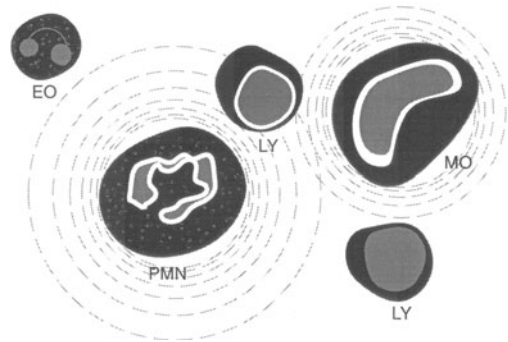
To eliminate false interpretation, inclusion of control cells, like lymphocytes, is therefore mandatory to discriminate P-ANCAs from homogeneous or peripheral non-organ-specific ANAs. Lymphocytes from the buffy coat donor are very reliable for this purpose if they are present in sufficient numbers in the smear or if they are separated from neutrophils being deposited in a separate field on the slide. ANAs that give rise to a homogeneous or peripheral nuclear reactivity will then be seen to be reactive with neutrophils, eosinophils, and lymphocytes (Fig. 4), whereas P-ANCAs will selectively stain neutrophil and monocyte nuclei and sometimes a lymphocyte lying just adjacent to a neutrophil, but the majority of lymphocytes as well as eosinophils will be negative (Fig. 3). If non-organ-specific ANAs and P-ANCAs are found in the same serum sample, twofold titration of the sample can be done; a clearly higher P-ANCA level (at least 2 dilution steps) indicates


FIGURE 3 Diagram showing typical peripheral staining of neutrophil (PMN) and monocyte (MO) nuclei and the nucleus of an adjacent lymphocyte (LY), while a more distantly located lymphocyte and an eosinophil (EO) are not stained. The artifactual ANA-like pattern on positive cells is due to redistribution of soluble, diffusible molecules (such as the cationic MPO) onto the anionic nuclei located close by, here symbolized by the circles around the PMN and monocyte.

the presence of both autoantibodies. P-ANCAs are detected at 1:20 dilution on blood neutrophils whereas ANAs are detected at 1:160 dilution on HEp-2 cells. Therefore, titers cannot be directly compared. If the ANAs are very characteristic and distinguishable on the lymphocyte nuclei (e.g., nucleolar patterns, nuclear dot patterns, or centromere patterns), P-ANCAs are separable from such ANAs already at the screening dilution and titration is not necessary.

To summarize, in patients with primary vasculitides, P-ANCA reactivity is ordinarily due to autoantibodies to MPO. P-ANCA-positive sera must be studied for MPO-ANCA by ELISA, since strong MPO-ANCA activity is very characteristic of primary SVV or a drug-induced syndrome, whereas weak or absent MPO-ANCA activity in the presence of P-ANCA is more characteristic of another chronic inflammatory disease, e.g., rheumatoid arthritis, ulcerative colitis, chronic active hepatitis, primary sclerosing cholangitis, or systemic lupus erythematosus (8), altogether diseases that are much more frequent than AAV and thus recognized by finding NSA and not ANCA.
FIGURE 4 Diagram showing typical peripheral staining of all leukocyte nuclei by serum containing anti-double-stranded DNA. Diffusion of soluble and freely diffusible molecules such as MPO is symbolized by the circles around the PMN and the monocyte (MO). LY, lymphocyte; EO, eosinophil. Note that all cell nuclei in the field are positive.

Attempts at Standardizing Direct ELISA Techniques

Since data from the First and the Second International Workshops on ANCAs clearly indicated that results obtained by solid-phase techniques were not comparable, a collaborative study among seven European laboratories was organized in 1991. The aim was to study the available solid-phase methods for quantifying ANCA and to standardize the most promising techniques. These methods could then be used to evaluate their clinical utility in large populations of patients with primary SVV by using critical disease control patients with secondary vasculitides as well as healthy donor controls, including data from 14 different vasculitis centers all over Europe.

It quickly became apparent that PR3 and MPO were the main neutrophil autoantigens in primary vasculitides and that purified PR3 and MPO were superior to various mixed extracts from neutrophils or azurophil granules, probably due to the scarcity of the important antigens in such crude extracts. MPO could be obtained either from commercial sources or by simple purification methods, so the second part of the study concentrated on isolation of PR3 in four laboratories which all used different purification methods. Purity was judged by sodium dodecyl sulfate-polyacrylamide gel electrophoresis, immunoblotting, and direct ELISA techniques with specific antibodies to possible contaminants. The PR3 preparations were then applied in direct ELISAs by using the assay procedures recommended by the laboratory that delivered the preparation and a series of well-characterized but coded ANCA-positive sera (3).

After six rounds of testing in which assay conditions were gradually more strictly defined, the variability among all participating centers had reached a level of <20%. There was no significant difference among the three different PR3 preparations used regarding intracenter or intercenter variability. One preparation of MPO was used by all groups for direct ELISA with the assay specifications from Copenhagen, Denmark. Whereas PR3 is stable, it was found that MPO is very unstable if it is used to coat plates to be sent from one center to another, but if it is used for coating locally just before use, it was found to be suitable and gave reproducible results. The direct ELISAs detailed below reflect the assay conditions recommended from Copenhagen in the study described above. PR3 can now be obtained from several commercial sources, can be isolated by published methods (3), or can be obtained as recombinant PR3 (10, 12). An international reference preparation for C-ANCAs was established in 1988, but new International Union of Immunological Societies standards are being developed for MPO-ANCA and PR3-ANCA for distribution through the Centers for Disease Control and Prevention in Atlanta, Ga.

Direct PR3-ANCA ELISA

1. The wells of high-level-of-binding microtiter plates (Maxisorb; Nunc) are coated with 100 ml of PR3 (0.5 mg/ml) in 0.05 M sodium carbonate buffer (pH 9.6) containing 0.01% Triton X-100. The plates are incubated overnight at 4°C.
2. The plates are washed three times in 0.15 M NaCl containing 0.05% Tween 20, each time leaving the washing solution in the wells for 1 min before removal.
3. A negative control serum sample, a PR3-ANCA-positive serum sample with an intermediate level of antibody (or three standard serum samples with different antibody levels), and the patient sera are diluted 1:50 in 20°C incubation buffer (0.05 M Tris, 0.15 M NaCl, 0.05% Tween 20, and 0.2% bovine serum albumin).
4. These samples are added to duplicate wells (100 μl per well), and the plates are incubated for 1 h at room temperature.
5. The wells are washed three times with washing solution as described above.
6. Alkaline phosphatase-conjugated goat anti-human IgG (Sigma) diluted 4,000 times in incubation buffer (Tris-bovine serum albumin) is added to each well (100 μl per well), and the plate is incubated at room temperature for 30 min.
7. The wells are again washed three times with washing solution as described above.
8. To each well is added 100 μl of substrate consisting of 1 mg of para-nitrophenyl phosphate disodium per ml in 1 M diethanolamine buffer (pH 9.8) (97 ml of diethanolamine, 700 ml of distilled H_2O [the pH is adjusted to 9.8 with 5 M HCl–0.101 g of $MgCl_2 \cdot 6H_2O$; distilled H_2O is added to 1 liter]), and the plate is incubated at room temperature for 30 min. This buffer will keep for 4 weeks if 2 ml of NaN_3 is added to prevent bacterial growth.
9. The optical densities at 405 nm are measured in an ELISA reader.
10. The values relative to the values on the standard curve are calculated in arbitrary units.

Direct MPO-ANCA ELISA

1. Microwells of high-level-of-binding microtiter plates (Maxisorb; Nunc) are coated with 100 μl (1 μg/ml) of purified MPO in cold 0.05 M sodium carbonate buffer (pH 9.6) containing 0.01% Triton X-100, and the plates are incubated overnight at 4°C to be used the next day. Coated microplates may be stored under nitrogen in the dark for several months.
2. The procedure is continued with MPO-ANCA controls and the procedures described above in steps 2 through 10 for the PR3-ANCA ELISA.

Interpretation of Direct ELISA Results

When a decision as to the cutoff levels for PR3-ANCA and MPO-ANCA ELISAs must be made, it is advised that testing be done not only with sera from healthy donors but also with sera from patients with various forms of chronic or long-standing immunoinflammatory diseases, which in practical clinical work may pose differential diagnostic problems. The most important disease controls are those of vasculitis related to infections, rheumatoid arthritis, or other systemic rheumatic diseases. The diagnostic specificity toward disease controls should be >95%, and that toward healthy controls should be 100%. Such high degrees of specificity will eliminate most positive results in the gray area, albeit at the expense of a slightly lower nosographic sensitivity. Note that cutoff values for commercial ELISAs should be set locally in just the same way, since the diagnostic value of the results must be evaluated for local control patients with the ethnic composition and the differential diagnostic spectrum prevailing in the individual center.

Pitfalls and Troubleshooting

Since sera studied for ANCAs by ELISA may contain "sticky IgG" (probably immune complexes, conformationally altered IgG, or high levels of IgG), many laboratories will prefer to run all sera also in control wells that have been left uncoated in parallel with wells coated with autoantigen. If high background values are seen in uncoated wells, the problem must be taken into account when results are

reported, although no general formula on how to do that can be given. The background problem seems to arise especially when sera from pediatric patients and patients with systemic lupus erythematosus are studied by using wells with a blocking agent, e.g., bovine serum albumin, ovalbumin, or gelatin. In such patients, levels of antibodies to blocking agents such as bovine serum albumin or ovalbumin are higher than those in healthy controls, and human serum albumin in the incubation buffer or on the solid phase may thus be preferred, if a blocking agent is used at all. Low-avidity antibodies to MPO can actually be present in sera from patients with systemic lupus erythematosus, and the conditions in the ELISA may be adjusted to eliminate weak MPO reactivity by increasing the ionic strength or the concentration of Tween 20 in the incubation buffer. These variables of method refinement need to be looked at locally whether in-house or commercial ELISAs are used. Since only one ANCA specificity is ordinarily present in a given serum sample, positivity for two ANCAs should arouse suspicion of false assay positivity.

Other Methods Used To Detect ANCA

Radioimmunoprecipitation and immunoblotting have been used previously to detect ANCAs, but these techniques are not practical for use in a routine serology setting. Monoclonal mouse antibodies to PR3, MPO, and EL have been used to capture the respective antigens from cell extracts, and the captured antigen has then been used as the target in an ELISA (1). This type of assay should ideally use capture antibodies recognizing epitopes that are rarely or never seen by human antibodies. Although promising results have been obtained by use of such assays (11, 13), the clinical applicability must be tested in multicenter studies.

A quantitative immunoprecipitation method based on binding of [³H]diisopropyl fluorophosphate ([³H]DFP) to PR3 and EL was recently introduced (7) for PR3-ANCA (and EL-ANCA) quantitation, and preliminary results indicating that this assay will reflect the presence of ANCAs directed solely to conformationally preserved enzymes look promising. In this respect, both the capture PR3-ANCA ELISA and the [³H]DFP quantitative immunoprecipitation assay may better reflect the particular types of PR3-ANCA being produced in patients with active vasculitis (7, 13).

Introduction

C. LYNNE BUREK

119

Autoimmunity is common, while autoimmune disease is not. It is not clear how or why a benign autoimmune response becomes "malignant," thereby leading to pathogenic changes of a target organ. Few autoimmune diseases fulfill the strict criteria by which the autoimmune response is directly related to pathogenesis. However, many findings, either cellular or humoral, can provide circumstantial evidence that autoimmunity is strongly associated with a particular disease. Often, the humoral responses that we detect in the laboratory are best considered to be markers rather than causes of disease. They are useful for diagnosis or prognosis, for excluding other conditions, for classifying disease, or for monitoring therapy. However, whenever we test for autoimmune disease by evaluating autoantibodies, we must consider that individuals without evidence of disease may also exhibit these autoantibodies. Therefore, all results must be evaluated in context with the entire clinical picture; autoantibodies are never the sole criteria for disease.

Autoimmune disease can be divided into two types. The first type, the systemic diseases, are conditions in which the whole body may be involved. They include such disorders as systemic lupus erythematosus and rheumatoid arthritis. The second category consists of the organ-specific autoimmunities. These conditions generally involve one particular organ of the body. In earlier editions of this manual, the section covering organ-specific autoimmunity was small and was combined within the overall section on autoimmune diseases. In the 5th edition, organ-specific autoimmune diseases warranted their own section. In the 6th edition, the section was expanded approximately 25%. In this edition, topics have been expanded to include molecular methods of diagnosis. In certain chapters, such as the one on endocrinopathies, some things have changed only a little. Like in the previous edition, the endocrinopathy chapter contains collected descriptions of the various procedures currently used to detect circulating autoantibodies in patients with immune-mediated endocrine disease, i.e., thyroiditis, Graves' disease, insulin-dependent diabetes mellitus, Addison's disease, and pernicious anemia. However, certain of the neurological autoimmunities and the section on hemolytic anemia will be found only in the 6th edition. Since the number of organ-specific diseases that display diagnostically important autoantibodies is ever expanding, we have included a new section on autoimmune uveitis. The test strategies change once individual antigens are identified. More and more of the assays are now based on enzyme-linked immunosorbent assay using purified antigens or recombinant antigens. However, there is still a role for the "older" assays, such as indirect immunofluorescence, that can be used for screening tests and for identification of antibodies for which the precise antigen is not yet known. Certain new assays use immunoblots of tissue extracts or digested purified antigens. These assays have promise for screening several antigens or epitopes simultaneously.

As antigens are identified, more and more commercial sources are producing reagents for assays in the form of Food and Drug Administration-approved kits. However, manufacturers often use different processes to obtain components (e.g., native antigens versus recombinant peptides). There is no standardization among the assays. The result is that different antibody specificities may be recognized, which is one reason not all kits give identical results. The role of the clinical laboratory is changing from one in which new assays are developed to one of evaluating the new technologies. Yet our goal of helping the patient remains the same.

Endocrinopathies

120

In this chapter, we have collected descriptions of the various procedures currently used to detect circulating autoantibodies in patients with endocrine disease, i.e., thryoiditis, Graves' disease, insulin-dependent diabetes mellitus, Addison's disease, and pernicious anemia.

AUTOANTIBODIES IN CHRONIC THYROIDITIS, ADDISON'S DISEASE, AND PERNICIOUS ANEMIA
(This section was written by C. L. Burek, P. E. Bigazzi, and N. R. Rose.)

General Method for Indirect IF Test for Antibodies
The general method of indirect immunofluorescence (IF) is the screening test used most frequently to detect tissue- or organ-specific autoantibodies. The procedure is essentially the same for all of the autoantibodies, except for the selection of an appropriate tissue that contains the antigen of interest.

Materials

Phosphate-buffered saline (PBS), pH 7.2

Rabbit or goat antiserum to human immunoglobulins conjugated to fluorescein isothiocyanate (FITC conjugate). Most conjugates are commercial preparations and include information by the company on their characteristics, i.e., immunologic analysis of conjugate to show its specificity; antibody, protein, and fluorescein concentrations; and fluorescein-to-protein ratio. When a commercial conjugate is obtained, the lot number should be recorded, and the optimal dilution should be checked by testing several dilutions in a chessboard titration. The same lot should then be used as long as possible.

Buffered glycerol. Mix 9 volumes of glycerol with 1 volume of phosphate buffer (pH 7.2).

Cryostat-cut frozen sections (4 µm thick) of the appropriate tissue on a glass slide

Coverslips

Procedure

1. Prepare 1:10 dilutions in PBS of all sera to be tested (unknown and positive and negative controls). Sera may be screened at 1:10 dilutions or titrated in serial twofold dilutions until the endpoint is reached.

2. Incubate diluted sera with cryostat-cut sections of tissue in a humid chamber at room temperature for 30 min.

3. Wash the slides in PBS for 30 min at room temperature. Effective washing can be performed by gently stirring with a magnetic stirrer and changing the wash solution three times.

4. Incubate sections with the appropriate dilution of FITC conjugate in a humid chamber at room temperature for 30 min.

5. Wash again for 30 min as described in step 3.

6. Mount the coverslip with buffered glycerol, and read with a UV microscope.

Antibodies to Thyroid-Specific Antigens
Sera from patients with chronic thyroiditis (Hashimoto's disease) may contain several types of antibody to thyroid antigens. Antibodies to thyroglobulin or to cytoplasmic antigens of the thyroid epithelial cell are most commonly detected by routine diagnostic procedures; antibodies to the second colloid antigen (called CA2) and to antigens of the thyroid cell surface are less frequently observed and are not of clinical value. In addition to being found in chronic thyroiditis patients, these antibodies may be found in patients with other thyroid disorders, such as primary myxedema, hyperthyroidism, colloid goiter, nodular goiter, and thyroid tumors (3). Thyroid antibodies have also been observed in sera of patients with pernicious anemia, adrenal insufficiency, diabetes mellitus, and other conditions. Screening for thyroid autoantibodies in pregnant women appears to be an effective way to identify individuals who may develop postpartum thyroiditis (8). Finally, antithyroid antibodies are seen in a certain proportion of healthy subjects, as discussed below (3).

Antibodies to Thyroglobulin
Thyroglobulin antibodies can be demonstrated by several procedures, such as precipitation in agar, indirect IF, passive hemagglutination of cells coated with thyroglobulin, radioimmunoassay, and enzyme-linked immunosorbent assay (ELISA) (3). Precipitation in agar is simple to perform but of low sensitivity, detecting only antibodies present in relatively large amounts. Passive hemagglutination tests with the use of tanned erythrocytes (tanned-cell hemagglutination [TCH]) or chromic chloride-treated erythrocytes (chromic chloride hemagglutination [CCH]) are very sensitive and thus detect antibodies to thyroglobulin in patients with a variety of conditions other than thyroiditis, a possible

disadvantage from the diagnostic point of view. Commercial hemagglutination kits for thyroglobulin antibodies are less sensitive than the TCH test described below (5). The frequency of thyroglobulin autoantibodies is dependent upon the assay used for evaluation (discussed elsewhere in depth [5]). Indirect IF is less sensitive but reportedly can detect nonagglutinating antibodies that are missed by hemagglutination procedures (3). ELISA procedures for thyroglobulin antibodies are also highly sensitive and demonstrate both agglutinating and nonagglutinating antibodies. Commercial ELISA kits for thyroglobulin autoantibodies are also available and are very sensitive. Indirect IF can also detect antibodies to CA2, which are undetectable by hemagglutination.

TCH Test for Antibodies to Thyroglobulin

Erythrocytes treated with tannic acid are capable of adsorbing protein antigens on their surfaces. When added to serial dilutions of patient serum, these erythrocytes will react with the appropriate antibody, if present, with a visible agglutination reaction. Tanned erythrocytes coated with thyroid extract or purified thyroglobulin are used to detect antibodies to thyroglobulin. The method is highly sensitive but requires fresh erythrocytes and reagents for best results. The procedure, which is described in detail in the previous editions of this manual, has generally been replaced by the CCH test.

CCH Test for Antibodies to Thyroglobulin

Chromic chloride can be used to couple thyroglobulin to erythrocytes, providing a simpler alternative to the tannic acid method (3). The CCH and TCH tests appear to be comparable in sensitivity and specificity. The method of microtitration is given.

Materials

Patient serum (heat inactivated at 56°C for 30 min)

Saline solution (8.5 g of NaCl in 1 liter of double distilled water). Phosphate ions must be avoided, since they interfere with the coupling of antigens to erythrocytes.

Normal rabbit serum (NRS) diluent (heat-inactivated NRS diluted 1:100 in saline)

Chromic chloride solution

1. Stock
   0.125 g of $CrCl_3 \cdot 6H_2O$
   10 ml of saline
2. Wash solution
   0.1 ml of stock
   100 ml of saline
3. Coating solution (0.1% solution made up fresh)
   0.8 ml of stock solution
   9.2 ml of saline

Human thyroglobulin. In a 50-ml tube, mix 0.1 ml of human thyroid extract (prepared by mincing thyroid tissue in PBS, incubating it overnight in the cold, and then centrifuging it at $64,000 \times g$ for 45 min) with 5.0 ml of saline solution. Purified thyroglobulin can be prepared by precipitation with 1.60 to 1.70 M ammonium sulfate followed by filtration through Sephadex G-400. The first peak should be separated and concentrated. Thyroglobulin can be lyophilized or stored frozen. It is used as a 200-μg/ml solution. Do not repeatedly freeze and thaw thyroglobulin.

Human group O erythrocytes. Collect 10 ml of human group O erythrocytes in 3.8% sodium citrate. Use for up to 10 days.

Inactivated test sera; positive and negative control sera

Plates, pipettes, diluters, and tube

Procedure

1. Wash human group O erythrocytes three times with the chromic chloride wash solution. Pack. Centrifuge at $200 \times g$ for 10 min. Remove fluid by aspiration.

2. Pipette 0.2 ml of packed erythrocytes into a 12-ml centrifuge tube.

3. In the centrifuge tube, combine 0.2 ml of packed erythrocytes, 0.2 ml of $CrCl_3$ coating solution, and 0.2 ml of diluted thyroglobulin (or 1:200 NRS for control cells). Mix, and incubate for 4 min at room temperature.

4. Add 10 ml of saline to stop the reaction. Centrifuge as before.

5. Wash the mixture twice in NRS diluent.

6. After the last wash, suspend the erythrocytes in 19.8 ml of NRS diluent to make a 1% suspension.

7. With NRS diluent, prepare 1:5 dilutions of sera to be tested, including control sera.

8. With a pipette dropper, place 0.025 ml of NRS diluent into each of wells 1 through 12.

9. With a 0.025-ml microtitration diluter, take a loopful of 1:5 serum dilution and place it in the first well. Mix and transfer a loopful to the next well, and so on until well 9.

10. With a 0.025-ml microtitration diluter, take a loopful of 1:5 serum dilution and place it in well 11. Mix, and transfer a loopful to well 12. (Alternatively, the dilutions can be made using a multichannel pipette with a 0.025-ml volume.)

11. Repeat these steps for all sera to be tested, including positive and negative control sera.

12. Add 0.025 ml of antigen-coated erythrocytes to wells 1 through 10. Add 0.025 ml of control cells to each of wells 11 and 12.

13. Gently shake the plate to mix.

14. Incubate the plates at room temperature until the cells settle (usually 1 h), and then incubate the plates overnight at 4°C. To avoid evaporation, stack the plates on top of one another, and cover the top plate with plastic or another empty plate.

15. Read the patterns of sedimentation on the bottom of the wells. Strong agglutination usually gives an even mat over the bottom of the well. Weaker reactions give ragged doughnut-shaped patterns, whereas the absence of agglutination gives a smooth, doughnut-shaped, compact button of cells in the center of the well. The reciprocal of the last serum dilution to give a positive reaction is considered to be the titer.

Interpretation of Hemagglutination Test Results

At present, the TCH or CCH test is most commonly used for the detection of antibodies against thyroglobulin. The prevalence of these antibodies detectable by the TCH test is approximately 90% in patients with chronic thyroiditis, 75% in patients with myxedema, and 40% in patients with Graves' disease or thyroid tumors. Approximately 30% of patients with chronic thyroiditis have CCH titers ranging from 1×10^3 to 2.5×10^6. Such high titers are found in only about 10% of patients with Graves' disease. Low titers of thyroglobulin antibodies may be found in juveniles with autoimmune thyroiditis. Low titers of thyroglobulin antibodies may also be found in healthy individuals. The prevalence of such antibodies in subjects without overt thyroid disease is higher in women than men. The incidence also increases with age: 18% of women over 40 years old have antibodies to thyroglobulin.

Indirect IF Test for Antibodies to Thyroglobulin

Indirect IF performed on sections of human or monkey thyroid can demonstrate antibodies to thyroglobulin, CA2, and microsomes of thyroid epithelial cells, and antinuclear antibodies. Tests for these antibodies may be performed on unfixed sections, but in most laboratories, IF for antibodies to thyroglobulin and CA2 is performed on methanol-fixed (56°C methanol for 3 min) or acetone-treated sections. The pattern of staining that is obtained when methanol-fixed sections are used with thyroglobulin antibodies is characteristic and has a floccular "puffy" appearance (3). The less commonly observed CA2 pattern has been described as diffuse, with a "ground glass" appearance. This test is rarely performed for thyroglobulin antibodies.

Interpretation of IF Test Results

The same considerations apply for results of the IF test as for results of the hemagglutination tests except that the sensitivity of IF seems to be lower.

ELISA for Antibodies to Thyroglobulin

ELISA is increasingly used for the measurement of antibodies to thyroglobulin.

Materials

Prepare human thyroglobulin as for the CCH test (see above).

Procedure

1. Dilute thyroglobulin to a concentration of 1 μg/ml in carbonate-bicarbonate buffer (1.56 g of Na_2CO_3 plus 2.93 g of $NaHCO_3$ made up to 1 liter with distilled water and adjusted to pH 9.6). Add the diluent (200 μl) to each well of an Immulon II ELISA plate (Dynatech), and incubate the plate in a humid chamber overnight at 4°C to allow passive adsorption of the thyroglobulin to the surface.
2. Remove unreacted material by washing the plate three times with PBS-Tween (0.15 M PBS [pH 7.4] containing 0.05% Tween 20). Shake the plate dry before adding the next reagent.
3. Dilute the test serum or plasma specimens 1:100 in PBS-Tween, and add 200-μl samples to wells in the plate, permitting duplicate tests on each sample. Incubate the plates for 4 h at 37°C in a humid chamber.
4. Repeat the washing as described in step 2.
5. Add conjugate (200 μl), consisting of goat anti-human globulin labeled with alkaline phosphatase standardized and diluted in PBS-Tween, to each well, and incubate the plate overnight at 4°C.
6. Repeat the washing as described in step 2.
7. Add to each well 200 μl of the enzyme substrate (p-nitrophenyl phosphate [1 mg/ml] in 10% diethanolamine buffer [97 ml of diethanolamine and 800 ml of H_2O with 1 M HCl added to yield a pH of 9.8, made up to 1 liter with H_2O]), and incubate the plate for 20 min at room temperature.
8. Add NaOH (50 μl of 3 M NaOH) to each well to stop the enzyme substrate reactions.
9. Read at A_{405} in an ELISA reader.

Chessboard Titrations

It is necessary to determine the optimal concentration of thyroglobulin for coating the plates and the optimal dilution of the serum or plasma to be used in the tests. These determinations are made by a chessboard titration of positive and negative sera on plates coated with various concentrations

of thyroglobulin. A coating solution containing 1 μg of thyroglobulin per ml generally gives the best separation of values between the reference positive and negative sera to be used in subsequent tests.

Interpretation of ELISA Results

The overall correlation of ELISA and CCH titers is presented in Fig. 1. Of samples for which CCH was negative, 95% gave ELISA values below 1.4. Values over 1.4 were considered positive. Only three of the CCH-negative individuals had values significantly greater than 1.4. All were hospital patients. One person (ELISA value of 4.0) had sustained a traumatic injury to the thyroid; the other two patients (ELISA values of 2.2 and 2.4) had antibodies to the microsomal fraction of the thyroid as measured by indirect IF. Values for Fig. 1 were based on an ELISA that used polyvinyl plates. While protein adsorption appears to be higher for polyvinyl, it is impractical for current ELISA readers. Therefore, Immulon II plates have been substituted. Optical density values are much lower with Immulon plates but still show their relative reactivity as on the polyvinyl plates. Many (45%) of the sera with very low (2, 4, or 8) CCH titers had ELISA values under 1.4, as did 22% of the sera with low (16, 32, 64, or 128) CCH titers. All sera with medium (256 to 2,048) or high (4,096 to 16,384) CCH titers were positive by ELISA values and CCH titers (Fig. 1). The Spearman rank correlation is 0.82 ($P < 0.001$). It is apparent that ELISA readily detects antibody to thyroglobulin in those sera that have medium to high CCH titers but is not very efficient at discriminating between negatives and those samples with low CCH titers. The reason for this lack is not clear; possibly the
FIGURE 1 Overall correlation between the CCH test and ELISA. Each dot represents the mean ELISA value for the group of sera with the individual CCH titers.

ELISA is less sensitive than CCH to particular subclasses of antibody to thyroglobulin. Recent evidence shows that the antigenic specificity of autoantibodies to thyroglobulin in patients with thyroiditis is different from that in people with antibody but no disease. The naturally occurring antibodies from healthy individuals are directed primarily to sites on the molecule that are shared among species (i.e., conserved), whereas those found primarily in patients are directed to human-specific regions (4). In the future, a test for thyroglobulin autoantibodies specific for those individuals with disease may be of more value in diagnosis.

Antibodies to TPO

The microsomal antigen of the thyroid epithelial cell has been identified as thyroid peroxidase (TPO) (6). The most commonly used tests for determining TPO antibodies are indirect IF and commercially available hemagglutination assays or ELISAs. Preparations of isolated thyroid microsomes are often contaminated with thyroglobulin. Therefore, the commercially prepared tanned-cell kit uses a special diluent containing thyroglobulin to block any antibody that may inadvertently react. Special attention must be paid to any serum that contains high titers of thyroglobulin autoantibodies. There may be insufficient thyroglobulin to remove all traces of the antithyroglobulin antibody, and the serum will give a false-positive result. Serum titers obtained by the indirect IF procedure may reach 1,200 or higher. Titers of TPO antibody obtained by TCH may reach well over 25,000. ELISAs using either purified microsomes or recombinant TPO are also available in commercial kits. These ELISAs are also very sensitive (9). However, those kits that use recombinant antigens may be less sensitive, as the posttranslational modification of the antigens may be lacking. The antibodies to TPO belong predominantly to the immunoglobulin G (IgG) class and, when detected by indirect IF, stain the cytoplasm of thyroid cells (Fig. 2). The nucleus is unstained. This
FIGURE 2 Indirect IF for antibodies to thyroid microsomes with an unfixed, air-dried section of monkey thyroid. Only the cytoplasm of the thyroid epithelial cells is stained. (Magnification, ×80.)

pattern of staining must be distinguished from the much coarser granular cytoplasmic staining obtained with mitochondrial antibodies. For better differentiation, sera should be tested on both thyroid and kidney sections.

Indirect IF Test for Antibodies to TPO

Materials and Procedure
The reagents and procedures described above for the general indirect IF test are used. Frozen sections of primate tissue (unfixed and air dried) are used as the tissue substrate.

Interpretation of Test Results
The indirect IF test for antibodies to TPO is positive for approximately 90% of patients with chronic thyroiditis. It is also positive for 64% of patients with primary hypothyroidism, 50% of patients with thyrotoxicosis, 10% of patients with simple goiters, and 17% of patients with thyroid tumor (3, 9).

Antibodies to Adrenal Antigens

Patients with idiopathic Addison's disease have circulating antibodies to adrenal antigens. Such antibodies have been detected by a variety of procedures (3), but the method most commonly used is indirect IF. Antibodies detected by IF stain the cytoplasm of cells of the adrenal cortex and are directed to an antigen associated with the microsomes of these cells. The antibodies belong predominantly to the IgG class and, in general, have rather low titers (not higher than 100). Recent studies suggest that different steroidogenic enzymes of the cytochrome P-450 family may be the target autoantigens of autoimmune Addison's disease. Sera from patients with autoimmune Addison's disease contain autoantibodies to 21-hydroxylase (21-OH) or 17-α-hydroxylase (1, 2, 11). A sensitive radioimmunoassay using the 21-OH antigen has been developed, but the usage is limited (2). Patients with autoimmune polyendocrine syndrome type I (Addison's disease plus hypoparathyroidism and chronic mucocutaneous candidiasis) have circulating autoantibodies to the P-450 cholesterol side chain cleavage enzyme. It is still uncertain whether these autoantigens are expressed on the surfaces of adrenal cells or are otherwise accessible to adrenal antibodies in vivo.

Indirect IF Test for Antibodies to Adrenal Antigens

Materials and Procedure
The reagents and procedures previously described for the general indirect IF test are used. Frozen sections of primate adrenal tissue are used as a substrate. These sections are available commercially from certain vendors that deal with autoimmune test kits. Positive and negative control sera can also be purchased commercially.

Interpretation of Test Results
Antibodies to adrenocortical cells are detected in the serum of 38 to 60% of patients with idiopathic Addison's disease (2, 3). The antibodies are present in 7 to 18% of patients with tuberculous Addison's disease and in 1% of healthy subjects. The presence of antibodies to adrenocortical cells is a good indication that the disease is idiopathic and not of a tubercular or other nature. Different patterns of staining have been observed: most sera stain the whole cortex, with a brighter fluorescence in the glomerulosa zone (Fig. 3 and 4), but a few sera stain only the fasciculata and reticularis zone, not the glomerulosa zone. The latter pattern has been reported with sera that also stain the interstitial cells of the testis and the theca interna cells of the ovary.
FIGURE 3 Indirect IF for antibodies to adrenal cortex, with an unfixed, air-dried section of monkey adrenal cortex. All layers of the adrenal cortex are stained. (Magnification, ×32.)

Antibodies to Antigens of Ovary, Testis, and Placenta

Antibodies staining the cytoplasm of cells of the theca interna, interstitial cells and corpus luteum cells of the ovary, interstitial cells of the testis, and trophoblast of the placenta have been detected in the sera of patients with Addison's disease and of patients with premature ovarian failure (2, 3). The antigens involved have not been very well characterized,
FIGURE 4 Same as Fig. 3 but at a higher magnification. Only the cytoplasm of the adrenal cells is stained. (Magnification, ×80.)

and the test itself is at present more of research than of diagnostic interest (see chapter 126).

Antibodies to Parathyroid Antigens

Sera from patients with idiopathic hypoparathyroidism (IHP) contain antibodies to antigens of parathyroid cells. Such antibodies have been detected by indirect IF on sections of normal human parathyroid tissue obtained at autopsy (3). They are directed not against parathyroid hormone but against cytoplasmic antigens of parathyroid cells.

Indirect IF Tests for Antibodies to Parathyroid Antigens

Materials and Procedure
The reagents and procedures are the same as those used for the other IF tests. The test is performed with unfixed cytostat sections of primate parathyroid as the substrate.

Interpretation of Test Results
Antibodies to parathyroid cells are found in the serum of approximately 38% of patients with IHP, 26% of patients with idiopathic Addison's disease, 12% of patients with chronic thyroiditis, and 6% of controls. Since approximately 60% of patients with IHP do not have demonstrable parathyroid antibodies, a negative test obviously does not exclude IHP. On the other hand, a positive test, while indicating IHP, is not necessarily diagnostic, since the patient may have adrenal insufficiency or thyroiditis or a combination of these disorders.

Antibodies to Gastric Parietal Cells

Circulating autoantibodies to intracytoplasmic antigens of gastric parietal cells (parietal cell antibodies), to the Bl2 binding site of intrinsic factor, and to the intrinsic factor Blt complex occur with high frequency in patients with autoimmune gastritis leading to end-stage disease of pernicious anemia (10). Antibodies to intrinsic factor may be detected by several radioassay procedures. However, these methods are not yet regularly performed in most hospitals. Parietal cell antibodies are detected primarily by indirect IF. Parietal cell antibodies, when detected by indirect IF, bind to the cytoplasm of parietal cells of the gastric fundal mucosa of humans and various animals, like monkeys, rats, and guinea pigs (Fig. 5). As noted above, the pattern of staining resembles that seen with mitochondrial antibodies; therefore, a control test on kidney should be performed. The autoantigens to which gastric parietal cell antibodies are directed have been identified as the alpha- and beta-subunits of the gastric H/K ATPase, the enzyme responsible for acid secretion in the stomach (7).

Indirect IF Test for Antibodies to Gastric Parietal Cells

Materials and Procedure
The materials used are the same as those described previously for other IF tests. Unfixed sections of rat stomach (gastric mucosa) are used as the substrate. Unfixed rat kidney sections are used as controls for staining because of mitochondrial antibodies.

Interpretation of Test Results
Parietal cell antibodies are found in about 90% of patients with pernicious anemia (10). These antibodies are also present in patients with a number of other conditions,
FIGURE 5 Indirect IF for antibodies to parietal cells of the gastric mucosa, with an unfixed, air-dried section of rat stomach. The cytoplasm of most cells is stained. (Magnification, ×100.)

such as chronic thyroiditis (33%), Sjögren's sicca syndrome (15%), atrophic gastritis (60%), and gastric ulcer (22%). Antibodies to parietal cells have been reported for about 20 to 30% of patients with *Helicobacter pylori*-associated gastritis, although the titers may be lower than in autoimmune gastritis (10). Whether *H. pylori* is an environmental agent triggering the autoimmune condition is still not known. The antibodies are also found in the healthy population, with an incidence that varies according to age, i.e., from 2% in subjects younger than 20 years to 16% in subjects older than 60 years. They are more common in women than in men. It is also not known whether these antibodies are a biomarker of latent disease, as the interval between autoimmune gastritis with parietal cell antibodies and pernicious anemia may be as long as 20 to 30 years (10). As of yet, no longitudinal studies have addressed this issue.

HYPERTHYROIDISM OF GRAVES' DISEASE AND ANTIBODIES TO THE THYROTROPIN RECEPTOR

(This section was written by M. Zakarija and J. M. McKenzie.)

Thyroid function and growth are under control of the pituitary hormone thyrotropin (TSH), with thyroid hormones exerting negative feedback control of TSH secretion. Binding of TSH to its receptor (TSH-R), a member of a subfamily of G protein-coupled receptors for polypeptide hormones, follicle-stimulating hormone, luteinizing hormone, and TSH, initiates metabolic events in the gland mainly by activating a cyclic AMP (cAMP) cascade and, to a minor degree, phospholipase C (for a review, see reference 22). The major structural difference between TSH-R and receptors for follicle-stimulating hormone and luteinizing hormone is a 50-amino-acid insertion in the extracellular domain, the cleavage of which leaves an extracellular A subunit and a transmembrane B subunit, linked by disulfide bonds. Further degradation of B subunit, with the dissolution of disulfide

bonds, releases the A subunit, at least from cultured cells. This may have implications for the induction of autoimmunity to the TSH-R (18). In Graves' disease, hyperactivity and enlargement of the thyroid are due to an antibody that mimics the action of TSH on its receptor (for reviews, see references 15 and 16). From the initial discovery of this activity (16), named long-acting thyroid stimulator, and its identification as an IgG, through gradual development of better assay techniques accompanied by numerous acronyms, the present name—thyroid-stimulating antibody (TSAb)—has been agreed upon. That TSAb truly stimulates human thyroid in vivo was established by the finding of neonatal hyperthyroidism due to transplacental passage of the antibody from mother to fetus.

In contrast to the agonist action of TSAb, another antibody (also an IgG), thyroid-blocking antibody (TBAb), was found to act as an antagonist by inhibiting TSH binding and action. TBAb is a probable cause of hypothyroidism in some patients with atrophic thyroiditis and is responsible for transient hypothyroidism in neonates of mothers who have this antibody (16). The final proof that TSAb and TBAb interact with the TSH-R came from work with the cloned receptor (14, 16, 17, 22), and the term TSH-R antibodies (TRAb) encompasses both antibodies.

Current Assays for TSH-R Antibodies

In the last decade, FRTL5 cells (a cloned Fisher rat thyroid cell line) have been the most uniform and widely used preparation for the stimulation-type assay of TSAb. These cells depend on TSH for function and growth and are propagated in a well-defined medium that includes TSH. After withdrawal of TSH for several days, metabolically quiescent cells become sensitive to both TSH and TSAb. More recently, Chinese hamster ovary cells transfected with the recombinant human TSH-R (CHO–TSH-R) have become the preparation of choice because they express the homologous receptor for TSAb and are easier and cheaper to maintain in culture. The assay entails incubation of cells with either purified IgG or polyethylene glycol-precipitated immunoglobulins from patients' sera. The endpoint of the assay is the concentration of cAMP in the cells (Fig. 6) when the incubation medium is isotonic Hanks' balanced
FIGURE 6 TSAb-induced cAMP accumulation in FRTL5 and CHO–TSH-R cells incubated in isotonic medium. Cells were incubated for 2 h in the absence (control) or presence of the indicated concentrations of TSAb (purified IgG), and cAMP was measured in cell extracts.

salt solution (pH 7.4) buffered with HEPES and supplemented with 3-isobutyl-l-methylxanthine (blocker of cAMP phosphodiesterase). Improved sensitivity to TSAb is achieved with the use of a low-salt solution (Hanks' balanced salt solution devoid of NaCl), in which case cAMP released into the medium is measured. With this method, detection of TSAb in patients with Graves' disease reaches almost 100%. Results are usually expressed as percent increase in cAMP over that in the control wells (cells incubated with normal IgG), and values of >130 to 150% are considered positive.

The ability of TSAb to displace ^{125}I-TSH from the TSH-R is the basis of another technique, called the TSH binding inhibition (TBI) assay (Fig. 7). Commercially available kits use solubilized porcine thyroid cell membranes as a source of the receptor. The attraction of this assay is the ease of its performance and the use of whole serum instead of extracted immunoglobulin. Unfortunately, the method lacks the sensitivity and specificity of the stimulation assay; false-negative results usually occur with sera of low stimulating potency, and some positive results are due to the presence of TBAb. The assay can also be performed with cultured cells exposed to IgG in a low-salt medium, a procedure still confined to research laboratories. Results from all procedures are expressed as a TBI index, with positive values starting at 10 to 15% and maximum inhibition being 100%, a level almost never attained by even the most potent TSAb (Fig. 7). TBAb is equally effective in blocking TSH- and TSAb-induced stimulation of cAMP accumulation (Fig. 8A), and the activity is often termed the thyroid stimulation-blocking antibody (TSBAb). When measured in the TBI assay (Fig. 7), the activity is designated TSH binding-inhibiting antibody. The highest titers of TBAb so far described have been found in mothers of infants with transient neonatal hypothyroidism (Fig. 7).

It has been long recognized that TSAb and TBAb may coexist in some patients with either Graves' disease or Hashimoto's thyroiditis. This is reflected in a biphasic dose-response in the stimulation-type assay (Fig. 8B) and a higher

FIGURE 8 Assays with CHO–TSH-R cells in a low-salt medium. (A) Inhibitory effect of TBAb on TSAb- and TSH-induced accumulation of cAMP. (B) Biphasic effect of a patient's IgG (IgG-Z). Cells were incubated for 2 h with the test substances (TRAb as purified IgG) and concentrations indicated, and cAMP in the medium was measured.

inhibition of ^{125}I-TSH binding than would be expected from the TSAb activity alone. Thus, if they are used as an aid in clinical management, results from a single assay and a fixed concentration of TRAb should be interpreted with caution.

Characteristics of TSH-R Antibodies

Despite tremendous advances in the fields of immunology and molecular biology, TRAb have not been obtained in monoclonal form, and they are still defined by their biological activities in in vitro assays. With the use of immunochemical techniques for purification, TSAb was shown to be oligoclonal (and sometimes even monoclonal) in terms of its IgG subclass distribution (exclusively IgG1) and light chain-type association (predominantly λ). Resolution by preparative isoelectric focusing, showing a peak TSAb activity at pH 8.5 to 9, supports the notion of its oligoclonal origin. Limited data for TBAb show less subclass restriction, and an exclusive association with κ light chain was found in a single patient of four tested. Both TRAb are also effective as Fab fragments, suggesting that cross-linking of the receptor is not the basis of their action.

That the stimulating activity might not be the property of a single species of antibody came from the analyses of sera from patients with unusual clinical presentations. Two antibodies, distinct from TSAb, have been characterized by their properties in different assays; one appears to be human TSH-R specific, and the stimulating effect of the other is not inhibitable by TBAb (16). The incidence of these antibodies is unknown, since differing bioactivities cannot be detected in a single stimulation-type assay, a common practice in screening patients' sera. Heterogeneity of TBAb has also been suggested by the finding that some patients' sera block TSH-induced stimulation without affecting the binding (16).

Cloning of the TSH-R has contributed to the understanding of its structure-function relationship and interactions of TRAb and TSH. It is clear that TRAb bind to highly conformational epitopes on the extracellular domain of TSH-R and do not recognize linear sequences (12), a fact reflected in their failure to facilitate cloning of the receptor (22). Part of individual conformational epitopes for TSAb, TBAb, and TSH obviously overlap. Studies with TSH-R-luteinizing hormone

FIGURE 7 TBI assay with a commercial kit (Kronus, Inc., Boise, Idaho). Dilutions were carried out with pooled serum from healthy humans. A, B, C, and D refer to sera from mothers, all on replacement therapy, who had hypothyroid neonates. TSAb was from a mother who was treated with ^{131}I for hyperthyroidism of Graves' disease and subsequently had two hyperthyroid neonates. (Reprinted, with permission of The Endocrine Society, from M. Zakarija, J. M. McKenzie, and M. S. Eidson, Transient neonatal hypothyroidism: characterization of maternal antibodies to the thyrotropin receptor, *J. Clin. Endocrinol. Metab.* **70:**1239–1246, 1990.)

receptor chimeras were able to distinguish two populations of stimulating antibodies (17), and the coexistence of TSAb and TBAb in some hypothyroid patients was confirmed using TSH-R mutants (14). Further characterization of TRAb, especially at the molecular level, will depend on their availability as monoclonal antibodies. So far, only one adequately characterized human monoclonal TSAb-IgG has been reported (19).

The importance of the cAMP cascade in the regulation of thyroid function and growth has recently been reinforced by the discovery of spontaneously occurring mutations in the TSH-R and their consequences (20, 21), thus supporting the notion that the effect of TSAb and TBAb on the thyroid is sufficient to explain the respective clinical presentations. Lack of absolute correlation of TSAb titers with the degree of hyperthyroidism and goiter size could be attributed to modifying influences of various cytokines, elaborated by thyroid-infiltrating lymphocytes. Lymphocytic infiltration of the thyroid in Graves' disease varies widely, from none to that seen in Hashimoto's thyroiditis, and there is evidence for negative correlation between the size of the gland and the degree of infiltration. In addition, some TRAb have been shown to activate phospholipases C and A_2 (13). Another variable probably contributing to the disparity is the coexistence of TBAb in approximately 30% of patients with Graves' disease (16).

Clinical Application of Assays for TSH-R Antibodies

The assays offered by commercial diagnostic laboratories are quite expensive and, in most instances, unnecessary; the usual clinical and biochemical criteria are sufficient for establishing the diagnosis. Circumstances in which the assay of TRAb, as TSAb and/or TBAb, is merited in the clinical management of patients with autoimmune thyroid disease encompass the following situations. Persistence of TSAb at the end of a course of antithyroid drugs predicts the relapse of hyperthyroidism and the need for thyroid ablation (surgical resection or administration of radioactive iodide). In pregnancy complicated by Graves' disease, high titers of TSAb in maternal blood at the end of gestation are predictive of neonatal hyperthyroidism, which may have a deleterious effect on the child's development if not recognized and treated on time. Since ablative treatment, with consequent eu- or hypothyroidism, does not necessarily ensure immunologic remission, i.e., the disappearance of TSAb, the measurement of TSAb in pregnant women so treated is imperative; without the protection of antithyroid drugs, stimulation of the fetal thyroid by TSAb and the ensuing hyperthyroidism can lead to irreversible abnormalities. Screening for a specific TRAb is also necessary in all pregnant women who have had a previous child with neonatal hyper- or hypothyroidism. We stress here that all such women are clinically affected, but the diagnosis does not always match the outcome in the neonate; women with hypothyroidism of Hashimoto's thyroiditis may give birth to a hyperthyroid infant, and those previously treated for Graves' hyperthyroidism and still having TSAb may give birth to a hypothyroid infant. Thus, autoimmune thyroid disease cannot be distinguished solely on the basis of the type of TRAb. Different TRAb can occur any time during the autoimmune process and may coexist in an individual patient, with the more potent antibody responsible for the clinical presentation in the neonate. Postnatal effects are transient, with the duration related to the initial level of TRAb and the time required for catabolism of maternal IgG. Timely, but limited in duration, treatment of affected infants usually leads to an excellent outcome.

The usefulness of TRAb assays will undoubtedly increase in the future. Achieving this increased usefulness will entail full characterization of all TRAb, both currently known and still to be identified, and the development of simpler techniques with high sensitivities and specificities for their detection.

PANCREAS

(This section was written by L. Yu, J. Wang, and G. S. Eisenbarth.)

Introduction

Diabetes mellitus is made up of a heterogeneous group of disorders. Approximately 10% of patients with diabetes mellitus have the immune-mediated form of the disease, now termed type 1A diabetes (American Diabetes Association 2004 [25]). Prior terms for this form of diabetes include juvenile-onset diabetes and insulin-dependent diabetes. In that as many patients develop type 1A diabetes as adults as children, and that at the time of diagnosis many individuals are not dependent upon insulin for survival, the term type 1A has been adopted to reflect disease etiology. A type 1B form of diabetes represents severe loss of insulin secretion on a nonautoimmune basis, but at present a clear example of this form of the disorder is lacking. Type 2 diabetes is characterized by insulin resistance and moderate loss of insulin secretory capacity and makes up the bulk of patients with diabetes. Finally, separate diabetes mellitus categories consist of gestational diabetes and "specific types of diabetes" usually with defined mutations or accompanying pathology (e.g., pancreatic abnormalities, endocrinopathies, or drug induced).

The great majority of non-Hispanic Caucasian (>90%) and approximately 50% of Hispanic and African-American children developing diabetes have the type 1A form of the disease, while between 5 and 15% of adults presenting with diabetes (depending upon the population) have type 1A diabetes. Type 1A diabetes is highly associated with specific HLA class II (DR and DQ) alleles, with both high-risk and protective genotypes present. In particular, DQ8 (DQA1*0301 and DQB1*0302) and DQ2 (DQA1*0501 and DQB1*0201) are present in 90% of Caucasian patients with the disease and 40% of the general population, and DQ6 (DQA1*0102 and DQB1*0602) is present in 20% of the population and 1% of children with type 1A diabetes. The nomenclature and detailed associations of specific HLA alleles and additional genetic polymorphisms with type 1A diabetes can be found at http://www.barbaradaviscenter.org, *Immunology of Diabetes* web textbook, chapter 7. There are no tests that can absolutely exclude a diagnosis of type 1A diabetes, and it is possible for individuals to have evidence of both type 1A (e.g., anti-islet autoantibodies) and type 2 diabetes (e.g., severe insulin resistance). In general, however, the presence of anti-islet autoantibodies measured with highly specific assays (≥99% specificity) in a patient with diabetes is pathognomonic of the disorder, and the presence of anti-islet autoantibodies can be used to predict the disease with various positive predictive values (45) depending on the spectrum of autoantibodies expressed (Fig. 9). Though there is general agreement that T lymphocytes rather than autoantibodies are the primary pathogenic mechanism, at present there is a lack of assays for anti-islet T cells with sufficient specificity and sensitivity to contribute to laboratory diagnosis or disease prediction.

Autoantibodies

Anti-islet autoantibodies are usually present years before clinical onset of type 1A diabetes (45). A decade ago, anti-islet
FIGURE 9 Progression to overt type 1A diabetes of first-degree relatives of patients with type 1A diabetes (DM) relative to number of anti-islet autoantibodies expressed (autoantibodies to GAD65, ICA512, and insulin). ◆, three antibodies; ■, two antibodies; ▲, one antibody. (From http://www.barabaradaviscenter.org, *Immunology of Diabetes*.)

autoantibody tests were limited to measuring cytoplasmic islet cell autoantibodies (ICA) and insulin autoantibodies (IAA). Currently, recombinant autoantibody assays with biochemically defined autoantigens (Table 1), including insulin, glutamic acid decarboxylase (GAD), ICA512 (IA-2), I-A2β (phogrin), and carboxypeptidase H, are available.

ICA were first discovered in the early 1970s in patients with polyendocrine autoimmunity (29), and antibodies in the sera from these patients reacted with frozen sections of human pancreas. These patients with type 1A diabetes have ICA that frequently persist for decades, while in the majority of patients with type 1A diabetes the ICA slowly disappear. ICA was soon identified in patients with the more common form of type 1A diabetes and was found to be present long before clinical onset of diabetes (36, 37). The Diabetes Prevention Trial—Type 1 (DPT-1) demonstrated that all

TABLE 1 Biochemically characterized autoantigens

Antigen	Sensitivity (%)	Comment
Insulin	49–92	Higher levels in young children
GAD	84	Higher sensitivity with sera from patients with adult-onset type 1A diabetes
ICA512/IA-2	74	Tyrosine phosphatase-like molecule
IA-2β/phogrin	61	Tyrosine phosphatase-like molecule
Carboxypeptidase H	10	Infrequent
GLIMA38	14–38	Not yet sequenced
GM2-1	?	Ganglioside: chromatography assay
ICA69	?	Western blot assay with poor specificity
ICA12	<20	Diabetes relatedness requires further study

anti-islet autoantibodies tested for in the trial, including ICA, GAD autoantibodies (GAA), and ICA512 autoantibodies (ICA512AA), in relatives were relatively stable, with 75 to 85% of all positivity (90 to 95% with high levels) confirmed during follow-up. ICA has been shown to be present in 70 to 80% of newly diagnosed type 1A diabetics and is predictive for the development of diabetes in both relatives of patients with diabetes and the general population. ICA is a heterogeneous mixture of IgG isotype autoantibodies against a variety of islet cell molecules. To date, three autoantigens have been defined that contribute to the ICA positivity, including GAD, insulinoma antigen 2 (IA-2 [ICA512] and a homologous antigen, IA-2β), and glycolipids (26, 28, 31, 38, 42). However, there are likely other autoantibodies still to be identified (Fig. 10). Approximately 5% of ICA-positive individuals without biochemical autoantibodies in the DPT-1 trial progressed to diabetes, indicating that there is another autoantigen(s) playing a role in type 1A diabetes autoimmunity. We believe that the current three major autoantibody assays in general can replace the ICA test for initial screening even though there remains an additional unidentified ICA autoantigen(s) (antigen "X" [Fig. 10]).

The first ICA antigen component to be determined was a 64-kDa protein that was later identified (26) as the enzyme GAD. GAD is present in all human islet cells (e.g., α, β, and δ) and other endocrinological organ tissues like testes, ovary, and neurons, though only pancreatic β cells are destroyed in type 1A diabetes. The GAA of patients with stiff man syndrome had been previously identified and are unusual in that they react with fixed sections of the brain and react with denatured GAD molecules on Western blots and with GAD protein fragments (33). In contrast, most sera from diabetic patients only target GAD protein epitopes dependent on protein conformation and do not bind GAD protein fragments or react with denatured GAD protein. There are two isomers of GAD, GAD65 and GAD67, which are 76% homologous in amino acid sequence. Autoantibodies to GAD65 are predominant over those to GAD67, and the autoantibodies binding to GAD67 in diabetic patients seem to represent antibodies to epitopes shared with GAD65 (35).

The second identified ICA antigen component was IA-2 (or ICA512), a protein tyrosine phosphatase, and its homologous antigen IA-2β (phogrin) (38, 42). The two isomers are most homologous in their antigenic intracellular regions to which essentially all of the autoantibodies are directed. Almost all autoantibodies to IA-2β also react with IA-2, while approximately 10% of diabetic patients have autoantibodies only reacting with IA-2 and not with IA-2β. In addition, two differentially spliced ICA512 (IA-2) mRNAs are expressed in islets, with one form lacking exon 13, which includes the transmembrane region of the molecule (40). In our laboratory, an ICA512 clone (ICA512bdc) was used to develop an autoantibody radioassay. Approximately 10% of patients developing type 1 diabetes have autoantibodies reacting with only one of the two forms of alternatively spliced IA-2 molecules.

To date, insulin is the only known β cell-specific autoantigen of humans (all other islet autoantigens are also produced by human non-β islet cells). IAA were found by Palmer and coworkers (39) in patients with newly diagnosed type 1A diabetes and were soon demonstrated to be present for many years before the clinical onset of disease. IAA is so far the only autoantibody dramatically age dependent in its prevalence and level (34). The levels of IAA inversely correlate with the age of disease onset, and less than half of individuals developing type 1A diabetes after age 15 have detectable
FIGURE 10   The current well-identified anti-islet autoantibody assays. (From http://www.barbaradaviscenter.org, *Immunology of Diabetes*.) Islet autoimmunity is defined as one or more autoantibodies *persistent* for at least 3 to 6 months.

IAA levels. IAA is usually the first autoantibody to appear in young children developing type 1 diabetes (46). For most patients, treatment with exogenous insulin also induces insulin antibodies. The current IAA assay is not able to distinguish between natural IAA and induced insulin antibodies. In the rare insulin autoimmune syndrome (44), also termed Hirata syndrome, patients express high levels of IAA, often with episodes of severe hypoglycemia.

General Assay Methodology

The first useful islet autoantibody assay was the ICA test utilizing indirect IF with frozen sections of human pancreas as a substrate. A standard for ICA was established utilizing a serial dilution of a calibrated serum with assigned JDF (for the Juvenile Diabetes Foundation) units. To date, the ICA test remains cumbersome, and the Immunology of Diabetes Society (IDS) workshops demonstrated that there existed large variation among laboratories in terms of sera called ICA positive.

The current major format for determination of islet autoantibodies uses fluid-phase radioimmunobinding assays,

applied to all three major islet autoantibody tests, including GAA, ICA512AA, and IAA. A semiautomated format is available where labeled antigen is incubated with patient sera; both are placed in 96-well filtration plates, where the immune complex is precipitated with protein A- and/or protein G-coupled Sepharose; free radioactivity is separated by filtration washing; scintillation fluid is added directly to the plates; and counting is performed on multichannel beta counters able to handle the plates (Fig. 11).

ELISAs employing plate-bound antigen are the most common assay formats for basic immunologic research. In multiple diabetes autoantibody workshops, for either human or mouse models, standard ELISA formats lack both sensitivity and specificity compared to the fluid-phase radioassay formats. In the most recent international workshop only a single modified ELISA (for GAA) attained levels of specificity and sensitivity equivalent to those of the radioassays (30).

It is recommended that all laboratories attempting to measure anti-islet autoantibodies take part in Diabetes Antibody Standardization Program (DASP) workshops organized by the IDS and the Centers for Disease Control and Prevention. As demonstrated in multiple workshops, though the majority of laboratories have excellent assays for GAA and ICA512AA, many laboratories have IAA assays with unacceptable sensitivity and specificity when evaluating in blind the DASP panel of 100 control sera and 50 sera from patients with type 1A diabetes of recent onset.

Determination of ICA by Indirect IF

Sample Requirements

Samples are stored at $-20°C$ or below until analyzed. Approximately 200 μl of serum per sample is needed for this assay. Hemolyzed or lipemic blood samples may have artificially low ICA titers and thus should not be used for analysis with this method. In order to obtain high-quality serum and prevent or decrease the possibility of hemolysis, the yellow-top gel serum separator tubes are recommended.

1. Mix ^{125}I-insulin and sera

2. Incubate 72 hours at 4°C

3. Add Protein A/G-Sepharose to reaction mix in a 96-well filtration plate

4. Incubate for 45 min at 4°C

5. Wash each well using the vacuum-operated 96-well plate washer

6. Count radioactivity with 96-well plate beta counter
FIGURE 11   General outline of fluid-phase 96-well plate assays for autoantibodies. In this example ^{125}I-insulin is utilized, but the format is identical for GAD65 and ICA512 assays.

Materials, Reagents, and Equipment

Cryostat

Frozen 5-μm sections of human blood group O pancreas

Fluorescein-antibody conjugate [goat anti-human IgG F(ab)$_2$ fragment-FITC or rabbit fluorescein-conjugated antihuman IgG (Behringwerke AG, Marburg, Germany) or sheep anti-human IgG–FITC conjugate (Sigma, St. Louis, Mo.])

Fluorescence microscope with epi-illumination 20× objective (Leica, Wetzlar, Germany)

Reciprocal shaker

Principle

We highly recommend human pancreas with blood type O of cadaveric donors taken while the heart is still beating, because the pancreas is very prone to autolysis. Five-millimeter cubes of the pancreas are quickly frozen in isopentane at −70°C, sealed in a freezer-container, and stored at −80°C. Five-micrometer-thick frozen sections are cut with the temperature of cryostat held between −25 and −30°C and then placed onto the glass microscope slides (usually four sections per slide), air dried for 30 min with a fan, and then directly used or stored at −80°C. The freezer-stored slides must be brought to room temperature with air drying in front of a fan for 30 min before use. The slides to be used should be well labeled, and the sections on the same slide need to be isolated from each other with a hydrophobic marker. Serum sample is then applied on each section, and tissue-bound specific autoantibodies from patient's serum will be revealed by an animal (goat, sheep, or rabbit) anti-human IgG–fluorescein conjugate under a fluorescence microscope with epi-illumination.

Procedure

1. In the initial experiment, 50 μl of undiluted serum is applied on each tissue section and incubated for 30 min at room temperature in a moisture chamber.

2. Each slide is rinsed gently with 0.5 M PBS (pH 7.4), with care to not damage or remove each tissue section.

3. The slides are completely submerged in 0.5 M PBS (pH 7.4) and gently washed on a reciprocal shaker for 5 min; this wash step is repeated twice, each time in fresh PBS for 5 min.

4. Both sides of the slides are then quickly dried with a low-lint Kim Wipe, with care to not touch the tissue sections on each slide, and then placed back into the incubation chamber to prevent complete dehydration before the next step.

5. Each section is then covered with 50 μl of diluted (often 1/20 dilution determined empirically) fluorescein-antibody conjugate in PBS (containing 1% bovine serum albumin [BSA]) and incubated for 30 min at room temperature in a moist chamber.

6. The slides are washed as in steps 2 and 3.

7. The slides are quickly dried as in step 4, a slide cover is placed with a glycerol solution (90% glycerol–10% [wt/vol] PBS), and a coverslip is applied and sealed with nail polish.

8. The slide is observed for islet cell-specific fluorescence under a fluorescence microscope fitted with a 20× epi-illumination objective.

9. All samples with detectable ICA are titrated by retesting the serum in serial dilution. The endpoint titer is compared with the 80-JDF unit international standard used by the IDS workshops.

Standardization, Quality Control, and Quality Assurance

1. To determine the appropriate dilution of fluorescein-antibody conjugate, a known negative serum sample, a weakly positive serum sample, and a strongly positive serum sample need to be tested with various dilutions of conjugate; the optimal dilution is the highest dilution that gives the strongest specific islet cell reaction with a lower nonspecific staining.

2. A standardization procedure should be applied for each new lot of pancreas by serially diluting the 80-JDF unit standard in both negative sera and PBS. A five-point curve of standard diluted in negative serum versus standard diluted in PBS should be linear, and JDF units are calculated from this curve by interpolation of patient serum endpoint titer in PBS.

3. Strongly positive, weakly positive, and negative control samples should be included in each assay. A known positive serum sample is recommended for storage in aliquots and testing every 3 months to monitor assay drift. The ICA assay, including quality control samples, should be analyzed with the reader blinded to the sample identity.

Biochemically Defined Autoantibody Radioassay

Sample Requirements

We recommend that the serum be obtained from red top or tiger top (separator) blood collecting tubes and be hemolysis and lipemia free. Only 5 μl of serum is required to measure both GAA and ICA512AA, and 12 μl of serum is required for micro-IAA (mIAA). The method we utilize measures GAA and ICA512AA (IA-2AA) simultaneously.

Materials, Reagents, and Equipment

Human GAD65 cDNA clone

Human ICA512 (IA-2) cDNA clone. The two most utilized clones are IA-2ic (intracytoplasmic IA-2) and ICA512BDC (clone lacking exon 13 [transmembrane] domain of IA-2).

TNT Sp6 coupled in vitro translation kit (Promega)

RNasin RNase inhibitor (Promega)

[^{35}S]methionine (GE Health Care)

[^{3}H]leucine (GE Health Care)

^{125}I-insulin (GE Health Care)

Protein A-Sepharose Fast Flow (GE Health Care)

Protein G-Sepharose Fast Flow (GE Health Care)

NAP-5 column (GE Health Care)

48-well PCR plate (Fisher)

96-well filtration plates (Fisher)

Bottle-top 500-ml filter units (Fisher)

TopSeal (Perkin-Elmer)

MicroScint-20 (Perkin-Elmer)

TopCount beta counter (Perkin-Elmer)

Vacuum-operated 96-well plate washer (Millipore)

96-well plate shaker (Wallac-Delfi)

GAA and ICA512AA Assay

General Principle

Labeled GAD65 and ICA512 are produced by in vitro transcription/translation with differential labeling (^{3}H-GAD65 and ^{35}S-ICA512). The patient serum is incubated with the labeled

antigens together overnight, and antibody-bound labeled antigens are separated from unbound labeled antigens with protein A-Sepharose precipitation in a 96-well plate. Radioactivity is counted on a 96-well plate beta counter. Emission spectra of ^{35}S and ^{3}H partially overlap and can be corrected, allowing simultaneous measurement of antibodies against the two antigens. Results are expressed as standard World Health Organization (WHO) units as in DASP workshops and are described in detail in the procedure below. Many laboratories are currently still using their own index that adjusts the counts per minute of the test serum for the counts per minute of positive and negative control sera in each assay with the following formula: (cpm of the test serum – cpm of the negative serum)/(cpm of positive serum – cpm of the negative serum), where cpm is counts per minute. A cutoff for positivity above the 99th percentile of normal controls is often utilized.

Procedure

Part I: In vitro transcription/translation to produce labeled GAD65 and ICA512 (IA-2)

IMPORTANT NOTES. All reagents, tubes, and tips must be RNase free. All reagents should be kept on ice while on the bench. An incubation temperature of 30°C is critical for production efficiency. The reticulocyte lysate must be stored at −80°C and thawed rapidly just before use. Each tube can be thawed only twice, after which there will be a significant decrease in its efficiency.

PROCEDURE

1. Follow the kit protocol for one-step in vitro transcription/translation. The total reaction volume can be adjusted (decreased or increased) as needed.
2. Purify the labeled product with the NAP-5 column.
3. Analyze the activity of labeled antigen by trichloroacetic acid precipitation as described in the kit protocol. The labeling efficiency significantly varies with different cDNAs and plasmids.

Part II: Radioassay (2 days)

DAY 1

1. Prepare antigen-buffer solution: With the optimized condition, 20,000 cpm in 50 μl of buffer is usually applied per well. For a 96-well plate with 25% extra volume to ensure enough volume for aliquoting into each well, the total counts per minute is $96 \times 20,000 \text{ cpm} \times 125\%$, i.e., 2.4×10^6 cpm for both ^{3}H-GAD65 and ^{35}S-ICA512; the total volume is $96 \times 50 \text{ μl} \times 125\%$, i.e., 6 ml.
2. Prepare the serial dilution of a calibrated standard serum with known WHO unit. The calibrated standard sera with known WHO units in serial dilution are available from the Centers for Disease Control and Prevention and many laboratories. We recommend a standard curve covering a wide range of antibody levels with calibrated standard serum in each assay.
3. Incubation of serum with antigen-buffer: One well per serum sample will be used for incubation and then split into two wells during precipitation with protein A-Sepharose. Add 5 μl of serum and 125 μl of antigen-assay buffer (150 mM NaCl, 20 mM Tris-HCl, 0.1% BSA, and 0.1% sodium azide, pH 7.4) containing both ^{3}H-GAD65 and ^{35}S-ICA512 into a 48-well PCR plate and incubate overnight at 4°C. The standard positive control and negative control serum samples for both GAA and ICA512AA must be included in each

assay, and only one corresponding labeled antigen is added into these control wells, from which the spill rates of ^{3}H and ^{35}S into two windows of the beta counter will be obtained.

4. Preparation of 96-well filtration plates: Coat the plate with BSA by adding 200 μl of assay buffer to each well, put the plate on aluminum foil, and incubate overnight at room temperature.
5. Preparation of protein A-Sepharose: Use only plastic tubes because the protein A sticks to glass. Pull 20 ml of protein A-Sepharose into a 50-ml tube, spin the solution down at 1,500 rpm for 3 min, remove the fluid phase, and resuspend into assay buffer. Repeat this twice and make a final 50% (vol/vol) solution of protein A-Sepharose assay buffer.

DAY 2

1. Remove the assay buffer from the 96-well filtration plate and add 25 μl of well-mixed 50% protein A-Sepharose to each well.
2. Transfer 50 μl from each well of the overnight incubation to two wells on the 96-well filtration plate, and shake the plate on a plate shaker at low speed for 45 min at 4°C.
3. Place the plate on a vacuum plate washer and wash the plate three times with 200 μl of assay buffer per well each time. Then remove the plate, add 100 μl of assay buffer per well, and shake the plate for at least 5 min at 4°C.
4. Wash the plate two more times with 200 μl of assay buffer per well each time, change the plate orientation, and wash the plate another two times.
5. Blot the plate on a paper towel and place the plate under a lamp for around 15 min. After drying, add 30 μl of scintillation liquid (MicroScint-20) to each well, seal the plate with a piece of TopSeal, and count the plate on a TopCount beta counter with window A set at 2.9 to 10 for ^{3}H and window B set at 10 to 256 for ^{35}S.
6. Obtain the counts-per-minute distribution of ^{3}H and ^{35}S in windows A and B from positive control wells in which only one corresponding labeled antigen was added. Correct the spill rate and calculate the ^{3}H and ^{35}S counts per minute for each sample well.
7. Calculate the index with the following formula: (cpm of the test serum – cpm of the negative serum) / (cpm of positive serum – cpm of the negative serum).
8. Calculate WHO units: Using the counts per minute from the serial dilution (seven to nine points) of a calibrated standard serum with known WHO units, plot a chart with $\log_2$ (WHO units) versus counts per minute in Excel as in Fig. 12. With the curve formula, $\log_2$ units can be calculated for each test sample by replacing "x" in the formula with the counts per minute of the test sample and then converting $\log_2$ units into WHO units by anti-$\log_2$ (power 2).

Standardization, Quality Control, and Quality Assurance

1. The laboratory should keep enough volume of the calibrated standard sera and positive and negative control sera for long-term use. Each of these serum samples should be aliquoted and stored at −20°C.
2. All the assays are run in duplicate, with a standard curve for WHO unit calculation and including positive and negative control samples for quality control and for lab index calculation. In our assay, GAA positivity is any value greater than index 0.032 and ICA512AA value greater than 0.049.
3. The results of analysis of negative and positive controls should be monitored to detect drift and evaluate assay
FIGURE 12 Standard curve for calculation of WHO units. The *x* axis shows the counts per minute from the assay after removing the background counts per minute, and the *y* axis shows known $\log_2$ WHO units.

performance. Our positive control range for both GAA and ICA512 is an index of 1.0 ($\pm 25\%$) (0.75 to 1.25). The negative control must be less than the 99th percentile of normal controls for the assay results to be valid (e.g., <0.032 [GAD65Ab] or <0.05 [ICA512] for our assay and index standards).

4. Every positive sample in the first assay is confirmed by retesting that sample in a different assay. If the confirmatory assay result is negative, a third run is performed. We utilize the results of two assays which agree (negative and negative or positive and positive) for the determination of a positive or negative result.

mIAA Assay

General Principle

The mIAA assay is a competitive radioassay. The patient serum is incubated with ^{125}I-insulin with and without cold human insulin overnight, and antibody-bound labeled antigens are separated from unbound labeled antigens with protein A/G-Sepharose precipitation in a 96-well plate. Radioactivity is counted directly on a 96-well plate beta counter for the β emission of ^{125}I. The levels are expressed as index that adjusts the delta counts per minute of the test serum for the delta counts per minute of positive and negative control sera in a particular assay. A WHO unit is not available for IAA at present.

Procedure (2 Days)

Day 1

1. Prepare ^{125}I-insulin-buffer solution with and without cold human insulin: Use 1 ml of 5% BSA in PBS to dissolve the powder of 10 μCi of ^{125}I-insulin as stock solution. We utilize 20,000 cpm in 30 μl of buffer per well. For a 96-well plate with 10% extra to ensure enough volume for aliquoting into each well, the total counts per minute is $96 \times 20,000$ cpm $\times$ 110%, i.e., 2.1×10^6 cpm, which is equal to 160 μl of ^{125}I-insulin stock solution; the total volume is 96×30 μl $\times$ 110%, i.e., 3.2 ml, which needs to be divided in half (half with and half without cold human insulin [100 U/ml]) as follows:

1,520 μl of buffer 1	1,392 μl of buffer 1
80 μl of ^{125}I-insulin	80 μl of ^{125}I-insulin
1.6 ml	128 μl of cold insulin
	1.6 ml

2. Incubation of serum with antigen buffer: Four wells per serum sample are used for both competition and noncompetition in duplicate. Add 6 μl of serum and 30 μl of antigen assay buffer (150 mM NaCl, 20 mM Tris-HCl, 1% BSA, and 0.1% sodium azide, pH 7.4) to a 96-well PCR plate, mix well, keep at room temperature for 2 h, and then incubate overnight at 4°C. The index positive control and negative control serum samples must be included in each assay.

3. Preparation of 96-well filtration plates: Coat the plate with BSA by adding 200 μl of assay buffer to each well, put the plate on an aluminum foil sheet, and incubate overnight at room temperature.

4. Preparation of protein A/G-Sepharose: Use only plastic tubes because proteins A and G stick to glass. Pull 20 ml of protein A-Sepharose and 5 ml of protein G-Sepharose into two 50-ml tubes, spin the solution down at 1,500 rpm for 3 min, remove the fluid phase, and resuspend into assay buffer. Repeat this twice and make a final 62.5% (vol/vol) solution for protein A-Sepharose with assay buffer and a 40% (vol/vol) solution for protein G-Sepharose. Mix 4 parts protein A-Sepharose solution with 1 part protein G-Sepharose solution to form a final working solution with 50% (vol/vol) protein A-Sepharose and 8% protein G-Sepharose.

Day 2

1. Remove the assay buffer from the 96-well filtration plate and add 50 μl of well-mixed protein A/G-Sepharose to each well.

2. Transfer 30 μl from each well of the overnight incubation to a corresponding well on the 96-well filtration plate, and shake the plate on a plate shaker at low speed for 45 min at 4°C.

3. Place the plate on a vacuum plate washer and wash the plate three times with 200 μl of washing buffer (150 mM NaCl, 20 mM Tris-HCl, 0.1% BSA, and 0.1% sodium azide, pH 7.4) per well each time. Then remove the plate, add 100 μl of assay buffer per well, and shake the plate for at least 5 min at 4°C.

4. Wash the plate two more times with 200 μl of assay buffer per well each time, change the plate orientation, and wash the plate another two times.

5. Blot the plate on a paper towel and place the plate under a lamp for around 15 min. After drying, add 50 μl of scintillation liquid (MicroScint-20) to each well, seal the plate with a piece of TopSeal, and count the plate on a TopCount beta counter.

6. Calculate the index with the following formula: (Δcpm of test sample −Δcpm of negative control) / (Δcpm of negative control −Δcpm of negative control).

Standardization, Quality Control, and Quality Assurance

1. The laboratory should keep enough volume of the positive and negative control sera for long-term use. Each of these serum samples should be aliquoted and stored at −20°C.

2. All of the assays are run in duplicate and must include positive and negative control samples. In our assay, mIAA positivity is any value greater than index 0.010, the 99th percentile of normal controls.

3. The results of controls should be monitored to detect drift and general assay performance. In addition to the index of positive and negative control samples, a pair of standard positive and negative serum samples were included in each assay in our laboratory. The standard positive serum is at

very low level of mIAA. The acceptable standard low positive control range is an index of 0.02 to 0.08 for our low-positive standard. The negative control must be <0.01 for results of the assay run to be utilized.

4. Every positive sample in the first run is confirmed by retesting that sample in a different assay. If the confirmatory assay comes out negative, a third assay is necessary. The results of two assays which agree (positive and positive or negative and negative) will be the final determination of positivity or negativity.

New Technology

ELISA

For most autoimmune disorders and for basic immunologic research, ELISAs employing plate-bound antigen are popular. Many laboratories and biotech companies have adopted this method for anti-islet autoantibody assays, and different ELISA kits are available. Multiple workshops utilizing sera from patients with type 1 diabetes and multiple mouse strains have demonstrated that standard ELISA formats lack both sensitivity and specificity compared to fluid-phase radioassay formats. For IAA, the ELISA formats were able to detect high-capacity antibodies following insulin immunization (e.g., therapy with subcutaneous injections of human insulin), but not the IAA of prediabetic individuals. To date in international workshops only one ELISA kit for GAA has attained a level of specificity and sensitivity equivalent to those of the radioassay. This assay depends on using a free antibody arm to capture biotinylated GAD (developed by Kronus and published in May of 2003 [30]). In brief, the ELISA plate was coated with GAD65 protein, and 25 μl of test serum was added for incubation with shaking for 1 h at room temperature. The wells were then washed three times with washing buffer, and 100 μl of biotinylated GAD65 was added. After a further 1-h incubation, the plate wells were washed three times and incubated for 20 min with 100 μl of streptavidin peroxidase conjugate. A wash step was then followed by addition of 100 μl of tetramethylbenzidine and, after 20 min, 100 μl of 0.5-mol/liter H_2SO_4 and measurement of absorbance at 405 and 450 nm. This "ELISA" is actually a form of fluid-phase reaction of labeled antigen with bound autoantibody with specificity enhanced by the requirement for each arm of the immunoglobulin to react with antigen.

Epitope Assays

Comparisons of the epitope repertoires of autoantibodies to insulin, GAD65 and ICA512, provide a tool to further analyze type 1 diabetes-related autoantibodies (23, 35, 47). Most sera from type 1 diabetes patients only target GAD65 protein epitopes dependent on protein conformation and do not bind GAD65 protein fragments or react with denatured GAD65 protein with immunoblotting. In contrast, sera from patients with stiff man syndrome have antibodies that bind GAD65 protein fragments consisting of N-terminal, middle, and C-terminal regions. The majority of sera from type 1 diabetes patients target more than two epitopes on ICA512 molecules, while non-disease-related antibodies usually react with only one epitope. For the methodology of these epitope assays, laboratories usually use the same radioimmunoassay format as described above with cloned protein fragments containing the epitope to be utilized or with a chimerical protein (e.g., GAD65/GAD67, which contains epitopes of GAD65 and sequences of non-antibody-reactive GAD67 to retain protein conformation). For IAA epitope

testing, proinsulin, insulin analogs, and insulin molecules from different spices are used as competitive inhibitors in the regular IAA radioassay.

Autoantibody Subclass and Isotype Determination

There were some reports that there is heterogeneity of immunoglobulin subclass antibodies to GAD65 in newly diagnosed type 1A diabetic patients and ICA-positive first-degree relatives who progressed or did not progress to diabetes (32). New-onset diabetics and progressors were found to have a predominance of IgG1, GAA, and ICA, while nonprogressors had predominantly IgG2 and/or IgG4. A recent study on IAA also indicated that heterogeneity of IgG subclass is related to the risk of developing type 1A diabetes (24).

For the methodology of isotype analysis, a modified standard radioimmunoassay format is used. On day 1, prepare reagent and serum mixtures for overnight incubation at 4°C in two separate tubes. In one tube, incubate 2.5 μl of serum with 25 μl of radiolabeled antigen; in the other tube, incubate 5 μl of biotin-labeled anti-IgG subclass monoclonal antibody with 10 μl of streptavidin-Sepharose (BD Pharmingen), with shaking. On day 2, after washing the Sepharose incubation tube three times, mix two incubations together in a 96-well filtration plate and incubate for 1 h at 4°C, with shaking. The rest of the steps for washing and counting are the same as described above.

Interpretation

Analysis of Data

In general it is important to utilize assays for anti-islet autoimmunity that have high specificity, usually defined as a specificity of ≥99%. Even with specificities set at this level, if one is measuring three different anti-islet autoantibodies, 3% of the "normal" population will be found to express one or more of the autoantibodies. Obviously expression of multiple anti-islet autoantibodies is a relatively rare event, though even here for low-risk populations (1/300 children, for instance, in the United States develop type 1 diabetes) there will be some individuals expressing anti-islet autoantibodies who may never progress to overt diabetes. As with all autoantibody tests it is also important to recognize that for low values, particularly for levels just above the cutoff points for defined "positivity," a repeat assay of the same sample (particularly for low-risk populations) may fail to confirm the presence of the autoantibody as often as one-third of the time (27). Repeat analysis of an independent sample is important for assessing risk, as subjects with "transient" islet autoantibodies are at relatively low risk. After the onset of type 1A diabetes a significant subset of patients lose (over decades) their GAD65 and ICA512 anti-islet autoantibodies.

A major caveat is that insulin antibodies appear in most individuals treated with subcutaneous insulin (even human insulin). Thus, after approximately 10 days of insulin therapy, the presence of insulin antibodies (which cannot be distinguished from autoantibodies with current assays) cannot be used to diagnose type 1A diabetes.

Clinical Application

Anti-islet autoantibodies find their primary application in the differential diagnosis of the forms of diabetes and in predicting risk of progression to overt diabetes.

It is clear that adults presenting with diabetes who express anti-islet autoantibodies (in particular GAD65 autoantibodies) more rapidly progress to utilization of insulin compared to typical patients with type 2 diabetes (43). Such adults

with "type 1A" diabetes are termed LADA patients (for latent autoimmune diabetes of adults). In a similar manner, a significant number of obese children presenting with diabetes do not have anti-islet autoantibodies and appear to have forms of type 2 diabetes (41), and it is likely that this will become an increasingly common problem. For many endocrinologists, having the diagnosis, for example, of atypical type 1A diabetes (e.g., LADA) leads to the immediate initiation of insulin therapy rather than a trial of oral hypoglycemic agents. For children with presumed type 2 diabetes who lack all anti-islet autoantibodies and have evidence of insulin resistance, there are trials evaluating oral medications such as metformin. In addition, a diagnosis of type 1A diabetes alerts one to the risk of accompanying autoimmune disorders (e.g., thyroid autoimmunity in 1/4, celiac disease in 1/20, and Addison's disease in approximately 1/200). Relatives who are being evaluated for renal donation to a patient with type 1A diabetes may express anti-islet autoantibodies, and knowledge of increased diabetes risk may influence donor considerations. In addition, young children expressing anti-islet autoantibodies should be carefully monitored for metabolic abnormalities (e.g., glucose determination at 3-month intervals), as early diagnosis of diabetes can prevent hospitalization with ketoacidosis.

Autoantibodies to Glycolipids in Peripheral Neuropathy

HUGH J. WILLISON

121

Peripheral neuropathies constitute a diverse group of diseases caused by a wide range of genetic, toxic, metabolic, and inflammatory insults to the peripheral nervous system. A considerable proportion of neuropathies are believed to have an autoimmune basis, either as a feature of systemic autoimmune diseases, vasculitides, paraneoplastic or postinfectious syndromes, in association with lymphoproliferative diseases, or as isolated peripheral nerve syndromes. In clinical practice, the cause of sporadic neuropathies is often obscure, resulting in the frequent use of multiple screening tests to aid in diagnosis. Over the last 15 years, there has been a widespread increase in the use of antiganglioside antibody assays as diagnostic tools, based on the recognition from research studies that gangliosides are important autoantigens in many patients with autoimmune peripheral nerve disorders (20).

Early progess in this field stemmed from the discovery that immunoglobulin M (IgM) paraproteins with anti-myelin-associated glycoprotein (anti-MAG) activity present in patients with IgM paraproteinemic neuropathy also reacted with carbohydrate epitopes on a sulfated glucuronic acid-containing glycosphingolipid termed sulfated glucuronyl paragloboside (SGPG) (10). Further studies soon showed that cases of IgM paraproteinemic neuropathy that were anti-MAG or anti-SGPG antibody negative often had antibodies reactive with various other glycolipid and ganglioside antigens. Anti-GM1 ganglioside IgM antibodies were then found in a large proportion of patients with a syndrome termed multifocal motor neuropathy (MMN), thereby catalyzing a vast body of clinical research into the association between anti-GM1 antibodies and other motor nerve syndromes (12). At the same time, interest centered on identifying antiganglioside antibodies in Guillain-Barré syndrome (GBS) and its variant forms, including Miller-Fisher syndrome (MFS) (3, 5), an area of research that remains highly topical.

Both preceding and in parallel with this evolving field of neuropathy research and clinical practice, antiganglioside and antiglycolipid antibodies have also been reported in a vast range of other diseases and syndromes, as well as for persons of normal health (8, 11). Antiglycolipid antibodies are viewed as forming an important part of the natural autoantibody repertoire directed towards microbial carbohydrate structures, which has the potential to be expanded in both specific and nonspecific ways. This may explain their ubiquitous presence in both healthy and diseased patient populations and may account for some of the misleading studies that have claimed disease-specific associations, further confounded by technical difficulties in their measurement. This chapter only addresses their relationship to autoimmune neuropathy, for which diagnostic testing is widespread.

Table 1 displays the main clinical syndromes in which a well-defined antiglycolipid antibody specificity has been identified. In patients with IgM paraproteinemic demyelinating neuropathy, paraproteins with anti-MAG activity also react with carbohydrate epitopes on SGPG and its higher lactosaminyl homologue SGLPG. Another paraproteinemic neuropathy syndrome is a chronic large fiber sensory neuropathy with prominent ataxia (18). The IgM paraprotein reacts with gangliosides bearing NeuNAc(α2-8)NeuNAc-linked disialosyl groups, including, but not limited to, GD3, GD1b, GT1a, GT1b, and GQ1b. The patients may also have cold agglutinin syndrome by virtue of the presence of sialylated glycan epitopes on human red blood cells with which the IgM paraproteins can cross-react. Ophthalmoplegia is also variably present in this syndrome.

In MMN with demyelinating conduction block, antibodies to GM1 ganglioside are present in about half of the cases (9). Patients with MMN and anti-GM1 antibodies are mostly male and have a clinical picture comprising a chronic asymmetric motor syndrome, usually with distal onset in an upper limb. The average age of onset is in the fourth decade and the illness runs an indolent course, with patients usually remaining ambulant and physically independent 10 to 20 years after onset. The electrophysiological examination classically shows focal motor conduction block, and intravenous human immunoglobulin is standard therapy.

A wide variety of antiganglioside and antiglycolipid antibodies have been reported in up to 50% of GBS cases in many series (4, 21). Antibodies against GM1, GD1a, GM1b, and GalNAc-GD1a mark a form of GBS with prominent motor axonal involvement, now called AMAN (acute motor axonal neuropathy). In MFS, an acute self-limiting variant of GBS comprising ataxia, areflexia, and ophthalmoplegia, anti-GQ1b and anti-GT1a IgG antibodies are present in over 90% of cases; the antibodies also react with GD1b and/or GD3 in about half the cases (3, 20).

As research into clinical-serological associations between neuropathy phenotypes and antiglycolipid antibodies

TABLE 1 Clinical syndromes associated with specific antiglycolipid autoantibodies

Clinical syndrome	Antibody specificity	Antibody isotype
Chronic sensorimotor demyelinating neuropathy	MAG, SGPG, SGLPG	IgM (monoclonal)
Chronic ataxic neuropathy	NeuNAc(α2-8)NeuNAc epitopes on GD1b, GD3 GQ1b, GT1b, GT1a, and GD2	IgM (monoclonal)
MMN	Gal(β1-3)GalNAc epitopes on GM1, GA1, and GD1b	IgM
Chronic motor neuropathy	GM2, GalNAc-GM1b, and GalNAc-GD1a	IgM
AMAN	GM1a, GM1b, GD1a, and GalNAc-GD1a	IgG
Demyelinating GBS	GalC, LM1, SGPG, GM1, and GM2	IgG
MFS	GQ1b, GT1a, GD3, and GD1b	IgG

evolves, it is likely that more requests for clinical testing will enter the diagnostic laboratory. The most commonly sought antibodies at present are to GM1 and GQ1b gangliosides.

METHODS

Sample Requirements

Antiganglioside antibodies are best measured in serum, although they can also be estimated in plasma. Cerebrospinal fluid may contain small amounts of antiganglioside antibody (filtered from the systemic circulation), but there is no evidence to indicate any local intrathecal synthesis of antibody, and measurement in cerebrospinal fluid has no advantage over measurement in serum. Serum antiganglioside antibodies are stable for short periods (i.e., days) at standard ambient temperature and can be stored at 4°C for 1 to 2 weeks without adverse effect. Interlaboratory shipping of serum can be conducted at ambient temperature. Repeated freeze-thawing prior to testing should be avoided. In chronic peripheral neuropathy syndromes, antiganglioside antibodies are usually IgM, occurring either as paraproteins (often monoclonal gammopathies of undetermined significance) or as polyclonal antibodies. Measurement can be performed at any stage of the clinical illness. In acute-onset, self-limiting neuropathies such as

GBS, the antiganglioside antibodies are usually IgG but may be IgM or IgA. They are at highest titer at clinical onset and then disappear over ensuing weeks or months and should therefore be sought immediately after clinical presentation, ideally before any therapeutic intervention. Plasma exchange or intravenous immunoglobulin therapy may substantially reduce or mask titers.

Materials and Reagents

Gangliosides are sialic acid-containing glycosphingolipids composed of a long-chain aliphatic amine, ceramide, attached to between one and five hexoses, at least one of which must be sialylated. It is the presence of a sialic acid molecule(s) attached to a galactose residue(s) in the hexose core which defines a glycosphingolipid as a ganglioside. In the human nervous system, the sialic acid is *N*-acetylneuraminic acid (NeuNAc). Common structures are shown in Table 2. Ganglioside nomenclature is according to that of Svennerholm (6), in which the prefix G refers to ganglio; M, D, T, and Q refer to the number of sialic acid molecules (mono, di, tri, and quad); and the Arabic numerals and lowercase letters refer to the order of migration of the gangliosides on thin-layer chromatograms (TLC).

Although total chemical or enzymatic synthesis of gangliosides is possible in specialized laboratories, most diagnostic laboratories purchase purified gangliosides from commercial

TABLE 2 Examples of clinically relevant ganglioside structures

Name	Carbohydrate sequence
GM1	Gal(β1-3)GalNAc(β1-4)Gal(β1-4)Glc(β1-1) ceramide (α2-3) NeuNAc
GD1a	Gal(β1-3)GalNAc(β1-4)Gal(β1-4)Glc(β1-1) ceramide (α2-3) (α2-3) NeuNAc NeuNAc
GD1b	Gal(β1-3)GalNAc(β1-4)Gal(β1-4)Glc(β1-1) ceramide (α2-3) NeuNAc (α2-8)
GQ1b	Gal(β1-3)GalNAc(β1-4)Gal(β1-4)Glc(β1-1) ceramide (α2-3) (α2-3) NeuNAc NeuNAc (α2-8) (α2-8) NeuNAc NeuNAc

sources or purify them from bovine brain. Chloroform-methanol extraction followed by DEAE-Sephadex chromatography is one of several commonly used procedures (14). Characterization is aided by chemical and enzymatic derivatization, TLC, and more sophisticated techniques such as fast atom bombardment mass spectrometry and high-performance liquid chromatography. The major gangliosides in brain are GM1, GD1a, GD1b, and GT1b, but there are also many minor gangliosides in both brain and peripheral nerve and in other tissues.

Gangliosides can be purchased from a wide variety of commercial sources. Rare gangliosides should be sought by personal requests to relevant investigators. Many preparations are only partially pure; for example, commercial preparations of GT1a and GT1b are often contaminated by significant amounts of GQ1b and vice versa. Care should be taken to control for this in nondiscriminatory immunoassays, such as enzyme-linked immunosorbent assays (ELISAs) or dot blots.

Antiganglioside autoantibodies are referred to by their specificity, either in terms of individual gangliosides (e.g., anti-GM1 IgG antibodies) or in terms of the reactive carbohydrate epitope [e.g., anti-Gal(β1-3)GalNAc IgM antibodies]. When generalizing, it is often more appropriate to use the term antiglycolipid antibodies (as opposed to antiganglioside antibodies), since many neuropathy-associated autoantibodies react with glycolipids which are not strictly gangliosides, such as SGPG, sulfatide, asialo-GM1, and galactocerebroside, as these molecules do not contain sialic acid.

The Current Procedure

Methodology for antibody detection presents difficulties, largely because the physical properties of gangliosides do not lend themselves well to development of uniform assays. Although antiganglioside antibodies can be detected by a variety of different methods, the principal and most commonly used screening method is ELISA (13, 19). A typical ELISA procedure is as follows.

1. Using a standard 96-well ELISA plate selected for high glycolipid binding properties (e.g., Immulon 2; Dynatech), coat each well of rows A, C, E, and G with 200 ng of GM1 or GQ1b in 100 μl of 100% ethanol and each well of rows B, D, F, and H with 100 μl of 100% ethanol alone by evaporation to dryness at room temperature, and then store at least overnight at 4°C. Coated plates are stable at 4°C for up to 2 weeks.

2. Block all 96 wells with 200 μl of phosphate-buffered saline–bovine serum albumin (PBS-BSA) (pH 7.4, 1% BSA) for 2 h at 4°C. Discard PBS-BSA by flicking or automated washing.

3. Prepare serum samples by mixing gently and then centrifuge out any fibrin or particulate debris. Dilute test serum to 1/100 in PBS–0.1% BSA, add in duplicate to ganglioside-coated and uncoated wells, and serially dilute from 1/100 to 1/500, 1/2,500, and 1/12,500.

4. Leave test serum to incubate overnight at 4°C.

5. Wash plate six times in PBS wash buffer cooled to 4°C, by dunking and flicking or using an automated washer.

6. Add 100 μl of peroxidase-conjugated anti-human IgM or IgG, diluted to 1/3,000 (dilution optimized by checkerboard analysis) in PBS–0.1% BSA. Incubate for 2 h at 4°C.

7. Wash plate six times in PBS wash buffer.

8. Develop plate by adding substrate solution comprising one 15-mg o-phenylenediamine tablet in 60 ml of citrate buffer with 20 μl of 30% hydrogen peroxide and letting it stand for 20 min.

9. Stop peroxidase reaction with 50 μl of 3 M H_2SO_4.

10. Read optical densities (ODs) in an automated plate reader at 490 nm.

11. Calculate titers by endpoint dilution analysis as follows.

   a. Subtract blank-well ODs from coated-well ODs to obtain working ODs.

   b. Obtain means of working ODs from duplicate wells.

   c. On semilog paper, plot linear ODs (x axis) against the log test serum dilution (y axis).

   d. Draw a best-fit dilution curve and assign the titer to the point at which the dilution curve crosses the OD at 0.1 unit.

There have been some attempts to recommend standard methodology, although most laboratories have established in-house protocols. In multicenter comparative studies there has been fair agreement on clearly positive or negative cases but variable results with borderline samples (22). Important factors in setting up the ELISA include (i) the choice of ELISA plates, including glycolipid binding properties, batch variations, and storage conditions (checks on individual batches of plates are made by using a positive serum sample and calculating the lowest coefficient of variance over the whole plate while giving an optimal signal); (ii) the temperature at which the assay is performed, including all incubation and washing steps, 4°C being most commonly recommended; (iii) the duration of serum incubation, which should be at least 4 h; and (iv) the presence or absence of Tween 20 as a detergent (gangliosides are soluble in detergent and will therefore be removed from the polystyrene plate). Assay results are usually reported as titers calculated by endpoint analysis.

In addition to ELISA, the TLC overlay technique is widely used (17). TLC overlay involves separating glycolipids on aluminum-backed silica plates in a solvent system and then performing an immunoverlay with serum and labeled antibodies. Although not readily amenable to quantitative titration, TLC overlay has the advantage of allowing unambiguous identification of a particular glycolipid and is thus considered the "gold standard" method. This is especially useful when specific glycolipids are not available in pure form. Dot blots are also widely used, but as with TLC, it is harder to obtain readily quantifiable data. A technically straightforward and rapid agglutination assay has recently been reported (2). Antibodies have been recently described that react with ganglioside complexes (7), and the important role of accessory lipids also needs consideration; however, these issues at present remain outside the scope of a routine diagnostic laboratory.

CONSIDERATIONS

There is no antiganglioside antibody investigation that is absolutely essential for diagnosis of a particular subtype of peripheral neuropathy, since independent investigation, principally electrodiagnostic tests in the context of an appropriate clinical picture and exclusion of other causes, is usually adequate. However, an antiganglioside antibody investigation may be useful (i) to confirm a diagnosis, such as MMN, AMAN, or MFS; (ii) to subclassify an existing diagnosis, such as IgM paraproteinemic neuropathy, into those with anti-NeuAc(α2-8)NeuAc activity or anti-SGPG activity, etc.; and (iii) to exclude or differentiate among several possible diagnoses, such as botulism, brain stem demyelinating disease, and MFS (anti-GQ1b antibody testing), or

between MMN and amyotrophic lateral sclerosis (anti-GM1 antibody testing).

INTERPRETATION

A normal range of IgG and IgM titers for each glycolipid antigen must be established within a laboratory since antiglycolipid antibodies form part of the normal autoantibody repertoire and antibodies to some gangliosides may be found at low titer in both normal and disease control sera. The distribution of antiganglioside antibodies in the population does not follow a normal pattern but is skewed, with some control subjects having high antibody levels against some gangliosides (titers of >1/1,000) and most having undetectable levels (titers of <1/100). As a result, defining a clinically meaningful normal range or reference range, even when using logarithmically transformed data, is problematic. In my laboratory we set the upper limit of the normal range as 2 standard deviations above titers obtained using a panel of at least 50 healthy control subjects of all ages and both sexes; for most antiganglioside antibodies this equates with an antibody titer being positive if >1/500 by endpoint dilution analysis (19).

With respect to the sensitivity and specificity of antiganglioside antibodies in particular clinical settings, no clear data are available from large multicenter studies. Some syndromes (e.g., "anti-MAG neuropathy") are to an extent defined by the presence of a particular antiglycolipid antibody. Anti-GQ1b IgG antibodies are a highly sensitive (>90%) and specific (>90%) marker for MFS and related syndromes accompanied by ophthalmoplegia (16). Anti-GM1 IgM antibodies are found in ~50% of cases of MMN (1, 9, 15). Anti-GM1 and anti-GD1a IgG antibodies are very specifically associated with acute motor dominant forms of GBS, including AMAN, occurring in ~50% of cases (4). Anti-MAG antibodies are found in ~50% of cases of IgM paraproteinemic neuropathy, and a proportion of the remainder react with other glycolipid antigens. Anti-GD1b IgM antibodies are highly specific for a rare form of chronic ataxic neuropathy termed CANOMAD, although the sensitivity is unknown.

Detection of Antimitochondrial Autoantibodies in Primary Biliary Cirrhosis and Liver Kidney Microsomal Antibodies in Autoimmune Hepatitis

PATRICK S. C. LEUNG, MICHAEL P. MANNS, ROSS L. COPPEL,
AND M. ERIC GERSHWIN

122

The immunodetection of autoantibodies has been technically difficult because (i) serum autoantibodies from patients usually react to a broad spectrum of antigens, (ii) some of these autoantibodies may have low titers, (iii) the biochemical nature of these autoantigens has been unknown, and (iv) many autoantigens are present at low concentrations and often require sophisticated procedures for their biochemical purification. The development and application of immunohistochemical, biochemical, and molecular biological techniques have redefined approaches for the study of autoimmune diseases, in particular the immunological detection of autoantigens. This is exemplified by two autoimmune diseases of the liver, namely, primary biliary cirrhosis (PBC) and autoimmune hepatitis (AIH) . This chapter will focus on the detection of antimitochondrial antibodies in PBC and the detection of liver-kidney microsomal antibodies (LKM antibodies) in AIH.

PBC

PBC is an autoimmune disease of the liver characterized by autoimmunity-mediated destruction of intrahepatic bile ducts with progressive inflammatory scarring and, eventually, liver function failure (23). Immunologically, PBC is characterized by the presence of antimitochondrial autoantibodies (AMA) in the circulation (32) and the infiltration of T cells into the liver (24, 25). AMA can be detected in >95% of patients with the disease (15, 29). These mitochondrial autoantigens were shown to be the E2 subunits of the 2-oxo-acid dehydrogenase complex (14, 59, 62) (Table 1). Subsequently, extensive molecular and immunological studies of PBC, including cloning of mitochondrial autoantigens (16), antigen-specific isotype studies (52, 59), mapping of B- and T-cell epitopes (10, 21, 28, 30, 48, 53, 56, 57), and analyses of human, murine, and baculovirus monoclonal antibodies (5, 12, 13, 28, 51), have provided valuable information and reagents for an understanding of the immunopathogenesis of PBC as well as for the development of accurate and specific diagnostic reagents with recombinant autoantigens (27, 42, 58). Immunohistochemical studies have shown the presence of either pyruvate dehydrogenase complex subunit E2 (PDC-E2) or a cross-reactive molecule in the luminal region of bile duct epithelial cells (BDEC) for PBC, but not in control cells (4, 5, 22, 41, 55). These data, together with recent reports on apoptotic cleavage of

PDC-E2 in apoptotic BDEC (39, 40, 44), suggest that antibodies targeting BDEC of the PBC liver may be pathogenic. Recently, immunoglobulin G (IgG) and IgA AMA were detected in saliva and urine from patients with PBC, suggesting that a locally driven mucosal response is involved in PBC (46, 54).

DETECTION OF AMA

AMA can be detected by the following methods: (i) indirect immunofluorescence (IF) (61), (ii) immunoblotting (30), and (iii) enzyme-linked immunosorbent assays (ELISAs) (27, 58).

Immunohistochemical Staining for AMA in PBC Sera by IF

Among the various methods of detection of AMA, IF is by far the most commonly used clinical test for AMA and is performed with HEp-2 cells or tissue sections from mice or rats. A detailed protocol is described below.

1. Prepare smears of HEp-2 cells on clean glass slides and air dry.
2. Fix cells in cold acetone for 10 min at 4°C and air dry.
3. Place each glass slide in phosphate-buffered saline (PBS) for 5 min.
4. Apply diluted patient sera (usually 1:40, 1:80, 1:160, 1:320, and 1:640) onto slides and incubate the slides for 60 min at room temperature.
5. Wash the slides with PBS three times for 3 min each time.
6. Apply diluted fluorescein isothiocyanate (FITC)-conjugated goat anti-human IgG with Evans blue, and incubate the slides for 60 min at room temperature.
7. Wash the slides with PBS three times for 3 min each time.
8. Mount samples with 90% glycerol in PBS.
9. Examine samples under a fluorescence microscope.

HEp-2 slides can also be obtained commercially (e.g., Immunoconcepts, Sacramento, Calif., or Immco Diagnostics, Buffalo, N.Y.). Results of a typical IF test with AMA-positive PBC serum on HEp-2 cells are shown in Fig. 1. Alternatively, rat and mouse kidney sections can also be used for immunohistochemical staining for AMA. However, IF lacks the specificity of identifying specific

TABLE 1 Summary of 2-oxo-acid dehydrogenase mitochondrial antigens in PBC

Antigen	Molecular mass (kDa)[a]	Frequency (%) in PBC patients[b]
PDC-E2	70	>95
Branched-chain 2-oxo-acid dehydrogenase complex E2 subunit (BCOADC-E2)	52	53–55
2-Oxo-glutarate dehydrogenase complex E2 subunit (OGDC-E2)	48	39–88
PDC-E1α	41	41–66
E3BP (protein X)	55	>95

[b]Determined from different studies.

antigens. In addition, background levels which are caused by nonspecific binding are common. Therefore, accurate detection of AMA by IF requires serial dilutions of sera (usually 1:40, 1:80, 1:160, 1:320, and 1:640) and also an optimal dilution of FITC-labeled anti-human Ig. The precise optimal dilution of secondary FITC-antibody may also vary from batch to batch. Thorough washing steps and changes of washing solutions are also necessary to reduce the background.

Immunoblotting for Detection of Specific AMA against Mitochondrial Antigens

A total mitochondrial homogenate from mammalian tissues is best suited to testing of AMA by immunoblotting. Briefly, mitochondrial preparations from a bovine heart, rat liver, human placenta, or other tissues are resolved in a sodium dodecyl sulfate (SDS)-polyacrylamide gel, transferred onto nitrocellulose filters, and probed with sera from patients with PBC. AMA reactivity against mitochondrial antigens is usually detected by enzyme-conjugated anti-human Ig and chemiluminescence.

Preparation of Mitochondria from Mammalian Liver

A convenient method for preparing mitochondria is described below.

1. Homogenize rat or mouse liver (15 g) in 30 ml of ice-cold buffer I (0.5 M sorbitol, 0.1 mM EDTA, 50 mM Tris, pH 7.4) and centrifuge the homogenate at $250 \times g$ for 10 min.
2. Filter the supernatant through four layers of cheesecloth.
3. Spin the supernatant at $250 \times g$ for 10 min at 4°C.
4. Take the supernatant and spin it at $8,000 \times g$ for 10 min at 4°C.
5. Resuspend the pellet in 15 ml of buffer I and spin it again as in step 4.
6. Repeat step 5.
7. Resuspend the pellet in 4 ml of buffer I with 0.05% bovine serum albumin (BSA) and store it in a 1-ml aliquot. Store the sample at −20°C; the final concentration should be about 40 to 60 mg/ml.

Test of AMA Reactivity against Mammalian Mitochondria by Immunoblotting

1. Electrophoretically resolve 20 μg of mitochondrial preparations in an SDS–10% polyacrylamide gel, using a preparative comb (Hoefer Scientific, San Francisco, Calif.). Run molecular weight protein standards in parallel.
2. Stop the gel when the bromophenol blue dye reaches the bottom of the gel and transfer the resolved protein onto a nitrocellulose filter.
3. After the transfer, stain the blot with Ponceau S (Sigma, St. Louis, Mo.) to check for the efficiency of transfer. If the transfer is satisfactory, cut 3-mm strips from the blot with a sharp razor blade.
4. Incubate each strip with 1 ml of diluted PBC serum (1:1,000) for 1 h at room temperature. Run positive control sera and negative control sera in parallel.
5. After incubation, wash each strip with PBS containing 0.05% Tween three times for 10 min each time.
FIGURE 1 Detection of AMA by IF on HEp-2 cells. Note the characteristic mitochondrial staining pattern by PBC sera.

6. Incubate each strip with a predetermined optimal dilution of secondary antibody (e.g., enzyme-conjugated secondary antibodies) and wash as in step 5.

7. Detect signals with a substrate for the enzyme-conjugated secondary antibodies. If horseradish peroxidase-conjugated secondary antibodies are used, the blots can be blocked with milk for 10 min after being washed and the signals can be detected by chemiluminescence on X-ray film. Chemiluminescence kits can be obtained from common vendors such as Pierce.

Figure 2 depicts typical patterns of AMA reactivity against various subunits of the 2-oxo-acid dehydrogenase complex. AMA reactivites are directed against the 70-kDa PDC-E2, 55-kDa E3 binding protein (protein X), 52-kDa branched-chain 2-oxo-acid dehydrogenase complex E2 subunit (BCOADC-E2), 48-kDa 2-oxo-glutarate dehydrogenase complex E2 subunit OGDC-E2, and 41-kDa PDC-E1α proteins. Note that sera from PBC patients do not necessarily react to all five mitochondrial autoantigens and that the pattern of reactivity may vary from patient to patient (29, 31).

Test for AMA Reactivity in PBC Sera by ELISA with Recombinant Autoantigens

Several studies have demonstrated the successful application of recombinant proteins as test antigens for PBC by ELISA (20, 30, 43). An ELISA using recombinant proteins is versatile, specific, and sensitive. In addition, ELISA is also efficient and allows the testing of multiple sera at several serial dilutions simultaneously. cDNAs encoding PDC-E2, BCOADC-E2, OGDC-E2, E3BP, and PDC-E1α have been cloned and expressed in *Escherichia coli* with isopropyl-β-D-thiogalactopyranoside (IPTG)-inducible plasmid vectors. Recombinant proteins can be easily purified from IPTG-induced bacterial cultures as described previously (43). Recently, the use of designer molecules (42) expressing AMA-reactive epitopes has greatly facilitated the testing of multiple sera for AMA. The availability and application of recombinant proteins clearly provide the cleanest and most specific reagents for AMA assays.

A standard procedure is as follows:

1. Dilute recombinant antigen to 5 µg/ml in carbonate buffer, pH 9.6.
2. Coat a 96-well ELISA plate with 100 µl of recombinant antigen from step 1/well. Store the plate at 4°C overnight.
3. Wash the plate three times with 100 µl of PBS containing 0.05% Tween (washing buffer). Shake off the washing buffer between washes.
4. Block the plate with 100 ml of 1% BSA in PBS; incubate the plate at room temperature for 1 h.
5. Add test sera (serial dilutions) in PBS containing 1% BSA and 0.05% Tween; incubate the plate at room temperature for 1 h.
6. Wash the plate as in step 3, and then add 100 µl of a predetermined dilution of secondary antibody, such as horseradish peroxidase-conjugated anti-human Ig. Incubate the plate at room temperature for 1 h.
7. Wash the plate as in step 3. The presence of bound AMA can be determined by adding 100 µl of substrate for horseradish peroxidase (e.g., ABTS [2, 2-azinobis 3-ethylbanzthiazoline sulfonic acid] [Sigma]). Incubate the plate for 10 min at room temperature, and stop the reaction by adding 100 µl of 5% SDS. The intensity of color developed can be measured in an ELISA plate reader at 405 nm.

For ELISA, it is necessary to include a positive serum control, a negative serum control, and a well containing no primary antibody to correct any data or values caused by nonspecific binding of antibodies and background. A test serum is considered positive when the optical density reading is at least two times higher than the normal serum reading and the data are reproducible.

INTERPRETATION OF AMA DATA

Although AMA are highly reliable for the diagnosis of PBC, some limitations and precautions are noted below. Firstly, the high titer of AMA and the sensitivity of the test demand
FIGURE 2 Reactivity of PBC sera to bovine heart mitochondria. Bovine heart mitochondria were resolved by SDS-PAGE, transferred to a nitrocellulose filter, and tested for their reactivity with PBC sera (lanes 1 to 5). Note the different patterns of AMA reactivities for various patients with PBC to the 70-kDa PDC-E2, 55-kDa E3 binding protein (protein X), 52-kDa BCOADC-E2, 48-kDa OGDC-E2, and 41-kDa PDC-E1α proteins. Sera from healthy controls do not react to any of these mitochondrial proteins (lane 6).

extreme caution to avoid cross-contamination of sera and false-positive results. Secondly, about 5 to 10% of PBC patients are AMA negative. Other clinical diagnostic features are also critical for a differential diagnosis (Table 2). Thirdly, neither the titer nor the specificity of autoantigens is related to the severity of the disease and therefore cannot be used to monitor the clinical course. Most importantly, positive and negative antibody controls should be included in the assay. Despite these limitations, cloned autoantigens and their recombinant proteins are extremely valuable diagnostic tools for clinicians.

AIH

Chronic hepatitis is a heterogeneous syndrome characterized by clinical, biochemical, and morphological criteria (8). Hepatitis viruses B and C may cause chronic hepatitis. In contrast, AIH, drug-induced hepatitis, and cryptogenic hepatitis are other subgroups of chronic hepatitis that presumably differ etiologically. AIH is a syndrome of unknown etiology. The annual incidence of AIH among Northern Europeans is 1.9 per 100,000. Women are more affected than men, but all ages are susceptible (3). The loss of tolerance against the patient's own liver is regarded as the main pathogenic mechanism. While hitherto poorly defined defects of the immune system are responsible for chronic viral hepatitis, a hyper-reaction of the patient's immune system towards autologous

TABLE 2 Clinical characteristics of PBC

Clinical symptoms
  Skin itching or jaundice appears in some cases
  Portal hypertension and ascites or esophageal varices may
    appear
  Osteoporosis according to the insufficiency of vitamin D or
    calcium may occur

Laboratory data
  Presence of AMA
  Elevation of bile duct-associated enzymes (ALP, γ-GTP) in serum
  Elevation of serum bile acid
  Elevation of total cholesterol
  Elevation of serum IgM

Histological parameter
  Chronic nonsuppurative destructive cholangitis (CNSDC) in
    middle-size interlobular or septal bile ducts, vanishing bile
    ducts, and granulomas

Complications
  Skin xanthoma (especially when hypercholesterolemia continues)
  Autoimmune diseases such as Sjögren syndrome, rheumatoid
    arthritis, and chronic thyroiditis also occur

Diagnosis
  The patient is determined to have PBC when one of the following features is recognized.
    1. CNSDC is recognized in a liver specimen, and laboratory
      data are compatible with PBC. In some rare cases, the AMA
      test is negative.
    2. AMA or anti-pyruvate dehydrogenase antibody test is
      positive, and liver histology is compatible with PBC even
      though CNSDC is not recognized.
    3. AMA or anti-pyruvate dehydrogenase antibody test is
      positive and clinical features or present history is compatible
      with PBC even though liver histology is not checked.

TABLE 3 Diagnostic criteria for AIH

Parameter[a]	Score[b]
Hypergammaglobulinemia	+3
Autoantibodies	
ANA, SMA, LKM-1	+3

[b]If the total value of scores is >15 before or >17 after therapy, then AIH is certain; if the total value of scores is 10 to 15 before or 12 to 17 after therapy, then AIH is probable.

liver tissue is responsible for autoimmune hepatitis (9). Autoantibodies are the hallmarks of the diagnosis of autoimmune hepatitis (Table 3). It is debated whether different patterns of autoantibodies characterize clinically or etiologically distinct subgroups of autoimmune hepatitis (6, 19, 34). For example, antinuclear antibodies (ANA) are very heterogeneous, but their association with autoimmune liver diseases has not been identified, whereas smooth muscle antibodies (SMA) in autoimmune liver diseases are particularly directed against F-actin. Serologically, AIH can be divided into the following three subgroups: antinuclear and smooth muscle antibody positive (ANA/SMA; type 1), liver-kidney microsomal antibody positive (LKM-1; type 2), and soluble liver antigen/liver-pancreas antigen antibody positive (SLA/LP; type 3) (49). However, there are no significant clinical implications resulting from this classification. Recently, significant progress has been achieved in the characterization of microsomal antigens associated with liver diseases (Table 4). Three members of the cytochrome P450 supergene family and two members of the UDP-glucuronosyl-transferases (UGTs) have been identified as hepatocellular autoantigens. These antigens are of particular interest since they characterize subgroups of autoimmune hepatitis and some forms of drug-induced hepatitis and also occur in a small proportion of patients with chronic viral hepatitis C or D (33). Recent data showed that autoantibodies to SLA (anti-SLA) and autoantibodies to a cytoplasmic antigen shared by the liver and pancreas (anti-LP) recognize the same target antigen, which was identified as a non-liver-specific cytosolic UGA-suppressor tRNA-associated protein (60).

LKM antibodies have been defined due to their typical immunofluorescent staining of liver and kidney tissue. LKM-1 antibodies homogeneously stain the whole liver lobule and the proximal renal tubule (47). They react mainly with human cytochrome P450 2D6 (18, 35). LKM-2 antibodies react with cytochrome P450 IIC9 (2), and LM antibodies react with liver-specific cytochrome P450 IA2 (37). LKM-3 antibodies react with a major autoepitope on family 1 UGTs, and some sera react in addition with a minor epitope on family 2 UGTs (45). LKM-1 antibodies are serological markers of

TABLE 4 Heterogeneity of microsomal antigens

Antibody	Size (kDa)	Target antigen	Associated disease
LKM-1	50	Cytochrome P450 2D6	AIH type II (hepatitis C)
LKM-2	50	Cytochrome P450 2C9	Ticrynafen-induced hepatitis
LKM-3	55	Family 1 UGT	Hepatitis D-associated AIH
LM	52	Cytochrome P450 1A2	Dihydralazine-induced hepatitis (AIH), autoimmune polyendocrine syndrome type 1 (APS-1)
Unknown	50	Cytochrome P450 2A6	Autoimmune polyendocrine syndrome type1, hepatitis C
	57	Disulfide isomerase	Halothane-induced hepatitis
	59	Carboxylesterase	Halothane-induced hepatitis
	59	Unknown	Chronic hepatitis C
	64	Unknown	AIH
	70	Unknown	Chronic hepatitis C

autoimmune hepatitis type 2 (Table 4), a syndrome that frequently starts in childhood. In autoimmune hepatitis, the main epitope is an eight-amino-acid linear epitope that shares sequence homology with the immediate-early protein of herpes simplex virus type 1 (IE 175). LKM-1 antibodies occur in 0 to 7% of patients with hepatitis C; these microsomal antibodies react either with a larger sequence of P450 IIC9, other epitopes on this protein, or conformational epitopes that are not recognized on immunoblots. Furthermore, sera from patients with hepatitis C may react with other microsomal proteins. LKM-2 antibodies did occur in a drug-induced form of hepatitis caused by a diuretic drug called tienilic acid which has only been used in the United States and France. The drug has been withdrawn from the market, and thus these antibodies have only been described in France. LKM-3 antibodies are associated with 5 to 13% of patients with chronic hepatitis D and also occur in some patients with autoimmune hepatitis type 2 (Table 4). In rare cases, they may be the only marker of autoimmune hepatitis (50). LM antibodies occur in a proportion of patients with autoimmune hepatitis type 2 and drug-induced hepatitis caused by dihydralazine. Interestingly, like the case for LKM-1 antibodies, these LKM-3 autoantibodies in autoimmune liver diseases have a higher titer, because the autoepitope is linear and small, than low-titer antibodies to conformational epitopes in viral hepatitis. It is unknown whether LKM antibodies are involved in pathogenesis. It is likely that the antibodies themselves do not mediate tissue destruction, but rather that tissue damage is mediated by liver-infiltrating T lymphocytes, possibly directed against cytochrome P450 molecules.

METHODS OF DETECTION OF LKM ANTIBODIES

LKM autoantibodies can be detected by the following methods: (i) IF (47), (ii) competitive ELISA (17, 36), (iii) immunoblotting with human liver microsomes (1, 26), and (iv) immunoblotting with recombinant antigens (35, 38).

Detection of LKM Autoantibodies in AIH by IF

IF (38, 47) on rat liver and kidney sections is commonly used to detect LKM autoantibodies in patients with autoimmune hepatitis. Patient sera are serially diluted 1:40, 1:80, and 1:160. Additionally, the optimal dilution of the FITC-conjugated secondary antibody must be determined for each batch of

antibody to avoid strong background fluorescence, which makes the evaluation of LKM-positive sera difficult. The method is described in detail below.

1. Prepare frozen sections from rat livers and kidneys on glass slides and air dry.
2. Apply patient sera to slides at the appropriate dilutions and incubate the slides at room temperature for 1 h.
3. Wash the slides three times with PBS.
4. Apply FITC-conjugated goat anti-human IgG and incubate the slides for 30 min at room temperature.
5. Wash the slides three times with PBS.
6. Mount the samples with 90% glycerol in PBS.
7. Evaluate slides under a fluorescence microscope.

There are some similarities between AMA and LKM antibodies, which sometimes causes problems to investigators inexperienced in routine immunofluorescence. While LKM antibodies do not stain distal renal tubules, LM antibodies do not stain the kidney at all, since they react with a liver-specific antigen. For IF, LKM antibodies very strongly stain the whole liver lobule (Fig. 3A), while on kidney tissue, they only stain proximal renal tubules (Fig. 3B). In contrast, AMA stain proximal and distal renal tubules. If the medulla of the kidney is not part of the tissue, LKM antibodies may be misdiagnosed as AMA. Since only two childhood cases of PBC have been reported (7), a positive AMA result for children is almost always due to LKM antibodies. If in IF only the liver stains and no reaction is seen in the kidney, one must suspect LM antibodies, which are directed against the liver-specific cytochrome P450 IA2.

Detection of LKM Autoantibodies by Competitive ELISA

An additional method to detect and further differentiate LKM autoantibodies in patient serum is competitive ELISA. An immunoglobulin fraction of serums, e.g., an LKM-1- or LKM-3-positive serum, is used to coat the plates. At the same time, an aliquot of this immunoglobulin fraction is biotinylated.

Preparation of Microsomes from Rat Liver for ELISA

Microsomes from rat liver tissue isolated by differential centrifugation are used as antigens for the competitive ELISA to test for LKM autoantibodies.
FIGURE 3 Detection of LKM antibodies and AMA by IF on cryostat rat liver and kidney sections. (A) Staining of liver lobule by LKM-1 antibodies. (B) Staining of proximal but not distal renal tubules by LKM-1 antibodies.

Procedure

All steps should be done at 4°C.

1. Remove liver and wash in 0.9% NaCl.
2. Homogenize liver in ice-cold 250 mM sucrose.
3. Centrifuge sample for 10 min at $1,800 \times g$.
4. Centrifuge supernatant for 15 min at $12,000 \times g$.
5. Spin supernatant for 60 min at $200,000 \times g$.
6. Resuspend pellet in a small volume of PBS and determine the protein concentration.

Biotinylation and Preparation of IgG Fraction from Patient Sera for ELISA

An IgG fraction is prepared from LKM-1- or LKM-3-positive patient serum by precipitation with ammonium sulfate. An aliquot of this fraction is biotinylated according to the instructions given by the manufacturer.

Procedure

1. Dilute the IgG fraction of an LKM-positive patient serum to a concentration of 20 mg/ml in PBS.
2. Coat an ELISA plate with 50 μl of the IgG fraction/well.
3. Wash the plate once with PBS containing 0.1% Tween.
4. Block the plate with 200 μl of 1% BSA in PBS/well and incubate it for 24 to 48 h at 4°C.
5. Wash the plate once with PBS-Tween.
6. Dilute liver microsomes to a concentration of 100 μg/ml and place them in an ultrasound water bath for 3 min.

7. Add liver microsomes (50 ml/well) and incubate the plate at room temperature for 60 min.
8. Wash the plate two times with PBS-Tween.
9. Dilute patient sera (1:10) in PBS containing 10 mM EDTA, add 50 ml/well, and incubate the plate for 60 min at room temperature.
10. Wash the plate as in step 8.
11. Dilute biotin-labeled immunoglobulin fraction (1 mg/ml) 1:100 in PBS-BSA, add 50 μl/well, and incubate the plate for 60 min at room temperature.
12. Wash the plate three times with PBS-Tween.
13. Dilute avidin peroxidase appropriately in PBS-BSA, add 50 ml/well, and incubate the plate for 60 min; wash the plate as in step 8.
14. Add ABTS (50 ml/well), wait for the color reaction, add stop buffer (100 mM citric acid, pH 2), and measure the color intensity in an ELISA reader at 450 nm.

Immunoblotting with Human Liver Microsomes to Test for LKM

Procedure

1. Prepare liver microsomes as described for ELISA. Instead of rat liver, use a small piece of human liver tissue.
2. Resolve 1 mg of microsomes in sample buffer by SDS–10% polyacrylamide gel electrophoresis (SDS–10% PAGE). In parallel, run a molecular weight standard.
3. Stop the gel when the bromophenol blue dye reaches the bottom of the gel, and transfer the proteins onto a nitrocellulose filter.

4. Cut the nitrocellulose filter into 3-mm strips, block the strips for 60 min in Tris-buffered saline (TBS)–Tween containing 2% milk powder, and then add patient sera, positive control sera, and negative control sera diluted 1:100. Incubate the strips in 1 ml of diluted sera for 60 min at room temperature.

5. Wash each strip three times with TBS-Tween for 5 min each time.

6. Add 1 ml of an appropriately diluted alkaline phosphatase-conjugated goat anti-human IgG and incubate the strip for 60 min at room temperature.

7. Wash the strip three times and then detect the signal by using a substrate for the enzyme-conjugated second antibody, such as NBT/BCIP (Nitro Blue Tetrazolium/S-bromo-4-chloro-indolyl phosphate).

Interpretation

Characteristic LKM-1 autoantibodies react with a 50-kDa microsomal protein of human liver microsomes, and some sera from patients with autoimmune hepatitis type 2 react with a protein of 64 kDa. LKM-1 antibodies in patients with chronic hepatitis C are more heterogeneous (11). They may react with other microsomal proteins of 59 and 70 kDa. Approximately 50% of sera from patients with hepatitis C do not react with human microsomes in immunoblots since these antibodies react with conformational epitopes.

Immunoblotting with Recombinant Liver Antigens

P450 IIC9 (38) and P450 IA2 (37) cDNAs were expressed in *E. coli*. UGT 1.1 cDNA (45) was expressed in baculovirus.

Procedure

1. Resolve 50 mg of recombinant P450 11D6 or IA2 or 200 mg of UGT 1.1 by SDS–10% PAGE. In parallel, run a molecular weight standard.

2. Stop the gel when the bromophenol blue dye reaches the bottom of the gel, and transfer the proteins onto a nitrocellulose filter.

3. Follow steps 3 to 7 from the previous section.

Interpretation

Since almost all cytochrome P450 enzymes have a molecular mass of about 50 kDa, a precise differentiation of different cytochrome P450 antibodies may only be possible if recombinant antigens are used. The identification of cytochrome P450 IA2 as a hepatocellular antigen resulted from the observation that a serum reacted with a 50-kDa protein but not with the recombinant cytochrome P450 IID6. In immunoblots with human liver microsomes, a distinction between P450 IID6 and P450 IA2 was not possible.

GENERAL REAGENTS

PBS, pH 7.4: Dissolve 32 g of NaCl, 0.8 g of KCl, 4.6 g of Na_2PO_4 (anhydrous), and 0.8 g of KH_2PO_4 (anhydrous) in 4 liters of distilled water. Adjust the pH to 7.2 to 7.4.

TBS-Tween: Dissolve 1.2 g of Tris and 8.7 g of NaCl in 1 liter of distilled water. Adjust the pH to 8.0 and add 500 μl of Tween 20.

3% milk in PBS: Dissolve 3 g of nonfat dry milk in 100 ml of PBS. Adjust the pH to 7.2 to 7.4 by adding a few drops of 2 N NaOH.

Carbonate coating buffer: Dissolve 0.8 g of Na_2CO_3, 1.46 g of $NaHCO_3$, and 0.1 g of NaN_3 in distilled water. Adjust to a pH of 9.6 and a final volume of 500 ml.

5× citrate buffer, pH 5.2: Dissolve 50.0 g of citric acid monohydrate and 7.4 g of Na_2HPO_4 in 150 ml of distilled water. Adjust the pH to 5.2. Adjust the final volume to 200 ml.

ABTS substrate: Prepare 1 mM ABTS solution by adding 55 mg of ABTS to 100 ml of citrate buffer. Add hydrogen peroxide to 0.05% immediately before use.

NBT/BCIP substrate: Mix together 33 μl of NBT and 16.5 μl of BCIP in 5 ml of alkaline phosphatase buffer.

Alkaline phosphatase buffer: Dissolve 12.1 g of Tris and 1.0 g of $MgCl_2$ in 1 liter of distilled water. Adjust the pH to 9.5.

Skin Diseases

CARLOS H. NOUSARI AND GRANT J. ANHALT

123

The dermis and epidermis have a dense network of adhesion proteins and fibrous structural proteins that provide mechanical strength to the skin. A number of these adhesion molecules are known to become targets of autoantibodies, and antigen-antibody interactions in the skin lead to the clinical manifestations of autoimmune bullous skin diseases. Demonstration of the characteristic autoantibodies in the tissue and circulating in the blood is the critical diagnostic feature of numerous such diseases. In most of these diseases, the circulating autoantibodies have also been shown, by passive transfer in animal models, to directly cause the characteristic tissue injury. For each of these diseases, we describe the expected findings in tissue and serum and outline immunochemical tests that may be useful in diagnosis. Additionally, there are some inflammatory skin diseases in which immunologic changes have been identified, but these changes are not essential diagnostic features and causality has not been established. These diseases are discussed in brief.

IIF OF SERUM FOR DIAGNOSIS OF SKIN DISEASES

Technical Aspects

Indirect immunofluorescence (IIF) is a semiquantitative procedure whereby a double immunolabeling is performed to evaluate the presence and titer of circulating autoantibodies (16, 46, 73). Blood is drawn into a tube without anticoagulant, and serum is serially diluted with phosphate-buffered saline (PBS) with 0.05% sodium azide. An initial dilution of 1:10 and doubling dilutions thereafter are usually used. Substrates most commonly used are 6-mm frozen sections of monkey skin and esophagus, human skin, guinea pig lip or esophagus, and murine bladder. All nonhuman substrate sections are available from commercial laboratories. Human skin is usually obtained from neonatal foreskins or discarded surgical specimens. Use of multiple substrates may increase the sensitivity of detection of circulating antibodies (3). The sections are incubated with serum dilutions for 30 min at room temperature and then washed with PBS-azide. Antibodies bound to the substrate are detected by incubation with fluorescein isothiocyanate-labeled hyperimmune goat serum (a source of anti-human class-specific immunoglobulins), followed by two washings with PBS (48, 50). Routinely, anti-human immunoglobulin M(IgM), IgG, and IgA are used.

Salt-Split Skin IIF

The sensitivity and specificity of IIF for basement membrane zone (BMZ) autoantibodies when human skin is used are markedly increased by salt splitting the tissue before use. Normal human skin is trimmed into 4-mm squares, the dermis is shaved as thin as possible, the squares are incubated for 48 to 72 h in 1 M NaCl at 4°C, excess salt is removed by washing in PBS-azide, and then the epidermis is manually separated from the dermis. (Additional details are found in chapter 48 of this volume.) The epithelium is placed on the dermis, and the tissue is frozen and sectioned at 6 μm. The use of this substrate for IIF is crucial for the diagnosis of subepidermal bullous diseases characterized by deposition of immunoreactants along the BMZ, e.g., to differentiate bullous pemphigoid (BP) from epidermolysis bullosa acquisita (EBA) (86) and to identify the anti-epiligrin (laminin 5) mucous membrane pemphigoid (MMP) from other types of MMP (57).

Immunochemical Techniques

Immunochemical detection and definition of the antigenic specificity of serum autoantibodies in bullous diseases constitute a powerful way of defining these diseases but are not yet widely used. Research applications of these tests have been common since the early 1980s and generally employ three techniques: Western immunoblotting using sodium dodecyl sulfate (SDS) extracts of skin, immunoprecipitation using metabolically labeled keratinocyte cultures, and enzyme-linked immunosorbent assay (ELISA) using recombinant antigens. These techniques are applicable in those cases where circulating antibodies are present in reasonably high titers (essentially all cases of pemphigus and approximately up to 85% of cases of subepidermal blistering diseases) and provide precise diagnosis by documenting binding of autoantibodies to skin autoantigens, identified by their characteristic molecular weights. Technical problems that have delayed implementation are as follows. (i) These adhesion molecules are present in small quantities in tissue, are insoluble, and are difficult to extract and prepare in commercial quantities. (ii) Western blotting still requires separation of skin antigens by SDS-polyacrylamide gel electrophoresis immunoblotting with serum and comparison with internal controls. This is very time-consuming and expensive. (iii) In many cases, Western immunoblotting is no more sensitive than IIF in detecting circulating autoantibodies. (iv) Immunoprecipitation requires use of cell cultures, SDS-polyacrylamide gel

electrophoresis, and radioactive amino acids, techniques not used in most diagnostic laboratories.

Fortunately, development of ELISA techniques has progressed substantially in recent years. Recombinant proteins that contain the major antigenic epitopes recognized by autoantibodies have been successfully used for pemphigus vulgaris (PV) and pemphigus foliaceus (PF) (desmogleins 3 and 1, respectively) and for the BP 180 antigen (BP antigen 2 [BP Ag2]). The ELISA for desmogleins 1 and 3 and BP 180 is currently available commercially from Medical and Biological Laboratories (Nagoya, Japan; http://www.mbl.co.jp). However, because the technology to produce the protein is intensive, the cost of the plates is quite high, and in some states, the reimbursement for the test falls short of the material costs. A standardized ELISA to detect circulating autoantibodies for paraneoplastic pemphigus (PNP) and EBA is not available yet, but recently, significant progress has been made in this area (15, 20, 28, 75, 80).

SKIN DISEASES IN WHICH IMMUNOLOGIC ABNORMALITIES ARE AN ESSENTIAL COMPONENT OF THE DIAGNOSTIC CRITERIA

Pemphigus

There are four major forms of pemphigus: PV, PF, PNP, and IgA pemphigus. All forms are characterized by a loss of normal epidermal cell-to-cell adhesion (acantholysis) and by the presence of pathogenic autoantibodies reacting against desmosomal adhesion molecules. Pemphigus is a potentially lethal disease; to establish the diagnosis with certainty, the presence of both tissue-bound and circulating autoantibodies must be demonstrated.

PV

Tissue

Direct immunofluorescence (DIF) of perilesional skin shows the characteristic linear deposition of IgG and C3 on the surface of epidermal cells (Fig. 1) (62, 67). Previously, it was thought that the autoantibodies bound a substance in the intercellular spaces between keratinocytes, and the staining pattern was referred to as intercellular space or intercellular substance staining. It is known that this pattern is due to binding of autoantibodies to a transmembrane adhesion molecule of the keratinocyte, desmoglein 3 and 1, but the older terminology is still used. IgG deposition is rather uniform throughout the epithelium, although there may be some preferential staining of the suprabasilar cells, especially in oral biopsy samples. C3 immunostaining is more focal, occurring in areas where acantholysis is evident. The absence of deposition of immunoreactants at the BMZ, in the context of positive cell surface immunostaining, constitutes the hallmark IF features of PV (Fig. 1). False-positive deposition of IgG is not expected but can be seen if the skin biopsy sample is not adequately washed prior to sectioning or if the transport medium is old and has become acidic. False negatives can occur if the biopsy is too distant from lesional tissue. Isolated C3 deposition on the epidermal cell surfaces without concomitant deposition of IgG can be found in impetigo and in some cases of drug-induced pemphigus.

Serologic Studies

IIF should be positive for all patients with active disease, and monkey esophagus is the optimal substrate for detection (3, 31). The expected finding is a linear binding of IgG over the epithelial cell surfaces, producing a chicken wire pattern of fluorescence. There is no binding to the esophageal BMZ (Fig. 2).

Sensitivity and Specificity

The titers of circulating autoantibody show a rough correlation with disease activity, although detection of circulating antibodies can lag behind the development of clinical disease, especially early in the course, and low titers (up to 1:160) may not have a reliable direct correlation to clinical activity (23). Low titers of antiepithelial antibodies, directed at other cell surface proteins such as blood group antigens, have been detected occasionally in patients with skin burns, in penicillin-allergic individuals, in those with dermatophyte infections, and in some healthy subjects, but they are not frequently observed (2, 5, 26, 32).
FIGURE 1 (Left) DIF of oral mucosa in PV showing linear IgG deposits on the epithelial cell surfaces; (right) DIF of oral mucosa in PNP showing linear IgG deposits on the epithelial cell surfaces as well as along the BMZ.
FIGURE 2 (Left) IIF in PV showing the presence of circulating IgG autoantibodies binding the epithelial cell surfaces of monkey esophagus substrate with sparing of BMZ and the basal third of the epithelial stratum; (right) IIF in PNP showing the presence of circulating IgG autoantibodies binding the epithelial cell surfaces as well as the BMZ of monkey esophagus substrate.

Immunochemical Techniques

The epitopes recognized by autoantibodies in PV are largely conformational and usually cannot readily be detected by a denaturing technique such as Western immunoblotting. Immunoprecipitation in the presence of nondenaturing detergents is relatively sensitive and very specific for characterization of these antibodies; however, the technique is expensive and of limited availability and thus is used only in research protocols or for unusual cases. For these reasons, ELISA using the extracellular portion of the desmoglein 3 molecule, produced in a baculovirus expression system, is becoming a useful diagnostic test (45). The sensitivity of the ELISA for PV and PF is approximately 95%, and the specificity approaches 98%, when only samples with very significantly elevated levels of antibody are considered true positives (6). In PV, when only oral epithelium is affected, elevated levels of serum antibodies against desmoglein 3 alone are expected. If patients have both skin and oral lesions, the serum autoantibodies should react with both desmoglein 3 and desmoglein 1 (Table 1) (7).

PF

Four clinical subsets of PF have been identified: idiopathic PF, endemic PF, drug-induced PF (72, 81), and pemphigus erythematosus.

TABLE 1 Antibody profiles in pemphigus variants

Disease	Antibody reactivity
PF	Desmoglein 1
PV (oral lesions only)	Desmoglein 3
PV (oral and skin lesions)	Desmogleins 3 and 1
IgA pemphigus	
	Desmocollins 1, 2, and 3
	Desmogleins 3 and 1
PNP	
	Plakins
	Desmogleins 3 and 1

Tissue

With the exception of pemphigus erythematosus, the pattern of IgG deposition in the epidermis is the same in all subsets of PF and indistinguishable from that observed in PV. In pemphigus erythematosus, there is combined immunoreactant deposition similar to that seen in pemphigus and in lesions of lupus erythematosus (LE); i.e., there is linear IgG on the epidermal cell surfaces as well as granular deposition of immunoreactants along the epidermal BMZ (37, 83). IgA PF, also known as intercellular IgA dermatosis, is a newly described and rare condition characterized by linear deposition of only IgA on the epidermal cell surfaces. The inclusion of this entity as a form of pemphigus is controversial.

Serologic Studies

Patients with PF produce an autoantibody specific for another transmembrane adhesion molecule of stratified squamous epithelium, desmoglein 1. IIF using monkey esophagus as a substrate will detect circulating IgG autoantibodies in more than 90% of patients with PF, and the titer of autoantibody roughly correlates with the clinical disease activity (29). The pattern of binding of PF antibodies is indistinguishable from that of PV.

Sensitivity and Specificity

About 10% of patients have levels of circulating autoantibody that are undetectable when monkey esophagus is used. Guinea pig lip or esophagus appears to be somewhat more sensitive, in that it will identify most of these false-negative sera. Additionally, the IF titer on guinea pig mucosa is usually higher than that measured using monkey esophagus (79). In pemphigus erythematosus, antinuclear antibody activity may also be detected in the serum. In IgA PF, circulating IgA antiepithelial antibodies may be detected, but the incidence is not certain and the antigen specificity is not clear. There is some evidence that IgA autoantibodies may react with two related transmembrane adhesion molecules, desmocollins 1 and 2.

Immunochemical Techniques

As in PV, Western blotting and immunoprecipitation techniques are difficult and expensive and are not routinely performed. The ELISA for desmoglein 1 is also proving very useful. In PF, the expected result is the detection of autoantibodies against desmoglein 1 but not desmoglein 3. With a sensitivity of about 95%, this assay should soon become standard for the diagnosis of PF.

PNP

PNP is associated with underlying lymphoproliferative disease or thymomas and has clinical and immunologic specificities that clearly distinguish it from other forms of pemphigus.

Tissue

DIF of perilesional tissue shows deposition of IgG in the intercellular spaces of the affected skin and mucosal epithelial cells, in a pattern similar to that seen in PV or PF, but the deposition can be faint and/or focal. A distinctive finding is the combined presence of linear complement deposition along the BMZ in addition to the epithelial cell surface binding of IgG (Fig. 1) (11). Frequently, patients have high levels of coexistent autoantibodies against cytoskeletal proteins, producing high background cytoplasmic staining in the epithelium and obscuring specific autoantibody deposition.

Serologic Studies

In most cases of PNP, circulating IgG autoantibodies reactive with the cell surface of monkey esophagus will be detectable by IIF. In most cases, the pattern of binding will be similar to that observed with PV or PF serum antibodies. In a minority of cases, circulating antibodies that additionally bind along the epithelial BMZ are present, but in most cases it is not possible to distinguish PNP from other forms of pemphigus by this technique alone. Patients with PNP have a complex humoral autoimmune response, with serum antibodies known to be specific for proteins of the desmosomes and hemidesmosomes (desmoplakins I and II and the BP Ag1) as well as two keratinocyte proteins, envoplakin and periplakin. The key to differentiation of PNP from other forms of pemphigus by IIF lies in the tissue distribution of these autoantigens. The PV and PF antigens, desmogleins 1 and 3, are produced only by stratified squamous epithelia. Serologic markers for PNP are autoantibodies against plakin proteins, which include desmoplakins I and II, envoplakin, periplakin, and plectin (Table 2) (9). Desmoplakins are expressed in stratified squamous epithelia and in many other epithelia and adhesion structures throughout the body. The finding of autoantibody reactivity that is either (i) restricted solely to stratified squamous epithelia or (ii) reactive with both stratified squamous and other epithelia implies the presence or absence, respectively, of antidesmoplakin autoantibodies. The most commonly used nonstratified squamous epithelium for this purpose is rat or mouse urinary bladder epithelium. By IIF, binding of serum antibodies to the cell surface of only esophagus indicates PV or PF, and binding to both esophagus and urinary bladder epithelium indicates PNP (Fig. 3). With monkey esophagus as a substrate, the fact that the PNP autoantibodies would bind the epithelial cell surfaces consistently and homogeneously throughout the entire epithelial stratum (due to the ubiquitous location of plakin proteins), in conjunction with the BMZ staining, should raise a strong suspicion for PNP (Fig. 2).

Sensitivity and Specificity

The sensitivity and specificity of IIF for PNP using urinary bladder are estimated to be 75 and 83%, respectively (Fig. 3) (44).

Immunochemical

Although IIF procedures are reasonable for diagnostic screening in suspected cases of PNP, up to 25% of cases cannot be diagnosed by IF alone. Definition of the complex antigen specificity of the autoantibodies requires more precise techniques. Almost all patients with PNP have antibodies against desmoglein 3 that can be detected by ELISA, and about two-thirds have antibodies also against desmoglein 1. To properly distinguish PV from PNP, one must show antibodies both against the desmogleins and against the plakin proteins. Immunoprecipitation with ^{14}C-labeled keratinocytes

remains the standard diagnostic method (11) but is available only from laboratories doing research in this field. By immunoblotting for antibodies to the plakin proteins, usually only envoplakin and periplakin antibodies can be detected; however, the demonstration of antibodies against these two plakin proteins in addition to desmoglein autoantibodies is usually confirmatory of the diagnosis. Antidesmoplakin antibodies have recently been detected in some PV patients, namely, children with significant mucosal disease and even in patients with BP. Therefore, strict clinical and immunopathological correlation as well as exclusion of other antiplakin antibodies, e.g., envoplakin and periplakin, by immunoblotting or immunoprecipitation is recommended for these patients.

BP and GP

Both BP and gestational pemphigoid (GP) are characterized by subepidermal cutaneous blisters and by the presence of autoantibodies against hemidesmosomal proteins (8, 66).

Tissue

By DIF, BP is characterized by linear deposition of C3 along the epidermal BMZ in virtually all perilesional specimens and by similar linear deposition of IgG in up to 90% of specimens (59, 65). Occasionally, concomitant but much weaker linear deposition of IgA is observed. Linear deposition of IgM along the BMZ has been reported as a rare and sole DIF finding in BP (43). With direct NaCl-split biopsy specimens (see chapter 48), the linear IgG deposition is found exclusively on the epidermal side (roof) of the induced blister. However, the linear C3 deposition may be observed at both epidermal and dermal locations, even in patients with IgG exclusively on the epidermal side. GP (also known as herpes gestationis) is a form of BP that occurs during pregnancy. Immunologic abnormalities are almost identical, with perilesional skin consistently showing linear deposition of C3 along the BMZ and linear deposition of IgG in 40% of the biopsy specimens (64).

Serologic Studies

Standard IIF using monkey esophagus will detect circulating anti-epidermal BMZ autoantibodies in only about 50% of cases. BP antibody titers do not correlate well with the clinical disease activity (Fig. 2). The detection of these antibodies is increased to about 70% if normal human salt-split skin is used as the substrate. Additionally, the IgG autoantibodies will be localized only on the epidermal side (roof) of the induced blister (Fig. 4) (41), which differentiates the disease
FIGURE 4 (Left) IIF in BP showing the presence of circulating IgG autoantibodies binding the epidermal side (roof) of human salt-split skin; (right) IIF in EBA showing the presence of circulating IgG autoantibodies binding the dermal side (floor) of human salt-split skin.

from EBA and other dermolytic subepidermal blistering diseases with certainty. In GP, low titers of complement-fixing IgG autoantibody, also specific for keratinocyte hemidesmosomal proteins, are present in the serum. This autoantibody was originally called the herpes gestationis factor, before its identity as an immunoglobulin was proven, but the terminology still persists. The autoantibody is generally present in titers too low to be detected by standard IIF techniques, and so a complement immunofixation technique is required to demonstrate its presence. Salt (1 M NaCl)-split normal human skin is sequentially incubated with a 1:10 dilution of heat-inactivated patient serum, fresh normal human serum as a source of complement, and fluorescein isothiocyanate-labeled anti-C3. The anti-C3 detects complement that is activated and bound to the IgG on the roof of the induced blister. This method is positive for the majority of the patients with active disease (49, 51).

Specificity
The finding of anti-BMZ antibodies that bind the epidermal side of split skin is abnormal and is expected to occur only in variants of pemphigoid.

Immunochemical Techniques
In BP and GP, autoantibodies against two distinct proteins of the keratinocyte hemidesmosome are present: (i) a 230-kDa intracellular hemidesmosomal plaque protein called BP Ag1 and (ii) a 180-kDa transmembrane protein of the hemidesmosome called BP Ag2. Antibodies against a small epitope present on the extracellular domain of the BP 180 antigen have been shown by passive transfer into mice to induce blister formation in vivo (58). It is not known whether antibodies against BP Ag1 can cause tissue injury, and so studies on antigen detection have focused on the BP 180 antigen (BP Ag2). Antibodies specific for the BP 180 antigen can be detected by Western blotting and by ELISA, using recombinant proteins representing the immunodominant epitope of BP Ag2 (38). In general, immunoblotting is not more sensitive than IIF on salt-split skin for detection of antibody, but the ELISA technique is much more sensitive and is capable of detecting specific antibody in about 94% of cases of BP and GP (89). The finding of (i) epidermal BMZ localization of in vivo-bound IgG on the epidermal side of salt-split skin by DIF or (ii) circulating IgG on the epidermal side of salt-split skin by IIF is so characteristic of pemphigoid that antigen-specific serologic testing is simply not necessary for diagnosis in most cases.

MMP (Cicatricial Pemphigoid)
MMP is a variant in which lesions occur primarily on mucous membranes and the lesions heal with scarring. MMP is a clinical diagnosis, and the typical clinical, histologic, and immunopathological features can be associated with more than a single antigen-antibody system. The majority of patients with cicatricial pemphigoid have antibody reactivity with the BP antigens; however, a minority have a similar clinical syndrome but with antibodies directed against laminin 5, type VII collagen, hemidesmosomal integrins (17), or other BMZ antigens.

Tissue
DIF findings are similar to those for BP except that coincident weaker linear deposition of IgA along the BMZ is often seen (12, 33, 56). Using IIF of salt-split human skin, the linear deposition of IgG is seen on the epidermal side in most cases, but in a minority, IgG deposition is seen on the floor of the induced blister as in anti-epiligrin MMP or predominantly mucosal EBA (30, 53, 55).

Specificity
The diagnosis cannot be made without showing immunoreactants along the BMZ. There is substantial sampling error, and false-negative DIF is common, occurring in as many as 10% of cases after a single biopsy. If clinical suspicion warrants it, biopsies should be repeated. Also, when perilesional mucosa is biopsied, the epithelium often peels off the lamina propria and can be lost during processing of the tissue.

Serologic Studies
In most cases where lesions are localized to mucosal surfaces, circulating antibodies will not be detectable. In about 15% of cases, IgG anti-BMZ antibodies are present but in low titers.

Immunochemical Techniques
Immunochemical techniques are not possible in most cases because of the absence of circulating autoantibodies. Preliminary studies show that the BP 180 ELISA yields more sera with detectable antibodies, but the level of detection is still low (less than one-third).

DH
Dermatitis herpetiformis (DH) is an extremely pruritic papulovesicular eruption of the skin, associated with the HLA-B8,DQ2 haplotype and an asymptomatic gluten-sensitive enteropathy.

Tissue
DH is diagnosed by the characteristic deposition of granular IgA scattered along the BMZ, with more dense accumulation in the tips of the dermal papillae and along the dermal microfibrils since these IgA deposits have high binding affinity for fibrillin 1 (Fig. 5). These IgA deposits persist even after treatment with dapsone and will decrease only after prolonged observance of a strict gluten-free diet (34).

Serologic Studies
Antiendomysial IgA antibodies, now known to react with tissue transglutaminase, are present in DH patients. They can be detected in most cases by ELISA (78) and in 50 to 80% of cases by IIF binding with the endomysial lining of smooth muscle bundles in the muscularis mucosa of monkey esophagus. These autoantibodies are present in most active cases of DH with gluten-sensitive enteropathy of grades III
FIGURE 5 DIF of DH showing characteristic granular IgA deposits along the BMZ, with accentuation at the tip of the dermal papillae and microfibrils.

and IV (21). Despite their potential use in monitoring the clinical response to a gluten-free diet, they are not often used in clinical practice.

LABD and CBDC

Linear IgA bullous disease (LABD) and chronic bullous disease of childhood (CBDC) are characterized by pruritic blisters of skin, but disease subsets exist. Most patients have IgA antibodies against a secreted fragment of BP Ag2 and have a blistering cutaneous disease that resembles BP (77, 87). However, up to 20% of LABD patients have a scarring mucosal disease similar to MMP (52), in some cases induced by drugs such as vancomycin (68). Therefore, the diagnosis of LABD or CBDC includes several different conditions that are mediated by a single immunoglobulin isotype.

Tissue

LABD and CBDC are defined by the finding on DIF of linear deposition of IgA along the epidermal BMZ. Other immunoreactants, aside from very weak deposition of C3, are not detected.

Serologic Studies

In LABD and CBCD, circulating IgA anti-BMZ antibodies are detectable in about 50% of patients when human split skin is used (85). In the majority of LABD sera, circulating IgA reacts with the BP 180 antigen on the epidermal side of the induced blister. However, in some cases of both LABD and CBDC, namely, the vancomycin-induced variant, the immunoreactant may be found on the dermal surface, again reflecting the heterogeneity of the disease as currently defined.

EBA and BSLE

The cutaneous immunologic features of EBA and bullous systemic LE (BSLE) are identical: in both syndromes, subepidermal blistering is caused by autoantibodies against type VII collagen. In EBA, the autoantibodies are the sole immunologic abnormality; in BSLE, they arise in a patient with coexistent systemic LE.

Tissue

There is dense linear deposition of IgG and C3 along the epidermal BMZ. The deposition is similar to that observed in pemphigoid but on close inspection may appear thicker and more fibrillar (14, 35). In direct NaCl-split biopsy specimens,

the linear deposition of immunoreactants in EBA and BSLE is characteristically present on the dermal side (floor) of the induced blister (36).

Serologic Studies

Circulating autoantibodies are detectable in about 50% of patients. Salt-split human skin IIF shows linear deposition of IgG only on the floor of the induced blister (86). Western immunoblotting is as sensitive as IIF for detection of these antibodies, and an ELISA has been developed (20); however, both techniques are currently available only from research laboratories. These techniques are useful in that they can distinguish with certainty EBA and BSLE from less common and incompletely characterized bullous diseases that may have similar IF findings (19, 22, 88).

Cutaneous Vasculitides

Tissue

Even though the diagnosis of vasculitis is made on histologic grounds (82), DIF plays a very important role, in some cases a critical, if not sine qua non, role in the classification and workup of cutaneous vasculitides, namely, in the small size types.

In the so-called "cutaneous leukocytoclastic angiitis" (previously known as hypersensitivity vasculitis), rare systemic disease is encountered and thus granular weak IgM with even weaker C3 is commonly found in small dermal vessels. In contrast, in cutaneous vasculitides associated with high titer of rheumatoid factor, such as rheumatoid vasculitis and cryoglobulinemia II, strong granular IgM and C3 is almost the rule on skin DIF examination. In antineutrophil cytoplasmic antibody-mediated cutaneous vasculitides, granular IgG and weaker IgM and C3 constitute a common vascular pattern, whereas in connective tissue disease-associated vasculitides, strong vascular IgG and C3 deposits are characteristically found.

DIF plays a sine qua non role in IgA vasculitis and hypocomplementemic urticarial vasculitis. In IgA vasculitis (Henoch-Schoenlein purpura) in children and adults, granular IgA with or without other weaker immunoreactants is found in eventually all patients from early lesions, in the very superficial postcapillary papillary venules (13). Hypocomplementemic urticarial vasculitis almost always presents as a syndrome that falls into the spectrum of systemic LE; therefore, the DIF vascular pattern is typically characterized by granular IgG deposits along the BMZ and in and around upper dermal vessels (27) (Fig. 6).

Serologic Studies

An assay for detection of circulating IgG or IgA immune complexes can be performed but is of very limited clinical value.

DISEASES IN WHICH IMMUNOLOGIC ABNORMALITIES ARE HELPFUL BUT NOT ESSENTIAL IN DIAGNOSIS

Cutaneous Porphyria

Porphyria cutanea tarda is diagnosed by demonstration of increased urinary excretion of uroporphyrins and coproporphyrins. Because of the presence of subepidermal blisters, DIF is frequently performed; the results demonstrate thick, homogeneous, and linear deposition of IgG, IgA, and weaker C3 both around superficial dermal vessels and along the BMZ. The blood vessels are typically thickened, giving a
FIGURE 6 (Left) DIF of skin of IgA vasculitis (Henoch-Schoenlein purpura) showing granular IgA deposits in and around superficial papillary dermal vessels; (right) DIF of skin in hypocomplementemic urticarial vasculitis showing granular IgG deposits in and around superficial papillary dermal vessels as well as along the BMZ (lupus band-like).

doughnut-like appearance (24, 61). These IF findings represent not an antigen-antibody reaction but a trapping phenomenon of immunoglobulins to increased and altered glycoproteins in BMZ and blood vessels. Similar IF findings are seen in pseudoporphyria (74), a condition that mimics porphyria cutanea tarda but has no demonstrable abnormality of porphyrin metabolism. Pseudoporphyria is often precipitated by treatment with nonsteroidal anti-inflammatory drugs from the caproic acid group and furosemide, exposure to UVA light in tanning parlors, or hemodialysis (8).

Erythema Multiforme

In early lesions of erythema multiforme, there may be deposition of IgM and C3 in the walls of superficial dermal vessels. The sensitivity and specificity of these findings are still debatable (18).

Cutaneous Lupus

DIF findings in skin can often assist the diagnosis of LE, but one must ascertain whether the biopsy was obtained from lesional or nonlesional skin.

Lesional Skin

In cutaneous lupus, there is granular deposition of IgM and C3, as well as IgG and IgA, along the BMZ of epidermis and adnexal structures (25). This pattern can be seen in lesional specimens from a variety of cutaneous lupus conditions, including discoid LE, systemic LE, subacute cutaneous LE, and lupus profundus (54). A similar pattern is also seen in dermatomyositis and mixed connective tissue disease. However, subtle differences in the DIF pattern often help

lead to a better clinicopathological correlation in the evaluation of cutaneous connective tissue diseases.

In discoid LE, dense granular IgM with weaker other immunoreactants primarily found around adnexal BMZ is quite characteristic (Fig. 7).

Most cases of subacute and anti-Ro cutaneous LE are characterized by granular IgG along the BMZ as well as throughout the lower third of the epidermal stratum, giving a characteristic cytoplasmic "dusting" or fine speckling (84).

The so-called tumid LE, which is characterized by minimal epidermal-dermal junction but periadnexal inflammation, typically presents with immunoreactants deposited around the adnexal rather than the epidermal BMZ.

Systemic LE is characterized by granular IgG and C3 along the epidermal BMZ (Fig. 7). On the other hand, dermatomyositis is characterized by granular C5b-9 and weaker IgG and IgM and C3 (60).

Nonlesional Skin

Biopsy of normal skin to aid in the diagnosis of systemic LE is known as a lupus band test (4, 76). The demonstration of IgG or IgM deposition along the BMZ of normal skin is considered a positive lupus band test and implies but does not directly correlate with (i) the presence of circulating immune complexes, (ii) antibodies against native DNA, (iii) the frequent presence of anti-Sm antibodies, and (iv) a high incidence of lupus nephritis (42, 69). The need for this test is questionable, as there are much more sensitive and specific diagnostic tests to detect the presence of circulating immune complexes and complement activation in lupus.
FIGURE 7 (Left) DIF of skin in discoid LE showing dense granular IgM deposits along the follicular (adnexal) BMZ; (right) DIF of skin in systemic LE showing granular IgG deposits along the epidermal BMZ.

Lichen Planus

Tissue

In oral lesions of lichen planus, a distinctive dense linear and shaggy deposition of fibrin along the BMZ extending into the lamina propia is present in most cases. The presence of abundant cytoid bodies scattered along the BMZ is also characteristic (1, 39, 40, 56). In cutaneous lesions, IF findings are less helpful, characteristic fibrin deposition is not detected, and frequently only cytoid bodies are found.

In oral biopsy samples, this pattern of fibrinogen and cytoid bodies often helps differentiate lichen planus from other lichenoid mucositis such as contact allergic mucositis, graft-versus-host disease, oral connective tissue diseases, and lichenoid variant of PNP.

Serologic Studies

There have been reports of circulating antibodies specific for a lichen planus-specific antigen and detectable by IIF (71), but this test has not proven to be useful.

Cardiovascular Diseases

J. BRUCE SUNDSTROM, C. LYNNE BUREK, NOEL R. ROSE, AND AFTAB A. ANSARI

124

Cardiovascular diseases comprise a broad spectrum of disorders which cause cardiac dysfunction. Vascular diseases such as hypertension, atherosclerosis, and acute and chronic coronary artery disease, which adversely influence systemic hemodynamics, indirectly cause cardiac dysfunction by causing acute myocardial infarction (AMI) or by promoting heart muscle disease. A standardized classification and definition of heart muscle diseases or cardiomyopathies was most recently established in 1995 by the World Health Organization and International Society and Federation of Cardiology Task Force (24). Cardiomyopathies are classified as hypertropic, restrictive, dilated, arrhythmogenic right ventricular, unclassified, or specific. Specific cardiomyopathies describe heart muscle diseases that have been further defined based in part on their etiologies and their association with specific systemic or cardiac disorders. These include (i) ischemic cardiomyopathy, (ii) valvular cardiomyopathy, (iii) hypertensive cardiomyopathy, (iv) metabolic cardiomyopathy, (v) general system disease, (vi) muscular dystrophies, (vii) neuromuscular disorders, (viii) sensitivity and toxic reactions, (ix) peripartum cardiomyopathy, and (x) inflammatory cardiomyopathy. Inflammatory cardiomyopathy, which is now defined as myocarditis with cardiac dysfunction, is further categorized as idiopathic, autoimmune, or infectious. Multiple factors, including age, genetics, infection, and nutrition, contribute to the morbity and mortality of heart disease. However, this chapter will focus exclusively on the current knowledge of immunologic aspects involved in the etiology and pathogenesis of cardiomyopathies and the application of immunological and molecular techniques for measuring and characterizing relevant biomarkers used in the detection and assessment of myocardial damage and in determining the diagnosis and prognosis of related cardiovascular diseases.

SEROLOGIC DIAGNOSIS AND ASSESSMENT OF AMI

AMI most often results from a lack of sufficient blood supply to the heart, a condition usually associated with acute coronary syndrome (ACS). When emergency room or crisis care patients with ACS present with symptoms of chest pains, a rapid diagnosis and characterization of the extent of AMI are essential for prescribing appropriate treatment, e.g., early intervention with antithrombolytic therapy or angioplasty, to minimize the risk of (further) cardiac injury and death. The ability

to accurately interpret symptoms of chest pains and to be able to distinguish between patients with unstable angina and those with AMI is required so that high-risk patients needing immediate attention and low-risk patients that can be clinically managed by outpatient care can be properly sorted by triage. Serologic measurements of soluble biomarkers released during myocyte necrosis are used in conjunction with electrocardiograms and more sophisticated imaging techniques, e.g., echocardiography and perfusion scintigraphy, to characterize the presence and extent of AMI. Serum biomarkers have a greater advantage of detecting recent myocardial injury, which is not easily distinguishable by cardiac imaging techniques, in patients with clinical evidence of preexisting heart disease.

Serologic monitoring of myocardial injury involves the measurement of levels of serum biomarkers that correlate well with levels of cardiac myocyte injury and necrosis. In ACS, myocardial injury results from insufficient oxygen during episodes of ischemia. Whether the cellular damage is reversible or irreversible usually depends on the duration of ischemia. Myocyte necrosis is an example of irreversible injury that results in the rapid and complete release of cytoplasmic proteins that soon become detectable in the serum. However, under mild ischemic conditions or stress, proportionally smaller amounts of cytoplasmic proteins and macromolecules may be released from cardiac myocytes at levels correlating with reversible myocardial tissue injury. The ideal serum biomarker of myocardial injury would have the following characteristics. (i) It would be heart specific, expressed only in cardiac tissues and not in noncardiac tissues, even during pathological conditions. (ii) It would be highly sensitive, so that clinically significant interpretations could be made at low levels of expression. (iii) The levels of expression would be proportional to the extent of myocardial damage and therefore would provide the ability to discriminate between reversible and irreversible myocardial injury. (iv) It would be able to allow monitoring of reperfusion therapy and an estimation of infarct size and prognosis. (v) The release and decay kinetics would allow rapid diagnosis and the ability to distinguish recent from recurrent myocardial injuries. (vi) It would be rapid, sensitive, quantitative, and cost-effective (23).

Historical Background

The earliest conventional serum biomarkers used to assess AMI were enzymes involved in cellular metabolism, such as aspartate aminotransferase (AST; formerly called ASAT

or SGOT) (1). Levels of AST in the serum appeared to correlate with AMI, and biochemical assays that measured their functional enzymatic activity were very sensitive. Nevertheless, assays measuring AST expression lacked cardiac tissue specificity, thus detracting from their clinical relevance for the diagnosis of AMI.

Lactate dehydrogenase (LD), a cellular enzyme involved in the conversion of pyruvate to lactate in glucose metabolism, later replaced AST. Although LD is expressed in almost all tissues, it exists as five different isoenzymes and thus had the advantage of increased specificity and improved clinical efficacy as a biomarker for AMI. The LD isoenzymes have a tetrameric structure made up of different combinations of 34-kDa "M" (muscle) and "H" (heart) subunits with the following structures: LD-1, H_4; LD-2, H_3M_1; LD-3, H_2M_2; LD-4, H_1M_3; and LD-5, M_4. LD is found in many tissues, but the distribution of different isoforms varies among different tissues. Although LD-1 is the major isoform found in the heart, it is also present in other tissues, including the kidneys, brain, red blood cells, stomach, and pancreas. A significant amount of LD-2 is also present in cardiac tissues, but LD-3, LD-4, and LD-5 are only present in trace amounts. Levels of LD-2 in the plasma rise relative to those of LD-1 within 8 to 12 h after AMI, and LD-1/LD-2 ratios have been used to detect and monitor the development of recent cardiac tissue necrosis (28). LD-1/LD-2 ratios of ≤0.76 measured in plasma are consider normal, whereas LD-1/LD-2 ratios of ≤1.0 are considered reasonably specific for AMI. However, increased LD-1/LD-2 ratios in plasma may occur in the absence of AMI in patients with chronic skeletal muscle injury, stomach, kidney, or pancreatic disorders, or significant erythrocyte damage, thus limiting its positive predictive value (23).

Myoglobin is a low-molecular-mass (17.8 kDa) heme-binding protein abundant in both cardiac and skeletal muscle that is rapidly released (1 to 2 h) after AMI, peaks at ~7 h, and returns to normal levels in plasma by 24 h after the onset of symptoms in the absence of renal disease. Myoglobin is one of the earliest expressed plasma markers of myocyte necrosis, and thus the frequent collection of blood samples early after the onset of symptoms is recommended. A doubling of myoglobin levels above the baseline has been considered diagnostic of AMI. However, due to their lack of specificity, myoglobin measurements only have a reported predictive value of 43% and therefore are mainly used in conjunction with measurements of more heart-specific biomarkers (15). Nevertheless, myoglobin does have a high predictive negative value and thus has been used for identifying patients with unstable angina without AMI. Creatine kinase (CK), a cellular enzyme that catalyzes the transfer of high-energy phosphate from ATP to creatine, later replaced LD as the preferred serum biomarker of AMI.

The active CK enzyme is a dimer consisting of "M" (muscle) and "B" (brain) subunits, each with a molecular mass of approximately 41 kDa. Cytosolic CK exists as three isoenzymes; namely, CKBB (CK-1), CKMB (CK-2), and CKMM (CK-3). Although CK is present in most tissues, CKMB constitutes approximately 15 to 30% of CK in myocardial tissue and only 1 to 3% in skeletal muscle tissue (19). Biochemical assays that measure total CK activity in the serum or plasma required that samples be pretreated with reducing agents, e.g., β-mercaptoethanol, to prevent oxidation and a loss of activity. Determination of the levels of the three CK isoenzymes in plasma requires electrophoretic separation in agarose gels which are subsequently overlaid with appropriate substrates. Quantitative measurements of CK isoenzymes are made by densitometry. However, these measurements can be technically complicated by artifacts present in patient serum, e.g.,

bilirubin, drugs, etc. The introduction of monoclonal antibody-based assays that measure the total CKMB mass in either serum or plasma has not only eliminated these concerns but also given significantly greater sensitivity (34). Levels of CKMB in plasma increase by 6 to 10 h after the onset of symptoms, peak around 24 h, and then return to normal by 36 to 72 h. Measurements of levels of CKMB in plasma of ≥7 ng/ml are considered diagnostic of AMI. CKMB has generally been considered a specific biomarker for irreversible myocardial injury; however, the specificity for AMI is not 100%. Vigorous exercise, chronic renal failure, or skeletal myopathies and hypothyroidism can all increase levels of CKMB in plasma. Furthermore, reports of studies of endomyocardial biopsies performed on patients with unstable angina have revealed evidence of micronecrosis in the absence of elevated levels of CKMB in serum (11). Modifications in CKMB measurements have been introduced in efforts to increase the specificity of CKMB measurements for myocardial necrosis. The CKMB index represents the following: (total CKMB/total CK) × 100%. Values of >2.5% (ranging from 2 to 5%) are considered to represent the myocardium-derived MB isoenzyme (19). Measurements in serum of the two CKMB isoforms, CKMB2 (tissue subform) and CKMB1 (plasma-modified subform), have also been used to increase the assay specificity. The two isoforms can be separated and quantitated by high-voltage electrophoresis. A CKMB2/CKMB1 ratio of >1.5 has been used as a threshold for heart-specific tissue necrosis with a sensitivity of >90% (37). Furthermore, CKMB isoform ratios are apparently diagnostic of AMI earlier than those of CKMB mass. Nevertheless, the implementation of testing for new more sensitive and specific biomarkers, such as cardiac troponins, as well as a strategy for utilizing multiple biomarkers of myocyte necrosis, is currently being practiced in select clinical settings for more accurate diagnosis of AMI.

Cardiac troponins (Tns) represent a class of serum biomarkers that are emerging as the new "gold standard" for the diagnosis of AMI due to their greater specificity and sensitivity for myocardial necrosis. The Tns comprise a group of regulatory proteins uniquely located on the thin filament of striated muscle. The Tn complex is composed of the following three subunits: TnT, which serves to attach the Tn complex to tropomyosin; TnI, which regulates actin-myosin interactions by attenuating actinomyosin ATPase; and TnC, which binds calcium (20). Immunoassays for cardiac TnT (cTnT) and cTnI first introduced in the early 1990s have been improved and so extensively implemented in clinical settings that cTn levels are now included in the Joint European Society of Cardiology/American College of Cardiology Committee's consensus definition of MI (3). Heart-specific isoforms exist for TnI (cTnI) and TnT (cTnT) and can be detected in plasma or serum by specific monoclonal antibodies without cross-reactivity with skeletal muscle Tns. Unlike CKMB, cTns are not found in the sera of healthy patients (i.e., in the absence of cardiac tissue injury), thus providing troponin measurement with a superior signal-to-noise ratio and enhancing their usefulness and risk stratification for the evaluation of patient responses to therapy. However, troponins are released relatively slower after myocardial injury and have a longer half-life in serum than CKMB. Thus, despite their superior specificity, troponins are not as effective for the diagnosis of recent AMIs. Therefore, it has been recommended that cTn testing be used in combination with myoglobin testing when patients are admitted within 2 to 6 h and with CKMB mass measurement when they are admitted within 6 to 8 h. Other clinical studies have shown that combined measurements of myoglobin, CKMB, and cTnI at 0, 3, 6, 9 to 12, and 24 h offer the best

strategy for therapeutic monitoring and optimal risk stratification of recurring AMI or death within 30 days (33, 49).

Need for Improved Assays for Cardiac Markers of AMI

Cardiovascular disease holds the distinction of having the highest morbidity and mortality rates in the Western world. Approximately 8,000,000 patients are evaluated in hospital chest pain centers for acute cardiovascular disorders in the United States each year, and of these approximately 3,000,000 are classified as having no evidence of AMI (41). The rate of AMI misdiagnosis among these 3,000,000 patients ranges from 1 to 3% (or between 30,000 and 90,000 patients)(35). Thus, there is a critical need for early and accurate diagnosis after the onset of symptoms for risk stratification and optimal patient care and survival from AMI. Toward this objective, a strategy of utilizing rapid point-of-care testing and assays that screen for multiple biomarkers of myocyte necrosis is currently being pursued for faster and more accurate diagnosis of ACS. New immunoassays are being introduced to improve the early diagnosis of AMI and to provide rapid turnaround times and point-of-care results. New testing methods for serum fatty acid binding protein (FABP) provide an example of this evolving trend in serological testing. FABP is an intracellular fatty acid carrier that exhibits release kinetics during AMI similar to those of myoglobin. Due to its relatively low expression in plasma in the absence of myocardial injury, it has been considered to be more sensitive for the detection of AMI. However, the turnaround time for standard capture enzyme-linked immunosorbent assays (ELISAs) for FABP is approximately 45 to 60 min. Microparticle-enhanced turbidimetric assays for plasma FABP have been developed that can now be performed on clinical chemistry analyzers with a turnaround time of 10 min (38). More sensitive capture immunoassays for FABP, utilizing electrochemical immunosensors and an amperometric detection system, have been described and have a performance time of 20 min (38). In addition, biotechnology companies are now offering new multiplexed assays featuring arrays for multiple cardiac markers, including CKMB. Troponin-1, CKMB, and C-reactive protein assays (see below) are also being developed, utilizing chemiluminescent detection systems for enhanced sensitivity (Panomics, Redwood City, Calif.). One major limitation is that at present, standardization for many of these new testing methods has not yet been established. A list of biomarkers currently used for diagnosis risk stratification for AMI is provided in Table 1.

PATHOGENESIS OF CMI

Serum biomarkers used for clinical diagnosis, monitoring, and risk stratification for AMI are selected because they possess release and decay kinetics that correlate well with sudden necrotic cardiac myocyte death. On the other hand, chronic myocardial injury (CMI) is characterized by a much slower process accompanied by myocyte dropout, which is usually associated with apoptotic processes involved in the pathogenesis of dilated cardiomyopathy (DCM). DCM is a consequence of maladaptive compensatory tissue remodeling responses to reduced cardiac systolic output that evolves in a complex manner in the context of different genetic and environmental backgrounds over sustained but variable periods of time. These remodeling responses are mediated by a variety of endogenous stress-induced proteins, including tumor necrosis factor alpha (TNF-α), interleukin-1 (IL-1), IL-6, endothelin 1, angiotensin II (ANG-II), matrix metalloproteinases (MMPs)(2, 16, 17, 39, 50), transforming growth factor beta (TGF-β) acidic and basic fibroblast growth factors, vascular endothelial growth factor (VEGF), and others (10, 25–27, 51). These stress-induced proteins act directly on both cardiac myocytes, to induce hypertrophy, cytoprotection, or repair, and nonmyocyte cardiac tissues, to increase vascularization and to effect extracellular matrix (ECM) remodeling and fibrosis. Thus, cardiac tissue remodeling results in changes in both myocyte volume and the volume of supporting nonmyocyte cardiac tissues. Regardless of the initial precipitating event, the progression towards heart failure eventually proceeds independently along a common pathway for all forms of DCM. In some cases, DCM is thought to arise subsequent to a low-grade inflammation of cardiac tissue, usually (but not necessarily always) secondary to a viral infection of cardiac tissues by adenovirus or specific strains of coxsackievirus (22). Experimental animal models of postinfectious autoimmune myocarditis (14) or autoimmune myocarditis induced by immunization of mice with heart-specific peptides in the presence of complete Freund adjuvant and in the absence of cardiotropic viral infection (45) all develop

DCM and cardiac-specific autoimmunity. Left ventricular (LV) hypertrophy and dilatation with a reduced ejection fraction are common manifestations in DCM. This is a compensatory response to a chronic volume overload that results from myocyte loss and reduced contractile function. Thus, LV tissue remodeling in response to acute or chronic cardiac tissue injury is a common factor of DCM. Tissue remodeling responses are initiated and directed in part by cellular components of innate immunity resident in cardiac tissues, such as cardiac mast cells and dendritic cells. These responses are focused on both directly reorganizing the cardiovascular architecture by degrading ECM components through MMPs, promoting replacement fibrosis, and developing new ECM and vascular beds and recruiting and directing other components of adaptive immunity to remove damaged and necrotic tissues. During this process of tissue remodeling and repair, certain cryptic cardiac antigens, e.g., myosin, mitochondrial proteins, heat shock proteins, etc., become exposed to immature dendritic cells, which under the influence of other "danger signals" present during the injury and remodeling process (such as CD40 ligand expressed on activated platelets) undergo maturation and become able to initiate subsequent heart-specific autoimmune responses which may or may not contribute significantly to further cardiac tissue injury. Therefore, the level of cardiac tissue injury required to result in irreversible DCM is determined by three major factors: (i) the extent or severity of the original insult, (ii) the extent or severity of the tissue injury and remodeling response by innate immune components, and (iii) the extent of severity of heart-specific autoimmune responses engendered and directed by reparative innate immune responses. Another variable in the etiology of DCM that may be dependent on these three major factors is the period of time from the original insult required for DCM to develop. Furthermore, the presence of bacterial and viral products capable of signaling through Toll-like receptors on cardiac dendritic cells and mast cells may further contribute to the remodeling and subsequent autoimmune phenomena involved in DCM. As a result, DCM develops along with evidence of heart-specific autoimmune responses in the form of antibodies specific for heart-specific autoantigens.

Increases in the hemodynamic burden and volume overload can also contribute to cardiomyocyte damage and DCM. Several reports from different laboratories indicate that cardiac hypertrophy is associated with signaling through the Gαq subtype of G proteins (GTP-binding proteins) expressed on cardiac myocytes (9, 47). Molecules such as endothelin 1 and ANG-II, which are upregulated in response to increased pulmonary pressure and chronic volume overload, signal through Gαq-mediated pathways, causing a reactivation of embryonic genes such as atrial natriuretic factor (ANF), skeletal α-actin, and β-myosin heavy chain and ultimately resulting in cardiac myocyte hypertrophy. However, excessive hemodynamic stress can lead to myocyte apoptosis instead of hypertrophy, resulting in rapid decompensation and DCM. Reports from studies involving chronic volume overload in experimental murine models of pulmonary hypertension have indicated a role for mast cells in LV remodeling (46). Increases in pulmonary artery blood pressure lead to rapid increases in the number of activated mast cells in the heart. Furthermore, in experimental models of chronic volume overload, cardiac mast cell chymase replaces angiotensin-converting enzyme (ACE) as the major enzyme responsible for producing ANG-II from ANG-I (40). In addition, other mast cell-expressed mediators, such as MMPs, TNF-α, TGF-β, tryptase, prostaglandin E2, VEGF, and others, have also been shown to be involved in processes of cardiac tissue remodeling, including cardiac myocyte apoptosis, proliferation of nonmyocyte

cardiac tissues, fibrosis replacement, and ECM remodeling. Other nonmyocyte cardiac tissues also express mediators that contribute to the process of cardiac tissue remodeling, e.g., endothelial expressed endothelin-1 and reactive oxygen species, which have been associated with cardiomyopathy. Reactive oxygen species also activate mast cells, thus further contributing to chronic tissue remodeling and LV remodeling. Thus, monitoring serum biomarkers that correlate with the dysregulation of pulmonary normotension and compensatory cardiac tissue remodeling is useful in the diagnosis and risk assessment of DCM and congestive heart failure (CHF).

Serologic Monitoring of CMI

During CHF, chronic overstimulation of the renin-angiotensin-aldosterone system leads to increases in blood pressure and electrolyte concentrations and edema, thus inducing compensatory vasodilation and diuretic and natriuretic responses by the natriuretic peptide system (42). A-type natriuretic peptides (ANP) are produced by and released from the atria in response to dilatation. C-type natriuretic peptides (CNP) are produced by cardiovascular endothelial tissues in response to sheer stress. B-type natriuretic peptides (BNP) are released from the ventricles in response to prolonged increases in end-diastolic volume and pressure and thus have emerged as an excellent biomarker for LV dysfunction in DCM. BNP is derived from its high-molecular-weight precursor, pro-BNP (amino acids [aa] 1 to 108), whose expression is genetically regulated and which is not stored preformed in vesicles. The mature form, BNP-32, consists of the 32 C-terminal amino acid residues (aa 77 to 108) of the parent pro-BNP. It has been suggested that elevated levels of amino-terminal pro-BNP (Nt-proBNP) in plasma are better indicators of early cardiac dysfunction that BNP-32 (36). Levels of Nt-proBNP in plasma are determined with a competitive inhibition enzyme immunoassay (EIA). Individual replicate wells contain constant amounts of immobilized antibody specific for Nt-proBNP and of peroxidase-labeled Nt-proBNP (tracer) and variable amounts of unlabeled Nt-proBNP (present in standards or patient plasma). With increasing concentrations of unlabeled peptide, the binding of the competing tracer is proportionally reduced. After an incubation period, the unbound tracer is removed by washing, and a colorimetric peroxidase substrate is added. The amount of (peroxidase enzyme-mediated) color change is inversely proportional to the amount of Nt-proBNP in the sample. Increasing concentrations of serum BNP or Nt-proBNP significantly correlate with decreasing ejection fractions ($P < 0.001$) and with increasing levels of heart failure according to the New York Heart Association classification (36). Currently, the only commercially available clinical ELISAs for BNP that are U.S. Food and Drug Administration approved have a diagnostic sensitivity of 90%, specificity of 76%, positive predictive value of 79%, and negative predictive value of 89% (31). However, new rapid point-of-care tests for Nt-proBNP are likely to also become approved soon for use in clinical immunology laboratories.

Other biomarkers that are associated with CMI fall into three overlapping categories: (i) markers of inflammation, (ii) markers of tissue remodeling, and (iii) markers of vascular endothelial activation. The clinical significance of most, if not all, of the biomarkers listed in Table 2 continues to be defined in research studies involving animal models and in human clinical investigations.

Markers of Tissue Remodeling Associated with CMI

Myocardial tissue remodeling is triggered by LV dysfunction and is associated with cardiomyocyte hypertrophy and

death, remodeling of the ECM, and replacement fibrosis. Chronic low but significant levels of myocyte dropout induce structural remodeling of the LV ECM to compensate for the loss of LV function. Increased expression levels of MMPs and cardiac mast cell tryptase in plasma and tissue correlate with evidence of LV remodeling and dysfunction in CHF (21, 44).

Markers of Inflammation Associated with CMI

Levels of IL-6 and certain related cytokines of the IL-6 family, e.g., cardiotrophin-1, in plasma have been shown to increase proportionally with the severity of CHF in both human clinical studies and experimental animal models (6, 43). Although the exact tissue sources of IL-6-related cytokines have not been identified, vascular endothelium and smooth tissues, as well as cardiac tissues, have been implicated. Intracellular signaling on cardiac myocytes is mediated via different multimeric IL-6 family cytokine receptors, which all share a common gp130 transmembrane subunit. The homeostatic regulation of IL-6 expression during CHF is complex and is influenced by a larger network of other cytokines and neurohormones, including TNF-α, ANG-II, epinephrine, and norepinephrine. Indeed, ACE inhibitors or β-blockers have been shown to have a lowering effect on IL-6 expression during CHF (13). IL-6 appears to mediate the detrimental effects of CHF by influencing the hypertrophy and apoptosis of cardiac myocytes (48). TNF-α promotes LV remodeling by altering the ECM. TNF-α mediates such structural modifications through its ability to activate proenzyme forms of MMPs in

myocardial tissues. TNF-α also promotes the activation of vascular endothelium. The expression of TNF-α is triggered by myocardial tissue damage and by inflammation, especially in viral myocarditis.

IL-1 is another cytokine whose expression is interrelated to the cascade of proinflammtory mediators released during CHF. IL-1 causes a negative inotropic effect on LV function by inducing NO expression and by promoting the production and release of IL-18.

Markers of Vascular Endothelial Activation

Inflammation associated with tissue remodeling and the progression towards CHF in DCM also results in increases in serum of the levels of soluble adhesion molecules, e.g., sICAM-1, E-selectin, P-selectin, and VCAM-1, expressed by activated cardiovascular endothelial cells. Although such measurements are not yet approved for clinical monitoring and staging of CHF, recent research reports have shown that levels of sICAM-1 in serum, as measured by capture ELISA, accurately correlated (p < 0.001) with the intramyocardial expression of ICAM-1 in patients with DCM and correlated with the New York Health Association classification of DCM (32). Thus, multiple serum biomarkers of tissue remodeling, inflammation, and endothelial activation have been shown to correlate with the development and progression of DCM (Table 3); however, other, more invasive procedures involving immunohistochemical characterization of endomyocardial biopsies are required for definitive diagnosis and staging of inflammatory cardiomyopathies.

PATHOGENESIS AND IMMUNODIAGNOSIS OF INFLAMMATORY CARDIOMYOPATHIES

Inflammatory cardiomyopathies belong to a class of dilated cardiomyopathies that do not result from the effects of ischemia or increased hemodynamic burden, but rather result from multiple infectious (viral, bacterial, fungal, and parasitic) and noninfectious (drugs, genetics, nutrition, age, idiopathies, etc.) etiologies (Table 3). As mentioned above, inflammatory cardiomyopathy is defined as myocarditis with cardiac dysfunction and includes idiopathic, autoimmune, and infectious myocarditis. In infectious myocarditis, myocyte damage occurs through both the direct and indirect effects of pathogenic agents (30). Certain cardiotropic viruses, e.g., coxsackie B virus (CVB), can cause direct myocyte damage and necrosis. Other viruses, e.g., adenoviruses, may induce apoptosis as a way of escaping immune system recognition. Infectious agents can also cause heart disease indirectly by inducing immunopathological responses that result in myocyte damage. Myocytolysis may occur due to the nonspecific cytotoxic effects of cytokines expressed by infiltrating lymphocytic effector cells, or it can be secondary to hypoxic ischemia due to vasospasms or endothelial dysfunction caused by viral myocarditis (18). Immunity-mediated myocyte damage may also result from the specific cell-mediated cytotoxic actions of T cells and NK cells, or it can be caused by the humoral cytotoxic effects of complement-fixing heart-reactive antibodies produced by epitope mimicry in autoimmune myocarditis (Table 4). Chronic rheumatic heart disease is one of the best examples of the involvement of epitope mimicry in valvular heart disease (12). In rheumatic fever, a sequel to group A streptococcal pharyngitis, antibodies specific for epitopes on the M surface protein cross-react with human tissue antigens. The valvular heart disease is thought to be mediated by antibodies that cross-react with streptococcal sialyl Lewis X oligosaccharide residues and human cardiac selectin.

TABLE 3 Infectious and noninfectious etiologies of inflammatory cardiomyopathy

Category	Disease or organism	Etiology
Infectious		
Viral myocarditis	Enterovirus	Coxsackie B3, B4 virus
	Herpesvirus	Cytomegalovirus, varicella-zoster virus
	Orthomyxovirus	Influenza virus
	Paramyxovirus	Parainfluenza virus
	Parvovirus	
	Retrovirus	Human immunodeficiency virus
	Adenovirus	
	Flavivirus	Hepatitis C virus
	Reovirus	
Bacterial myocarditis	*Streptococcus*	Pyogenese group A
	Staphylococcus	*S. aureus*
	Serratia	*S. marcescens*
	Chlamydia	
	Salmonella	
	Aerococcus	*A. urinae*
	Erlichia	
	Vibrio	*V. cholerae*
Parasitic/protozoal/ spirochetal myocarditis	Chagas' disease	*Trypanosoma cruzi*
		Toxoplasma gondii
	Lyme disease	*Borrelia*
Rickettsial myocarditis	Q fever	
	Rocky Mountain spotted fever	
	Scrub typhus	
Fungal myocarditis	*Cryptococcus*	*C. neoformans*
	Candidiasis	*C. albicans*
	Histoplasmosis	
	Aspergillus	
Noninfectious		
Autoimmune myocarditis	Rheumatic fever	
	Systemic lupus erythematosis	Systemic
	Sjögren's syndrome	
	Dressler's syndrome	Post-MI
	Postpartum cardiomyopathy	
	Kawasaki disese	
	Sarcoidosis	
Drug-induced myocarditis	Cardiotoxic myocarditis	Cocaine 999, catecholamines, doxorubicin
	Hypersensitivity myocarditis	Antibiotics, diuretics, others

Laboratory diagnosis is made after the onset of rheumatic fever by measuring elevated anti-streptolysin O titers. Elevated titers of anti-DNase B, antihyaluronidase, and antistreptozyme are also used to confirm this disease (Table 4).

The same immune responses engendered during the infectious phase of myocarditis may persist after viral clearance and develop into autoimmune postinfectious myocarditis. Such immunopathologies can evolve from a breakdown of tolerance (or from immunologic ignorance) to self antigens due to epitope mimicry, as in chronic rheumatic fever, or from sensitization by sequestered immunogenic self antigens exposed to the host immune system as a result of myocyte necrosis (Table 4). Supporting experimental evidence for the latter scenario comes from murine studies with susceptible (BALB/cA/J, BALB/cA.CA, and BALB/cA.SW) and nonsusceptible (C57B1/10 and C57B1/6) strains infected with cardiotropic CVB3 (8). Results from these studies describe a pathogenic pathway in which infiltrating macrophages or resident cardiac dendritic cells take up and process antigenic host cardiac myosin (released by virally damaged myocytes in susceptible hosts), which is then presented to specific T cells during the inductive phase. Macrophage-derived cytokines, e.g., IL-1β, TNF-α, and IL-12, not only cause further myocyte damage but also support and direct a TH1 type of immune response and the induction of myocyte-specific CD8$^+$ cytotoxic T cells. The significance of the influence of cytokines in the induction of CVB-initiated autoimmune myocarditis is evidenced by the observation that the introduction of recombinant IL-1β or TNF-α into genetically resistant B.10 mice restores the progression from virus infection to autoimmune myocarditis. Primary autoimmune myocarditis can be induced by immunizing susceptible strains with murine cardiac myosin in complete Freund's adjuvant and nonsusceptible strains with the coadministration of IL-1β or TNF-α. In this model, both cellular and humoral immune responses develop, with complement-fixing heart-reactive antibodies recognizing myosin on the surfaces of cardiac myocytes, as well as BCKD and ANT. It has been proposed that cellular and humoral autoimmune responses to cardiac tissues evolve during the chronic activation of Toll-like receptors (TLRs) expressed on

TABLE 4 Autoantibodies detected in inflammatory cardiomyopathies

Antigen specificity	Type of mimicry
Alpha cardiac actin	Enterovirus
HSP-60	Enterovirus
β-Adrenergic receptor	*T. cruzi*

cardiac dendritic cells primed with cardiac antigens in post-infectious myocarditis (7). Thus, the development of autoimmune myocarditis relies on cooperation between innate and adaptive immunity during prolonged periods of (smoldering) inflammation. Since similar cellular and humoral autoimmune responses are detected in human patients with inflammatory cardiomyopathies, immunosuppression has been considered as a therapy option. However, the results of the recent Myocarditis Treatment Trial showed no significant improvement in LV ejection fraction or mortality after immunosuppressive therapy with either cyclosporin, azathioprine, or prednisolone in patients with Dallas criteria-diagnosed myocarditis (29). Although some controversy still exists regarding the criteria utilized for the diagnosis of myocarditis, it may be that immunosuppressive therapy might be more effective at earlier stages of disease or, indeed, may be more effective for primary autoimmune myocarditis,

whereas when applied to cases of infectious myocarditis, it may inhibit immune clearance of the pathogen. Therefore, what is needed is effective diagnosis and treatment and refined techniques for identifying true etiologies when myocarditis is suspected.

The diagnosis of myocarditis, inflammatory myocarditis, or lymphocytic myocarditis has traditionally been determined by histochemical analysis of endomyocardial biopsies (EMBs) by use of the Dallas criteria in conjunction with evidence of a fourfold increase in antibody titers between acute- and convalescent-phase sera (5). The Dallas criteria, established in 1986 by Aretz (4), define active, borderline, and absent myocarditis as the presence of lymphocytic infiltrates with adjacent myocyte necrosis, the presence of lymphocytic infiltrates without myocyte necrosis, and the absence of infiltrating lymphocytes, respectively. This approach has several limitations. The collection of EMBs is a relatively invasive procedure, with a bias toward select tissues of the heart; furthermore, accurate diagnosis relies on histochemical evidence of a focal lesion, which may be easily missed upon biopsy and which is often only expressed during the acute phase of an active infection, when such biopsies may be difficult to obtain.

Currently, immunohistochemical staining and molecular immunological techniques, e.g., PCR and in situ hybridization, are being applied to EMB to enhance the sensitivity and specificity of this procedure for the diagnosis of myocarditis. Enzyme-conjugated monoclonal antibodies with specificities for lymphocyte CD antigens are used to distinguish different subsets of infiltrating lymphocytes, macrophages, and neutrophils. Molecular assays, e.g., PCR and in situ hybridization, are now being applied to detect specific viral sequences within EMBs. These techniques, which are able in some cases to distinguish between productive and nonproductive infections, are useful for discriminating between active, chronic, and postinfectious cases of myocarditis.

Although the immunohistological characterization of leukocytic infiltrates in EMBs is improving, histological confirmation of myocyte damage has been a greater challenge and a source of interobserver variability in the clinical diagnosis of myocarditis by the Dallas criteria. This difficulty in assessing myocyte damage in EMBs may be one explanation for the low frequency (10%) of Dallas criterion-positive EMBs reported in 1996 in the Myocarditis Treatment Trial, which enrolled over 2,200 patients with reduced ventricular

TABLE 5 Clinical immunological assays for detection and characterization of inflammatory heart disease

Specimen type	Result	Method[a]	Criterion
EMB	Lymphocytic infiltrates	H&E histology	Cellular morphology
	B-cell infiltrates	IHC/IFA	Detection of CD20 surface antigen
	CD4+ T-cell infiltrates	IHC/IFA	Detection of CD3/CD8 surface antigen
	CD8+ T-cell infiltrates	IHC/IFA	Detection of CD3/CD8 surface antigen
	NK cell infiltrates	IHC/IFA	Detection of CD56 surface antigen
	Macrophage infiltrates	IHC/IFA	Detection of CD14/CD68 surface antigen
	Infection with specific virus	IHC/PCR	Detection of virus-specific DNA or RNA
	Necrosis	H&E histology	Cellular morphology
	Apoptosis	Cardiac TUNEL assay	Fragmented DNA
Serum	Heart-reactive antibodies	IFA/EIA	Detection of immunoglobulin G anti-cardiac myosin antibodies
	Cardiac myocyte damage	EIA	Dectection of TnT, TnI, or CKMB
	Cardiac myocyte damage	Anti-myosin scintigraphy	Nuclear imaging with [111]indium–anti-myosin
	Diagnosis of viral myocarditis	ELISA	Fourfold rise in specific immunoglobulin G titer
	Diagnosis of rhematic myocarditis	Anti-streptolysin O test	

[a]H&E, hematoxylin and eosin, IHC, immunohistochemistry; IFA, immunofluorescence assay; ISH, in situ hybridization.

function and no evidence of coronary artery diseases (29). A number of new, currently available histochemical and molecular assays, e.g., annexin binding assays, terminal deoxynucleotidyltransferase dUDP-biotin nick end labeling-based assays, and immunochemical assays for the detection of apoptosis-related caspases, are now being used to identify and discriminate between apoptotic and necrotic cells within EMBs (Table 5).

Kidney and Lung Disease Mediated by Anti-Glomerular Basement Membrane Antibodies: Detection by Western Blot Analysis

A. BERNARD COLLINS AND ROBERT B. COLVIN

125

Several diseases of the kidney with overlapping histological and clinical features are characterized by a rapid loss of renal function, crescentic glomerulonephritis, and sometimes lung hemorrhage. In affected patients it is crucial to establish the diagnosis as quickly as possible, since early medical treatment can inhibit the rampant downhill course of the disease, which results in permanent renal failure or even death due to lung hemorrhage. The histological examination of renal biopsy specimens typically shows a lesion of crescentic necrotizing glomerulonephritis in all of these diseases. Direct immunofluorescence studies performed on frozen tissue can distinguish these diseases into the following categories: (i) anti-glomerular basement membrane (anti-GBM)-mediated glomerulonephritis (Goodpasture syndrome), (ii) immune complex-mediated glomerulonephritis, and (iii) pauci-immune glomerulonephritis. The last category of diseases includes Wegener's granulomatosis, microscopic polyarteritis nodosa, Churg-Strauss syndrome, and related overlapping forms of these vasculitides (16, 24). Anti-neutrophil cytoplasmic antibodies (ANCA) are almost always detected in this group, and these diseases are currently referred to as ANCA-associated diseases (36a).

Serological assays for the detection of ANCA and anti-GBM autoantibodies are important diagnostic tools in the evaluation of patients with rapidly progressive renal failure and/or pulmonary hemorrhage, providing a rapid non-invasive method for establishing a diagnosis. These tests are sensitive and highly specific and can provide definitive diagnostic information for the effective clinical management of patients with a rapidly progressive course of disease. This chapter describes the detection of circulating anti-GBM antibodies by serological techniques. ANCA assays are described in reference 36a.

Goodpasture syndrome is an autoimmune disease mediated by circulating autoantibodies with specificity to the GBM and alveolar basement membrane. The nephrotoxic activity of these antibodies in the pathogenesis of this disease has been clearly shown (6, 9, 23, 38). The anti-GBM antibodies react with type IV collagen, the major structural component of mammalian basement membranes (35). The protomeric form of type IV collagen is composed of three α chains which are divided into three structural domains: a 7S, or minor collagenous, domain in the N-terminal region; a triple helical, or major collagenous, domain in the middle region; and an NC1, or noncollagenous globular, domain in

the C-terminal region (10). The three α chains are assembled into a network with NC1-NC1 and 7S-7S interactions to form a macromolecular superstructure. Most basement membranes in the body contain only the classical α chains, α1(IV) and α2(IV) (17, 34), but specialized basement membranes such as those of the kidney, lung, and eye contain the novel α chains α3(IV) and α4(IV) (10, 11, 13). The α5(IV) chain also has limited distribution in basement membranes of the body. The gene encoding the α5(IV) chain is located on the X chromosome, and mutations of this gene are responsible for approximately 85% of the cases of Alport syndrome (1, 12, 39, 40). Ultrastructurally the GBM of patients with Alport syndrome is abnormal, showing areas of thickening and thinning, scalloping, and laminations. In the normal GBM the α3(IV) and α5(IV) chains are incorporated together, but in the case of patients with Alport syndrome with an X-linked mode of inheritance for the disease, there may be partial or complete loss of the α3(IV) chain as well as the α5(IV) chain. Staining by indirect immunofluorescence for the α3(IV) chain using Goodpasture serum is frequently negative (15, 25, 30). Therefore, there is a risk that patients with Alport syndrome who receive a renal transplant may develop alloantibodies to antigens in the donor GBM. We have detected in the sera of patients with Alport syndrome who develop posttransplant anti-GBM nephritis antibodies that are directed against either the α3(IV) chain (Fig. 1) or the α5 chain (Fig. 2). Similar findings have been reported elsewhere (3, 19). Anti-GBM nephritis in Alport syndrome patients posttransplantation is rare but has been reported (20) to occur in approximately 3 to 4% of male Alport syndrome patients who have undergone transplantation. It usually occurs within the first year following transplantation, with approximately 75% of the transplanted kidneys failing irreversibly within the first few weeks or first few months following transplantation. Posttransplantation anti-GBM nephritis usually recurs in patients receiving subsequent new transplants and usually recurs at an accelerated rate. The length of the interval between retransplantation or the absence of detectable circulating anti-GBM antibodies appears to have no effect on the likelihood of recurrence. The gene for the α6(IV) chain was discovered in 1993 by Zhou et al. (41). Specifically, the reactivity of anti-GBM antibodies has been shown to be directed to the noncollagenous, or NC1, domain of the α3(IV) chain, termed the Goodpasture antigen (13, 35, 36).
FIGURE 1 Western blot analysis of a serum sample from an Alport syndrome patient who developed posttransplant anti-GBM nephritis (lane 1). The reactivity of the antibody is to the α3(IV) chain, the Goodpasture antigen, at 28 and 48 to 50 kDa. The reactivity is identical to that seen with a monoclonal antibody to the α3(IV) collagen chain (lane 2) and with that of a serum from a patient with renal-biopsy-proven Goodpasture syndrome (lane 3).

All patients with Goodpasture syndrome have autoantibodies that react primarily with the α3 chain of type IV collagen (10, 32, 33); however, lower-titer reactivity to other α chains has been reported (10). The α3(IV) NC1 antibodies recognize a restricted group of epitopes, as demonstrated by the fact that the autoantibodies in the sera of most patients are partially blocked by monoclonal antibodies to the α3(IV) NC1 chain (31). Kalluri et al. in 1991 (18) further localized the Goodpasture epitope to the carboxyl-terminal region of the α3(IV) NC1, encompassing residues 198 to 223, as the primary antibody interaction site. The Goodpasture antigen is released as NC1 hexamers after bacterial collagenase treatment of the GBM (35). The hexamers are composed of the subunits of the NC1 domains of the various α chains
FIGURE 2 Western blot analysis of another serum sample from an Alport syndrome patient who also developed post-transplant anti-GBM nephritis. However, when immunoblotted on the collagenase digest of the human GBM it shows reactivity to a lower-molecular-mass antigen in the monomer region of the NC1 domain, at approximately 26 kDa instead of 28 kDa (lane 3). It shows the same reactivity to a higher-molecular-mass antigen in the dimer region, at approximately 48 to 50 kDa. The reactivity is to α5(IV) chain collagen and is identical to reactivity of a monoclonal antibody to the α5(IV) chain collagen (lane 2). Serum from a patient with renal-biopsy-proven Goodpasture syndrome is in lane 1.

that comprise the two intertwined protomers. When the hexamers are then subjected to sodium dodecyl sulfate-polyacrylamide gel electrophoresis (SDS-PAGE), they further dissociate into monomeric and dimeric subunits, which are used as an antigen in Western blot analysis for detecting reactivity to the Goodpasture antigen (13).

The earliest technique used for the detection of circulating anti-GBM antibodies was indirect immunofluorescence (13, 26, 27). In the assay, normal human kidney frozen tissue sections are incubated with the patient's serum, as well as with positive and negative control sera. Specific bound immunoglobulin to the GBM, usually immunoglobulin G (IgG), is detected by using a fluorescein-labeled antiserum to human IgG or to human immunoglobulins (IgG, IgA, and IgM). Difficulties in interpretation of the assay are related to the nonspecific accumulation of IgG along the GBM in the normal kidney tissue substrate used as a source of GBM, particularly in autopsy tissue. This nonspecific accumulation makes subjective interpretation of positive staining very difficult and results in a high percentage of false positives and negatives. Furthermore, standardization is difficult or impossible since there is a great variability in the reactivity between different kidney specimens.

Wilson in 1974 (37) developed a radioimmunoassay (RIA) for detecting anti-GBM antibodies, using a collagenase digest of the GBM as an antigen. The assay was a double-antibody RIA which incorporated the use of radiolabeled human IgG to assess the adequacy of immunoglobulin precipitation by the second antibody. Quantitation and objectivity were the greatest advantages that the RIA technique offered over the indirect immunofluorescence technique. The disadvantage, however, was that the crude digest of human GBM contained not only the Goodpasture antigen but also other components of the glomerular basement, such as laminin and entactin. Therefore, false-positive binding could arise from antibodies reactive with other basement membrane components; such reactivity has been reported for several glomerular diseases (5).

WESTERN BLOT ANALYSIS

Our laboratory has developed a sensitive and specific assay for the detection of circulating anti-GBM antibodies using Western blot analysis. The assay has the advantage that the exact molecular weight of the antigen recognized by the autoantibody can be determined accurately and compared to the reactivity of a known Goodpasture serum to the α3(IV) chain. The antigen used in the assay is a collagenase digest of isolated human GBM prepared by the enzymatic digestion of the GBM, which releases the NC1 domains of the type IV collagen, including the α3(IV) NC1, the Goodpasture antigen. Separation of the soluble proteins by PAGE followed by transfer to nitrocellulose paper for immunoblotting allows discrimination between antibody reacting to the Goodpasture antigen and those reacting with other components of the GBM.

Isolation of Glomeruli and Preparation of GBM

GBM is prepared from normal human kidneys obtained at autopsy or from nephrectomy specimens in the operating room. Use of autopsy specimens is limited to no more than 10 to 12 h after death, and in the case of surgical specimens, only the normal portion at least 1 to 2 cm distal from any tumor is taken. The kidneys are then stored frozen at −70°C for glomerular isolation.

The tissue is thawed in 0.01 M phosphate-buffered saline (PBS), pH 7.2, containing 10 mM phenylmethylsulfonyl

fluoride as a protease inhibitor. All subsequent isolation steps are carried out in the presence of phenylmethylsulfonyl fluoride. The cortical portion of the kidneys is cut away from the medulla and placed in ice-cold PBS. Glomeruli are isolated from the cortical tissue using differential sieving according to the method of Edgington et al. (7), as modified by Gang (8). The glomeruli are washed two or three times with PBS. After the final wash with PBS, the glomeruli are washed twice with distilled water to rupture the cell membranes. To further remove cellular material, the glomeruli are sonicated by pulsation using a W200 P Sonifier cell disrupter (Heat Systems—Ultrasonics, Inc., Plainview, N.Y.) equipped with a microtip at 40% duty cycle. After the initial sonication the preparation is examined using phase microscopy and the sonication step is repeated until only refractile GBM remains. The GBM is dialyzed against distilled water overnight at 4°C, lyophilized, and stored in a desiccator at 4°C.

Enzymatic Digestion of the GBM

The GBM is digested using chromatographically purified collagenase type VII prepared from *Clostridium histolyticum* (Sigma, St. Louis, Mo.). The collagenase preparation is substantially free of nonspecific protease, clostripain, and tryptic activities. Ten milligrams of lyophilized GBM is suspended in 2 ml of 0.1 M Tris-HC1 (pH 7.5) in a 15-ml centrifuge tube with 5 mM $CaCl_2$ added to facilitate digestion. The mixture is sonicated for 30 min in a Bransonic 220 water bath sonicator (Branson Co., Shelton, Conn.). Collagenase type VII (1,000 U/mg of GBM) is added and the GBM is digested at 37°C in a shaking water bath for 48 h according to the method of Wieslander et al. (35). The pH is monitored at 30, 60, and 120 min and adjusted to 7.5 if necessary using 1 N Tris-HC1 or 1 N Trizma base. After digestion, 1 ml of 0.1 M Tris-HC1, pH 7.5, containing 2 mM EDTA is added to chelate free Ca^{2+} and thus quench the reaction. The particulate solution is centrifuged at $1,500 \times g$ for 30 min at 4°C. The clear supernatant is recovered and assayed for protein concentration using the Lowry method (22). The solubilized antigen is then stored frozen at -70°C in 50-μl aliquots.

In initial studies the GBM was subjected to various durations of enzymatic digestion from 24 to 96 h to maximize the degradation of the collagenous portions of the membrane. Protein determinations by the Lowry method were performed, and the results obtained showed that approximately 50 to 60% (wt/wt) of the membrane was solubilized in the first 24 h. The solubilization occurred less rapidly after that, but continued up to 72 to 96 h.

PAGE and Transfer to Nitrocellulose Paper

An aliquot of the soluble antigen preparation obtained from the collagenase digestion of the GBM is thawed, and 200 μg is added to each gel and then separated by SDS-PAGE as described by Laemmli (21) in 12% unreduced gels using a Mighty Small II gel apparatus (Hoefer Scientific, San Francisco, Calif.) at a constant current of 40 mA for 1 h. Included as a marker is a low-molecular-weight standard (Bio-Rad, Richmond, Calif.). After PAGE, the separated proteins are transferred to nitrocellulose paper (Pharmacia Biotech, San Francisco, Calif.) using a TE series Transphor electrophoresis unit (Hoefer Scientific) and a PS 500X DC power supply. The transfer electrophoresis is carried out using a constant current of 200 mA for 1 h with a circulating water cooling system according to the method of Burnette (4). In order to verify and visualize the separated

transferred proteins, the nitrocellulose paper is cut from one side of the paper to include the molecular weight standard and the soluble GBM antigen digest and placed into 0.1% India ink on a slow rotator for 30 to 60 min, followed by a PBS wash. The remainder of the nitrocellulose paper is stored dry between two pieces of Whatman filter paper at room temperature. Storing paper in this manner allows sera to be tested quickly and efficiently. Paper can be stored dry for up to 2 months.

Western Blotting

Upon receiving sera for anti-GBM testing by Western blot analysis, an appropriate piece of the dried nitrocellulose paper is cut for the number of sera to be tested and placed into 5% skim milk buffer for 1 h, with agitation for blocking. After blocking, the nitrocellulose paper is cut into 3- to 4-mm wide strips and placed into the wells of a Mighty Small incubation tray (Hoefer Scientific). The strips are incubated in 1 ml of test serum diluted 1:10 in 0.5% skim milk buffer for a minimum of 1 h. After incubation, the excess serum is aspirated and the strips are washed three times for 5 min each time with 0.5% skim milk buffer and then incubated with 1 ml of biotin-conjugated goat anti-human IgG (heavy and light chains; Vector Labs, Burlingame, Calif.) at 1:250 for 1 h, with agitation. After incubation, excess conjugate is aspirated and the strips are washed with 0.5% skim milk buffer. To detect bound labeled antibody, the strips are incubated in 1 ml of avidin-biotin complex (Vector Labs) for 60 min, the excess reagent is aspirated, and the nitrocellulose strips are washed in the 0.5% skim milk buffer as described above. The last incubation is with 3-amino-9-ethyl carbazole (1 ml per well), a chromogen for horseradish peroxidase. Finally, the strips are washed in distilled water for 5 to 10 min and blotted dry between two pieces of Whatman filter paper, so that the strips can be examined for reactivity to the α3(IV) NC1 (the Goodpasture antigen) or reactivities to other NC1 domains of type IV collagen. The total time for performance of the test is 4 to 5 h.

Background

Western blot analysis for the detection of anti-GBM antibodies was developed in our reference laboratory at Massachusetts General Hospital in 1988, and since then it has been used routinely for analysis of sera referred for screening of anti-GBM antibodies, typically in a setting of rapidly progressive disease with kidney and lung involvement. Since January 2004 approximately 10,000 (9,597) sera have been tested for anti-GBM antibodies. Subsequently we retested by Western blot analysis samples of frozen sera from 1981 to 1988 that had previously been found to be positive by indirect immunofluorescence, enzyme-linked immunosorbent assay (ELISA), or RIA in order to compare sensitivities. We have detected anti-GBM antibodies in the sera of 165 (1.7%) patients from samples sent to our reference laboratory between 1981 and 2003. Virtually all patients with a positive test for anti-GBM antibodies have been found to have clinical or pathological features consistent with anti-GBM disease. In a series of 18 patients with biopsy-proven anti-GBM disease and a positive Western blot, 85 to 90% were positive by indirect immunofluorescence and 100% were positive by RIA or ELISA.

A comprehensive serological workup for patients with a pulmonary renal syndrome should include ANCA testing since, in our experience, the syndrome of lung hemorrhage and glomerulonephritis is most often due to an ANCA-associated disease (28). In 1996, Niles et al. (28) reviewed the medical records of 750 patients that had serum sent to our laboratory for anti-GBM testing from 1981 to 1993.

In this group, 88 patients had evidence of lung hemorrhage and glomerulonephritis and 48 were found to have ANCA, 6 had anti-GBM antibodies, 7 had both, and 27 were negative for both. Furthermore, 30 to 40% of patients with anti-GBM antibodies also have ANCA (2, 14). Studies from our laboratory by Niles et al. in 1991 (29) reported that of 123 patients with rapidly progressive glomerulonephritis who were studied serologically for anti-GBM antibodies and ANCA, 42 had pauci-immune necrotizing glomerulonephritis by light microscopy, 18 had anti-GBM disease, and 63 had other forms of renal disease as diagnosed by renal biopsy. The 63 patients with other forms of glomerulonephritis included those with minimal change, systemic lupus erythematosus, membrano-proliferative glomerulonephritis types I and II, membranous glomerulonephritis, IgA nephropathy, Henoch-Schönlein purpura, focal segmental glomerulosclerosis, antitubular basal membrane disease, acute hemolytic-uremic syndrome, mixed cryoglobulinemia, systemic light chain disease, and postinfectious glomerulonephritis. Healthy laboratory personnel were analyzed as controls. Only the sera of the patients with biopsy-proven crescentic and necrotizing glomerulonephritis by light microscopy and positive direct immunofluorescence (diffuse, linear IgG along the GBM) reacted with the specific molecular weight components of the Goodpasture antigen when screened for circulating anti-GBM antibodies by Western blot analysis (Fig. 3). No positivity was detected in the sera of patients with other forms of glomerulonephritis or in the sera of the 917 healthy controls that were also analyzed. Of the 18 patients with anti-GBM antibodies, 8 also had ANCA; 2 were specific for proteinase 3 and 6 were specific for myeloperoxidase. Histologically, there was no clear difference seen between patients with anti-GBM alone and those with both anti-GBM and ANCA.

Our Western blot analysis results showed that only the sera from patients with biopsy-proven anti-GBM reacted with the Goodpasture antigen in the 28-kDa and 48- to 50-kDa regions corresponding to the monomeric and dimeric forms of α3(IV) NC1 (the Goodpasture antigen) as defined by Weislander et al. (35). In approximately 40% of the sera
FIGURE 3 Western blot analysis of sera from seven patients with biopsy-proven anti-GBM nephritis (lanes 3 to 8). Note the reduced intensity of the bands in lane 7 compared to lane 8. The serum sample in lane 7 was from the same patient as that in lane 8, but after 11 plasmapheresis exchanges. Positive control serum and normal control serum are in lanes 1 and 2, respectively. The antigen preparation is a collagenase digest of human GBM, which is separated by PAGE and immunoblotted onto nitrocellulose paper. The reactivity seen in the positive sera is to the same two molecular mass regions at 28 and 50 kDa, which represent the α3(IV) NC1 (Goodpasture antigen) in its monomeric and dimeric forms.

analyzed, reactivity to antigens of different molecular weights was detected. Thus, Western blot analysis provides a definitive means of differentiating between the specific reactivity of anti-GBM antibody in the sera of patients with anti-GBM disease and the reactivities of antibodies with other specificities. These other reactivities are probably due to a secondary antibody response to other proteins released from the damaged GBM as a result of the binding of the nephritogenic anti-GBM antibodies to the GBM.

ELISA FOR α3(IV) NC1

Western blot analysis is a sensitive and specific assay for detecting anti-GBM antibodies, but quantitation is needed for the purpose of monitoring disease activity. Therefore, in positive sera the level of anti-GBM antibody is quantitated using an antigen-specific immunoassay (ELISA). A reasonably satisfactory monitoring commercial ELISA kit (SciMedex Corp., Denville, N.J.) uses microtiter strips coated with the monomer of the α3(IV) NC1 subunit. The value, in ELISA units (EU), for each unknown serum is determined from a standard curve constructed from analysis of known positive sera containing assigned values of 5, 20, 80, and 320 EU/ml. A positive serum and a negative serum are also included in each determination. The level of antibody is expressed as EU per milliliter; a value equal to or greater than 15 EU/ml is considered positive, a value equal to 5.1 to 14.9 EU/ml is considered equivocal, and a value equal to or less than 5 EU/ml is considered negative. Differences in sensitivity and specificity were observed when the results of ELISA and Western blot analysis using the same serum were compared. The differences in results were evident for treated patients, particularly when plasmapheresis was part of the treatment regimen. However, the ELISA is clearly less sensitive than Western blotting. Often after treatment, the ELISA will become negative, while the Western blot analysis remains positive. False positives are also a problem in this ELISA; we have obtained positive ELISA results with sera from nine patients with no evidence of anti-GBM disease by biopsy or Western blot analysis. Therefore, the most sensitive and specific current method for detecting circulating anti-GBM antibodies is Western blot analysis. In our laboratory, positive anti-GBM antibody results obtained by ELISA are never reported without confirmation by Western blot analysis. It is also important to note that the antibody "titer" obtained in the ELISA for different patients cannot be used as a measure of the disease severity, since the antibodies may have different affinities and biological activities. The test is most useful for monitoring an individual patient, comparing subsequent samples with the initial sample.

Autoimmunity of Testis, Ovary, and Spermatozoa

RICHARD A. BRONSON, JULIA LUBORSKY, AND KENNETH S. K. TUNG

126

Experimental studies indicate that infertility may have an immune basis, resulting from spontaneous or induced autoimmune disease that targets the testis, the ovary, or the spermatozoa (51). In humans, these diseases are represented by granulomatous orchitis, premature ovarian failure (POF), and sperm antibody-associated infertility in male and female subjects (50). Two immunologic mechanisms may be operative. Sperm antibodies can impair spermatozoal motility or viability by complement-dependent cytotoxicity, interfere with spermatozoal transport in the female genital tract, or block the cellular interaction in the fertilization process. Alternatively, antibody- and T-cell-mediated inflammation may result in atrophy of the gonads, associated with loss of germ cells.

In this chapter, we describe spermatozoal antibody-mediated infertility, with emphasis on the methods of sperm antibody detection with respect to the laboratory procedure, clinical indications, and interpretation of results. We describe an emerging assay for detection of antibodies to ovarian antigens. We then briefly discuss the human testicular and ovarian autoimmune diseases and the diagnostic dilemma they present.

SPERM-ASSOCIATED ANTIBODY AS MECHANISM OF MALE AND FEMALE INFERTILITY

When endocrinologic problems or sequelae of genital infection have been excluded, there remain a substantial number of patients with idiopathic infertility. In this subset of patients, spermatozoal antibodies may have an important causal role. Antisperm antibodies also develop in men following vasectomy, and they may account for infertility in some men following vasovasostomy for restoration of fertility (41, 49). Autoantibodies to sperm may also occur in patients with cystic fibrosis and congenital absence of the vas deferens (6, 12, 21).

Normally, spermatozoal antigens do not elicit immune responses in normal males and females. This is because systemic tolerance mechanisms are operative, and seminal plasma contains immunosuppressive molecules that may normally control immunity to spermatozoa. Autoimmunity ensues following stimulation by foreign microbial antigen that mimics gonadal antigen (19), when antigen is presented to T cells in the context of a vasectomy-induced granuloma, or

invoked by endogenous antigen when an immunoregulatory mechanism, such as regulatory T cells, is defective (49, 54).

Most clinical evidence for spermatozoal antibodies in infertility has come from correlative studies. These studies do not define the causal nature of the antibodies in the infertile state. More direct evidence has come from clinical studies in in vitro fertilization (IVF) and embryo transfer programs. In the presence of spermatozoal head-directed antibodies, when nearly all spermatozoa are coated with immunoglobulin (Ig), the fertilization rate has been significantly reduced, according to reports from several IVF programs (8, 9, 28, 39, 44). When serum from women with antisperm antibodies was used in IVF medium, fertilization rates were decreased. Sixty percent of women with unsuccessful pregnancy had sperm head-directed serum antibodies, compared with 6% of women with successful pregnancy (39, 52).

Spermatozoal Antibody Detection Methods

Spermatozoal antibodies may be detected in serum, or they are bound to the ejaculated spermatozoa. Studies comparing methods of sperm antibody detection indicated that antibodies to surface antigens of viable spermatozoa correlate best with infertility, whereas antibodies to internal spermatozoal antigens do not. Tests based on sperm agglutination were quite reproducible but lacked sensitivity (40). In contrast, the immunobead test, the mixed-antiglobin reaction (MAR) test, and the complement sperm immobilization tests are most sensitive. These tests are used most frequently by clinical laboratories and are described below in detail (see also references 3 and 40).

Direct Immunobead Assay

In the direct immunobead method, which detects Ig (presumed antibody) bound to spermatozoa in vivo, ejaculated spermatozoa are reacted with polyacrylamide beads coated with antibody to human Ig (immunobeads) (3, 5, 8). Immunobeads coated with rabbit anti-human IgA, IgG, or IgM (Irving Scientific, Santa Ana, Calif.) in phosphate-buffered saline (PBS) are dispensed in concentrations that optimize spermatozoal contact. This concentration is usually 6 to 7 mg/ml, although the exact concentration should be determined for each lot of immunobeads. Sodium azide is removed from the immunobeads by centrifugation in 4 ml of PBS at $800 \times g$ for 10 min. Immunobeads are then suspended in PBS containing 10 mg of bovine serum albumin fraction V (BSA;

ICN Immunobiologicals) per ml that has been presterilized by passage through a 0.22-μm-pore-size filter unit (Millipore). To avoid bead aggregation, each class of beads is sonicated before initial use for approximately 20 s at continuous pulse and at medium setting. Thereafter, beads can be vortexed to remain in suspension if they are allowed to stand for more than 2 h. Beads should be stored at 4°C. Lyophilized beads appear to be stable for at least a year, while beads reconstituted in buffer have a shelf life of at least 4 to 6 weeks if not contaminated. A convenient approach is to weigh out a small aliquot of dry immunobeads and suspend them in sterile PBS every 2 weeks. Immunobeads contaminated by bacteria or human serum will not bind to spermatozoa coated with antibodies.

To prepare sperm suspension, fresh semen samples (10 to 50 μl), liquefied at room temperature for 45 min postcollection, are added to glass test tubes (12 by 75 mm) and mixed with 4 ml of PBS containing 5 mg of BSA per ml (PBS–0.5% BSA). For samples with low spermatozoal count and those with poor motility and progression, a larger amount of semen is required. After centrifugation at $300 \times g$ for 8 min, the cell pellet is suspended in 500 μl of PBS–0.5% BSA. The spermatozoal suspension is transferred to a 0.5-ml Microfuge tube and centrifuged for 8 s on a Beckman Microfuge E. After the Microfuge procedure has been repeated twice, the spermatozoal pellet is suspended in 80 μl of PBS–0.5% BSA. When necessary, to promote motility in samples with weak spermatozoal motility, 10 to 20 μl of horse serum (Flow Laboratories) is added. Horse serum is prepared by heating the sample at 80°C for 10 min and discarding the coagulum by dislodging it with a Pasteur pipette and centrifuging the sample. Small aliquots of heat-inactived horse serum are kept at −20°C.

To evaluate the reaction between immunobeads and spermatozoa, a 10- to 15-μl volume of the spermatozoal suspension is added to 50 μl of immunobeads in a glass tube (12 by 75 mm). The contents are mixed by gentle pipetting with a mechanical pipetter (Eppendorf); then a drop of the suspension is placed on a glass slide and covered with a coverslip (22 by 22 mm). Slide preparations are examined serially under phase-contrast optics, at ×200 magnification, over a 10- to 15-min interval. At a final cell concentration of 10^6/ml, the spermatozoal suspension yields approximately 10 cells per microscopic field. Results obtained include (i) percent motile spermatozoa with bound immunobeads, (ii) approximate number of immunobeads per cell, and (iii) location of bound immunobeads on the spermatozoa. Immunobeads on the slides are kept in suspension by tapping the coverslip occasionally, and observation should be completed within 10 to 15 min. Observation is made in areas with high concentrations of immunobeads, and replicates of 100 motile spermatozoa are examined. If the duplicates differ by more than 10%, an additional 200 spermatozoa are recorded.

As controls, known positive and negative sera are studied simultaneously based on the indirect immunobead test (see below). Also, the specificity of a positive reaction may be verified by the addition of normal human serum (10 μl) to the reaction mixture. Serum Igs block anti-Ig on the immunobeads and prevent binding of anti-Ig to spermatozoa.

Indirect Immunobead Test

In the indirect immunobead method, antisperm antibodies are first reacted with the biological fluids; the antibodies captured on the spermatozoa are in turn detected by reaction with immunobeads (3, 5, 10).

1. Spermatozoa, preferably from the husband or from a fertile donor known to be free of antisperm antibodies, are obtained by the swim-up method. This is accomplished by overlaying 0.5 ml of PBS–0.5% BSA in a test tube (12 by 75 mm). After incubation at 37°C for 60 min, the spermatozoa in the top 0.4 ml of the pooled PBS–5% BSA layers are carefully collected and counted.

2. Spermatozoa are added to serum samples from the patient and to known positive and negative control sera that have been heated (56°C, 30 min) and diluted appropriately in PBS. The final serum dilutions are 1:10 and 1:100.

3. The sperm-serum mixture is incubated in a water bath at 37°C for 60 min. Following centrifugation at $300 \times g$ for 8 min, the cell pellet is suspended in 400 μl of PBS–5% BSA and transferred to the 500-μl Microfuge tubes.

4. The spermatozoa are washed four times by centrifugation for 8 s in a Beckman Microfuge E. Care must be taken to remove all supernatant from the cell pellets during the washing steps, as residual serum Ig can interfere with the immunobead assay by blocking the anti-Ig sites on the beads.

5. The washed spermatozoa are suspended to an appropriate concentration, mixed with immunobeads, and examined as described for the direct immunobead test.

Comment: The currently available immunobeads are not specifically manufactured for use in clinical laboratories. Although the lot-to-lot variability in sensitivity appears to be low, it is important to compare the results between assays. It should be stressed that serum and microbial contamination of immunobeads will interfere with the sensitivity of the immunobead test.

MAR Test

The MAR test (26), popular in Europe, detects IgG and IgA antisperm antibodies bound in vivo to the plasma membrane of motile spermatozoa. Whereas immunobeads coupled with anti-Ig are able to bind directly to the sperm-bound Ig, in the MAR antiserum, anti-IgG or anti-IgA is added to agglutinate the spermatozoa with Ig-coated, glutaraldehyde-fixed sheep erythrocytes.

1. Prepare Ig-bound sheep erythrocytes as follows. Sheep erythrocytes in Alsever's solution are washed four times by centrifugation at $2,000 \times g$ for 5 min in a total of 20 volumes of phosphate-buffered glucose (PBG; 76 ml of 0.15 M disodium phosphate, 24 ml of 0.15 M monopotassium phosphate, and 100 ml of 5.4% glucose in distilled water, pH 7.2) and after centrifugation are resuspended in PBG as a 20% solution. The erythrocytes are fixed by addition of an equal volume of 0.2% glutaraldehyde dissolved in PBG and incubation with the erythrocyte mixture in a 37°C water bath for 15 min. The erythrocytes, washed five times with 0.85% sodium chloride and resuspended as a 10% solution in 0.85% sodium chloride containing 0.1% sodium azide, are stored at 4°C. The shelf life of fixed cells exceeds 4 years.

To coat erythrocytes with Ig, fixed erythrocytes (5 ml) are washed twice with PBG (pH 7.2) and suspended in 2 ml of PBS. Then 1 ml of purified human IgG or colostral IgA (LN antisera; Behringwerke AG, Marburg, Germany) at 1 mg/ml is added together with 0.5 ml of 1% sodium azide. After thorough mixing, the cells are incubated at 37°C for 16 h on a rotating platform. The cells are washed three times in PBS, resuspended as a 20% solution in 2 ml of 50% glycerol in PBS, and stored at 4°C. The shelf life exceeds 2 years.

2. For the MAR test, the Ig-coated cells are washed three times and resuspended in PBS as a 2% solution. On a slide, 10 μl of the erythrocytes is added to 10 μl of fresh, liquefied semen from the patient or from antibody-negative and antibody-positive individuals. To this mixture is added 10 μl

of undiluted rabbit antiserum IgG to human IgG or IgA. The rabbit antisera are first dialyzed against PBS to remove the preservatives and are kept at −70°C. The cell-antibody mixture is covered with a coverslip and incubated in a moist chamber at 37°C for 15 min for IgG-specific MAR. The cell reaction is examined by phase-contrast microscopy at ×400 magnification. The percentage of motile spermatozoa involved in mixed agglutination with one or more erythrocytes is determined; a result of 10% or greater is considered positive.

Comment: The MAR test detects IgG class antisperm antibody with sensitivity comparable to that of the immunobead assay. In contrast, the MAR test detects IgA class antibody with a sensitivity lower than that of the immunobead test (40). Ig-bound erythrocytes are also not commercially available.

Complement-Dependent Spermatozoal Immobilization Test (25)

1. Test sera and positive and negative control sera are heated at 56°C for 30 min and centrifuged at $1,350 \times g$ for 10 min.
2. Guinea pig sera nontoxic to human spermatozoa with complement activity exceeding 200 50% hemolytic complement units are stored at −80°C until used. An active but nontoxic guinea pig complement source is critical for a successful assay.
3. A fresh sample of ejaculated human semen is liquefied for 20 min at room temperature, counted, and centrifuged at $1,350 \times g$ for 5 min. After being washed once with 10% negative control human serum in normal saline, actively motile spermatozoa are collected by the swim-up method as described earlier. The spermatozoal number is adjusted to 40×10^6/ml.
4. Next, 0.25 ml of test or control serum, 0.025 ml of human spermatozoal suspension, and 0.05 ml of guinea pig serum (containing approximately 10 50% hemolytic complement units) are mixed in a small test tube and incubated in a gently shaking water bath at 32°C for 60 min.
5. To ensure that the guinea pig serum is not toxic to the spermatozoa, an important control is to add guinea pig serum to spermatozoa without test serum. The test is not valid when guinea pig serum is toxic.
6. A drop of spermatozoal mixture is transferred by Pasteur pipette to a clean glass slide and examined immediately, without a coverslip, at ×200 magnification. The percentage of motile spermatozoa among 200 spermatozoa is recorded in triplicate samples. The percentages of motile spermatozoa in the negative control (%C) and test (%T) samples are obtained. The ratio of these percentages is designated the spermatozoal immobilization value. A value of 2 or higher is determined to be positive for antisperm antibodies.

Comment: Complement-dependent immobilization, popular in Japan, is highly specific, with minimal false-positive reactions. However, the test does not detect non-complement-fixing antibodies. The concentration of antibody on the sperm surface also dictates the extent of complement-mediated immobilization (5).

PCT To Assess Function of Antibody-Bound Spermatozoa

Antibodies may interfere with penetration of cervical mucus by spermatozoa and impede the transport of spermatozoa to the ovulated oocyte. Since the postcoital test (PCT) directly examines the interaction between spermatozoa and cervical mucus, it provides a functional assessment of spermatozoal antibodies (4).

Cervical mucus of good quality is best inspected by phase-contrast microscopy for the presence of motile spermatozoa. It should be collected from the endocervical canal, after cleaning the cervix with a dry cotton swab. Its volume should be noted, as well as its clarity and stretchiness (spinnbarkeit) and pH. A low pH (<7) suggests contamination of the specimen with vaginal secretions during its collection. At low magnification, the mucus is surveyed microscopically for distribution of spermatozoa and heterogeneity of spermatozoal density. At high (×400) magnification, the number of viable spermatozoa per high-power field in selected areas is determined. The presence of white blood cells is noted, as this suggests the possibility of local infection and the need to screen for sexually transmitted diseases.

Since the quality of cervical mucus is hostile to spermatozoa during most of the menstrual cycle, the timing of PCT is critical. Cervical mucus obtained within a short time before ovulation is optimal for spermatozoal penetration, and this is the optimum time for PCT. In the past, accurate timing was possible only retrospectively by noting a rise of basal body temperature 1 to 2 days following PCT. Currently, monitoring of urinary luteinizing hormone is used to determine the best time for PCT. Daily monitoring should begin 3 to 4 days before the anticipated ovulation. It should be noted that the sensitivity of commercially available kits to detect luteinizing hormone within urine varies widely. The preovulatory gonadotropin surge may be initiated in approximately two-thirds of women in the morning and one-third in the afternoon. The couple should be advised to have sexual relations on the evening of the day the ovulation predictor test turns positive, and cervical mucus should be assessed the next morning, within 12 h of coitus. There is controversy about what constitutes a normal test (4). The presence of fewer than five motile sperm per high-power field, or restricted motion of sperm within preovulatory cervical mucus of good quality (immobilization or shaking motions), requires further evaluation, including semen analysis and tests for antisperm antibodies. Poor mucus may result from cervicitis, prior in utero exposure to diethylstilbestrol, or cervical cauterization.

Clinical Indications of Antisperm Antibody Tests

Spontaneous Agglutinated Ejaculated Spermatozoa
For the rare patient, the finding of agglutinated spermatozoa in the semen specimens should alert one to the possibility of autoimmunity to spermatozoa.

Abnormal PCT
An important indication of the presence of antisperm antibody is an abnormal PCT, particularly when the semen quality is normal and the cervical mucus, obtained at late follicular phase, is well hydrated and acellular. In this setting, if the number of spermatozoa in the cervical mucus is unexpectedly low or spermatozoa are absent, it is important to rule out the presence of antisperm antibodies.

If the antibodies are bound to the principal piece of spermatozoal tail or to the spermatozoal head, the spermatozoa may exhibit a shaking or "cogwheel" motion, with little forward progression, or they may be completely immobilized after a period of 5 to 6 h following entry into the mucus after coitus. Antibodies confined to the end piece of the spermatozoal tail are not associated with a reduced fertility rate.

Patients with Idiopathic Infertility

While an abnormal PCT is suggestive of the presence of antibodies, a negative result does not preclude antibody testing. Patients with infertility for which there is not an apparent cause, despite rigorous clinical evaluation, are also candidates for antisperm antibody testing.

Prospective Vasovasostomy Patients

Men who have had vasectomy and subsequent sterilization reversal should also be screened for spermatozoal antibodies. However, while the majority of these men have serum antisperm antibodies, only a minority of them have antibody-coated sperm in their ejaculates. In the latter group, impaired fertility has been found. It should be noted that infertility in these patients is not always immune mediated.

Correlation between Antisperm Antibodies Detected by the Immunobead Test and Clinical Status

One in 150 healthy young men screened for antisperm antibodies in a semen donor recruitment program was found to have Ig on more than 20% of the spermatozoa, whereas 7% of men among unselected infertile couples have similar antibodies (4).

A general correlation has been found between the proportion of spermatozoa with bound immunobeads and reduction of motile spermatozoa within postcoital cervical mucus. When 100% of the spermatozoa were coated with antibodies, zero to five spermatozoa were found per high-power field in a well-timed PCT. When less than 50% of spermatozoa were coated with Ig, the number of spermatozoa within cervical mucus was within the normal range.

The presence of spermatozoal antibodies also parallels in a general way the reduction in pregnancy rate. Among 108 infertile couples wherein more than 50% of the husbands' spermatozoa were coated with antibodies, the pregnancy rate was 22%. In contrast, among couples in whom less than 50% of the spermatozoa were coated with antibodies, 44% became pregnant. In a subset of infertile patients in whom the dominant or sole factor leading to infertility was identified as autoimmunity to spermatozoa, the conception rate in couples in whom more than 50% of the spermatozoa were Ig bound was 15%, whereas for the couples in whom less than 50% of the spermatozoa had bound Ig, the conception rate was 60%.

The antigenic locations also have clinical significance. Head-directed antibodies significantly reduced the fertility rate, antibodies to the spermatozoal tail (main piece) had variable effects on fertility, and antibodies to the tip of the spermatozoal tail had no effect (39). Antibodies of the IgG and IgA classes are more predictive of fertility reduction, whereas IgM antibodies are not predictive of infertility. IgM antibodies may be detected within serum but only rarely are detected in the ejaculate, on spermatozoa.

In some infertile patients, antibodies to spermatozoa are detected only in the seminal plasma (23). Since antibodies are not detected in the sera of these patients, the antibodies are likely produced locally. In a group of men suspected of autoimmunity to spermatozoa, for whom matched serum samples and serum samples from women were directly compared, antibodies were found solely in the ejaculate in 15% of the patients, and they were mainly of the IgA class.

At this stage of development, without the benefit of quantitative assay and a "gold standard," the clinical interpretation of antisperm antibody is in part an art. Care must be exercised in distinguishing between a positive result and a clinically significant result based on the immunobead or any antisperm antibody assay. If most spermatozoa are not present within cervical mucus and the majority of the spermatozoa have detectable Ig on their surface, the result of immunobead binding is considered clinically significant. However, apart from the unequivocal cases, direct immunobead binding results should not be interpreted in the absence of clinical correlates. Similarly, serological tests for antisperm antibodies in men, including indirect immunobead binding, are not sufficient by themselves to document the presence of clinically significant autoimmunity to spermatozoa. Finally, a decision on therapy should not be implemented solely on the basis of a serological test, whatever the detection method.

Future Prospects

A useful diagnostic autoantibody assay would be one that recognizes antigens that are responsible for the pathogenesis of the autoimmune process. An important approach in sperm and oocyte antigen identification has benefited from recent contraceptive vaccine research (reviewed in reference 18). Antibodies from infertile couples have been used to identify sperm-specific molecules as potential contraceptive vaccine immunogens. In addition, monoclonal antibodies to sperm and oocytes that inhibit fertility or fertilization in vitro have been generated. These antibodies have identified antigens that are available as recombinant proteins or as peptides representing defined native B-cell epitopes. The antigen function has been verified in some cases by antibody interference during IVF assays, and in others in rodent and primate fertility trials following active immunization. This systematic approach has identified sperm and oocyte antigens that may serve as target antigens in future serological tests.

OVARY-ASSOCIATED ANTIBODY IN DIAGNOSIS OF OVARIAN AUTOIMMUNE DISEASE, POF, AND FEMALE INFERTILITY

The evidence for an autoimmune disease of the ovary includes (i) frequent association with other autoimmune diseases, (ii) lymphocytic infiltration of the ovary, and (iii) association with serum ovarian antibodies (36). Approximately 70% of patients with POF and 70% of women with unexplained infertility had serum antibody to ovarian and/or oocyte antigens. The predictive value of a poor pregnancy outcome after IVF in individuals with autoantibodies was 82% (33).

Ovarian dysfunction is determined by abnormalities in menstrual cycle patterns and measurement of early follicular-phase follicle-stimulating hormone and estradiol. However, endocrine tests do not differentiate between endocrine and autoimmune etiologies for ovarian dysfunction (32, 36). Detection of ovarian autoantibodies supports the diagnosis of ovarian autoimmunity. Autoantibodies are associated with POF and unexplained infertility and are rarely detected in sera of women from a blood bank or other infertility clinics (31). About 1% of women in the United States have POF (35), and 60 to 70% of these may be due to an etiology of ovary autoimmunity (15, 29). From clinical studies, 20% of women with infertility have an unexplained cause, and of the women with unexplained infertility, 50 to 70% have ovarian and/or oocyte antibodies.

In addition, during ovarian hyperstimulation for IVF, about 20% of women do not respond with adequate estradiol production in response to follicle-stimulating hormone stimulation. When this occurs in younger women with ovarian or

oocyte antibody, an autoimmune basis is considered (36, 42). In general, women with ovarian autoimmunity have lower success rates during infertility treatment (20, 24, 33). The ovarian antibody test is useful in (i) confirming a diagnosis of autoimmune premature menopause, (ii) potentially predicting the risk for premature menopause, (iii) diagnosing and differentiating an autoimmune etiology from an endocrine etiology in female infertility, and (iv) predicting poor responses to estrogen-induced ovulation and reduced probability of pregnancy following IVF.

Antiovarian and Antioocyte Antibody Immunoassays

Serum antibody of some patients with autoimmune ovarian disease reacts with either oocyte extracts, ovarian extracts, or both. Therefore, independent immunoassays for ovarian antibodies and oocyte antibodies (37) have been developed for clinical diagnosis. The nature of the target oocyte or ovarian antigen has not been determined. For antiovarian antibody, an 85% concordance was noted between results based on human versus rat ovarian antigens, so rat ovarian extract is used in the assay. Human oocytes are obtained as a by-product of IVF treatment for infertility. Positive values are determined by comparison to values for control sera from women of similar age with normal menstrual cycles without clinical evidence of autoimmune disease.

Reagents

Enzyme-linked immunosorbent assay (ELISA) buffer: 10 mM phosphate buffer, 30 mM NaCl, and 1 mM MgCl$_2$, pH 7.4

Wash buffer: 0.05% Triton X-100 in ELISA buffer

Dilution buffer for serum and antibody: Wash buffer plus 1% BSA (A7050; Sigma)

Blocking solution: Wash buffer plus 5% BSA

Alkaline phosphatase (AP) substrate buffer: 24 mM MgCl$_2$, 1 M diethanolamine (pH 9.8) (D8885; Sigma), and AP reagent (1 mg of p-nitrophenylphosphate/ml of AP buffer). AP reagent is not stable and should be prepared immediately before use.

Homogenization buffer: 40 mM Tris-HCl, 5 mM MgSO$_4$, and 0.25 M sucrose, pH 7.4

Comments: For blocking nonspecific reaction, we use BSA preselected for maximum antibody binding but minimal nonspecific binding. The BSA preparations obtained from the manufacturer change over time, and each new batch should be monitored. Quality control water is purchased from Baxter (no. 2F7115) and is used in all buffer preparations and cell washes.

Ovarian Extract Preparation

Rat ovaries are removed from 3-week-old rats 36 to 48 h after they have been stimulated by serum from a pregnant mare and human chorionic gonadotropin (34).

1. Add chilled homogenization buffer, at 1 ml per 80 to 100 mg (wet weight) of tissue (or ~1 rat ovary), to a Dounce homogenizer.
2. Homogenize by hand with 10 to 20 strokes on ice.
3. Centrifugation

   a. Transfer homogenate to a cold 15-ml conical centrifuge tube, bring final volume to 10 ml with homogenization buffer, and centrifuge at 1,000 × g, and 4°C for 10 min.

   b. Transfer supernatant to a 15-ml centrifuge tube and centrifuge at 10,000 × g, 4°C for 30 min.
   c. Discard supernatant and suspend the pellet in homogenization buffer at 1 ml per 100 mg (wet weight) of tissue.
   d. Freeze aliquots on dry ice and store at −70°C.

Oocyte Extract Preparation

The antioocyte assay uses oocytes that failed to fertilize during IVF procedures (37). The oocytes should be intact, and adherent granulosa cells should have been removed. However, it is critical to freeze and store oocytes in the homogenization buffer and to inactivate any enzymes that were used for isolation (14).

1. Collect human oocytes into homogenization buffer and rinse once by centrifugation in a 1.5-ml Microfuge tube in a Microfuge system at 1,000 × g for 0.5 min.
2. Freeze the final pellet, devoid of buffer, in aliquots on dry ice and store at −70°C.
3. Disrupt oocytes by freezing, homogenization, and vigorous mixing.
4. Thaw frozen oocytes (~15 min), and rinse ~100 oocytes by centrifugation in a Microfuge system (~1,000 rpm) for 0.5 min, remove supernatant, and repeat rinse twice in homogenization buffer.
5. Add 0.1 ml of cold Tris buffer (no sucrose) per 20 oocytes and vortex at high speed for 15 to 30 s.
6. Homogenize in a Microfuge tube with a micropestle by hand with 10 to 20 strokes and vortex; repeat until solution appears uniform (repeating three or four times), and use immediately.

Preparation of Antigen-Coated Immunoassay Plates

1. Use high-protein-binding plate (for example, Nunc Maxisorb).
2. Thaw tissue extract just before use and vortex well. Dilute the tissue in ELISA buffer to 2 μg of protein per ml (human) or 1 μg of protein per ml (rat). Vortex well and use immediately. For oocytes, dilute the homogenate with ELISA buffer to ~0.1 ml per oocyte (i.e., 10 oocytes/1 ml).
3. With a multichannel pipette, add 100 /μl of extract to each well; place in a moisture box.
4. Wrap plates individually in Saran Wrap and incubate for 1 h at room temperature.
5. Store in a −70°C freezer for up to 6 months.

ELISA

Day 1

1. Thaw plates in a moisture box for 1 h at room temperature.
2. Discard excess fluid in wells by "flicking" the plate; blot quickly on fresh paper towels.
3. Add 200 μl of blocking buffer to all wells with a multipipette; cover plates and incubate in a moisture box at room temperature for about 1 h and then overnight in a refrigerator.

Day 2

1. Bring plates to room temperature and thaw stored serum.
2. Dilute each serum sample to 1:100 in dilution buffer.
3. Flick excess fluid from plates and wash wells three times with 200 μl of wash buffer.

4. Add test or control sera (100 μl at 1:100) in duplicate.

5. Incubate for 1.5 h at room temperature and then wash three times with wash buffer.

6. During incubation, dilute conjugated second antibody [Sigma; goat anti-human F(ab′)₂-specific IgG conjugated to AP] in dilution buffer, at an appropriate dilution determined previously (about 1:10,000).

7. Add 100 μl of conjugated second antibody to the wells and incubate at room temperature for 1 h.

8. Wash twice with 200 μl of ELISA buffer (no Triton X-100) and then four times with 200 μl of distilled quality control water.

9. *Immediately* before use add AP reagent to AP substrate buffer at 1 mg/ml. Plates can be "held" in ELISA buffer (no Triton X-100) from step 8, after removal of second antibody, while substrate is being prepared.

10. Develop color reaction by adding 100 μl of AP substrate reagent to each well.

11. Determine absorbance at 405 nm (optical density [OD]) in an ELISA reader. Endpoint readings should be taken at 15, 30, 45, and 60 min (Fig. 1). Data should be determined at the linear portion of the enzyme reaction curve just below the plateau (usually within 30 to 60 min). Alternatively, add appropriate stop solution at 45 to 60 min and determine absorbance.

Comments: A small amount (10 μl each) of second antibody solution and AP substrate should be mixed in a test tube to test for a yellow color reaction prior to the addition of the substrate to the plate. If no color reaction occurs, prepare fresh substrate buffer (check pH) and test again. If a color reaction still fails to occur, test a new antibody-AP conjugate.

Control Sera Included in Each ELISA

Second antibody control: for each plate two wells contain antigen, conjugated second antibody, and reagent only (omit primary serum), to assess nonspecific background, which should be less than 0.10.

Negative controls: Serum from normally cycling women without diagnosed autoimmune disease. Use at least 6 to 8 controls.

Positive control: Serum previously identified to be positive for ovarian or oocyte antibody

Buffer control (optional): for each plate two wells contain antigen, blocking solution, and substrate solution only (no antibodies), to monitor any substrate reaction with tissue enzyme; their absorbance should be <0.1.

Data Analysis

1. Determine the cutoff value for positive results. Calculate (i) the average total OD of the controls and (ii) the standard deviation (SD) of average total OD for controls. The SD of the controls is usually <0.1 unless there is an outlier among the controls. The cutoff value for positive results is the control average plus 2 SDs (95% confidence level, or $P < 0.05$). The coefficient of variation for the assay should be less than 10%.

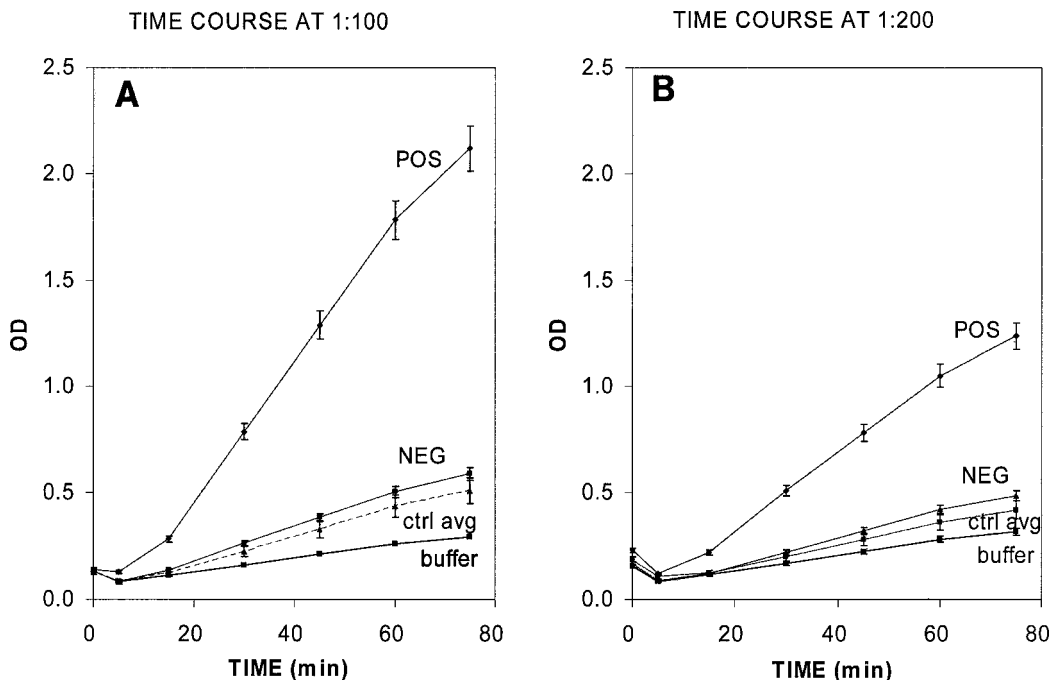
2. Evaluate assay performance. The second antibody control should be less than 0.1 OD unit below the control mean. If this control is similar to the values of test sera on the plate, then the block might have been omitted (or there is a problem with the BSA in the blocking buffer). In addition, the control mean should be 0.5 to 0.6 OD unit or less, with an SD of <0.1. If the SD for the control mean is large, check if


FIGURE 1   Kinetics of enzyme immunoassay reaction for ovarian antibody test. The graph compares the OD (at 405 nm) for the control average (ctrl avg) ($n = 5$) at each time point with the ODs of a positive control sample (POS), a negative sample (NEG), and the background (buffer) for serum dilutions of 1:100 (A) and 1:200 (B).

(i) there are outliers among the control values (with five or more controls, one outlier control can be omitted, as is routine in radioimmunoassay analysis) or (ii) the values of multiple replicates are too far apart (i.e., check individual SDs for replicates). This is usually an operator error, either in plate preparation or assay performance, and the assay will need to be repeated. Positive control values should be at least two times greater than the control mean (preferably three to four times at 1:100). The size of this difference is an indication of the "differentiation power" of the assay. If the positive control is less than 1.5 times over the assay control mean, the assay should be repeated. Consider inadequate antigen, too much antigen, or incorrect serum dilution as a potential source of error.

3. Result interpretation. Calculate the specific signal for all test samples by subtracting the cutoff value from the total average OD for each sample. The result is considered positive if the sample shows a definite signal above the cutoff value. It is considered negative when a specific signal is detected at or below the cutoff value. It is indeterminant when the sample, on repeated testings, yields variable results.

Human Autoimmune Ovarian Disease

Human autoimmune ovarian disease is associated with POF or unexplained infertility (17, 29). POF may occur as an isolated disease or as a component of the autoimmune polyglandular syndromes (APS) in association with adrenal or thyroid autoimmunity. About 20% of APS patients have been reported to have POF (53). The antigen in Addison's disease is CYP21, a member of the P450 steroidogenic enzyme family, and is found at a high rate in Addison's disease and APS associated with Addison's disease (38). Antibodies to P450 enzymes are found in POF associated with APS but rarely in isolated POF (2, 7, 11, 38, 46). Although it is hypothesized that the corresponding ovarian CYP17 homolog is a major antigen in POF, only 10 to 20% of sera from patients with isolated POF had detectable antibody to CYP17 (11, 30). It has been suggested that women with POF and anti-CYP17 or steroid cell autoantibodies are at risk for APS or Addison's disease and should be further evaluated.

Recent studies indicate that APS type 1 is associated with mutations of the autoimmune regulator gene (27, 47); however, an association with isolated POF has not been reported. Several antigens have been suggested as targets of ovarian autoantibodies (1, 16, 17, 22, 29), but information on a major antigen still is needed.

Diagnosis of ovarian autoimmunity depends on the detection of serum autoantibodies to crude preparations of ovarian antigens or to oocyte antigens and the exclusion of an infectious cause for the ovarian inflammation (reviewed in reference 29).

HUMAN AUTOIMMUNE TESTICULAR DISEASE

Male infertility can result from autoimmune disease that affects the testis and its excurrent ducts. Some human testicular diseases have immunopathological features that resemble the testicular changes of autoimmune orchitis of the infertile mink (50). They include (i) granulomatous orchitis of noninfectious basis that presents as enlarged testis (a differential diagnosis of testicular tumor) (43), (ii) aspermatogenesis without orchitis in testis with local immune complexes, and (iii) epididymal granulomas of noninfectious origin (50). Nonspecific orchitis associated with viral infections, such as

mumps virus and human immunodeficiency virus, may also have an autoimmune basis (13).

EXPERIMENTAL AUTOIMMUNE DISEASE OF THE OVARY AND TESTIS

Spontaneous autoimmune orchitis and spontaneous infertility occur in mink, horses, dogs, and rats (51). In contrast, spontaneous autoimmune ovarian disease in experimental animals has not been reported. Experimentally, autoimmune orchitis and oophoritis are induced by immunization with testis and ovarian antigen in adjuvant. In addition, both diseases occur spontaneously in mice thymectomized on day 3 of life (45, 48). Orchitis is associated with T-cell and antibody responses to sperm antigens, whereas oophoritis is associated with responses to oocyte antigens (oocyte cytoplasmic antigens and the zona pellucida) and antigen of steroid-producing cells. In both diseases, antigen-specific CD4$^+$ T cells elicit inflammation of the gonads, and this is followed by atrophy, loss of the germ cells, and appearance of serum autoantibodies. Studies based on the thymectomy model indicate that occurrence of the autoimmune diseases is prevented by a population of regulatory T cells that express the CD25 (interleukin 2 receptor alpha chain) marker, present in normal adult humans or mice.

SUMMARY

Antibody to spermatozoa appears to be responsible for infertility in some men and women with unexplained infertility, particularly in the setting of an abnormal PCT. The popular sperm antibody assays include the immunobead, MAR, and sperm immobilization assays described in this chapter. Regardless of the assay, the result of the antibody test should be interpreted in the context of clinical findings. It is likely that the current efforts to discover sperm antigens relevant to the fertilization process will advance sperm antibody detection assays in the future. Autoimmune testicular disease results in infertility of animals, but its human counterpart has not been unequivocally documented. Human autoimmune ovarian disease is better defined; however, the diagnosis is difficult, further refinement of diagnostic assay is required, and the prevalence of disease remains speculative.

Immunologic Testing for Celiac Disease and Inflammatory Bowel Disease

JAMES A. GOEKEN

127

The diagnostic usefulness of serological testing for celiac disease (CD) is well established since the antigens and the immune response involved in its pathogenesis are now known. The importance of serological screening of patients suspected to have CD has been recently emphasized by the 2004 National Institutes of Health (NIH) Consensus Conference on Celiac Disease (http://consensus.nih.gov/cons/118/118celiac.htm). Numerous publications have reported the clinical utility of these tests, encouraging clinicians to utilize them routinely for patient screening and monitoring.

Serological tests for inflammatory bowel diseases (IBDs) (Crohn's disease and ulcerative colitis [UC]) have been relatively recently developed, and although clinical use is growing, controversy about their role in diagnosis and management continues.

CD

CD (also known as celiac sprue or gluten-sensitive enteropathy) was first described in 1888 by Samuel Gee. Typical symptoms include diarrhea, intestinal cramps, frequent stools, flatulence, weight loss, chronic fatigue, and poor growth in children. Signs may include chronic anemia (usually due to iron deficiency), poor dentition, amenorrhea and infertility in adult females, and osteoporosis in adults of both sexes (14, 17, 23). Dietary intolerance was considered a possible etiology of CD soon after its recognition but was not proven until 1953 (10). CD was believed until relatively recently to be a rare disease primarily affecting children, but with the advent of better serological tests and availability of endoscopic biopsy to obtain histological confirmation, increasing numbers of both children and adults been diagnosed with CD. CD is now recognized to be one of the most common inherited diseases in humans, and serological testing has become an indispensable tool for detecting it (13, 15, 22). The latter is true because in addition to its high prevalence, clinical signs and symptoms are varied in both location and intensity. Although the small intestine is the primary organ involved, extraintestinal complaints may predominate, making it possible for physicians to miss the diagnosis without an effective screening test (5, 24).

Population Affected by CD

CD occurs most frequently in Caucasians, Middle Easterners, North Africans, and East Indians but is uncommon in East Asians and Black populations. In Europe and other parts of the world settled by Europeans, the prevalence of symptomatic CD is relatively high. In Europe and the United States, recent population studies indicate a frequency of CD of approximately 0.5 to 1% (13, 15).

CD is a familial disorder linked to two haplotypes of the major histocompatibility locus, HLA-DQ2 and HLA-DQ8. Expression of HLA-DQ2 is found in 90 to 95% of individuals with CD, while HLA-DQ8 is found in 5 to 10%. Other factors, including non-HLA genes and the environment, are also involved, since approximately 30% of the Caucasian population is positive for either HLA-DQ2 or -DQ8 but the majority do not develop CD (30).

Pathogenesis

CD is due to immunologic intolerance to gluten, a protein-carbohydrate complex of wheat, or to similar components of the related grains barley and rye (17, 24). Individuals with CD make an immune response directed at a combinatorial antigen involving gliadin (the ethanol-soluble protein of gluten) and tissue transglutaminase (tTG), a ubiquitous enzyme which uses gliadin as a source of glutamine residues that it adds to tissue proteins (12). The initial response is mediated by T lymphocytes, which infiltrate the small intestinal epithelial cells. Increased numbers of intraepithelial lymphocytes (IEL) are the initial histological evidence of CD (24). Non-antigen-specific T gamma/delta lymphocytes are the first to accumulate, followed by gliadin-specific CD8+ T alpha/beta lymphocytes. CD4+ T cells are present in small numbers among the IEL but are the majority of the cells that infiltrate the intestinal submucosa. It is believed that CD4+ T cells are responsible for most of epithelial cell injury via their secretion of gamma interferon and other cytokines (19).

The destruction of intestinal epithelial cells causes intestinal villi to shorten and atrophy, resulting in loss of absorptive surface and malabsorption leading to the characteristic disease symptoms and signs of diarrhea and weight loss. More than half of affected individuals are asymptomatic or have only extraintestinal manifestations despite typical small intestinal histological abnormalities and positive serological tests associated with CD (5, 17, 23, 31). This condition is known as "silent CD." Even asymptomatic patients are at risk for the long-term complications of untreated CD, including iron deficiency anemia, osteoporosis, and intestinal malignancies (particularly T-cell lymphomas in the small intestine) (23).

Test Methods for CD

AGA

Antigliadin antibody (AGA) was the first serological test used to detect CD and to monitor patient compliance with a gluten-free diet (10, 23). Both immunoglobulin G (IgG) AGA (AGA-G) and IgA AGA (AGA-A) are clinically employed (17, 23). Reported sensitivities for both AGA-A and AGA-G vary from ~60 to 90%, with reports differing as to which has greater sensitivity, although clinicians believe that AGA-G does (17, 23, 28). AGA-G levels become elevated in a variety of intestinal inflammatory processes, and therefore this test lacks high specificity for CD (17, 29). Its chief value is in screening patients with selective IgA deficiency for CD. That condition is found in 1 to 3% of CD patients, in whom it is about 10 times more frequent than in the normal population (4, 7). Reported AGA-A specificity for CD ranges from 74 to 93%, with the majority between 80 and 85% (5, 6, 18, 24, 29).

Enzyme immunoassay (EIA) is the method most commonly used to measure AGA. Gliadin extracts are usually employed as the substrate, but deamidated gliadin has been recently reported to give greater test sensitivity and specificity for CD (1). Commercial EIAs utilizing this substrate are now available.

Anti-R1 Reticulin Antibodies

IgA anti-R1 reticulin antibody was identified in CD in the 1980s and was discovered to be more specific than AGA (Table 1). It is detected by indirect immunofluorescence microscopy (IIFM) on connective tissue fibers surrounding proximal renal tubules and hepatocytes on frozen sections of murine kidney and liver. Only IgA anti-R1 reticulin antibodies are specific for CD. This assay is more difficult to interpret than antiendomysial antibody (AEMA) (discussed below) because antibody to other variants of reticulin can be confused with anti-R1 reticulin (2). This test has proven sensitive and specific in specialized laboratories that frequently perform it; however, AEMA immunofluorescence assay and anti-tTG EIA (discussed below) have proven to be more sensitive and specific. Participants in the NIH Consensus Conference on Celiac Disease did not recommend IgA anti-R1 reticulin antibody testing since it does not add diagnostic sensitivity to that achieved with either AEMA or anti-tTG testing (http://consensus. nih.gov/cons/118/118celiac.htm).

AEMA

AEMA reacts with a cell membrane component of the smooth muscle cell demonstrated to be tissue tTG (discussed
FIGURE 1 Characteristic staining pattern of IgA AEMA on monkey esophagus section as revealed by IIFM.

below). It is detected by indirect IIFM on fresh frozen sections of monkey esophagus or human umbilical cord. On cross-sections of esophagus, AEMA is detected as a grid-like pattern of staining surrounding smooth muscle cells in the muscularis mucosa, vessel walls, and muscularis propria (2) (Fig. 1). AEMA is best demonstrated in the muscularis mucosa. On human umbilical cord sections, AEMA stains the exterior surface of vascular wall smooth muscle cells and cells within Wharton's jelly (23).

Both IgA and IgG class AEMA (AEMA-A and AEMA-G) are clinically useful. AEMA-A is very specific (94 to 100%) for CD in individuals with normal IgA levels (6, 8, 16, 18, 23). The test is also very sensitive, with reports of up to 100% sensitivity published. This high sensitivity is based on the diagnosis of CD by intestinal biopsy showing villous atrophy. Test sensitivity is lower for patients tested very early in the course of their disease before histological evidence of villous atrophy is detectable (although some patients are seropositive when increased IEL are the only abnormality of the small intestinal mucosa) (29). When patients with early CD are added to those with IgA deficiency (see below) and a chronically seronegative group estimated to be 3 to 6% of the total, AEMA-A sensitivity achievable in a clinical laboratory is unlikely to exceed 90% (8, 17). One study comparing AEMA-A testing in six reference laboratories using sera from controls and confirmed CD patients demonstrated sensitivities ranging from 57 to 90%, but with 100% specificity (25). Determination of AEMA-A titer has been used to monitor dietary compliance since titers decrease after patients adopt gluten-free diets and typically fall below detectable limits within 6 months (6, 7).

AEMA-G is useful to detect CD in patients with IgA deficiency (6, 7, 21). Similar to AGA-G, AEMA-G does not disappear after patients go on a gluten-free diet, so the test is not useful to monitor dietary compliance.

AEMA testing requires a fluorescence microscope and experienced laboratory personnel. Monkey esophagus substrate slides are available commercially from several sources or can be prepared in the lab if fresh monkey tissue is available. Tissue from the distal two-thirds of the esophagus should be selected because it contains the necessary smooth muscle. Screening for AEMA-A should be carried out at serum dilutions of no more than 1:5 due to risk of missing significant low-titer AEMA at higher dilutions. In testing for

TABLE 1 Sensitivity and specificity of serological tests for CD[a]

Test name	Method	Sensitivity (%)	Specificity (%)
AGA-A	EIA	63–91	74–93
AGA-G	EIA	63–94	63–76
Anti-R1 reticulin-A	IIFM	~75	90
AEMA-A	IIFM	90–100	94–100
AEMA-G	IIFM	NA	NA
Anti-hutTG-A	EIA	91–100	85–100
Anti-gptTG-A	EIA	76–100	35–100
Anti-hutTG-G	EIA	98[b]	98[b]

[b]IgA-deficient patients.

AEMA-G, I have found use of monkey-absorbed anti-human IgG conjugates as the secondary antibody superior to nonabsorbed reagents because they reduce the level of background staining caused by cross-reactivity of anti-human antibody with the monkey tissue substrate. A 1:5 screening dilution of serum is satisfactory in AEMA-G testing if monkey-absorbed conjugate is employed.

Anti-tTG Antibody

tTG (EC 2.3.2.13) is a widely distributed calcium-rich enzyme that cross-links gliadin peptides to connective tissue proteins (collagens II, V, and XI; procollagen; fibronectin; etc.) (12). It is highly expressed in areas of tissue damage and healing, where it is thought to strengthen the provisional extracellular matrix. It was identified in 1997 as the autoantigen of CD and the antigenic specificity of AEMA (12). EIA is the method of choice for detecting anti-tTG. The antigen source initially utilized for this test was isolated from guinea pig liver; however, human tTG purified from erythrocytes or produced with recombinant DNA technology is now preferred. Studies comparing guinea pig anti-tTG EIA with human anti-tTG EIA have demonstrated that the human tTG-based tests have greater sensitivity and specificity (3, 33). Human tTG-based test kits are available from multiple commercial sources (33). Sensitivities and specificities reported for human anti-tTG EIAs are up to 100%; however, the issues mentioned above regarding AEMA-A also apply to this test. IgG class anti-tTG (anti-tTG-G) EIA using human antigen has shown greater sensitivity and specificity for CD in IgA-deficient patients than AGA-G (20).

IgA Antiactin Antibody

IgA antiactin antibody, previously considered mainly as a source of interference in IIFM detection of AEMA-A, has been reported to be positively associated with the degree of intestinal mucosal atrophy present in patients with CD (26). EIA is utilized to detect this antibody. Extensive evaluations have not been reported yet, so the value of this assay is not firmly established. IgG antiactin (anti-smooth muscle) antibody is quite common at low titers in healthy individuals, moderate titers in many chronic liver diseases, and high titers in autoimmune hepatitis type 1; it is therefore unlikely to be of use in IgA-deficient CD patients.

Test Selection

The NIH Consensus Conference on Celiac Disease (2004) issued the following statement concerning diagnostic testing (http://consensus.nih.gov/cons/113/118celiac.htm):

> In summary, serological testing is recommended for screening individuals whose clinical signs and symptoms suggest possible celiac disease. Either AEMA-A or ATTG-A may be utilized for initial screening test because of their comparable high sensitivity and specificity. It was felt there was no additional advantage of performing AGA-A, AGA-G or ARA-A due to the lesser sensitivity and specificity of these tests. If AEMA-A or ATTG-A is negative, quantitative IgA should be performed to rule out IgA deficiency. If IgA is absent, test for AGA-G, AEMA-G, or ATTG-G to rule out CD.

Some reports state that an additional 20% of patients proven to have CD on subsequent small bowel biopsy can be serologically identified by performing AGA testing in addition to AEMA and anti-tTG testing at initial screening (11). A significant number of false positives will also be detected if the gliadin extract AGA tests are utilized, however. The clinical advantage of additional testing is not clear since it would lead to significantly increased numbers of small intestinal biopsies to identify relatively few additional patients.

Despite the NIH Celiac Disease Consensus Conference opinion that screening with either AEMA-A or anti-tTG-A is sufficient, there are circumstances in which performance of both assays seems warranted. There have been a number of reports concerning false-positive anti-tTG assays, the majority of which appear to have occurred with guinea pig tTG-based tests (3, 32). One study of patients with congestive heart failure and no evidence of CD found false-positive anti-tTG results with both guinea pig and human tTG-based tests and proved by Western blotting that the patients did have anti-tTG autoantibody (27). Reports have also shown that the specificity of AEMA-A is slightly higher than that of anti-tTG-A, so when patients have positive anti-tTG-A tests but no clinical evidence of CD, it is probably worthwhile to perform confirmatory AEMA-A testing before subjecting the patient to intestinal biopsy (32).

Remarks and Conclusions

Serological screening is useful in selecting patients with suspected CD for endoscopic biopsy, a procedure involving significant risk as well as being invasive and costly.

AEMA-A and anti-tTG-A are the most sensitive and specific tests currently available and are useful in monitoring dietary compliance. AGA-A and AGA-G antibodies are commonly available in clinical laboratories and have been traditionally used for screening but lack the sensitivity and specificity of the two newer tests.

IBD

IBD is a general term for noninfectious, idiopathic chronic inflammation of the intestines. The two major IBDs are Crohn's disease and UC. Although the clinical behavior and pathological features of these diseases differ, many of their symptoms and signs are similar. These include cramping, abdominal pain, intermittent diarrhea (sometimes bloody), nausea, vomiting, and laboratory evidence of inflammation in the form of increased levels of the acute-phase reaction proteins, such as C-reactive protein and fibrinogen (34, 42). Physical examination is rarely able to distinguish Crohn's disease and UC. Invasive radiographic studies, endoscopy, and mucosal biopsy are usually necessary for that purpose. Discussion continues as to whether these are fundamentally different diseases or are opposite ends of a continuum of intestinal inflammatory processes. Evidence for the latter view has been increasing. About 10 to 15% of IBD patients have clinical and histological features of both diseases and are designated as having "indeterminate colitis" (42). Half of these eventually assume the features of either Crohn's disease or UC, while the rest remain diagnostically indeterminate. Treatment of both diseases primarily involves rectal administration of anti-inflammatory drugs (corticosteroids and various nonabsorbable 5-aminosalicylate-based compounds, e.g., sulfasalazine) (42).

UC

UC primarily affects the colon and rectum. The mucosa is infiltrated with neutrophils, and inflammation is symmetrical and continuous. Crypt abscesses form in the deeper parts of the colonic and rectal mucosa, and superficial ulceration is widespread. Patients often have severe bowel cramps and bloody diarrhea. Occasionally, the colon becomes greatly dilated (toxic megacolon) and may rupture, causing peritonitis (34, 42). The clinical course of UC is characterized by

remissions and relapses, similar to most autoimmune diseases. After 10 or more years of ulcerative colitis, rapid intestinal epithelial cell turnover leads to a 20- to 30-fold increase in carcinoma of the colon (34, 42). Total colectomy may be prophylactically performed in some UC patients after passage of this length of time or when dysplasia is detected in colonic mucosal cells. Patients with Crohn's colitis have a similar risk of colon carcinoma.

Crohn's Disease

Crohn's disease in the majority of patients predominantly affects the small intestine, although 20 to 30% of patients have colon-limited disease (Crohn's colitis) (42). Inflammation in Crohn's disease is segmental, with affected areas alternating with normal areas in the small intestine. Ulcers and "skip areas" of uninvolved mucosa alternate with diseased segments. The pathology involves deeply penetrating mucosal ulcers extending into the muscularis propria and sometimes through the serosa. Thickening of the involved bowel wall and narrowing of the lumen occur in areas of inflammation. Where the serosa is involved, an adhesion between segments of bowel occurs. Both adhesions and luminal narrowing may lead to bowel obstruction, a major complication of Crohn's disease. Histological features of the disease are mixed acute and chronic inflammation in the involved mucosa and the penetrating ulcers. Noncaseating granulomata are found in the bowel wall in approximately 50% of patients, but are not numerous. Their absence does not rule out Crohn's disease (42).

Treatment of Crohn's disease was formerly limited to anti-inflammatory drugs, rest, and good supportive care. Surgical intervention was not undertaken unless bowel perforation or obstruction occurred because the disease has a marked tendency to recur at bowel segment anastomoses (34, 42). Within the past few years, a new approach to therapy has proven very successful in patients with predominantly small intestinal involvement. Monoclonal antibodies to tumor necrosis factor alpha (TNF-α), a cytokine critical in the inflammatory pathways in Crohn's disease, or TNF-α receptor analogues are able to block TNF-α activity and dramatically reduce inflammation and clinical symptoms (42). Not all patients respond to this therapy, particularly those with Crohn's colitis.

Populations Affected by IBDs

Both Crohn's disease and UC affect men and women in equal numbers. Both diseases have their onset between 15 and 30 years, with a second, smaller peak between 50 and 70 years. The adult incidence of UC is $\sim 6 \times 10^5$ to 12×10^5 and that of CD is $\sim 5 \times 10^5$ to 7×10^5 in the United States and northern Europe (34, 42). Children are also affected but with lower frequency than adults. IBD is most common in industrialized countries of the northern hemisphere; southern Europe, South Africa, and Australia all have a lower incidence of IBD (2×10^5 to 8×10^5 for UC and 0.1×10^5 to 4×10^5 for Crohn's disease) (34, 42). Both forms of IBD have an increased incidence (10- to 15-fold) in immediate relatives of patients with IBD, and family studies have found that 10 to 35% of patients have affected family members (42). Northern Europeans and Ashkenazi Jews have the highest incidence (43). Genetic factors (especially involving components of the immune response) contribute to disease susceptibility, but environmental factors also play a role in pathogenesis, as demonstrated by differences in incidence rates in the northern and southern hemispheres in populations with similar genetic makeup (42).

Testing for IBD

Two serological tests are most often ordered in the workup of patients with suspected IBD. These tests are described below.

ANCA

Anti-neutrophil cytoplasmic antibody (ANCA) is widely used to screen patients for small vessel necrotizing vasculitides (SVV) such as Wegener's granulomatosis, microscopic polyangiitis, and Churg-Strauss syndrome (46, 50). ANCA testing is done by IIFM on ethanol-fixed human neutrophil substrate. Two patterns of ANCA are associated with SVV: C-ANCA and P-ANCA, so named for the area of ethanol-fixed neutrophils stained (cytoplasm or perinuclear zone) (50).

Association of UC with antibodies to neutrophils (so-called "granulocyte-specific ANA") preceded discovery of ANCA in vasculitis patients (40). Antibodies to neutrophil antigens in patients with IBD were rediscovered early in the investigation of ANCA in vasculitis. In most cases, these produce a P-ANCA staining pattern on ethanol-fixed neutrophils (atypical cytoplasmic, mixed atypical cytoplasmic and perinuclear, and, rarely, "typical" C-ANCA patterns may also be found) (Fig. 2). P-ANCA in IBD may be indistinguishable from vasculitis-associated P-ANCA, although staining is generally restricted to the nuclear membrane rather than extending into the nucleus. Variability in reproducibility of the staining pattern due to a variety of factors led the International Group for Consensus on ANCA Testing and Reporting to recommend using the generic term "P-ANCA" for both IBD- and vasculitis-associated variants (45, 46). Since much of the literature concerning ANCA in IBD utilizes the term "atypical P-ANCA" (UC-ANCA, X-ANCA, and antineutrophil nuclear antibody were also used in early references), it is used in this chapter for convenience. In most instances, sera positive for atypical P-ANCA produce no staining or weak, patchy, nongranular cytoplasmic staining of formalin-fixed neutrophils. This is in contrast to myeloperoxidase (MPO)-specific P-ANCA, which usually produces granular cytoplasmic staining (although rare examples fail to stain formalin-fixed neutrophils) (46). Atypical P-ANCA does not have specificity for either anti-MPO or anti-proteinase 3 (anti-PR3), the two major vasculitis-associated specificities most commonly associated with P-ANCA and C-ANCA, respectively (46). The specificity of atypical P-ANCA has not yet been satisfactorily defined; several different specificities have been reported, including bactericidal/permeability-increasing protein, catalase, elastase, α-enolase, histone H1, high-mobility-group proteins (HMG1 and HMG2), lactoferrin, and nuclear membrane proteins (39, 45). Most do not have specificity for neutrophil nuclear membrane, which IIFM staining suggests is important.

Approximately 50 to 70% of UC patients are positive for atypical P-ANCA (36, 37, 39, 41, 44). Atypical P-ANCA is also found in approximately 10 to 30% of Crohn's disease patients, 65 to 80% of primary sclerosing cholangitis (PSC) patients, 90% of autoimmune hepatitis type 1 patients, 90% of Felty syndrome patients, and up to 30% of patients with active rheumatoid arthritis (45). These diseases are probably not all associated with the same autoantibody specificity, but proof awaits identification of the antigen or antigens involved. Atypical P-ANCA may be the same in UC, Crohn's disease, and PSC patients. ANCA-positive Crohn's patients typically have colon-limited rather than the more common small intestinal fibrostenotic disease (49). PSC is associated with coexisting IBD, usually UC (47). In contrast, neither
FIGURE 2 Staining pattern of atypical P-ANCA associated with IBD on ethanol-fixed human neutrophils as revealed by IIFM. Contrast with typical P-ANCA in Fig. 2, chapter 118, this volume (12).

patients with autoimmune hepatitis, Felty syndrome, nor rheumatoid arthritis typically have any form of IBD.

Testing Methods for ANCA

The routine procedure for ANCA testing is described by Wiik (50). Commercial substrate slides are readily available and satisfactory. Recommendations concerning interpretation and reporting of ANCA made by an international consensus group included the following points. (i) P-ANCA⁺ sera should be tested for ANA and by EIA for anti-MPO and anti-PR3 to eliminate false-positive ANCA reports due to ANA and to specifically identify vasculitis-associated ANCAs. (ii) P-ANCA⁺ sera with negative anti-MPO and anti-PR3 EIA results should be reported as atypical ANCA. (iii) Titration of atypical ANCA in IBD is not necessary, as it has not been demonstrated to have clinical significance (45).

ASCA

Anti-*Saccharomyces cerevisiae* antibody (ASCA) is directed at an oligomannoside of bread and beer yeast (43) and is present in individuals with Crohn's disease more frequently and at higher titers than in patients with UC (35, 37, 38, 41–44, 47–49). Both IgG and IgA class ASCA determinations appear to be useful. IgG ASCA is present in 50 to 80% of patients with Crohn's disease, and IgA ASCA is present in 35 to 50%, compared with 2 to 14% of UC patients and 1 to 7% of healthy controls (35, 37, 38, 41–44, 47–49). Test specificity is higher for Crohn's disease if both IgG and IgA ASCAs are present but test sensitivity of this combination is only 50 to 55%.

EIA is the method used for ASCA testing. Various investigators of ASCA used different preparations of the antigen, ranging from whole-yeast extracts to highly purified *S. cerevisiae* oligomannoside, so reported ASCA sensitivities and specificities are variable. Commercial sources of IgA ASCA

and IgG ASCA reagents are available. Comprehensive comparison studies of various commercial ASCA kits are not yet published.

Remarks and Conclusions

The clinical utility of combined ANCA and ASCA testing for IBD continues to be debated. The combination of these tests may have utility in evaluation of patients with symptoms consistent with IBD. One or more positive tests would provide an argument for performing the invasive procedures (radiographic, endoscopic, and biopsy) necessary for diagnosis.

Autoimmune Thrombocytopenia

THOMAS S. KICKLER

128

The diagnosis of autoimmune thrombocytopenia is one of exclusion. In patients with a low platelet count and the absence of other hematologic disorders, administration of thrombocytopenia-producing drugs, or splenomegaly, the diagnosis is usually made. Either immunoglobulin G (IgG) or IgM antiplatelet antibodies directed against membrane platelet glycoprotein mediate reticuloendo-thelial destruction of platelets. This process may be acute and self-limited, as is frequently the case in children. A chronic form of autoimmune thrombocytopenia exists and is the clinical course most often seen in adults. With characterization of the immunopathological features of autoimmune thrombocytopenia, a variety of methods have been developed to measure the antiplatelet autoantibodies that mediate the immune destruction of platelets in this disorder (1, 3, 7).

ACUTE IMMUNE THROMBOCYTOPENIA

Acute immune thrombocytopenia occurs primarily in children, with a peak age of 2 to 6 years. Typically, there is a history of an antecedent viral infection followed by the acute onset of bruising, petechiae, and mucosa bleeding. If thrombocytopenia persists longer than 6 months despite therapy, the child should be considered to have chronic auto-immune thrombocytopenia. The risk of chronicity increases with increased age of the child; otherwise, there are no prognostic features, either clinical or laboratory, that will predict whether a child with acute immune thrombocytopenia will recover spontaneously. Our understanding of the pathogenic mechanisms of acute immune thrombocytopenia is lacking. It appears that viral illnesses are responsible for evoking an immune response and that antibodies to platelets or immune complexes are involved in shortened platelet survival. Increased levels of immunoglobulin found on the platelets of these patients may reflect the deposition of immune complexes that have bound to the platelet Fc receptor. It is also possible that transient production of autoantibodies may be induced by viral infections. There is little evidence to suggest that microbial agents produce some factor that alters the surface of platelets, making them immunogenic (3).

CHRONIC AUTOIMMUNE THROMBOCYTOPENIA

Immunopathological Features

Early observations by Harrington and coworkers showed that thrombocytopenic pregnant women frequently delivered babies with thrombocytopenia (4). This suggested that some plasma factor crossing the placenta mediated the newborn's thrombocytopenia. Plasma infusions from patients with thrombocytopenia were shown to produce thrombocytopenia in healthy volunteers Subsequently, Shulman et al. (16) showed that the degree of thrombocytopenia was dependent on the amount of plasma infused, with splenectomized or corticosteroid-treated subjects being more resistant to the effects of the infused auto-immune thrombocytopenic plasma. The pathogenic factor present in the plasma reacted with normal and autologous platelets and could be isolated and removed from the gamma fraction of plasma by adsorption with platelets. These early studies provided a basic understanding of the pathogenic mechanisms of the factors involved in platelet destruction (16).

The first direct evidence that autoantibodies are present on platelets was the observation that eluates prepared from the platelets of patients with autoimmune thrombocytopenia bind to normal platelets (19). These eluate studies also documented that the major antigenic target for these antibodies was platelet glycoprotein IIB/IIIA. This observation was based on the failure of the eluates to react with platelets from patients who are deficient for platelet glycoprotein IIb/IIIa (Glanzmann thrombasthenia). Subsequent studies using Western blotting (immunoblotting) or immunoprecipitation demonstrated that the autoantigens were principally found on platelet glycoprotein IIIa. Some patients may have autoantibodies that react with one or more platelet glycoproteins, including platelet glycoprotein Ib/IX or Ia/IIa (8, 13, 20).

The distribution of the heavy chain type of autoantibodies present on the platelets, frequently referred to as platelet-associated immunoglobulin, is a follows: 95% of patients have IgG either alone or in combination with IgA or IgM; 5% have IgM alone. A variety of studies have shown a broad

range for the IgG subclass distribution that may be found; however, subclass determination has not been shown to have prognostic importance (5).

The autoantibodies found in chronic autoimmune thrombocytopenia may bind to megakaryocytes and possibly impair thrombopoiesis. The binding of antiplatelet antibodies to megakaryocytes was first demonstrated by immunofluorescent studies. Careful isotopic platelet kinetic studies have demonstrated increased platelet turnover associated with normal or decreased thrombopoiesis. Using in vitro culture systems for megakaryocyte colony formation, investigators have shown that antibodies can impair megakaryocyte differentiation and platelet production (3).

Clinical Features

Patients with chronic autoimmune thrombocytopenia typically present with petechiae and mucosa bleeding. Symptoms may be present for months, or some patients may experience more acute manifestations. If bleeding has been significant, anemia may be present. Alternatively, some patients may have concomitant autoimmune hemolytic anemia, which accounts for the assisted anemia. Physical examination is unremarkable except for bleeding manifestations. The peripheral smear shows reduced to absent platelets having an increased mean platelet volume. The bone marrow is normal (3).

Platelet Autoantibody Detection

A variety of methods to measure antiplatelet antibodies are available (9–12, 14). The earlier assays employing complement fixation or platelet lysis lacked sensitivity and are no longer used. Quantitative measurements based on antiglobulin consumption give falsely high values for platelet-associated immunoglobulin because antiglobulin binds differently to membrane-bound IgG than to the IgG in the solution used to calibrate the standard curve. Assays for total platelet immunoglobulin performed by detergent lysis of platelets and then measurement of the immunoglobulin by radial diffusion or nephelometry were developed before it was realized that a large amount of normal immunoglobulin constituted the platelet alpha granule. These assays should be considered of little clinical importance (2, 15).

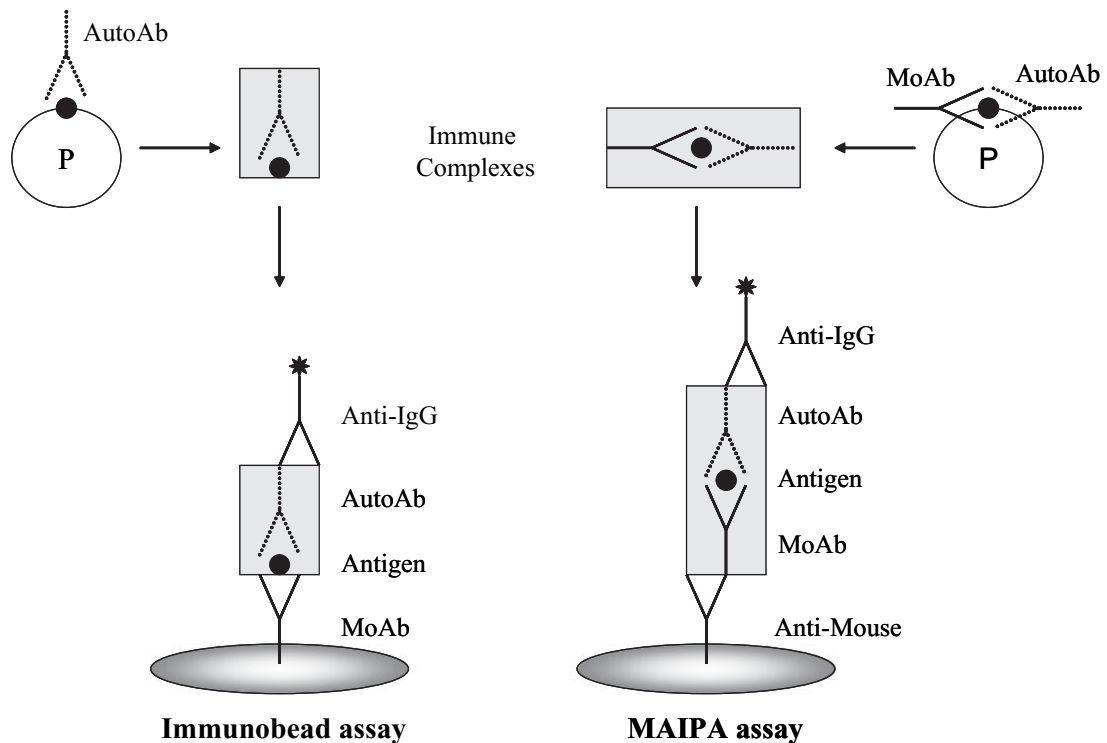
Of the available approaches, the platelet glycoprotein capture assays offer the best sensitivity and specificity. There are two types of capture assays, the solid-phase (immunobead) method and the monoclonal antibody-specific immobilization of platelet antigen assay (MAIPA). Figure 1 gives a general description of these assays. Both of these methods are straightforward and can measure both platelet-associated and plasma


FIGURE 1 Platelet autoantibody assays. In the solid-phase assay, a microtiter well or plastic bead is coated with a monoclonal antibody (MoAB) to a specific platelet glycoprotein, such as GPIIb-IIIa or Ib-IX. Platelets from a patient with idiopathic thrombocytopenia purpura are washed, solubilized with detergent, and added to the coated surface to allow capture by platelet glycoprotein complex and bound autoantibody (AutoAb). The autoantibody is measured using labeled anti-human IgG. The MAIPA is similar, except that the murine monoclonal antiplatelet glycoprotein antibody is added to the autoantibody-sensitized platelets and the immune complex composed of platelet glycoprotein, mouse monoclonal antibody, and human immunoglobulin is captured with an anti-mouse antibody.

antibodies. When platelet-associated antibodies are assayed, approximately 80% of samples will have detectable antibody when a panel of monoclonal antibodies is employed to capture the platelets. The relative sensitivity for serum antibodies is approximately 50% (1, 12–14, 18). The details of performing the MAIPA are given below. Since IgG, IgM, and IgA auto-antibodies may be found in autoimmune thrombocytopenia, the labeled antiglobulin used should have specificity for these three classes of immunoglobulin.

Antigen capture assays have advantages over the previously mentioned tests for detecting autoimmune antibodies because interference by nonspecific immunoglobulin is reduced, native conformation of platelet antigens is maintained by using nondenaturing detergents, and determination of target platelet glycoprotein is possible. Tsubakio and coworkers pointed out the importance of monoclonal antibodies being used as a determinant in the detection of platelet autoantibodies (18). They showed that if the monoclonal antibody was directed to epitopes identical or closely adjacent to those to which the autoantibody was directed, no binding would occur. Conversely, they hypothesized that if the epitopes were widely separated, maximum antibody binding would occur. If epitope locations were relatively close, intermediate antibody binding might occur (13). Subsequent investigators have confirmed these observations in the detection of autoantibodies.

Immunoblotting has been utilized as a research tool rather than as a diagnostic test (6, 17). After the platelet membranes are washed and solubilized, the various platelet glycoproteins are separated by sodium dodecyl sulfate-polyacrylamide gel electrophoresis. The platelet proteins are then electrophoretically transferred to nitrocellulose paper. Patient serum is then incubated with the membranes, and a labeled secondary antibody is used to determine the proteins against which the patient's antibody is directed. When this technique is applied, one may find detectable antibody present in normal sera. Since many patients with autoimmune thrombocytopenia may have cytosolic antibodies to platelet glycoprotein, immunoblotting may detect antibodies that have no pathological significance.

TEST PROCEDURE: MAIPA

Reagents

Coating buffer: 1.59 g of Na_2CO_3, 2.93 g of $NaHCO_3$, and 0.2 g of NaN_3. Add distilled H_2O to 1 liter and adjust pH to 9.6.

TBS wash buffer: 3.03 g of Tris, 22 g NaCl, 12.5 ml of Nonidet P-40, 1.25 ml of Tween 20, and 1.25 ml of 1 M $CaCl_2$. Add distilled H_2O to 2.5 liters.

Solubilization buffer: 1.21 g of Tris dissolved in 950 ml of isotonic saline, pH 7.4. Add 5 ml of Nonidet P-40, and add isotonic saline to 1 liter.

Goat anti-mouse IgG (code 115-005-071; Jackson ImmunoResearch). Dilute to 3 μg/ml in coating buffer.

Peroxidase-conjugated goat anti-human IgG (code 109-035-008; Jackson ImmunoResearch). Dilute to 1 in 5,000 to 1 in 30,000 (determined by previous experiment) in TBS wash buffer.

Substrate solution: Dissolve four 3.5-mg tablets of 1,2-phenylenediamine dihydrochloride (OPD·2HCl) (code S 2045; Dako) in 12 ml of distilled water in a foil-covered container. Add 5 μl of 30% H_2O_2 immediately before use.

Stop solution: Add 28 ml of 95 to 97% H_2SO_4 to 972 ml of distilled water.

Warning: Use only freshly prepared reagents.

MAIPA (Microplate Method)

Method

A. Preparation of coated F-well microplate
 1. Prepare goat anti-mouse IgG as described above and aliquot 100 μl/well into two flat-well microplates (44204A; Nunc) for duplicate testing.
 2. Incubate microplates at 4°C overnight (or at least 2 h at room temperature).
 3. Store sealed coated plates for up to 2 weeks at 4°C.
 4. Thirty minutes before the plates are required on the day of testing, wash them four times with TBS wash buffer.
 5. Leave last wash in wells for 30 min at 4°C to block plates and prevent nonspecific binding at subsequent stages. Decant buffer before use.

B. Preparation of platelets
 1. Take blood from group O donors into EDTA or citrate.
 2. Centrifuge at 1,800 rpm for 10 min in a benchtop centrifuge.
 3. Remove the top three-fourths of the PRP from the top of the tube and transfer to a 10-ml conical centrifuge tube.
 4. Add phosphate-buffered saline (PBS)-EDTA buffer to 10 ml and centrifuge at 1,500 × g for approximately 5 min.
 5. Decant supernatant, resuspend cells gently in 2 ml of buffer, and repeat step B.4 twice.
 6. Resuspend platelets in PBS-EDTA at approximately 200 × 10⁹/liter. Store at 4°C for up to 2 weeks.

C. First incubation
 1. For each sample to be tested, aliquot 100 μl of platelet suspension into a U-well microplate and spin at 1,500 × g in a benchtop microplate centrifuge for 3 min. Include two negative controls and one weakly positive control.
 2. Decant supernatant and resuspend platelet pellets in 50 μl of test serum or plasma and incubate at 37°C for 30 min.
 3. Wash platelets by adding 200 μl of PBS-EDTA to each test and centrifuge at 1,500 × g for 3 min. Resuspend platelet pellet by using a microplate shaker and wash once more.

D. Incubation with monoclonal antibody
 1. Resuspend platelet pellets in 40 μl of diluted mouse monoclonal antibody (make sure cells are fully resuspended using a microplate shaker or pipette) and incubate for 30 min at 37°C.
 2. Wash platelets three times.

E. Lysis
 1. Lyse platelets by resuspending each pellet in 130 μl of solubilization buffer. Resuspend cell pellet using a pipette, *not* the microplate shaker, to avoid carryover. Incubate for 30 min at 4°C.
 2. Block the coated F-well microplate; see steps A.4 and A.5 above.
 3. Centrifuge microplate at maximum speed in a benchtop centrifuge (approximately 3,000 rpm) for 15 min at room temperature.

4. For each test, aliquot 130 µl of TBS wash buffer into a U-well microplate.
5. Remove 100 µl from each supernatant from step E.3 and dilute in 130 µl of TBS wash buffer from step E.4.

F. Attachment to solid phase
1. Transfer 100 µl of diluted platelet lysate, in duplicate, to a precoated and blocked well microplate; add 100 µl of TBS wash buffer to four to eight precoated wells on each plate (reagent blank). Incubate at 4°C for 90 min or overnight.
2. Wash microplate wells four times with 200 µl of TBS wash buffer.

G. Anti-IgG incubation
1. Add 100 µl of diluted peroxidase-labeled anti-human IgG to each well and incubate at 4°C for 90 min.
2. Wash microplate wells six times with 200 µl of TBS wash buffer. Blot top face of microplate dry between washes by placing on absorbent paper.

H. Color development
1. Add 100 µl of substrate solution to each well and leave plate at room temperature.
2. Stop the reaction by adding 100 µl of 0.5 M H_2SO_4 when a suitable color intensity has developed. Read the absorbance at 490 nm (for dual-wavelength enzyme-linked immunosorbent assay readers, a reference filter between 630 and 650 nm is suitable) within 1 h.

Note: Two-milliliter microcentrifuge tubes can be used instead of U-well microplates, in which case the centrifugation in step E.3 can be increased to >10,000 × g for 20 min at 4°C.

Specimen
Serum or EDTA- or citrate-collected plasma or platelets prepared from EDTA-anticoagulated whole blood are used.

Interpretation
1. Calculate the mean optical density for all controls and samples.
2. The positive cutoff is the mean of the negative control plus three standard deviations.
3. The positive control should be at least three times the optical density of the negative control.

Monitoring Autoimmune Reactivity within the Retina

JOHN J. HOOKS, MARIAN S. CHIN, CHI-CHAO CHAN, AND BARBARA DETRICK

129

Immune-mediated vision loss is a rapidly expanding area of research and therapy. This chapter deals with the identification of antiretinal immune reactivity in patients with retinal diseases.

EYE: IMMUNE UNIQUE (PRIVILEGE) SITE

It is important to note that there are at least two major distinctive features of the eye. The first unique characteristic of the eye is easy visibility (17). When examining the eye, one has the remarkable advantage of being able to visualize inflammatory processes, vascular leakage, and cellular damage without using invasive procedures. Moreover, electrophysiological testing is easily performed and readily evaluates the retina's ability to respond to light stimulus. The second extraordinary feature of the eye is its immune status. The immune response that occurs within the eye is different from the systemic immune response, and this unique characteristic has been referred to as immune privilege. Several components contribute to this state. Anatomic features, such as the lack of lymphatic drainage and the presence of a blood-ocular barrier, limit access by the immune system. Additional factors contributing to immune uniqueness include limited expression of the major histocompatibility complex molecules; increased expression of the cell surface molecule CD57, which inhibits complement activation; local production of the immunosuppressive cytokine transforming growth factor β; and constitutive expression of the regulatory molecule FasL. Despite these remarkable features of ocular immunity, inflammatory processes do occur in the eye, and these are frequently referred to as uveitis. Uveitis is the fifth leading cause of vision loss in the world (18). Most ocular inflammatory processes that we recognize have a cellular component associated with them. Here, the severity of the inflammation can be graded by direct visualization of the inflammatory processes. The laboratory can be useful in identifying lymphocyte reactivity to specific retinal antigens and in distinguishing between primary intraocular lymphoma and inflammatory processes. We also know that antibody-mediated pathology can occur. Laboratory assays are designed to detect and characterize antiretinal antibody reactivity.

CLASSIC EXAMPLES OF AUTOIMMUNE DISEASE IN THE RETINA

Retinal autoimmunity exists as a naturally occurring disease in humans and as an experimentally designed animal model system. In humans, sympathetic ophthalmia (SO) is a classic example of a T-cell-mediated disease (4, 5). SO is an ocular inflammatory (autoimmune) disease that occurs after a perforating injury to one eye. The injured eye undergoes a massive lymphocytic granulomatous infiltration. At any time from the first week to several years following the trauma (peak is second week to 3 months), a spontaneous lymphocytic granulomatous infiltration occurs in the noninjured, "sympathizing" eye. Several studies have shown that the infiltrate consists predominantly of T cells. Today, SO is a rare disease; posterior uveitis is more frequently seen and is also associated with lymphocytic infiltrates that can be predominantly of T-cell origin. Within the retina, a number of uveitogenic antigens have been identified and characterized. Two of these, retinal S antigen (arrestin) and interphotoreceptor retinal binding protein (IRBP), have been used to develop a model of T-cell-mediated autoimmune ocular disease which is termed experimental autoimmune uveoretinitis. These retinal proteins are now utilized to monitor human T-cell reactivity to retinal tissue.

RETINOPATHIES ASSOCIATED WITH ANTIRETINAL ANTIBODIES

Human retinopathies associated with the production of antiretinal antibodies can be categorized into three groups: (i) visual paraneoplastic disorders, (ii) infection-associated retinopathies, and (iii) retinal degenerative disorders (Table 1).

Progressive blindness as a remote effect of cancer was first reported in 1976 (19). The two most frequently observed forms of visual paraneoplastic disorders are referred to as cancer-associated retinopathy (CAR) and melanoma-associated retinopathy (MAR). Clinical and experimental observations in CAR and MAR probably provide the best evidence for a pathological role of autoreactive antibodies in human retinopathies. First, affected patients suffer from a retinopathy that is characterized by retinal tissue damage and the presence of antiretinal antibodies. Second, some patients respond to plasma exchange and immunosuppressive therapy. Third, retinal cell damage can be induced by the autoreactive antibodies in vitro, and there is evidence of passive transfer of disease to animals (1, 10).

CAR is most commonly associated with small-cell carcinoma of the lung, but it has also been reported for patients with breast, endometrial, and other cancers (15, 21). In

TABLE 1 Antibody responses directed against retinal antigens in sera from patients with retinal diseases[a]

Retinal disease	Immunologic reactivity	Ag
Visual paraneoplastic disorders		
CAR	Photoreceptor outer segment	Recoverin (23 kDa), retinal enolase, TULP1, and others
MAR	Outer plexiform layer and INL	Bipolar cells
Infection-associated retinopathies		
Toxoplasmosis	Photoreceptor layer	Not known
Onchocerciasis	Neural retina and RPE	Cross-reactivity between *O. vulvulus* Ag (OV39) and RPE Ag (hr44)
Retinal degenerative diseases		
RP	Neural retina	Carbonic anhydrase II (30 kDa) and enolase (45 kDa)
RAR	Photoreceptor outer segment	Recoverin (23 kDa)
ARMD	Photoreceptors	Neurofilaments
Idiopathic retinopathy	Neural retina	Variety of retina Ags: S Ag, IRBP, and LEDGF
Neurologic disease (stiff man syndrome)	Neural retina	GAD

[a]Ag, antigen; RP, retinitis pigmentosa; RAR, recoverin-associated retinopathy; ARMD, age-related macular degeneration.

these patients, antibodies develop with reactivity to the retina, and this response is associated with rod and cone dysfunction. Visual loss occurs over months and may even precede the identification of the malignancy. Using immunofluorescent-antibody (IFA) assays on retinal tissue sections, one can demonstrate that sera from CAR patients react with the photoreceptor outer segments and ganglion cells. Analysis of retinal antigens has revealed that a variety of antigens may be involved in this process. The primary antigens identified are a 23-kDa antigen (recoverin), a retinal enolase (46 kDa), and a group of reactivities with retinal antigens identified as 40-, 43-, and 60-kDa molecules. Although over 15 retinal antigens have been described in the CAR syndrome, the most common antigen linked to CAR is the 23-kDa recoverin, a calcium-binding protein found in both rods and cones.

MAR is a second paraneoplastic syndrome that occurs in patients with melanoma (12, 14). Progressive visual loss develops over months and is frequently associated with metastatic cutaneous melanoma. Again, IFA technology can be used to identify antibody in MAR patient sera that reacts to bipolar cells in the outer nuclear layer and their dendrites in the outer plexiform layer of the retina.

The second group of retinopathies associated with anti-retinal antibodies is retinal disorders that are triggered by an infectious agent (9). In humans, onchocerciasis and toxoplasmosis fall into this category. Infection with the nematode parasite *Onchocerca volvulus* can result in severe eye disease, often referred to as river blindness. It is estimated that approximately 18 million people in tropical Africa, the Arabian Peninsula, and Latin America are infected with this organism, and of these approximately 1 million to 2 million are blind or have severe visual impairment. Humans are infected with the helminth larvae by the bite of a black fly of the *Simulium* genus.

Posterior ocular onchocerciasis is characterized by atrophy of the retinal pigment epithelium (RPE), and as lesions advance, subretinal fibrosis occurs. A number of studies indicate that affected patients have antiretinal antibodies in

their sera and vitreous (6). Reactivity was observed in the inner retina and photoreceptor layers by IFA analysis. Characterization of the autoantigens revealed that a recombinant antigen in *O. volvulus* showed immunologic cross-reactivity with a component of the RPE. By Western blot analysis, an antibody to a 22,000-molecular-weight antigen (OV39) of *O. volvulus* recognized a 44,000-molecular-weight component (hr44) of the RPE cell. Although OV39 and hr44 are not homologous, they did show limited amino acid sequence identity. Immunizations of Lewis rats with either OV39 or hr44 induce ocular pathology. These studies indicate that molecular mimicry between *O. vovulus* and human RPE protein may contribute to the retinopathy found in patients with onchocerciasis (2, 13).

Toxoplasmosis, which occurs in over 500 million humans worldwide, is caused by the obligate intracellular parasite *Toxoplasma gondii*. *T. gondii* is also the most frequently identified infectious agent in posterior uveitis, and *Toxoplasma* retinochoroiditis is an important cause of blindness in young adults. Since the 1980s, several reports have documented a high prevalence of antiretinal antibodies in sera from *T. gondii*-infected patients (23). These antibodies are directed against the photoreceptor layer. Moreover, leukocytes from these patients have been shown to proliferate in response to retinal S antigen (16).

The third group of retinopathies associated with antiretinal antibodies is classified as the retinal degenerative disorders. These include retinitis pigmentosa with cystoid macula edema, recoverin-associated retinopathy, age-related macular degeneration, idiopathic retinopathies, and retinopathies associated with autoimmune neurologic diseases. Table 1 identifies serum antibody responses directed against retinal antigens in patients with retinal diseases. These are described in more detail in reference 10. Recently, we have characterized a subgroup of patients with retinal degenerative disease, referred to as a cone rod degeneration, that has reactivity to retinal ganglion and inner nuclear layer (INL) (Chin et al., unpublished data).

LABORATORY MONITORING OF ANTIRETINAL ANTIBODIES

Standard immunohistochemical assays or immunofluorescent assays are used to identify antibody reactivity within the retina. In addition to human retina, rodent (mouse or rat) or monkey eyes are frequently used as the substrate. After enucleation, eyes are immediately placed in OCT and frozen and stored at −70°C. Using a cryostat, whole rodent eye sections can be prepared and placed on SuperFrost slides. When using monkey or human eye tissue as the substrate, the frozen eye must be cut into smaller blocks of tissue before cryosections of the eye are cut. Slides containing the retina are stored at −70°C until used.

Procedure

1. Briefly, the standard procedure consists of fixing and permeabilizing the ocular tissue sections with acetone-methanol (1:1) and rinsing them with phosphate-buffered saline (PBS), pH 7.4. Endogenous peroxidase activity is quenched by incubating the sections in 0.6% H_2O_2 prior to incubating the tissue in a blocking solution. A standard blocking solution is 10% normal goat (NGS) or rabbit (NRS) serum in PBS. Bovine serum albumin, glycine, and/or cold-water fish gelatin can be added to the standard blocking solution if necessary to reduce nonspecific binding by the primary antibody.

2. Serial twofold dilutions of sera (1:40 to 1:640) from patients with retinal degeneration and healthy controls are incubated with the tissue sections either for 1 to 2 h at room temperature or overnight at 4°C.

3. Slides are washed in PBS with 1% NGS or NRS, and a dilution of the secondary antibody (horseradish peroxidase-conjugated anti-human immunoglobulin G) is applied to the tissue for 1 h.

4. Detection of bound immunoglobulin molecules is accomplished using a peroxidase substrate such as 3,3′-diaminobenzidine. Instead of horseradish peroxidase, the secondary antibody may be conjugated to alkaline phosphatase.

However, the peroxidase substrates produce more pronounced precipitates and give sharper localization than alkaline phosphatase substrates.

5. Slides are counterstained, dehydrated, and cleared and coverslips are mounted prior to examining the tissue sections under a microscope.

Interpretation

Studies in our laboratory demonstrate that immunofluorescence or immunocytochemical tests using rodent or monkey tissue and serum from individuals with no history of retinal disease are usually negative or reactive only at low serum dilution. In contrast, high titers of antibody are found in patients with selected retinal degenerative diseases. Sera from 18 healthy individuals demonstrated immunoreactivity to normal mouse ocular tissue in 33% of samples at a 1:40 dilution, in 13% of samples at a 1:80 dilution, and in 3% of samples at a 1:160 dilution, and no reactivity was noted at a dilution of 1:320 or 1:640. In contrast, in selected patients with retinal degenerative disorders we can detect reactivity in serum samples at dilutions of 1:160 to 1:1,280. Because the majority of the serum samples from healthy individuals did not show immunoreactivity to mouse ocular tissues at a dilution of 1:160 and the sera from patients with retinal degenerations were immunoreactive at a dilution of 1:1,280, we have selected 1:160 as the dilution that can discriminate between healthy individuals and patients with retinal degenerative disorders. It is interesting that this is similar to the dilution scheme used to discriminate antinuclear antibody reactivity in patients with systemic lupus erythematosus from positive antinuclear antibody results for healthy individuals (20).

Cellular location can be important to report. At least five patterns of immune reactivity are commonly observed: photoreceptor outer segments, INL, outer nuclear layer, ganglion cells, and RPE cells. In CAR patients, reactivity with the outer segment layer of photoreceptors is frequently seen and is associated with antirecoverin antibodies. In MAR patients, staining is frequently observed with bipolar cells in
FIGURE 1 Immunohistochemical staining for antiretinal antibodies. Frozen sections of normal mouse retina were incubated with "normal" nonreactive human sera (A) or with sera from patients with retinal degenerative disease (B and C). Note reactivity with photoreceptor outer segments in panel B (arrowhead) or with ganglion cells (upper arrow), INL (middle arrow), and outer nuclear layer (lower arrow) in panel C.

the INL. An example of patterns of immune reactivity in the retina is shown in Fig. 1.

LABORATORY MONITORING OF T-CELL REACTIVITY

Procedure

1. Approximately 10 ml of heparinized or EDTA venous blood is needed for T-cell assays. Peripheral blood leukocytes (PBL) are recovered following Ficoll-Hypaque separation techniques. PBL are resuspended in RPMI medium supplemented with 5% (vol/vol) fetal bovine serum.

2. Determine the number of viable PBL by trypan blue exclusion. Adjust the cell concentration to 2×10^6 ml.

3. Deliver 100 μl of the cell suspension into triplicate wells of a 96-well plate.

4. Add 100 μl of stimulant or control as follows: medium (negative control), phytohemagglutinin or concanavalin A (positive control), and retinal antigen (S antigen or IRBP).

5. Incubate cells at 37°C for 72 h.

6. Assay the response of lymphocytes to stimulation by monitoring cell proliferation or production and release of cytokines. Cell proliferation assay can measure [3H]thymidine incorporation into cellular DNA. Alternatively, one can use enzyme immunoassays (EIAs) to measure the release of gamma interferon or interleukin 2 (IL-2) in the supernatant fluid.

Interpretation

The appropriate incorporation of controls into these assay systems is essential for interpretation. PBL from a healthy individual (known nonresponder) should be used each time the test is performed. In addition, in each test a medium control (negative/baseline) and a T-cell stimulant (phytohemagglutinin, concanavalin A, etc.) must be included. When determining cell proliferation by [3H]thymidine assay, the samples are evaluated by stimulation index (SI). The SI is obtained by dividing the counts per minute for retinal-antigen-treated cells by those for medium-treated cells. An SI of >2.0 is considered positive.

LABORATORY MONITORING OF OCULAR CYTOKINES (IL-6 AND IL-10)

Vitreous biopsies are frequently performed to distinguish between ocular inflammation associated with uveitis and ocular malignancy due to primary intraocular lymphoma (PIOL) or primary central nervous system lymphoma (PCNSL). Cells within the vitreous are collected by cytospin and evaluated by a cytopathologist to identify lymphoma cells. The majority of PIOLs and PCNSLs are diffuse large B-cell lymphomas (7, 11). These tumor cells produce high levels of IL-10, a growth and differentiation factor for B cells. In contrast, the inflammatory cells in uveitis produce high levels of IL-6, a proinflammatory cytokine. We and other investigators have found elevation of vitreal IL-10 with a ratio of IL-10 to IL-6 greater than 1 in PIOL (3, 8, 22, 24). Using this ratio analysis, the sensitivity and specificity of the assay are 75%. Evaluation of IL-10 and IL-6 concentrations in vitreous samples is performed using standard EIA methodology.

SUMMARY AND FUTURE DIRECTIONS

Analysis of immune-mediated vision loss is in its infancy. In patients with established retinal disease, the presence of autoantibodies can help define the nature of the disease and

provide markers to classify the disease and to monitor therapy. Today, laboratory monitoring of antiretinal antibodies is frequently used to assess patients with paraneoplastic syndrome. Laboratory monitoring of T-cell reactivity to retinal antigens is frequently used to assess uveitic patients undergoing immunomodulatory therapies. Finally, laboratory monitoring of ocular cytokines is frequently used to aid in the differential diagnosis of ocular inflammation and ocular malignancy.

Measurement of antiretinal immune reactivity is difficult to perform in the clinical laboratory. Analysis of immunocytochemical or immunofluorescent staining of retina tissue sections requires special training for interpretation. Nevertheless, with the characterization of specific retinal antigens, the future should include the development of standard EIA and Western blot assays to monitor patients with this form of vision loss.

Introduction

As succinctly stated by Winters et al. (chapter 134), "Cancer is a disease of dysregulated protein function and expression. Altered protein networks and signaling pathways drive the malignant phenotype, resulting in cell survival, invasion, and metastasis." The Cancer section in this 7th edition of the *Manual of Molecular and Clinical Laboratory Immunology* contains four chapters that focus on immunologic methods that are useful in detecting and quantifying proven and investigational tumor markers. These markers are mostly proteins that have proven or anticipated use in the diagnosis and management of cancer patients and patients receiving immunologic therapies. Where possible, molecular biology methods are introduced, and the Cancer section concludes with an exciting glimpse into the application of proteonomics in the quest to identify new cancer markers that will lead to enhanced diagnosis and management of oncology patients.

Diagnostic oncology and immunology laboratories all over the world currently measure a number of biomolecules released from tissue into body fluids that are markers of tumor presence and growth. The measurement of these analytes assists oncologists in making more accurate diagnoses and managing their patients with cancer, especially as it relates to monitoring therapy, detecting cancer recurrence, and assessing the patient's prognosis. This has been a challenging area of diagnostic immunology because most tumor markers are not elevated under all cancerous conditions and others are elevated under non-cancer conditions such as benign or nonmalignant disease. Fortunately, the concentrations of select tumor markers are known to correlate with tumor progression and aggressiveness. Rai and Chan overview the design and performance of several well-established tumor marker assays in chapter 131. They discuss the limitations and potential interferences of these assays within the context of three tumor marker examples: prostate-specific antigen (human kallikrein-3), a serine protease of ~33 kDa that is used to screen and monitor prostate cancer; cancer antigen 125, a membrane protein involved in ovarian cancer detection; and carcinoembryonic antigen, an oncofetal glycoprotein of ~200 kDa that is useful in assessment of colon and lung cancer.

Chapter 132 examines immunologic and molecular tumor markers that have been useful in the diagnosis and classification of malignancies of the immune system, namely, lymphomas and, to a lesser extent, non-lymphoid neoplasms

that originate from cells involved in antigen presentation and processing. After an historical overview of the development of current classification schemes, Raffeld and Jaffe discuss the use of flow cytometry in quantifying the presence and density of cell surface markers and immunohistochemistry, using paraffin and frozen sections to visualize the immunologic phenotype of cancerous cells within the context of their in situ organization and cellular morphology. The authors highlight advances related to the availability of new monoclonal antibody specificities, molecular biology assays for clonality and molecular cytogenetic analyses involving in situ hybridization, and PCR-based assays for the detection of chromosomal translocations, chromosome copy number, gene copy number, and mRNA expression. Finally, the chapter provides an excellent overview of how these test results are interpreted within the context of the diagnostic algorithm for tumors of the immune system.

Chapter 133 focuses on the selection, performance, and quality control of immunological tests that are used to monitor the vast array of immunologic therapies involving monoclonal antibodies, cytokines, growth factors, activated cells, cellular products, immunotoxins, and immunomodulatory agents. Therapeutic use of these immunomodulating agents is designed to enhance capabilities of the innate and adaptive immune system to control disease. Whiteside overviews the design characteristics for clinical trials involving these biological agents. Selection of the appropriate specimens to assess the humoral and cellular compartments and timing of sample collection need to be tailored so that the specific hypothesis at the basis of the study is appropriately investigated. The chapter then highlights criteria for selecting the appropriate assays for soluble cell products (e.g., immunoglobulins, cytokines, complement components, lymphocyte receptors, enzymes); cell surface phenotypic markers and intracytoplasmic markers with flow cytometry; and assays that assess cell function. Emphasis is placed on the rationale behind systematic selection of the most informative assays, based on the specific hypothesis being tested and the design of appropriate controls to ensure assay quality.

Winters et al. complete the Cancer section by discussing the future of proteomics and immunoproteomics in cancer diagnostics. The proteome encompasses the large complement of expressed proteins some of which are overexpressed in cancerous cells. The goal of proteomics is to identify protein patterns and indicators of posttranslational modifications

to proteins (e.g., phosphorylation, glycosylation, cleavage) in biological fluids that reflect abnormal or excessive cellular growth. Surface-enhanced laser-desorption ionization/time-of-flight (SELDI-TOF) mass spectroscopy and artificial-intelligence-based pattern recognition algorithms are combined to assess the complex patterns of the proteome. The chapter tantalizes the reader by introducing new technologies involving high-resolution mass spectrometers, isotope-coded affinity tag methods, and two-dimensional polyacrylamide gel electrophoresis run in tandem with mass spectrometry. Finally, examples of specific applications are presented, such as the identification of major histocompatibility class I and class II molecules that are associated with cancer cells, and the quantification of plasma telomerase, an enzyme detected in approximately 90% of all tumor types that is elevated in malignant cells.

Immunologic Approaches to Tumor Markers: Assays, Applications, and Discovery

ALEX J. RAI AND DANIEL W. CHAN

131

A tumor marker is defined as a molecule, whether protein or nucleic acid, from a tissue or body fluid, that can be used to determine the presence of a tumor (2). The first tumor marker, which was discovered in the 1800s, was used in the treatment of multiple myeloma (3). In recent decades, several additional markers have been identified by immunizing mice with extracts from cancerous cell lines or tumors derived from animals with malignancies. These explanted cells elicit immune responses in the new host, and the resulting antibodies are used to screen new samples. Many of the cancer antigens, e.g., cancer antigen 125 (CA-125), were discovered in this manner.

Today, tumor markers are used daily in diagnostic laboratories all over the world (see Table 1 for Food and Drug Administration-cleared tumor markers). Many clinicians rely on their measurement to monitor patient therapy and to detect cancer recurrence. In this chapter, we review the design, performance, and application of tumor marker assays; interferences; specific tumor markers; and the impact of new technologies on the discovery of novel tumor markers.

CLINICAL PARAMETERS AND CONSIDERATIONS IN THE USE OF TUMOR MARKER ASSAYS

Several terms are used in evaluating the performance of tumor marker assays (8). These include diagnostic sensitivity and specificity, and positive and negative predictive values. The diagnostic sensitivity of an assay reflects the fraction of those subjects with a specific disease that the assay correctly identifies as positive. The diagnostic specificity of an assay reflects the fraction of those subjects without the disease that the assay correctly identifies as negative. The positive predictive value refers to the probability that an individual with a positive test result has the disease. The negative predictive value corresponds to the probability that an individual with a negative result does not have the disease.

There is an inverse relationship between the sensitivity and specificity which is related to the assigned cutoff value that is used for a particular test to segregate diseased populations from those with no disease. In most populations, there is an overlap between the noncancer and cancer groups, since individuals without cancer may exhibit elevated levels of a marker and some individuals with cancer may not show elevations in a particular marker. Hence, the

cutoff value for a particular assay will determine the diagnostic sensitivity and specificity of the test based on the numbers of individuals that are diagnosed with and without disease.

The optimal cutoff value can be selected using a receiver operating characteristic curve, where the sensitivity is plotted against 1-specificity (false-positive rate). This analysis allows for the determination of the accuracy of a test by continuously varying the threshold over the entire range of values (11).

APPLICATIONS OF TUMOR MARKERS

The possible applications for tumor markers include screening, diagnosis, monitoring of therapy, detection of disease recurrence, and determination of prognosis. Each of these applications will be described further along with the ideal characteristics of the tumor markers that are required for each application.

Screening

An ideal screening test would identify those individuals in a population who have disease. However, most of the present tumor marker assays do not exhibit the appropriate sensitivity and specificity to be useful for this purpose. Many tumor markers are not elevated under all cancerous conditions (i.e., corresponding assays are not highly sensitive), and others are elevated under noncancerous conditions such as the presence of benign or nonmalignant disease (i.e., corresponding assays are not highly specific). Thus, the possibility of false-positive and false-negative results exists in the use of such markers for screening. The prevalence of most cancers in the population is low, but with the inappropriate sensitivity and specificity of some tumor marker assays, false-positive results may be generated. False-positive results can induce emotional and psychological distress in addition to an unnecessary and costly medical workup for the patient in question. However, there are limited cases in which screening for cancer within a population is possible, under particular conditions (Table 1).

Diagnosis

Diagnosis is the process by which an individual is investigated for the disease of interest. Most tumor marker assays lack the diagnostic sensitivity and specificity to be useful for

TABLE 1 Food and Drug Administration-approved tumor marker tests

Cancer type	Tumor marker(s)	Applications	Gene ontology classification
Breast	CA 15-3, CA 27.29	Detection of recurrence; monitoring of therapy and disease progression in metastatic disease	Membrane protein fragment
	HER-2/neu	Determination of prognosis; detection of recurrence; monitoring of therapy	Membrane protein (extracellular domain)
Prostate	Free PSA (fPSA), total PSA (tPSA), complexed PSA (cPSA)	Screening and diagnosis; detection of recurrence	Secreted protease
Ovarian	CA-125	Monitoring of therapy; determination of prognosis; detection of recurrence	Membrane protein fragment
Colorectal	CEA	Identification of patients with aggressive disease; determination of prognosis; detection of recurrence; monitoring of response to treatment	Membrane protein fragment
Pancreatic	CA 19-9	Monitoring of disease progress and response to therapy; detection of recurrence	Membrane protein fragment
Liver	Alpha fetoprotein (AFP)	Screening of high-risk populations (in conjunction with ultrasound); detection of residual disease; monitoring of therapy; detection of recurrence	Secreted protein
Bladder	NMP-22 (urine)	Detection of residual disease	Nuclear protein

this purpose. In select cases, tumor markers can be used as an adjunct to other diagnostic modalities in the detection of cancer. Possibilities for increasing the sensitivity and specificity for diagnosis include the use of multiple, instead of single, markers.

Monitoring of Treatment

Treatment monitoring is one of the most important applications of tumor markers in clinical use today. Remission and relapse of disease can be monitored by the fall and rise in concentrations of defined tumor markers. It is important to note that this monitoring should be done with serial samples measured by the same assay. Baseline values for a particular patient should be established, and evaluation of subsequent samples can use this value for comparison. It is important to note that different assays may produce different values. Such differences can be related to the use of antibodies with different specificities or other subtle variations in assay methodologies and instruments. It is also important to note that standardization among different assays may be difficult because of the use of different reagent systems or calibrators.

Concerns related to the diagnostic specificity of an assay also are important when the assay is used for monitoring treatment. Inflammation and/or illness can cause increases in levels of particular tumor markers, and a lack of assay specificity may be mistaken for relapse. Nevertheless, the success of surgery, treatment, and drug therapy has been effectively monitored using tumor marker assays. The rate at which the tumor marker falls or rises also provides important information. Surgical removal of the tumor should result in a dramatic fall of the tumor marker, consistent with its half-life.

In contrast, the rise in a tumor marker may indicate relapse; a steep increase may suggest that treatment is no longer effective and requires modification.

Detection of Recurrence of Disease

Once the patient has been diagnosed with disease, they often undergo surgery to remove the tumor. As the cancer type is already known, the specificity of the tumor marker assay becomes less of a concern. Sensitivity in this case becomes the critical factor since it is important to measure low concentrations of the analyte as an indicator of disease recurrence. The rate of increase can be used to dictate the frequency of testing, and it may influence the therapy that is prescribed.

The assay format and sample requirements make the measurement of tumor markers for the monitoring of disease recurrence a popular choice. The levels of certain circulating tumor markers have been shown to be increased before the appearance of other physical manifestations of tumor recurrence.

Determination of Prognosis

The ability of a particular tumor marker to assist in predicting the outcome of a patient's disease defines its application in determining prognosis. Concentrations of tumor markers are known to correlate with tumor progression and aggressiveness. Thus, high levels of a particular marker at the time of diagnosis may indicate a disease that has progressed rapidly and may be indicative of poor prognosis. Low levels of the same tumor marker indicate that the disease is still in its early stages or confined to a particular organ. More research

is needed to better stratify good- and poor-prognosis patients by using levels of tumor markers.

Prediction of Therapeutic Response

Some tumor markers can act as surrogate markers for disease characterization, and thus, they can be used to aid clinicians in determining the most appropriate therapy. Examples include the use of estrogen receptor testing to predict response to chemotherapy and HER2/neu testing to predict response to specific cytotoxic agents.

IMMUNOASSAYS

In the 1950s, Michaelis and Menten and others elaborated on the specificities and kinetics of enzyme-substrate interactions. Clinical laboratorians sought to take advantage of these new findings by using enzymes as the basis for quantitative measurement of analytes. These were the first quantitative assays developed to measure specific molecules. It was later realized that the specificity of the antibody-antigen interaction is greater than that of the enzyme-substrate interaction and, therefore, the antibody-antigen interaction could also be exploited for the selective targeting of analytes.

Immunoassays take advantage of the unique properties of antibodies for the specific targeting of their cognate antigens. The antigen harbors an epitope, which is a region of the molecule recognized by a specific portion of the antibody, a region called the paratope. Antibodies can be employed for specific targeting of analytes in many complex biological matrices, including blood (whole or a portion thereof), urine, and other fluids. For an overview of immunoassays and their practical application, the reader is referred to reference 1 and chapter 3, this volume. Over the last few decades, there have been many improvements and advancements in the field of immunoassays, including developments in monoclonal antibody technology, availability of new solid phases, and the development of new labels for more sensitive detection (9).

TYPES OF IMMUNOASSAYS

Limited-Reagent Versus Excess-Reagent Assays

There are two major formats for immunoassays—limited-reagent and excess-reagent formats. Limited-reagent assays use a fixed amount of antibody that is not present in saturating amounts. This limited amount of antibody is captured in the microwell. Subsequently, the sample is added in the presence of a labeled antigen and a competition is thus established (Fig. 1). The antigens, both that in the sample and the labeled antigen, compete for the limited antibody binding sites. The greater the concentration of analyte in the sample, the fewer labeled molecules will bind and the lower the generated signal. Thus, there is an inverse relationship between the concentration of the antigen in the sample and the signal obtained. These competitive binding assays are particularly useful for smaller analytes which do not have a second epitope that is recognized by an antibody.

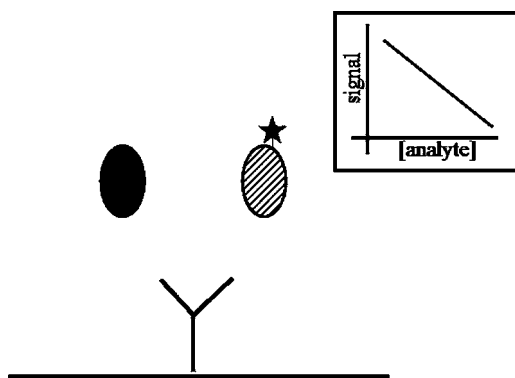
In the excess-reagent format, an excess quantity of antibody is used to bind an antigen. The most common version of these assays is the two-site immunometric assay ("sandwich" assay) (Fig. 2). This assay uses two antibodies to capture and detect the antigen. The capture antibody is present in excess and is bound to a solid phase. A sample is added containing the antigen of interest. Subsequently, a second antibody (detection antibody) is added. The latter reagent


FIGURE 1 Competitive assay format. In this format, a labeled antigen is added in the presence of antigen from the sample. A competition is established, resulting in an inverse relationship between the sample concentration and the assay signal.

binds to a second, noninterfering epitope of the molecule of interest and forms a sandwich. Coupled to this detection antibody is a signal molecule, such as an enzyme, radioisotope, or fluorophore, which aids in detection. Addition of a substrate for the enzyme, or the measurement of radioactivity or fluorescence, is used to obtain a signal. This signal correlates with the level of the analyte of interest and provides accurate quantification. Most tumor marker assays in use today are monoclonal antibody-based noncompetitive immunometric assays.

For noncompetitive immunoassays, there are at least two format types that can be employed. Both are enzyme immunoassays, the first of which employs antibodies from two different species and the second of which uses two different monoclonal antibodies (see Fig. 2). In the first, two different antibodies are selected that target different epitopes on the antigen molecule. To increase the sensitivity of the system, one should select the polyclonal antibody for coating so that the greatest number of molecules present in the sample will be captured in the microwell. Only those that bind to the second detection antibody will be used in quantitation.
FIGURE 2 Sandwich enzyme-linked immunosorbent assay (ELISA) format. There are two alternatives for this design, as shown in the figure. In panel A, the analyte is sandwiched by the capture and detection antibodies, and a third antibody coupled to a signal molecule is added. An example of this format would be the use of two antibodies from two different species and a third universal reagent. In panel B, the detection antibody is directly coupled to the signal molecule; when it forms the sandwich, it can generate signal for quantification. An example of this format would be a custom antibody coupled to horseradish peroxidase.

In this one-step incubation procedure, the sample and detection antibodies are added simultaneously, resulting in greater sensitivity and a faster turnaround time relative to a two-step procedure. The hook effect may, however, occur when this format is used. In this situation, the concentration of analyte is too high and it results in a reduced signal (see below).

The second assay format uses a two-step procedure in which two different monoclonal antibodies target separate epitopes (Fig. 2B). The coating antibody captures the sample while the labeled detection antibody binds a different epitope of the same molecule.

CONSIDERATIONS FOR TEST DESIGN

In designing a clinical test, one must consider the test's intended use. Present tumor markers are used mostly for monitoring therapy. In this case, precision and a wide dynamic range are the most important performance parameters. In contrast, for assays detecting recurrence, sensitivity is the most important factor. At the core of optimizing each of these parameters is the appropriate selection of antibodies used in assay design.

Antibody Selection

Most tumor markers are present in very low concentrations in serum. Thus, assays are preferred that detect low levels of the specified analyte and that involve low cross-reactivity. These performance parameters are largely dependent on the antibodies used in assay. Ideally, the solid-phase antibody should be of high affinity. In the competitive format, there is only one antibody and it should be of high affinity and specificity.

The antigen that is measured should be the same as the antigen used for antibody production. Proteins are known to be present in many forms throughout the body. Their conformations change during periods of maturation, processing, secretion, and degradation, which can result in fragments that enter the circulation. Heterogeneity of the protein antigen can result in subtle differences that may manifest as altered biochemical characteristics, including the ability or inability to be bound by antibodies.

The specificity of the antigen-antibody interaction, coupled with the exquisite sensitivity of enhanced signal detection methods available today, makes immunoassays the method of choice in laboratory medicine. Quantitative measurements can be made from complex fluids, including serum, plasma, urine, and other body fluids.

INTERFERENCES IN IMMUNOASSAYS

An interference is defined as any condition that can cause a deviation of the measured value of an analyte from its true value (8a). There are a number of interferences which have been described. Most testing errors occur during the analytical phase and are related to bias and imprecision. In general, these can be minimized by good internal quality control procedures. However, there are errors that escape detection using even good quality control procedures. Thus, external proficiency checks are also needed for broader surveillance. There may also be endogenous errors that are caused by problems with the specimens. Some of these occur sporadically while others are specimen dependent. In these cases, clinical suspicion and error detection are facilitated by good communication with clinicians. Examples of interferences include those inherent to samples, cross-reactivity, the presence of antireagent antibodies, the presence of rheumatoid factor, and the high-dose-antigen hook effect (see reference 8a).

Types of Analytical Errors

- Sample interferences, e.g., lipemic specimens. In some cases, specimens from fasting subjects are preferred over lipid-rich specimens. The results obtained from postprandial samples need to be treated with caution, as the excess lipids may interfere with the immunoassay. Other examples of sample interferences include hemolyzed or icterus specimens, which can cause falsely low or high results for particular analytes and assays.

- Cross-reactivity. Errors relating to cross-reactivity can be either positive or negative. These are less likely to occur with the use of monoclonal antibodies than with polyclonal antibodies. The former are directed towards a single epitope, and the latter target multiple epitopes. These errors are also less likely with two-site immunometric assays, which employ two noninterfering epitopes on the same molecule and, hence, confer greater specificity. However, even in the latter case, some analytes, e.g., glycoprotein hormones, are still problematic.

- The presence of antireagent antibodies. Antireagent antibodies bind both the capture and detection antibodies and can form an immune complex. These interfering antibodies produce either a negative or positive result, depending upon the assay design. Nonimmune immunoglobulin G (IgG) can be used to quench this reaction and suppress interference. However, the amount of IgG required will need to be determined empirically. Heterophilic antibodies are produced mostly against animal Igs. The production of some of these antibodies may be iatrogenic (see the example of human anti-mouse antibody interference described below). They have been characterized in individuals such as farm workers that have been exposed to animals, individuals that have a large number of pets, and also individuals that consume large quantities of dairy products. In the last case, there is a transfer of dietary antigens through the gut wall, which elicits an immune response. Some individuals may also experience a similar heterophilic antibody response if they have been recently treated with pharmaceutical or diagnostic remedies derived from animals, e.g., cancer patients that are treated therapeutically with mouse antibodies. Human anti-mouse antibodies can interfere with immunoassays, particularly tumor marker assays. Patients treated with these antibodies harbor antibodies to the animal Igs in their blood, and thus, their sera interfere in laboratory assays that employ mouse antibodies.

- The presence of rheumatoid factor. Rheumatoid disease produces autoantibodies that can bind to the Fc fragment of assay antibodies. These autoantibodies are usually of low affinity and can cause a problem in assays based on turbidimetry, latex particles, and agglutination. Several possibilities for circumventing the interferences exist, including the use of blocking agents, dilution studies, testing for the presence of autoantibodies, the use of other methods to check questionable results, and the use of other samples such as serum or urine to measure and verify the presence of the same analyte.

- The presence of protein complexes. This interference is not abolished by nonimmune serum and is caused by the presence of oligomeric complexes of the target protein. Discrepant results have been anecdotally described in the case of prolactin, specific steroids, and troponin, among others.

- The hook effect. The hook effect occurs when there is an excess of antigen present in the sample. This can occur
FIGURE 3 Hook effect. Excess analyte results in the binding of both antibodies, but no signal is generated.

with an analyte whose concentration can vary widely, such as a tumor marker. When there is an excess of antigen in the sample, the capture and detection antibodies will both bind to the antigen, but a sandwich will not be formed (Fig. 3). Thus, the signal obtained from such an event will not be proportional to the amount of antigen present but instead will be lower than expected. A true result can be measured by subsequent dilution and reassay of the sample.

Erroneous results are sometimes subtle and may not be questioned. However, they can have serious consequences, and thus it is important to limit immunoassay interferences. To circumvent the issues of interference, there are a number of possible solutions. In the case of heterophilic antibodies, one can use blocking reagents, which are commercially available. Simply preincubating the patient's sample with blocking solution prior to measuring the sample by immunoassay should remove the interference. Another approach is specimen dilution. If a linear response is not observed, then it is likely that there is interference. Another option is to use a different antibody or a different assay (preferably employing a different methodology) to reassay the sample. Depending on the nature of the interfering substance, it may or may not produce a similar result when reassayed.

ILLUSTRATIVE TUMOR MARKERS

Three representative tumor markers will now be discussed: prostate-specific antigen (PSA), a secreted molecule useful in the assessment of prostate cancer; CA-125, a membrane protein involved in ovarian cancer detection; and carcinoembryonic antigen (CEA), an oncofetal antigen which is useful in the assessment of colon and lung cancer.

PSA

PSA, also known as human kallikrein 3 (hK3), is a serine protease of ~33 kDa. It is a member of the hK family, which comprises approximately 15 genes located on chromosome 19 (6). Many of the proteins encoded by this locus are expressed highly in the prostate, including hK2, hK4, and hK15, in addition to PSA. As a secreted protein, PSA undergoes maturation during its progression through the secretory pathway in prostate epithelial cells. It is initially expressed in a "prepro" form in these cells. This prepro protein contains a 17-amino-acid signal sequence which is later removed to form proPSA. This proPSA molecule is inactive

but is targeted for cleavage by hK2, expressed in the prostate lumen ducts. The hK2 protease cleaves PSA and converts it into its mature form of 237 amino acids. It is this mature molecule that is secreted into the serum, where it forms complexes with other circulating proteins.

PSA plays an important role in the treatment of prostate cancer. It is one of the only markers employed for cancer detection. It is also used to monitor therapy and to detect the recurrence of disease. PSA is known to be elevated in the presence of prostate cancer but can also be elevated under benign conditions of this organ, such as benign prostatic hyperplasia and prostatitis. The reference value for normal individuals is <4 ng/ml, whereas levels of >10 ng/ml usually indicate the presence of disease. Levels between 4 and 10 ng/ml correspond to the diagnostic grey zone. At these values, it is difficult to assess cancer presence and it is helpful to assess additional analytes to evaluate the presence of disease, including specific forms of PSA. PSA exhibits significant heterogeneity in serum. While some assays measure total PSA (tPSA), other fractions can be measured. The majority of PSA protein circulates in the serum as a complex with protease inhibitors. The main protease inhibitors include α1-antichymotrypsin, α1-protease inhibitor, and inter-α-trypsin inhibitor. This complexed PSA corresponds to 70 to 90% of tPSA, and the remaining 10 to 30% is unbound and is known as free PSA (fPSA). This fPSA component can be further fractionated into additional forms—proPSA, benign prostatic hyperplasia-associated PSA, and intact PSA. Recent studies using two-dimensional gel electrophoresis suggest that there are additional protein variants in this fraction that are less appreciated (5). It is desirable to have fPSA levels as high as possible, preferably >25%. fPSA values of <10% are usually associated with disease.

CA-125

CA-125 was first identified and characterized with a murine monoclonal antibody raised against an antigen from an ovarian cancer cell line. The antigen is associated with a large glycoprotein of >200 kDa that resides in the plasma membrane. CA-125 is elevated in >80% of nonmucinous epithelial ovarian cell cancers, the most common of which are serous ovarian cancers. In contrast, it is not usually elevated in individuals with nonserous ovarian cancers, including mucinous, endometriod, and clear cell carcinomas. It is widely used for the assessment of ovarian cancer, although it can be elevated in individuals suffering from benign conditions such as inflammatory conditions, pregnancy, menstruation, and endometriosis. Presently, it is widely used in the monitoring of therapy and follow-up in ovarian cancer.

CA-125 levels have been shown to decrease during tumor regression and increase with tumor progression. Once ovarian cancer patients are treated with chemotherapy, a baseline value can be measured and they can be tested periodically by CA-125 measurement. A rise in the level of CA-125 can be used to detect recurrent or metastatic disease, even before clinical signs are evident. The lead time of CA-125 elevation before the clinical progression of disease has been shown to range between 1 and 15 months. However, it is not yet clear whether this lead time translates into improved patient outcomes or a better quality of life for patients.

Recently, the gene which encodes CA-125, *MUC16*, was cloned. It resides on chromosome 19. The encoded polypeptide consists of three domains—the carboxy-terminal, extracellular, and amino-terminal domains. There are a number

of commercial assays that measure CA-125. They utilize a limited number of antibodies and target various fragments of the CA-125 molecule. Values of >35 U/ml are considered to be elevated and associated with disease.

CEA

CEA was one of the first tumor markers described. It is a glycoprotein of approximately 200 kDa and belongs to the class of tumor markers that are oncofetal antigens. It is expressed in the fetal and embryonic gut, but its expression usually stops before birth so it is not present in normal, healthy adults.

It has been widely used in the treatment of individuals with colon cancer and lung cancer but may also be present in individuals with pancreatic, breast, and ovarian cancers. It has also been shown to be elevated under nonmalignant conditions including chronic obstructive pulmonary disease, cirrhosis, ulcerative colitis, and Crohn's disease. It is increased in the bloodstreams of smokers relative to those of nonsmokers.

CEA is one of several similar antigens which were first described in the 1960s by Gold and Freedman (4). It was initially thought to be specific to gastrointestinal cancers but was later shown to be more nonspecific. Its applications include determining whether cancer is localized or metastatic (particularly for colon cancer), monitoring cancer treatment, and also checking for recurrence.

There are presently several assays available for CEA, and the reference intervals vary among assays. The reference interval is usually 0 to 3 ng/ml for nonsmokers and 0 to 5 ng/ml for smokers. Levels of >20 ng/ml are highly suggestive of cancer.

RECENT DEVELOPMENTS IN TUMOR MARKER DISCOVERY

Single Markers Versus Multiple Markers

It has become evident during the last ~15 years that single markers will not likely be able to distinguish between diseased and nondiseased groups. Instead, it is more likely that a multimarker panel will be more useful in segregating these populations (10). Much of this situation may be due to the fact that cancer is a heterogeneous disease. There are subtypes of cancers, each characterized by mutations in different genes causing activation and inactivation of different signal transduction pathways and resulting in different phenotypes. Thus, it is appropriate that over the last few years, new technologies with the ability to simultaneously investigate the expression of hundreds of genes or proteins have been developed. These technologies include the use of nucleic acid arrays and protein-based methods and are described in more detail in subsequent paragraphs and in other reports (e.g., reference 7). These techniques will become the new tumor marker assays of the future. The new approaches use the power of multiple markers, whereas the previous methods and assays measured only single entities.

NEW TECHNOLOGIES

cDNA- or Oligonucleotide-Based Arrays

Gene expression analyses have been used for the last 7 to 8 years to identify differences in gene expression levels between two samples. Although differences can be identified, it is important to verify the alteration at the protein level, as proteins are the functional workhorses in the cell. Furthermore, RNA levels and protein levels do not necessarily correlate well. Thus, a protein-based detection method

should be used as an adjunct to confirm alterations that are suspected based on genetic assessments.

Protein-Based Methods: Mass Spectrometry, Gel Electrophoresis, and Antibody Arrays

With regard to protein-based methods for tumor marker discovery, there have been tremendous advancements over the last 10 to 20 years. Most discovery paradigms comprise several steps, including protein separation, bioinformatics analysis, protein identification and characterization, database searching, and verification of alterations. With each of these steps, there have been advancements over the last few years that have enhanced our ability to detect more proteins. Protein separation has been enhanced through the use of newly developed reagents such as improved detergents for greater protein solubility, better reducing agents, improved protocols, and commercially available kits for protein fractionation and improvements in two-dimensional gel technology allowing for greater reproducibility. Taken together, these advances allow us to visualize a greater portion of the proteome than previously possible.

With regard to bioinformatics, there has been great progress. First, there are newly developed algorithms that allow us to analyze large volumes of data from high-throughput experiments. The algorithms employ one of many procedures for the analysis of data. Multiple procedures are available and can be selected for custom applications (10). Nucleotide and protein databases are another aspect of bioinformatics that has contributed greatly to the assessment of the human genome and proteome. The genomes of a number of organisms have been completely sequenced, and gene or protein candidates can now be mapped to cDNA or genes, with the corresponding full-length proteins being identified. The presence of orthologs from different species can also be quickly determined for follow-up studies and for in-depth functional analyses using genetically tractable organisms.

Lastly, protein identification methods have advanced over the last ~15 years. High-resolution instrumentation, e.g., the Pro-TOF mass spectrometer (Perkin Elmer), and new methods, e.g., FTICR-MS (Fourier transform ioncyclotron resonance-mass spectrometry), allow for the precise measurement of peptides, affording unambiguous identification of peptides after protease digestion.

FUTURE PROSPECTS

The future looks hopeful for the discovery of new tumor markers. With the completion of the sequencing of the human genome, strides are being made in the characterization of the human proteome and there are advancements in high-throughput nucleic acid and protein analysis technologies. It is envisioned that these advancements will help identify new tumor markers with greater capabilities that can be used alone or in combination with other markers or diagnostic modalities with greater accuracy than was previously possible. The increased sensitivity and specificity will result in the development of improved assays for tumor markers. This will provide the laboratorian and clinician with earlier and more accurate information on cancer biomarkers and the prospects of translation into improved patient care.

Malignancies of the Immune System: Use of Immunologic and Molecular Tumor Markers in Classification and Diagnostics

MARK RAFFELD AND ELAINE S. JAFFE

132

Malignancies of the immune system are primarily represented by the malignant lymphomas and a smaller number of non-lymphoid neoplasms that originate from cells involved in antigen presentation and processing. The diagnosis and classification of these tumors have benefited enormously from advances in cellular and molecular immunology, as well as from careful dissection of the molecular genetics of the cancers themselves. Our ability to correctly diagnose tumors of the immune system, which in many instances show little morphological variation, requires the careful application of both immunologic tumor markers and molecular (DNA- or RNA-based) tumor markers. Therefore, malignancies of the immune system not only are interesting models of normal immune cells but also are excellent examples of the variety of molecular and immunologic approaches for assessing cancers.

The classification of the malignant lymphomas and non-lymphoid tumors of immune cells has undergone significant reappraisal over the past 40 years. Early classification systems of malignant lymphomas, such as the Rappaport classification and the Working Formulation, were based on architectural and cytological characteristics of the neoplastic elements (71, 82). However, with increasing knowledge of the complexity of the immune system a more functional approach was sought. The next generation of classification schemes (Kiel, and Lukes and Collins) attempted to integrate immunologic function with morphological parameters, with the premise that each of the lymphomas was an expansion of normal cellular counterparts (34, 65). These classification schemes still relied heavily upon the ability to correlate cytological characteristics of tumor cells with the cytological characteristics of normal counterparts. In practice, this proved to be an extremely difficult endeavor, even for experienced hematopathologists, and it became apparent that a more objective and reproducible classification scheme was needed. The decades from the 1970s through the 1990s saw an explosion of basic information in both cellular and molecular immunology, and in cancer genetics. The application of monoclonal antibodies, developed in the course of studying the normal immune system, provided one powerful approach for establishing objective diagnostic criteria, while the development of molecular testing based on rapid advances in the molecular genetic understanding of these tumors provided a second approach. By incorporating these technologies into the diagnostic armamentarium, it became possible to develop a more objective classification scheme that would take into account the molecular and immunologic characterization of the tumors.

In 1994 the International Lymphoma Study Group, a consortium of hematopathologists from the United States and Europe, met and concluded that a classification system should consist of a list of agreed-upon disease entities defined by multiple parameters, rather than being driven by a single overriding principle, such as clinical outcome (Working Formulation) or cellular differentiation (Kiel). For the first time immunophenotype and molecular genotype were recognized as critical elements in establishing a biologically meaningful classification scheme (39). This breakthrough meeting led to the development of the first modern lymphoma classification system based upon biological principles, the REAL classification, and its successor, the current World Health Organization (WHO) classification (Table 1) (48).

A major premise underlying the current classification systems was that lineage must be the starting point for a lymphoma classification. The application of modern immunologic techniques and concepts has permitted the development of a conceptual framework that may be used to decipher the morphological diversity of these neoplasms and has shown the relationship of lymphoid and mononuclear phagocytic neoplasms to the normal immune and hematopoietic systems. The development of monoclonal antibodies reactive with lymphoid, monocytic, and myeloid subsets can be used in the classification, primary diagnosis, and staging of hematopoietic malignancies and as adjunctive tools for immunotherapy in both in vivo and in vitro settings. In addition, many disease entities, particularly among the B-cell lymphomas, have a highly specific immune profile that can aid greatly in differential diagnosis. Other markers associated with lineage and cellular differentiation help to relate the various lymphoproliferative disorders to distinct stages in the development of the normal immune cells, and they are of particular interest in evaluating lymphoblastic neoplasms and in differentiating germinal-center (GC) from postgerminal-center B-cell neoplasms. Monoclonal antibodies to oncogene or tumor suppressor gene products such as cyclin D1, BCL-2, and p53 have also proved useful in diagnosis and prognostication, and in understanding the pathogenetic mechanisms of lymphomagenesis.

The WHO and REAL classification schemes also recognized the importance of cytogenetic and correlative

TABLE 1 WHO classification of lymphoid neoplasms

B-cell neoplasms
    Precursor B-cell neoplasm
        Precursor B-lymphoblastic leukemia/lymphoma
    Mature (peripheral) B-cell neoplasms
        SLL/CLL
            B-cell prolymphocytic leukemia
            LPL
            Splenic MZL (with or without villous lymphocytes)
            Hairy cell leukemia
            Plasma cell myeloma/plasmacytoma
            Extranodal MZL of MALT type
            Nodal MZL (with or without monocytoid B cells)
            FCL
            MCL
            DLBCL
                Mediastinal large-B-cell lymphoma
                Primary effusion lymphoma
                Intravascular large-B-cell lymphoma
             Burkitt lymphoma/Burkitt cell leukemia

T- and NK-cell neoplasms
    Precursor T-cell neoplasm
        Precursor T-lymphoblastic lymphoma/leukemia
    Mature (peripheral) T-cell and NK-cell neoplasms
        T-cell prolymphocytic leukemia
        T-cell granular lymphocytic leukemia
        Aggressive NK-cell leukemia
        ATL(HTLV-1$^+$)
        Extranodal NK/T-cell lymphoma, nasal type
        Enteropathy-type T-cell lymphoma
        Hepatosplenic T-cell lymphoma
        Subcutaneous panniculitis-like T-cell lymphoma
        Mycosis fungoides/Sézary syndrome
        ALCL, T/null cell, primary cutaneous type
        PTL, not otherwise characterized
        AILT
        ALCL, T/null cell, primary systemic type

molecular genetic abnormalities in contributing to the pathogenesis of particular entities. At the time the REAL classification was proposed, it had become clear that certain lymphoid neoplasms possess recurrent cytogenetic abnormalities involving oncogenes or tumor suppressor genes that play key roles in the pathogenesis of particular tumors. Many of the morphological entities that hematopathologists had long recognized were found to be associated with specific translocations, such as the t(8;14) translocation and its variants that involve the c-MYC gene in Burkitt's lymphoma (20), the t(11;14) translocation that involves the cyclin D1 gene in mantle cell lymphoma (MCL) (114), and the t(14;18) translocation that involves the BCL-2 gene in the vast majority of follicle center lymphomas (104). These associations not only validated the morphological component of the classification scheme but also enabled the further development and refinement of categories of lymphomas that were difficult to separate by morphology alone. The continued molecular dissection of lymphomas has further revealed characteristic cytogenetic and molecular genetic abnormalities in mucosa-associated lymphoid tissue (MALT) lymphomas, in anaplastic large-cell lymphomas (ALCLs), and in plasma cell neoplasms, as well as in many other lymphoma subtypes. The development of molecular technologies, particularly fluorescent in situ hybridization (FISH) and PCR,

has brought molecular diagnostics into the routine clinical laboratory and has enabled molecular genotyping to increasingly become a part of the classification criteria.

MOLECULAR AND IMMUNOLOGIC TESTS UTILIZED IN LYMPHOMA DIAGNOSTICS

Immunologic Approaches

Lymphoid and histiocytic neoplasms can be studied in fluid phase by flow cytometry or in paraffin or frozen sections by immunohistochemistry. Flow cytometry is particularly useful in assessing cell surface markers and has the advantage of being able to provide semiquantitative information regarding antigen density. Furthermore, advances in fluorescent-dye chemistry and in laser technology have made the simultaneous detection of multiple antigens routine (9). The disadvantages of flow cytometry are that in situ tissue organization is lost and the detection of cytoplasmic and nuclear antigens is technically challenging, requiring permeabilization of the cells during specimen processing. In addition, cell suspensions may not be representative of the pathological process due to fibrosis or abundant stromal elements, and specimens must be processed at the time of procurement, necessitating careful planning when obtaining the sample.

In contrast to flow cytometry, immunohistochemical techniques allow one to visualize the immunologic phenotype in the context of the in situ organization and cellular morphology. This approach is useful when one considers that lymphomas are rarely pure populations of neoplastic cells, and that a variety of normal cell types are invariably present. Moreover, in some situations, such as in Hodgkin's disease (HD) and T-cell-rich large-B-cell lymphomas, the neoplastic cells represent a minority of the cells present. Such minor populations of cells may be difficult to study by flow cytometry but can be easily identified by the combination of immunohistochemistry and morphology.

In recent years, an increasing number of mouse monoclonal antibodies have become available for use in paraffin sections, eliminating the need to perform immunohistochemistry on frozen tissue sections (Table 2). The development of these reagents has occurred not by chance, but rather by targeting the antigenic conformations present in fixed tissues (67). Another important advance in immunohistochemistry has been the recent development of rabbit monoclonal antibodies (95). These antibodies generally have a much higher affinity than comparable mouse monoclonal antibodies and have shown great promise for diagnostic applications (89).

Paraffin section immunohistochemistry has also been greatly facilitated by the development of heat-induced antigen retrieval techniques (57, 93). Previous antigen retrieval techniques involving chemicals or proteolytic enzymes had relatively limited success in diagnostic immunohistochemistry, beyond their ability to improve intermediate filament staining. Heat-induced antigen retrieval procedures proved to have broad applicability, allowing for the detection of numerous antigens rendered nonreactive during the fixation and paraffin embedding processes. The advances in antigen retrieval techniques eliminated the need for the specialized processing at the time of surgical removal and made it possible for immunophenotyping to be performed on all diagnostic biopsy specimens. There are excellent reviews of both flow cytometry and immunohistochemistry in chapters 20 and 47 of this manual.

TABLE 2 Antigens detectable in paraffin sections by immunohistochemistry[a]

Antigen (antibody)	Immune cells and/or tumor cells detected
CD20 (L-26)	B cells, L&H cells, RS cells +/−
CD79a (mb-1)	Pre-B cells, B cells, plasma cells
Kappa, lambda	Pre-B cells +/− (cytoplasmic), B cells, plasma cells
CD3	T cells
CD45RO	Memory T cells
CD43	T cells, some B cells, myeloid cells
CD15	Granulocytes, RS cells
CD30	RS cells, ALCL, immunoblasts
MPO	Myeloid cells
CD68	Histiocytes, myeloid cells
TdT	Lymphoblasts
MIB-1/Ki-67	Proliferating cells
Bcl-2	Useful in differential diagnosis of FH vs. FL
	Negative in GCs, positive in FL and other low-grade lymphomas
CD4, CD8	T-cell subsets
CD5	T cells, CLL, MCL
CD10	FL, follicle center cells, AILT
BCL6	Normal and neoplastic GC cells
IgD	Mantle cells, MCL, SMZL
CD21	FDCs, AILT
CD23	FDCs, CLL
CD1a	LC, cortical thymocytes
TIA-1, perforin, granB	Cytotoxic T cells, NK cells
CD56	NK cells, nasal T/NK-cell lymphoma, γδ TCL
CD57	Cytotoxic T cells, NK cells
LMP-1	RS cells, EBV[+] cells with latency 2 and 3 phenotypes
EMA	ALCL, plasma cells, L&H cells
Clusterin	ALCL, FDCs, FDC neoplasms
CD-99	Lymphoblastic lymphoma, Ewing's sarcoma
Langerin	LC and related neoplasms
Cyclin D1	MCL, HCL (weak)
ALK	ALCL
MUM-1	Subpopulation of GC B cells and plasma cells
p53	Tumor suppressor gene, accumulates when mutated

[a]Abbreviations: MPO, myeloperoxidase; LMP-1, latent membrane protein; GranB, granzyme B; TCL, T-cell lymphoma; FH, follicular hyperplasia; FL, follicular lymphoma, SMZL, splenic MZL; HCL, hairy cell leukemia.

Molecular Approaches

The molecular tests that are commonly applicable to tumors of immune cells fall into two categories: assays for clonality and molecular cytogenetic assays. Clonality assays are rarely used in nonlymphoid malignancies; however, there are occasions in which they may be useful. The clinically applicable molecular cytogenetic assays include in situ hybridization (ISH) studies and PCR-based assays which are utilized primarily for translocation detection. The principles behind molecular cytogenetic assays are applicable to both lymphoid and nonlymphoid tumors.

Clonality Assays

By far the most common molecular test used in the assessment of hematologic malignancies is clonality testing. Many reactive conditions simulate lymphomas, and it is critical to distinguish between a self-limited benign lymphoid proliferation caused by an immune response to a drug or virus and an uncontrolled neoplastic proliferation. The basis of clonality testing in lymphoid proliferations lies within the unique molecular biology of antigen receptor genes. When progenitor hematopoietic stem cells become committed to either the B- or T-cell lineage, they undergo a structural change in their DNA encoding their respective antigen receptor genes.

This structural change is maintained throughout the life of that cell and is inherited in all daughter cells. Likewise, if a neoplastic event occurs in a lymphoid cell possessing a rearranged antigen receptor gene, all daughter cells will inherit the identical rearrangement, creating a tumor-specific molecular marker. Structural changes of antigen receptor genes have traditionally been evaluated using restriction fragment analysis of genomic DNA followed by Southern blotting (106). In this procedure, DNA is digested by restriction enzymes that cut at known sites in the germ line. The restricted DNA is size fractionated, generally by agarose gel electrophoresis. The fractionated DNA is transferred by Southern blotting to a solid nylon or nitrocellulose matrix, and the position (which is proportional to the size) of the fragment containing the antigen receptor gene of interest is visualized by hybridization with a labeled probe that is directed to the antigen receptor gene. Germ line DNA (i.e., DNA that has not undergone rearrangement) generates a single restriction fragment that reflects the distance between the restriction enzyme sites that encompass the probe sequence. However, DNA that has undergone rearrangement will show an altered restriction fragment, different in size from the germ line fragment, reflecting the structural change that has occurred as a result of the rearrangement.

Although this procedure is capable of accurately assessing nearly 100% of all clonal B- or T-cell neoplasms, it is time-consuming and requires a relatively large amount of DNA (>20 μg) and is therefore not as well suited as PCR techniques for clinical laboratory testing.

Unlike restriction fragment analysis, the basis of PCR assays for clonality lies within differences in the sizes of the *junctional* regions that are formed during V-J or V-D-J segment recombinations. The biological basis of these size differences lies primarily with the activity of terminal deoxynucleotidyltransferase (TdT) and exonuclease activities that add and delete nucleotides in a nontemplated manner, generating junctional regions of various lengths. Physiologically this process plays a major role in creating antibody diversity, in combination with somatic mutation of the antigen receptor genes. The junctional "repertoire" can be analyzed using consensus primers that span the junctions (V and J region primers). In a reactive polyclonal population of B or T cells, the junctional sequences generated by PCR will vary from one cell to the next, generating many different-sized PCR fragments visualized as a ladder of bands on an ethidium-stained acrylamide gel. In lymphomas, all daughter tumor cells bear the identical rearranged antigen receptor gene containing identical junctional sequences. In this case, PCR will generate a single-sized product visible on the ethidium-stained gel. This product is specific for and a signature of the tumor from which it was generated.

PCR can be performed with 100 ng or less of DNA, is rapid, and is extremely easy to perform. For these reasons PCR has become the assay of choice in the clinical laboratory to test for clonality. Detection of the resulting PCR fragments is most frequently performed by gel or capillary electrophoresis. The disadvantage of PCR is that it typically has a much higher false-negativity rate than the genomic Southern blot approach, approximating 20% or more for B-cell clonality and 10% or more for T-cell clonality, depending upon the specific method chosen and the primers used. Recently a large consortium of European laboratories collaborated in a large study designated as BIOMED-II (105). The consortium developed and tested a multiplex system comprised of multiple primer pairs designed to lower the false-negativity rate of the commonly used assays for B- and T-cell clonality. These sets of primers were shown to perform extremely well, approaching detection rates of 100% for both B- and T-cell rearrangements. However, in order to reach this high level of diagnostic sensitivity, more than 31 primers multiplexed in five separate reactions were required for the assessment of immunoglobulin heavy-chain gene (IGH) rearrangements, and 44 primers multiplexed in five separate reactions were required for the assessment of T-cell receptor (TCR) rearrangements. Furthermore, these primer sets were validated primarily for freshly isolated DNA and did not perform as well in paraffin tissue, in which DNA may be partially degraded. Nonetheless, this comprehensive study demonstrates that it is possible to attain high levels of diagnostic sensitivity using PCR assays for clonality. The BIOMED-II primers are available through InVivoScribe Technologies (Carlsbad, Calif.; http://www.invivoscribe.com).

Clonality testing is rarely used in nonlymphoid malignancies, but there are occasions in which it can be useful. Simple PCR-based approaches for the assessment of clonality in nonlymphoid malignancies are the HUMARA (see below) and related assays that exploit X-linked chromosomal inactivation (23). Since the cells comprising a tumor are descendants of a single progenitor cell, the entire population of tumor cells will carry the identical inactivated maternal or paternal X chromosome that was present in the ancestral progenitor. This phenomenon has been known for many years, and the immunologic assessment of the A and B isoforms of the X-linked glucose-6-phosphate dehydrogenase enzyme, with all of its limitations, was the common method for assessing clonality until the development of molecular technologies (72). A molecular genetic feature of X-linked chromosomal inactivation is promoter hypermethylation of genes located on the inactivated chromosome (85). In a monoclonal population of cells, either 100% of the paternal or 100% of the maternal alleles will be hypermethylated, while in a polyclonal population of cells, 50% of the paternal and 50% of the maternal alleles will be hypermethylated, as a result of random X inactivation in the population. The assessment of hypermethylation is performed through the use of methylation-sensitive restriction enzymes, in combination with PCR. Prior to PCR, the DNA of interest is cut using a methylation-sensitive restriction endonuclease. Subsequently, PCR is performed using primers that encompass the promoter region. The methylated alleles remain uncut and generate a PCR product, while the nonmethylated alleles are cut by the restriction enzyme, which prevents the generation of a PCR product. In order to assess whether both maternal and paternal alleles have been amplified, the promoter chosen must also contain a highly polymorphic site that allows one to distinguish between the two alleles. The complete loss of one allele (maternal or paternal) indicates the presence of a clonal population. Because the X-linked <u>hum</u>an <u>a</u>ndrogen <u>r</u>eceptor (HUMARA) gene contains a highly polymorphic sequence in proximity to its promoter, this locus has become the target of choice for X-linked clonality assays (55). The HUMARA assay can be performed on DNA extracted from formalin-fixed paraffin-embedded tissue, is relatively simple, and is adaptable to the clinical molecular diagnostics laboratory. As for all assays exploiting X inactivation, the primary disadvantage of the HUMARA assay it that it can be performed only for female patients.

Molecular Cytogenetics

ISH

ISH is a powerful technology that allows in situ visualization of specific chromosomal translocations, chromosome copy number, gene copy number, and mRNA expression. Translocations are assessed through the use of DNA probes that recognize regions of chromosomes involved in translocations. These probes fall into two general categories: so-called break-apart probes, which are generally used singly, and fusion probes, which are used in pairs. Break-apart probes are designed to span a breakpoint region of interest. Therefore, if the targeted chromosome is split by a translocation, three signals will appear, one from the normal nontranslocated chromosome and one from each of the two derivative translocated chromosomes. Break-apart probes can provide information that the targeted region is involved in a translocation; they do not provide information identifying the partner chromosome. Break-apart probes are particularly useful when one does not know one translocation partner, or when multiple partners exist, such as for translocations involving the *bcl*-6 locus on 3q27. Fusion probes, on the other hand, are designed to recognize both chromosomal regions involved in the translocations, so that one can precisely identify both translocation partners. In the case of fusion probes, each member of the differentially labeled probe pair hybridizes with its targeted chromosomal region, generating

four signals. In cells containing the targeted translocation, two of the signals from each of the chromosomes involved in the translocation fuse into one and only three signals are seen. In practice, fusion probes are generally labeled in different colors (green and red), so that the fusion signal generally is a mixture of the two different probe colors (yellow). Probes are generally labeled with fluorescent dyes (FISH), but chromogens (CISH) have been used successfully as well for some applications. FISH can be performed on metaphase chromosome spreads, but its greatest success in diagnostic pathology has been its adaptation to interphase nuclei in either frozen or fixed tissues (53). FISH has the highest diagnostic sensitivity of any available test for identifying specific chromosomal translocations and numerical chromosome alterations. However, FISH is labor-intensive and is not available in all diagnostic laboratories due to the high cost of the associated equipment.

FISH overcomes some of the limitations of PCR in the assessment of translocations, since large chromosomal regions can be analyzed, greatly reducing the problem of false negatives due to the focal nature of PCR. As previously mentioned, the disadvantages of FISH are that it is technically challenging when applied to tissue sections, is time-consuming, and requires relatively expensive equipment and an experienced practitioner, preferably a cytogeneticist. Nonetheless, when available, FISH is the method of choice to identify most of the lymphoma-specific translocations. Probes for most of the clinically important translocations are available commercially through Vysis, Inc. (Downers Grove, Ill.).

PCR

PCR of chromosomal breakpoint junctions is also a popular method for identifying translocations because of its rapidity and simplicity. The translocations that occur in lymphoid neoplasms are of two general types, those that result in the deregulation of normal cellular genes without disrupting the coding sequence (type 1) and those that result in the fusion of two normal cellular genes to create a novel chimeric gene product (type 2). The majority of type 1 translocations involve one of the antigen receptor gene loci. These include translocations such as t(8;14) involving the MYC gene on chromosome 8 and the IGH locus on chromosome 14, t(11;14) involving the cyclin D1 locus on chromosome 11 and the IGH locus, and t(14;18) involving the BCL-2 gene and the IGH locus. In all of these cases, the translocations deregulate the target gene by disrupting its regulatory elements or by placing it under the control of elements of the involved antigen receptor gene. A minority of the type 1 translocations do not involve an antigen receptor gene, such as some of the variant translocations involving the BCL-6 gene on chromosome 3q27. Nonetheless, the result is similar in that the target gene's coding sequence is left intact, but its regulatory elements are altered through the substitution of control elements from the various genes on the partnering chromosomes. Whereas the type 1 translocations leave the coding sequences of the potential oncogenes intact, type 2 tranlocations occur between two unrelated genes and result in the creation of a novel mRNA and protein encoded by portions of the two fused genes. Typically both genes are transcription factors and the resulting chimeric proteins display highly aberrant transcriptional activities. Representative of the type 2 translocation is the pre-B-cell acute lymphocytic leukemia (ALL) t(12;21) translocation, which fuses the TEL gene on chromosome 12 to the AML1 gene on chromosome 21.

The molecular detection strategies for the two types of translocations differ in that for the type 1 translocations the targeted template is generally the junctional sequence *within the DNA*, while in the type 2 translocations the primers generally target the junctional sequence *within the message (cDNA)* encoding the novel protein. For both types of translocations, a PCR product will be generated only from the tumor cells bearing the junctional DNA or cDNA sequences created by the translocation, which therefore serves as a tumor-specific marker. Detection is generally carried out by either gel or capillary electrophoresis. Alternatively, PCR and detection may be combined in real-time PCR instruments. These instruments monitor the accumulation of product during the PCR using fluorescent detection technologies (6).

The use of PCR to detect type 1 translocations can be highly effective when the breakpoints on the partnering chromosomes are clustered, as occurs with the t(14;18) translocations in follicle center lymphomas. However, if the breakpoints are instead spread over a larger area, as they are with the t(11;14) translocation in MCLs, this technique will miss many translocations. While DNA-based PCR assays have a very high analytic sensitivity, capable of identifying 1 in 10^6 abnormal cells, these tests have a much lower diagnostic sensitivity than FISH, since each PCR primer set can target only a DNA segment of a few hundred base pairs, while an appropriate FISH probe can identify translocations involving all potential breakpoint regions.

Type 2 translocations occur most frequently in pre-B-cell and B-lymphoblastic lymphoma/leukemias, but they also occur in some of the mature B- and T-cell lymphomas, including ALCL and MALT lymphoma. These are extremely interesting events from the biological point of view, as they create chimeric proteins that have novel oncogenic activities. For diagnostic purposes, the chimeric RNA serves as the tumor-specific PCR product. Reverse transcription (RT)-PCR assays targeting the chimeric RNA sequences generally have a much higher diagnostic sensitivity than those that target the corresponding chromosomal breakpoint regions because in most cases, gene splicing events create junctions precisely between the exons of the fused genes, even when the breakpoint sequences themselves may be spread diffusely throughout intronic sequences. For example, 75% of ALCLs possess a t(2;5) translocation joining the nucleophosmin (NPM) gene on chromosome 5 to the ALCL tyrosine kinase (ALK) gene on chromosome 2. The breakpoints are spread throughout intron 4 of the NPM gene and within a single intron of the ALK gene, which presents difficulties in the design of a simple DNA-based PCR test. However, splicing events in the novel transcript bring exon 4 of the NPM gene into contiguity with a 5′ coding exon of the ALK gene in all cases. This allows the design of a simple RT-PCR assay, using only a single primer pair, that can reliably identify all of the t(2;5) translocation.

Other Molecular Tests Used in Lymphoma Diagnostics

PCR is also used to identify the presence of viruses that are associated with different lymphoma subtypes. Chapters in section J (Viral Diseases) of this manual (e.g., chapter 89) discuss these viral detection assays in more detail. PCR to detect viral DNA can be especially helpful in the diagnosis of human T-cell leukemia virus type 1 (HTLV-1)-associated lymphomas, human herpesvirus 8 (HHV-8)-associated pleural effusion lymphomas, and lymphoproliferations associated

with Epstein-Barr virus (EBV), such as EBV posttransplant lymphoproliferative disorders, nasal NK/T-cell lymphoma, angioimmunoblastic T-cell lymphoma (AILT), and Burkitt's lymphoma. However, the identification of a viral product by PCR should be correlated with in situ or morphological studies since the presence of these viruses is not tumor specific. For example, HHV-8 may also be found in Kaposi's sarcoma and Castleman's disease, and EBV may be identified in non-neoplastic immunoproliferative conditions, particularly when immunosuppression is present. Furthermore, it is important to recognize that because of the extremely high sensitivity of PCR-based tests, nonpathological levels of some viruses that are present at low levels, such as EBV, may be detected.

FISH and the related technique CISH are also well suited for identification of mRNA in situ and for identifying viruses such as EBV (4). The advantage of CISH is that it can be assessed using an ordinary light microscope. However, it is limited by the number of chromogens available and by the resolution of the technology. CISH can be used as a secondary technique to assess light-chain exclusion, when exclusion cannot be definitively assessed at the protein level. CISH is commonly used in hematopathology laboratories for the identification of EBV infection and has become an important ancillary test for diagnosing cases of NK/T-cell lymphoma, Burkitt's lymphoma, AILT, and other EBV-associated lymphoproliferative disorders, including posttransplant lymphoproliferative disorders.

cDNA microarray studies have recently been utilized to further the classification of lymphomas (2, 35, 86, 88, 91). Clinically significant subcategories within morphologically homogeneous lymphoma entities, such as diffuse large-B-cell lymphoma (DLBCL) and chronic lymphocytic leukemia (CLL), have been identified through the use of this technology. While cDNA microarrays are not yet ready for clinical diagnostics, it is only a matter of time before this powerful technology evolves into a more user-friendly format and becomes an integral part of the molecular diagnostic laboratory. cDNA microarray technology is discussed in detail in chapters 4 and 5.

INTERPRETATION AND APPLICATION OF IMMUNOLOGIC AND MOLECULAR MARKERS IN THE DIAGNOSIS OF TUMORS OF THE IMMUNE SYSTEM

Precursor Lymphoid Neoplasms

Lymphoblastic malignancies (LBL) are neoplasms of precursor T and B lymphocytes. They may present clinically as either lymphoblastic lymphoma or ALL, and morphologically the T- and B-lineage varieties of LBL are indistinguishable. Virtually 100% of these neoplasms are positive for TdT, which can be detected by immunocytochemical techniques using rabbit antisera or murine monoclonal antibodies directed against it.

Precursor T-cell LBL most often present as lymphoma, usually with a mediastinal mass, with or without bone marrow involvement and a leukemic phase. They usually have an immature T-cell phenotype that correlates with different stages of intrathymic maturation (Fig. 1). The earliest T-cell-associated antigen with some lineage specificity is CD7. However, it is also expressed in rare cases of acute myeloid leukemia, where it may represent evidence of lineage infidelity, often seen in primitive hematopoietic malignancies. CD3, linked to the T-cell antigen receptor, is expressed in the cytoplasm prior to its presence on the surface and thus may not be revealed by immunofluorescence techniques on living cells (77). In this situation a T-cell LBL may be CD3 positive in tissue sections but negative by routine flow cytometry. However, techniques that permeabilize the cell membrane are available to detect cytoplasmic antigens by flow cytometry. It should be noted that the normal thymocytes
FIGURE 1 Schematic diagram showing stages of T-cell differentiation. Neoplasms can be related to precursor and mature or peripheral T lymphocytes. Antigenic phenotype correlates with maturational stage. Note that CD7 is the earliest T-associated antigen.

encountered in a lymphocyte-rich thymoma would be phenotypically similar to the cells of a T-cell LBL. Immunohistochemical analysis will be necessary to detect the thymic epithelial cells numerous in the former condition.

T-lymphoblastic lymphomas are clonal neoplasms, and most will have TCRβ or TCRγ rearrangements (99). About 20% of T-lymphoblastic lymphomas also have IGH rearrangements, a phenomenon known as lineage infidelity (100). Lineage infidelity is common in early-lineage T- and B-cell neoplasms but is rare in mature B- and T-cell neoplasms. Therefore, when assessing clonality in lymphoblastic lymphomas, antigen receptor rearrangements cannot be used to assign B- or T-cell lineage. Up to 50% of T-lymphoblastic lymphoma/leukemias have recurrent translocations most frequently involving one of the TCR gene loci (Table 3). These can be detected by FISH and in many cases by PCR.

Precursor B-cell LBL present as leukemia more often than as lymphoma. In cases presenting as lymphoma, common clinical manifestations include skin involvement (often of the scalp or face), lytic bone lesions, or lymphadenopathy. The risk of involvement of the central nervous system is less than for pre-T-cell LBL. Although these precursor B-cell tumors do not normally express immunoglobulin, other markers of B-cell lineage, such as CD19 and CD79a, will be present (Fig. 2) (13). These antigens are expressed at the time of IGH rearrangement, usually indicating commitment to the B-cell lineage. In cases of so-called pre-B-cell ALL, the cells contain cytoplasmic μ heavy chains but are still negative for surface immunoglobulin. The CD20 antigen is not acquired until the stage of light-chain gene rearrangement, and it is expressed in approximately 50% of cases (56). Thus, pre-B-cell LBL is often negative for CD20 in paraffin sections.

TABLE 3 Chromosomal translocations, involved genes, and detection methods in B- and T-cell lymphoma/leukemias[a]

Translocation	Genes	Tumor	Translocation type	Primary test(s)
B-lymphoblastic leukemia/lymphoma

[b]Major cluster region primers identify about 35% of translocations.
[c]RT-PCR to the cyclin D1 mRNA will detect close to 100% of cases.
[d]3q27 partners with various (v) chromosomal partners and loci.
[e]MPS, multiple partner genes.
FIGURE 2 Schematic diagram showing stages of B-cell differentiation. Lymphomas can be related to precursor B-cell, mature B-cell, and secretory B-cell (plasma cell) stages of differentiation. Note that CD79a has the broadest range of reactivity, staining precursor, mature, and secretory B cells. Abbreviations: PRE, precursor; IMMAT, immature; MAT, mature; ACTIVD, activated; HCR, heavy-chain gene rearrangement; κ and λ R/D, κ and λ light-chain gene rearrangement/deletion; sIg, surface immunoglobulin; LPL, lymphoplasmacytic lymphoma.

All pre-B-cell and B-cell lymphoblastic lymphomas are clonal neoplasms, and the vast majority have IGH rearrangements. In some cases the IGH rearrangements are incomplete, showing only D-to-J segment joining (101). B-cell lymphoblastic lymphomas have an extremely high frequency of lineage infidelity, with 90% of cases having clonal rearrangements of one or more TCR loci (TCRβ [35%], TCRγ [60%], or TCRδ [55%]) (98). About 30% of cases have characteristic chromosomal translocations (Table 3). A high percentage of these involve two non-antigen receptor genes that can be identified by FISH or by RT-PCR.

Both pre-T-cell and pre-B-cell LBL may be negative for the leukocyte common antigen (CD45). In addition, they both express CD99, the *mic-2* gene product, in a large proportion of cases. This antigen is expressed in Ewing's sarcoma, a nonlymphoid malignancy presenting in children and young adults, often with lytic bone lesions of the distal extremities. Because of potentially overlapping histological and clinical features, an extensive immunohistochemical panel as well as molecular analysis may be required for accurate differential diagnosis (74).

Mature B-Cell Lymphomas

A variety of malignancies composed of small mature B lymphocytes are recognized in the WHO classification. These include small lymphocytic lymphoma (SLL)/CLL, follicular lymphoma (FCL), MCL, extranodal marginal zone lymphoma (MZL) of MALT type, nodal MZL, splenic MZL, and hairy cell leukemia. In most of these neoplasms, the cells are arrested prior to the secretory stage of B-cell development and express pan-B-cell antigens such as CD19, CD20, and CD22. Evidence of plasmacytoid differentiation is most commonly seen in MZL and is a consistent feature of lymphoplasmacytic lymphoma (LPL). Each of the small B-cell malignancies has a characteristic immunophenotypic signature that is highly useful in differential diagnosis (Table 4).

Monoclonal surface immunoglobulin expression is usually readily detected in frozen sections but is generally not evident in paraffin sections. Even in frozen sections, abundant serum

[b]Most commonly expressed heavy-chain class.

immunoglobulins in the interstitial space may result in high background staining, which can obscure cellular staining and make interpretation difficult. This problem is frequently observed in tissues from patients with polyclonal hypergammaglobulinemia. In paraffin sections, cytoplasmic immunoglobulin can be detected, but it is usually most evident in cells showing evidence of plasmacytoid differentiation. Positive staining in the perinuclear space is highly reliable and is usually not subject to technical problems.

The ability of the cells to form follicles correlates with the presence of dendritic reticulum cells (DRC), which can be identified in frozen and paraffin sections by using monoclonal antibodies reactive with CD21, CD23, CD35, or clusterin. DRC are numerous in FCL and intimately associated with the neoplastic nodules, even in extranodal locations. Staining for DRC will often enhance a vaguely nodular pattern that is difficult to see in routine histological sections. DRC are rare in SLL but are present with an irregular, vaguely nodular distribution in MCL.

CD5 is very useful in the subclassification of low-grade B-cell lymphomas. This antigen is found on normal T cells but on few normal B cells. Both SLL and MCL are usually positive for CD5, but it is almost never expressed in true FCL. Thus, this antigen is useful in the differential diagnosis of MCL with a vaguely nodular growth pattern versus a true FCL. CD5 is also useful in the differential diagnosis of SLL and MCL with lymphomas of MALT. MALT lymphomas arise in extranodal sites (e.g., lung, gastrointestinal tract, and salivary gland) and are composed of small round and small-cleaved (centrocyte-like) cells, which may resemble the cells of SLL and MCL. MALT lymphomas are usually CD5 negative (29). CD23 is very useful in the differential diagnosis of SLL/CLL and MCL, since SLL/CLL is nearly always CD23 positive and MCL is nearly always CD23 negative (59). The common ALL antigen (cALLa) or CD10 is found much more often in FCL than in the other small B-cell lymphomas (51). For unknown reasons, MCL and hairy cell leukemia both express λ light chain much more frequently than do the other B-cell lymphomas, which usually express κ.

Cytogenetic and molecular genetic studies are also extremely valuable in differential diagnosis, and monoclonal antibodies to oncogene products can be used as surrogate markers in some situations (Table 5). FCL is characterized by the t(14;18) translocation that juxtaposes the *BCL-2* gene with the IGH promoter/enhancer, resulting in BCL-2 overexpression (104). While the translocation results in BCL-2

overexpression, BCL-2 expression, however, is not specific for the translocation, as other low-grade lymphomas express this antiapoptotic protein (32). Thus, while the detection of overexpressed BCL-2 by immunohistochemistry is useful in differentiating follicular lymphoma from follicular hyperplasia, it is not helpful in distinguishing follicular lymphoma from other SLLs. PCR assays targeting the most common breakpoint cluster involved in the t(14;18) translocation can identify up to 65% of cases, while FISH analysis is capable of detecting all cases (42).

The t(11;14) translocation is present in all MCLs (68). This translocation involves the cyclin D1 gene, resulting in the overexpression of the protein, which is not expressed in nonneoplastic lymphoid cells or in other small lymphocytic neoplasms, with the exception of a small percentage of myeloma cases that have t(11;14) and hairy cell leukemias which express very low levels of cyclin D1 (81). The development of new mouse and rabbit monoclonal antibodies to cyclin D1 have greatly improved the detection of these aggressive SLLs, and molecular testing for the translocation is generally not necessary (95). PCR analysis for identification of t(11;14) breakpoint sequences has a relatively low yield unless multiple primer pairs are used, and therefore this method is not widely used. However, RT-PCR targeting the overexpressed cyclin D1 transcripts has been successfully employed in diagnostics (12). This assay exploits the fact that normal lymphocytes and other lymphomas do not express cyclin D1 message, except for a minority of myelomas and hairy cell leukemias at low levels. FISH assays for t(11:14) will identify 100% of cases. Recently cDNA microarray analyses have been performed on cases of MCL (88). While these studies have confirmed the homogeneity of this lymphoma, they have also shown that it is possible to stratify cases and predict survival based upon the expression of a set of genes associated with cellular proliferation.

The t(11;18) translocation involving *API2/MLT(MALT)* genes is the most common recurring cytogenetic abnormality in MALT lymphomas of the gastrointestinal tract and lung, where it is found in about one-third of all cases (8). However, other less common translocations also occur in MALT lymphomas, including the t(14;18) translocation involving the IGH gene and the MLT gene and the t(1;14) translocation involving BCL-10 and IGH (43). The t(14;18) translocation preferentially involves non-gastrointestinal tract MALT lymphomas such as those in the lung and ocular

TABLE 5 Evaluation of oncogenes and tumor suppressor genes by immunohistochemistry and molecular diagnostic techniques[a]

Antigen	Disease association	Genetic abnormality	Applicable genetic test(s)	Immunohisto-chemistry result
BCL-2	Follicular lymphoma	t(14;18)	GS, PCR, FISH[b]	+, nonspecific
Cyclin D1	MCL	t(11;14)	GS, PCR, FISH[b]	+, specific[b]
	Multiple myeloma (15%)	t(11;14)	RT-PCR[b] (cyclin D1)	+, specific[b]
p53	Progressed lymphomas	17q deletion	LOH, SSCP, FISH	+, probable[b,c]
	Aggressive lymphomas	Mutation	Sequencing[c]	Mutation
BCL-6	DLBCL (GCB > ABC)	t(3;14)	GS, FISH[b]	+, nonspecific
	3q26 variants	Mutation		
ALK	ALCL	t(2;5)	GS, RT-PCR, FISH[b]	+, specific[b]
		2p23 variants		

[a]Abbreviations: GS, genomic Southern blot analysis; SSCP, single-strand conformational polymorphism analysis; GCB, germinal center B cell-like; ABC, activated B cell-like.

[b]Method(s) of choice for detection of genetic abnormalities in the clinical molecular diagnostics laboratory.

[c]p53 overexpression is generally correlated with the presence of mutation; however, lack of expression is poorly correlated with lack of mutation. Sequencing is required for definitive proof of mutation.

adnexa, while the t(1;14) translocation tends to be found in advanced-stage MALT lymphoma. It is of interest that these three translocations perturb two genes (BCL-10 and MLT) that are involved in antigen receptor NF-κB activation (43). The most common of these translocations, t(11;18), can be readily assessed using commercially available FISH probes, or by RT-PCR using published primers to the API2 and MLT genes.

CLL lacks a characteristic recurrent translocation but displays other cytogenetic abnormalities, including deletions of 13q14, trisomy 12, and deletions of 11q and 17p, which are both associated with a more aggressive clinical course (25). The 13q14 deletion occurs in a very high percentage of CLL cases and results in the consistent loss of genes encoding micro-RNAs (15). Micro-RNAs are small antisense RNAs encoded in the genome that appear to regulate the translation of critical proteins (16). The micro-RNAs that are deleted at 13q14 are miR15 and miR16, which are regulators of the antiapoptotic BCL-2 protein, implicating the loss of these micro-RNAs in the abnormally high levels of BCL-2 found in CLL (18). FISH analysis tends to underestimate the frequency of micro-RNA loss because a significant number of the deletions at 13q14 are small.

Over the past several years there have been a number of studies that have clearly shown that there are two distinct clinicopathological subtypes of CLL that can be distinguished by the presence or absence of IGH mutation, CD38 expression, and ZAP70 expression (103, 110). Nonmutated CLL tends to be CD38 positive and ZAP70 positive. Patients with nonmutated CLL have a 5-year survival of about 40 months, compared to 120 months for their counterparts with ZAP70-negative mutated CLL. Gene microarray studies have confirmed the presence of these two clinicopathological subgroups (86). At present, either mutational analysis or ZAP70 expression by immunohistochemistry or flow cytometry is recommended to distinguish these two CLL subtypes.

Tumors of fully differentiated B cells synthesize and secrete immunoglobulin, giving rise to monoclonal immunoglobulin spikes that can be detected by serum immunoelectrophoresis. LPL is the histological counterpart of Waldenström macroglobulinemia. In this disease the cell is arrested between the B lymphocyte and the plasma cell. Class switching from immunoglobulin M (IgM) to IgG, IgA, etc., has not yet occurred, and clinically the process resembles a low-grade lymphoma with widespread involvement of lymphoid organs. Although rare patients carry the t(9;14) translocation which juxtaposes the PAX5 gene to the IGH locus, the molecular pathogenesis of these rare tumors is largely unstudied.

Multiple myeloma, which arises from terminally differentiated B cells, may show monoclonal IgG, IgA, IgM, or IgD, in that order of frequency. The cells at this stage of differentiation lose most B-cell markers, such as CD20, CD19, and CD22. However, CD79a is still found (67). All myelomas have clonally rearranged immunoglobulin genes and express monoclonal immunoglobulin, which is mainly cytoplasmic and can be most readily detected in paraffin sections. Of practical significance, it should be noted that normal and neoplastic plasma cells are CD45 (leukocyte common antigen) negative but are positive for epithelial membrane antigen. The pathologist should be alert to these characteristics in the eventual differential diagnosis of anaplastic carcinoma versus multiple myeloma. Multiple myeloma has several characteristic recurrent translocations (Table 3). Interestingly, many of these result in the overexpression of cyclin D, either directly or indirectly, and it has been proposed that overexpression of cyclin D is a common pathogenetic mechanism unifying all of the different translocations (11). FISH is the method of choice for detection of the various translocations.

DLBCL is not a single disease entity but a category that includes both primary aggressive B-cell lymphomas and histologically progressed lymphomas. Because there are as yet no immunophenotypic or morphological features that lead to reliable subclassification of these lymphomas, it was deemed most advisable to retain most morphological variants of DLBCL in a single category, pending further data and delineation of other entities. Notably, some specific entities have been defined, and these include mediastinal or thymic-B-cell lymphoma, primary effusion lymphomas (HHV-8 associated), and intravascular DLBCL (17, 24, 63, 64).

Therefore, it is not unexpected that most cases of DLBCL do not display unique phenotypic profiles but express the mature-B-cell characteristics seen in diverse low-grade B-cell tumors. For example, expression of CD10 usually correlates with the presence of the t(14;18) translocation (27). In some cases, the presence of CD5 indicates that the process arose in the background of a small lymphocytic malignancy (SLL/CLL), so-called Richter's syndrome, although de novo CD5$^+$ DLBCLs also exist. p53 is commonly expressed and is often an indication of an acquired *p53* mutation associated with histological progression (90). p53 protein expression also is a poor prognostic marker (113). *BCL-6* is expressed in the majority of DLBCL cases, in many instances indicating a derivation from the germinal center (GC). However, both translocations and mutations of *BCL-6* occur frequently as well. While translocations of *BCL-6* are clearly important pathogenetically, *BCL-6* mutations are a normal physiological event in the GC. Recent data from several laboratories using cDNA microarray studies have begun to identify distinct differences within the DLBCLs (2, 92). Mediastinal B-cell lymphomas have been shown to be quite distinct in their gene expression signature from other DLBCLs and, in fact, have a signature closer to that of HD (92). "Standard" DLBCL has been shown to be composed of at least three different subgroups: a GCB subgroup, simulating the gene expression signature of GC B cells; an activated B cell-like (ABC) subgroup, simulating the signature of activated peripheral B cells; and a third, unclassified subgroup (2, 87). The ABC subgroup has been shown to have a significantly worse prognosis than the GCB subgroup, demonstrating that the subclassification has clinical relevance. Pathologists have been able to extract from these data a small panel of genes, amenable to immuohistochemical study, that have been shown to be effective in dividing the GCB group (BCL-6, CD10) from the ABC group (MUM-1/IRF4) (38).

A morphological variant of DLBCL is so-called T-cell-rich large-B-cell lymphoma. The neoplastic cells comprise less than 5% of the population in the lymph nodes, with most of the infiltrating cells being reactive polyclonal T cells. Staining of paraffin sections with L-26 is especially helpful in the recognition of T-cell-rich large-B-cell lymphoma and will highlight the large tumor cells. Cell suspensions prepared from such lymph nodes usually contain >75% T cells (up to 90% or more) and may be erroneously diagnosed as T-cell lymphomas with flow cytometric techniques. In many of these cases, the neoplastic cells resemble the L&H cells (so-called lymphocytic plus histiocytic variants) of nodular lymphocyte predominant Hodgkin's lymphoma, and a relationship between these entities has been postulated (22). There is as yet no reliable immunohistochemical or molecular test to distinguish these two disease entities, and the diagnosis remains heavily reliant upon clinical-pathological parameters.

Another DLBCL variant that has been clearly separated from the vast majority of DLBCLs is the pleural effusion lymphomas associated with human immunodeficiency virus (HIV) infection. Not only do these B-cell lymphomas have the unusual clinical feature of presenting as an effusion, most often without a solid or leukemic phase, but also they have an unusual immunophenotype and contain HHV-8 (17). These lymphomas have a plasmablast-like B-cell phenotype, but paradoxically generally do not display membrane or cytoplasmic immunoglobulin by immunohistochemistry. However, all cases have rearrangement of their immunoglobulin genes as detected by either genomic Southern blotting or PCR. HHV-8 can be easily demonstrated in the tumor cells by specific antibodies to the ORF76 protein or by PCR of involved fluids (73).

Burkitt's lymphoma is a high-grade malignancy that expresses CD20, CD19, and CD22. Surface immunoglobulin is usually of the IgM class, and the cALL antigen (CD10) is nearly always positive. Burkitt's lymphoma can rarely present as acute leukemia (L3) in the FAB (French-American-British) scheme. This lymphoma is TdT negative, helping to distinguish it from LBL, which is always TdT positive. Burkitt's lymphoma is characterized by translocations involving the MYC gene (54). Translocations involving MYC are best detected by FISH, as the chromosomal breakpoints are not sufficiently clustered to allow simple PCR testing. Burkitt's lymphoma is a highly proliferative tumor, with 100% of the cells in cycle (MIB-1$^+$), and is consistently BCL-2 negative. It is positive for BCL-6, indicating a relationship to the GC.

Mature T-Cell Neoplasms

Neoplasms of mature or peripheral T-cell origin demonstrate marked cytological heterogeneity. However, in contrast to the case with B-cell lymphomas, cytological features are less useful in defining disease entities. While nearly all cases of peripheral T-cell lymphoma (PTL) possess clonal rearrangements of at least one of the TCR genes, these lymphomas do not display consistent immunophenotypic profiles. In addition, the molecular pathogenesis remains to be defined for most of the T-cell lymphomas. Therefore, at present, clinical parameters play a major role in the classification of T-cell lymphomas, as cytological, immunophenotypic, and molecular features are insufficient to define these neoplasms. As a group they tend to be much more aggressive than B-cell lymphomas (70).

PTL, unspecified, is a category somewhat analogous to DLBCL (50). It is felt to be heterogeneous, and probably contains several yet-to-be-recognized entities. PTLs display a wide morphological spectrum, with cells of diverse sizes and appearances. PTL often has an inflammatory background composed of eosinophils, histiocytes, and plasma cells. This polymorphous cellular composition may lead to difficulty in distinction from HD. The presence of cytological atypia in the background lymphocytes argues against a diagnosis of HD. Immunophenotypic markers are also useful in this differential diagnosis.

Immunophenotypic markers for clonality are not readily available in the T-cell system. Therefore, molecular assays for the assessment of clonality are often extremely helpful. The major subset antigens CD4 and CD8 are not clonal markers analogous to light-chain restriction in the B-cell system. Although most PTLs express only CD4 or CD8, some reactive conditions can also show marked subset restriction, most commonly of the CD4 subset. If a proliferation coexpresses CD4 and CD8 or fails to express either CD4 or CD8, that profile is suggestive of malignancy (75).

Other abnormalities of antigenic phenotype are commonly observed in PTL (Table 6). If a battery of pan-T-cell monoclonal antibodies is used, PTL will often fail to express one or more of the major markers CD7, CD5, CD3, and CD2. The antigen most frequently absent is CD7. However, because this antigen is expressed on only 85% of normal T cells, its absence is not unequivocal evidence of a malignancy. Indeed, some reactive T-cell proliferations will be CD7 negative.

A prominence of postcapillary venules is a feature often noted in PTL. AILT is a specific subtype of PTL characterized by an especially florid proliferation of postcapillary venules (31). The predominant infiltrating cells in AILT are CD4-positive T cells. Interestingly, the tumor cells have recently been shown to express CD10 and CXCR13, suggesting that these tumors originate from a subset of CD10-positive T cells that populate the GCs (7, 37). A prominent inflammatory background is present, including polyclonal plasma cells, histiocytes, and eosinophils. A disordered meshwork of CD21-positive reticulum cells distributed around blood vessels is highly characteristic of this lymphoma type.

Most cases of AILT show clonal TCRβ or TCRγ gene rearrangement. B cells are variable in frequency and in some cases may be numerous. In addition, some B cells positive for EBV are seen in nearly all cases (107). These EBV$^+$ cells may be monoclonal as detected by IGH PCR techniques, and in rare cases the EBV$^+$ B cells may progress to a DLBCL (1). In other rare instances the EBV$^+$ cells may also simulate Hodgkin's lymphoma morphologically and immunophenotypically (79). It is postulated that the expansion of EBV$^+$ B cells is secondary to the underlying immunodeficiency so characteristic of this disease.

Adult T-cell leukemia/lymphoma (ATL) is a unique clinicopathological entity associated with the human retrovirus HTLV-1 (14). The neoplastic cells have a mature T-cell phenotype. They are CD4 positive and strongly express interleukin-2 receptors (CD25). Elevated levels of soluble interleukin-2 receptors may be found in the serum and correlate with disease activity. They have a high proliferative rate with MIB-1, in keeping with the aggressive clinical

TABLE 6 Immunophenotype in the differential diagnosis of nodal PTLs[a]

Disease	Immunophenotypic features
AILT	CD10 +, mixed CD4/CD8, proliferation of FDCs (CD21$^+$ cells), EBV$^+$ blasts
PTL, unspecified	CD4 > CD8, Ag loss (CD7, CD5, CD2)
ATLL	CD4$^+$, CD25$^+$, CD7-, CD30$^{+/-}$, CD15$^+$
ALCL	ALK$^+$, CD30$^+$, clusterin $^+$, EMA $^+$, CD25 $^+$, CD4 $^+$, CD3$^{+/-}$
TCRBCL	Large CD20 $^+$ blasts in CD3 $^+$ background
Reactive	Mixed CD4/CD8, intact architecture, variable CD25, CD30; scattered CD20 $^+$

[a]Abbreviations: Ag, antigen; TCRBCL, T-cell-rich large-B-cell lymphoma.

TABLE 7 Extranodal NK/T-cell lymphomas[a]

Subtype	EBV	CD3	TIA-1	GranB/Per	CD56	TCR Major	Minor
SPTCL	−	+ s	+	+	±	αβ	γδ
EATL	±	+ s	+	+	±	αβ	γδ/NK
Nasal	+	+ c	+	+	+	NK	γδαβ?
Hep/spl	−	+ s	+	−	+	γδ	αβ

[a]Abbreviations: SPTCL, subcutaneous panniculitis-like T-cell lymphoma, EATL, enteropathy-associated T-cell lymphoma; Nasal, nasal NK/T-cell lymphoma; Hep/spl, hepatosplenic T-cell lymphoma; GranB/Per, granzyme B/perforin; s, surface CD3; c, cytoplasmic CD3.

course. In vitro they exhibit suppressor cell function. As with many PTLs, they are CD7 negative. All cases of ATL have clonal TCRβ and TCRγ rearrangements and are associated with clonally integrated HTLV-1 retrovirus. Serologic testing for HTLV-1 as well as the identification of viral genomic sequences by PCR can be of great help in diagnosing this lymphoid neoplasm. However, only a minority of infected patients will develop ATL, and it is important to correlate serologic positivity for HTLV-1 or a positive PCR result with the presence of a clonal T-cell lymphoproliferation. Recurrent translocations are not reported in ATL, but numerical abnormalities and deletions of the long arm of chromosome 6 as assessed by both cytogenetic and loss-of-heterozygosity (LOH) studies are frequent (40).

Extranodal NK/T-cell lymphomas represent a distinctive group and share many histological and immunophenotypic features (49). This observation is in keeping with the close relationship between NK cells and cytotoxic T cells (96). They include intestinal T-cell lymphoma, subcutaneous panniculitis-like T-cell lymphoma, and nasal and extranasal NK/T-cell lymphoma. Most of the extranodal T-cell lymphomas appear to be derived from cytotoxic T cells; they express granzyme B, the cytotoxic granule-associated protein TIA-1 (also known as granule membrane protein GM-17), and perforin (21). CD56, an antigen expressed on NK cells, may also be present, but it is most common in nasal NK/T-cell lymphoma (Table 7). These lymphomas as a group present in and spread to extranodal sites, with infrequent lymph node involvement. They frequently contain extensive necrosis, sometimes associated with angioinvasion. Apoptosis of tumor cells also is prominent, in part related to the cytotoxic features of the neoplastic cells. EBV is universally found in nasal and extranasal NK/T-cell lymphoma and may be seen sporadically in intestinal T-cell lymphoma. EBV is generally absent in subcutaneous panniculitis-like T-cell lymphoma. Hepatosplenic T-cell lymphoma also belongs to this broad group of cytotoxic T-cell lymphomas.

Within the extranodal NK/T-cell lymphomas, there is some variation in lineage, a feature which departs from the general principle that lineage is a defining feature of disease entities. For example, nasal NK/T-cell lymphoma is usually of NK-cell derivation, but in rare cases it may be derived from either γδ or αβ T cells. Similarly, intestinal T-cell lymphoma is usually of αβ T-cell derivation, but a minor proportion of cases are derived from γδ T cells.

Nasal NK/T-cell lymphomas express some T-cell-associated antigens but are probably of NK-cell derivation (46). Necrosis is seen in most cases. The midline nasal area is the most common site of involvement, but the disease can also present itself in other extranodal sites. In other sites it is referred to as nasal-type NK/T-cell lymphoma (46). The neoplastic cells generally lack T-cell gene rearrangements. The cells are positive for CD2 and CD7 but negative for surface CD3. However, they usually express CD3ε within the cytoplasm, which can be detected in paraffin sections with both polyclonal and monoclonal antibodies. CD56 is present in virtually all cases. The neoplastic cells are EBV positive, and the EBV genome is monoclonal based on terminal-repeat analysis (41). p53 is overexpressed in nearly all cases, but there have been no confirmatory mutational studies (80). There are few classical cytogenetic studies of these lymphomas, and while numerical abnormalities have been reported, no recurrent translocations have been identified (115). LOH studies show a high frequency of chromosomal loss at 6q, 13q, 11q, and 17p (the site of the p53 gene) (94). Recent studies using spectral karyotyping have identified a cryptic translocation involving Xp21 and 8p23 (116). The genes involved have not been identified.

The hepatosplenic T-cell lymphomas are most often derived from immature γδ T cells (19). The cells express the cytotoxic granule-associated protein TIA-1, but they lack expression of the effector proteins, the granzymes and perforin. This feature may explain the lack of tissue necrosis in these tumors. In addition to expressing TCRδ, an indication of a γδ cell receptor, the cells are positive for CD56 and either CD4−/CD8− or positive for CD8. CD5 is usually absent as well. This lymphoma, as the name implies, presents with marked hepatosplenomegaly, but occult bone marrow involvement is usually present as well. However, lymph node involvement is absent. This lymphoma is associated with isochromosome 7q and trisomy 8 as consistent cytogenetic abnormalities (3). Interestingly, an identical form of hepatosplenic lymphoma composed of αβ T cells can be encountered in rare cases (62).

A distinctive subtype of T-cell lymphoma is ALCL (10). It can occur at any age but is most common in children and adolescents (26). Although the cells express some T-cell antigens, they usually have a markedly aberrant phenotype, and some cases may appear to be of null cell phenotype (Table 8). However, at the genotypic level, all cases appear to have rearranged TCR genes (30). CD30 is an antigen initially detected on the neoplastic cells in HD. It is found on Reed-Sternberg (RS) cells, a subset of activated T cells, EBV-infected B cells, and in all cases of ALCL. Other characteristic markers include epithelial membrane antigen (EMA) and clusterin (109). The neoplastic cells also exhibit cytotoxic molecules (58).

Histologically, ALCL most often is composed of large, often lobulated, cells that preferentially involve lymph node sinuses, and in the past such lesions were often interpreted as malignant histiocytosis (97). Tissue section immunohistochemistry is very helpful in the diagnosis of this entity because the malignant cells may not be numerous and staining for CD30 highlights their sinusoidal distribution. The

TABLE 8 Differential diagnosis of ALCL and HD[a]

Disease	CD30	CD15	LCA	CD3	TIA-1	EMA	Clusterin	ALK	CD20
ALCL	+	−	+	±	+	+	+	+	−
cHD	+	+	−	−	−	−	−	−	±
NLPHD	−	−	−	+	−	±	−	−	+
PTL, unspecified	±	−	+	+	±	−	−	−	−
DLBCL	±	−	+	−	−	±	−	−	+

[a]LCA, leukocyte common antigen; cHD, classical HD.

CD30 antigen can be detected in either paraffin or frozen sections.

ALCL was first recognized based on characteristic histological features (sinusoidal invasion) and a distinctive immunophenotype (CD30+). However, neither sinusoidal invasion nor CD30 positivity proved to be entirely specific. Subsequently, a characteristic cytogenetic abnormality was identified, the t(2;5) translocation, which led to identification of the genes involved in the most common translocation of ALCL (*NPM/ALK*) and insights into the pathogenesis (69, 83). Generation of monoclonal antibodies to the aberrantly expressed ALK can be used diagnostically and has led to improved definition of the diagnostic entity, with important clinical and prognostic implications (78). Utilizing these biological tools, the ultimate histological spectrum of ALCL is both broader and narrower than originally believed. ALK expression can now be considered a defining feature, as ALK-negative cases of ALCL probably represent different entities (44).

In addition to the classical t(2;5) translocation that is found in about 75% of ALCLs, additional variant translocations occur in the remainder of cases (61). All variant translocations involve the ALK gene on chromosome 2, but a different partner chromosome. Regardless of the partnering gene involved in the translocation, ALK is activated in all cases and is believed to play a central role in ALCL pathogenesis (108). The diagnosis of ALCL can be assisted by RT-PCR, which will identify the 75% of cases with classical NPM/ALK fusion genes, or by FISH, which will detect both classical and variant translocations.

Primary cutaneous ALCL is a different disease and is closely related to lymphomatoid papulosis, a chronic lymphoproliferative disease of the skin (111). These cases do not have a t(2;5) translocation and do not express ALK protein. Notably, although all cases of true ALCL are ALK positive, ALK expression can be detected in other rare entities, such as myofibroblastic tumors, and ALK-positive CD30-negative large-B-cell lymphomas.

HD (Hodgkin's Lymphoma)

HD is an unusual neoplastic disorder because the neoplastic cells represent only a minority of the cells present in the tumor mass. The neoplastic cells, the RS cells and their mononuclear variants, are admixed with normal lymphocytes, histiocytes, eosinophils, neutrophils, and plasma cells. The paucity of RS cells has led to difficulty in their characterization by flow cytometric techniques and has severely impeded the molecular analysis of this neoplasm. The normal lymphocytes within HD are usually identifiable as T cells, predominantly CD4+. However, the nature of the malignant cell in HD has taken a long time to unravel.

The tumor cells express CD15, an antigen found in normal granulocytes, histiocytes, and many epithelial cells. They also express the CD30 antigen, first identified on cell lines derived from HD. Leukocyte common antigen (CD45) is frequently absent. The identification of CD20 on at least some of the neoplastic cells led to speculation that HD was B-cell derived (76). Immunohistochemistry to assess light-chain restriction is also usually not helpful for the assessment of clonality, as the amount of immunoglobulin produced is small, the cells tend to stain nonspecifically, and background staining for immunoglobulin tends to be high. Traditional molecular studies of HD generally failed to detect clonal IGH rearrangements because of the low percentage of tumor cells in the population. The diagnostic sensitivity of IGH PCR is about 2 to 3% tumor cells (of total B cells), and frequently the number of clonal RS cells is below this threshold. However, by enriching RS cells through the use of microdissection techniques, several investigators were able to confirm a clonal B-cell origin in virtually all cases (52, 60). In addition, the cells were shown to have somatic mutations of the IGH genes, indicative of a GC stage of differentiation. Similar to the classical forms of HD, the nodular lymphocyte-predominant variant (NLPHD) has also been shown to be of B-cell origin; however, because of its distinctive immunophenotypic and clinicopathological characteristics, NLPHD is now considered to be a separate entity (66). There are no characteristic recurrent translocations of significance known in either classical HD or in NLPHD, and molecular profiling studies have been difficult to perform due to the difficulty in obtaining pure populations of tumor cells.

NONLYMPHOID TUMORS OF THE IMMUNE SYSTEM: "HISTIOCYTIC" DISORDERS

Normal Histiocytic Subsets

The cells of the histiocytic system consist of two major subsets of antigen-presenting cells: dendritic cells and phagocytic cells (45). The follicular DRC are found in follicles and present antigen to B lymphocytes, but they may not be of hematopoietic origin. They are positive for CD21, CD23, CD35, and clusterin but are CD45 negative. The interdigitating dendritic cells (IDC) and Langerhans cells (LC) are bone marrow-derived cells that present antigen to T lymphocytes. LC are found primarily in the skin but also in other organs. IDC are found in lymph nodes and other lymphoid organs. Both LC and IDC are S100 positive. The relationship between these cells is controversial. Both types are CD1a positive, although IDCs show variable expression dependent upon their maturational stage. However, unlike LCs, IDCs do not possess the characteristic Birbeck granule. Fibroblastic reticular cells are involved in transport of cytokines and other mediators (36). In lymph nodes, they ensheathe the postcapillary venules. They are of mesenchymal rather than hematopoietic origin, and they express smooth muscle actin (5).

All of the macrophages of lymph nodes share many enzyme histochemical and immunophenotypic characteristics. They have abundant and diffuse activity for lysosomal enzymes, including acid phosphatase and nonspecific esterase. As stated above, all of these cells can also demonstrate phagocytosis under appropriate conditions. Activity for lysozyme and alpha-1-antitrypsin can be seen in all of the above subtypes but is most prominent in epithelioid histiocytes. Activity for lysozyme decreases abruptly with phagocytosis, presumably because of its loss into lysosomal vacuoles. CD68 is the most useful antigen for detection of macrophages in routine paraffin sections.

A variety of monoclonal antibodies that react with monocytes and macrophages have been derived. Unfortunately, most of these antibodies lack specificity for the mononuclear phagocytic system, and many react with other hematopoietic cells as well: myeloid cells, T cells, or B cells. For example, CD11c is present on monocytes and macrophages, and is weak or absent on normal T and B lymphocytes. However, this antigen is found on the cells of hairy cell leukemia (a B-cell lymphoproliferative disorder) and in some cases of B-cell CLL. Cross-reactivities with T cells are present as well. For example, CD4 is found in normal monocytes and macrophages. CD25, in addition to being found on activated T lymphocytes, is found on normal monocytes and macrophages. CD68, strongly positive on histiocytes, also reacts with granulocytic precursors. The CD14 antigen is present on monocytes and macrophages and probably has the greatest specificity for the macrophage lineage among available reagents.

Proliferative Histiocytic Lesions

Proliferative lesions of antigen-presenting cells are relatively rare (28). The principal proliferative lesion of the dendritic cell system is LC histiocytosis (LCH). Recent studies, using the HUMARA method described above, have shown that the cells of LCH are monoclonal, but the disease usually has a self-limited course, especially in older children and adults (112). It may be fatal in infants. The cells of LCH have the characteristics of LC, including CD1 expression, langerin expression, and Birbeck granules (33). In contrast to normal LC, the cells also express antigens associated with phagocytic histiocytes, such as CD14 and CD11c. While comparative genomic hybridization studies have revealed losses or gains of a variety of chromosomal regions, there are no consistent genetic abnormalities associated with this disease.

Although the cells of LCH may sometimes appear to be cytologically atypical, even with abnormal mitotic figures, histological features are said not to be an important prognostic indicator in this disease. The prognosis is best correlated with the age at presentation and the extent of organ system involvement. Patients under 2 years of age tend to have a poor prognosis, whereas those older than 6 years have an excellent prognosis. Multisystem disease also is a poor prognostic factor.

There are rare tumors described that have a derivation from IDC. These lesions are usually based in lymph nodes and are often associated with an inflammatory background and/or necrosis. There is overlap in histology and phenotype with true histiocytic tumors, and they may have an aggressive clinical course. By contrast, follicular dendritic cell (FDC) sarcomas usually present with localized lymph node involvement. They may recur locally but usually do not disseminate. These neoplasms are also rare. Rare tumors of fibroblastic reticular cell origin also are seen in lymph nodes. The expression of clusterin, CD21 (DRC sarcomas), S100

(IDC tumors), CD1a (IDC tumors), and actin (fibroblastic reticular cell tumors) can be helpful in distinguishing these three stromal neoplasms of lymph nodes (5). There are no specific cytogenetic abnormalities or molecular tests associated with these tumors.

Malignancies of mononuclear phagocytes include acute monocytic leukemia and histiocytic sarcoma. In rare instances, histiocytic sarcomas may be disseminated, fulfilling criteria for what has been termed in the past "malignant histiocytosis." However, most instances of malignant histiocytosis reported previously represent other entities, such as ALCL (45).

Acute monocytic leukemia relates to a bone marrow-derived monoblast. This malignancy arises in the bone marrow compartment, with secondary involvement of the peripheral blood and usually a markedly elevated leukocyte count. In contrast to acute myeloid leukemia, there is a somewhat higher incidence of involvement of nonhematopoietic sites, with frequent involvement of skin and gingiva.

Histiocytic sarcoma represents a malignancy of the mononuclear phagocytic series at the stage of the fixed-tissue histiocyte. Therefore, the lesions in histiocytic sarcoma represent localized, relatively discrete tumefactions. In addition to the reticuloendothelial system, common sites of involvement include skin and bone. Because there are few, if any, markers with absolute specificity for macrophages, the investigator must rigorously exclude other cell lineages with both immunophenotypic and molecular means.

In the absence of special studies, morphological evidence of phagocytosis by the neoplastic cells, most commonly erythrophagocytosis, had been proposed as a criterion for a derivation from mononuclear phagocytes. However, phagocytosis is inconspicuous in most mononuclear phagocytic malignancies. Moreover, it is not a specific finding and has been described for lymphoid, plasmacytic, and even epithelial tumors. Even if phagocytosis is observed, it is virtually always clinically insignificant. The hemophagocytic syndrome is the most common and clinically significant of the proliferative disorders of macrophages. However, it is not a neoplastic process. It is usually seen in association with immunodeficiency or another hematopoietic malignancy (47, 84). This syndrome appears to be pathogenetically related to an excessive production of cytokines and chemokines capable of stimulating mononuclear phagocytes (102). The cells in hemophagocytic syndromes are morphologically and phenotypically activated macrophages.

CONCLUSIONS

Tumors of the immune system are of interest not only because they represent models of normal immune cells but also because they provide excellent examples of how immunologic and molecular tumor markers may be used in clinical diagnosis. Because the lymphomas simulate normal cellular counterparts, it has been possible to develop modern classification schemes that take advantage of and utilize the large panels of antibodies that were primarily developed to study and characterize normal immune cells. The investigation of the molecular genetic abnormalities found in tumors of the immune system, particularly the translocations that occur in lymphoid neoplasms, has resulted in the discovery of oncogenic classes of genes that have been further exploited for the development of diagnostic testing and tumor classification purposes. The assimilation of both immunologic and molecular approaches has been largely

responsible for the current biologically based WHO classification scheme.

The example provided by the WHO classification scheme has not gone unnoticed in the study and classification of other cancers. While many of the other tissues in which cancers arise may not be as complex as the immune system, the classification of nonlymphoid tumors has also benefited from advances in the detection of immunologic and molecular genetics of the tumors. One such example has been the refinements that have occurred in the classification and diagnosis of the so-called small cell tumors of childhood, in which both protein and molecular markers have been used to dissect out the origins and provide the tools to accurately classify these morphologically similar tumors. Small blue cell tumors include neuroblastomas, rhabdomyosarcomas, Ewing's sarcomas, and other rare tumors. Each of these is now known to be associated with characteristic cell surface markers and tumor-specific translocations. Thus, the same approaches discussed for the lymphomas can be applied to the investigation and classification of these and other cancers. There is little doubt that the next generation of classification schemes developed for both tumors of the immune system and other types of tumors will continue to benefit from and incorporate information from advances in our understanding of the biology of normal cellular counterparts, as well as from the voluminous data being generated from the ongoing molecular dissection of the tumors themselves.

Monitoring of Immunologic Therapies

THERESA L. WHITESIDE

133

Biologic therapies have gained considerable acceptance in recent years. A broad array of biologic agents have become available for the treatment of inheritable or acquired immunodeficiency, autoimmune diseases, cancer, or persistent infections. Among them, immune system-based therapeutics utilizing antibodies, immune cells, or immunomodulators are now widely available. These agents target the immune system and represent potentially useful alternatives to conventional therapies, and increasingly frequently, they are being used in conjunction with chemotherapy, radiation, surgery, or even behavior-modifying therapies.

Biologic therapies can be categorized as follows: (i) monoclonal antibodies (MAbs), (ii) cytokines, (iii) growth factors, (iv) activated cells, (v) cellular products, (vi) immunotoxins, and (vii) other immunomodulatory agents. The rationale for the therapeutic use of immunomodulating agents is their ability to enhance the capabilities of the innate and/or adaptive immune system to control disease. Because immunotherapies largely remain in the experimental domain, the selection of an immunologic agent for therapy is preceded by extensive in vitro studies and in vivo experiments with animal models of disease designed to define the presumed mechanism(s) of its therapeutic activity. Frequently, however, preclinical studies fail to identify a complete spectrum of biologic activities for a new agent. This reflects the fact that most immune system-based agents are pleiotropic, acting on a variety of cellular targets and components of molecular pathways, so that a precise definition of each activity may not always be possible. Also, their systemic effects might be different from those mediated at the disease site. In general, mechanisms of action defined for immune agents in preclinical studies with animal models of disease often turn out to be quite irrelevant to those operating in vivo in patients with disease. Nevertheless, animal models remain useful for evaluating the toxicity of immunotherapies and their overall effects on the disease process. Ex vivo preclinical studies of the new agent with human mononuclear cells (MNC) are often helpful in providing a rationale for targeting therapy to a particular subset of these cells or for focusing mechanistic studies on a particular cell population.

CLINICAL TRIALS WITH BIOLOGIC AGENTS

Following preclinical evaluations, a therapeutically promising immunologic agent is introduced to the clinic in the form of a phase I protocol. An investigational new drug application is filed with the Food and Drug Administration (FDA). The application includes a clinical protocol. Agency approval is necessary for clinical evaluations of any experimental biologic agent. Following a review of the proposed clinical protocol, preclinical results, and animal safety studies, the FDA will intervene by putting the study on hold if additional information or clarifications are needed. Clinical trials involving gene therapy need approval by the Recombinant Advisory Committee. In addition, institutional approvals from the institutional review board and the biosafety committee have to be obtained prior to opening the trial for patient accrual.

The design of a phase I study is based on the predicted mechanism of action of an immunologic agent, as determined in preclinical experiments. Biologic agents are available as natural or recombinant materials which may have potent immunomodulatory activities. When administered systemically in high doses, they often induce considerable toxicities. However, the maximal tolerated dose (MTD) for a given biologic agent is not necessarily the dose that produces the desired biologic or therapeutic effect. In fact, low doses of biologics might have greater or different therapeutic effects than high doses without accompanying toxicity. This observation suggests that in contrast to the case for pharmacologic or chemotherapeutic agents, which are usually characterized by a linear dose-response curve, biologic agents have a distinctive bell-shaped response curve. The optimal biologic dose (OBD) for each biologic agent is thus likely to be different from the MTD and needs to be defined in phase I/II clinical trials in order to preserve and optimize its therapeutic benefits and limit its toxicity. The developmental strategy for a therapeutic agent involves determination of the mechanism-specific OBD, that is, the dose that optimally activates the postulated mechanism of action with tolerable toxicity. A clinical trial designed to determine the OBD is referred to as phase Ib, in contrast to a phase Ia trial, in which only the clinical toxicity of a new biologic agent is defined as the MTD (12). It is important to remember that the OBD may be different from the MTD for a given biologic agent. In addition, the same agent might have quite disparate OBDs for different immunologic characteristics. Interleukin-2 (IL-2), for example, which is a cytokine currently approved for therapy of renal cell carcinoma and melanoma, has a much lower OBD for the activation of

circulating T and natural killer (NK) cells than for supporting the generation of lymphokine-activated killer (LAK) activity (10).

In general, phase Ib trials are intended to measure the pharmacokinetics and biodistribution of a biologic agent, together with selected immunologic parameters which, on the basis of the postulated immune mechanism, are likely to influence the disease process. For example, in a patient with cancer who is treated with IL-2, one postulated mechanism for antitumor effects might be an up-regulation of T-cell and/or NK activity in the peripheral circulation (12). In this case, monitoring of LAK activity in the peripheral blood of this patient during therapy might be expected to serve as a surrogate measure for the therapeutic effects of IL-2, and the dose of IL-2 resulting in the maximal LAK activity or cytolytic T-lymphocyte (CTL) activity with tolerable toxicity would be selected as the OBD. However, it is now known that IL-2, by binding to cells which express the IL-2 receptor (IL-2R), activates $CD4^+ CD25^+ T_{reg}$ cells, among other cell subsets (19). T_{reg} cells are capable of down-regulating immune responses, including the antitumor activity of effector cells, which is clearly an undesirable situation in a patient being treated for cancer (19). Further, newer data suggest that stimulatory versus inhibitory in vivo effects of IL-2 may be dose dependent. Hence, it seems important to define the OBD for IL-2 which promotes immune activation in a patient with cancer. On the other hand, for subjects with autoimmune diseases, the OBD for IL-2-based therapy might be different, as inhibitory effects are a desired end point. This type of rationale is likely to apply to immune system-based therapy in general, and therefore the goal of establishing the OBD is a critical component of the developmental strategy for biologic agents and their application to various diseases.

In most phase Ib trials performed to date, surrogate immunologic end points are achieved much more easily than clinical responses. During IL-2 therapy for renal cell carcinoma, for example, virtually all patients develop high levels of endogenous LAK activity, while only a fraction of these patients achieve objective antitumor responses (10). In other words, surrogate immunologic end points selected on the basis of preclinical results do not appear to correlate with clinical responses, possibly because these end points seldom reflect the entire spectrum of physiologic mechanisms mediated by a biologic agent. In considering the pleiotropic activities of biologic agents, it appears that no single surrogate end point is likely to correlate with their therapeutic effects and thus with a clinical response. On the other hand, it is possible that a panel of carefully selected monitoring assays might provide a clue about the in vivo effects of an agent. For this reason, the current approaches to monitoring favor multiparameter analyses employing new high-throughput technologies, including genomics and proteomics. The possibilities for multiparameter testing now extend to immunologic monitoring, allowing evaluations of more than one surrogate end point in patients treated with biologic agents to identify those that are clinically meaningful.

In view of the difficulties experienced to date in selecting immunologic end points for monitoring of phase Ib trials, it could be anticipated that a direct measure of the dose of a biologic agent inducing the best therapeutic, e.g., antitumor or antiviral, effects would be preferable to the use of surrogate biomarkers. However, practical and ethical considerations rule out the direct approach of determining the best therapeutic dose. Since antitumor response rates for single biologic agents generally range between 10 and 30%, dose-finding studies would require excessively large numbers of patients and would expose many of them to ineffective doses of the agent tested. For this reason, the goal of phase I trials is to determine the toxicity and to define the promising OBD of a biologic agent, with the caveat that this OBD might relate only to a particular biologic activity of this agent and that it may not relate to its therapeutic activity. In fact, it is not uncommon to see few or even no clinical responses in phase I trials. But having obtained evidence of safety and a lack of toxicity, it is then possible to expand the earlier clinical observations in phase II clinical studies and to begin asking questions about the dose and mechanisms of action of a biologic agent. Ultimately, an agent's therapeutic efficacy has to be determined in large-scale randomized phase III clinical trials in which the placebo arm is compared to the experimental arm. It is encouraging that in recent years several biological therapeutics, including MAbs and cytokines, have reached the stage of being evaluated for efficacy in phase III clinical trials (15).

IMMUNOLOGIC MONITORING OF CLINICAL TRIALS WITH BIOLOGIC AGENTS

The rationale for monitoring immunologic parameters in clinical trials with biologic agents is based on the premise that these agents achieve therapeutic effects as a result of their ability to modify one or more components of the patient's immune system. The expectation is that by serially measuring immune markers, which change relative to the pretherapy baseline level, it might be possible to define the immunologic mechanism responsible for the activity of a biologic agent. In addition, the objective is to determine whether the observed changes in the immunologic phenotype or function correlate with clinical responses, toxicity, resistance to other therapies, or any other phenomena likely to influence the therapeutic outcome.

The first step toward rational immunologic monitoring is the selection of the most informative assays. This selection cannot be arbitrary and has to be based on a specific hypothesis. It is, of course, best to formulate the hypothesis on the basis of preliminary data available to the investigator from personal preclinical experience and from the current literature. The investigator is obliged to use judgment and collective experience to address the likely mechanisms responsible for therapeutic effects. But since most biologic agents have multiple biologic effects, more than one hypothesis of action can be postulated. Which of these hypotheses is ultimately selected for testing depends on the individual insights and preferences of the clinical investigator. However, it is not advisable to test too many hypotheses at once, for fear of making the design of a clinical trial too complex and the accompanying monitoring too extensive. There is no way to guarantee that the hypothesis selected for testing in a clinical trial is correct; hence, the selection of a hypothesis is the most crucial aspect of the trial design and has to be formulated only after a complete review of all preclinical data. As such, a clinical trial is not different from any other hypothesis-driven scientific experiment.

The next step of the scientific process calls for a design of an experimental plan in which the proposed hypothesis can be tested in the most satisfactory fashion. This includes the selection of assays to be performed and the frequency of monitoring. For phase I clinical trials, it is prudent to begin by considering a broad array of immunologic effects because the biologic activity of the evaluated biologic agent may be incompletely understood. It may be advantageous at this

stage to consider alternative explanations for its biologic and, possibly, therapeutic effects. Hence, the selected assays should be sensitive rather than specific in order to detect biologic effects when they are induced by therapy. In phase II and III clinical trials, it might be possible to narrow down the selection of immunologic assays to those that were observed to reflect biologic activity or to correlate with clinical responses in previous clinical trials. In place of sensitive screening assays, more specialized specific or confirmatory assays could be introduced at this time to better focus on the mechanisms of activity mediated by the biologic agent. While no well-defined criteria exist for the selection of optimal monitoring assays, a general principle may be defined as follows. The choice of immunologic assays to be used for monitoring of phase I trials has to be based on solid preliminary data derived from relevant animal models of disease as well as in vitro experiments with human cells. In phase II and III clinical trials, the choice of assays to be used has to depend on previous results derived from phase I trials.

STRATEGY FOR IMMUNOLOGIC MONITORING: A PRACTICAL GUIDE

The choice of a strategy for immunologic monitoring of clinical trials with biologic agents is neither simple nor straightforward. No single assay or experimental approach is appropriate for all therapeutic interventions. The selection of the "right" monitoring assays requires familiarity with immunologic assays, judgment, and a considerable understanding of the biologic and therapeutic effects induced by the biologic agent used. Therefore, clinical investigators are obliged to make a number of well-informed and practical decisions, each of which is likely to influence the overall quality of monitoring and, hence, the final results of the trial. To facilitate assay selection and use in monitoring of clinical trials, several practical guidelines are given below, with the proviso that these are neither comprehensive nor applicable to all situations.

The frequency of immunologic assays to be performed is an important component of the trial design. Clearly, it is essential to establish a pretherapy baseline and posttherapy values. Beyond that, the number of time points selected for monitoring during the course of therapy depends on the characteristics of the biologic agent administered. For example, it is well known that cytokines usually have rapid and often dramatic effects on the total number and functions of cells in the circulation or on the levels of other cytokines or soluble cytokine receptors in the serum. Thus, with IL-2 administered as a bolus, rapid lymphopenia followed by a rebound in the number of circulating lymphocytes is observed (20). In contrast, when low intravenous doses of IL-2 are given continuously over a period of time, a gradual rise in the number of circulating $CD3^- CD56^+$ NK cells is observed (5). More recent data suggest that IL-2 delivery may also increase the frequency of T_{reg} cells in the circulation or tissues and promote activation-induced cell death (21). These initial effects of IL-2 are followed by delayed effects due to the induction of secondary cytokines. The well-known result of high-dose IL-2 therapy, i.e., transient hypotension observed 4 to 8 h after IL-2 bolus administration, is induced by the secondary cytokines tumor necrosis factor alpha and IL-1β, which are released in response to IL-2 (18). In clinical trials with cytokines, it is important to measure the pharmacokinetics of the cytokine used for therapy as well as the levels of secondary cytokines in serum, which might be responsible for toxicity of the therapy.

A well-described effect of long-term therapy with biologics is the development of antibodies (Abs) to the administered biologic agent (2). Such antidrug Abs do not arise in every patient treated, and they may not appear until weeks or months into therapy or until multiple courses of the drug are administered. However, their presence in the plasma of individuals treated with the biologic agent is an important factor for the outcome of therapy, because they may either neutralize the drug or contribute to the development of immune complex disease. Therefore, it seems reasonable to monitor for the appearance of such Abs during the course of therapy. This requirement is obviously necessary when therapy with anti-idiotypic Abs is considered, e.g., for some patients with malignancies. Such patients may be treated with an anti-idiotypic Ab (Ab2) which is an internal image of the antigen and can include the production of Ab1 and Ab3, both of which are able to bind the antigen. Since Ab3 is therapeutic and Ab1 may not be, the presence and levels of Ab1 and Ab3 in serum are crucial for the interpretation of immunologic as well as clinical responses (8). Another important consideration is the transient nature of some immune responses. For example, in vaccination protocols for patients with cancer or viral infections, the appearance of antigen-specific effector cells in the circulation may be short-lived after single or even multiple vaccinations. In this case, assays for the detection and frequency of such effector cells have to be performed often and soon after vaccination. With other vaccines, however, the appearance in the peripheral circulation of the effector cells may be delayed, so their frequency will not increase until late into the vaccination regimen. It thus appears that a decision to monitor the immediate versus delayed effects of therapy with any biologic agent has to be made with caution, after considering possible implications of these effects on the interpretation of immunologic and therapeutic results of the trial. The relative complexity and cost of the assay often influence the frequency of monitoring. For this reason, simple, robust assays that can be reliably performed on serially collected, cryopreserved samples are necessary for frequent immunologic monitoring.

A decision to select cellular versus humoral immunologic assays for monitoring is directly related to the mechanism of action proposed for the biologic agent. While it may be difficult to prioritize on the basis of the limited understanding of such mechanisms, the consideration of practical aspects of monitoring can help in reaching a reasonable decision. Limitations in the frequency of phlebotomy or the total blood volume obtained from the patient during treatment are an important consideration. The variability of cell yields, day-to-day assay variability, and problems with the functional activity of cryopreserved effector cells often restrict the use of cellular assays. These assays are more difficult and more costly to perform than serum-based assays. It is advisable to consider serum- or plasma-based (hereafter referred to as serum/plasma) assays first, especially when they can substitute for cellular assays. For example, the levels of cytokines released by activated cells, the enzymatic activity known to be induced by a particular biologic agent (e.g., interferon-induced 2',5'-adenylate synthetase), and the presence of inhibitors or antagonists of biologic agents (e.g., IL-1ra) or products of activated cell subsets (e.g., soluble cytokine receptors, β_2-microglobulin, or neopterin) can be more readily monitored with serum or plasma than with cells.

The only in vivo assay available for measurements of cellular immunity in humans, the skin test for delayed-type

hypersensitivity (DTH), is often underutilized or misinterpreted, largely because of difficulties in the recording and interpretation of test results. Yet when performed and read according to the guidelines, a DTH assay remains the best available measure of epitope-specific cell-mediated immunity in patients with immunodeficiencies, particularly when it is combined with a biopsy to confirm the nature of cells infiltrating the skin. Reagents for purified protein derivative, tetanus, *Candida*, and other antigens are commercially available. Other antigens, e.g., tumor-derived purified or synthetic peptides which are not yet commercially available or commercially available viral peptides, can also be used, provided that they have passed the safety requirements. A change in the DTH skin test from unreactive to reactive as a result of biotherapy is a significant result.

Monitoring of numbers or functions of MNC in peripheral blood during therapy often does not adequately reflect immunologic events that take place at the site of disease. Systemic effects of cytokines and certain other biologic agents are generally distinct from their local or locoregional effects, and monitoring of lesions, tissues, or organs involved in a disease is likely to yield more informative data than will the same assays performed with cells or cell subsets obtained from the peripheral blood. The obvious difficulty with this strategy is that blood is more readily available than tissues. Only superficial lesions or sites accessible to repeated biopsies can be monitored. Nevertheless, during a clinical trial, it might be feasible to obtain serial biopsies for in situ studies, and this opportunity should not be overlooked. An alternative possibility is to obtain body fluids (e.g., pleural fluids and ascites), in addition to peripheral blood, to be able to detect longitudinal changes in organ-associated immune cells or their products relative to those in peripheral circulation. This approach is especially recommended when intracavitary therapy with a biologic agent is considered.

Monitoring of immune functions generally requires considerable cell numbers, fairly large volumes of blood or other body fluids, and facilities to process these samples for cell recovery. Vigorous attempts are being made to miniaturize immunologic assays and to perform them with whole blood. Newer, more sensitive technologies, including molecular assessments, flow cytometry, electrochemiluminescence, and more sophisticated single-cell assays, that are generally performed on whole blood greatly facilitate monitoring, decreasing the required blood volume and dispensing with blood processing. The concept of bringing immunologic monitoring to the bedside, with only drops of blood needed for each assay, is slowly beginning to emerge. This approach must wait for further technical advances and for strong correlations to be established between immunologic biomarkers and clinical end points. Meanwhile, it appears that a profile of several immune measures determined in the course of therapy and analyzed using specially created software can provide useful prognostic information (9). These preliminary results are encouraging, and they indicate that immune profiling is likely to be more widely adopted for monitoring in the near future.

In general, a protocol schema specifies the time points for sample collection. These samples must be recovered from the peripheral blood, body fluids, or tissues and either used fresh or preserved for future monitoring. For studies of pharmacokinetics, a special effort has to be made to collect the specimens at the precisely designated time intervals and to process them in accordance with the experimental protocol to avoid degradation, inactivation, or loss of activity. In the planning of immunologic monitoring, not only the timing of specimen collections but also the nature of anticoagulants needs to be considered. For example, to measure levels of cytokines in body fluids, plasma rather than serum is preferable, since cytokines tend to be trapped in the clot, with subsequently low levels of cytokines measured in the serum (24). While the separation of serum/plasma or MNC from the peripheral blood is a routine laboratory procedure, the recovery and fractionation of cells from tissues or body fluids containing normal or malignant tissue cells are time-consuming and require special expertise and considerable effort (6). The use of individual separated subsets of tissue-infiltrating or blood MNC is not recommended for serial monitoring, mainly because of a need for tissue sampling and large blood volumes. Also, the lack of uniformly acceptable procedures for cell separations and unpredictable yields of cells recovered from tissues hamper the use of cell separation techniques for monitoring. Nevertheless, the advantage of studies performed with highly purified subsets of immune cells obtained from the site of disease is obvious. When it is feasible to obtain a biopsy prior to and after therapy and to recover viable cells for monitoring of cellular functions, or even of cellular phenotypes, investigators are encouraged to incorporate such procedures in a protocol schema.

It is often unclear which immunologic assays can be reliably performed with fresh versus cryopreserved cells. From a practical viewpoint, it would be more convenient to use serially harvested frozen aliquots of serum/plasma or batched cryopreserved immune cells instead of freshly harvested specimens for immunologic monitoring. The ability to reliably cryopreserve immune effector cells for future use in retrospective studies or for batching of serially collected specimens to eliminate the interassay variability is highly desirable. In fact, the only reliable way to determine differences between pretherapy and posttherapy assays is to perform them at the same time. This strategy calls for banking of cryopreserved specimens (batching) and for assays which can be routinely performed with cryopreserved cells. However, certain immunologic assays, especially those that measure cell functions, e.g., cytotoxicity, are best performed with freshly harvested samples. Cryopreservation may introduce artifacts, even when a rate-controlled drop in temperature is implemented. Therefore, each laboratory is obliged to compare fresh and frozen cells to ascertain that a test can be reliably performed with either before attempting to use them for monitoring. Assays which can be reliably performed with frozen cells and batched specimens are the best candidates for monitoring, but in situations that require the use of fresh immune cells, it is essential to determine the interassay variability to be able to distinguish spurious from therapy-induced changes.

Immunologic cellular assays performed with whole blood as opposed to separated MNC are especially useful for serial monitoring. Their advantages include the ability to measure the phenotype and functions of effector cells without separation from other blood cells and plasma. Separation procedures are likely to modulate and alter functions of effector cells. Since phenotypic markers on immune cells are generally assessed in whole blood by flow cytometry, it would seem to be preferable to also monitor functions of these cells in the same way. At the very least, the correlations between the phenotypic and functional immune parameters might improve under these assay conditions. The disadvantage is that whole-blood assays have to be performed with freshly harvested specimens, thus eliminating the possibility of batching serial samples.

Technical advances and new insights into immunologic mechanisms have led to the recent development of new

types of immunoassays. As a result, a clinical investigator generally has a choice between phenotypic versus functional, specific versus nonspecific, and direct versus indirect assays. The range of assays currently available for monitoring predicates that careful consideration needs to be given to selection of the optimal assay. Assay validation is expensive and requires special expertise. Monitoring of patients enrolled in clinical trials should only be performed in laboratories with established quality assurance (QA) and quality control (QC) measures which meet the standards for good laboratory practice, as defined by the FDA. It is important for clinical investigators to realize that serial immunologic monitoring of clinical trials is more rigorous and demanding than performing a series of research assays. To monitor trials with credibility, the laboratory has to have methods in place to ensure reliable serial data (see section on QC below).

PHENOTYPIC ASSAYS FOR IMMUNOLOGIC MONITORING

In many trials with biologic agents, a high priority is given to cell surface phenotype assays, which are generally performed with fresh whole-blood specimens or cells separated from the peripheral blood, body fluids, or tissues. Flow cytometry-based assays are now widely and easily accessible and highly accurate. A vast array of labeled MAbs suitable for multi-color and multiparameter flow analyses are commercially available, allowing the measurement of the proportions of various immune cell subsets. Percent changes in these subsets as well as alterations in the activation level of the cells can be readily assessed during immunotherapy. In designing a clinical trial, flow cytometry markers should be judiciously selected. There has been a tendency to indiscriminately include large panels of immunologic markers to monitor changes in the proportions of several MNC subsets induced by therapy. However, phenotypic assays, like all other immunologic assays used for monitoring, should be selected in order to test the hypothesis advanced as part of a clinical trial. Through the skillful selection of marker panels, it is possible to focus on a single population of effector cells or on several phenotypically distinct subsets, on cells expressing activation markers, or on cells that express a particular constellation of adhesion molecules. Various receptors for growth factors and cytokines on the cell surface can further be used to assign the cells to subsets and to relate their phenotypes to the functional potential of these cells. Thus, phenotypic analysis is a powerful tool for monitoring the effects of therapy on immune cells, and the selection of markers to be monitored on T, B, and NK cells and monocytes or granulocytes for shifts induced by therapy and based on the predicted mechanism of action of a tested biologic agent can be informative.

Today, two-color flow cytometry for surface markers on immune cells has been largely replaced by three-color or four-color flow cytometry assays in monitoring of immunotherapies. Improved software for data analysis and a wide application of novel gating strategies have increased acceptance of multiparameter flow cytometry for monitoring. Although complexities associated with the data analysis and interpretation of results are time-consuming, the advantages of multiparameter panels far outweigh their demand for expert execution. A combination of activation markers, growth receptors, cytokine or chemokine binding sites, etc., on distinct and identifiable subsets of MNC provides a powerful tool for monitoring. Whole-blood specimens can be shipped by overnight carriers for flow cytometry analysis

without compromising their quality. If multiparameter analysis is considered desirable but not feasible within one's own institution, it may be advisable to make arrangements with a flow facility specializing in immunologic monitoring. This alternative is strongly recommended for the monitoring of multicenter or cooperative group trials.

Surface phenotypic characteristics of immune cells are often utilized for assessments of absolute numbers of these cells in whole blood. The recent development of single-platform methods, which are performed entirely on a flow cytometer, has significantly improved the assay precision and accuracy. The most popular technique is based on four-color flow cytometry in the presence of counting beads. The identification of lymphocytes by the surface expression of bright CD45 and low side-scatter signals is followed by the quantification of T-cell subsets based on the expression of CD3, CD4, and CD8 and performed in parallel with counting of fluorescent beads. The number of labeled cells per microliter of blood is obtained as follows: number of counted cells $\times$ concentration of beads/number of beads counted. In a recent study, we found absolute numbers of $CD3^+$, $CD4^+$, and $CD8^+$ T cells to be significantly decreased in the circulation of patients with head and neck cancer (16). In contrast, the percentages of these cells were not decreased, thus indicating that absolute numbers and not percentages of lymphocyte subsets should be measured in disease. The usually reported cell percentages are misleading because they do not consider a total white blood cell count, which is frequently altered in patients with advanced diseases, particularly after previously administered therapies.

In addition to surface phenotyping, flow cytometry has been widely used to measure intracytoplasmic markers. This method requires cell permeabilization to allow for access of MAbs used for detection to cellular components in the cytosol or cellular compartments. Because this method detects the expression of cytokines, signaling molecules, or enzymes, it has been frequently used as a functional end point in recent clinical trials. Intracytoplasmic proteins, such as granzyme, perforin, antigen-presenting machinery components, caspases, and other enzymes, including cytokines, signal transduction molecules and transcription factors, measured in phenotypically defined cells can provide useful information about the activation state of the individual cells or subsets of cells and about their functional attributes. In performing these assays, use can be made of quantitative flow cytometry, which allows for quantification of the expression level of each protein. By use of a mixture of four types of beads with known fluorescence intensities and unlabeled blank beads, a standard curve is generated which expresses the fluorescence intensities of each bead set in terms of molecular equivalents of soluble fluorochrome (MESF) units for every assay. The mean fluorescence intensity of each unknown sample can be transformed into MESF units by use of this calibration curve. This minimizes day-to-day variability, thus providing a stable and standardized method for use in clinical laboratories. The method has been applied to assessment of the individual antigen-presenting machinery component expression in human dendritic cells (DC) (26) as well as to quantitation of other intracellular molecules such as the T-cell receptor (TCR)-associated ζ chain in human T lymphocytes (26).

Functional attributes of cells, e.g., proliferation and cytotoxicity, can be measured by flow cytometry simply and more efficiently than by familiar radiolabel-based assays, providing not only an estimate of proliferative or lytic activity, respectively, but also the identity of effector cells at the population

or single-cell level. By using differently labeled responder and stimulator cells, these methods can be adapted to the quantitation of functional responses in individual cells, cell subsets, or entire populations of cells. For example, the proliferative history of fluorescently labeled cells can be established by determining the number of mitoses experienced by these cells. The principle of the method is that the amount of fluorescent dye taken up by the cell is equally partitioned between daughter cells during mitosis and therefore decreased by half at each cell division. Dyes such as carboxyfluorescein diacetate succinimidyl ester (CFSE) diffuse into a cell and are cleaved by intracellular esterases into compounds that are fluorescent and react with amino groups of intracytoplasmic proteins (11). By combining surface marker staining with CFSE, it is possible to monitor a cell or cell subset through successive mitoses and to determine the number of cell divisions. The use of CFSE allows for quantitative resolution of up to eight cell division cycles (11), and by comparing the number of cells that divided with those that did not divide, a precursor frequency as well as the expansion potential of antigen-specific T cells can be calculated with Cell Quest software.

The frequency of peptide-specific T cells present in mixed lymphocyte populations can be determined based on the use of biotin- or streptavidin-labeled complexes containing the peptide linked to HLA class I molecules (3). These complexes, referred to as tetramers, represent oligomeric complexes of HLA molecules with a peptide, which have an increased avidity for T cells expressing the relevant TCR. When tetramers bind to the TCR on T cells able to recognize the peptide, a strong, easily detectable fluorescent signal is generated that can be measured in a flow cytometer. The specificity of tetramers for peptide-specific T cells, which is considered their greatest asset, cannot be taken for granted, however, as nonspecific binding may occur under unfavorable experimental conditions. Nevertheless, tetramers are currently widely used to monitor changes in the frequency of peptide-specific T cells in lymphocyte populations before and after vaccinations. Tetramer analysis provides the frequency of epitope-specific T cells with a sensitivity of 1/10,000 but gives no information about their function.

Another category of flow cytometry assays that has recently gained wide acceptance is cytokine flow cytometry (CFC) (22). This is another single-cell assay which allows for quantitation of individual cells positive for a cytokine detectable in permeabilized cells by the use of cytokine-specific MAbs. CFC is performed following a brief (4 to 6 h) coincubation of lymphoid cells with an antigen to induce cytokine expression in antigen-responsive cells. CFC has been used to measure the frequency of T cells able to respond to antigens expressed by infectious agents such as cytomegalovirus, Epstein-Barr virus, or human immunodeficiency virus type 1, tumor-associated antigens such as MUC-1, or melanoma differentiation antigens. CFC can provide the phenotype of epitope-specific responder cells and defines the frequency of cells poised to secrete but not yet secreting the cytokine accumulating in the Golgi apparatus. Its sensitivity is perhaps a little better than that of tetramers, and it lends itself well to serial monitoring.

A special advantage of multiparameter flow cytometry for monitoring is the possibility for the use of a combination of tetramers or CFC for a cytokine with differentiation markers characterizing T-lymphocyte subsets. In trials with biologic agents, especially vaccines, which might alter the process of lymphocyte maturation, differentiation or migration from, e.g., the naïve to memory pool or the circulation to target

tissues, the use of such combinations has been found to be informative. Staining of lymphocyte surfaces for markers such as CCR7, CD45RO or CD45RA, CD27, or CD28 and at the same time for tetramer binding or CFC allows determinations of the percentage of naïve, central memory, effector, or terminally differentiated T cells. This type of analysis indicates how a biologic agent modulates the T-cell turnover in the peripheral circulation or changes populations of infiltrating tissue T cells.

Still another type of flow cytometry assays frequently used today provides means for enumerating cells that have initiated apoptosis, i.e., are able to bind annexin V, have an altered mitochondrial membrane potential, express high levels of caspase-3 activity or a high Bax/Bcl2 ratio, show evidence of DNA fragmentation (TUNEL+ cells [terminal deoxynucleotidyltransferase-mediated dUTP-biotin nick end labeling-positive cells]), or have decreased or absent expression of the TCR-associated ζ chain (25). In patients with advanced cancer or with chronic, persistent infections, a considerable proportion of circulating T cells are destined to undergo apoptosis, and flow cytometry offers an opportunity to monitor changes in the numbers of these cells before, during, and after immunotherapy. These methods depend on the use of special substrates, chromogens, or MAbs for the detection of proapoptotic or antiapoptotic molecules in the target cell and generally include cell permeabilization as well as a combination of surface and intracellular staining. The availability of reagent kits that are commercially distributed makes measurements of apoptosis relatively simple, with the caveat that freshly harvested cells are required for analyses of annexin binding to cells, as cryopreservation may impair the integrity of cellular membranes.

Multiparameter flow cytometry has greatly expanded opportunities for serial monitoring of therapy-induced changes in immune cells. It has provided means for measuring several molecules at once and for a combination of surface and intracytoplasmic biomarkers. In addition to rare event analysis, including tetramer-based or cytokine-based detection of peptide-specific T cells, flow cytometry has been widely used to quantitate the expression of various cellular components by incorporating calibration beads with different fluorescence intensities. The numerous advantages of flow cytometry have to be counterbalanced by the requirement for special expertise in its performance and data interpretation. The reproducibility of flow cytometry-based assays is strictly governed by the operator's skills of setting the gates and excluding nonspecific events and is therefore open to considerable subjectivity. Aside from gating strategies, which can greatly influence results and thus impose a need for a careful and standardized selection of the most appropriate settings, the interpretation of flow cytometry data in serial monitoring requires stringent controls for interassay variability and a great deal of judgment. While daily calibration solves the problem of instrument variability, other challenges exist. For example, some of the lymphocyte subsets encompass only a small proportion of cells in the gate, and to be able to distinguish shifts induced by therapy from daily assay variability, it may be necessary to acquire a large number of cells for such rare event analyses. Changes in the phenotype of effector cells should be interpreted in conjunction with changes observed in functional assays. Specifically, it is important to consider whether changes in function induced during therapy correlate with changes in the number of effector cells or are due to the augmentation of effector function in a small subset of cells. It is also possible that therapy alters both the number and function of effector cells. During

therapy, these changes can be dramatic or subtle, and they can simultaneously occur in several subsets of cells. Analyses of these changes and the establishment of correlations between their magnitude and frequency require special statistical approaches, as discussed below. Since alterations in the proportion or absolute number of effector cells and alterations in function may be mediated by entirely different mechanisms (e.g., increased blood vessel permeability and up-regulation of NK activity during therapy with IL-2, respectively), it should not be expected that phenotypic and functional data will necessarily correlate with clinical responses. More likely, no significant correlations will be detected, even though significant changes in the immune cell number and/or function may be registered during therapy. This should not be interpreted as evidence that the immune system has no impact on the disease but rather as evidence that despite therapy-mediated immunomodulation, the disease process persists, undoubtedly because of the involvement of factors unrelated to immune system activity.

Phenotypic studies of immune cells need not involve flow cytometry. With the broad availability of excellent Abs, the immunohistochemical evaluation of cells in situ is a powerful method for recording therapy-induced changes in the composition or activation state of effector cell subsets. The importance of in situ studies cannot be overemphasized. In a recently completed retrospective study of 132 tumor biopsies obtained from patients with oral carcinoma, we were able to correlate a lack of or low expression of the TCR-associated ζ chain in tumor-infiltrating lymphocytes (TIL) with significantly decreased 5-year survival (17). In a subsequent immunohistologic examination of the number of S100+ DC in the same tumors, both the low number of DC and the absent or low ζ expression in TIL were found to be independent and highly significant predictors of poor survival for these patients. Thus, these two biologic markers are currently emerging as robust correlates of overall survival, disease-free survival, and time to recurrence for patients with oral carcinoma (17).

FUNCTIONAL ASSAYS FOR IMMUNOLOGIC MONITORING

In Table 1, assays that are currently in use for immunologic monitoring are divided into two broad categories: serum/plasma assays and cellular assays (phenotypic and functional). The rationale for utilizing serum/plasma assays for monitoring instead of more technically demanding and expensive cell-based measurements was discussed above. In the same vein, among cellular assays, flow cytometry is faster, more accessible, and frequently more reproducible than most other assays, particularly those involving radioactive labels. In addition to monitoring changes in levels of serum immunoglobulins or specific antibodies by routinely available rate nephelometry or enzyme-linked immunosorbent assays (ELISAs), a spectrum of other assays can be used to obtain a longitudinal serum profile reflecting changes in one or more cellular products. Generally referred to as proteomics, these assays are discussed below. In some cases, soluble products can serve as activation markers for a particular subset of immune cells, such as neopterin for monocytes or soluble IL-2R α chain (CD25) for T-helper cells. Body fluids can be readily frozen and banked to allow batch processing of the planned assays or for future studies.

TABLE 1 Immunologic assays currently available for monitoring of phase I clinical trails with biologic agents

Assay type and parameter	Sample type
Soluble cellular products	
Immunoglobulin levels	Serum, plasma, body fluids
Cytokine levels and pharmacokinetics (ELISA, multiplex format)	Serum, plasma, body fluids
Cytokine receptors and antagonists	Serum, plasma, body fluids
Other lymphocyte surface receptors (e.g., CD8, CD25, sFas, HLA molecules)	Serum, plasma, body fluids
Ligands (FasL, TRAIL) and growth factors	Serum, plasma, body fluids
Enzymes (e.g., 2',5'-adenylate synthetase and terminal deoxynucleotide transferase)	Serum, plasma, body fluids
Neopterin	Serum, plasma, body fluids
β_2-Microglobulin	Serum, plasma, body fluids
Phenotypic markers	
Proportions of cells (antigen specific versus unrestricted)	Whole blood, tissue biopsy, body fluids
Absolute cell numbers	Whole blood, tissue biopsy, body fluids
Cellular subpopulations (e.g., Th1, Th2, effector, memory, or naïve T cells, T_{reg})	Isolated lymphocytes
Single-cell flow cytometry (e.g., CFC, tetramers)	Isolated lymphocytes
Functional assays	
In vivo DTH skin test	Visual inspection or biopsy
Cytotoxicity (ADCC[a], LAK, NK, or T-cell specific)	MNC or subpopulations of MNC
Cytokine production (ELISA, ELISPOT)	MNC or subpopulations of MNC
Proliferation	MNC or subpopulations of MNC
Chemotaxis	MNC or subpopulations of MNC
Signal transduction (ζ chain, Zap-70, NF-κB, other molecules)	MNC or subpopulations of MNC
Superoxide generation	MNC or subpopulations of MNC
Apoptosis assays (annexin V binding, caspase activity, TUNEL)	MNC or subpopulations of MNC

[a]ADCC, antibody-dependent cellular cytotoxicity.

Monitoring the functions of immune effector cells is considered to be necessary, since their phenotypic characteristics may not adequately convey their functional capabilities. Functional assays are usually performed with peripheral blood MNC and only rarely with effector cells obtained from the site of disease. Thus, functions of "substitute" cells that are easily accessible for monitoring in the circulation are measured instead of those of the effector cells at the sites of disease. This is by far the greatest limitation of monitoring, since systemic effects of biologic agents on immune cells are likely to be different from local or locoregional effects. The surrogate results obtained with peripheral blood lymphocytes should not be expected to closely reflect the biologic activity of the drug on functions of immune cells in situ. Additionally, investigators need to be aware that at any given time point, circulating lymphocytes represent <2% of a total lymphocyte pool, and that the turnover of circulating lymphocytes is responsible for constant changes occurring at the rate determined by the events in the periphery. To overcome these limitations, attempts are being made to study serial tissue biopsies, utilizing immunostaining and/or in situ hybridization or reverse transcription-PCR for cellular proteins and/or mRNA coding for the proteins involved in, e.g., cytotoxicity (perforin, granzymes, and tumor necrosis factor), proliferation (growth factors and cytokines), or signal transduction (the ζ chain and protein tyrosine kinases). The field of genomics has greatly facilitated these studies, providing a new set of tools for rapid screening of gene expression, as discussed below. In some cases, it may be possible to recover a limited number of cells from serial biopsies to perform functional studies. Obviously, these studies are very difficult to perform with human tissues, and they are not practical for the monitoring of many patients at multiple time points. Nevertheless, they are extremely valuable because they allow comparisons to be made between local and systemic effects of a biologic agent on immune effector cells and will eventually justify or discredit the common practice of monitoring alterations in cellular functions in the peripheral blood alone.

Cytotoxicity measurements have occupied a special place in the monitoring of immunotherapies. There is a good rationale for monitoring cytotoxicity in clinical trials with biologics, which often tend to augment this effector function in many different cell types. In oncology protocols, antitumor cytotoxicity, whether mediated by class I major histocompatibility complex (MHC)-restricted autotumor-specific T cells, nonspecific NK cells, monocytes, or antibody-dependent FcγR+ effector cells, has been extensively monitored. The evidence derived from animal models suggests that tumor growth and the elimination of metastases are mediated, at least in part, by cytotoxic effector cells. In some clinical trials with biologics, autotumor cytotoxicity mediated by tumor antigen-specific T lymphocytes has emerged as the only significant in vitro correlate of clinical responses (1). However, more recent data indicate that tumor regression and metastasis elimination are complex events involving multiple mechanisms and many cellular interactions, only some of which are mediated by immune cells. The process of antitumor cytotoxicity may involve other events in addition to perforin- or granzyme-mediated lysis, as measured in vitro by the release of ^{51}Cr from labeled, sensitive targets. Cellular interactions leading to necrosis, apoptosis, or both and involving activated effector cells of various types, cellular receptors, enzymes, antibodies, cytokines, and other factors may significantly contribute to effector cell-mediated lysis. It is clearly not possible to monitor all of these multiple events in the course of a clinical trial, although assays are available to measure them individually. A great majority of these assays have not yet been used for monitoring, and their value as reliable in vitro correlates of the process of antitumor immune activation in vivo remains to be determined. It is also apparent that a classical cytotoxicity assay measuring only the secretory function of effector cells is not able to adequately reflect the many mechanisms involved in the process of cytotoxicity in vivo. For this reason, the cytotoxicity assay has been largely replaced in monitoring by more informative, simpler, and cheaper single-cell assays based on multiparameter flow cytometry or image analysis and the enumeration of spots reflecting antigen-specific cytokine production by individual cells.

The choice of the type of cytotoxicity assay for monitoring depends on the hypothesis tested and practical considerations of assay availability. For most viral diseases, the presence of virus-specific cytotoxic T cells is necessary for recovery, and at least one goal of immunotherapy in patients with chronic viral infections is to induce the in vivo generation or activation of such virus-specific cytotoxic T cells. Obviously, measurements of virus-specific T-cell-mediated cytotoxicity are advisable in this case, although considerable practical difficulties might be encountered in assembling the components of this demanding assay (as described elsewhere). Similarly, for a cancer patient immunized with a tumor peptide vaccine in order to induce a memory T-cell response directed at the tumor, it might be desirable to monitor for the appearance of tumor-specific cytolytic T cells, under the presumption that they will mediate antitumor effects. Since, however, the number of these cells in the circulation may be small even after reimmunization, in vitro priming followed by enzyme-linked immunospot (ELISPOT) assays to quantitate the responding T cells and/or cytotoxicity assays with the autologous tumor cells as targets would be required. In the assessment of antigen-specific responses, the choice of a specific as well as sensitive assay becomes all important. The currently available data indicate that frequencies of single-epitope-specific T cells in non-antigen-primed circulating lymphocyte populations can be as low as 1 in 10^5 to 1 in 10^6. Considered from this point of view, the standard ^{51}Cr-release cytotoxicity assay does not qualify for monitoring of antigen-specific CTL precursors (CTLp) because of its relatively low sensitivity, which is estimated to be 1 CTL in 1,000. The frequencies reported in the literature for CTLp specific for some of the well-defined human MHC class I-restricted epitopes in the peripheral circulation of patients with cancer are too low to be detected in cytotoxicity assays. Furthermore, cytotoxicity assays measure the activity of the population of cells and provide no information about the frequency of individual tumor-specific T cells without an additional step of limiting dilution analysis. Today, the ELISPOT assay for gamma interferon (IFN-γ)-producing immune cells has largely replaced ^{51}Cr-release assays in monitoring of clinical trials. The ELISPOT assay can be used with cryopreserved MNC and is sufficiently sensitive to detect 1 IFN-γ-secreting T cell among 100,000 plated cells (4). When used with autologous DC pulsed with cell lysates or individual peptides, for example, the assay can detect not only CD8+ but also CD4+ responses, which is important in view of accumulating evidence that CD4+ helper cells play a crucial role in the induction and maintenance of immune responses. The assay does not require labeled, viable cells as targets. Instead, cell lysates, synthetic or natural antigens, or whole cells can be used as stimulators. It can be set up in a variety of formats, allowing for

substantial flexibility in the choice of antigen-presenting cells, ratios of responder to stimulator cells, and the use of in vitro sensitization for the expansion of antigen-specific T cells. The ELISPOT assay performed with patients' peripheral blood mononuclear cells without in vitro sensitization measures the frequency of peptide-specific precursor cells able to respond by cytokine production to the cognate peptide. Like all other assays for the detection of antigen- or peptide-specific T cells, it is HLA restricted.

Monitoring of epitope-specific T-cell cytotoxicity in clinical trials is logistically and practically difficult, as it requires prior HLA typing of participants. Often, the nature of antigens necessary for sensitization is unknown, or no appropriate targets are available. Instead, non-MHC-restricted cytotoxicity is measured, and the assay is adjusted to measure lysis mediated by NK cells, activated T cells, NKT cells, monocytes, or granulocytes. The selection of targets (e.g., NK-sensitive K562 versus NK-resistant Daudi cells), length of the assay (4 h for lymphocytes and 18 h for monocytes), and use of targets coated with the target-specific antibody are some of the variables that can be considered. In addition, cytotoxicity is often measured following the in vitro incubation of effectors in the presence of a drug or an activating agent to induce the generation of primed or activated effector cells. A good example is the generation of LAK cells in the presence of IL-2, followed by measurements of cytotoxicity against Daudi cells or other NK-resistant targets (13). LAK activity measured in freshly isolated lymphocytes is a useful measure of the ability of a biologic agent to induce nonspecific cytolytic effector cells in vivo. However, at present, attention has been focused on assays able to measure antigen-specific T-cell responses, largely due to the commonly held conviction that adaptive immune responses are responsible for therapeutic effects.

Assays that measure cytokine levels in serum/plasma or other body fluids have become an important part of monitoring. Both bioassays and immunoassays are available for assessments of cytokine levels (24), but only the latter are practical for the monitoring of clinical trials. Body fluids can be frozen and batched for immunoassays. Currently, multiplex-type assays using antibody-coated colored beads for the capture of multiple cytokines in a small (0.5-ml) sample and laser-type detectors to measure the fluorescence intensity of the individual beads are gaining popularity, replacing conventional ELISA. Like ELISA, mutiplex cytokine assays are antibody based but have the advantage of providing a profile of cytokines in a body fluid at a reasonable cost. Assays for inflammatory cytokines, hematopoietic cytokines, inhibitory cytokines, etc., can be selected to profile cytokines associated with a disease process and to assess changes in this profile following therapy. A number of problems with the assessment of cytokines in sera exist, including the ability of cytokines to bind to and form complexes with serum proteins and the presence of soluble cytokine receptors or antagonists, natural inhibitors, or anticytokine antibodies (24). All of these factors may contribute to difficulties in the interpretation of cytokine profiles, and knowledge of cytokine biology is important for accurate assessments and interpretation of cytokine levels in biologic fluids.

The ability of immune effector cells to produce and release cytokines in response to a biologic agent can be used as a monitoring strategy. This approach calls for incubation of cells alone (spontaneous production) or in the presence of an activating agent (stimulated production) and subsequent quantitation of cytokines in cellular supernatants (24). The assay can be used to measure the immunocompetence of cells by including stimulators such as phytohemagglutinin or lipopolysaccharide or the ability of cells to produce cytokines in response to the stimulator of choice. The assay also allows for the assessment of in vivo activation of cells by measuring spontaneous cytokine release. Once released, cytokines in cellular supernatants can be measured in multiplex-format assays. Cytokine production assays have been reproducibly performed with either fresh or cryopreserved cells (24), allowing for batching of cells or of cellular supernatants. This is a practical advantage of monitoring, as is the possibility of assaying the levels of several cytokines in one supernatant. The assay can also be performed with separated subsets of MNC, permitting the monitoring of cytokine profiles in these cell subsets, and it lends itself especially well to serial monitoring.

The proliferation of immune cells in response to a biologic agent or to mitogens and/or antigens has been in the monitoring repertoire for a long time. It can be used as a measure of immunocompetence following stimulation with an activating agent and can be performed with banked cryopreserved cells or as a whole-blood assay. In newer, modified versions, it can be nonradioactive. Proliferation assays can require very few cells if performed in Terasaki plates. As discussed above, it is also possible to use a flow cytometer to read the assay and to confirm the phenotype of proliferating cells. Proliferation assays can be used in conjunction with measurements of cytokines and cytotoxicity. These assays are informative, practical, and adjustable to fit the specific trial design or circumstances in a monitoring laboratory.

Apoptosis of immune effector cells in the circulation of patients with cancer or persistent infections has been observed and may contribute to the poor immunocompetence associated with these diseases (23). The observation that most T lymphocytes, including the subset responsible for antigen-specific responses, undergo spontaneous apoptosis in patients but not in healthy controls suggests that a rapid turnover of these cells is a characteristic feature of the disease process. Immunotherapy might be able to protect immune cells from apoptosis and prolong their survival. Thus, changes in the proportion of T cells destined to undergo apoptosis during biotherapy might correlate with improved immunologic or clinical responses. For these reasons, apoptosis assays, many of which are flow cytometry based as described above, have assumed an important place in monitoring of clinical trials.

New molecular assays are being introduced for the monitoring of immune cells. In cancer and certain immunodeficiency diseases, abnormalities in signal transduction have been identified, and they appear to be responsible for defective functions of immune cells in these diseases (7). Since it might be possible to correct these abnormalities and thus repair immune functions with immunotherapy, monitoring for the presence and extent of signaling defects is indicated, at least before and after such therapy. The TCR-associated ζ chain is one of the key signaling molecules, and its absence or decreased expression in T cells reflects impaired functions. Since ζ is also a component of FcγRIII, its lower-than-normal expression in NK cells signifies the presence of signaling defects in these effector cells as well. The expression of ζ in MNC is measured by two- or three-color flow cytometry following staining of permeabilized cells with ζ-specific as well as cell surface-specific Abs. Both a lower-than-normal mean fluorescence intensity for ζ and the proportion of MNC with absent ζ expression can be reliably used for quantitative evaluations. The assay can be calibrated against fluorescent beads, with the results expressed in MESF units (see above). As with other immunologic evaluations, pre- and posttherapy

comparisons are performed with the same assay, using cryopreserved cells. The expression of ζ, NF-κB, Zap-70, or other signaling molecules in MNC can also be determined by Western blots or gel mobility shifts, but flow cytometry analyses are quantitative and simpler to use for monitoring. Immunostaining in situ, which allows for assessment of the signaling molecules in T or NK cells accumulating at the site of disease, is a very useful indirect measure of the functional state of these cells. The expression of ζ in TIL is an important biomarker of survival for patients with oral carcinoma, as discussed above, and changes in the mobility of the NF-κB subunits have been related to impaired function of immune cells in renal cell carcinoma. Thus, monitoring for the expression of signaling molecules in immune cells has biologic as well as clinical significance (25).

GENOMICS AND PROTEOMICS IN IMMUNOLOGIC MONITORING

Advances in technology now allow for the simultaneous analysis of different genes in cells or tissues by the use of DNA chips or microarrays. Rapid and cost-effective screening for the expression of multiple genes coding for cytokines, activation markers, components of major signaling pathways, etc., offers a powerful new approach to monitoring of cell activation, differentiation, or proliferation in response to biotherapy. The technology involves mRNA extraction from cells or tissues and its subsequent labeling and hybridization to the microarray. The hybridized products are visualized in a phosphorimager and analyzed with software capable of comparing control with test samples to detect differences in the expression of selected genes. In this way, up-regulation or down-regulation of gene expression in tissues or cells exposed to a biologic agent can be monitored.

Similar to gene arrays, technologies combining two-dimensional polyacrylamide gel electrophoresis with mass spectrometry allow for simultaneous analysis of many hundreds of proteins in body fluids or tissues. It is expected that pathologic changes in tissues or cells are reflected in distinct protein patterns detectable in body fluids or cellular supernatants. Proteomic technologies are able to discriminate between normal and pathologic protein patterns and can be used to map protein changes associated with a disease process. The potential of these technologies for capturing distinct protein patterns that could serve as biomarkers or be correlated with clinical responses or prognoses is being actively explored.

Gene and protein profiling, whether by multiplex immunoassays, microarrays, or proteomic detection methods, may be of special importance in relation to cytokine-based therapies. The clinical use of cytokines for therapy of human diseases has been increasing. Discoveries of new cytokines and their availability as recombinant proteins as well as cytokine gene therapies have facilitated the pharmacologic use of cytokines. Systemic or local therapies with these mediators, which induce one another and amplify cytokine circuits, call for careful monitoring of cytokine levels in relation to clinical end points. Given the dynamic and rapid progress in cytokine assay development, it appears likely that such monitoring will shortly provide a wealth of clinically useful information about cytokine involvement in human disease.

QC IN IMMUNOLOGIC MONITORING

QC of immunologic assays, particularly cellular assays, is difficult, and QC of serial immunologic measures represents a special challenge. To meet the challenge, a well-designed and rigorously maintained QC program is a requirement in a monitoring laboratory. Such a QC program contains several components, including the definition of standard operating procedures, training of personnel, instrument maintenance, reagent control, review of quality, and proficiency testing. Laboratories performing immunologic monitoring for clinical trials are required to implement their own QC programs to ensure that acceptable data are generated. Currently, no model QC programs exist, but monitoring laboratories are encouraged to follow the good-laboratory practice guidelines defined by professional groups such as the College of American Pathologists or the departments of health in some states. No proficiency testing programs are available for most immunologic monitoring assays, except for those designed for flow cytometry or hematology (leukocyte count and differential), and participation in these programs is highly recommended.

An important aspect of serial immunologic monitoring is documenting changes from baseline upon treatment. This is possible only when measurements taken over time are assessed accurately. Thus, each assay selected for monitoring has to be vigorously controlled for intra-assay and interassay variability. Also, the reproducibility of the same assay used for individual patients tested at different times has to be ensured (biologic variability). This requires considerable effort and expense.

The process of QC begins with sample collection and processing, which have to be organized to meet the protocol schema and occur at specified times of the day and, presumably, before the next cycle of therapy. Blood samples for immunologic monitoring need to be routinely harvested in the morning to avoid diurnal variability. The flow of specimens and the recording of the collection and arrival times of samples are important activities in a monitoring laboratory. Although immunologic monitoring assays should be scheduled in advance, times of sample arrival tend to vary. The laboratory is obliged to establish strict guidelines for sample handling and to document problems in accordance with the quality assurance requirements. A precise history of each sample must be maintained. Processing must be uniform and follow standard operating procedures which are available in writing and regularly updated. Frequent checks of reagent quality and equipment performance have to be implemented. The decision to cryopreserve cells or use fresh cells is made prior to the clinical trial and has to be based on preliminary comparative studies using fresh and cryopreserved lots of the same normal MNC, which need to be performed for every assay. This is a crucial decision for monitoring, because the selection of assays that can be batched (i.e., performed at the same time for all cells collected in the course of the trial) will avoid day-to-day variability and considerably decrease the cost of monitoring.

Regardless of whether cryopreserved or fresh samples are used, standardization of all assays has to be performed prior to beginning a clinical trial. The importance of the reproducibility of assays used for longitudinal monitoring cannot be overemphasized. The standardization data are obtained by repeatedly performing the assay with cells obtained from healthy individuals under invariant and previously optimized experimental conditions to establish the mean, median, 80% normal range, and coefficient of variation. The intra-assay variability is also determined. When the standardized assay is ready for monitoring, a set of appropriate controls is selected, and these depend on whether fresh or cryopreserved cells are used. With fresh cells collected at different time points, repeated testing of preserved control

samples (e.g., cryopreserved lots of normal MNC with a pre-determined range of reactivity) is necessary to control for day-to-day variability. With fresh cells, it may also be advisable to include fresh control cells obtained from a healthy volunteer. A pool of volunteers repeatedly tested over time can be established for this purpose. A QC program in place will ensure that the values obtained for an individual control sample remain within an acceptable range over time and specify when the assay results are considered out of the normal range. With cryopreserved cells or frozen serum/plasma, it is best to batch and test all serial samples from a patient in one assay. Even in this case, however, it is necessary to control for day-to-day variability to have some assurance that the assay performs equally well for all patients in a protocol. The data obtained from control samples, evaluated in parallel with each patient sample, can help to ensure the validity of the results for a particular day's assay. Whenever universally accepted standards are available (e.g., the World Health Organization standards for cytokines), these should be regularly included in the monitoring of assays. Alternatively, internal controls initially compared with the standards can replace the standards, which are often available in finite quantities, for routine use.

STATISTICAL ANALYSIS OF DATA FROM IMMUNOLOGIC MONITORING

In preparation for final data analysis, the results of immunologic monitoring are "cleaned," i.e., purged of errors made during data entry. We have found it helpful to monitor for such errors at several levels. First, the technologist who performs the test enters the results into the computerized database, after examining the daily controls and finding the assay acceptable. The technologist is least likely to make errors in entering the results of an assay that he or she just performed. Second, prior to the final analysis, a statistician generates summary data sheets, which are screened by the laboratory monitor, often a laboratory supervisor, who is intimately familiar with the assays. All outlier values identified by the computer are checked and verified by the monitor against the laboratory records. Third, all variations from the protocol schema are noted for each patient. It is necessary to confirm that all measurements were made at the time points specified in the original treatment schema. Because of the importance of the timing of samples relative to the treatment, a change in the schedule or dose of therapy or in the sequence of sampling may have profound effects on the results of immunologic monitoring.

The biostatistician performing the analysis of immunologic data should interact closely with the clinical immunologist. The statistician should be consulted with respect to trial design and should be involved in its planning. The statistician's input is vital in determining the number of patients necessary to adequately define an OBD.

Immunologic data are often normalized for analysis with a logarithmic scale. The statistical analysis selected depends on the trial design and hypotheses tested, but since pre- and posttreatment changes are generally measured, the analysis seeks to determine if the changes from baseline are significant. Typically, pretreatment baseline levels are established by computing medians of three pretreatment determinations. Medians are preferable to means, as they are not influenced by extreme data points. Nonparametric tests for differences in posttreatment levels relative to the pretreatment baseline can include tests such as the Wilcoxon signed rank test or analysis of variance with Fisher's protected least-significant-difference method to determine pairwise differences between two specific time points. Comparisons between treatment groups can be accomplished by multiple regression analysis to permit simultaneous contrasts between groups, using a pooled estimate of the variance for all groups. Dose-response analysis utilizes parametric repeated-measure dose-response models which are fitted to posttreatment data, controlling for between-patient differences by including the pretreatment level as a covariate. Repeated-measure analyses are potentially sensitive to occasional extreme data points, and the use of robust fitting methods, which downweigh the influence of extreme data points, is important. The monitoring data are generally presented as a series of time plots, which are adjusted by subtraction of the estimated contribution of each patient's baseline level, so that the plots depict the relationship that would exist if all patients' baseline values were equal to the overall pretreatment average.

ROLE OF THE CLINICAL IMMUNOLOGIST IN IMMUNOLOGIC MONITORING OF CLINICAL TRIALS

The clinical immunologist should play a major role in the design, execution, and analysis of clinical trials which include immunologic monitoring. Many clinicians fail to consult or include the clinical immunologist in the trial design, expecting only to utilize the technical expertise of such an individual. Equally, many clinicians forget that the interpretation of immunologic data is never straightforward and requires special training and considerable experience. The clinical immunologist is likely to be well aware of the preclinical evidence regarding the biologic agent which is being evaluated and can help design a trial based on the agent's mechanism of action. The clinical immunologist can help not only by formulating a correct and rational hypothesis but also by giving advice regarding how best to test this hypothesis by utilizing the assays at hand. The clinician will be best served by working closely with the laboratory staff when monitoring is ongoing, and close daily interactions between the clinical and laboratory teams are necessary for collecting samples and obtaining meaningful data. It is desirable to have the clinical immunologist oversee the performance of assays and be responsible for the QC program in the monitoring laboratory. Equally important responsibilities of the clinical immunologist are the interpretation of results and data analysis, with the latter being performed in conjunction with the statistician. Ongoing discussion between the principal clinical investigator, the immunologist, and the statistician is necessary for the correct analysis and interpretation of immunologic monitoring data.

Immunologic monitoring of clinical trials has entered a new era. Technical developments and molecular insights into interactions of immune cells have expanded the field of opportunities for capturing and analyzing multiple therapy-induced changes in the phenotype and functions of immune cells. The greatest challenge, i.e., relating these changes to clinical end points, remains, however, and still requires close and effective teamwork between the clinician, the laboratory immunologist, and biostatistical personnel. Contributions from informatics experts are likely to become equally important. Cooperation and insights provided by each team member will facilitate meaningful monitoring, and the benefits of utilizing combined expertise in all aspects of clinical trials with biologic agents or any other trials monitoring immune responses can be considerable.

The Future of Cancer Diagnostics:
Proteomics, Immunoproteomics, and Beyond

MARY E. WINTERS, MARK LOWENTHAL, ANDREW L. FELDMAN,
AND LANCE A. LIOTTA

134

Cancer is a disease of dysregulated protein function and expression. Altered protein networks and signaling pathways drive the malignant phenotype, resulting in cell survival, invasion, and metastasis. The large complement of expressed proteins is known collectively as the proteome, and the study of these proteins is known as proteomics. Some potential benefits of advances in proteomics are the abilities to predict who will develop cancer; select optimized, individualized therapy; and monitor how the cancer responds to therapy. Emerging proteomic technologies include identification of diagnostic proteomic patterns in biological fluids, high-throughput protein arrays that immobilize the entire repertoire of proteins from a population of cells, and identification of immunogenic structural features shared and conserved between different antigens, known as immunoproteomics, which could guide development of broadly protective vaccines.

The advent of these technologies has brought the ability to quantitatively measure thousands of proteins, enabling global measurements of protein expression, and the ability to profile the interactions and pathways of these proteins. In addition, these techniques provide data on posttranslational events, such as protein phosphorylation and cleavage, which are not obtainable by gene microarray analysis. Mass spectral analysis of serum proteomic patterns is emerging as an effective method for the early diagnosis of diseases such as ovarian cancer (14). Surface-enhanced laser-desorption ionization–time-of-flight (SELDI-TOF) mass spectrometry rapidly assesses complex protein mixtures in body fluids. Combined with artificial intelligence-based pattern recognition algorithms, this emerging technology can generate highly accurate diagnostic information. Reverse-phase protein microarrays capture the entire repertoire of proteins from a population of cells, enabling the study of changes in protein expression and function before, after, and during treatment. A new paradigm for cancer diagnostics is that the concept of a biomarker for cancer detection and monitoring is not limited to a single protein but can comprise a proteomic pattern of many individual proteins and the changes this pattern undergoes when tissues transform from a normal to a malignant state. The goal is to identify cancer at its earliest stages and to identify people at high risk of developing cancer. Proteomic profiling has emerged as a powerful tool in the large-scale analysis of protein expression, structure, and function, as well as a means to identify proteins and biochemical pathways involved in aberrant biological processes. The techniques are constantly

evolving in an effort to provide optimized and validated protocols that will be clinically useful. This chapter will address the issues related to technology development, validation, and quality assurance and discuss trends in future diagnostic strategies.

MS

The importance of mass spectrometry (MS) to the fields of proteomics and cancer diagnostics is undeniable. Mass spectrometers are powerful and versatile analytical instruments with the ability to detect and characterize biomolecular structures on a global scale, both qualitatively and quantitatively. Although the first-generation mass spectrometer was developed by J. J. Thompson in 1897 as no more than a gas phase electron conductor, functional mass spectrometers are in their relative infancy of development. In the early 1950s, Wolfgang Paul envisioned and invented the quadropole mass filter and the quadropole ion trap, designs that continue today to form a basis for mass spectrometer hardware. Over the last decade, design development has been rapid, leading to high-resolution, sensitive instruments. The recent sequencing of the human genome has generated enormous attention in the area of protein and peptide research and has accelerated the mass spectrometer to the forefront of present disease diagnosis and therapeutic monitoring techniques. Although the mass spectrometer can be found in many designs and is used for various functions, nearly all mass spectrometers can be described as the combination of three basic components: the ion source, the mass analyzer, and a detector. Here we describe the importance of the three most popular ionization techniques for MS: matrix-assisted laser desorption ionization (MALDI), SELDI, and electrospray ionization (ESI). In addition, new developments and applications in the field of MS will be discussed.

IONIZATION TECHNIQUES

MALDI-TOF MS

MALDI–time-of-flight (MALDI-TOF) MS is an analytical technique that can measure mass/charge (m/z) ratios of biological compounds with high accuracy and subpicomole sensitivity. Because of its theoretical and technical simplicity and reproducibility, MALDI has become a widespread analytical

tool for peptides, proteins, and most other biomolecules (oligonucleotides, carbohydrates, natural products, and lipids). A basic principle of MALDI-MS is the laser-induced ionization of analytes (that are dried onto the surface of a sample plate) by using an efficient and directed energy transfer as a matrix-assisted laser-induced desorption event. Sample preparation is relatively simple and can be adapted for different types of experiments. The analyte is first cocrystallized with a large molar excess of a matrix compound, usually a UV-absorbing weak organic acid. The choice of matrix varies depending upon the physical properties of the analyte, such as molecular weight and chemical composition. Pulse-UV laser radiation of this analyte-matrix mixture results in the vaporization of the matrix, which carries the analyte into a flight tube and eventually to the mass analyzer. In the analyzer, the momentum of the analyte upon a detector plate induces an electron cascade event that allows the quantitative determination of the analyte's m/z (Fig. 1A).

Advantages of using MALDI-MS include the infinite theoretical molecular weight range detection limits of ionized biomolecules, the capacity for direct quantitation of protein m/z values, and the efficient throughput and straightforward laboratory methodology. Investigators may also utilize MALDI-MS for qualitative analysis of enzymatically digested proteins by peptide mass fingerprinting experiments, in which measured peptide masses are compared to information in a theoretically generated database of enzyme-specific cleavage sites. Quantitative techniques, such as isotope-coded affinity tagging (ICAT) (3, 15), stable isotope labeling by amino acids in cell culture (7, 8), and quantitative cysteinyl-peptide enrichment technology (1), allow direct measurement of absolute protein concentrations in complex mixtures as well as the determination of differences between diseased and healthy or before- and after-treatment sample sets. MALDI-MS is also being used for protein profiling directly from sectioned tissue (6). These techniques provide a window into the changes of the cellular proteome in response to disease and provide data sets which may be mined for diagnostic and prognostic information related to the disease state. Disadvantages of MALDI-MS include high intolerances for salts and other species in biological samples, an inability to sequence amino acid structure directly, and the necessity to work with homogeneous samples for peptide mass fingerprinting and isotopic quantitative experiments.

SELDI-TOF MS

SELDI-TOF MS is presently at the forefront of discovery of tumor-associated biomarkers that have potential for development into clinical diagnostic assays. SELDI is a sister technique of MALDI-MS, as both use a laser to desorb and ionize analytes for direct mass determination. The patented protein chip array (Ciphergen Biosystems, Inc.) (21) distinguishes SELDI-TOF MS from other MS-based systems. In contrast to the metal plate used in MALDI-TOF MS for application of the analyte and matrix, SELDI chips provide a variety of surface chemistries for researchers to optimize protein capture and analysis. Each sample is spotted directly onto the chip surface, and the unique affinity capture chemistry binds a subset of the sample proteome. The chip is washed to remove non-covalently bound species, and finally an energy-absorbing molecule solution, which acts like a matrix in MALDI-MS, is spotted on top of the sample. The chip, containing up to eight samples, is inserted into a vacuum chamber, where it is irradiated with a laser. Mass spectra can be analyzed by using complex algorithm-based computer-assisted tools that classify a subset of the spectra by their characteristic patterns of m/z

and relative intensity (Fig. 1B). There are various proprietary chemistries that permit simplification of complex samples ranging from raw serum and other bodily fluids to cell lysates. The choice of binding surfaces includes hydrophobic surfaces for reverse-phase capture, cation and anion exchange surfaces, immobilized metal affinity capture surfaces for metal-binding proteins, and preactivated surfaces for investigation of antibody-antigen, DNA-protein, and receptor-ligand interactions.

The protein chip system (Ciphergen Biosystems, Inc.) detects and accurately calculates the masses of compounds ranging from small molecules and peptides of less than 1,000 Da up to proteins of 500 kDa or more based on a measured TOF to the detector plate. This technology is being applied primarily to the analysis of cancer patient sera to identify distinctive protein patterns that may be characteristic of specific tumor types (19). Patterns that distinguish between cancer patients and normal subjects with remarkable accuracy have been reported for several types of cancer, including breast, ovarian, prostate, and pancreatic cancer.

The proteomic patterns generated by these technologies have broad implications as they represent the sum of many alterations in metabolic and signaling pathways and networks that confer a survival advantage to the cancer cell. Because proteins are the primary functional effectors of these cellular processes, analysis of the proteome offers a snapshot of the state of molecular pathways in vivo. Furthermore, analysis of the proteome allows the detection of functionally relevant posttranslational modifications, such as phosphorylation, and has the potential to provide information not present at the genomic or gene expression level.

ESI MS

ESI MS requires more extensive sample preparation and theoretical expertise than MALDI- or SELDI-MS; however, it is the most powerful MS technique available. ESI MS is a soft ionization technique that produces ions directly from the liquid phase, allowing it to be easily coupled with high-performance liquid chromatography (HPLC) front-end hardware. Hundreds of distinct proteins from a heterogeneous sample can be simultaneously identified by ion fragmentation of proteolytically digested peptides in a single analysis, and homogeneous samples or very simple mixtures can be quantitatively analyzed by isotopic labeling techniques. The dynamic range of protein concentrations present in typical bodily fluids is simplified by prefractionation techniques, including immunochemistry, carrier protein isolation, dissociation, depletion, and multidimensional liquid chromatography. Disadvantages to using an ESI source include low-throughput data analysis, technical intricacy, and high instrumentation cost.

Electrospray mass spectrometers come in many configurations that differ in m/z ranges covered, the mass accuracies, and achievable resolutions. Typical mass spectrometer setups consist of an ionization source (where the liquid phase analytes are ionized into a fine mist and injected into the mass spectrometer), a tandem separation-isolation region coupled to a fragmentation region (these include hybrid configurations of quadrupoles, TOF analyzers, magnetic sectors, and quadrupole ion traps), and a detector (photomultiplier, electron multiplier, and the microchannel plate detectors). ESI is well suited to the analysis of polar molecules ranging from less than 100 Da to more than 1,000,000 Da in molecular mass.

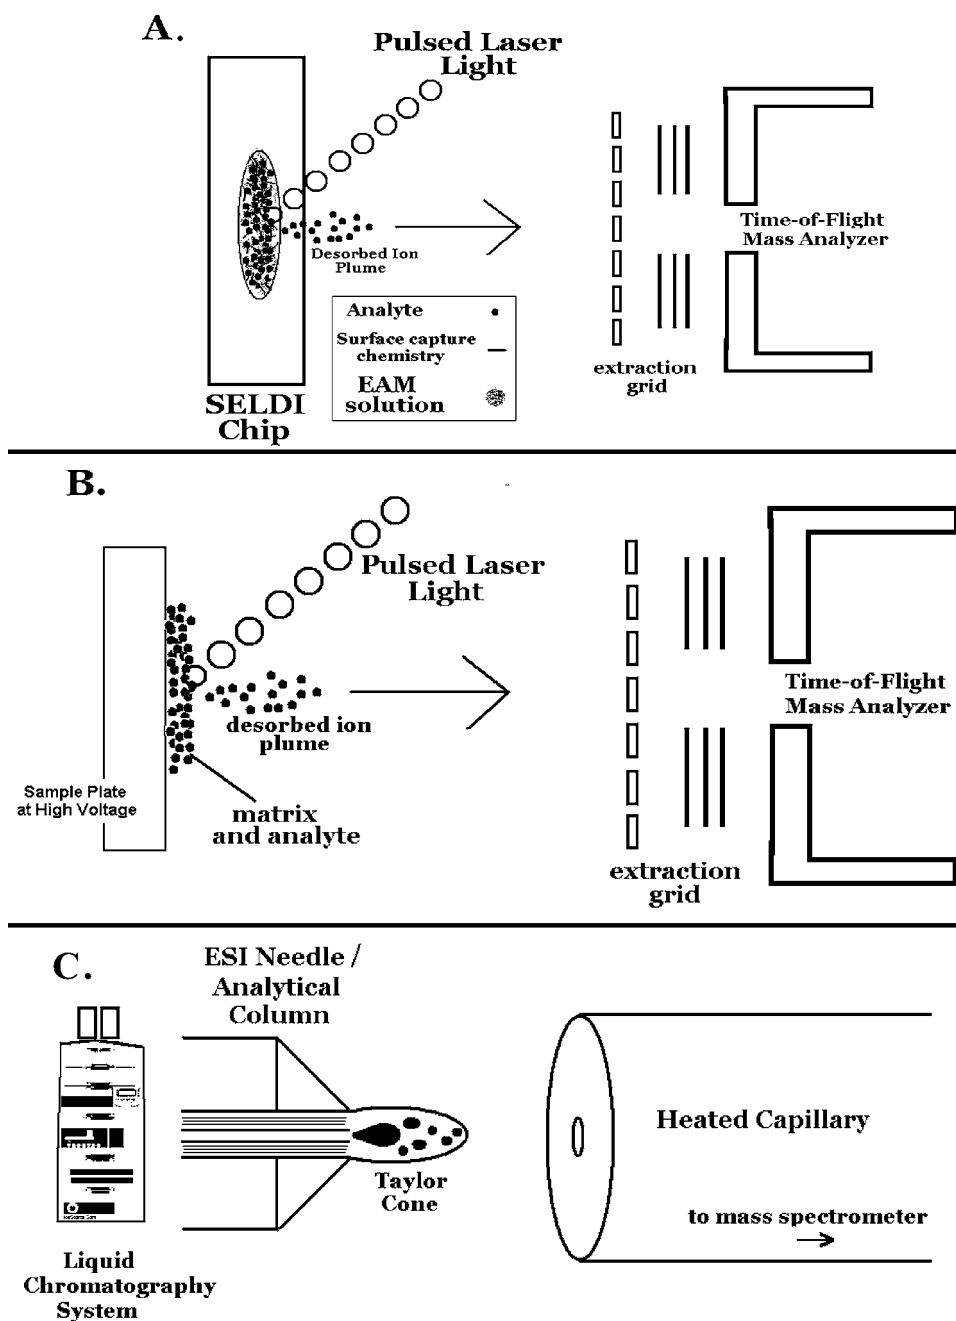
In ESI experiments, samples obtained from polyacrylamide gels or polyvinylidene difluoride membranes or


FIGURE 1 Schematic representation of three typical ionization and sample introduction techniques for MS analysis. Following ionization, analyte molecules are accelerated into a mass analyzer and detector of an appropriate instrumental configuration. (A) SELDI utilizes energy-absorbing molecule solution to absorb laser energy and induce ionization of immobilized analyte molecules. The analyte is covalently bound to a chip surface by one of many surface-capture chemistries (e.g., cation-anion exchange or reverse phase). (B) In MALDI, microliter volumes of the analyte and excess matrix can be dissolved in organic solvents and spotted by one of many techniques onto a plate. The matrix (e.g., alpha-cyano-4-hydroxycinnamic acid or sinapic acid) contains a chromophore that absorbs energy from the laser pulse and produces a plasma, resulting in vaporization and ionization of the analyte. Only molecular ions of the analyte molecules are produced, and almost no fragmentation occurs. (C) ESI utilizes a high positive or negative potential at an atmospheric, liquid junction to ionize a sample into the gas phase. This production of ions, called pneumatic nebulization, disperses the emerging solution into a very fine spray of charged droplets. As the solvent evaporates, droplet size decreases while the surface charge increases until, at the Rayleigh limit, Coulomb repulsion overcomes the droplet's surface tension and the droplet explodes. The process continues until each analyte ion is individually charged, often producing multiply charged ions. EAM, energy-absorbing molecule.

directly from solution are digested with a proteolytic enzyme (e.g., trypsin or Lys-C) into peptide fragments prior to injection into an HPLC system. The peptides are bound to solid-phase affinity columns (typically reverse phase or ion exchange) and are eluted (and thus separated in time) from these columns by changing the organic solvent gradient concentration (Fig. 1C). The simplification of peptide heterogeneity over time is essential to the success of a tandem MS (MS-MS) experiment.

Interpretation of data generated by ESI MS relies heavily on computer processing and database searching. Real MS-MS data are compared to theoretically generated fragmentation spectra inferred from a species' genome, and correlation scores are evaluated by the scientist to determine which amino acid sequences suggest unique protein identifications. Advantages of ESI MS include abilities for direct amino acid sequencing, posttranslational modification analysis, quantitative proteomic determination, and the analysis of complex mixtures (1). Disadvantages of using an ESI source include low-throughput data analysis, technical intricacy, and instrumentation cost.

NEW DEVELOPMENTS AND APPLICATIONS

High-Resolution Mass Spectrometers

The most commonly used instrument for MS is the ion trap mass spectrometer, which is reasonably sensitive and has a reputation for being durable, reliable, and easy to use. However, conventional three-dimensional ion traps have limited trap capacity. Newer mass spectrometers have triple quadrupoles of which the last quadrupole can be operated as a conventional quadrupole mass filter, or as a linear ion trap, allowing decoupling of precursor ion isolation and fragmentation from the ion trap itself. This provides more sensitive MS-MS and allows the identification and measurement of low levels of posttranslational modification in a single liquid chromatography–MS-MS run.

Another type of MS is Fourier transform ion cyclotron resonance MS (FTMS), which offers both high resolution and the ability to perform MS-MS experiments. In FTMS, charged particles orbit in the presence of a magnetic field. While the ions are orbiting, a radio frequency signal is used to excite them and the ions produce a detectable image current on the cell in which they are trapped (2, 7). The time-dependent image current can then be Fourier transformed to obtain the component frequencies of the different ions that correspond to their m/z. Combined with ESI and MALDI, FTMS has the potential to become an important research tool offering high accuracy with errors as low as ±0.001%.

Biomarker Amplification by Serum Carrier Protein Binding

Mass spectroscopic analysis of the low-molecular-mass (LMM) range of the serum-plasma proteome is a rapidly emerging frontier for biomarker discovery. Mass spectroscopic analysis of human serum following molecular mass fractionation has demonstrated that the majority of LMM biomarkers exist bound to carrier proteins. Moreover, the pattern of LMM biomarkers bound specifically to albumin has been shown to be distinct from the pattern of those bound to non-albumin carriers. In a recent study (16), prominent SELDI-TOF ionic species (m/z, 6631.7043) previously shown to correlate with the presence of ovarian cancer were amplified by albumin capture. Several insights emerged: (i) accumulation of LMM biomarkers on circulating carrier

proteins greatly amplifies the total concentration of the measurable biomarker in serum and plasma; (ii) the total biomarker concentration in serum and plasma is largely determined by the carrier protein clearance rate, not by the unbound-biomarker clearance rate itself; and (iii) examination of the LMM species bound to a specific carrier protein may reveal important diagnostic information. These findings shift the focus of biomarker detection to the carrier protein and its biomarker content. The value of this technique is that potential biomarkers are amplified to measurable quantities that could be quantified in readily available body fluids such as serum or urine.

ICAT Strategies

ICAT is a quantitative technique that allows direct measurement of absolute protein concentrations in simple mixtures as well as determination of differences between diseased and healthy or before- and after-treatment sample sets. This method relies on the labeling of protein samples from two different sources with two chemically identical reagents that differ only in masses as a result of isotope composition. Differential labeling of samples by mass allows the relative amounts of protein in two samples to be quantified. Protein extract from two different samples is reacted with one of two forms of the ICAT reagent, an isotopically light form in which the linker contains eight hydrogen atoms or a heavy form in which the linker contains eight deuterium atoms. The ICAT reagent reacts with cysteine residues in proteins via a thiol-reactive group and contains a biotin moiety to facilitate purification. Peptides are recovered on the basis of the biotin tag by avidin affinity chromatography and are then analyzed by MS (Fig. 2). The difference in peak heights between heavy and light peptide ions directly correlates with the difference in protein abundances in the cells. Thus, if a protein is present at a threefold higher level in one sample, this will be reflected in a threefold difference in peak heights. Following quantitation of the peptides, they can be fragmented by MS-MS and the amino acid sequence can be obtained. Thus, using this approach, proteins can be identified and their expression levels can be compared in the same analysis. One advantage of this method is the elimination of the two-dimensional (2D) gel for protein separation and quantitation. As a result, an increased amount of sample can be used to elevate levels of low-abundance proteins. Alternatively, the cell lysate can be fractionated prior to reaction with the ICAT reagent. This can allow an increase in levels of low-abundance proteins before analysis. The main disadvantages are that presently this method works only for proteins containing cysteine, even though this includes the majority of proteins. In addition, peptides must contain appropriately spaced protease cleavage sites flanking the cysteine residues. Finally, the ICAT label is large (~500 kDa) and remains with each peptide throughout the analysis. This can make database searching more difficult, especially for small peptides with limited sequences. Sensitivity may also be of concern since tagged peptides derived from low-copy-number proteins are likely to be poorly recovered during the affinity step as a result of nonspecific interactions with avidin-Sepharose. Studies have been performed to optimize the labeling of proteins with the ICAT reagent; therefore, despite these limitations, this approach may have applications for the study of protein expression profiles in cancer and other diseases.

2D PAGE and MS Paradigm

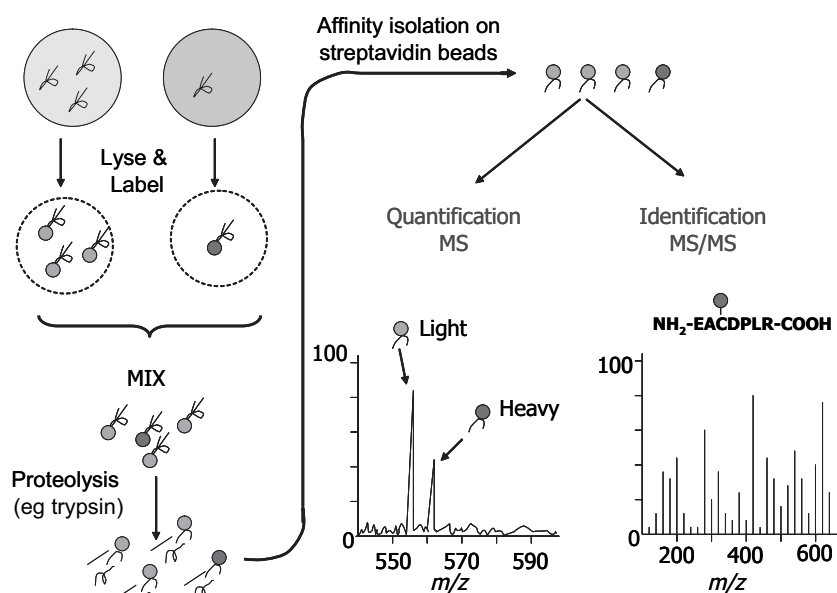
Two-dimensional polyacrylamide gel electrophoresis (2D PAGE) has been used traditionally to separate complex


FIGURE 2 ICAT MS-based protein profiling. This method relies on the labeling of protein samples from two different sources with two chemically identical reagents that differ only in masses as a result of isotope composition. Protein extract from two different samples is reacted with one of two forms of the ICAT reagent, an isotopically light form in which the linker contains eight hydrogens or a heavy form in which the linker contains eight deuterium atoms. The ICAT reagent reacts with cysteine residues in proteins via a thiol-reactive group and contains a biotin moiety to facilitate purification. Peptides are recovered on the basis of the biotin tag by avidin affinity chromatography and are then analyzed by MS. Example of a labeled peptide.

mixtures of proteins by both pI (first dimension) and mass (second dimension). Use of 2D gels and MS in tandem is a powerful tool that can highly resolve proteins on a global scale and identify them through querying of DNA and protein databases. This combined technique has the potential for identifying novel as well as known proteins. It also allows the parallel comparison of a number of samples at one time to determine differential protein expression. Miniaturization, automation, and increasing speed of analysis are occurring at both the separation and MS phases. However, separation by 2D PAGE tends to be a time-consuming, labor-intensive technique that is difficult to automate. Also, imperfect separation (and subsequent lack of identification) can occur with basic (pH, >9) proteins, such as hydrophobic or membrane proteins, and high-molecular-mass (>150-kDa) or LMM (<10-kDa) proteins.

TECHNICAL ISSUES

Among the technical issues associated with MS, preanalytical variables may be the most problematic. These include variations due to inconsistent sample collection, handling, and preprocessing procedures. These sources of variations are compounded by biological variables such as unknown subphenotypes among study populations. Preanalytic variation should be eliminated or minimized whenever possible through good experimental design, careful analytic procedures, and quality control protocols. Since collection practices, sample handling, and storage conditions may vary from institution to institution, samples from multiple sites should

be randomly divided into a discovery (training) data set and a validation (testing) data set. Biological variation may be more difficult to account for, especially when a protein profiling experiment is used for de novo discovery. When no prior knowledge exists about the protein the researcher is studying, adequate sample size is hard to define because the complexity of the final model and the peaks included in that model are unknown beforehand.

ANALYTICAL ISSUES

The unified maximum separability analysis algorithm was developed for genomic and proteomic expression data. The rationale behind unified maximum separability analysis is that information about the overall data distribution can be used to prequalify any training sample to be a support vector, i.e., a set containing boundary datum points. After selection of a limited number of protein peaks as candidate biomarkers, more traditional linear modeling techniques may be used. Methods such as logistic regression allow the user to define a relationship between protein peaks as well as evaluate each peak's contribution to the multivariate relationship. To test the robustness of the final model, the full set may be split using a stratified random sampling procedure. Two data sets are constructed from the original data set, and the decision rule derived using one data set is tested for the second data set. Bootstrap analysis may be used if the number of samples collected for the study is too small for a stratified random sampling procedure. Regardless of what technique is employed, verification of analysis results is imperative.

DATA HANDLING

Like the genome project, more sophisticated data mining and learning algorithm software programs will be required to reproducibly and efficiently collect and analyze the information being generated by proteomic technologies. Furthermore, present proteomic projects are generating a wealth of data for a wide range of tissues, and it is critical that results are organized and presented in a form that makes analysis as simple and accessible as possible. To this end, a number of databases have been constructed containing both visual and textual data with extensive links to both protein and nucleic acid databases. The ability to effectively search such databases for the identification of ions from spectral data has become an essential step in the study of proteomes. The ability of analytical techniques used in protein characterization and their associated database query programs to determine identity at the functional group level has been examined for proteins with low levels of homology at the gene-protein sequence level. Such theoretical data manipulations may help predict the utility of data acquired experimentally with non-sequence-dependent software for proteome analysis. Genomes of eight organisms have now been fully sequenced, and the results have been distributed within publicly accessible gene and protein databases. These databases of model organisms have been proposed as a starting point for studies of either the total proteome or the functional proteome (defined as gene product expression under specific environmental or laboratory conditions).

THE FUTURE OF MS

MS is a powerful tool for the detection and characterization of biomolecules. The greatest strength of this technology is its diversity of applications. Selecting the best tool for each application depends on the complexity of the sample, desired throughput times, and the need for sequence determination or mass measurement of an analyte. The laser desorption techniques (MALDI and SELDI) are ideally suited for high-throughput sample analysis of intact proteins. These techniques are relatively simple to perform with minimal training and can be used for global pattern analysis of complex samples. Sequence determination can be performed only with homogeneous samples. SELDI-MS occupies a niche in proteomic research as a technique that can measure m/z "fingerprints" in a specific subproteome. ESI is the most powerful tool for sequencing proteins in complex samples. This technique is well-suited to front-end fractionation, atomic-scale resolution, and subattomole sensitivity (using FTMS). One can envision using ESI for determining posttranslational modification, comparing protein dysregulation levels between samples by using isotopic labeling techniques, or quantitating absolute protein concentrations in complex mixtures. Electrospray devices are found in numerous hardware configurations that differ in operational costs (sensitivity, resolution, speed, and accuracy) and practical costs (technical know-how, instrument size, and monetary considerations).

2D DIGE

In the last few years, improvements in relative protein quantitation have been made using differential gel electrophoresis (DIGE) technology. DIGE labels two protein samples with either Cy3 or Cy5 and then separates these different protein populations on the same 2D PAGE gel. Separation on the same gel eliminates potential errors introduced from overlaying electronic images from two different gels. The stained 2D PAGE gels are converted into fluorescence-specific electronic images and analyzed by algorithms that match and compare protein expression levels from each sample. Zhou et al. utilized 2D DIGE to quantify the differences in protein expression levels between laser capture microdissection (LCM)-procured esophageal carcinoma cells and normal epithelial cells and to define cancer-specific and normal-specific protein markers (23). In addition to confirming down-regulation of annexin I, this study demonstrated up-regulation of tumor rejection antigen (gp96) in esophageal squamous cell cancer.

PROTEIN MICROARRAYS

Techniques

Protein microarrays are presently being utilized in several ways relevant to cancer research: (i) to discover novel ligands or drugs that bind to specific bait molecules on the array, (ii) to conduct multiplexed immunoassays to develop a miniature panel of serum biomarkers or cytokines, and (iii) to profile the activation state of specific members of known signal pathways and protein networks. For categories (i) and (ii), a variety of competing technologies already exist for protein discovery. For category (iii), reverse-phase protein arrays offer a robust new method of quantitatively assessing expression levels and the activation status of proteins (18). Reverse-phase arrays comprise spots containing immobilized analyte molecules. Each spot represents an individual test sample, typically consisting of solubilized proteins extracted either from a tissue section or from a pure population of cells collected by LCM. Each array represents multiple different samples. The reverse-phase array is probed with a single detection molecule, and a single analyte is measured for each spot on the array across multiple samples. This format allows multiple samples to be analyzed under the same experimental conditions for any given analyte. An analyte-specific ligand (e.g., antibody) is applied in the solution phase; bound antibodies are detected by secondary tagging. Signal amplification is critical for achieving the sensitivity required for analysis of low-abundance proteins. A reliable method capitalizes on the catalyzed reporter deposition technology developed for immunohistochemical assays. This technology is based on the enzyme-mediated deposition of biotin-tyramide conjugates at the site of a biotinylated antibody-ligand complex (CSA kit; DakoCytomation, Carpinteria, Calif.) (Fig. 3). Each array is scanned, the spot intensities are analyzed, data are normalized to the total protein level, and a standardized, single value is generated for each sample on the array. This single datum point may then be used for comparison to those of every other spot on the array. Such a data set may be used for generation of protein expression profiles across patient samples and may provide insights into the cellular signaling network for each individual patient.

Analytical Challenges

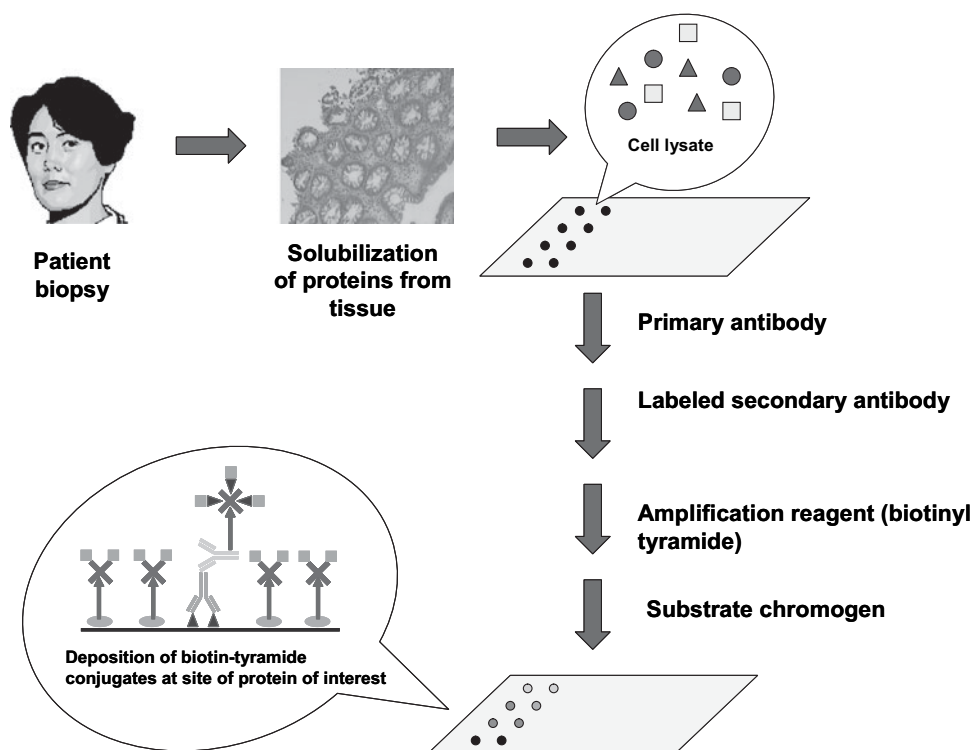
Protein microarrays pose a significant set of analytical challenges not raised by gene arrays (5, 24). The first challenge is the vast range of analyte concentrations to be detected. Protein concentrations demonstrate a broader dynamic range than mRNA concentrations (by up to a factor of 10^{10}). Furthermore, low-abundance analytes exist in a complex biological mixture containing a vast excess of contaminating proteins. If, for example, the specificity of a detection antibody is 99% but a cross-reacting protein exists in a thousandfold (or greater) excess, then for each analyte


FIGURE 3 Reverse-phase protein microarrays. Nanoliter amounts of tissue lysate are arrayed in dilution curves onto multiple nitrocellulose-coated slides. An analyte-specific ligand (e.g., antibody) is applied in solution phase; bound antibodies are detected by secondary tagging. Signal amplification is a prerequisite for achieving the sensitivity required for analysis of low-abundance proteins. A reliable method capitalizes on the catalyzed reporter deposition technology developed for clinical immunoassays. This technology is based on the enzyme-mediated deposition of biotin-tyramide conjugates at the site of a biotinylated antibody-ligand complex (CSA kit; DakoCytomation). Upon image analysis, the relative proportion of the analyte protein molecules in the total protein can be determined. Each array is scanned, spot intensities are analyzed, data are normalized to the total protein level, and a standardized, single value is generated for each sample on the array. This single datum point may then be used for comparison to those of every other spot on the array. This data set may be used for generation of network profiles across patient samples.

molecule detected, there will be 10 cross-reacting contaminating molecules detected and the signal-to-background ratio will be unacceptable. Another significant challenge for protein microarrays is the requirement for antibodies, or similar detection probes, that are specific for posttranslational modifications representing the activation state of the target protein. Presently, high-quality modification state-specific antibodies are commercially available for only a small percentage of the known proteins involved in signal networks and gene regulation. A significant challenge for cooperative groups, funding agencies, and international consortia is the generation of large, comprehensive libraries of fully characterized specific antibodies, ligands, and probes. A major initiative of the Human Proteome Organization is the production and qualification of antibody libraries that will be made available to the scientific community (9, 22).

Accuracy and precision are paramount for protein microarrays. A small shift in a signaling pathway in the protein circuitry can dramatically affect the ultimate biologic outcome. This issue is critical in pathologic states such as progression of premalignant lesions. Immunohistochemistry (and, by extension, multiplexed tissue arrays) can provide information about histomorphological and subcellular localization of proteins. However, immunohistochemistry is inherently subjective and semiquantitative at best and may not be adequately sensitive for low-abundance analytes. Variability in the intensities of immunohistochemical staining can result from variation in tissue handling and fixation practices, accessibility of the antigenic epitope based on antigen retrieval procedures, and cellular heterogeneity. In the face of these limitations, the ability to obtain a sensitive, functional proteomic analysis from a sample lysate only a few hundred micrometers in diameter and containing the solubilized cellular material itself is a promising development in cancer research and diagnostics.

Sensitivity Requirements

PCR-like direct amplification methods have not yet been developed for proteins. Consequently, protein microarrays require indirect, and very stringent, amplification chemistries (13, 17, 20). Adequate sensitivity must be achieved (at least in the femtomolar range) with acceptable background. Moreover, the labeling and amplification method must be linear and reproducible to ensure reliable quantitative analysis. Finally, the

amplification chemistry must be tolerant of the large dynamic range of the analytes and the complexity of the biologic samples. The biologic sample may naturally contain endogenous biotin, peroxidases, alkaline phosphatases, fluorescent proteins, and immunoglobulins, all of which can substantially reduce the yield or increase the background of the amplification reaction. The high sensitivity of reverse-phase protein arrays is possible in part because the detection probe (e.g., antibody) can be tagged and the signal is amplified independently from the immobilized analyte. Amplification chemistries available take advantage of methods developed for highly sensitive third-generation commercial clinical immunoassays (4, 11). For example, coupling the detection antibody with highly sensitive tyramide-based avidin-biotin signal amplification systems can yield detection sensitivities of fewer than 1,000 to 5,000 molecules/spot. Reverse-phase protein array methodology assesses only one protein per slide but has the advantage that all samples can be analyzed side by side in a single array. This is particularly advantageous for clinical samples for which protein levels across samples can be compared simultaneously under identical conditions on a single slide.

Clinical Samples

The clinical power of protein microarrays can be realized only if the technology can be directly applied to biopsy specimens, tissue cell aspirates, or body fluid samples. In such cases, the input sample for protein microarrays often is small in volume and low in analyte concentration. The total number of cells available for analysis from a core needle biopsy specimen or a cell aspirate may be fewer than 100,000. Moreover, since tissues are highly heterogeneous, the population of target cells may compose a small percentage of the total. Thus, only a few thousand cancer cells may be procurable from a core biopsy specimen. Since many proteins of interest and their phosphorylated counterparts exist in low abundance, the total concentration of analyte proteins in each sample often is low. Consequently, if the analytic method does not have adequate sensitivity, the number of cells required for the assay may not be clinically obtainable.

Sample Preparation

Sample preparation methods are critical in proteomic analysis, as some proteins are insoluble in a heterogeneous mixture of cells. An important advance in sample preparation was the development of LCM. Prior to LCM, "pure" cell populations were obtained from tissues manually. Although manual microdissection can achieve good precision, it is time-consuming and labor-intensive and requires a high degree of manual dexterity. The LCM system allows a one-step procurement of selected cells from a heterogeneous section of tissue. LCM has been used successfully to obtain pure populations of cancer cells from both frozen and paraffin-embedded tissues, stained or unstained, for molecular analysis of macromolecules. LCM is capable of isolating single cells, making it possible to procure pure populations of neoplastic cells from lesions less than 1 mm in diameter without encroachment of adjacent nonneoplastic cells. Using this technique, it has been possible to compare matched samples of normal epithelial cells, stromata, benign cells, preneoplastic cells, and cancer cells.

FUTURE DIAGNOSTIC STRATEGIES

MHC Antigens

Diagnostic strategies based on immunoproteomics exploit the natural response of the human immune system by identifying antigens associated with major histocompatibility complex (MHC) class I and class II molecules that are uniquely associated with cancer cells. These novel diagnostic tools are based on the identification of the following:

- Endogenous antigenic peptides associated with class I and II MHC molecules.
- Autoantibody-reactive proteins identified using serological analysis.
- Membrane proteins on the surfaces of diseased cells that are putative targets for novel monoclonal antibody therapeutics.

New technologies use automated, data-dependent high-throughput MS techniques to sequence all of the peptides extracted from class I and II MHC molecules on a diseased cell. Direct identification of endogenous MHC-associated peptides is very powerful because it identifies multiple shared antigens in the same tumor type from several different patients as well as antigens common to different tumor types. Novel peptide isolation, purification, and MS technologies can determine which MHC-associated peptides and surface-expressed proteins are differentially displayed on normal versus diseased cells by directly comparing the peptides or proteins from the diseased and normal tissues. Differential analysis methodology is also applied to identify autoantigens by screening serum autoantibodies in patients. The MHC-associated antigens can then be compared with information in autoantigen databases to identify diagnostic antigens. This approach, which exploits the presence of tumor-reactive antibodies present in cancer patient serum, identifies antigens that are present at very early stages of disease, before tumors are detectable by other commonly used methods, such as imaging.

Recursive Partitioning of TAAs

The sera of cancer patients contain antibodies which react with a unique group of autologous cellular antigens called tumor-associated antigens (TAAs). The low frequency of positive reactions against any individual antigen has precluded the use of autoantibodies as useful diagnostic markers. However, multiple-antigen arrays may provide accurate and valuable tools for cancer detection and diagnosis. Koziol et al. found that the use of recursive partitioning resulted in the selection of subsets of a panel of seven TAAs which differentiated between tumors and controls, and these subsets were unique to each cancer cohort (12). Recursive partitioning is a multivariate statistical methodology for constructing a decision tree. During the process of decision tree induction, questions must be asked to direct the user down the appropriate path. For instance, if each potential question could have a true or false answer, any particular node would have at most two paths leading from it to the next node(s) in the path. Every possible value of every possible feature within the training set represents a potential split in the decision tree. At each node, the data are split into two independent groups—this is referred to as partitioning. Once there are two new nodes (child nodes) linked to a previous node (the parent node), the process can be repeated for each child node independently by using only the observations present in that child—the recursive step. This initial study was based on seven selected TAAs. Panels of TAAs could be expanded to include other known TAAs such as HER-2/neu, ras, cyclins, and antigens involved in cell-mediated immune reactions, many of which might have concomitant humoral immune responses.

Plasma Telomerase as a Cancer Biomarker

A research group at the University of Maryland is using a telomeric repeat amplification protocol to evaluate the utility of measuring telomerase in body fluids for the diagnosis of malignancy and for use as a monitoring tool during therapy (10). Telomerase, an enzyme detected in approximately 90% of all tumor types, is found in elevated levels in malignant cells. This project is unique because it will assay telomerase levels in body fluids rather than cellular material. Investigators will do the following:

• Use a variety of technologies, including an automated telomeric repeat amplification protocol assay, laser-induced fluorescence detection, quantitative reverse transcription PCR, and other molecular and biochemical techniques, to measure telomerase activity in non-cellular fluids for early lung cancer detection.

• Examine a large group of patients with a variety of cancers, including malignancies of the lung, esophagus, and gastrointestinal tract, to evaluate telomerase as a biomarker for early cancer detection.

Combination Strategies for Biomarker Development

The Biomarker Development Laboratory at Moffitt uses a combination of proteomic and DNA-based technologies to evaluate biomarkers for earlier lung cancer detection. The focus of this group is to develop better detection tests for preclinical lung cancer. Some of the biomarkers under investigation include a difucosylated ceramide, lacto-N-fucopentose III, transforming growth factor β receptor type II, SMAD 2, SMAD 4, and SMAD 7. Because the existing technology for early lung cancer detection is not very sensitive, there is a need to improve the sensitivity of detection techniques and develop a screening approach that uses multiple markers. Investigators will do the following:

• Use proteomic and DNA-based strategies in pursuit of the project objectives.

• Evaluate a variety of biomarkers in archived sputum specimens from a cohort of smokers and former smokers. This archive will provide clinical material associated with known subsequent cancer outcome for a case control study of biomarker utility.

• Perform subsequent analyses on a high-throughput screening platform presently under development through a collaborative research and development agreement with an industrial partner.

CONCLUSION

In the dawning age of targeted anticancer therapeutics, the ability to accurately identify the molecular aberrations present within an individual tumor is critical in determining appropriate treatment. For patients, this will mean better management of their disease and better outcomes. Advances in the understanding of cancer biology and the development of powerful proteomic technologies are leading to the identification of many previously unknown abnormalities in preneoplastic cells and cancer cells. This progress has promoted the identification of novel biomarkers and therapeutic agents, leading to important advances in detection, diagnosis, and treatment of human cancers.

Histocompatibility Testing after Fifty Years of Transplantation

MARY S. LEFFELL

135

The year 2004 marks the 50th anniversary of the first successful renal transplant, which was performed by Drs. Murray, Merrill, and Harrison at Peter Bent Brigham Hospital in Boston (18). During the next decade, clinical transplantation was extended to liver, lung, heart, pancreas, and bone marrow transplants (2, 10, 11, 16, 28). Early attempts in human transplantation were limited by the immunosuppressive regimens which comprised primarily steroids, irradiation, and azathioprine. It is generally agreed that major advances in transplantation began with the discovery of cyclosporine (5) and its subsequent introduction in the United States after receiving Food and Drug Administration approval in 1984. Today, second- and third-generation drugs, such as tacrolimus, rapamycin, and mycophenolate mofetil, are continuing to reduce the incidence and severity of allograft rejection while permitting reduced steroid doses with a concomitant reduction in the side effects of immunosuppression. In the United States, 1-year survival rates for renal and renal-pancreatic transplants average 90% and average rates approach or exceed 80% for other solid-organ transplants (24). The development of clinical transplantation has also fostered growth in understanding of the alloimmune response and of the major histocompatibility complex and in histocompatibility assessment. The first recognition that HLA antigens could provoke alloantibodies was in 1952 when Dausset described the antigen "Mac," later to be named HLA-A2 (7). The term HLA was derived from the early studies of leukoagglutinins in the sera of multiparous women or transfused patients, combining the human-1 (Hu-1) and leukocyte antigen (LA) designations of Dausset and Payne et al., respectively (23). Some 30 years later, Bjorkman et al. defined the structural basis for normal and allo-immune antigen recognition with the crystalline structure of HLA-A2 (4). Given the remarkable advances that have occurred during the development of transplantation, it seems fitting that this anniversary was also marked by the initiation of the first collaborative clinical trial to induce human tolerance for transplantation (6).

For much of the past 50 years of transplantation, the primary assay for histocompatibility testing, which can be used both for typing and for alloantibody detection, has been the complement-dependent cytotoxicity test. In 1968, the cytotoxicity assay was miniaturized into "micro-lymphocytotoxicity," which became the standard technique for serologic typing, antibody screening, and crossmatching (19). The "Terasaki"

tray was a boon to histocompatibility, not only because it simplified testing, but also because it conserved precious typing sera by requiring only 1 μl per test well. Histocompatibility laboratories no longer rely exclusively on complement-dependent serology, since molecular techniques are available for typing and since solid-phase immunoassays, using solubilized HLA antigens and single recombinant HLA antigens, are providing more sensitive and cost-effective antibody screening and identification. Cytotoxicity still has an important role in histocompatibility laboratories as it remains the standard assay for antibody crossmatches. Today's histocompatibility laboratories, therefore, often utilize multiple techniques and have expanded their testing further to other immunogenetic systems, including the genes encoding cytokines and killer immunoglobulin-like receptors (KIR).

Molecular typing methods and solid-phase immunoassays are enabling histocompatibility laboratories to adapt testing to meet the changing needs of transplant patients. In solid-organ transplantation, the most urgent problem is the shortage of available deceased-donor organs. The number of patients on the national waiting list is over 85,000, with an average of only 20,000 donor organs available annually (29). The donor shortage has placed increased emphasis on attempts to use live donors when possible and on efforts to maximize the longevity of transplanted organs by earlier and better diagnosis of rejection. Ongoing efforts are also aimed at inducing tolerance or graft acceptance such that immunosuppression treatments, particularly steroids, can be safely reduced or withdrawn. More than one-third of renal transplant patients have the additional problem of some degree of prior sensitization to HLA antigens, manifested as circulating anti-HLA antibodies (29). Since the late 1960s, when HLA antibodies were discovered to cause hyperacute rejection of renal allografts, the presence of anti-HLA antibodies at titers sufficient to give a positive cytotoxicity crossmatch has been considered a contraindication for transplantation (14, 22, 30). Clinical protocols using high-dose intravenous immunoglobulin or a combination of intravenous immunoglobulin and plasmapheresis are being used to successfully desensitize and perform transplants on patients who otherwise might have waited years for a compatible deceased-donor organ (12, 31). Similar protocols are also being used for ABO blood group-incompatible organ transplants, and some centers are even finding compatible donors for sensitized patients through paired exchanges of

living-donor organs (8). Laboratory support for these innovative clinical protocols is vital and is highly dependent upon the accurate assessment of the levels and specificities of patients' antibodies. Three of the chapters in this section focus on the methods that are being used to monitor and evaluate transplant patients. Reinsmoen and Zeevi discuss approaches to evaluate cellular sensitization that can be employed in steroid withdrawal protocols and post-transplant monitoring for rejection or tolerance. Hartono et al. describe molecular techniques that permit earlier and more-sensitive detection of allograft rejection, and Zachary and colleagues compare the various techniques for defining clinically relevant alloantibodies and illustrate the utility of these assays in clinical desensitization protocols.

The availability of suitable donors is also problematic for many patients who are candidates for bone marrow transplantation or hematopoietic stem cell transplantation (HSCT). The ideal donor for HSCT is an HLA-identical sibling, but at most only 30% of patients have suitable related donors. Efforts to increase the number of available donors have fostered altruistic donor registries, with more than 50 such registries worldwide. One of the largest registries is that of the National Marrow Donor Program (NMDP), which presently lists more than 5 million typed potential marrow and peripheral blood stem cell donors and has more than 30,000 cord blood units (20). The increasing use of registry donors has permitted a recent retrospective analysis of the impact of HLA matching among 1,874 recipients of unrelated-donor HSCT (9). Mismatches at the antigen or low-resolution level, not surprisingly, had greater impact on patient survival and the risk of graft-versus-host disease than did mismatches at the allele level. Importantly, mismatches at HLA-C were found to confer a level of risk similar to those conferred by mismatches at HLA-A, HLA-B, and DRB1; therefore, NMDP recommendations for evaluating unrelated donors now include allele-level typing for HLA-C. The NMDP analysis also highlighted the reduced likelihood of finding "perfect" matches (i.e., those in which the recipient and donor match for both alleles at HLA-A, HLA-B, HLA-C, and DRB1) when typing resolution is increased from the antigen to the allele level. Of the study pairs that were matched for HLA-A, HLA-B, HLA-C, and DRB1 at low resolution, 34% had one or more mismatches as determined by high-resolution typing (9).

In practice, HLA polymorphism reduces the probability of finding perfectly matched unrelated donors unless the candidate has HLA alleles and haplotypes that are relatively common. Consequently, newer HSCT protocols permit certain degrees of HLA mismatching. This includes the use of one-haplotype-matched related donors and one- or two-allele-mismatched unrelated donors. Stem cells from one-haplotype-matched donors can be given as "mini" transplants under protocols that use nonmyeloablative conditioning regimens. Nonmyeloablative conditioning using reduced doses of cytotoxic drugs and other chemotherapy permits transplantation in older patients who cannot tolerate doses for complete ablation (17, 27). Alternative sources of stem cells include cord blood and peripheral blood following mobilization with growth factors (1, 3). Peripheral blood stem cells may be used not only for primary transplantation but also for additional immunotherapy via a secondary infusion to promote the "graft-versus-leukemia" effect (26). Investigations are also under way to determine if mismatching for certain KIR genes can potentiate the anti-cancer effect mediated by natural killer cells (15, 25). These

newer HSCT protocols are requiring additional testing from histocompatibility and cytogenetic laboratories. High-resolution definition of HLA alleles is essential for selection of compatible unrelated donors for HSCT. Evaluation of the degree of donor chimerism is needed in the protocols that result in mixed populations of self- and donor-derived leukocytes in transplant recipients and in assessments to determine when secondary infusions of donor cells may be warranted. For transplants with some degree of HLA mismatching, accurate determination of humoral sensitization is required to assess the risk of engraftment failure due to antibody-mediated rejection. The remaining chapters in this section address these newer issues for bone marrow and stem cell transplantation. The chapter by Hurley and colleagues explains the premises behind the different molecular techniques that can be used to differentiate HLA alleles and how to apply one or more of these methods to achieve the degree of typing resolution required for a given clinical application. Baxter-Lowe discusses the techniques that can be employed to determine both engraftment of donor stem cells and the relative degree of donor-recipient chimerism. Lastly, Tyan and Carrington focus on the polymorphism of the KIR genes and report that defining KIR alleles and haplotypes is applicable not only in HSCT, as KIR genotypes may affect susceptibility to autoimmunity and viral infections (13, 21).

INTRODUCTION AND BACKGROUND

A Comparison of HLA Typing Methods

Molecular biology techniques aimed at identification of HLA polymorphism at the gene level have largely replaced HLA typing assays based on identification of HLA proteins (15). Both DNA-based testing and serology are used to evaluate differences found in key HLA protein regions (antigen binding domains) that are known to have significant biologic relevance in modulating the immune system. This evaluation is performed either directly by using human alloantiserum-based assays to define key epitopes within these HLA proteins or by evaluating the sequences of the corresponding DNA regions coding for this portion of the HLA molecule. The advantages of DNA-based testing over the longer-established protein-based assays are summarized in Table 1 and in previous publications (1, 13, 14, 16, 18). Most of the DNA-based assays rely on PCR to amplify the HLA genes and the detection of nucleotide sequence differences among HLA alleles to predict HLA types.

HLA Genes

The HLA genes encode at least six different HLA molecules, HLA-A, -B, and -C (class I molecules) and HLA-DR, -DQ, and -DP (class II molecules). (Note that other HLA genes such as the HLA-G gene are not yet included in HLA typing schemes since their importance in transplantation is not yet known.) The HLA molecules are encoded by the most polymorphic genetic loci known in humans (21). The genes (or loci) encoding one chain of the HLA class I molecules (the heavy chain) and both chains (alpha and beta) of the HLA class II molecules are clustered in one region of human chromosome 6, termed the major histocompatibility complex. The products of the A, B, and C loci associate with the product of the β_2-microglobulin locus to form the class I molecules. The products of alpha (A) and beta (B) loci of DR, DQ, and DP associate with one another to form the class II molecules. For example, the product of the DQB1 locus, the DQ beta chain, associates with the product of the DQA1 locus, the DQ alpha chain, to form a DQ molecule. Other class II A and B gene pairs that may be identified in HLA typing include: DPA1 and DPB1 (specifying a DP molecule), DRA and DRB1 (specifying a DR molecule), DRA and DRB3 (specifying a DR52 molecule), DRA and DRB4 (specifying a DR53 molecule), and DRA and DRB5 (specifying a DR2-like molecule [DR51]).

The numbers that often follow A and B (e.g., DQA1 and DRB3) were added to distinguish these genes from other class II A- and B-like genes in the DNA of the cell. Individuals carry either one or two different functional DRB loci on chromosome 6. Most versions of chromosome 6 found in the population carry the DRB1 locus. Some versions of chromosome 6 also carry a DRB3 or DRB4 or DRB5 locus. Thus, some individuals express two DR molecules encoded by a single copy of chromosome 6 (e.g., carrying DRB1 and DRB5 loci) or, potentially, four DR molecules in all (e.g., encoded by DRB1 and DRB5 loci on one copy of chromosome 6 and by DRB1 and DRB4 on the second copy of chromosome 6).

At the DNA level, the HLA loci have multiple alternate forms (alleles). β_2-Microglobulin is not polymorphic. New alleles are described in reports of the World Health Organization (WHO) HLA nomenclature committee (e.g., reference 11), and a summary appears on a website (http://www.anthonynolan.org.uk/HIG/index.html) (22). The total number of alleles present in the entire human population at each locus differs. For example, more than 360 alleles at the DRB1 locus have been described but only 3 alleles at the DRA locus have been described. Thus, each individual carries a limited set of HLA alleles (e.g., two HLA-A locus alleles, two HLA-B locus alleles, and two HLA-C locus alleles, etc.) while the entire population carries a very diverse and extensive collection of HLA alleles. Because many HLA alleles exist in the population, most outbred individuals carry two different alleles at a locus and are heterozygous. Individuals who carry two identical alleles at a locus are homozygous for that locus. The frequencies of individual alleles vary in different human populations (3).

Within each HLA gene, the polymorphism is clustered into one or two of the approximately six to eight expressed gene segments (exons). In the HLA class I alleles, the majority of the differences among alleles are found in exons 2 and 3; in the HLA class II alleles, the majority of the differences are found in exon 2. DNA-based HLA typing focuses on these polymorphic exons to identify HLA alleles.

HLA Nomenclature

Each HLA allele is designated by the name of the gene followed by an asterisk and a four- to eight-digit number indicating the allele (11; http://www.anthonynolan.org.uk/HIG/index.html). For example, DPB1*010101 is an allele of the

TABLE 1 Comparison of HLA typing methods

Assay parameters	DNA-based molecular assays	Protein-based[a] assays	
		Serology	Cellular assays[b]
Type(s) of assay	SSP, SSOPH, RSCA, SBT, other	Complement-dependent cellular cytotoxicity assay	Mixed lymphocyte culture, primed lymphocyte typing
Sample and quantity	Nucleated cells, e.g., <1 ml of whole blood	Peripheral blood lymphocytes isolated from 5 to 10 ml of blood	Peripheral blood lymphocytes isolated from 10 to 50 ml of blood
Sample limitations	Viable cells not required	Viable cells required; other limitations dependent on patient health, treatment	Viable cells required; other limitations dependent on patient health, treatment
Reagent(s)	Synthetic oligonucleotides	Human alloantisera, some monoclonal antibodies	Lymphocytes or lymphocytes primed in culture
Reagent specificity and resolution	DNA polymorphisms detected based on known alleles; reagents can be developed as new alleles are described; resolution adjustable depending on reagents and techniques used; not known which polymorphisms are relevant for transplantation outcome	Based on sensitization of serum donor; reagent usually reacts with multiple allelic products; difficult to identify reagents for new specificities; reagents derived during sensitization in vivo so may detect biologically relevant differences	Very sensitive to HLA differences; cultured cells may lose specificity; reagents derived during sensitization in vivo so may detect biologically relevant differences
Reagent availability	Unlimited source with defined specificity	Reagents derived from humans so source limited and varied over time	Reagents derived from humans so source limited and varied over time; difficult to generate and maintain cellular reagents
Commercial kit availability	Available	Available	Not available
Time to complete assay[c]	4 h to 3 days depending on the resolution required	1 day	7 to 8 days

[a]Other protein-based assays used in the past but difficult to apply clinically include isoelectric focusing and two-dimensional gel electrophoresis.

[b]Cellular assays are used to identify HLA types and to measure the level of T-cell reactivity to HLA differences between two individuals. Chapter 138, this volume, will cover the latter in more detail.

[c]Single sample.

HLA-DPB1 gene, DQB1*0304 is an allele of the HLA-DQB1 gene, and B*2701 is an allele of the HLA-B gene. The first two numbers in the numerical designation of each allele are based on similarity to other alleles and sometimes on the serologic type of the resultant protein molecule. For example, the HLA-A molecule expressed by the A*02010101 allele bears the A2 serological specificity defining the HLA-A2 molecule (or antigen). The A*0226 allele has a DNA sequence similar to those of alleles specifying molecules bearing the A2 serological specificity; however, the HLA-A molecule specified by A*0226 has not been characterized using serology and so no information is available on its serologic specificity (25). The second example illustrates an allele whose name is based on its similarity to other alleles, in this case, similarity to A*02010101, A*0202, A*0203, and so forth. New alleles which appear significantly different in nucleotide sequence from previously described alleles may receive a unique WHO assignment for the first two digits of their names. Thus, B*8101, whose product was frequently serologically typed as B7, received a unique designation setting it apart from the B*07 allele family (5). The third and fourth digits in an allele designation refer to the order in which the allele was discovered. For example, DRB1*030101 was the first DRB1*03 allele to be discovered and DRB1*030201 was the second.

Some combinations of alleles share the first four digits of a six-digit designation (e.g., DRB1*110101 and DRB1*110102). The digits indicate that the two alleles differ in DNA sequence but that the HLA proteins specified by the two alleles do not differ (i.e., they differ by silent or synonymous substitutions). Some combinations of alleles are identified by eight-digit designations (e.g., DRB4*01030101 and DRB4*01030102). These alleles differ in DNA sequence only outside of their protein-encoding sequences. In some cases, these differences may affect the expression of the alleles. In the case of DRB4*0103102, the allele is not expressed due to a defect in an mRNA splice site. The addition of an "N" indicates the presence of an allele which is not expressed as a normal HLA protein at the cell surface . The N may not always be included but is implied (i.e., DRB4*01030102N = DRB4*01030102). Other letters indicate HLA products that might be secreted (B*44020102S) or expressed at a low level (A*24020102L).

Different HLA alleles defined by DNA typing can specify HLA proteins which are indistinguishable by methods based on protein identification, such as serology (25). For example, an individual carrying the B*070201 allele would be found to have the same serologic type (B7) as an individual carrying the B*0705 allele. Because serologic reagents specific enough to define this subdivision (or "split") are not available, serology cannot distinguish between the two proteins specified by the two alleles B*070201 and B*0705. There are many other examples of alleles defined using DNA typing which cannot be individually identified using protein-based typing methods.

Resolution of Molecular Typing Protocols

Based upon the level of information needed, the DNA-based strategy may focus just on regions of exons 2 and/or 3 that are highly polymorphic or the strategy may also include the evaluation of additional, less common polymorphisms located within rather conserved regions of these exons to obtain a greater level of DNA sequence information (resolution). A multistep approach is often used to identify HLA alleles by DNA-based typing. For this reason, HLA assignments (i.e., types) defined by DNA-based typing may be reported at different levels of resolution: low-resolution (or generic or serologic)-level DNA-based typing produces a result which is similar in appearance and detail to a serologic type. For example, a DNA-defined type, DRB1*04, is the approximate equivalent of the serologic type DR4. At this level of resolution, it is not possible to determine without further testing which of the over fifty DRB1*04 alleles described in the current WHO nomenclature report (e.g., DRB1*0401, DRB1*0402, and DRB1*0403, etc.) is carried by the individual being tested. Intermediate-resolution-level DNA-based typing may narrow down the choices by listing several different possibilities for the type carried by an individual, for example, DRB1*0404 and DRB1*0410. Due to the complexity of the typing system and the frequent need to enter typing information into a database, codes for multiple allele alternatives are sometimes used to express these various possibilities for the types carried by an individual. For example, the possibility DRB1*0404 or DRB1*0410 is expressed as DRB1*04HT in the National Marrow Donor Program database, where HT indicates the 04 or 10 allele combination (codes are listed at http://www.nmdpresearch.org). The letter codes are used to help hematopoietic stem cell transplantation centers identify the most closely matched individuals from a file of more than eight million volunteer donors (9). Additional DNA-based typing is then performed to find the closest match. Allele level resolution DNA-based typing identifies the specific allele carried by an individual (e.g., DRB1*0410).

One caution in interpreting DNA-based typing results is that a type is often defined by a pattern of reactivity of a panel of reagents. DNA sequence differences lying outside of the regions of the gene tested will not be detected (7). Thus, the assignment of a particular type, e.g., DRB1*0410, actually means that the pattern of reagent reactivity is consistent with that particular allele and that only DRB1*0410 is known to exhibit that pattern of reactivity at the time that the typing is carried out. If another allele exists with that same pattern and that second allele has not yet been characterized at the time of the typing, that allele will be missed. In addition, since some typing strategies analyze a mixture of two alleles at a locus, the polymorphisms detected by the typing reagents may be shared by two or more allele combinations. These "ambiguous" combinations are listed on the HLA nomenclature website (http://www.anthonynolan.org.uk/HIG/index.html).

The level of resolution obtained by DNA-typing methods is controlled by the choice of typing protocols. In the widely used sequence-specific priming (SSP) and sequence-specific oligonucleotide probe hybridization (SSOPH) protocols, the level of resolution is controlled by the number of oligonucleotide primers and/or probes used in the assay. This number may depend on the purpose of the typing, the time available for carrying out the typing, the cost of the typing, and the expertise of the laboratory. For example, typing of a cadaveric kidney donor requires results to be obtained in 3 to 6 h. Most DNA-based typing methods can produce a typing result within this time frame; however, the level of resolution obtained in that time will be limited. In the case of solid-organ transplantation, low- to intermediate-resolution assays satisfy the National Organ Procurement and Transplantation Network requirements for antigen level matching.

In the design of an unrelated marrow donor registry, like the one developed by the National Marrow Donor Program, the resolution of donor HLA typing is determined by balancing the need for accurate, cost-effective, high-volume HLA typing in order to provide a sufficiently large registry of HLA types and the desire to provide the maximum HLA information possible to assist a transplant center carrying out a patient search in identifying potentially HLA-matched donors. The low-intermediate level of resolution of HLA typing used for donor recruitment typing effectively allows transplant centers to identify a few potentially matched donors, who may then undergo more-extensive, higher-resolution HLA typing in order to identify the optimally matched unrelated donor for the patient.

It is also important to realize that the decisions made concerning the resolution of the HLA typing of the patient, which will be used to search a registry of unrelated hematopoietic stem cell donors, are also extremely important in the overall outcome of the search process. The results of numerous studies have shown that initially typing the patient at the highest resolution possible creates the best foundation for the search process. The transplant center is thus faced with similar challenges, primarily, the costs of high-resolution typing and the time required to perform this level of typing. Overall, this high-resolution-typing approach will allow an evaluation of the difficulty of the search, will increase the effectiveness of the donor selection process, and finally will allow better matching, which together will result in better transplant outcomes and fewer complications (8).

Correlation of DNA-Based and Serologic Typing

The nomenclature used to assign DNA-based HLA types is based on that used in serology; however, there are many examples in which the assignments applied to an allele and to its product appear to differ from each other. These differences are often the result of the complex nature of serologic testing and the nomenclature system used to assign allele names. A more detailed discussion of this topic has been published previously (25). The National Organ Procurement and Transplantation Network, which is operated under contract by the United Network for Organ Sharing, maintains a list of serology equivalents for molecular types for solid-organ transplantation. The United Network for Organ Sharing list for both alleles and serologic splits can be found at http://www.unos.org/PoliciesandBylaws/policies/ in Policy 3A.

TECHNOLOGY AND INSTRUMENTATION

One common method of DNA-based typing utilizes a panel of sequence-specific oligonucleotide primers in multiple PCRs to define HLA alleles by the presence or absence of amplification. At least one member of each primer pair is designed to bind to a specific polymorphic sequence in the HLA gene being characterized. A second common method of typing utilizes PCR to amplify all alleles at a specific HLA locus. The amplified DNA is denatured and hybridized to a panel of synthetic oligonucleotide probes to identify HLA alleles. This method of typing is termed SSOPH. Comparison of the polymorphic sequences present and absent as detected by the reagents with the sequences of known alleles is used to identify the alleles that might be present (Fig. 1). Still other DNA-based methods in more

FIGURE 1 DRB1 nucleotide sequences from a few DRB1 alleles. Dashes indicate identity with the sequence of DRB1*0101. The numbers indicate the codons. Only part of the sequence of the DRB1 gene is shown; the polymorphic exon 2 includes codons 5 through 95. Probes identifying polymorphic sequences distinguishing these alleles are boxed.

limited use rely on electrophoresis of DNA strands (heteroduplex analysis, reference strand-mediated conformational analysis [RSCA], and sequence-specific conformational polymorphism) or DNA sequencing (sequence-based typing [SBT]) to identify HLA alleles. The following sections describe the many commercial kits used for DNA preparation and HLA typing and provide a protocol for DNA sequencing. References describing all DNA-based typing methods are found in Tables 2 through 5.

QA AND QC

Extensive guidelines for quality control (QC) and quality assurance (QA) related to all stages of DNA-based HLA testing are described in the American Society for Histocompatibility and Immunogenetics (ASHI) standards for HLA testing (http://www.ashi-hla.org/) and in the ASHI *Laboratory Manual* (10). ASHI, the European Federation for Immunogenetics, and other organizations have standards for DNA-based HLA typing and an accreditation process. Additional ASHI guidelines apply for laboratories performing high-volume (>50,000 tests per year) HLA testing. These include duplicate typing of a subset of the samples tested, use of enhanced sample-tracking mechanisms, and implementation of QC measures for automated procedures and equipment. Proficiency testing samples can be obtained from the College of American Pathologists, the UCLA International Cell Exchange, the Southeast Organ Procurement Foundation, and ASHI.

TEST VALIDATION

HLA typing assays are validated by testing a panel of cells with known HLA alleles. DNA from HLA-characterized reference cells is usually derived from Epstein-Barr virus-transformed B lymphoblastoid cell lines. Such reference cells are available from cell repositories (e.g., the 13th International Histocompatibility Workshop repository [http://www.ihwg.org] and the National Marrow Donor Program [http://www.nmdpresearch.org]). The panel should be large enough to include cells carrying alleles commonly found in the population undergoing routine testing. Typing should also include DNA prepared from sample types (e.g., whole blood) which will be tested in the laboratory. These samples might be tested through parallel testing with a well-established HLA typing laboratory.

COST ASSESSMENT

HLA typing is used primarily to identify histocompatible organ and hematopoietic stem cell donors (6, 20), but it is also used for identification of those at risk for HLA-associated autoimmune diseases (17), for identification of potential responders to peptide-based vaccines (26), and for paternity testing. All of the HLA testing assays described herein require DNA preparation and PCR amplification. The choice of a testing method (i.e., SSP versus SSOPH versus RSCA versus SBT) and selection of a commercial kit will depend on (i) the number of samples to be typed; (ii) the expertise of the laboratory; (iii) the speed, efficiency, cost, and reliability of the method or kit; (iv) the HLA loci to be identified and the resolution required at each locus; and (v) the QA and QC required.

INTERPRETATION

Interpretation of the assays should yield HLA assignments indicating the presence of one or two alleles at a locus for

[a]This list is not comprehensive.

each cell. If assays include more than one reagent to define an HLA type, the results must be consistent. Software for data interpretation should be used because of the complexity of the HLA system and should be updated to include the most recently described HLA alleles. The most current and accurate information can be obtained from the HLA nomenclature website (http://www.ebi.ac.uk/imgt/hla/download.html) (22). If a single allele is observed at a locus (i.e., the sample appears to be homozygous for the gene), the amplification results should be reviewed for potential failure to amplify one of the alleles. HLA assignments should be reviewed by an expert to evaluate the frequency of the assigned alleles in the population tested and common associations between alleles at several loci to determine if the result makes sense based on knowledge of the HLA system. All alternative assignments must be listed on the assay report form.

The continuous discovery of new alleles at every HLA locus requires continual updates of the typing strategy and the addition of new reagents or the use of additional assays to achieve the desired resolution. Typing systems may yield ambiguous typing results for certain allele combinations (Fig. 2). In these situations, the typing system does not distinguish among alternative allele combinations; for example, the same DNA sequence of a mixture of two alleles may be interpreted as DRB1*1101, DRB1*1301, or DRB1*1102, and DRB1*1109. In this case, the alternative allele combinations carry the same polymorphisms but the *cis* and *trans* associations of the polymorphic residues differ (i.e., which polymorphisms are located on one copy of chromosome 6 [*cis* association] and which polymorphisms are located on different copies of chromosome 6 [*trans* association]). To resolve this issue, an amplification strategy aimed at amplifying a single allele of the heterozygote for sequencing is required. Alternative typing strategies such as RSCA can also be applied to resolve the typing results to a single combination of two alleles. In some cases, the polymorphism that distinguishes two or more alleles lies outside of the commonly tested exons (e.g., the distinction between A*0101 and A*0104N lies outside of exons 2 and 3, in exon 4). A list of the alleles with these types of differences is provided on the WHO HLA nomenclature website (http://anthonynolan.org/uk/HIG/index.html).

PREPARATION OF DNA

Molecular biology-based HLA typing methods utilize DNA as a starting material. DNA can be prepared from any source of nucleated cells, although whole blood is the usual source of samples. Further isolation of the buffy coat component of blood containing leukocytes and platelets without heme-containing red blood cells yields more DNA at a higher concentration and removes a PCR inhibitor (heme). Protocols for DNA extraction begin with lysis of cells by using detergents and release of DNA from associated proteins. DNA is isolated in one of several ways. DNA can be precipitated from the solution with ethanol, and the dry pellet can be dissolved with sterile water. Alternatively, the DNA can be centrifuged through a solid-phase column that binds the DNA and the DNA is eluted in a subsequent step with a suitable buffer. Another purification protocol involves the addition of solid-phase modified magnetic particles to capture the DNA. The use of magnetic particles allows the use of manual or robotic manipulation based on magnetic separation, filtration, or purification.

Selection of a DNA preparation method or kit should depend on (i) the type of specimen (e.g., whole blood, blood spotted onto filter paper cards, and swabs of epithelial cells) that is regularly processed in the laboratory; (ii) the ability to obtain PCR-amplifiable DNA from the specimen; (iii) the speed, efficiency, and cost of the method; (iv) the number of samples that need to be processed; and (v) the requirement for long-term storage of DNA.

Sample Requirements

Whole blood treated with acid citrate dextrose is the recommended sample. Blood drawn in anticoagulants containing heparin is not recommended since heparin can interfere with the subsequent gene amplification step. Other sample sources include clotted whole blood, buffy coat cells, frozen white blood cell pellets, cryopreserved lymphocytes, lymphoblastoid cell lines, and blood dried on specially treated paper cards. For the latter, IsoCode cards (Schleicher & Schuell Bioscience, Keene, N.H.), FTA cards (Whatman Inc., Clifton, N.J.), Generation capture cards (Gentra

[a]This list is not comprehensive.

procedure (10) or with procedures especially designed for the sample type (manufacturers' protocols).

Materials and Reagents

A number of methods and commercial kits are available for the preparation of DNA (Table 6). Reagents required are listed in the manufacturer's protocol for each kit. Water for all protocols is distilled and deionized (ddH$_2$O) unless otherwise specified.

Equipment and Instrumentation

Most of the procedures are carried out in a laminar flow hood. Dedicated pipettors, sterile pipette tips with an aerosol barrier, and sterile tubes or plates are used. Equipment required for all protocols includes a microcentrifuge capable of $12,000 \times g$, a Vortex mixer, an adjustable water bath or heat block that reaches 65 to 70°C, and an ice bucket or benchtop cooler. For work in the laboratory, a suitable lab coat, disposable gloves, and protective goggles should be worn.

DNA Preparation Procedure

All procedures are carried out in a laminar flow hood by using an aseptic technique. Precautions should be taken in

FIGURE 2 Example of two heterozygous allele combinations that cannot be distinguished from one another when both HLA-A alleles are characterized as a heterozygous mixture (i.e., ambiguous combinations). Some of the polymorphic nucleotides that distinguish the alleles and their *cis* and *trans* associations are diagrammed in the figure. The heterozygous combination A*02010101 and A*6601 (ambiguous combination 1) cannot be distinguished from the alternative, A*023501 and A*2603 (ambiguous combination 2), unless a single allele is isolated and characterized. Identification of the alleles present relies on the laboratory's ability to link the first polymorphic sequence (located at codons 9-10, TTC ACA) to one of the two alternative second polymorphisms (CAC or CAG at codon 70). If CAC is in *cis* (i.e., found on the same DNA strand) with TTC ACA, then the first ambiguous combination is present.

working with potentially infectious human material. Instructions for each kit are provided by the manufacturer. If purified DNA is to be stored up to 24 h, storage at 2 to 8°C is recommended. For storage for longer than 24 h, the DNA should be dissolved in buffer (10 mM TrisCl, 0.5 mM EDTA [pH 9.0]) and stored in aliquots at −70°C. Since DNA degrades, only the amount of DNA required for the assay should be prepared at any one time. If the Tris-EDTA buffer is not compatible with subsequent applications, DNA may be dissolved in water at pH 7.0. Water with an acid pH may result in DNA degradation.

The work area should be separate from work areas exposed to PCR-amplified DNA. Appropriate precautions must be taken to avoid contamination of samples with previously amplified DNA. The dedication of an isolated work area with a laminar flow hood and dedicated equipment and reagents is recommended. For laboratories doing large-volume testing, a dedicated room with restricted access is recommended.

If whole-blood samples are not processed immediately, it is recommended that they be held at room temperature in the original sterile container. If processing is delayed, it is recommended that the samples be distributed into 0.5- to 1-ml aliquots and frozen at −70°C. Blood samples older than 1 week (stored at 4°C) may produce poor yields and/or poor-quality DNA. Blood can be frozen for at least 1 year to provide a long-term supply of DNA. An advantage of using blood spotted onto cards is the long-term stability of the sample and the ease of storage and shipping. A disadvantage, depending on the type of card, is that the extraction of DNA may be more difficult than that from a fresh blood sample.

Yield is dependent on the white cell count of the sample. For samples with known low counts ($<$ 3,000 white blood cells/mm^3), the buffy coat should be isolated. When the sample yields a small cell pellet or a small amount of DNA, amplification may fail due to insufficient DNA. If a cell pellet is brown or green, the PCR failure rate is high, likely due to the contamination with hemoglobin and/or poor proteolytic digestion. If a DNA pellet is isolated, the pellet should not be overdried as it becomes difficult to dissolve. Unbuffered DNA in storage is subject to degradation resulting from low pH as well as from the presence of nucleases. DNA preparation protocols differ in the purity of the prepared DNA and therefore in its stability under long-term storage.

QA and QC

The quality of the DNA is monitored by its ability to be amplified in the PCR as judged by the appearance of an ethidium bromide-stained band of amplified DNA of appropriate size

TABLE 6 Kits for the isolation of DNA

Company, location	Name of kit(s)	Specimen(s) required	Basic process or system
Qiagen, Valencia, Calif.	QIAmp DNA MINI kit	Whole blood, plasma, serum, buffy coat, body fluids, lymphocytes, tissues, swabs, dried blood spots, or cultured cells	Spin column
Pel-Freez Clinical Systems, LLC, Brown Deer, Wis.	DNA isolation kit	Whole blood or buffy coat	DNA precipitation
Gentra, Minneapolis, Minn.	Puregene; GENERATION capture cards	Whole blood or bone marrow; dried blood spots on cards	Elution of DNA or amplification from the immobilized DNA
Eppendorf, Hamburg, Germany	Perfect gDNA blood mini kit	Whole blood or buffy coat	Spin column
Promega, Madison, Wis.	MagneSil blood genomic max yield system	Whole blood or buccal swabs	Paramagnetic particles
	Ready Amp genomic DNA purification system; Wizard SV genomic DNA purification	Whole blood or blood stains; cultured cells or tissues	Resin-based system; spin column
AutoGEN, Holliston, Mass.	AutoGenprep 965 (high-throughput DNA extraction in a 96-well format [automated])	Whole blood	DNA precipitation
Omega, Doraville, Ga.	ENZA blood DNA kit	Whole blood, buffy coat, or specimens on filter paper	HiBind spin column

on an agarose gel. The purity of DNA can also be monitored by taking the ratio of the absorbance at the 260-nm wavelength (measuring primarily DNA) to that at the 280-nm wavelength (measuring protein) by using a spectrophotometer. Values in the range of 1.7 to 1.9 are optimal.

AMPLIFICATION OF HLA GENES

PCR is used to generate a large number of copies of an HLA gene for rapid detection of HLA types. PCR uses sequence-specific primer pairs (a 5′ [sense] primer and a 3′ [antisense] primer) and *Taq* polymerase to specifically amplify selected segments of DNA. By using two oligonucleotide primers that hybridize to opposite DNA strands and that flank the region of interest in the target DNA, a specific DNA sequence is enzymatically synthesized. If the protocol is followed by further analysis of the amplicon by hybridization, the amplification also serves to reduce nonspecific hybridization of oligonucleotide probes.

Primers are designed to amplify specifically all alleles at a locus or a subset of alleles. For class I typing, primers usually flank the most polymorphic exons, 2 and 3. For class II typing, primers usually flank polymorphic exon 2. The design of primers is based on sequence alignments of the HLA alleles published and available on the Internet (http://www.anthonynolan.org.uk/HIG/index.html) (22). When primers are designed to selectively amplify a group of alleles, the region of polymorphism used to discriminate alleles is positioned at the 3′ end of the oligonucleotide primer to eliminate the amplification of mismatched alleles. The length and sequence of the oligonucleotide primer will determine the specificity and hybridization conditions in the PCR. Most HLA typing utilizes oligonucleotide primers that are approximately 21 nucleotides in length.

Genomic DNA is denatured at 94 to 96°C. Synthetic oligonucleotide primers anneal to denatured DNA at temperatures selected to provide specific amplification.

Taq polymerase adds nucleotides onto the primers copying the DNA strands at 72°C. Repetition of the cycle of denaturation, annealing, and extension generates billions of copies of the selected DNA with termini defined by the 5′ ends of the primers. DNA can be labeled during amplification when the PCR is conducted using primers which are labeled (e.g., with biotin). Amplified DNA is detected by staining with ethidium bromide following electrophoresis on an agarose gel. Alternatively, the quantification of PCR products can be performed with a fluorescent DNA dye, PicoGreen, that is intercalated into double-stranded DNA but does not bind to single-stranded DNA or RNA.

Sample Requirements

DNA is prepared as described above. Usually, 2 to 10 μl of DNA is required for each 20- to 100-μl PCR mixture (200 to 500 ng of DNA/reaction).

Materials and Reagents

The key materials and reagents needed include PCR tubes or Microamp trays (ISC BioExpress, Kaysville, Utah), PCR buffer, $MgCl_2$, primers, deoxynucleoside triphosphates (dNTPs), and *Taq* polymerase. The PCR buffer often is provided with the enzyme. Commercial HLA typing kits are available which include reagents for amplification of genomic DNA. PicoGreen can be purchased from Molecular Probes, Inc., Eugene, Oreg.

Equipment and Instrumentation

A laminar flow hood or pre-PCR room which is isolated from the post-PCR area, a thermal cycler, a 37°C heat block, a Vortex mixer, and a microcentrifuge are needed.

Amplification Procedure

The amplification reaction mixture is prepared in a laminar flow hood or pre-PCR room by using an aseptic technique. Amplification and gel electrophoresis are carried out in an area separate from the preamplification area.

Briefly, the PCR reaction mix (without genomic DNA) is prepared according to manufacturers' recommendations, the mix is aliquoted into PCR tubes, and then DNA is added into each tube. Alternatively, DNA may be aliquoted into PCR tubes first and then PCR mix added. Precautions should be used when pipetting to avoid contamination. The manufacturer's instructions should be followed if a commercial kit is used. The amplified DNA can be stored at 4°C for a brief period of time. Amplification is detected by gel electrophoresis or by PicoGreen staining (Invitrogen, Carlsbad, Calif., vendor protocol).

The sample identification should be carefully checked to avoid sample switches. When a Microamp tray is used, precautions should be taken to label the tray orientation to avoid sample switches. Care must be taken to avoid contamination of samples and reagents with amplified DNA. Precautions include (i) physical separation of preamplification steps from amplification and postamplification steps, (ii) aliquoting of reagents so that an aliquot will be used up in a single assay, (iii) limitation of the number of PCR cycles used to amplify an HLA gene (<35 cycles), and (iv) use of wipe tests to monitor contamination of laboratory benches and equipment. Care must be taken in handling and storage of the DNA polymerase to avoid loss of activity and to avoid inaccuracies in measurement of the enzyme. Because DNA settles at the bottom of the tube, care must be taken to shake the tube to thoroughly mix the DNA with the enzyme. The PCR mix may evaporate during amplification if the tube is not tightly sealed. Nonspecific amplification or amplification failure may result from suboptimal amplification conditions. These may include an inadequate (in amount or purity) DNA template, incorrect primer concentration, suboptimal magnesium concentration, an annealing temperature that results in nonspecific amplification (temperature is too low) or no amplification (temperature is too high), suboptimal annealing and extension times, inadequate denaturation of the template, or mismatches of the primer to the DNA template. The thermal cycler should be carefully monitored to ensure correct temperature cycling. Oligonucleotides used as primers should be aliquoted into small volumes for storage since multiple freeze-thaw cycles can result in loss of primer specificity.

QA and QC

Controls to monitor and detect contamination with amplified DNA should be included in the assay. These should include tubes which contain all of the PCR reagents except DNA which are carried through the amplification cycles and analyzed by gel electrophoresis or DNA quantification and probe hybridization. Nonspecific amplification can be monitored by the use of reference DNA containing alleles which should be amplified or not amplified by specific primer sets. Equipment, such as thermal cyclers, must be calibrated periodically.

Interpretation

A discrete band of the expected size should be visible under UV light following gel electrophoresis. Additional bands indicate nonspecific amplification. The faster-migrating primers will also stain with ethidium bromide and should not be confused with the amplified DNA. When the PicoGreen method is used, an acceptable reading range should be met for successful amplification and the negative control should be below the preset acceptable reading.

AMPLIFICATION OF HLA GENES FOR HLA TYPING—SSP

In some cases, the goal of the PCR is to define which alleles might be carried by an individual by the presence or absence of amplification (termed SSP) (Table 2). A panel of primer pairs, each amplifying a subset of alleles, is used to narrow down the possible HLA alleles carried by an individual. Many of the concepts are described above under "Amplification of HLA Genes."

Materials and Reagents

A number of commercial kits are available for HLA typing by SSP (Table 7).

QA and QC

Amplification failure is a particular concern in utilizing the SSP typing approach, which requires multiple PCR primer pairs and relies on positive or negative amplification to identify HLA alleles. Each tube should contain a second set of primers which amplify a gene segment that is present in all

TABLE 7 Examples of sequence-specific primer typing kits[a]

Vendor, location	Loci (resolution)	No. of samples
Dynal Biotech Inc., Brown Deer, Wis.	HLA-A, HLA-B, HLA-C, HLA-DR, HLA-DQ (low resolution)	20 tests/kit
Pel-Freez Clinical Systems, LLC, Brown Deer, Wis.	Class I (high resolution), class II (high resolution)	10–12 tests/kit
GenoVision Inc., West Chester, Pa.	HLA-A, HLA-B, HLA-C, HLA-DR, HLA-DQ	12–72 tests/kit
One Lambda Inc., Canoga Park, Calif.	HLA-A, HLA-B, HLA-C, HLA-DR (low and high resolution)	8–40 tests/kit

Biotest Diagnostics Corp., Denville, N.J.	HLA-A, HLA-B, HLA-C, HLA-DR, HLA-DQ (low and high resolution)	12–24 tests/kit

[a]Information on procedures is available from the vendor websites.

DNA samples and that differs in size from the amplified HLA gene segment (19). The primer panel might also contain more than one primer pair to define an HLA type. Each panel of samples to be typed should include positive and negative reference DNA to detect contamination with previously amplified DNA, nonspecific amplification, and human errors. The laboratory should have a set of well-defined reference samples with known HLA alleles to validate the assay and to validate new lots of reagents, especially primers. It is recommended that the reference panel cover most of the polymorphisms that the primers detect.

Cost Assessment

This assay can be used at various levels of resolution depending on the purpose of the testing. SSP is able to obtain allele level resolution, although the number of primers required is large and new alleles might not be detected. SSP is difficult to use for large numbers of samples because of the number of thermocyclers required and the gel electrophoresis step. Use of other protocols besides electrophoresis to monitor amplification will aid in high-volume throughput.

Interpretation

A discrete band of the expected size should be visible under UV light following gel electrophoresis. The positive control band should also be visible, but it may be present in a lower quantity in tubes with positive amplification of HLA due to competition for reagents. Approaches for interpretation of SSP data have been described previously (2).

GEL ELECTROPHORESIS

DNA is negatively charged due to its phosphate composition; thus, amplified DNA will move toward the positively charged pole in an agarose gel matrix. The position of the migration is determined by the size of the DNA fragment; small fragments move faster than large fragments. The double-stranded DNA is visualized by staining with ethidium bromide. The mobility is assessed by using a commercially prepared set of DNA markers to determine the size of the amplicon.

Sample Requirement

3 to 5 μl of amplified PCR product. If large numbers of samples are being typed, only a subset (e.g., 10% of samples) needs to be evaluated by electrophoresis, and this evaluation should include amplified DNA from the positive and negative controls.

Materials and Reagents

Gel loading buffer (6×) made as a sterile solution but not autoclaved: 0.25% (wt/vol) bromophenol blue (Bio-Rad Laboratories, Hercules, Calif.; catalog no. 161-0404), 0.25% (wt/vol) xylene cyanol (Bio-Rad Laboratories; catalog no. 161-0423), and 15% (vol/vol) Ficoll (Sigma-Aldrich Co., St. Louis, Mo.; catalog no. F2637). Filter the buffer through a 0.2-μm-pore-size filter. Store at room temperature.

50× Tris-acetate-EDTA (TAE) gel buffer (autoclaved): 242 g of Tris base, 57.1 ml of glacial acetic acid, and 100 ml of 0.5 M EDTA. Bring the final volume to 1,000 ml with water. Adjust the solution to pH 8.0 with NaOH pellets. For 1× solution, add 10 ml of 50× TAE buffer to 490 ml of ddH$_2$O.

0.5 M EDTA, pH 8.0 (autoclaved and stored at room temperature): For 1,000 ml, dissolve 186.12 g of EDTA (372.24 g/mol) in ddH$_2$O and bring the volume to 700 ml. Adjust the pH to 8.0 with NaOH pellets. EDTA will dissolve when the correct pH has been obtained. Bring the final volume to 1,000 ml with ddH$_2$O.

Ethidium bromide (caution—this hazardous material is a carcinogen): Make as a sterile solution, 5 mg/ml in ddH$_2$O, but do not autoclave. Ethidium bromide can also be purchased as a concentrated solution (10 mg/ml; Bio-Rad Laboratories; catalog no. 161-0433).

Agarose (ultrapure; Gibco BRL, Life Technologies, Gaithersburg, Md.; catalog no. 15510-027)

Molecular weight DNA markers: 1-kb DNA ladder (Gibco BRL; catalog no. 156150-024)

Equipment and Instrumentation

- Heated stirring plate or microwave
- Horizontal agarose gel apparatus
- Power supply
- Short-wave UV box
- Camera

Gel Electrophoresis Procedure

1. Prepare agarose gel: 1.0% (wt/vol) agarose in 1× TAE buffer. Heat to boiling on a hot plate, stirring to dissolve agarose, or in a microwave for 1 to 2 min. When the solution is cool enough to touch, add 5 μl of 5-mg/ml ethidium bromide, swirl to mix, and pour into the gel electrophoresis apparatus. Place the comb (12 to 24 wells) into the gel. The percentage of agarose will be determined by the size of the DNA fragments analyzed (1.2% for analysis of the 300-bp DRB amplicon, 1.0% for the 800-bp class I amplicon). The amount of gel required will be determined by the choice of electrophoresis apparatus. Following solidification of the gel, fill the gel tank with 1× TAE buffer, submerging the gel in ~5 mm of buffer.

2. Add 1 μl of 6× gel loading buffer to 3 to 5 μl of amplified DNA.

3. Load samples and the molecular weight marker into the wells. The marker is diluted according to the manufacturer's instructions prior to loading.

4. Electrophorese the DNA to obtain clear separation of molecular weight ranges. Dye should separate towards the positive pole into two colors. For example, a 300-bp fragment is electrophoresed at 130 V for 30 min.

5. Photograph the gel with the short-wavelength UV-B 280- to 320-nm-wavelength transilluminator.

The dye should not be electrophoresed off the gel. DNA will not separate well with higher voltages or shorter running times. The DNA ladder could be degraded at higher voltage. The solidified gel containing ethidium bromide should be discarded in a solid biohazard waste container.

QA and QC

Markers with known molecular weights are used to measure the size of the DNA.

Cost Assessment

This procedure allows verification of amplification and determination of the size of the amplicon and uses inexpensive reagents. The quantitation of amplified DNA with the PicoGreen double-stranded DNA quantitation reagent (Molecular Probes, Inc.; catalog no. P-7581) can be used in place of gel electrophoresis. The PicoGreen double-stranded DNA quantitation reagent is an ultrasensitive fluorescent

nucleic acid stain for double-stranded DNA. The samples are excited at 480 nm, and the fluorescence emission intensity is measured at 520 nm by using a spectrofluorometer or fluorescence microplate reader (e.g., Perkin-Elmer HTS 7000 Plus bioassay fluorescent and absorbance microplate reader; PE Biosystems, Foster City, Calif.). The disadvantage to this technique is that the size of the amplicon and the presence of other DNA fragments are not evaluated; the advantage is the ability to analyze many samples rapidly.

Interpretation

For gel electrophoresis, a single brightly stained band of the correct size shows that the amplification was successful. A fast-moving stained band of unincorporated primers may also be detected. If PicoGreen is used, the sample fluorescence is corrected for background by using a reagent blank and a standard curve generated using reference DNA at various concentrations. The results should be validated locally as the optical density (OD) will vary depending on the size of the PCR product and the efficiency of the primers. Usually, the fluorescence reading for each amplicon must be at least three times the reading for the PCR negative control. The presence of amplification of the primers annealing to themselves is suggested if the fluorescence reading for the negative control is as high as that for the amplicons.

SSOPH

In SSOPH, extracted, amplified, and denatured DNA is hybridized with labeled oligonucleotide probes to identify the HLA type. Oligonucleotide probes are selected to hybridize to specific sequences in HLA alleles (Fig. 1). A panel of probes is used to define alleles or groups of alleles potentially present in the denatured amplified DNA. The design of probes is based on alignment of the HLA allele sequences published and available on the Internet (http://www.anthonynolan.org.uk/HIG/index.html) (22). In probe design, the region of polymorphism is usually positioned in the middle of the oligonucleotide. The length and sequence of the oligonucleotide will determine the specificity and hybridization conditions. Most HLA typing utilizes oligonucleotides that are approximately 18 nucleotides in length. Table 3 lists references for various HLA SSOPH typing strategies.

During hybridization, labeled probe will bind to a specific sequence in the amplified DNA. After several stringent wash steps, DNA that is nonspecifically bound to the probe is removed. Labeled DNA-probe complex is then detected. Probes are labeled so that their binding to denatured amplified DNA can be detected. There are several methods for labeling probes. The label added will depend on the detection system utilized. Probes may be detected by chemiluminescence, chromogenic reactions, fluorescence, or radioactivity. For example, for chemiluminescence detection, terminal transferase adds nucleotides, dATP and dUTP, to the 3′ end of the oligonucleotide. The dUTP utilized in the tailing reaction may be coupled to digoxigenin, which is detected with an antibody coupled to alkaline phosphatase. Addition of a substrate, Lumiphos 480 (Tepnel Lifecodes Corp., Stamford, Conn.) or CSPD (Roche Diagnostics, Indianapolis, Ind.), causes the emission of light, which is detected by X-ray film.

A panel of oligonucleotide probes is used to identify HLA alleles. The size of the panel and the specificity of probes will determine the resolution level of the typing (i.e., the ability to distinguish among alleles).

SSOPH Typing Systems

SSOPH HLA typing systems can be divided into two major categories: forward SSOPH and reverse SSOPH. In the forward system, denatured amplified DNA is blotted onto a solid support (e.g., membrane) and then hybridized with labeled oligonucleotide probes, which are in solution. In the reverse typing system, probes are attached to a solid support and hybridized with the labeled amplified DNA solution. For both systems, because the interpretation of the hybridization pattern to determine HLA assignments is very complicated, data analysis requires the help of a software program.

Many SSOPH commercial typing kits are available now. They are well developed and have been used by HLA labs for the past several years. The typing procedures are easy to follow and robust. Laboratories can also design their own probe-based typing systems. This may be cost-effective if they are engaged in large-volume HLA typing. Use of a homemade system will involve probe design, reagent synthesis and labeling, and interpretation software development.

Sample Requirement

DNA amplified by PCR, usually the product of a 100-μl PCR mixture, is sufficient.

Materials and Reagents

Table 8 lists the various kits currently available. Information on primers and probes for SSOPH typing of HLA loci is given in the 13th International Histocompatibility Workshop manual (http://www.ihwg.org/protocols/protocol.htm). An oligonucleotide probe labeling kit for chemiluminescence detection is available with detailed instructions (Roche Diagnostics).

Equipment and Instrumentation

Equipment needs are described in Table 8.

SSOPH Procedure

Information on SSOPH protocols can be downloaded from the kit vendors' websites. The amount of amplified DNA in each sample can be evaluated by agarose gel electrophoresis. It is not necessary to check the quality and quantity of PCR-amplifed DNA from each sample before hybridization. In cases in which a sample fails to produce an interpretable typing result due to absent or poor hybridization, it is better to reamplify the genomic DNA since unsatisfactory typing is most likely caused by failed amplification. The hybridization temperature is very critical for obtaining stringent hybridization, and it must be closely monitored during the operation.

QA and QC

Each panel of samples to be typed should include positive and negative DNA controls to detect contamination with previously amplified DNA, nonspecific probe hybridization, and human errors. In the high-throughput typing lab, it is necessary to add blind random repeats in each sample panel to a level of 1 to 3% to monitor sample mishandling during the entire testing process. The laboratory should have a set of well-defined reference samples with known HLA alleles to test new lots of reagents, especially probes. It is recommended that the reference panel cover most of the polymorphisms that the probes detect. Equipment, such as thermal cyclers, water baths, and detectors, must be calibrated periodically.

TABLE 8 Examples of SSOPH typing kits[a]

Type of SSOPH	Name of kit	Vendor (location)	Loci	Sample size[b]	Major equipment (vendor)	Description
Forward	Lifecodes HLA kit	Tepnel Lifecodes Corp (Stamford, Conn.)	HLA-A, HLA-B, HLA-C, DRB, DQB, DPB	Large	Thermal cycler, shaking water bath, Hydra-96 microdispenser (Art Robbins Instruments, Sunnyvale, Calif.)	PCR-amplified DNA blotted onto membrane; one membrane hybridized with one probe; probe-specific wash temperature may vary; chemiluminescence or colorimetric detection achieved; data reading has no time limit; addition of new probes requires extra membranes and hybridization step.
Reverse	LABType HLA kit	One Lambda (Canoga Park, Calif.)	HLA-A, HLA-B, HLA-C, DRB, DQB	Small, medium, or large	Thermal cycler, centrifuge, Luminex 100 system (Luminex, Austin, Tex.)	Multiplex PCR; probes attached to microspheres (beads); all probes hybridize and are washed at same temperature in one well (up to 100 probes/well); fluorescence detection achieved; data collection by Luminex 100 system can be delayed up to 3 to 7 days; addition of new probes with no extra steps.
	RELI-SSO HLA kit	Dynal Biotech (Brown Deer, Wis.)	HLA-A, HLA-B, HLA-C, DRB, DQB	Small or medium	Thermal cycler, Dynal AutoRELI 48 instrument	Probes bound on membrane strip; probes hybridize and are washed in AutoRELI 48 instrument at same temperature; color detection achieved; data reading has no time limit.
	LifeMatch HLA-SSO kit	Tepnel Lifecodes Corp. (Stamford, Conn.)	HLA-A, HLA-B, HLA-C, DRB	Small, medium, or large	Thermal cycler, Luminex 100 system (Luminex, Austin, Tex.)	Asymmetric PCR; no denaturation step; probes attached on microspheres (beads); all probes hybridize at same temperature in one well (up to 100 probes).
	Inno-LIPA HLA-SSO kit	Innogenetics (Alpharetta, Ga.)	HLA-A, HLA-B, HLA-C, DRB, DQB	Small or medium	Thermal cycler, Auto-LiPA (strip processor)	Probes bound onto membrane strip; probes hybridize and are washed in Auto-LiPA at same temperature; color detection achieved; data reading has no time limit.

[a]Information on procedures is available from the vendor websites.
[b]Sample size: small, 1 to 10 samples per test; medium, 11 to 50 samples per test; large, >50 samples per test.

Cost Assessment

This assay can be used at various levels of resolution, depending on the purpose of the testing. SSOPH is able to reach allele level resolution, although the number of primers and probes required is large and new alleles might not be detected. SSOPH can be used for both small numbers and large numbers of samples.

Interpretation

Kits containing a large number of probes for a single HLA locus or probes designed to link polymorphisms (i.e., to determine whether specific polymorphisms lie within the same allele) will reduce the percentage of results with several alternative HLA assignments and will produce higher-resolution typing data.

RSCA

The method of RSCA relies upon the separation of homo- and hetero-DNA duplexes in a gel matrix (Table 4). PCR is used to amplify a locus or a region of the gene. The strands of the amplification product, containing one or two HLA alleles, are hybridized with a fluorescently labeled reference strand from a known reference HLA allele, forming heteroduplexes. The fluorescent label allows heteroduplexes containing the reference strand to be detected.

The mobility of the labeled heteroduplexes is compared to the mobility of reference homoduplexes after separation by nondenaturing polyacrylamide electrophoresis. The use of laser-based instrumentation (e.g., Prism 310; Applied Biosystems Inc., Foster City, Calif.) and computer software in addition to internal DNA markers for correction of gel-to-gel variability allows discrimination among HLA alleles which may differ by only a single nucleotide within the DNA fragment.

Materials and Reagents
An RSCA kit is available from Pel-Freez Clinical Systems, LLC (Brown Deer, Wis.).

QA and QC
At least two fluorescently labeled DNA references are used to create heteroduplexes with the sample alleles. Fluorescently labeled reference DNA strands flanking the samples are used as markers to measure the mobilities of bands during electrophoresis.

Cost Assessment
RSCA is often useful for resolving typing ambiguities in which determination of the *cis-trans* associations of polymorphic motifs requires an additional typing step. RSCA has been used for high-resolution class I and II typing and matching for bone marrow donor selection.

Interpretation
Sequence differences between the HLA alleles in the sample and the fluorescently labeled reference strands lead to the production of homo- and heteroduplexes following denaturation and cooling. As a particular heteroduplex will migrate different distances relative to homoduplexes, measurement of mobility values allows alleles to be assigned.

DNA SEQUENCING
A final protocol for HLA typing is sequencing of HLA genes (Table 5). Amplification is used to obtain sufficient copies of a specific HLA gene for analysis by DNA sequencing. PCR amplification primers are chosen so that the resultant amplicon contains the genetic information from the polymorphic exons of a single allele or both alleles carried by an individual. For HLA class I genes, the primer sets used in the PCR bracket exon 2 and exon 3, including the intervening intron. For class II genes, the primers flank exon 2. If two alleles are present, their sequences are characterized as a mixture.

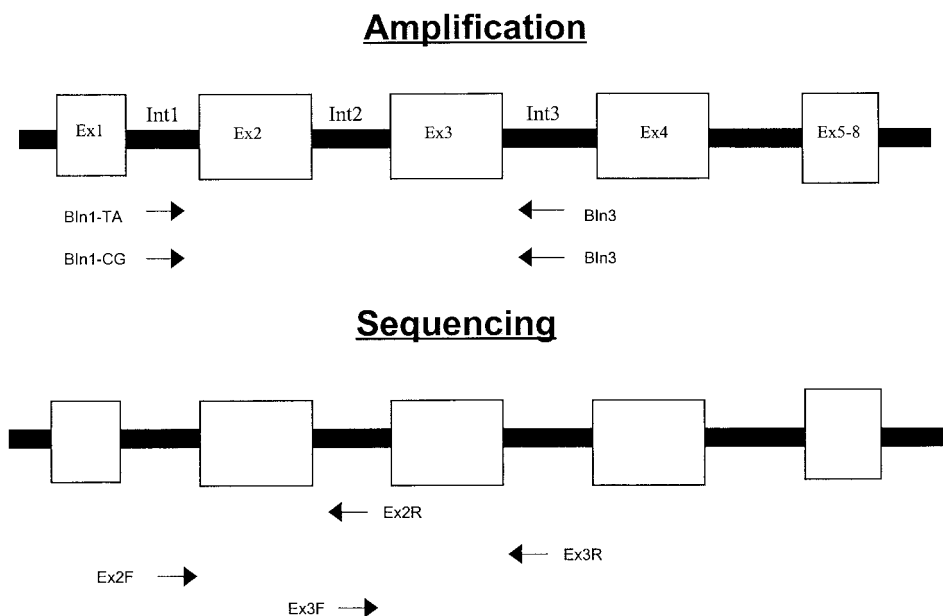
DNA synthesis (i.e., the DNA-sequencing reaction) is carried out using a single primer, the four nucleotides (dATP, dTTP, dGTP, and dCTP), and four dideoxynucleotides (dideoxy-dATP [ddATP], ddTTP, ddGTP, and ddCTP) (24). At each position in the sequence, the DNA polymerase has the option of incorporating a normal nucleotide or a dideoxynucleotide. If a normal nucleotide is incorporated, synthesis proceeds. If a dideoxynucleotide is incorporated, synthesis is halted. The result is a mixture containing DNA fragments ending at various positions along the length of the DNA sequence. Following denaturation, the newly synthesized strands are separated by size on a polyacrylamide gel. If the newly synthesized strands are labeled, through labeling of either the primer or the dideoxynucleotides, the strands can be visualized on the gel. The strands terminated by a single dideoxynucleotide are distinguished from the strands terminated by the other three dideoxynucleotides through the use of different fluorescent labels or through analysis of each reaction in a separate lane of the gel. Through this approach, the sequence of nucleotides comprising each HLA allele can be determined. Depending on the length of the region sequenced, two or more sequencing primers are used to obtain sense (forward) and antisense (reverse) sequences of exons 2 and 3 for class I and exon 2 for class II genes (Fig. 3).


FIGURE 3 Primer locations for sequence-based typing of the HLA-B gene. The locations at which amplification and sequencing primers anneal to the HLA-B gene are indicated by arrows. BIn3 includes both BIn3 and BIn3-AC primers. Ex, exon; Int, intron; F, forward; R, reverse.

Amplification of HLA Class I Genes for Sequencing

The HLA-B gene will be used as an example for amplification of HLA class I genes. PCR amplification primers are chosen so that the resultant amplicon contains the genetic information from the polymorphic exons of a single HLA-B allele or both HLA-B alleles carried by an individual. The primer sets used in the PCR bracket exon 2 and exon 3, including the intervening intron. The two alternative forward (or sense) primers anneal to a polymorphism in the intron before exon 2 (4) which subdivides the HLA-B alleles into two groups. Therefore, approximately half of the time, the two alleles in a heterozygous individual will be individually isolated for subsequent characterization. If the two alleles fall within the same amplification group, their sequences are characterized as a mixture. Two reverse primers are mixed together to achieve amplification of all B locus alleles. The BIn3-AC primer is required to amplify the B*7301 allele, which is not amplified by the BIn3 primer.

Sample Requirement

DNA (200 to 500 ng) previously heated to 95°C for 5 min in a heating block and stored on ice

Materials and Reagents

Automated sequencers and commercial kits for the amplification and sequence analysis of some HLA alleles are available (PE Biosystems; Amersham Pharmacia Biotech, Inc., Piscataway, N.J.; Visible Genetics Inc., Toronto, Ontario, Canada; and Abbott Laboratories, Abbott Park, IL [Atria Genetics Inc., Forensic Analytical Molecular Genetics]).

0.5-ml sterile disposable bubble-top tubes

10× PCR buffer (4): 500 mM Tris-HCl, pH 8.8; 150 mM ammonium sulfate; 500 μM EDTA; 0.1% (wt/vol) Knox gelatin; and 100 mM β-mercaptoethanol. Buffer is made without β-mercaptoethanol, autoclaved, and stored at room temperature. A working solution containing β-mercaptoethanol is made fresh just before use.

dNTP solution: 1.25 mM (each) dNTPs diluted in water and stored at 4°C for no more than 2 weeks. Stock solutions: 100 mM dNTP set (catalog no. 10297-018; Invitrogen, Carlsbad, Calif.)

Platinum *Taq* DNA polymerase at 5 U/μl (Invitrogen; catalog no. 10966-034)

PCR primers for HLA-B: 10 pmol of each sense primer/μl. The antisense primers are dissolved in water at a concentration of 10 pmol/μl, and 4 μl of BIn3 is mixed with 1 μl of BIn3-AC to yield the final antisense mixture.

Sense primers (4):

BIn1-TA, 5′-GGCGGGGGGCGCAGGACCTGA-3′

BIn1-CG, 5′-GGCGGGGGGCGCAGGACCCGG-3′

Antisense primers:

BIn3, 5′-GGAGSCCATCCCCGSCGACCTAT-3′ (where S is the International Union of Biochemistry code for G and C)

BIn3-AC, 5′-GGAGGCCATCCCGGGCGATCTAT-3′

Dimethyl sulfoxide (catalog no. D-8418; Sigma)

50 mM MgCl$_2$

Ultrapure reagent-grade water (New England Reagent Laboratory, East Providence, R.I.)

Agarose gel reagents

Equipment and Instrumentation

- Laminar flow hood
- 95°C heating block
- Thermal cycler (GeneAmp PCR system 9600; Perkin-Elmer, Norwalk, Conn.)
- Vortex mixer
- Microcentrifuge
- Agarose gel electrophoresis equipment

Amplification Procedure

In a sterile laminar flow hood:

1. Assemble two PCR mixes for each sample.
   i. To the heat-denatured DNA aliquot, add TA-PCR mix (volume indicated for one sample): 10 μl of PCR buffer (working solution), 10 μl of dimethyl sulfoxide, 2 μl of MgCl$_2$, 16 μl of diluted dNTP solution, 2 μl of each primer (sense primer BIn1-TA and antisense primer mixture [BIn3–BIn3-AC]), 0.5 μl of *Taq* DNA polymerase, and water to bring volume to 100 μl.
   ii. Assemble the CG-PCR mix as described for the TA-PCR mix but using a different primer set: BIn1-CG and antisense primer mixture.
2. Mix by vortexing and microcentrifuge briefly to bring liquid to the bottom of the tube.
3. Cycle the tubes in a thermal cycler according to the following temperature profile: 96°C for 5 min for one cycle; 96°C for 10 s, 65°C for 30 s, and 72°C for 60 s for five cycles; 96°C for 20 s, 60°C for 30 s, and 72°C for 60 s for 30 cycles; and 72°C for 10 min for one cycle.
4. Analyze an aliquot on an agarose gel. Store the remaining amplified DNA at 4°C.

Interpretation

The identification of amplification products of approximately 1 kb in size on an agarose gel is used to predict the sequencing result. If only one of the two amplifications shows a band upon gel electrophoresis, it is expected that the sequence analysis of the amplified DNA will include one or two alleles. If both amplifications are positive as judged by gel electrophoresis, the sequence analysis of each amplicon should yield a single allele.

Purification of Amplified DNA in Preparation for Nucleotide Sequencing

Amplified DNA is purified to remove any unreacted PCR primers and dNTPs. These components will interfere with the sequencing reaction. The amplified DNA is passed through a microconcentrator with distilled water. DNA is captured on a membrane during centrifugation. The unreacted PCR primers and dNTPs are collected in the waste tube. DNA is then recovered by subsequent centrifugation and denatured.

Sample Requirement

Amplified DNA

Materials and Reagents

Microcon-100 (catalog no. 42413; Amicon, Inc., Beverly, Mass.)

Ultrapure reagent-grade water (New England Reagent Laboratory)

Equipment and Instrumentation

- Fixed-angle microcentrifuge (model no. 5415C; Eppendorf-Netheler-Hinz GmbH, Hamburg, Germany)

Purification Procedure

Details of the purification procedure are provided in the Microcon microconcentrators operating instructions by Amicon, Inc. (publication I-394H).

1. Insert the filtrate cup into one of the Microcon-100 sample reservoirs.

2. Being careful not to touch the filter membrane with the pipette tip, pipette 400 μl of sterile distilled water into the blue concentrator column (filtrate cup).

3. Add the entire PCR mix to 400 μl of water. The total volume of DNA and water should not exceed 500 μl.

4. Place the assembled Microcon unit into the microcentrifuge and centrifuge at $2,000 \times g$ for 8 min.

5. Remove the concentrator assembly from the centrifuge. Separate the filtrate cup from the sample reservoir and remove the spin cap.

6. Carefully place the filtrate cup upside down in a new sample reservoir and centrifuge for an additional 3 min at $2,000 \times g$.

7. Approximately 2 μl of liquid should be recovered. Bring the volume to 20 to 30 μl with water. The amount of water to be added is estimated by the intensity of the amplified DNA following gel electrophoresis prior to Microcon purification and should yield 30 to 50 ng/μl.

8. Measure the OD at 260 and 280 nm and estimate the amount of DNA (an OD of 1 at 260 nm is equal to 50 μg/ml). The expected yield is 30 to 50 ng/μl after dilution. Ratios of absorbance at 260 nm versus that at 280 nm are about 1.7 to 1.9.

Sometimes Microcon filters are defective and the recovery may be greater than expected. If the yield is more than 20 μl following centrifugation, the mixture should be purified using a second Microcon filter. If the yield is low, the PCR should be repeated.

Nucleotide Sequencing

In the procedure described below, the HLA-B locus PCR product is sequenced by using BigDye terminator cycle sequencing kits with AmpliTaq DNA polymerase, FS (Applied Biosystems). DNA is first denatured at 96°C. Sequencing primers anneal to denatured DNA at 50°C. Four primers are used to obtain sense (forward) and antisense (reverse) sequences of exons 2 and 3 (Fig. 3). DNA polymerase adds nucleotides onto the primers, extending the DNA strands at 60°C until the addition of one of the four dye-labeled terminators ends the extension. Repetition of the cycle of denaturation, annealing, and extension generates billions of copies of the dye-labeled DNA. The DNA fragments obtained using dye terminator chemistry are precipitated with 100% ethanol containing sodium acetate. The supernatant, which contains unincorporated dye terminators, is discarded.

A polyacrylamide gel is formed by the copolymerization of acrylamide and bisacrylamide. The process begins when N, N, N, N-tetramethylethylenediamine (TEMED) reacts with ammonium persulfate (APS), causing linkage of the acrylamide monomers. The polymer chains are randomly cross-linked with bisacrylamide to form the gel matrix. The Long Ranger gel is generated in a similar fashion.

Sample Requirement

The DNA sequencing reaction is performed using 100 ng of purified amplified DNA.

Materials and Reagents

BigDye terminator cycle sequencing kits with AmpliTaq DNA polymerase, FS (Applied Biosystems; catalog no. 4336778 for 5,000 reactions)

Sequencing primers: 5 pmol of each primer. Primers used for HLA-B sequencing include the following:

Exon 2 sense primer, 5′-GCCGGGAGGAGGGTC-3′

Exon 2 antisense primer, 5′-GGATCTCGGACCCG-GAG-3′

Exon 3 sense primer, 5′-GGGGGACGGKGCTGA-CCG-3′ (where K represents G or T)

Exon 3 antisense primer, 5′-AGGCTCCCCACTG-3′

0.2-ml strip PCR tubes (catalog no. T-3013-Y; GeneMate, Kaysville, Utah) or a 0.2 ml-diameter PCR plate (catalog no. 1402-9600; USA Scientific, Inc., Ocala, Fla.)

100% and 70% ethanol

3 M sodium acetate, pH 4.6

Deionized formamide: Mix 10 ml of formamide (catalog no. 0606; Solon, Ohio) with 1 g of Amberlite MB-1 (Sigma; MB-1A). Stir formamide and resin together for 15 to 20 min but no longer than 30 min as the formamide will eventually dissolve the resin. Filter through a 0.2-μm-pore-size filter and store at −20°C.

25 mM EDTA, pH 8.0

Dye: 10 ml of 25 mM EDTA, pH 8.0, and 500 mg of blue dextran

Long Ranger 5% gel and buffer: Long Ranger gel solution (50% stock solution; catalog no. 50611; FMC Bio-Products, Rockland, Maine), APS (American Chemical Society grade; Amresco; catalog no. 0486-100G-APP), TEMED (electrophoresis purity reagent; Amresco; catalog no. 0761-25ML-APP), urea (Invitrogen; catalog no. 15505-035), and 10× Tris-borate-EDTA (TBE) buffer (16.6 g of EDTA, 216g of Tris, and 110 g of boric acid, with water added to bring the final volume to 2 liters [the pH should be approximately 8.4]), filtered with a 150-ml filter system with 0.22-μm-pore-size nylon (Nalgene; catalog no. 150-0020; Nalge Co., Rochester, N.Y.). Thoroughly mix the follwing ingredients; 18 g of urea, 5 ml of 10× TBE, 5 ml of Long Ranger gel stock solution, and 26 ml of water. Filter the acrylamide solution and degas for 5 min. Prepare 10% APS. Note that APS begins to decompose at once when dissolved in water. The result is loss of activity. For reproducible results, the APS solution should be prepared immediately before each use. Into the degassed acrylamide solution, add the following components gently: 250 μl of 10% APS and 35 μl of TEMED. Gently swirl the solution and pour the gel as indicated in the user manual for the sequencer. Polymerization begins when APS and TEMED are added to the gel solution. Alternatively, use the Long Ranger single pack (catalog no. 50691; Cambrex Bio Science Rockland Inc., Rockland, Maine) and follow the manufacturer's instructions.

1% TBE running buffer made by diluting 10× TBE with water

Equipment and Instrumentation

- Thermal cycler (Perkin-Elmer; model 9600)
- 95°C heating block
- Vortex
- Microcentrifuge with vertical rotor (Eppendorf; model 5403) or tabletop centrifuge with swing plate holder (Sorvall; model RT6000 D)
- Automated DNA sequencer (PE Biosystems; model 377)

Nucleotide Sequencing Procedure

Use an aseptic technique on the lab bench.

1. In 0.2-ml strip tubes or plates, assemble sequencing reaction mixtures (one for each primer) on ice. Add reagents as follows: 50 to 100 ng of purified PCR product (approximately 1 to 2 μl), 1 μl of primer (5 pmol), and 4 μl of terminator ready reaction mix, with water added to bring the total volume to 10 μl. (Alternatively, add reagents as follows: 50 to 100 ng of purified PCR product [approximately 1 to 2 μl], 1 μl of primer [5 pmol], 1 μl of terminator ready reaction mix, and 5 μl of Better Buffer [The Gel Company, San Francisco, Calif.], with water added to bring the total volume to 15 μl.)

2. Place the samples in the thermocycler. Denature DNA at 96°C for 2 min, and then start cycles: 96°C for 10 s, 50°C for 5 s, and 60°C for 3 min for 25 cycles.

3. Store the product at 4°C or ethanol precipitate immediately.

4. Prepare a fresh mix with 1 ml of anhydrous ethanol and 40 μl of 3 M sodium acetate, pH 4.6.

5. To each sequencing reaction mixture, add 25 μl of the ethanol-sodium acetate mix. Vortex to mix.

6. Place tubes or plates in a benchtop vertical microcentrifuge or a tabletop centrifuge with swing plate holders. Centrifuge the tubes or plates for 30 min at 1,500 to 3,000 × g (3,000 rpm; 16- to 17-cm rotor) at room temperature.

7. Immediately invert the tubes or plates onto paper towels. Place the inverted tubes or plates and paper towel in the centrifuge for 1 min at 150 × g (700 rpm; 16- to 17-cm rotor) to remove the remaining supernatant.

8. Add 50 μl of 70% ethanol to the tubes or plates.

9. Centrifuge for 5 min at 1,500 to 3,000 × g.

10. Immediately invert the tubes or plates onto paper towels. Place the inverted tubes or plates and paper towel in the centrifuge for 1 min at 150 × g (700 rpm; 16- to 17-cm rotor) to remove the remaining supernatant.

11. Samples can be stored as dry pellets at –20°C.

12. Prepare the loading buffer by combining deionized formamide and dye in a ratio of 5:1 deionized formamide to EDTA-blue dextran.

13. Resuspend the dried sample in 1.5 to 4 μl of loading buffer, depending on the gel comb size (e.g., for a 96-well comb, use 2 μl) and the intensity of the PCR product prior to sequencing. Vortex and briefly centrifuge the sample to bring liquid to the bottom of the tube.

14. Heat the sample at 95°C for 2 min in a heating block or thermal cycler to denature the DNA. Place the sample on ice until ready to load.

15. Analyze the sample on a 5% Long Ranger gel.

16. Load 0.5 to 2 μl of the preparation into the sequencing gel wells, depending on the size of the lanes and the sequencing chemistry used. The remaining sample can be kept at –20°C for up to 2 weeks.

17. Electrophoresis (1.69 kV; 20 to 30 mA; 5 to 6 h) and analysis should follow guidelines for the automated instrument (ABI PRISM 377-18 DNA sequencer user's manual, part 904210, PE Biosystems, www.pebio.com).

BigDye terminator ready reaction mix contains fluorescent dye and should be kept away from direct sunlight. Suboptimal results as judged by the lack of clearly defined peaks and a high background can be caused by inadequate amounts of the DNA template, poor quality of template, failure to remove contaminants prior to analysis of the sample, and problems with the gel or instrument. Some DNA fragments may have secondary structures which alter their mobility, resulting in incorrect sequence assignment. These anomalies can be identified by comparing to reference HLA sequences and by determining the nucleotide sequences of both coding and noncoding DNA strands. These and other problems are discussed in detail in the PE Biosystems automated DNA sequencing chemistry guide (PE Biosystems).

QA and QC

The conserved region of the HLA gene can serve as a control for the sequencing reaction and electrophoresis. Previously undescribed alleles need to be confirmed from a second independent PCR amplification and sequence reaction. If two alleles are sequenced simultaneously, the positions at which the two alleles differ in nucleotide sequence (i.e., heterozygous peaks) should be reviewed (23). All sequences should be compared to the matched sequence(s) and to the mismatched sequence(s) which most closely resemble the assigned sequence. Criteria for accepting a sequence should include evaluation of the number of uninterpretable positions and signal strength. The use of new lots of reagents should be documented and validated. A record of parameters (run temperature, milliamperes, and volts) for the automated sequencer should be maintained.

Cost Assessment

Sequencing is expensive due to the high cost of the DNA sequencer and the sequencing reagents. It is, however, the best approach to achieve allele level resolution typing of HLA alleles and is the preferred approach for characterization of patients requiring hematopoietic stem cell transplantation and their potential unrelated donors. The laboratory should be prepared to identify and/or design additional PCR or sequencing primers needed to resolve typing of alleles since commercial kits may not provide the resolution needed to obtain allele level resolution.

Interpretation

The sequence of nucleotides is refined using software tools provided with the DNA sequencer. The final sequence is compared to sequences in a database by the software to identify the allele(s) present (12, 23). Positions at which the sequence differs from those of the next most closely related alleles should be reviewed. Allele-specific amplification or sequencing primers may be required to resolve typing of alternative allele combinations (Fig. 2). For example, a sequence result of A*02010101, A*6601, or A*023501, and A*2603 requires the addition of a sequencing primer specific for one of the two alleles in each combination (e.g., annealing to the TTC ACA sequence at codons 9 through 10 which is found in both A*02 alleles). This will allow the laboratory to determine whether the codon 70 polymorphism (CAC) is linked to the TTC ACA sequence at codons 9 and 10 (identifying the allele combination as A*02010101 and A*6601) or not (identifying the allele combination as A*023501 and A*2603). A list of alleles with identical sequences in the commonly sequenced exons is provided on a website (http://www.anthonynolan.org.uk/HIG/index.html). Since no commercial kit includes the reagents required to resolve all ambiguous allele combinations encountered,

the laboratory must have the capability to design and validate these primers in-house.

INTRODUCTION

Relevance of Antibodies in Transplantation

Antibodies of the immunoglobulin G (IgG) class can damage tissues in a variety of ways, including (i) directly through complement activation, (ii) indirectly through the deposition of immune complexes, and (iii) indirectly through the recruitment of cytotoxic or inflammation-inducing cells. Very high levels of antibody result in hyperacute rejection and graft failure, an outcome that can be easily avoided by the performance of a lymphocyte crossmatch test prior to transplantation. However, clear elucidation of the relevance of donor-reactive antibodies of various strengths and specificities and of antibodies that arise after transplantation has been hampered by inadequate technologies and lack of reimbursement for posttransplantation monitoring of antibodies. Nonetheless, a deleterious effect of antibodies specific for mismatched donor HLA antigens has been demonstrated for every type of organ that has been transplanted in sufficient numbers. Further, there is evidence that anti-HLA antibodies are involved in acute and chronic as well as hyperacute rejection of organs (reviewed in reference 26). As the number of composite-tissue and HLA-mismatched bone marrow transplants increases, it is likely that antibodies will be a rejection risk in these transplants as well. In mismatched bone marrow transplants, there is a risk of immunocompetent tissues from sensitized donors producing antibodies to recipient tissues as well as of recipients making anti-donor tissue antibodies. In theory, antibodies specific for any antigen on transplanted tissue should be capable of damaging the transplant. Among those known to be deleterious to transplanted tissue are antibodies specific for antigens of the HLA and ABO systems. More recently, antibodies to MICA antigens encoded by genes in the HLA system have been shown to be involved in graft rejection. The focus of this chapter will be HLA-specific antibodies, and we will use the term donor-specific antibody (DSA) to refer to an antibody(ies) specific for donor HLA.

Among the reasons HLA-specific antibodies are so important are that HLA antigens are present on transplanted tissues (class I [HLA-A, -B, and -C] antigens are expressed on most nucleated cells, and class II [HLA-DR, -DQ, and -DP] expression, although more limited, is likely to be induced at the time of transplant); most transplants involve some degree of HLA mismatch; HLA antigens

provoke one of the strongest immune responses; and recipients may become sensitized to HLA antigens prior to transplantation through transfusion, pregnancy, and possibly environmental agents or after transplantation by the graft itself. The risk represented by HLA-specific antibodies is determined by the characteristics of the antibody, including titer, class, specificity, timing, and course (i.e., whether the antibody is increasing or decreasing), and by the relevant characteristics of the tissue, which are the extent and type of antigen expression and the resilience of the tissue to antibody-mediated damage. The level of risk, as measured by the timing and extent of damage to the graft, is directly proportional to the antibody titer. Regarding Ig class, IgG antibodies are established risk factors, the data are ambiguous for IgM antibodies, and there are data suggesting that HLA-specific antibodies of the IgA class are beneficial in transplantation (reviewed in reference 26). It has been clearly demonstrated that antibodies to either HLA class I or HLA class II antigens represent a risk and are capable of producing hyperacute rejection (reviewed in reference 26). However, the level of antigen expression varies among HLA loci. Antigens encoded by the HLA-C, -DRB3 (DR52), and -DRB4 (DR53) and possibly the -DRB5 (DR51) loci are expressed at much lower levels than those encoded by HLA-A, -B, and -DRB1 (5, 12, 21), and there may be a lower risk of rejection associated with their respective antibodies, although there has been at least one case of hyperacute rejection mediated by an antibody specific for a C locus antigen (3). Antibodies that are present at the time of transplantation or that develop after transplantation can damage tissues. In contrast, antibodies that were present only historically appear to represent little risk except in two situations: (i) when the present transplant shares a mismatched antigen with a previous transplant and (ii) when a previous graft was lost to an early immunologic rejection. The courses of antibodies, over time, may be relevant to the level of risk. Antibodies that are increasing in titer or expanding in specificity may represent a recent or ongoing sensitization, which may include newly developing antibodies to donor antigens, and are potentially of greater risk than those that are waning in titer or breadth, which may reflect senescence or an active down-regulation of the immune response and may be more responsive to intervention. Differences among organs and tissues in HLA antigen expression, extent of exposure to antibodies, and impact on function of antibody-mediated damage are well

known. However, a variety of factors, such as certain cytokines and hormones which can be released in response to trauma, infection, or certain treatments, can affect antigen expression, which in turn can provoke a humoral response and provide increased target for antibody binding.

Goals and Aims

Despite the danger presented by antibodies to donor HLA, the risk to the transplant can be overcome, in many cases, through appropriate intervention. Thus, the goal in testing for HLA-specific antibody should be to determine the level of risk to the transplanted organ or tissue. This, then, provides an opportunity to determine what treatment, if any, will overcome that risk—i.e., what has to be done to prevent or treat rejection. The risk is present in the form of existing antibody(ies) or an increased probability of making antibody(ies) to donor HLA. The most definitive source of information is the detection and characterization of antibodies both prior to and following transplantation. This includes assessing the antibody characteristics, identified above, that are associated with risk: Ig class, titer, specificity, and trend. However, even routine screening prior to transplantation reveals only a small window in the patient's history and there is a substantial opportunity for undetected sensitization. Therefore, obtaining information about potentially sensitizing events in the patient's history will increase the accuracy of the assessment of risk. This chapter will deal with the technical aspects of obtaining the information necessary to evaluate humoral sensitization to HLA antigens in the transplant patient.

Authors' Note

The minimal testing requirements for compliance with the Clinical Laboratory Improvement Act (1988) can be found in the Code of Federal Regulations, subpart 42, section 493.1278, which can be accessed at http://www.gpoaccess.gov/ cfr/index.html; search for 42CFR493.1278. There has been an ongoing expression of concern by some regarding the expense of testing for humoral sensitization. A review of the literature provides extensive evidence of the benefit of such testing in prolonging graft and patient survival and reducing injurious rejection episodes. More recently, several centers have initiated treatment protocols designed to overcome sensitization, the single largest barrier to transplantation, and antibody testing provides a means to identify the best candidates for these protocols and to monitor treatment efficacy. Given the high cost of treatment for rejection, of reduced graft survival, and of alternative treatment when transplants fail, testing for antibodies is a very cost-effective investment.

METHODS

Creating a Patient Profile

Certain patient information is useful for quantifying the risk of rejection, assessing how aggressive a responder a patient is, and interpreting results of antibody tests. The applicable information is outlined in Table 1. The table is reasonably self-explanatory and merits only a few additional remarks. Information about previous sensitizing events can be used to achieve a gross assessment of how aggressively a patient responds to exposure to HLA. Patients with a previous graft in place have a source of antigen for maintaining sensitization but may have artificially low levels of antibodies because the donor tissue is acting like an immunologic sponge, removing antibodies by adsorption onto the antigens expressed on the tissue or releasing soluble antigens that bind to the antibodies. Samples should be obtained approximately 2 to 4 weeks after a transfusion to optimize detection of a humoral response. Transfusion histories are extremely difficult to obtain, are often inaccurate, and should be

TABLE 1 Patient information

Category	Information needed	Relevance
Diagnosis	Specific disease	Reflects likelihood of presence of autoantibodies
Previous transplants	No. and duration	Degree of immunologic insult; possibility of repeated exposure
	Kind and date of each	Immunogenicity and graft duration
	Current condition[a] of each	Potential source of antigen for maintaining sensitization or absorbing antibody
	HLA type of each	Identity of mismatched antigens
Pregnancies	No.	Potentially sensitizing events
	No. that went to full term	Increased potential for sensitization
	Identity of paternal HLA antigens	Identifies specificity of potentially sensitizing antigens
Transfusions	Occurrence of previous transfusions	Possible sensitization
	Date of most recent	Selection of serum for testing; interpretation of results
Surgeries	Kind and date of each	Possible source of unreported transfusions
Medications administered	Humanized antibodies	Cannot be readily removed
	Therapeutic monoclonal antibodies	Panreactive in lymphocyte-based assays
	Other cytotoxic drugs	May result in nonspecific cell death in lymphocyte-based assays
	Other drugs	Possible interference with assays
Recent immunologically stimulatory events	Infections	May result in lymphocyte-reactive antibodies that are not specific for HLA; may cause a polyclonal activation that results in recurrence or increase of HLA-specific antibodies; may result in cytokine release and increased expression of HLA antigens on donor tissue
	Trauma	
	Hormone therapy	

[a]Whether or not the graft has been removed.

supplemented with information about previous surgeries that might have been occasions for transfusion.

Tests

There are two categories of test used to assess a humoral response, the crossmatch and the antibody screen, the latter of which may be further subdivided into screens that test simply for the presence of antibody and those designed to provide antibody characterization.

Crossmatch Tests

The crossmatch test assesses the presence, in the recipient's serum, of antibody reactive with donor antigens. The most commonly used medium for the antigen is donor lymphocytes, which are readily obtainable and express HLA antigens at high levels, although other cells and tissues have been employed in specialized studies. Recently, efforts have been directed at using solubilized donor antigens as targets in solid-phase immunoassays, the advantages of which are discussed below in "Techniques for Testing Antibodies." In HLA-mismatched transplants that include substantial amounts of immunocompetent tissues, such as transplants of bone marrow and possibly lung and small bowel, a reverse crossmatch test involving donor serum and recipient cells is also appropriate since engrafted tissue from a sensitized donor could produce antibodies reactive with recipient HLA. Another antibody-mediated problem, transfusion-related acute lung injury (TRALI), can occur when transfused blood contains a substantial amount of antibody specific for the transfusion recipient's HLA antigens (10). Although a reverse crossmatch test could identify such situations, it is more efficient and economical to screen plasma units for the presence of HLA-specific antibody.

The advantages of the crossmatch test are that it measures reactivity with donor antigens directly and can be used to track the trend of anti-donor reactivity through serum titration. The disadvantages are that (i) when cellular targets are used, the test does not readily differentiate HLA-specific antibodies from other antibodies that bind to lymphocytes and (ii) donor cells are not always available at the necessary time or in sufficient quantities, although it may be possible to use cells from a surrogate donor, as will be discussed later. New crossmatching methods, solid-phase immunoassays that utilize solubilized donor HLA antigens as targets, may avoid some of the technical problems of lymphocyte-based assays while assessing donor specificity directly. The advantages and disadvantages of the various techniques are discussed further below.

Antibody Screens

An antibody screen is simply a crossmatch or series of crossmatches against individuals selected according to their HLA phenotypes to represent, collectively, most HLA antigens. There are two types of antibody screens, those that utilize a pool of antigens or cells from multiple individuals to determine the presence or absence of antibody and those that utilize a panel of individual phenotypes or antigens to determine the HLA specificities of the antibodies. The antibody screen has multiple advantages. It can be performed at any time prior to or following transplantation and, thus, prevent unnecessary donor testing and/or shipment of organs. It provides information useful in performing and interpreting the results of a crossmatch test, such as which sera represent the array of HLA antibodies that the patient has ever had, which sera might contain interfering antibodies such as

autoantibodies or therapeutic antibodies, what is the most informative crossmatch technique, and whether or not a positive crossmatch result is due to antibodies to the donor HLA antigens. When performed on sequential samples, it provides information about trends in antibody activity. Finally, it provides a means of recognizing when sensitizing events or sample switches might have occurred.

The major disadvantages of the antibody screen are that it neither tests donor cells nor defines antibody directly. That is, most antibody assignments are based on a statistically significant association between the positive reactions of the antibody and the presence of one or more antigens. The development of solid-phase immunoassays using single antigen targets resolves some of that problem, but as will be discussed below, these assays are not a fail-safe method of determining antibody specificity. The high polymorphism of the HLA system mandates the use of panels of 50 to 100 phenotypes to be able to determine HLA specificities reliably. Even then, it is difficult to characterize sera containing multiple antibodies since antibodies to three or four common antigens can render a serum panreactive. Tests using single, purified antigen targets should resolve this problem. However, at present, these reagents are not characterized well enough to provide a stand-alone, definitive method. It should be noted that although using an antibody screening technique that is more sensitive than the crossmatching technique may provide information about levels of DSA too low to be detected in the crossmatch test, using a screening technique that is less sensitive than the crossmatching technique may result in difficulty in interpreting a positive crossmatch result.

Techniques for Testing Antibodies

General Principles

There are two categories of antibody-testing techniques differentiated by type of target: (i) those that utilize cells as targets—namely, cytotoxicity testing and flow cytometry—and (ii) those that utilize soluble HLA molecules bound to a solid matrix. The relevant factors for each type of assay and their advantages and disadvantages are summarized in Tables 2 and 3 and discussed below.

Complement-dependent cytotoxicity tests detect antibodies through a secondary process—cell lysis by a complement which has been activated by antibodies bound to target cells. The test usually consists of a sensitization phase in which target cells and serum are incubated together, followed by the addition of complement and subsequent incubation to allow the complement to be activated by the bound antibody. Microscopic evaluation following the addition of a vital stain permits a gross estimation of the percentage of viable cells (9). The sensitivity of the assay can be modified by altering incubation times and temperatures, performing washes to remove anticomplementary factors, and adding an antiglobulin reagent to enhance complement activation. The test is routinely performed on lymphocytes, which are usually further fractionated into T- and B-lymphocyte populations. Each test uses cells from a single individual.

Cell-based flow cytometry is an indirect assay that measures the binding of antibody to cells through the use of an antiglobulin labeled with a fluorescent marker. The specificity of the antiglobulin reagent permits identification of the Ig class of cell-bound antibodies. Further characterization of the cells can be achieved by gating on cells defined by physical parameters and staining of cells with labeled monoclonal antibodies specific for markers that are unique to certain cell

TABLE 2 Assay characteristics

Factor	Cell-based assays		Solubilized antigen-based assays		
	Cytotoxicity	Flow cytometry	ELISA	Flow cytometry with beads	Luminex
Sensitivity	Low to moderate	High	High	High	High
HLA specificity	Low to moderate	Low to moderate	High	High	High
Isotype detection	Gross; requires serum manipulation	Determined by conjugate specificity	Determined by conjugate specificity	Determined by conjugate specificity	Determined by conjugate specificity
Cost	Low	High	Moderate to high	High	High
Automation	None	Partial	Partial	Partial	Partial
Throughput	Can test multiple sera simultaneously but not rapidly	Limited	High	Limited	Very high

types. Although flow cytometric tests usually employ cells from a single individual, it has been demonstrated that the assay is sufficiently sensitive to detect antibody to cells from one subject in a mixture of cells pooled from up to six different individuals (19).

Solid-phase immunoassays utilize affinity-purified, soluble HLA antigens isolated from culture fluid or human plasma, solubilized from cell membranes, or synthesized via recombination technology. Several test methods are in current use. An enzyme-linked immunosorbent assay (ELISA) uses microtiter or microtest plates with the antigen bound to flat-bottom wells. After the addition of test serum to the wells, the presence of HLA-specific antibody is detected by the addition of an enzyme-conjugated antiglobulin and a chromogenic substrate which results in a color change in wells containing bound HLA-specific antibody. The antigens may be from a single individual or may be pooled from multiple individuals who, collectively, represent all or nearly all HLA antigens, and they may be of a single HLA class or a combination of HLA class I and HLA class II antigens (9, 25). The assay can be read manually, but the use of an auto-mated reader increases sensitivity and provides finer quantification of the reactions. HLA antigens bound to 5.6-μm-diameter polystyrene beads are employed in two different formats: standard flow cytometry and the Luminex format (4). In standard flow cytometry, a single dye is incorporated into beads in different concentrations to permit differentiation of beads bearing different antigens or antigen combinations. In the Luminex format, two different dyes, each at 10 different dilutions, are incorporated into beads to provide up to 100 different beads differentiated by color. The beads are examined in a specific instrument in which one laser is used to identify the particular bead and another is used to detect the presence of a fluorochrome-conjugated antiglobulin that has bound to the human antibody on the bead. The beads may be coated with pooled class I or class II antigens, antigens from class I or class II phenotypes, or antigens of a single HLA specificity.

Advantages and Disadvantages

Two of the major advantages of the cytotoxicity assay stem from its use for more than three decades: (i) it is usually

TABLE 3 Advantages and disadvantages of different assays

	Cytotoxicity	Flow cytometry	Solid-phase immunoassay
Advantages	No additional training needed Can adjust sensitivity 35 years of experience No special equipment needed Inexpensive; can run multiple dilutions for little additional cost	High sensitivity Can select isotype detected Simultaneous analysis of multiple cell types	High sensitivity Eliminates reactivity of non-HLA-specific antibodies Partial automation possible Readily distinguishes between cI- and cII-specific antibodies
Disadvantages	Extra manipulation required to differentiate between cI- and cII-specific antibodies Need adequate number of viable lymphocytes Does not readily distinguish HLA-specific antibodies from other lymphocyte-reactive antibodies Does not detect extremely low levels of antibody	Requires expensive equipment Cost of reagents Need adequate number of viable lymphocytes Does not readily distinguish HLA-specific antibodies from other lymphocyte-reactive antibodies Software may not interface with existing database	May require additional training Reagents can be expensive May get interference from immune complexes, high levels of IgM, or discoloration of serum Extensive quality control needed No reasonable way to assess levels of various antigens present Software may not interface with existing database

a standard test in laboratories performing histocompatibility tests for transplantation, and (ii) all the test variables, factors affecting the test, and quality control requirements have been well characterized. The test utilizes very small volumes of test materials (1 to 2 μl of serum and 2,000 to 2,500 cells per reaction) and is relatively inexpensive to run. Multiple serum samples can be tested at multiple dilutions, providing information about antibody titers and trends for one or multiple patients. Despite these advantages, however, the test has many shortcomings. It requires an adequate supply of viable lymphocytes, separate testing of T and B lymphocytes, and removal of class I-specific antibodies to identify class II-specific antibodies; depends on the activity of the complement, which is a highly variable and labile reagent; requires adequate amounts of the heterophile antibody found in rabbit serum used routinely as the complement source; is not sufficiently sensitive to detect extremely low levels of antibodies; and, most importantly, does not readily differentiate between HLA-specific and other lymphocyte-binding antibodies. Antibodies that may interfere in the assay include autoantibodies, therapeutic antibodies that react with all or some subsets of lymphocytes, and some anti-Lewis antibodies. Spurious reactions with B lymphocytes have been attributed to anti-viral antibodies. A gross evaluation of the class of antibody reactive in the assay is possible through inactivation of IgM with reducing reagents or heat aggregation. However, neither technique will completely abrogate the reactivity of high levels of IgM.

Cell-based flow cytometry provides a high degree of sensitivity, permits simultaneous analysis of multiple cell types without the need for separation of cells, and facilitates determination of Ig class through the selection of antiglobulin specificity. However, like the cytotoxicity assay, it requires an adequate number of viable cells and does not readily differentiate between HLA-specific and other lymphocyte-binding antibodies that either are of human origin or have been humanized. Further, it requires expensive equipment and specialized training and utilizes expensive reagents.

Solid-phase immunoassays using purified HLA antigens combine a high degree of sensitivity with increased specificity. We have found the sensitivity of ELISA to be comparable to that of cell-based flow cytometry (11, 25) and Luminex tests to be more sensitive. Solid-phase immunoassays readily distinguish between class I- and class II-specific antibodies by using antigens of only one class in a single test. Further, these assays provide a more refined quantification of reactivity with the different phenotypes, which enhances the characterization of antibody specificity. The solid-phase immunoassays have demonstrated an immunity to interference from a variety of non-HLA-specific antibodies, including therapeutic antibodies, including therapeutic antibodies specific for non-HLA lymphocyte surface markers. The high sensitivity of solid-phase immunoassays makes it possible to detect an antibody to a single antigen when a sample is tested against a pool of antigens. This is in contrast to the requirement for performing multiple tests against a variety of individual phenotypes in the cytotoxicity assay or against several sets each composed of a limited number of different phenotypes in the flow cytometric assay. The ability to test against pooled antigens represents a potential for substantial cost savings when sera are tested in batches. Further, beads differentiated by color permit multiple tests to run in a single assay that uses a very small serum volume. These assays have the potential of contributing substantially to our knowledge about the humoral response to HLA antigens and about the immunologic structure of the HLA molecule. However, solid-phase immunoassays are not without

disadvantages. These include a potential need for additional equipment and training, increased reagent cost for some of the assays, and a need for extensive quality control. The high sensitivity of these tests contributes to increased variability and necessitates extensive experience to optimize interpretation and use of the test results. Nonspecific binding of Ig may occur when the test serum contains immune complexes or aggregated Ig, rendering the test invalid. It has been found that high levels of IgM antibodies can affect test results, even when an IgG-specific antiglobulin is used (11). In assays using individual phenotypes, there is no way to ensure that each antigen of the phenotype is present in an adequate quantity. This may be a problem when the antigens are obtained from cell lines that may undergo mutation or viral transformation that affects synthesis of one or more antigens or when natural allele- and locus-specific variability affects antigen expression. There may not be uniform amounts of antigens among different beads that are each coated with HLA molecules of one specificity. HLA molecules may be distorted upon binding to a solid matrix, resulting in the loss of some epitopes or the creation of others. Finally, in any assay with computer-generated results, there is a potential for a problem in interfacing with the laboratory's existing database.

Quality Control

Crossmatch

There are three quality control procedures relevant to the crossmatch test. The objective of the first is to ensure that the cells being tested are from the right individual, which can be achieved by performing HLA typing in parallel to and with the same cells used in the crossmatch test. The objective of the second is to identify reactivity due to non-HLA-specific antibodies. Some of these antibodies, namely, autoantibodies and therapeutic lymphocyte-reactive antibodies, can be detected by performing an autologous crossmatch test. Finally, if one is using the crossmatch test to track the course of an antibody, including as a reference a serum sample that was previously tested by the same technique will provide a measure of variability in sensitivity.

Antibody Screen

Even though a positive control is included in all tests, it usually is not adequate to detect small variations in sensitivity. Such variations could result in a failure to detect antibodies present in levels that are at the border of the test's sensitivity. Inclusion of one or more well-characterized sera diluted to levels near their endpoints of reactivity would provide a means of recognizing this degree of variability.

Cytotoxicity Assay

Information about the cytotoxicity assay and relevant quality control measures is available in two excellent sources (8, 22), and we mention here only a few items particularly important in tests of antibodies.

Frequently, different lymphocyte subsets are used in the cytotoxicity test because of differences in the expression of various antigens. It is helpful to include controls specific for these subsets to estimate the relative purity of the cell preparation and detect contamination with unwanted cell types. These controls are usually monoclonal antibodies specific for a cell surface marker unique to or predominant in a certain cell type and most often are designed to identify T and B lymphocytes and, occasionally, monocytes.

Addition of an antiglobulin reagent is a frequent modification of the cytotoxicity test used for antibody detection. In these cases, it is important to include a control to validate the presence and efficacy of the antiglobulin reagent. This control should be a serum sample that activates complement only in the presence of the antiglobulin reagent.

Most background cell death (i.e., cell death not mediated by HLA-specific antibodies) is detected in the negative control wells. However, there may be occasions, particularly in the crossmatch test, that warrant additional discrimination. In these cases, the question of whether cell death is mediated by antibodies or not can be resolved by running a parallel test using a heat-inactivated (56°C for 30 min) complement.

Solid-Phase Immunoassays

Reagents
There are a number of factors that can contribute to variability among test reagent lots, including (i) changes in any component that affects test sensitivity, (ii) variability in the preparation procedures for one or more individual phenotypes, (iii) contamination of or absence of antigen in one or more wells of an ELISA plate or on one or more beads, (iv) changes in a cell line used as a source of antigens, and (v) manufacturing differences in the solid-phase media used. In turn, these factors can affect the threshold value for a positive test result, the background reactivity associated with an individual phenotype, and the ability of the antigens of an individual phenotype to yield a positive reaction with a specific antibody. Some of this variability can be assessed by testing each lot of reagents with a panel of well-characterized sera that includes sera known to contain HLA-specific antibodies as well as some known to lack such antibodies. In addition, each lot of reagents should be monitored throughout the course of its use to determine if the correct value has been selected as the threshold for a positive reaction and to determine if antigens of any individual phenotype are demonstrating an inordinate number of reactions that are discordant with the assigned antibody specificity (25). Recent reports have shown that normalizing reaction data to the amount of antigen present improves the interpretation of the results. It is likely that this sort of normalization is best conducted by the manufacturer on each lot of reagents rather than by each individual user, providing uniform standardization while minimizing the additional cost.

Tests
Batch tests of sera against pooled antigens provide little or no opportunity for detecting slight variations in test sensitivity or operator error such as sample switching or dilution error. Inclusion of two or more blinded characterized sera serves as a quality control measure of the test system as well as of testing personnel. The sera should vary in strength to provide a meaningful assessment of test sensitivity and should vary from run to run to serve as meaningful unknowns. Background reactivity may be caused by a variety of factors, including high IgM levels and immune complexes, among others. Background reactivity can result in false negatives when it occurs in the negative controls and false positives when it occurs in the test wells or beads. There are commercially available blocking agents designed to reduce nonspecific reactivity. Certain patients, notably those undergoing hemapheresis or plasmapheresis, have reduced background reactivity. In assays that use beads, the wash technique must be appropriate and consistent to avoid variable loss of beads. Of course, standard quality assurance measures, particularly instrument calibration, are essential to ensure consistent and reproducible results. Quality control factors relevant to tests of antibodies are summarized in Table 4.

TEST VALIDATION
The requirements for validation of laboratory assays are described in detail in the federal regulations (see above). Testing for HLA antibodies is confounded by the complexity of the HLA system and the antibody response to HLA antigens and by the lack of reference antibodies. Therefore, test validation can be prolonged and costly. To optimize evaluation of the assays and the clinical utility of the data generated, there should be an ongoing comparison of the

---

TABLE 4 Quality control factors

Test	Variable	Quality control measure	Purpose
Crossmatching	Cell identity	Serologic typing performed simultaneously with crossmatching	Verify identity of cells used in crossmatch test
	Antibody specificity	Autologous crossmatching	Test for presence of non-HLA-specific antibody
	Titer	Use of reference (previously tested serum)	Account for day-to-day variability
Antibody screening	Test sensitivity	Testing of serum at threshold of reactivity	Test for small variations in assay sensitivity
Cytotoxicity	Cell type	Use of cell-specific antibody	Assess proportion of different cell types in preparation
	Antiglobulin level	Use of antiglobulin-dependent serum	Test efficacy of antiglobulin reagent
	Cause of cell death	Heat inactivation of complement	Abolish antibody-mediated cell death
Solid-phase immunoassays	Presence or absence of nonspecific binding	Use of antigen-free matrix (well or bead)	Measure extent of nonspecific binding
	Phenotype validation	Use of panel of known sera	Test for presence of expected phenotypes
	Threshold for defining positive reaction	Ongoing comparison to results of other assays	Determine if value for positive reaction is correct
	Technical errors	Use of blinded controls	Determine if expected results are obtained

results of various tests—can the crossmatch test and antibody screen results for a specimen be reconciled? These comparisons reflect the sensitivities and specificities of the various assays. A frequently asked question is how many sera need to be tested for validation of an antibody screen assay. This question is impossible to answer with a specific number because of the thousands of possible combinations of antibodies that can be present in a specimen. The practical answer is that the validation must generate enough data for the user to be able to interpret the test results reliably. Some aspects of an assay's performance may be detectable only after extensive testing. Therefore, evaluation of an assay should continue after sufficient testing has been performed to place the assay into clinical use with confidence.

INTERPRETATION

Antibody Screen

Data Obtained

Five types of data may be obtained from antibody screens: (i) the strength of individual reactions, (iii) Ig isotype, (iii) titer, (iv) percent panel-reactive antibody (PRA), and (v) HLA specificity. Positive reactions of a serum sample with antigens of a variety of phenotypes may vary in strength because of differences among phenotypes in the number of antigens to which the serum contains antibodies; because of normal variability in antigen expression among individuals, cell types, and antigens and within an individual from day to day; and because of differences in the numbers and titers of various antibodies within a serum sample. There are abundant data regarding variability in antigen expression on cells. Class I antigens are expressed at higher levels on B cells than on T cells. Among various loci, HLA-C antigens are expressed at lower levels than are HLA-A and -B locus antigens and antigens encoded by DRB3 and -4 (and possibly -5) loci (DRw52, -53, and -51, respectively) are expressed at approximately 15 to 20% of the level of the DRB1-encoded antigens (DR1 to DR18). In tests of pooled antigens, differences in reaction scores obtained with different serum samples from the same individual reflect differences in the breadths of antibody specificities. Among sera from different individuals, these differences are determined by both the breadth of antibodies and the frequencies of the antigens in the pool. In tests of individual phenotypes, stronger reactions are obtained with phenotypes that are homozygous for a target antigen or that have more than one target antigen. This, in turn, may be useful in verifying antibody specificities. Quantification of the strength of reactivity is more refined in solid-phase immunoassays and flow cytometry than in cytotoxicity testing, and this information may be useful in confirming putative assignments of antibody specificity. Determining the molecular equivalents of soluble fluorochromes (MESFs) for flow cytometric or Luminex results permits comparison of test results from specimen to specimen and day to day. To determine MESFs, a standard calibration curve is created using beads labeled with different known amounts of a fluorochrome. The MESF value for a test serum is then obtained from the standard curve by interpolating the fluorescent channel values of the serum (18).

Ig isotype is most precisely defined in adherence assays that use an isotype-specific antiglobulin. In cytotoxicity assays, the Ig class may be approximated by heating serum (63°C for 10 min) or by adding reducing reagents to inactivate IgM. However, both methods have limited efficacy. Titer determination is easily achieved by testing serum at multiple dilutions.

The PRA is obtained by using the following equation:

$$PRA = \frac{\text{number of phenotypes with positive reactions}}{\text{total number of phenotypes tested}} \times 100$$

This statistic is frequently misinterpreted as an indicator of antibody titer, of changes in antibody reactivity in an individual over time, and of the likelihood of a positive crossmatch. PRA may reflect changes in antibody specificities over time but only if the phenotype panel remains constant, and then only when the loss of some antibodies is not compensated for by the addition of others with different specificities. The phenotypes in antibody screening panels are usually selected to optimize identification of antibody specificity and rarely, if ever, reflect the distribution of phenotypes and antigens in the donor population. Thus, PRA is a poor predictor of crossmatch outcome. However, identifying the HLA-specific antibodies in a serum sample permits one to calculate the probability of a positive crossmatch (27). Accurate characterization of the HLA-specific antibodies in a serum sample may provide the most valuable information for transplantation purposes. This information can be used to (i) reduce cold ischemia time by preventing the unnecessary shipment of organs and crossmatch testing of patients incompatible with a specific donor, (ii) avoid incorrectly passing over a sensitized patient by recognizing donors to whom the patient has no antibodies, (iii) determine the clinical relevance of a positive crossmatch by recognizing if the reactivity is due to HLA-specific antibodies or not, and (iv) permit preemptive treatment to avoid antibody-mediated rejection by detecting DSA present at levels too low to be detected in the crossmatch test and/or formed de novo after transplantation.

Phenotype Panel

In tests to determine antibody specificity, the most critical factor is the panel of phenotypes used. There are several goals to consider in establishing a panel, and these goals are often at odds with one another. The HLA antigens, collectively, should include the array of antigens in the donor population and occur in patterns that permit differentiation among antibodies of various specificities. The strong linkage disequilibrium of the HLA system may make it difficult to find a phenotype bearing an antigen without another with which it is frequently associated, such as B8 without A1. This problem is even more pronounced for HLA class II antigens. Also, some antigens are rare and may not be readily available for inclusion in a panel. Fortunately, antibodies to these antigens are also rare and reactivity is usually due to an antibody specific for an epitope shared with another, more common antigen. For example, reactivity with A36 occurs with antibodies specific for A1 and reactivity with B81 is usually mediated by an antibody to an epitope shared with B7. Thus, the absence of a rare antigen from a panel may be accommodated if one is willing to accept an antibody to a common antigen as evidence of sensitization to a rare, cross-reactive antigen.

Sensitized individuals, particularly those sensitized via transplantation, often display broad reactivity. This may be

due to either a large number of antibodies to different antigens or a small number of antibodies to epitopes shared among several antigens (7). In either case, precise definition of the antibody specificities may require tests against a large number of phenotypes. Establishing, maintaining, and using such a large panel are usually cost prohibitive. In some cases, information regarding antibody specificity may be obtained from other sources, such as crossmatch tests or special studies, but the possibility that a patient has unrecognized HLA-specific antibodies must always be considered. In these cases, solid-phase immunoassays that use single antigen targets may help resolve questions about critical antibodies.

Solid-phase immunoassays using purified, single HLA molecules as targets are available from more than one supplier; however, precise information about the quantity of each antigen and the extent to which structural conformation may have been compromised is not readily available. Further, when single-antigen reagents are used, the determination of the presence or absence of a particular antibody may rely on only a single reaction. In these cases, a technical failure that involves a key antigen could have serious consequences. Therefore, single-antigen reagents are probably best used as an adjunct to other antibody tests, in particular when other assays do not provide a clear identification of antibody specificities.

Specificity Determination

When a serum sample is tested against a variety of phenotypes, the basis of specificity determination is the association between the occurrence of an antigen and the reactivity of the serum. This can be demonstrated diagrammatically and defined statistically. The association can be shown in either of two ways for the purposes of statistical analysis. The first is a 2×2 table.

		Antigen		
		+	−	
Serum	+	a	b	A
	−	c	d	B
		C	D	n

The composition of the 2×2 table is as follows. The concordant reactions, when antigen and serum reactivity are both either present (+) or absent (−), are represented in cells a and d, respectively. The discordant reactions are those in which the serum yields a positive reaction in the absence of the antigen, represented in cell b, and in which the serum yields a negative reaction in the presence of the antigen, represented in cell c. The capital letters A to D represent the marginal totals (e.g., A = a + b), and n is the total sample size (n = A + B = C + D). The values are used in the statistics described below. The 2×2 data can also be presented in a linear display, shown here.

	Serum versus antigen			
Specificity	++	+−	−+	−−
	a	b	c	d

Note that the heading of this display, serum versus antigen, specifies the reaction order. That is, in the third column, "+−" means that the serum is serum positive and the antigen is absent (negative).

A correlation coefficient (r) or chi-squared (χ^2) value can be calculated (2) from these data by using the equations shown below.

$$r = \frac{ad-bc}{\sqrt{ABCD}} \text{ or } \chi^2 = \frac{n(ad-bc)^2}{ABCD}$$

The P values for the correlation coefficient are affected by the sample size, and for the chi-squared statistic, they are affected by the degrees of freedom, which are always 1 for a 2×2 table. These values can be found in standard statistical tables (6), and a few are given here.

Statistic	Probability			
	0.05	0.02	0.01	0.001
χ^2	3.841	5.412	6.635	10.827
r (n = 40)	0.304	0.358	0.393	0.490
r (n = 50)	0.273	0.322	0.354	0.443

Either statistic can be used, and the two are algebraically related when an uncorrected chi-squared value is calculated (i.e., $\chi^2 = r^2 n$). The correlation coefficient yields values on a scale of −1 to +1, with +1 and −1 reflecting complete positive and negative associations, respectively, and 0 being the absence of an association. The chi-squared numerical value can range from zero to infinity and varies with different values of n. Thus, the values cannot be compared meaningfully for sera tested against panels of different sizes. Although r values greater than 0.3 are statistically significant for panels in which n is ≥ 40, it is difficult to assign specificities with confidence with correlations below 0.5. In our experience, 95% of assignments have r of ≥ 0.5 and 85% had r of ≥ 0.6. One is more willing to accept correlations with lower values when there are other supportive data. For example, if the titer of an antibody decreases over time, the correlation will diminish with increasing numbers of false negatives. However, the remaining reactivity provides evidence of the antibody's continued presence.

Diagrams showing comparisons of antigen and serum reaction patterns are provided in Fig. 1 to 4. In all the figures, the panel members' phenotypes are shown in the columns, the columns collectively represent the entire panel, and the rows indicate the presence or absence of specific antigens in

phenotype	1	2	3	4	5	6	7	8	9	10	11	12	13	14	15	16	17	18	19	20	21	22	23	24	25	26	27	28	29	30	31	32	33	34	35	36	37	38	39	40	41	42	43	44	45	46	47	48
A2	X				X	X								X											X		X		X													X						
serum 1	X				X	X								X											X		X		X													X						

FIGURE 1 Determination of specificity: serum 1. Reactions and presence of antigen are indicated by X.

FIGURE 2 Determination of specificity: serum 2, first iteration. Reactions and presence of antigen are indicated by X. the phenotypes and the reactivity of test sera with the phenotypes. For economy of space, only specificities being discussed are shown. For example, in Fig. 2, phenotype 1 has neither A9 nor B35, phenotype 2 has both, and phenotype 3 has B35 but not A9. In Fig. 1, it can be seen that the pattern of reactivity of serum 1 with the panel is identical to the pattern of occurrence of the A2 antigen on the panel. The linear display of this association and the 2×2 table are given below.

<div align="center">

Serum versus antigen

Specificity	++	+−	−+	−−	r
A2	8	0	0	40	1.0

</div>

<div align="center">

HLA-A2

		+	−	
Serum 1	+	8	0	8
	−	0	40	40
		8	40	48

</div>

There are 8 concordant positives, 40 concordant negatives, and no false positives or false negatives.

Unfortunately, most sera do not yield such unambiguous patterns of reactivity. A more typical example is shown in Fig. 2. We have shown the patterns of the two antigens, A9 and B35, that have the strongest associations with the serum reaction pattern. The 2×2 data and correlations are as follows.

<div align="center">

Serum versus antigen

Specificity	++	+−	−+	−−	r
A9	9	4	3	32	0.62
B35	6	7	2	33	0.48

</div>

Although both correlations are highly significant statistically, neither is convincing. Both sera have a substantial number of discordant reactions. Since no better correlation was found with a single antigen, the next step is to look for one or more additional antigen patterns that account for the false positives. The high degree of homology among HLA antigens has resulted in sharing of antigenic epitopes among groups of antigens—the so-called cross-reactive groups of antigens, or CREGs. These shared epitopes are also referred to as public determinants, and those unique to a single antigen are referred to as private determinants (15). Antibodies produced in response to sensitization with HLA antigens are often specific for public determinants (16). A9 has been associated with two major CREGs, A2-A9-A28 and A1-A9. Figure 3 shows that neither of these CREGs can account for the serum reactivity. The serum has failed to react with any A1s; A2 accounts for one of the false positives, but the serum missed six other A2s and all three A28s. However, when we examine the B35 CREG (Fig. 4), we see an excellent correlation between the serum reactivity and this group of antigens as shown below.

<div align="center">

Serum versus antigen

Specificity	++	+−	−+	−−	r
B35 (6 of 8); 53 (4 of 4); 70 (3 of 3)	12	1	2	33	0.85

</div>

Numbers in parentheses indicate the number of positive reactions out of the total number of antigen occurrences.

Note that the correlation coefficient has been calculated for the CREG rather than for each antigen within the CREG. We believe that this provides a more accurate assessment of the serum reactivity.

Reactivity strength in cytotoxicity assays is measured on a discontinuous scale in which the percentages of dead cells are grouped into five categories. There are a large number of

FIGURE 3 Determination of specificity: serum 2, A9 CREGs. Reactions and presence of antigen indicated by X. False-negative reactions for assigned specificities are indicated by boldfaced X's. False-negative reactions for assigned specificities are indicated by O.

variables that can affect the assessed strengths of reactions in a cytotoxicity assay, including day-to-day variability in test conditions and variability among technologists in assessing reaction strengths. Reaction strength is measured on a continuous scale in solid-phase immunoassays, reaction results can be instrument read, and all phenotypes are tested simultaneously. The effect of this is that when the results are listed in descending order of reaction strength, the positively reacting phenotypes are often grouped by target antigen. This facilitates identification of at least some of the antibody specificities. Specificity determination is not an exact science; however, several things can be done to increase the accuracy of the interpretation. We have shown here the value of considering cross-reactivity. Another step is taking into account the phenotype of the person whose serum is being tested, since individuals do not normally make antibodies to their own HLA antigens. Tracking patients' reactivity patterns over time and identifying the phenotypes of the sources of sensitization, particularly transplantation and pregnancy, can provide confirmation of tentative specificity assignments. As noted earlier, the strongest reactions in solid-phase immunoassays are usually with phenotypes that correspond to two or more antigens with which the serum is reactive. For example, for a serum specimen with antibodies to A2 and A9, when the reactions are listed by strength, the phenotypes at the top of the list are likely to be those having both A2 and A9 or homozygous for one or the other, followed by those having A2 but not A9 and then those having A9 without A2. For broadly reactive sera, some specificities can be identified by testing the sera at multiple dilutions since different antibodies in the sera are likely to be present at different titers. In the example given here, the reactions at a 1:8 dilution may be limited to A2-bearing phenotypes and the undiluted serum reacts with all phenotypes having either A2 or A9. Importantly, however, one should avoid the temptation of trying to account for each serum reaction and assign only those specificities that can be assigned with confidence. Additional specialized techniques discussed later in this chapter may be useful in cases in which it may be crucial to confirm the presence or absence of a particular antibody.

Computerized Specificity Analysis

Most computerized analysis programs perform what is referred to as a tail analysis. This is an iterative process in which the pattern of serum reactivity is compared with the patterns of all of the various antigens. The specificity yielding the highest statistical value above a designated threshold is assigned, and then the positive reactions attributable to the assigned specificity are deleted from both the antigen patterns and the serum reaction pattern. The pattern of the remaining reactions is then compared to the abridged set of antigen patterns, and the process is repeated to a designated end point. Unaccounted-for serum reactions are the tail, and the phenotypes of these are then printed out. The problem with this approach is well illustrated in the example of serum 2, shown above. In this case, the A9 specificity would have been assigned, eliminating five of the eight B35 phenotypes, two of five B53s, and one of three B70s, leaving those three antigens with correlation coefficients of 0.30, 0.67, and 0.67, respectively. The most likely computer-assigned specificity would be A9, B53, and B70, with r of 0.80. Clearly, further investigation of this serum would reveal that the presence of antibodies to B35, B53, and B70 is more likely statistically and more logical biologically. Several steps can be taken to overcome this problem, at least in part. CREG patterns could be used for analysis in addition to the antigen patterns. Rather than having accounted-for reactions eliminated, the next most likely specificity could be added and the correlation with the collective specificities could be determined at each step. Finally, one could simply have a list of all the specificities yielding a certain degree of correlation printed out and then direct the computer to analyze for correlations with certain groups of antigens. The problem with any approach is simply that computer programs deal with algorithms, not biology. Thus, computer assignments should not be accepted without manual review of the data.

Crossmatch Test

There are two levels of interpretation to be considered in the crossmatch test: whether or not the test result is positive and what the test result means clinically. Although it is possible to detect cell death and changes in either optical density or fluorescence, the lack of reference reagents has made it impossible to determine what amount of antibody yields what degree of reactivity in any of the assays used. This is further complicated by test variability within and among assays, among laboratories using the same assay, and among treatment protocols and transplantation practices. Therefore, most interpretation is based on clinical outcome. Unfortunately, many of the studies performed to correlate crossmatch results with clinical outcome have not controlled for many of the relevant variables, including (i) timing of acquisition of the serum specimen relative to transplantation, (ii) Ig class of the antibody, (iii) antibody specificity, and (iv) antibody titer. Therefore, the conclusions of these studies are frequently in conflict with one another.

Specialized Procedures

Serum Absorption

Sera containing HLA class I-specific antibodies will react with both T and B cells, confounding the identification of

class II-specific antibodies in cell-based assays. When solid-phase immunoassays are not an option for testing for class II-specific antibodies, sera can be absorbed with pooled platelets to remove the class I-specific antibodies. Platelets do not actively synthesize HLA molecules and lose them from their surface over time. Therefore, the age of the platelets will affect their efficacy. The pool should also comprise platelets from a number of individuals sufficient to provide a reasonable assurance that the major HLA specificities are represented (17).

It may be desirable to remove selected HLA-specific antibodies from a serum sample. This can be achieved by absorbing with cells (platelets or lymphocytes) from a single individual. However, the limitations on the number of cells that can be obtained dictates absorbing very small volumes of serum, which in turn increases the risk of introducing a significant dilution factor. An alternative to absorption with cells is absorption with polystyrene beads to which solubilized HLA molecules have been affixed—although this may be cost prohibitive and the HLA molecules may have altered conformational epitopes. Following absorption, control cells must be tested to establish the efficacy of the absorption.

Tests with Selected Cells

Improved characterization of antibody specificity in sera containing multiple antibodies can be achieved by testing such sera against cells selected to have specific, limited antigenic differences from those of the serum donor. Cells can be selected as surrogates for those of a potential or real donor when the donor cells are not available, as frequently occurs with deceased donors. One might select certain types of cells for their particular antigen expression patterns. For example, B cells express both HLA-DR and HLA-DQ antigens. Monocytes express HLA-DR, but only 10% of monocytes express HLA-DQ, providing a means of differentiating antibodies specific for these different sets of class II antigens.

Dealing with Non-HLA-Specific Antibodies

Among the most common interfering antibodies occurring prior to transplantation are autoantibodies. Many of these antibodies are IgM and can be eliminated by heat inactivation or reduction. However, these techniques will not completely abolish reactivity when the antibody is present at high titer, and absorption with autologous cells, more-effective techniques to eliminate IgM such as chromatography and dialysis (1), or tests that use an isotype-specific conjugate may be necessary in order to achieve a meaningful crossmatch. The large IgM molecule may block IgG binding. This can be overcome, in part, by performing the serum-cell incubation at 37°C, a temperature that favors binding of IgG. Autoantibodies of the IgG class are less common but do occur and are much more problematic in tests. The removal of these antibodies requires absorption. Periodically, autoantibodies will be present in a donor otherwise appearing to be healthy. This circumstance is suggested when tests of donor cells persistently yield low background reactivity in the negative controls of cytotoxicity tests despite consistently good pretest viability. When this situation is suspected, it is worthwhile to do a donor autocrossmatch test for confirmation.

Therapeutic antibodies are problematic in cell-based assays. When the antibodies are of nonhuman origin, they can be removed by absorption with magnetic beads coated with a species-specific antiglobulin or the interference can be overcome by performing flow cytometry with antiglobulin reagents that have been absorbed to remove reactivity with all but human Ig. The increasing number of humanized antibodies in use, however, is problematic for cell-based assays.

These antibodies may be reactive in cell-based assays for months after the cessation of treatment. In some cases, the target antigen may be removed from the cell surface, abolishing antibody activity. For example, pronase treatment of B cells removes CD20, the target of rituximab, among other cell surface molecules (24). Pronase-treated cells can then be run in a flow cytometric assay, but the treatment usually renders the cells too fragile for use in a cytotoxicity assay. When the antibody target cannot be removed, absorption with cells bearing the target antigen but lacking donor HLA antigens becomes the only recourse.

APPLICATION

Whom To Test

Three groups of patients are at high risk for an adverse effect of HLA-specific antibodies: organ transplant recipients, patients receiving platelet and/or leukocyte support, and patients receiving HLA-disparate bone marrow transplants. In the case of bone marrow transplants, both the donor and recipient should be tested. A fourth group of patients are those at risk for TRALI (see above). Although this is a serious condition and responsible for more than 10% of transfusion-related fatalities, the incidence is low (<0.5% of all patients transfused) and can be averted by having plasma screened for HLA- and granulocyte-specific antibodies.

When To Test

Conventional wisdom and federal regulations indicate that testing should be performed at regular intervals prior to transplantation and following sensitizing events. Unfortunately, we do not always know about sensitizing events and it is becoming increasingly apparent that we have not identified all possible sensitizing events. Clearly, data from apparently nontransfused patients and evidence of similarities between microbial proteins and HLA antigens indicate that there may be much broader potential for sensitization or reactivation of a humoral response than has been previously appreciated (14). Further, inflammation itself may generate polyclonal B-cell activation that results in the production of HLA-specific antibodies.

It has been suggested that the low rate of sensitization and increasing waiting times dictate testing only when transplantation is imminent. Most data on sensitization are from cytotoxicity testing, and increased use of the more sensitive and specific solid-phase immunoassays indicates that the percentage of patients sensitized may be grossly underestimated (4). Antibody screening can be performed at a low absolute cost and at a cost much lower than that of other components of transplantation. Antibody screening provides information important to selecting patients and sera for and interpreting the results of a crossmatch test and can provide advance notice of the presence of factors, such as autoantibodies, that may adversely affect interpretation of the crossmatch results. Therefore, it would seem that trying to reduce costs by eliminating access to the important information obtained from antibody screening is penny wise and pound foolish.

Special considerations apply to patients being treated in a protocol designed to reduce or eliminate humoral sensitization and will be discussed in a separate section below.

Perhaps one of the greatest and most costly deficiencies of the present standard of practice is the lack of adequate posttransplantation testing, which results from the lack of financial reimbursement for such testing. Three factors argue in favor of such testing: (i) there are now treatment

protocols that produce a durable elimination of DSA, (ii) assays presently available are sufficiently sensitive to detect antibodies before a transplanted organ suffers extensive injury, and (iii) prolonging graft survival by avoiding antibody-mediated rejection not only prevents returning a renal transplant patient to costly dialysis but also prevents increasing the number of patients awaiting transplantation.

How To Test

Good management practices dictate applying the minimal number of protocols uniformly to maximize cost saving. Having one or a small number of test protocols does save money in the laboratory, which should mean reduced laboratory charges. However, it is quite possible that this approach extracts a much greater cost in rejection, treatment for rejection, and reduced graft survival. It has been a costly lesson of medicine, learned over and over again, that the shotgun approach cannot be applied to complex issues. Given the complexity of transplantation, it is probably more cost-effective overall to customize testing according to the complexity and emergent nature of the case.

Monitoring for Desensitization Protocols

Patients with HLA-specific antibodies have access to transplantation reduced in proportion to the breadth of their sensitization and, as a group, have poorer graft outcomes. Several treatment protocols have been tried in attempts to achieve long-lasting reduction or elimination of HLA-specific antibodies. Presently, desensitization protocols can be grouped into two general categories: those that utilize high-dose (1 to 2 g/kg of body mass) pooled intravenous Ig (IVIg) and those that use plasmapheresis combined with low-dose (100 mg/kg) cytomegalovirus hyperimmune globulin or IVIg (13, 20, 23). The former is used to eliminate some or all HLA-specific antibodies of patients awaiting transplantation from either a live or deceased donor, the latter is used to down-regulate antibodies specific for a particular donor's HLA, and both are used for rescuing an organ undergoing antibody-mediated rejection. Both types of protocols require accurate identification of the patient's HLA-specific antibodies prior to treatment. The efficacy of the high-dose IVIg protocol can be predicted with in vitro testing (23). The ability of the IVIg reagent to block reactivity of the test serum in vitro correlates with its ability to down-regulate reactivity in vivo. The test must be performed in a fashion that avoids problems associated with the high Ig concentration. After there has been sufficient time after treatment for the serum Ig concentration to return to levels that do not affect testing, the efficacy of the treatment can be assessed with routine crossmatch or antibody screening assays.

The goals of monitoring for the plasmapheresis–low-dose cytomegalovirus hyperimmunoglobulin protocol are to determine the risk of antibody-mediated rejection, monitor treatment efficacy, and generate information that helps guide and fine-tune treatment (13, 20). The pretreatment evaluation of the patient consists of (i) identification of previous, potentially sensitizing events and the response to those events; (ii) creation of an immunologic profile of the present transplant (i.e., the number of current mismatches, the number to which the patient has antibodies, the immunogenicity of the mismatched antigens, and the occurrence of repeat mismatches); and (iii) determination of the specificity and strength of the DSA. The patient's antibodies should have been monitored during the pre-transplantation period, and once treatment is started,

serum samples should be obtained before and after each treatment, immediately prior to transplant, and 48 to 72 h after treatment is stopped. The extent of treatment (the number of rounds of plasmapheresis and additional immunosuppressants) needed correlates most strongly with the titer of the DSA. Therefore, a crossmatch test to assess the titer should be performed at a time prior to the initiation of treatment that is sufficient to allow any needed adjustments in the treatment schedule. Once treatment is started, tests should be performed to monitor the course of the DSA. A cost- and time-efficient way to do this is to test all sera in a solid-phase immunoassay that uses pooled target antigens to chart the general trend of the antibodies and to monitor the strength of DSA by performing crossmatch or antibody identification tests on selected sera. Plasmapheresis removes many substances from the plasma, and background reactivity in solid-phase and flow cytometric assays usually decreases during treatment. This should be taken into account when the results of these assays are interpreted. There is a certain amount of day-to-day and technologist-to-technologist variability in the results of complement-dependent cytotoxicity crossmatch tests. This variability can be minimized to a certain extent by having the same technologist perform all crossmatch tests and including in each round of testing a reference serum, which would be a historic serum sample from the patient, with a known titer. Also, normalization of the data through the use of MESFs and other procedures will facilitate a more meaningful interpretation of test results. The data that should be examined are (i) the overall trend of the DSA titer and (ii) the extent of rebound that occurs between treatments. Once the transplant has been performed, a sample should be obtained 48 to 72 h after treatment is completed to check for DSA rebound. Whenever possible, transplant patients should undergo antibody monitoring posttransplantation for a minimum of 3 months and following any potentially sensitizing event.

The Whole Picture: the Assessment of Risk

As the opportunities for reducing antibodies and modulating the immune response improve, it will become increasingly important to produce a body of information that provides an assessment of risk to the transplant. Our increasing understanding of the role of the humoral response in transplantation indicates the need for certain types of information: (i) does the patient have antibodies; (ii) if so, what are the specificities, titers, and Ig classes; (iii) are the antibodies increasing or decreasing in strength or breadth; (iv) has the patient had antibodies in the past; and (v) has the patient experienced potentially sensitizing events. Neither the crossmatch test nor the antibody screen alone can answer these questions—the tests are complementary, and both are needed to get an accurate assessment of the patient's humoral immune status. The antibody screen may reveal very low levels of an antibody, indicating that a very sensitive crossmatching technique, such as flow cytometry, is appropriate or, conversely, may demonstrate that the antibody levels are such that this expensive technique is overkill. Even when both antibody screening and crossmatch tests are performed, it may not be possible to obtain an adequate picture of the patient's humoral immunity. In these cases, specialized techniques may be appropriate. Although the use of such ad hoc procedures will add to costs, in many cases and particularly when the information is applied to clinical care, the investment will be well worth it.

Evaluation of the Cellular Immune Response in Transplantation

NANCY L. REINSMOEN AND ADRIANA ZEEVI

138

Solid-organ transplantation has become an increasingly important therapeutic modality for patients with various end-stage diseases. Despite improved immunosuppression protocols, most transplant recipients face a variety of complications. Early posttransplant infection and rejection are the major causes of morbidity and mortality. Drug toxicity, chronic rejection, and malignancies are long-term complications.

Many attempts have been made to develop in vitro procedures that can assess the immunological status of the allograft reliably and accurately. Immunological monitoring could, in theory, differentiate rejection from other forms of dysfunction, such as infection or primary nonfunction. Furthermore, the ideal tool would be able to gauge accurately a patient's response to antirejection therapy and might help prevent overimmunosuppression. Immunological monitoring could also be important in predicting long-term graft outcome and thereby identify which recipients could have their immunosuppression therapy markedly reduced without increasing the risk of acute or chronic rejection.

Although there is no one ideal immunological test that can accomplish all of the above, there are a number of tests that can be used together to assess the immunological status of the transplant recipient. The most informative approach appears to be performing sequential analyses using assays that measure different immune functions.

MLC

Concept

Mixed leukocyte culture (MLC) is perhaps the most widely used of cellular assays. It represents a functional assay of cellular response to stimulatory determinants associated predominantly with HLA class II molecules, including HLA-DR and -DQ and, to a lesser extent, HLA-DP. The first descriptions of this assay as a measurement of cellular immunity (5, 6), together with the development of a one-way method of stimulation, allowed the correlation of proliferative responses between siblings. The conclusion was that a single genetic locus or region, now known as HLA, controlled the MLC reactivity. The recognition of disparate HLA class II molecules and the resulting T-cell activation (as measured by MLC) are thought to represent an in vitro model of the afferent arm of the in vivo allograft reaction.

MLC is an in vitro test of lymphocytes responding to stimulation by disparate HLA class II molecules, which are predominantly expressed on B cells and monocytes of the stimulator cell population. Proliferative reactivity to HLA class I molecules has been reported but plays a minimal role in the overall bulk MLC response. In MLC, stimulator cells have been inactivated, usually by X-irradiation, and can no longer divide. The resulting proliferation of responding cells involves the logarithmic expansion of multiple clones of alloactivated T cells. This expansion can be measured by incorporation of the radioisotope-tritiated thymidine into replicating DNA during the logarithmic phase of cellular expansion, usually on the fifth day of culture. The amount of thymidine incorporated into cellular DNA is then assayed by liquid scintillation spectrophotometry. Exogenous tritiated thymidine added to in vitro cultures is incorporated during DNA replication via the salvage pathway, in which free purine bases are formed by hydrolytic degradation of nucleic acid and nucleotides. Exogenous tritiated thymidine is added to cultures for a period of time that is longer than the S phase of the cell cycle but shorter than the cell cycle itself, usually 18 h.

The degree of reactivity observed correlates with the degree of antigenic disparity between responding and stimulating cells. MLC has been used clinically for donor selection, predominantly for bone marrow transplantation. With the more recent application of DNA-based HLA typing methods, MLC is used less often for donor selection but more often for monitoring of the recipient's posttransplant donor antigen-specific immune status. The difference between posttransplant and pretransplant antidonor MLC responses can be used to define any changes (increases or decreases). Studies have shown that solid-organ recipients who develop a decreased response (i.e., are hyporesponsive) are at low risk for immunological complications, such as late acute rejection episodes and chronic rejection. Hyporeactivity is defined as at least a 60% decrease in reactivity of the posttransplant antidonor response compared with that of the pretransplant antidonor response, assuming the response to third-party cells remains unchanged (33, 34).

Procedure

Sample Requirements

Collection of specimens: Care must be taken throughout the procedure to ensure a sterile specimen. Usually, 20 to 30 ml of sterile heparinized blood is obtained from the blood

donor. The specimen may be saved overnight but should be processed within 24 h of the phlebotomy. It should be maintained at room temperature even if it is being shipped by overnight carrier. Poor cell yields may result from temperature conditions that are too cold or too warm.

Materials and Reagents

Lymphocyte separation medium (LSM; Pharmacia Biotechnologies; catalog no. 17084003)

Culture medium: RPMI 1640 with HEPES buffer supplemented with 100 U of penicillin per ml, 100 U of streptomycin (Grand Island Biological; catalog no. 380-2400AJ) per ml, 10 U of preservative-free heparin (Monoparin heparin; Accurate Chemical & Scientific Corp.; catalog no. A6500) per ml, 2 mM L-glutamine, and 10 to 20% pooled human sera

Pooled human sera: sera from 10 to 20 healthy nontransfused male donors, heat inactivated at 56°C for 30 min (see "Pitfalls and Troubleshooting" below for additional specifications)

[^{3}H]thymidine (New England Nuclear; catalog no. NEN-027): specific activity of 6.7 Ci/mM. Commonly used amounts are 0.5 to 1.0 mCi per well.

Hanks balanced salt solution (Grand Island Biological; catalog no. 310-4170PJ)

Equipment and Instrumentation

Radiation source (usually gamma-emitting radiation source); alternatively, mitomycin (Sigma; catalog no. M0503)

Laminar flow hoods (Baker 60; The Baker Co., Sanford, Maine)

Liquid scintillation counter (1205 Betaplate; Pharmacia LKB)

Rate freezer (model 70014; CryoMed)

Liquid nitrogen refrigeration unit (model CAIIIL; CryoMed)

Mechanics and Controls

Mononuclear cells are isolated by centrifugation of peripheral blood diluted 1:2 with Hanks balanced salt solution over LSM. Peripheral blood mononuclear cells (PBMC) are removed from the LSM interface, diluted with Hanks balanced salt solution, and then centrifuged at $500 \times g$ for 10 min. The supernatant is decanted, and the wash steps are repeated two more times. The cells are resuspended in an exact quantity of complete culture medium. A leukocyte count is done, and viability is determined via dye exclusion. The cell suspension is diluted to a final concentration of 5×10^5 PBMC per ml by using the culture medium. Stimulator cells are inactivated either by irradiation at 1,500 to 3,000 rad or by incubation with mitomycin according to the manufacturer's instructions. With a repeating microliter pipette, stimulator and responder cells are added in triplicate to round-bottom microtiter plates (ICN; catalog no. 760-042-05) such that each well receives 100 μl of stimulator cells (5×10^4 PBMC) and 100 μl of responding cells (5×10^4 PBMC).

A complete culture setup includes the following:

1. Allogeneic cultures containing all possible combinations of responder and stimulator cells, including cells from three control cell donors of known HLA phenotypes

2. Autologous cultures containing the responder and stimulator cells from the same cell donor

3. Control wells containing either responder or stimulator cells alone, with an equal volume of complete culture medium

4. Double irradiation control cultures containing stimulator cells from two different cell donors

The cultures are incubated at 37°C in a humidified atmosphere of 5% CO_2 for 5 days, after which 0.5 to 1.0 μCi of tritiated thymidine is added to each well. The cultures are incubated for an additional 18 h. The culture plates can then be harvested immediately or sealed with pressure-sensitive film and placed in the refrigerator until harvesting. A number of different harvesting machines and counting systems are available: the cells can be harvested onto filter disk sheets, or the samples can be counted in vials or cassettes or directly, without the need for scintillation fluid. The manufacturer's instruction manual should describe the appropriate procedures.

Pitfalls and Troubleshooting

1. Drugs: If a patient is taking one of the following drugs, the proliferative response may be compromised: prednisone, Myleran, hydroxyurea, Cytoxan, or L-asparaginase.

2. Serum: One of the most common sources of technical problems in any cellular procedure is a poor serum source. Each individual lot of a serum source or, preferably, each individual serum unit within the lot should be screened for growth support capabilities and possible HLA antibodies. The screen should include a control response to a pool of allogeneic cells to measure maximum response and an autologous control to ensure low backgrounds. If sporadic high backgrounds are observed, an endotoxin test may be advisable.

3. Tritiated thymidine: If low counts per minute are observed, the scintillation counter and the shelf life of tritiated thymidine should be checked. The half-life of the tritium is 12.3 years, but the shelf life of the thymidine is considerably shorter.

4. Frozen cells: Cells to be used as responder cells in the cell cultures can be bulk frozen by a step-down procedure at $4, -30$, and $-70°C$ before use. However, viability and cell recovery are better if the cells are rate frozen and stored in the vapor phase of a liquid nitrogen storage unit.

The *American Society for Histocompatibility and Immunogenetics Procedure Manual* (35) is an excellent source of additional information and details on cellular methods.

Interpretation

Results are usually expressed as raw counts per minute of tritiated thymidine incorporation. The data may be reduced to allow for easier interpretation and comparability from one test to another. The two most common forms of data reduction are the stimulation index and the relative response (RR). The stimulation index is a simple ratio of the counts per minute for an experimental MLC combination to the counts per minute for the autologous control. The RR is the ratio of the net counts per minute (after subtraction of the autologous control counts per minute for an allogeneic MLC combination) to the counts per minute for a maximally stimulated or control MLC combination (usually the response to a pool of allogeneic cells), multiplied by 100 to obtain a percentage (35).

MLC VARIATIONS

MTT Method

A nonradioactive alternative to detecting proliferation is a colorimetric (3-4, 5-dimethylthiazol-2-yl)-2.5 diphenyl tetrazolium bromide salt (MTT) reduction assay. This assay detects the activity of a mitochondrial enzyme that is proportional to the number of metabolically active cells present in the culture. The MTT, a yellow aqueous solution, is taken up by the viable cells and reduced in the mitochondria to a purple crystal. After solubilization of these crystals, the reaction is measured with a spectrophotometer. An increase in the measured optical density parallels an increase in mitochondrial enzyme activity, which reflects an increase in the number of cells. This approach can detect increases in an interleukin 2 (IL-2)-sensitive line, CTLL2O. Van Buskirk et al. (47) have demonstrated that colorimetric detection of IL-2 production correlates well with the radioactive detection of T-cell proliferation and can be used interchangeably with the standard MLC.

Multiparameter Flow Cytometry

A second nonradioactive method to detect T-cell activation is a flow cytometry assay (FastImmune assay system; Becton Dickinson). It detects an early activation antigen, CD69, which reaches peak expression within 8 h of stimulation (24). The assay uses a three-color technique to detect CD3-, CD69-, and CD4-positive or CD3-, CD69-, and CD8-positive cells. Advantages are a short activation time (4 h), the absence of radioactivity, avoidance of peripheral blood lymphocyte separation, the ability to identify activated T-cell subsets, a quick turnaround (results can be obtained in hours), simplicity, and high sensitivity (24). This technique may be especially informative when mitogen or antigen stimuli are analyzed; however, analyzing a response to an allogeneic cell stimulus may be more difficult.

RELATED METHODS

T-Cell Precursor Frequency Determination by LDA

The frequency of T-cell precursors is determined by limiting dilution assays (LDA). Limiting numbers of responder cells are cultured with a constant number of stimulator cells and assayed for reactivity (cytotoxicity, proliferation, or cytokine release) against additional stimulator cells. In contrast to MLC, which measures a bulk response, LDA is a quantitative tool. It allows the investigator to estimate the frequency of lymphocytes with a given function and antigen specificity. LDA imply that the lysis is a single-hit process; that is, a single precursor cell will initiate the sequence of events that leads, in the case of cytotoxic precursors, to the eventual lysis of the cell. A frequency can be determined if the lymphocyte population is random; that is, the function of the lymphocyte population is not influenced by the presence of another lymphocyte population. The clear distinction between a response and a lack of that response is imperative. Making this distinction is more difficult in the cytotoxicity assay, where an arbitrary threshold that separates the spontaneous release of ^{51}Cr from the release from the lysed targets is set. The frequency of responding cells is determined by a maximum likelihood estimation by using a computer program (19).

LDA of HTL

Helper T lymphocytes (HTL) are detected by their ability to produce IL-2. The murine IL-2-dependent line CTLL2O is used as the indicator line in this bioassay. Adding CTLL2O cells directly to the micrometer wells is a more sensitive method than removing an aliquot of supernatant and adding it to the CTLL2O cells. Before adding the indicator line, the plates are irradiated to inhibit the responder cells from proliferating and incorporating [³H]thymidine. A low dose of irradiation does not block the continued production of IL-2 by the responding cells. In the absence of IL-2, the CTLL2O cells die rapidly. Therefore, any proliferation detected is due to division of the IL-2-stimulated CTLL2O cells.

Method

LDA can be done on fresh or cryopreserved cells. The cells are prepared as described in the section on the MLC protocol. Limiting numbers of PBMC (2×10^4, 1.0×10^4, 0.5×10^4, 0.25×10^4, 0.125×10^4, 0.0625×10^4, and 0.03125×10^4) are cultured in round-bottom microtiter plates with constant numbers (10×10^4) of irradiated (3,000 rad) stimulator cells. When HLA-identical pairs are tested, increased numbers of cells are often used such that the highest concentration is 4×10^4, 6×10^4, 8×10^4, or 10×10^4 cells per well. Multiple wells per dilution are necessary to ensure an accurate assessment of the frequency. Usually, 24 wells per dilution are set up. The culture medium is the same as that used in the MLC protocol. Control wells consist of 24 wells containing irradiated stimulator cells alone (for calculation of background activity), responder cells in medium alone (negative controls), and responder and stimulator cells set up separately against HLA-mismatched third-party cells (positive controls). The plates are incubated for 64 h at 37°C in a 5% CO_2 environment. The plates are irradiated with 2,500 rad. CTLL2O cells (1×10^3) are added in 25 ml of medium. The plates are incubated for 8 h with 1 mCi of [³H]thymidine in 25 ml per well. Cultures are reincubated for 16 h. Cultures are harvested and counted as outlined in the MLC protocol. The wells are considered positive if [³H]thymidine incorporation is greater than the mean plus 3 standard deviations of results for the 24 control wells. The frequency of responding cells is determined by a maximum likelihood estimation by using a computer program, and the variance is determined by the use of 95% confidence intervals. Regression analysis is used to generate a straight line. Chi-square analysis is used to show that the data obtained are in accordance with single-hit kinetics. A program that does all the necessary calculations for this analysis is listed in reference 19.

Pitfalls and Troubleshooting

The sensitivity of this assay depends on the condition of the IL-2 indicator cells. The proliferation of the CTLL2O line depends on murine or human IL-2 or murine IL-4, without which the cells will die rapidly. The line should be maintained at a concentration of 1×10^4 to 10×10^4 cells per ml in a solution containing RPMI 1640 (with HEPES), 100 U of penicillin/ml, 100 µg of streptomycin/ml, 2 mM L-glutamine, 1% sodium pyruvate (100 mM solution), 1% minimal essential medium amino acids (50×), 0.5% diluted beta mercaptoethanol (diluted 1:57 with phosphate-buffered saline [PBS]), and 10% pooled human serum (PHS) culture medium, supplemented with 500 U of IL-2. Great care should be taken to subculture this line every 2 to 3 days.

LDA of CTL

As mentioned before, the major advantage of the LDA is the ability to quantitate a particular T-cell function in an antigen-specific manner. The LDA for cytotoxic T lymphocytes

(CTL) requires a longer incubation time than that for HTL since the cytotoxic activity must be generated in the presence of growth factors and alloantigen. Thus, the cultures are incubated for 10 days; IL-2 is added on days 3 and 6. The target cells are labeled with ^{51}Cr, which is taken up by the target cells and linked to internal proteins by endogenous enzymes. The unbound ^{51}Cr is washed away. The targets are added to the LDA wells for 4 h. During this time, CTL lyse the targets and ^{51}Cr leaks out of the cell into the culture supernatant. The amount of ^{51}Cr detected in the culture medium is directly related to the number of target cells lysed by the CTL. Although ^{51}Cr does emit gamma rays, it is more efficient to assay for the Auger rays that are also emitted. The Auger rays have an energy level within the same wavelength range as those of tritium and, therefore, can be detected by the conventional scintillation counting method. Frequency determinations are done in a manner similar to that used for the HTL precursor (HTLp) method.

Reagents

Phytohemagglutinin (PHA), 28.75 U/ml (Burroughs Wellcome; catalog no. HA-17)

RPMI 1640

Method

Limiting numbers of PBMC (5×10^4 to 0.125×10^4) are cultured in round-bottom microtiter plates with constant numbers (5×10^4) of irradiated (3,000 rad) stimulator cells. Multiple wells per dilution are necessary to ensure an accurate assessment of the frequency. Usually, 24 wells per dilution are set up. The culture medium is the same as that used for the MLC method. IL-2 and additional culture medium are added on days 3 and 6 so that the final concentration is 5 U/ml. Target cells are prepared on day 7 by using unirradiated stimulator cells from the initial priming combination. The cell concentration is adjusted to 10^6 cells per ml, and 1 ml of the cells is placed with 1 ml of PHA in 4 to 6 wells of a 24-well microtiter plate and incubated at 37°C in a humidified atmosphere of 5% CO_2 for 3 days. On day 10, the cultures are assayed for cytotoxicity (or other functional assays are used) against ^{51}Cr-labeled target cells. PHA-stimulated target cells (2×10^6) are labeled with 0.5 mCi of ^{51}Cr for 1.5 h, washed, and adjusted to a concentration of 2×10^4 cells per ml. One hundred microliters of the medium is replaced in the priming cultures with 100 μl of labeled target cells, and the plates are spun at $100 \times g$ for 5 min and incubated for 4 h. Supernatants are harvested and tested for released ^{51}Cr by using either a gamma counter to detect the gamma rays or a beta counter to detect the Auger rays released. Wells are scored as positive by determining that the reactivity observed is significantly (>3 standard deviations) greater than the control background. Wells containing irradiated stimulator cells incubated without responder cells are used as background controls. As for the HTLp method outlined above, the frequency of cytotoxic cells is determined by a maximum likelihood estimation by using a computer program and the variance is determined by the use of 95% confidence intervals. A regression analysis is used to generate a straight line, and chi-square analysis is used to show that the data obtained are in accordance with single-hit kinetics. A program that does all the necessary calculations for this analysis is listed in reference 20.

Variation

A variation of the target cell labeling procedure for the cytotoxic limiting dilution analysis has been described by Van Besouw et al. (46). In this approach, the T-cell blast target cells are labeled with europium-diethylenetriaminepentaacetate (Fluka [Buchs, Switzerland] and Sigma Chemicals [St. Louis, Mo.]). The incubation period to measure cytolysis is the same as that previously described. The supernatant (20 μl) is transferred onto a low-background fluorescent 96-well plate (Fluoroimmunoplate; Nunc, Roskilde, Denmark), and 100 μl of enhancement solution (LKB-Wallac, Turku, Finland) is added to each well. Fluorescence of the released europium is measured in a time-resolved fluorometer (Victor 1420 multilabel counter; LKB-Wallac), and results are expressed in counts per second.

Cell Division and Precursor Frequency Analysis Using CFSE

Concept

The ability to determine the division history of specific cell populations proliferating in an immune response is useful in quantifying the phenotype and frequency of the responding cells, as well as functional changes during differentiation of T cells, B cells, and hematopoietic precursor cells. The intracellular fluorescent label carboxyfluorescein diacetate succinimidyl ester (CFSE) can be used to tag the proliferating cells. CFSE is cell permeant and nonfluorescent until cellular esterases cleave carboxyl groups from the molecule, rendering it nonpermeant and fluorescent. The succinimidyl moiety of CFSE covalently attaches to the cytoplasmic amine groups. The covalently bound CFSE is divided equally between the daughter cells, allowing for resolution of up to eight cell division cycles. The CFSE staining in combination with immunophenotyping allows comparison of the kinetics of proliferation in various cell populations. A quantitative assessment of antigen-specific-T-cell proliferation can be made by analysis of the flow cytometric histogram plots. The number of precursors that divided can be extrapolated and summed to determine the number of cells that responded to the antigen. By comparing the number of cells that divided to the number of those that did not divide, a precursor-responder frequency can be determined. The procedure outlined below is for testing human cells. Other references describe procedures for animal models (26, 27, 51).

Procedure

Sample Requirements
The collection requirements are the same as those for the MLC procedure.

Materials and Reagents
The lymphocyte separation medium, culture medium, pooled human sera, and Hanks balanced salt solution are the same as those for the MLC procedure.

CFSE is dissolved in dimethyl sulfoxide to the final concentration determined by the investigator. Aliquots can be stored at −20°C in a desiccator and protected from light for up to 1 year.

Equipment and Instrumentation
- Four-color flow cytometer (FACSCalibur; Becton Dickinson Immunocytometry Systems, San Jose, Calif.) and CellQuest software. Other instrumentation is the same as that for the MLC.

Mechanics and Controls

1. Staining procedure: For best results, the optimal dilution of CFSE in PBS, from a range of 1.25 to 2.5 mM, should be determined. The responder cell population is resuspended in PBS–0.1% bovine serum albumin (BSA) at a concentration of $<1 \times 10^7$ lymphocytes/ml and incubated with CFSE for 5 to 10 min (optimal time will need to be determined) at room temperature. Add an equal volume of pooled human sera and agitate for 1 min to quench the reaction. The cells are then washed three times in PBS and adjusted to the appropriate concentration in the culture medium. Alternatively, RPMI 1640 containing 10% pooled human sera can be used for the last two washes.

2. Culture conditions: As in the MLC, the responder cells are incubated with an equal number of peripheral blood stimulator cells. Epstein-Barr virus (EBV)-transformed lymphoblastoid cell lines (LCL) may be substituted for stimulator cells once the optimal LCL concentration that allows for minimal response to the EBV in seropositive donors is determined. The in vitro culture conditions are the same as those for the MLC, with positive and negative controls. The cell cultures are incubated for an optimal time (4 to 5 days) determined by the investigator. The cells are then harvested, washed, and stained with the appropriate antibodies for immunophenotyping as determined by the investigator (e.g., anti-CD3 [phycoerythrin {PE}] and anti-CD3 [peridinin chlorophyll protein {PerCP}]).

3. Flow cytometry analysis: The flow cytometer is set up for excitation at 488 nm, and the green fluorescence (i.e., CFSE) is collected with a 525-nm-pore-size band-pass filter. The immunophenotyping signals are collected with a 574-nm-pore-size band-pass filter for orange fluorescence (i.e., PE) and a 675-nm-pore-size band-pass filter for red fluorescence (i.e., PerCP and PE-Cy5). Four-color flow cytometry is performed (FACSCalibur), and the cells are analyzed using CellQuest acquisition and analysis software. A gate defining lymphocytes and blasts by forward and side scatter properties is used in all analyses.

Pitfalls and Troubleshooting

As in the MLC, the viability of the cells is crucial. Keeping a small amount of serum protein in the staining step helps to maintain viability. Protein also quenches the CFSE fluorescence; therefore, appropriate protein levels need to be determined by titration. The level of staining must also be determined since too heavy staining can cause problems with viability and compensation during acquisition and analysis.

Approximately eight division cycles can be identified before the autofluorescence obscures the peaks. If clear division peaks are not seen, optimal proliferating conditions may not have been obtained. It is helpful to start by setting parameters and culture conditions assaying a response obtained by stimulating with anti-CD3 or a recall antigen. Once reproducible results are obtained, a response to allogeneic cells can be optimized.

Interpretation

For quantitative assessment of the alloresponse, the number of cells within each CFSE fluorescent peak is determined by analysis of the flow cytometric histogram plots. The number of precursors that divided (P_{div}) is determined by analysis of the number of events comprising the various peaks of daughter cells with identical proliferative histories and extrapolated by dividing by $2n$, where n is the division cycle number. The number of precursors that divided makes up the numerator, and the denominator is the total number of cells (P_{tot}). The P_{div} is relatively straightforward to calculate; however, the P_{tot} determination is more complex and several approaches have been reported. To obtain a precursor frequency, the total number of potentially alloreactive cells, including those plated in culture but not recovered, must be considered as P_{tot}. Alternatively, the number of cells recovered may be considered as P_{tot}. To obtain a responder frequency, the number of cells that were activated but did not proliferate can be considered as P_{tot}. The investigator decides the method for determination of P_{tot}.

EBV-Transformed LCL

Long-term culture of cells can involve either normal cells or transformed cells. Normal B cells can be infected with EBV through the CD21 receptor. EBV-transformed LCL are often simply called LCL. An LCL panel or bank is a valuable source of reference DNA and reference reagents for tissue typing and can be used for cellular studies of epitopes recognized by antibody or T cells. Since the LCL have been transformed, they do not depend on the addition of exogenous lymphokines for their continual growth. These cell lines are easy to grow, but critical attention must be given to the sterility and growth conditions of the lines so that mycoplasma infection does not overtake the cultures.

Mycoplasma is an organism that lacks cell walls and, thus, is not susceptible to many antibiotics, nor is it readily visible by light microscopy. However, the effects of mycoplasma infection are readily evident and severe. *Mycoplasma* contains the thymine kinase enzyme, which interferes with nucleic and amino acid metabolism and subsequently with DNA replication in the contaminated cell culture. The growth rate of infected cells is affected, and they eventually die. Meticulous care must be taken, since mycoplasma infection can easily spread to other cultures in the laboratory. Mycoplasma infection should be suspected in short-term cultures if values for tritiated thymidine incorporation have decreased or are very low.

The single best way to prevent mycoplasma contamination is by using an aseptic culture technique. The cultures must never be allowed to overgrow the culture medium to the point where the medium is yellow. As outlined below, LCL must be checked and split at least every second day. A second common source of mycoplasma contamination is the water bath. When a frozen vial of LCL is thawed in a water bath, the outside of the vial should be wiped with a 2% bleach solution before it is opened. One of the first signs of mycoplasma infection of LCL is a dirty or gritty appearance of the cultures when viewed under the microscope. In addition, LCL generally will not divide at the usual rapid rate. They must be checked regularly for mycoplasma infection.

A variety of methods for mycoplasma detection are available, including Hoechst staining. Biochemical methods include nucleic acid hybridization using DNA probes. Simple kits for mycoplasma detection that rely on DNA hybridization techniques are now available (Gen-Probe; catalog no. 1591). The kit consists of small tritium-labeled DNA probes complementary to known specific sequences of mycoplasma RNA. These probes are added to the supernatant from cell cultures. If *Mycoplasma* is present, the DNA probe will bind to the mycoplasma RNA, forming hybrids that are then detected in a scintillation counter.

Procedure

Generation and Maintenance of LCL

The laminar flow hood must be cleaned daily with a 2% bleach solution, and the filters must be checked routinely.

Incubators must be cleaned monthly, including washing with a 2% bleach solution and autoclaving of all of the racks, and preferably, autoclaved water should be kept in the bottom of the incubator.

1. LCL culture medium: A commonly used medium is RPMI 1640 without HEPES buffer, supplemented with 100 U of penicillin per ml, 100 U of streptomycin per ml, 0.05 mg of gentamicin per ml, 2 mM L-glutamine, and 10% fetal calf serum.

2. EBV supernatant: The supernatant used to transform PBMC can be obtained by the culture of an EBV-shedding line, such as B95-8 cultured in LCL medium. The line is cultured for 2 weeks until the medium is yellow, at which time the culture is centrifuged at $1,500 \times g$ for 10 min and the supernatant is filtered through a 0.4-mm-pore-size filter.

3. CSA: Cyclosporine A (CSA) medium is stored as a stock, 50 mg/ml, at 40°C and is diluted in LCL culture medium to a final concentration of 0.5 µg/ml (also stored at 40°C).

Transformation

PBMC (2×10^6) are suspended in 1 ml of CSA culture medium, 1 ml of EBV supernatant is added, and the mixture is incubated for 21 days. Since the culture is shedding virus during this time, it should be isolated from other cultures. CSA culture medium is added during this period when the culture medium turns yellow. After 21 days, the cultures are removed from CSA culture medium and placed in regular LCL culture medium.

Maintaining LCL

The cultures are inspected for contamination, mycoplasmas, and cell density by using an inverted-phase microscope every other day. The cultures are split by diluting the cells to about 0.2×10^6 cells per ml. The LCL are controlled-rate frozen (usually at 5×10^6 to 10×10^6 LCL per vial) and stored in vapor phase liquid nitrogen.

Graft-Infiltrating Cells—Propagation of Lymphocyte Cultures from Allograft Biopsies

Concept

In solid-organ transplantation, the histological analysis of allograft biopsies remains the "gold standard" for diagnosing rejection (8). Although many cell types have been implicated in rejecting allografts, including B cells, macrophages, neutrophils, and eosinophils, it is generally accepted that CD3$^+$ T lymphocytes initiate allograft rejection (16, 50). Both CD4$^+$ (helper) and CD8$^+$ (cytotoxic) T cells are present in the graft and express IL-2 receptor and HLA-DR antigens, suggesting the presence of activated lymphocytes. The phenotype studies provide little information about the functional characteristics and their alloreactive specificity.

Another approach is to learn about the functional characteristics of graft-infiltrating cells through in vitro propagation in the presence of IL-2 (13, 15, 26, 27, 28, 32, 37, 54). Activation of T cells occurs as a result of recipient allorecognition of donor antigens, which leads to the expression of IL-2 receptors on the activated T cells. The lymphocyte growth assay is straightforward. Biopsy fragments are incubated in tissue culture medium supplemented with 5% human serum and 10 to 30 IU of recombinant IL-2. Lymphocyte growth in cardiac transplant recipients correlates with the histological grade of rejection, and positive growth from histologically negative biopsy fragments is associated with subsequent biopsy-proven rejection

(21, 49). A persistent lack of growth from biopsy fragments is associated with an increase in rejection-free cardiac allograft survival. These studies indicate that in vitro culturing of lymphocytes from endomyocardial biopsy fragments is clinically useful for the early diagnosis of acute cellular rejection. This conclusion may also apply to other organs. For lung transplant recipients, transbronchial biopsy fragments have been cultured to propagate infiltrating alloreactive T cells. Lymphocyte growth is virtually 100% for biopsy fragments with histological diagnosis of acute rejection or active bronchiolitis obliterans, a form of chronic lung rejection, and less than 30% of biopsy fragments with no major abnormalities show growth (29). The presence of activated T cells is indicative of a subsequent rejection episode. Lymphocyte growth from renal transplant biopsy fragments also correlates with acute cellular rejection, and the production of IL-2 by the infiltrating cells is associated with irreversible rejection (22). In liver transplant recipients, more lymphocyte growth is associated with rejection and less growth is seen for patients on OKT3 treatment for rejection (37).

A serious complication of heart transplantation is the development of accelerated graft coronary disease (GCD). Persistent growth from biopsy fragments during the first 3 months posttransplant is associated with a higher risk of GCD. More than 40% of patients whose biopsy fragments persistently grew lymphocytes developed GCD. In contrast, only 6% with non-grower biopsy fragments had subsequent GCD (55).

This section outlines the basic approach used to propagate cells from biopsy fragments. Other approaches, such as the use of donor or allogeneic cells as feeder cells, may be used at the discretion of the investigator. Since the ultimate goal is the early detection of activated cells infiltrating the allograft and not in vitro priming, this section deals with methods that minimize the possibility of priming against the donor antigens in vitro.

Procedure

Sample Requirements

An endomyocardial (or other tissue) biopsy specimen collected in a jar containing sterile physiological saline

Approximately 10 ml of heparinized blood obtained from the patient

Materials and Reagents

LSM Ficoll-Paque (Pharmacia)

500 ml of RPMI 1640 with L-glutamine (GIBCO) plus 12.5 ml of HEPES Buffer Solution 1M (GIBCO) and 2.8 ml of gentamicin reagent solution (10 mg/ml; GIBCO)

Pooled human sera type AB (NormIcera-Plus)—(Gemini Bio-Products)

Recombinant IL-2 (Hoffmann La-Roche)

Equipment and Instrumentation

Laminar flow biological safety cabinet (NuAire, Inc.)

Beckman centrifuge (model TJ-6)

Olympus biological microscope (model BHTU)

Forma Scientific water jacket incubator (model 3154)

Cesium-137 Gammacell irradiator

Test Procedure

Autologous feeder cells are separated from recipient blood by LSM centrifugation (see description of MLC

method). The biopsy specimens are placed in a small (35-by-10-mm) sterile petri dish by using a sterile transfer pipette, and with a surgical blade or sterile 20-gauge needles, the biopsy specimens are sectioned into three to four small fragments. Each biopsy fragment is transferred onto a 96-well round- (or flat-) bottom plate that contains 100 μl of IL-2-enriched medium (10 to 30 IU of IL-2 in 5% human serum–RPMI 1640). Autologous feeder cells are irradiated (4,000 rad) and added to each well at a concentration of 0.5×10^6/ml. The biopsy cultures are incubated at 37°C and 5% CO_2. Biopsy cultures are monitored for lymphocyte growth regularly. If the investigator wants to monitor rapid lymphocyte growth as a clinical test for rejection, then the biopsy fragments are incubated in IL-2-enriched medium without autologous feeder cells. This procedure allows the identification of graft-infiltrating cells that emigrate from the tissue to the culture well within 24 to 48 h. In the presence of feeder cells, the earliest report of lymphocyte growth is within 5 to 7 days. Once cell growth is observed, the cultures are split and expanded in culture plates with successively larger wells. The cultures are fed with medium containing IL-2 every other day and with autologous feeder cells once a week. All biopsy-derived cell cultures lacking cell growth are discarded after 3 weeks.

Pitfalls and Troubleshooting

When long-term cultures are required to achieve large numbers of cells, the addition of anti-CD3 monoclonal antibody may help expand the activated population without compromising the specificity. In addition, a cocktail of T-cell growth factors such as IL-2 and IL-4 may enhance the growth of graft-infiltrating cells.

Cytokine Measurements

Concept

The conventional assay of T-cell activation is the measurement of cellular proliferation in response to antigen stimulation. More recently, the determination of the frequency of cytokine-expressing cells has been possible through limiting dilution analysis, intracellular cytokine staining, and the enzyme-linked immunospot (ELISPOT) technique. The CD4 T-helper cells have been subdivided into three categories according to their cytokine secretion profiles: Th1 cells that secrete IL-2, gamma interferon (IFN-γ), and tumor necrosis factor alpha; Th2 cells that secrete IL-4, IL-5, IL-6, and IL-10; and Th0 cells that may secrete IL-2, IL-4, and IFN-γ (12, 29, 30). Many distinct patterns based on differential quantities of expression within the Th1 and Th2 phenotypes and mixtures of these phenotypes (Th0) are associated with graft rejection and acceptance.

ELISPOT Assay

The ELISPOT assay was developed in the laboratories of Peter Heeger, Anna Valujskikh, and Paul Lehmann (17, 36, 44, 45).

Procedure

Sample Requirements

Human peripheral blood collected in three or four green-top Vacutainer tubes with heparin

Antigen (sources are given in parentheses): alloantigen (donor or third-party spleen cells), mitogens (PHA or concanavalin A), or recall antigens (cytomegalovirus or purified protein derivative)

Materials and Reagents

LSM (Isoprep [Robbins Scientific] or Ficoll-Hypaque)

Culture medium: RPMI 1640 containing antibiotics and glutamine with 10% high-quality fetal bovine serum

Blocking solution: PBS–1% BSA—3 g of BSA (Sigma) added to 300 ml of PBS and allowed to sit for 15 min. Filter through a 0.22-mm-pore-size filter and store at 4°C.

PBS-Tween-BSA

Red spots: streptavidin-horseradish peroxidase (Dakoo, Carpenteria, Calif.) diluted 1:2,000 in PBS-Tween-BSA

Buffer for red substrate: 800 ml of 3-amino-g-ethyl carbazole (AEC) added to 24 ml of AEC buffer

AEC buffer (0.1 M sodium acetate buffer, pH 5.0): 0. 2 M acetic acid (11.55 ml of glacial acetic acid per liter of distilled water). Add 148 ml of 0.2 M acetic acid to 352 ml of 0.2 M sodium acetate. Bring volume up to 1 liter with distilled water.

AEC: Add 1 g of AEC (ImmunoPure AEC; Pierce; catalog no. 34004) to 100 ml of DMF (*N,N*-dimethylformamide; Fisher Scientific; catalog no. BP1160-500) using gloves and a mask and working under a fume hood. Wrap the bottle in foil and store at room temperature.

Antibodies from Pharmingen (San Diego, Calif.):

Coating antibody—IFN-γ (clone R46A2) at a final concentration of 2 μg/ml or IL-2 (clone JES6-1A12) at a final concentration of 6 μg/ml

Secondary detection antibodies—IFN-γ (clone XMG1.2 biotin) at a final concentration of 1 μg/ml and IL-2 (clone JES6-5H4 biotin) at a final concentration of 2 μg/ml

ELISPOT plates (Fisher Scientific, Millipore, or Cellular Technologies Ltd. [Cleveland, Ohio]; catalog no. M200-50)

Equipment and Instrumentation

Laminar flow hood

Incubator set a 37°C and 5% CO_2

Immunospot 2 analyzer from Cellular Technologies Ltd.

Test Procedure

Day 1. Mark the ELISPOT plate and add 100 μl of coating antibody/well diluted to the appropriate concentration in PBS. Wrap the plate in plastic and incubate it in a humid environment at 4°C overnight.

Day 2. In a sterile laminar flow hood, discard the coating antibody by shaking the inverted plate. Block the plate with a sterile solution of PBS–1% BSA at 150 μl/well and incubate the plate for 1 h at room temperature. Discard the liquid from the plate and wash the plate three times with sterile PBS. Until the assay, keep the plates with 200 μl of PBS/well at room temperature. Peripheral blood lymphocytes isolated from the whole blood are diluted to a concentration of 3 million per ml and are plated at 100 μl/well. Stimulator cells (irradiated or mitomycin C treated) are counted and resuspended at 3 million per ml, and 100 μl is used in each well. When needed, T-cell-depleted antigen-presenting cells

can be used to control the background. Mitogens (PHA) at a final concentration of 2 μg/ml and soluble protein antigens at different concentrations (0.1 to 50 μM) are added to the plates (final volume of 200 μl/well). The plates are incubated for 24 h at 37°C with 5% CO_2.

Day 3. The secondary antibody is diluted in PBS-Tween-BSA. Discard the fluid from the wells and wash the wells three times with PBS. After each wash, remove the liquid by tapping the plate onto clean towels. Wash the plate four times with PBS-Tween. Leave the last wash in the plate and incubate the plate for 5 min at room temperature. Discard the liquid and add 100 μl of the second detecting antibody/well. The plate is wrapped and incubated overnight at 4°C in a humid atmosphere or for 4 to 5 h at room temperature.

Day 4. Discard the second antibody and wash the plate three times with PBS-Tween. Add 100 μl of streptavidin-horseradish peroxidase/well and incubate for 90 min at room temperature. Near the end of incubation, prepare the reagent for spot development (AEC in AEC buffer plus 12 μl of 30% H_2O_2). Wash the plate four times in PBS (200 μl/well), and add 200 μl of substrate to each well. The spots should develop in 15 to 40 min. Stop the reaction before the background color becomes too strong by washing the plate four times with distilled water. Dry the plate and keep it covered because the spots are light sensitive and will fade if exposed to light. The plate can be kept covered in aluminum foil for counting the next day or stored at room temperature for future analysis. When the plate is fully dry, it can be analyzed with a dissecting microscope or with a computer-assisted image analyzer.

Pitfalls and Troubleshooting

The viability of the responder and stimulator cells is very important. Fresh cells are the best; however, frozen specimens can be used if the recovery is sufficient. The sources of fetal calf serum and antibodies are important for the success of the test. Keeping background staining low is crucial, and it is therefore important to stop the reaction in time. Also, the spontaneous release of cytokines from stimulator cells can be diminished by using T-cell-depleted antigen-presenting cells.

Clinical Significance

The ELISPOT assay has a number of advantages over other techniques. The assay is very sensitive and reproducible, and the detection of the secreted molecule occurs directly at the site of the secreting cells. The ELISPOT assay is 100- to 400-fold more sensitive than the enzyme-linked immunosorbent assay performed on culture supernatants. Since this assay can detect antigen-specific cells at the single-cell level, it is more sensitive than intracellular cytokine staining. The analysis is carried out with the help of an automated image analyzer that detects the spots based on predetermined size, shape, and color density characteristics, making the assay very reproducible. The ELISPOT assay may be used to discriminate between in vivo-primed alloreactive cells and naïve T cells. Antigen-primed T cells produce cytokines in less than 24 h after stimulation, but naïve T cells require 3 to 5 days of stimulation in vitro to differentiate into effector cells producing Th1 or Th2 cytokines. Heeger and colleagues have shown that a high frequency of donor-reactive memory T cells producing IFN-γ pretransplant correlates with an increasing risk of posttransplant acute rejection episodes in living related-donor kidney transplant recipients (17).

Intracellular Cytokine Analysis by Two-Color Flow Cytometry

Multiparametric flow cytometry can be used to study cytokine production at the single-cell level. It has the advantage of rapidly measuring the cytokine production by thousands by individual cells and of simultaneously detecting two cytokines in the same cell. Most of the reported studies used PBMC as the starting material (3, 18, 31). In addition, the intracellular cytokine analysis can be performed with whole blood (2, 14, 41). Whole-blood activation preserves the in vivo cellular and biochemical environment. The whole-blood assay is also particularly important to analyze the cytokine production in transplant recipients receiving long-term immunosuppressive drug therapy (2, 48).

Procedure

Sample Requirements

Human peripheral blood collected in two green-top Vacutainer tubes with heparin. In addition, tissue-propagated lymphocytes or cells from bronchoalveolar lavage fluid can be used.

Materials and Reagents

Chemicals for culture and stimulation of cells: phorbol myristate acetate (PMA; Sigma; catalog no. P-8139) and Ca ionophore A23187 (Sigma; catalog no. C7522)

Intracellular transport inhibitor: brefeldin A (Sigma; catalog no. B-7651). Dissolve in 100% dimethyl sulfoxide.

Directly conjugated monoclonal antibodies from Pharmingen: CD8 {mouse anti-human immunoglobulin G(κ) [IgG(κ)] HIT8a}, fluorescein isothiocyanate (FITC) labeled; IL-2 (rat anti-human IgG2a, MQ1-17H12); IFN-γ [mouse anti-human IgG1(κ) 4S.B3]; IL-4 (rat anti-human IgG1, MP4-25D2); and IL-10 (rat anti-human IgG2a, A5-4). All cytokine monoclonal antibodies are PE labeled.

Isotype control antibodies consisting of FITC-conjugated mouse anti-human IgG1(κ) (MOPC-21), PE-conjugated mouse anti-human IgG1 (MOPC-21), and PE-conjugated rat anti-human IgG2a (R23-95), each used at comparable concentrations of the antibody of interest

Staining buffer (fluorescence-activated cell sorter [FACS] medium): Dulbecco's PBS (DPBS) without Mg^{2+} or Ca^{2+}, 1% heat-inactivated fetal calf serum, and 0.1% (wt/vol) sodium azide. Adjust buffer pH to 7.4 to 7.6 filter 0.2 μM, and store at 4°C.

Fixation buffer: 4% (wt/vol) paraformaldehyde. Add paraformaldehyde to DPBS and warm in a 50°C water bath (fume hood) until dissolved (1 to 3 h). Adjust pH to 7.4 to 7.6 and store at 4°C.

Permeabilization buffer: DPBS without Mg^{2+} or Ca^{2+}, 1% heat-inactivated fetal calf serum, 0.1% (wt/vol) sodium azide, and 0.1% (wt/vol) saponin (Sigma; catalog no. S-7900). Adjust pH to 7.4 to 7.6 and filter.

FIX and PERM permeabilization kit (CALTAG Laboratories, Burlingame, Calif.) for whole-blood assay

Ficoll-Hypaque gradient

Human AB serum

"V"-bottom plates (Costar)

Instruments

FACscan flow cytometer (Beckman Coulter, Hialeah, Fla.)

Incubator set at 37°C and 5% CO_2

Test Procedure

Cell culture. PBMC or cells of interest are plated at 50,000 to 350,000 cells in 96-well "V"-bottom plates in a final volume of 100 μl of 5% AB RPMI 1640. Cells are cultured with or without PMA (50 ng/ml) and Ca ionophore (1 μg/ml) and brefeldin A (1.5 μg/ml). Incubate at 37°C in a humidified 5% CO_2 incubator for 4 h for PBMC cultures and for 2 h for bronchoalveolar lavage cells.

Whole blood (1 ml) is stimulated with PMA (50 ng/ml) and Ca ionophore (1 μg/ml) and brefeldin A (1.5 μg/ml). Unstimulated whole blood is cultured with RPMI 1640 alone and brefeldin A. Cell cultures are incubated for 4 h at 37°C in a humidified 5% CO_2 incubator.

Staining Procedure

PBMC cultures.

1. Centrifuge the plate for 5 min at 1,500 rpm (Beckman TJ-6), quickly flick the supernatants, and blot dry the plate.
2. Wash all wells with 150 μl of FACS medium and recentrifuge. Repeat flick, and blot dry.
3. Surface stain with 10 μl of anti-CD8 FITC antibody/well. Place the antibody in the well and gently resuspend cells >8 to 10 times. Wrap the plate it in foil and put it in the refrigerator for at least 20 min.
4. Wash wells with 200 ml of FACS medium and centrifuge for 4 min at 1,500 rpm (Beckman TJ-6).
5. Gently flick out the supernatant and fix cells with 150 μl of 4% paraformaldehyde. Incubate overnight in the refrigerator.
6. Centrifuge plates and blot dry. Add 150 μl of permeabilization buffer to each well.
7. Recentrifuge for 4 min, flick the plate, and repeat once. For the unstained wells, use just 10 μl of permeabilization buffer.
8. Stain with intracellular cytokine antibody for each particular cytokine (10 μl of a 1:10 dilution in permeabilization buffer).
9. Place the plate wrapped in foil at 4°C for 30 min.
10. Wash the plate with 200 μl of FACS medium, and centrifuge for 4 min at 1,500 rpm.
11. Flick the plate, add 200 μl of FACS medium, and transfer cells to labeled flow tubes.

Whole blood.

1. Do the surface marker staining with FITC-labeled anti-CD8 antibody prior to the intracellular staining.
2. Use the FIX and PERM cell kit according to the manufacturer's procedure.
3. Incubate 100 μl of whole-blood culture mixed with 100 μl of reagent A (fixation medium) in a 5-ml Falcon tube for 15 min at room temperature.
4. Wash the cells in PBS.
5. Add 100 μl of reagent B to permeabilize the cells.
6. Add the intracellular cytokine-specific antibody (10 μl), and incubate the mixture in the dark at room temperature for 15 min.

7. Wash the samples once in PBS and once in FACS medium.
8. Resuspend the samples in 200 μl of FACS medium and analyze them on a FACScan cytometer.

Data Analysis

- Typical forward and side scatter gates are set for lymphocytes, and a CD8$^+$ gate is set to exclude any dead or contaminating nonlymphoid cells.
- Ten thousand events per sample are acquired within the specific gate.
- Two-parameter histograms showing cytokine staining are created.
- Quadrant statistics are based on the staining of the negative isotype controls.
- Cytokine production is analyzed by detection of PE staining.
- The number of cells staining for each cytokine is expressed as a percentage of CD8$^-$ and CD8$^+$ cells, and the total number of cells is expressed per million PBMC.

Troubleshooting

Always set aside wells for controls and for unstained cells to use in setting the target cell gates. An appropriate Ig isotype control should be run with each assay. Initial blocking studies with recombinant cytokines should be done to establish antibody specificity. Reagents that block Fc receptors may be used for reducing nonspecific staining (especially when cells other than T cells are stained). After fixation, the plates can be kept overnight at 4°C. This step may also lower nonspecific background staining. The intracellular cytokine antibody should be diluted in permeabilization buffer containing saponin. Titers of antibodies should be determined for each cell type and source of stimulation. Finally, best results will be obtained when samples are run on the flow cytometer within a couple of hours following staining. For additional information on flow cytometry, see chapters 18 and 40, this volume.

Intracellular ATP Synthesis Assay: Immune Cell Function Assay

Recently, a method has been developed to measure the cell-mediated (T-cell, or T-lymphocyte) response directly in whole blood (43, 52, 53). The ImmuKnow assay (Cylex, Inc.) has been used to assess the overall basal immune response and to monitor the efficacy of different immunosuppressive protocols posttransplant (2, 41). This whole-blood assay measures increases in intracellular ATP synthesis by CD4$^+$ cells in response to stimulation with PHA in the presence of immunosuppressive drugs. Most immune cell functions depend directly or indirectly on the production of ATP, and thus, ATP has been used as a marker of lymphocyte activation (1, 4, 9, 10, 11, 39, 42). Reduced ATP levels directly inhibit the cascade of steps required for lymphocyte function, including the transcription of cytokine mRNA, cytokine production, and lymphocyte proliferation. ATP production precedes the appearance of most cytokines measured.

The immune cell function assay measures ATP synthesis which occurs as a result of stimulation with PHA for 15 to 18 h. Whole blood is also incubated in the absence of stimulant to assess basal ATP activity. Anti-CD4 monoclonal antibody-coated magnetic beads are added to immunoselect out CD4$^+$ cells from both the stimulated and nonstimulated wells. After washing of the CD4$^+$ cells on a magnet tray, the

cells are lysed to release intracellular ATP. Luminescence reagent (luciferin-luciferase) added to the released ATP produces light according to the following equation:

$$luciferin + ATP + O_2 \xrightarrow[\text{luciferase}]{Mg^{2+}} oxyluciferin + AMP$$
$$+ \text{ pyrophosphate} + CO_2 + light$$
The amount of light measured by a luminometer is proportional to the concentration of ATP. The concentration of ATP (in nanograms per milliliter) is calculated from a calibration curve and compared to ATP level ranges to assess the cell-mediated immune function of the sample. The ImmuKnow assay has been approved by the Food and Drug Administration and is commercially available.

Procedure: Sample Requirements, Collection, and Handling

Whole blood is collected into a specimen collection tube containing sodium heparin and stored and transported at room temperature. The assay must be set up within 30 h of specimen collection. Blood should be stored and transported at room temperature only (18 to 28°C). It is recommended that a normal control sample be drawn and run with each test sample.

Materials and Reagents

The Food and Drug Administration-approved assay kit ImmunoKnow (catalog no. 4400; Cylex, Inc.) contains the following materials and reagents.

Assay plate and cover: 96-well (12- by 8-well strips) plate coated with an inert substance to prevent nonspecific binding. Store at 2 to 28°C, desiccated in the resealable foil pouch.

Sample diluent: 25 ml. Store at 2 to 8°C.

Stimulant: PHA-L, 12.5 µg/ml. Store at 2 to 8°C.

CD4 Dynabeads (Dynal Biotech A.S.A., Oslo, Norway): magnetic beads coated with mouse monoclonal anti-human CD4, supported in buffered saline with BSA and preservative (6.5 ml). Store at 2 to 8°C.

Wash buffer: buffered saline with BSA (125 ml). Store at 2 to 8°C.

Lysis reagent: hypotonic basic solution with detergent (50 ml). Store at 2 to 8°C.

Calibrator panel: ATP concentrations, 0, 1, 10, 100, and 1,000 ng/ml (0.8 ml each). Store at 2 to 8°C.

Luminescence reagent: luciferin and luciferase in a buffered solution (33 ml). Store frozen upon receipt at −70°C or lower. (If a −70°C or lower-temperature freezer is not available, contact Cylex, Inc., for alternative storage instructions.) Thaw at room temperature (18 to 28°C) only. Mix well after thawing. The reagent may be thawed and refrozen up to four times.

Measurement plate: 96-well (12 8-well strips) black or white opaque plate (two of each plate). Store at 2 to 28°C in the resealable bag.

Reagent and Equipment Requirements

All reagents should be allowed to come to room temperature before use. Luminescence reagent must not be thawed above room temperature (i.e., do not thaw reagent at 37°C). Reagents should be thoroughly mixed immediately before pipetting.

The microtiter plate shaker must provide an adequate mix to fully resuspend settled blood cells following incubation without visible loss of material from the wells (i.e., no visible splashing should be observed on the assay plate cover). Once an appropriate setting is determined, use this setting throughout the assay. A vacuum pump with a strength of 150 to 200 mm Hg is recommended. If a stronger vacuum is used, care should be taken not to aspirate the Dynabeads during wash steps.

Equipment and Instrumentation

Luminometer: The luminometer must be formatted for a 96-well microtiter plate, capable of measuring "glow" luminescence, with a maximum emission of 562 nm, and maintain linearity over a measurement range of 5 decades of light output. A computer with Microsoft Excel version 95, 97, or 2000 is needed to support luminometer function.

Incubator set at 37°C with a 5% CO_2 humidified atmosphere

Magnet tray (Cylex, Inc. [catalog no. 1050]; also available in the Cylex immune cell function assay accessory pack [catalog no. 1004])

Cylex immune cell function assay data analysis software (Cylex, Inc. [catolog no. 1440]; also available in the Cylex immune cell function assay accessory pack [catalog no. 1004])

Vacuum aspiration system (Cylex, Inc. [catalog no. 1040]) or equivalent (also available in the Cylex immune cell function assay accessory pack [catalog no. 1004])

Eight-channel aspiration manifold with tubing connector (Cylex, Inc. [catalog no. 1070]) or equivalent (also available in the Cylex immune cell function assay accessory pack [catalog no. 1004])

Miscellaneous equipment: vacuum source, vacuum apparatus with disposable tubing and receiving flask, microtiter plate shaker, Vortex mixer, adjustable pipettes and tips capable of delivering 25- to 1,000-µl volumes, eight-channel multichannel pipette(s) and tips capable of delivering 50- to 200-µl volumes, reagent reservoirs, 12-by-75-mm tubes, and a timer.

Mechanics and Controls

Assay part 1: cell stimulation. Gently invert each control and patient whole-blood specimen several times to ensure uniform distribution of blood cells. Prepare a 1:4 dilution of each whole-blood specimen using sample diluent (e.g., 500 µl of whole blood plus 1.5 µl of sample diluent). Assemble the assay plate according to the worksheet supplied by the manufacturer by using one eight-well strip for each specimen and 25 µl of sample diluent in the first four wells. Dispense 100 µl of each diluted patient specimen into eight appropriately labeled wells, according to the worksheet. Replace the plate cover and shake the plate on a plate shaker for 30 s. Incubate the covered assay plate cover and shake the plate on a plate shaker for 30 s. Incubate the covered, assay plate in a 37°C and 5% CO_2 incubator for 15 to 18 h.

Assay part 2: CD4 cell selection and ATP release. Remove the assay plate from the incubator and shake it on a plate shaker for 3 min. Hand mix by gentle inversion the CD4 Dynabeads, and dispense 50 μl into each well. The magnetic beads must be thoroughly suspended to ensure accurate addition to each well. Cover the plate, shake it on the plate shaker for 15 s, and incubate it for 30 min at room temperature (18 to 28°C). Shake the plate for 15 s halfway through incubation and again at the end of incubation. Remove the strips from the assay plate and place them onto the assembled magnet tray. Wait 1 to 2 min for the Dynabeads to collect on the sides of the wells to isolate CD4 cells from the whole blood. Carefully aspirate whole blood from each well by using an eight-channel aspiration manifold attached to a vacuum system. Avoid dislodging the Dynabeads. Wash three times to eliminate residual unbound cells and interfering substances from the wells. Wash with 200 μl of wash buffer in each well, wait 1 min, and then aspirate. After the last wash step, remove the strip holder from the magnet base, shake the strips for 1 min on the plate shaker, and then replace the strip holder on the magnet base. Wait 1 min, and then aspirate.

Dispense 200 μl of lysis reagent into each well. Remove the strip holder from the magnet base and shake the strips on the plate shaker for 5 min. Place the strip holder onto the magnet base and wait 1 to 2 min.

Assay part 3: ATP measurement. If there will be a delay of more than 4 h before proceeding to assay part 3, the strips should be frozen at this time. Remove the strips from the strip holder and place them in the assay plate frame. Seal the strips, place the cover on the assay plate, and freeze at −20°C. Frozen strips are stable for at least 1 month. To continue, remove the plate from the freezer, allow it to come to room temperature (18 to 28°C), place the strips in the strip holder of the magnet tray, and dispense into measurement plates as described below.

The measurement plate should include one strip for each patient and two strips for the calibrator panel. Using a multichannel pipette, transfer 50 μl from each well of the magnet tray to the appropriately labeled wells of the measurement plate. Change pipette tips for each strip. Dispense 50 μl of each calibrator into duplicate wells of the measurement plate according to the worksheet. Using a multichannel pipette, dispense 150 μl of luminescence reagent into each well of the measurement plate. Following the luminometer manufacturer's instructions, read the plate between 3 and 10 min after addition of the luminescence reagent.

Calibration

The amount of ATP present in the cell lysate is calculated from an ATP calibration curve generated in each assay run. Relative light units (RLU) for control and patient samples are obtained from the luminometer and converted into nanograms of ATP per milliliter based on comparable RLU signals in the calibrators.

The RLU data from the luminometer are converted and analyzed using the Cylex immune cell function assay data analysis software. Luminometer RLU values provided in Microsoft Excel or tabular formats can be directly copied and exported into the data analysis software spreadsheet. ATP calibrator concentrations versus RLU values are plotted on a log-log scale, and linear regression analysis generates a calibration curve. To assess the linearity of the curve, each calibrator is reanalyzed by plotting RLU values on the curve and calculating corresponding ATP values. In addition, the correlation coefficient (r^2) of the calibration curve is calculated.

Calculation of Results

Calculate the ATP concentrations for the control and patient specimens by using the Cylex immune cell function assay data analysis software. After RLU values and specimen identification are entered into the spreadsheet and the calibration curve is generated, the following data are calculated and displayed in a report: ATP result for each replicate, average ATP value for replicates, standard deviation for replicates, and coefficient of variance of replicates. The coefficient of variance for stimulated wells must be <20%. If not, an analytical method to identify outlier values must be used and the results must be recalculated. Reported ATP values must be limited to the defined range of the calibrator panel. Samples with ATP values above the highest calibrator are reported as having values of >1,000 ng/ml. Samples with ATP values below the lowest calibrator are reported as having values of <1 ng/ml.

Pitfalls and Troubleshooting: Limitations

All of the following criteria must be met for the assay run to be considered valid:

- The ATP result for the nonstimulated control sample must be ≤60 ng/ml.
- The ATP result for the stimulated control sample must be ≥240 ng/ml.
- The ATP level for the nonstimulated sample must be less than the ATP level for the stimulated sample.

If the specimen meets these criteria, proceed with interpretation of the stimulated sample. If the nonstimulated sample does not meet these criteria, the specimen may have nonspecific production of ATP and the results are not valid. A new specimen should be drawn.

The linearity of the calibration curve must be accepted under the following criteria:

- The calculated value for the 1,000-ng/ml ATP calibrator must be 900 to 1,100 ng/ml (refer to the result in the "Average" column in Table IV of the data analysis software report).
- The calculated value for the 100-ng/ml ATP calibrator must be 85 to 115 ng/ml (refer to the result in the "Average" column in Table IV of the data analysis software report).
- The correlation coefficient (r^2) of the ATP calibration curve must be ≥0.97.

Interpretation of Results

The assessment of the cellular-mediated immune response of a specimen is made by comparing the ATP concentration for that specimen to fixed ATP level ranges. The ATP concentration for each specimen is calculated from the calibration curve established for the measurement plate in which the sample was run. Assay standardization is maintained by running the calibrator and a freshly drawn specimen from an apparently healthy individual with each assay run. The cutoffs for the ATP level ranges are 225 and 525 ng/ml (Table 1).

The ATP level ranges for the Cylex immune cell function assay were established by testing 155 apparently healthy

TABLE 1 Interpretation of PHA-stimulated sample results

ATP level (ng/ml)	Result	Interpretation
≤225	Low immune cell response	The patient's circulating immune cells are showing low response to PHA stimulation
226–524	Moderate immune cell response	The patient's circulating immune cells are showing moderate response to PHA stimulation
≥525	Strong immune cell response	The patient's circulating immune cells are showing strong response to PHA stimulation

adults and 127 transplant recipients with the assay. A cumulative frequency of differences was used to select the ATP levels that give the best balance of results between immunosuppressed and nonimmunosuppressed individuals. Note that this is a qualitative assay, and therefore, the results do not directly quantify the level of immunosuppression. Results of the Cylex immune cell function assay should be used in conjunction with clinical presentation, medical history, and other clinical indicators when establishing the immune status of a patient.

Expected Values

Freshly drawn whole-blood specimens from 155 apparently healthy adults and 127 transplant recipients were evaluated with the Cylex immune cell function assay. The distribution of results of the assay for these populations is summarized in Table 2.

The population of apparently healthy adults consisted of 37 (24%) females, 105 (68%) males, and 13 (8%) individuals of unknown gender, and the age range was 20 to 60 years. The ethnicity of the population was as follows: 59% (91) African-American, 28% (44) Caucasian, and 13% (20) other or unknown. The population of transplant recipients consisted of 55 (43%) females and 72 (57%) males, and the age range was 20 to 64 years. The ethnicity of the population was as follows: 24% (31) African-American, 69% (87) Caucasian, and 7% (9) other or unknown. The organs transplanted included kidneys (59% [75]), livers (34% [43]), pancreases (2% [3]), and multiple organs (5% [6]).

VALIDATION OF NEW CELLULAR ASSAY PROCEDURES

Several of the assays outlined in this chapter are being implemented in the clinical laboratory. A few assays, such as the MLC, have written standards (see the *American Society*

for Histocompatibility and Immunogenetics Procedure Manual [35]); however, most immune assays do not. Every new test must be validated before being implemented for patient testing, either by running parallel testing with another laboratory with a validated test procedure or by running known samples that have been tested by another validated method. Validation of a new test usually also includes an external quality assessment through a proficiency testing program. Although many agencies and associations offer programs for this purpose, none are available for the cellular immune assays outlined in this chapter.

When proficiency testing is not available, alternative validation procedures must be implemented, including split-sample and audit sample procedures. The split-sample procedure evaluates imprecision and testing errors. For external verification of test results, 5 to 10 samples are aliquoted and distributed to one or several other laboratories for parallel testing. Internal split-sample procedures test intertechnologist variation and operator-dependent variation. To test intertechnologist variation, samples are split and run by two different technologists. Audit samples, aliquots of control samples that are stored and analyzed periodically over time, assess the imprecision of the assay but not the accuracy. The standard deviation and coefficient of variation are statistics used to determine acceptable thresholds.

Analysis of Patient and Normal Control Subject Data

Tracking of the daily average of patient data has been used extensively for quality control measures. This technique compares the average of 20 consecutive patient values versus an established patient mean value. Optimal application of this method requires an adequate number of patient values obtained using criteria for exclusion of outlying values likely to be from abnormal subjects. In addition, data from two normal control subjects run with each assay have been used to detect shifts in method performance. Methods to monitor a daily mean or an average for normal control subjects have been applied as quality control measures for a number of clinical tests. For methods with small population variation, 10 to 100 results are required for valid quality control.

Analysis of Data from Validation Procedures

The laboratory should define the limits of acceptability for each validated procedure either by analysis of internal quality control data (e.g., a standard deviation form the mean of ±2 or 3) or by use of data in the literature.

Statistical Evaluation of Split-Sample Data

The laboratories involved in evaluation of split-sample data must agree on the criteria for validation, including the test methods, numbers of tests, criteria for determining agreement, and procedures to resolve discrepancies. The statistical

TABLE 2 Distribution of results of the Cylex immune cell function assay

ATP level (ng/ml)	Immune cell response	No. of transplant recipients with indicated results (n = 127)	No. (%) of apparently healthy adults with indicated results (n = 155)
≤225	Low	51 (40)	9 (6)
226–524	Moderate	66 (52)	102 (66)
≥525	Strong	10 (8)	44 (28)

procedure to determine agreement between laboratories uses a formula to calculate the confidence interval for the difference between two results.

Statistical Evaluation of Patient and Normal Control Data

The result values are placed in rank order. The central 68% of all values are selected, and the mean is calculated. If the distribution of values is normal, the low and high values of the central 68% of all values approximately equal 1 standard deviation below and above the mean. The mean and standard deviation provide measures for comparison with other laboratories, previous data from the same laboratory, and published data.

Proficiency Testing

For every test that is performed, the laboratory must participate in external proficiency testing, when available, to ensure quality of testing. The proficiency test samples must be handled in the same manner as the patient samples; that is, they must be introduced into the laboratory system in the same manner. Testing of the proficiency test samples should be rotated among all technologists who routinely perform the assay in question. The relationship between the results must be defined and evaluated. Corrective action must be initiated if a result is found to be unacceptable when compared to the consensus results. The accuracy for external proficiency testing should be >90%. When no commercial proficiency testing programs are available, parallel testing with another laboratory doing the same test must be done at least every 6 months. In-house proficiency testing should also be performed to assess variability between technologists. This comparison testing should be done at least every 6 months.

Quality Assurance for Cellular Assays

Quality assurance is a comprehensive program to ensure quality results from the initiation of a test through the end of result analysis by conforming to established written policies, monitoring compliance to policies, and documenting corrective actions. Each laboratory must have written policies for the requisition and collection of samples, the volume needed, the type of anticoagulant to be used, labeling, and sample storage and transportation for each test done in the laboratory. The policy must include criteria for sample acceptance or rejection. Each written requisition must match the sample and contain the following information: name of patient, identification number, date and time of sample acquisition, specific testing ordered, and referring facility.

Records of the types of problems encountered in sample acquisition should be kept and monitored for trends. Corrective action should be initiated and documented if problems persist. Compliance with requirements should be 95% or better.

Each laboratory should have a comprehensive procedure manual which details the standard operating procedure for each analysis performed, written in the NCCLS format. The procedure manual should be reviewed yearly by the director and all technical staff and signed and dated by the director prior to implementation. Minor corrections can be handwritten but need to include the date of revision and the director's approval.

Quality Control Procedures for Cellular Programs

The laboratory shall define and document quality control measures for each test performed. These measures must include written policies outlining the criteria for accepting or rejecting results, evaluating reagents for consistent quality, and documenting equipment performance. All quality control problems must be addressed. The corrective actions must be documented in writing and reported in the quality assurance report.

Each procedure description must indicate quality control measures employed and how they are used in the interpretation of the results. Acceptable ranges must be established, and corrective actions must be documented when the controls do not fall within these ranges. Results of the test are not reported if the quality control for the test procedure exceeds the acceptable limit.

Each laboratory shall have a written policy for labeling reagents with the name, date received, date prepared or expiration date, date opened, technologist's initials, and storage conditions. Written procedures for quality control for each reagent prior to use are required. Descriptions of specific quality control procedures should include the appropriate method for testing each reagent, which may include titration, parallel testing, and measure of cell growth support, as well as documentation of acceptable performance. The date the reagent is put into use must also be documented.

Written protocols must be in place for routine equipment performance checks and scheduled preventative maintenance. All maintenance and results must be documented, and such records must be stored. Tolerance limits for each equipment performance check must be established, and compliance must be documented. When acceptable limits are exceeded, corrective action may include a procedure for troubleshooting, criteria for instrument repair, backup procedures or instruments, and a power failure plan.

CLINICAL APPLICATIONS

Currently, cellular assays are used to define donor antigen-specific hyporeactivity, to investigate the function and specificity of graft-infiltrating cells, and to determine T-cell precursor frequencies. The MLC and cell-mediated lympholysis techniques are currently used to investigate the development of donor antigen-specific hyporeactivity post-transplant (34). These assays may be useful for identifying patients who are good candidates for discontinuing or tapering of immunosuppression therapy on the basis of apparent immunoregulation of response to disparate antigens. The development of donor antigen-specific hyporeactivity, as measured by MLC, correlates with improved late solid-organ transplant outcome, as evidenced by fewer late rejection episodes and fewer graft losses (34).

Propagation of T lymphocytes from kidney, heart, and liver allografts demonstrates a strong correlation between long-term T-cell growth and clinical acute cellular rejection (55). The primed lymphocyte test has been used to investigate the specificity of these graft-infiltrating cells. This technique demonstrates functional characteristics of graft-infiltrating cells and provides information on the activation state of the T-cell infiltrate.

Previous studies have suggested a correlation between CTL precursor (CTLp) frequency and the clinical grade of graft-versus-host disease in recipients of bone marrow from unrelated donors (19, 20). Recipients with CTLp frequencies higher than 1:100,000 tended to have more severe graft-versus-host disease than those with lower CTLp frequencies. Schwarer et al. (40) compared helper and cytotoxic anti-recipient T-cell frequencies in recipients who had received

unrelated-donor bone marrow. They found that the HTLp and CTLp assays provided similar predictive information for outcome; however, the HTLp method is more rapid and less labor-intensive and, thus, may be more useful for donor selection in unrelated-donor bone marrow transplantation. This approach may be useful in predicting graft-versus-host disease in unrelated-donor bone marrow transplant recipients. More recently, Van Buskirk et al. (47) have described the use of the CTLp assay to identify kidney recipients in whom immunosuppressive therapy can be safely reduced. Their data showed that kidney recipients with low or no frequency of donor-specific CTLp could safely have their immunosuppressive drug load tapered. The frequencies of intracellular IL-2- and IFN-γ-producing cells in normal individuals are similar in whole blood and isolated PBMC. However, in transplant recipients on tacrolimus or CSA, the frequency of IL-2-producing cells may be significantly inhibited in whole blood while little or no inhibition is observed when the cells are isolated prior to the in vitro stimulation (2). In addition, the concentration of tacrolimus in blood does not directly correlate with its inhibitory effect on cytokine production in peripheral T-cell subsets (2). Despite these caveats, monitoring the in vivo efficacy of tacrolimus or CSA in suppressing cytokine production in T-cell subsets may further improve the posttransplant management of transplant recipients. This approach can also identify patients who are less susceptible to tacrolimus- or CSA-mediated inhibition and who therefore may need other immunosuppression (2).

The immune function assay (ImmuKnow; Cylex, Inc.) is a Food and Drug Administration-approved assay currently being implemented as a clinical test at many transplant centers. The assay has been used to directly assess the immune system, individualize immunosuppressive therapy, monitor drug tapering, conduct vaccine trials, monitor the efficacy of different immunosuppressive regimens, and distinguish rejection from infections such as hepatitis C virus infection in transplant recipients. A recent multicenter study evaluated the Cylex ImmuKnow assay for the measurement of immune response in immunosuppressed transplant recipients (23). Most immunosuppressive drugs are currently administered on the basis of weight. However, the baseline levels of immune response in patients awaiting transplant vary enormously and are not a function of body weight. The investigators in this multicenter trial found that the level of tacrolimus as measured by the conventional immunoassay did not correlate with the degree of biological immunosuppression by the PHA-induced ATP levels (23). They observed that following transplant, recipients' responses were statistically distributed among three levels of reactivity (low, intermediate, and high) based on this assay. Further, the effectiveness of the immunosuppressive therapy appears to increase with time posttransplant since the number of recipients in the low-response-level category increased despite lower dosing of the drugs. Zeevi et al. (56) demonstrated that responses to recall antigen, alloantigen, and PHA were measurable by lymphoproliferation assays in immunosuppressed transplant recipients but were apparently suppressed when measured by the ATP assay. In addition, recent studies show that high pretransplant intracellular ATP levels in kidney and lung recipients correlate with an increased risk of early acute rejection episodes (unpublished data). Furthermore, the Cylex assay provides an objective measure of the net state of a patient's immunosuppression while minimizing the drug therapy (57).

CONCLUDING REMARKS

The long-term goals of using the cellular assays described in this chapter are to assess accurately the changing immunological statuses of transplant recipients, to predict long-term graft outcome, and to provide the immune response information needed to individualize immunosuppression therapy. By using methods that measure various immune functions in a serial fashion, an accurate assessment of the recipient's immune status can be obtained. Sequential evaluation of a patient's immune status should be considered in any protocols that incorporate modification of the immunosuppression therapy.

Molecular Characterization of Rejection in Solid Organ Transplantation

CHOLI HARTONO, DARSHANA DADHANIA, AND MANIKKAM SUTHANTHIRAN

139

Improved knowledge of the alloimmune repertoire, development and clinical application of new therapeutics, advances in surgical techniques, and effective infection prophylaxis have advanced transplantation to the forefront of modern medicine. Nevertheless, diagnostic and therapeutic challenges remain. Herein, we provide an outline of the immune cascade contributing to allograft rejection, emphasize molecular protocols that have been applied to investigate gene expression, and summarize molecular correlates of rejection of human kidney, heart, lung, liver, or pancreatic islet cell allografts.

The immune cascade culminating in allograft rejection is initiated following the physical interaction between the recipient's CD4+ T cells and CD8+ T cells and the antigen-presenting cells of donor origin (the direct pathway of allorecognition) and of recipient origin (the indirect pathway of allorecognition) (35, 92). The allopeptides, displayed on the surface of antigen-presenting cells, impart antigen specificity and provide the "first" signal. A costimulatory signal is obligatory for plenary T-cell activation (69). The activated T cells secrete cytokines such as interleukin 2 (IL-2) and gamma interferon (IFN-γ), and the education and recruitment of cytotoxic CD8+ T cells, antibody-forming B cells, and proinflammatory leukocytes culminate in allograft rejection (91, 92). Major histocompatibility complex (MHC) class I proteins present donor-derived allopeptides to the recipient's CD8+ T cells, whereas the MHC class II molecules present the allopeptides to the recipient's CD4+ T cells. Chemokines and adhesion molecules generate the requisite signals for cell trafficking and transmigration of proinflammatory cells into the allograft (41, 49, 55, 73). Toll-like receptors appear to play an important role not only in eliciting innate immunity but also in the amplification of acquired immunity directed at the allograft (3).

Acute rejection is a risk factor for chronic allograft nephropathy (CAN), and CAN is an established cause for late allograft failure (45). In addition to immunologic factors, nonimmunologic factors such as old donor age, donor death due to cerebrovascular accident, ischemia/reperfusion injury, and toxicity from calcineurin inhibitors contribute to the development of CAN (73), a relentlessly progressive process that is histologically distinguished by fibrosis and obliterative vascular disease.

Compelling evidence supports a dominant role for transforming growth factor β1 (TGF-β1) excess in the pathogenesis of organ fibrosis (14), and CAN is distinguished by overexpression of TGF-β1 (76). In experimental models, epithelial-to-mesenchymal transition (EMT) is a prerequisite for renal interstitial fibrosis (103, 105). The TGF-β1 molecule, normally associated with latency-associated protein, becomes activated by β6 integrin (53, 77). Activated TGF-β1, in turn, downregulates E-cadherin via stimulation of integrin-linked kinase in epithelial cells (44, 105). The downregulation of E-cadherin expression results in the loss of epithelial cell-to-cell contact and paves the way for the epithelial cells to undergo EMT (44).

MOLECULAR TECHNIQUES TO CHARACTERIZE GENE EXPRESSION

The advent of an in vitro assay, PCR, to amplify the nucleic acid sequences has greatly reduced the amount of starting material required for the identification and measurement of mRNAs in biological samples. The current technology not only allows testing of a hypothesis but also facilitates characterization of biological pathways via analysis of a single gene or a large group of genes in clinical samples. The following steps are required for the analysis of gene expression: (i) isolation of RNA (either total RNA or mRNA), (ii) reverse transcription of RNA to cDNA, (iii) amplification of the mRNA of interest, and (iv) detection and quantification of the amplified product.

RT-PCR Assay

Amplification of mRNA is performed using PCR, a technique first utilized for the diagnosis of sickle cell anemia by amplification of the beta globulin gene and restriction site analysis (65). Obtaining high-quality RNA with minimal degradation is a critical step in obtaining an accurate profile of the transcriptome. RNA is unstable and prone to degradation by RNases; precaution should be taken to use RNase-free material. Samples to be processed for RNA isolation should not be left at room temperature for more than 30 min and should be snap frozen in liquid nitrogen and stored in a −80°C freezer. With the use of RNase inhibitors like RNAlater, storage at 4°C for several days is feasible without significant RNA degradation. The starting RNA sample should have an A_{260}/A_{280} ratio of 1.8 to 2.0. RNA degradation and DNA contamination can be assessed by electrophoresis of the sample on a 1% denaturing agarose gel using the Agilent 2100 Bioanalyzer. High-quality RNA samples demonstrate clean 28S and 18S

rRNA peaks at a ratio of 1.5 to 2.0 (106). Since cDNA is more stable than RNA, RNA is generally reverse transcribed to cDNA prior to storage. The efficiency of reverse transcription (RT) may vary based on factors such as the presence of inhibitors, starting quantity, and the enzyme used for RT (89). An internal control, such as synthetic cRNA that is similar to the target mRNA but for a small deletion, is useful for monitoring RT efficiency.

Most RNA isolations have some DNA contamination, and the inclusion of DNase in the isolation procedure minimizes contamination. However, the use of DNase is associated with some loss of starting RNA material that may alter the gene expression profile. Furthermore, if the DNase is not properly inactivated prior to RT, there is also a potential for degradation of the cDNA sample.

A typical PCR mixture consists of target cDNA, free nucleotides, oligonucleotides as sense and antisense primers, and thermostable DNA polymerase. The cDNA copies serve as the template for the initial PCR, in which the single-stranded cDNA is converted to a double-stranded DNA. The gene of interest is amplified logarithmically in three sequential steps, denaturation, annealing of the primers, and primer extension, which are repeated with each PCR cycle. The primers are designed to obtain an amplicon of 90 to 150 bp. PCR products are separated by size using either polyacrylamide gel (for 5 to 500 bp) or agarose gel (for 200 bp to 5 kbp) electrophoresis (42). The amount of PCR product can be estimated using the following formula: $X = I (1 + E)^n$, where I is the starting cDNA amount, E is the average efficiency, and n is the number of cycles (65).

Competitive Quantitative PCR Assay

A competitive DNA fragment is constructed which is similar to the cDNA of interest with the exception of either a mutation at a specific enzyme restriction site or insertion of a small intron or sequence of DNA (43, 79). These principles are illustrated in our design and construction of gene-specific DNA competitors for the measurement of mRNAs for the cytotoxic attack molecules granzyme B and perforin and for the cyclophilin B gene, which is a housekeeping gene (Fig. 1).

In the competitive quantitative PCR assay, the cDNA is amplified with different concentrations of the gene-specific DNA competitor. The PCR products are resolved by electrophoresis, stained with ethidium bromide, and scanned by laser densitometry. The concentrations of naturally occurring gene transcripts are quantified by measuring the ratio of the cDNA band to the band of the specific competitor. For accurate calculations, the ratio of the target cDNA to the competitor should be between 0.66 and 1.5 (87).

Kinetic (Real-Time) Quantitative PCR Assay

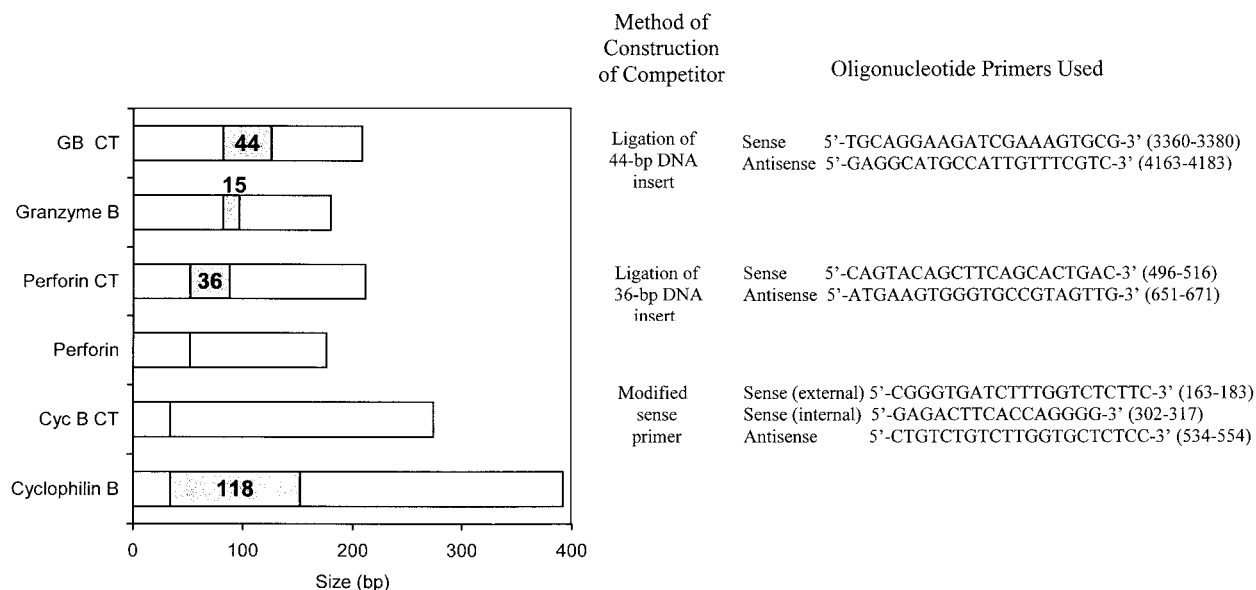
Real-time quantitative PCR incorporates the use of fluorescent signal that is released in "real-time" linearly with the amplification process. DNA-binding dyes or probes such as TaqMan probes are used to detect and measure the amplified products (29). The guiding principle for the development of the probes is the transfer of fluorescence resonance energy from the reporter dye to the quencher dye because of close physical proximity in the intact probe. When the probe is degraded, the reporter dye is no longer in physical contact


FIGURE 1 Design and construction of DNA competitors. A DNA competitor of granzyme B cDNA was prepared by digestion of the 180-bp naturally occurring product of PCR (GenBank accession no. M28879) with MseI and ligation of the subfragments with a 44-bp DNA insert with appropriate cohesive ends at the 5′ and 3′ ends. A DNA competitor of perforin cDNA was prepared by digestion of the 176-bp naturally occurring product of PCR (GenBank accession no. M28393) with N1aIII and ligation of the subfragments with a 36-bp DNA insert. The 274-bp cDNA competitor of cyclophilin was amplified with the use of a modified sense primer that contains the external sense primer at its 5′ end and a 16-bp subfragment internal sense primer at its 3′ end corresponding to sequences 302 to 317 within the naturally occurring product of PCR (GenBank accession no. M60857). (Reprinted from reference 43 with permission.)

with the quencher dye, which results in the emission of fluorescent signal (29). In real-time TaqMan PCR, the reagent mixture contains the gene-specific probe, sense and antisense primers, unknown cDNA, and DNA *Taq* polymerase. The probe is specific for the mRNA of interest and is designed to be located downstream from one of the primers. As the primer is extended from the 5′ to the 3′ end by *Taq* polymerase, the exonuclease activity of the enzyme degrades the probe and releases the reporter dye from the quencher. This process is repeated with each PCR cycle and as the fluorescent signal increases, an amplification plot of the change in fluorescence against the cycle number is created in real time. An arbitrary threshold is chosen where the fluorescence signal is increasing linearly (usually 10 times the standard deviation of the baseline), and the cycle number at this point is reported as the cycle threshold (CT). The CT value is used to extrapolate the mRNA quantity using a standard curve method or the 2C (delta C [T]) method; in the standard curve method, serial dilutions of known quantities of DNA or amplicons are used (22, 29), and in the comparative CT method, the relative expression compared to a reference sample is calculated after normalizing all of the reference and sample gene expression data to data for a housekeeping gene (29, 48).

The Invader RNA Assay

The Invader RNA assay quantifies the mRNA of interest from the amount of fluorescent signal released from a gene-specific probe. This technique utilizes mRNA without RT, and there is no target amplification (79). The detection limit is 1,000 or more RNA transcripts per cell. The mRNA transcripts themselves are used as the target, and therefore differences in RT efficiencies are not an issue. However, differences in the starting amount of RNA in each reaction can lead to incorrect quantification. This problem is minimized by the use of assays such as biplex Invader RNA assay, in which there is simultaneous detection of two different genes, the target gene and a housekeeping gene, within the same sample (79). Recently, Berggren et al. modified the Invader RNA assay and developed a high-throughput assay for measuring gene expression using matrix-assisted laser desorption ionization–time of flight mass spectrometry (11).

Global Gene Expression Analysis

The steps involved in global gene expression analysis involve (i) synthesis of an expression microarray, (ii) hybridization with labeled unknown cDNA or cRNA, and (iii) quantification and analysis of the signal resulting from the hybridization of the unknown sample to the probes on the microarray. There are two basic types of microarray platforms: an array that consists of gene-specific cDNA probes and an array that consists of synthesized oligonucleotide probes. Marshall and Hodgson have reviewed a number of available microarray platforms (50).

cDNA Microarrays

In cDNA microarrays, gene-specific probes are selected based on biological relevance. In addition, each array contains negative controls (plant or bacterial genes), positive controls (housekeeping genes), and key controls (genes with a known pattern of expression in the system being studied). The cDNAs are generally prepared in bacterial colonies, amplified using PCR, and subsequently purified using nucleic acid isolation procedures. The cDNA elements are arrayed using a robotic system onto a glass slide coated with a DNA binding substrate such as poly-L-lysine or silane (37). The DNA binding substrate is inactivated following the arraying process. The

unknown sample RNA and reference RNA are labeled with different fluorescent markers, such as Cy4 for the unknown sample and Cy5 for the reference sample. The fluorescent markers are linked to one of the nucleotides and incorporated into the samples individually during RT of RNA to cDNA. Unincorporated nucleotides are removed to minimize background noise, and the labeled reference and unknown samples are mixed in a hybridization solution. The mixture is placed on the array and hybridized over 14 to 16 h. The array is then washed and read in a microarray reader.

Oligonucleotide Microarrays

In oligonucleotide arrays, the oligonucleotide probes are synthesized in vitro and subsequently arrayed onto the solid support as in cDNA microarrays, or they can be synthesized in situ as in the Affymetrix GeneChip. The Affymetrix GeneChip system is unique in that multiple oligonucleotides of 20 to 25 nucleotides that are complementary to the different regions of transcript are synthesized in situ for each hybridization unit (37). In addition, the hybridization unit contains a mismatched oligonucleotide probe that differs by one nucleotide for each of the target-specific probes. Hence, a hybridization unit for each gene consists of a series of matched and mismatched probes synthesized in a 24- by 24-μm space.

mRNA is reverse transcribed to cDNA and then transcribed to cRNA using T7 RNA polymerase and biotin-labeled CTP and UTP. The biotinylated cRNA is chemically fragmented into fragments of 35 to 200 bases prior to hybridization. The hybridization cocktail is prepared with the buffer solution, control cRNA, and the biotinylated sample cRNA, which is later placed on the chip for hybridization. After hybridization, the biotinylated cRNA is fluorescently labeled by streptavidin-phycoerythrin. The array is scanned on the Affymetrix GeneChip scanner and analyzed using various software packages. The detection of the transcript is based on the degree of binding to the perfectly matched (PM) and mismatched (MM) probes in the hybridization unit. The software program calculates a discrimination score $[R = (PM - MM)/(PM + MM)]$ that is then adjusted, ranked, and assigned a P value based on non-parametric testing. The determination of whether a transcript is present, marginally present, or absent is based on the P value cutoffs set by the operator.

Serial Analysis of Gene Expression

Serial analysis of gene expression has the potential to identify the entire transcriptome of a biological sample as well as aid in the discovery of new transcripts previously not recognized due to alternative splicing or to low abundance (98). The technique relies on the principle that a site-specific nucleotide tag of 9 to 10 bp can uniquely identify a transcript.

MOLECULAR CHARACTERIZATION OF ALLOGRAFT REJECTION

Molecular Correlates of Acute Rejection of Renal Allografts

Cytotoxic T lymphocytes (CTL) destroy target cells via multiple effector mechanisms. In the granule exocytosis pathway, the cytotoxic attack molecules, perforin and granzyme B, function as molecular executors; in the death receptor pathway, cross-linking of Fas antigen by the Fas ligand results in target cell apoptosis.

Considerable data exist that cytotoxic attack mechanisms contribute to acute rejection of renal allografts. Lipman et al.,

with the use of RT-PCR assay to measure the levels of expression for granzyme B as well as mRNAs for IL-1β, IL-6, tumor necrosis factor alpha (TNF-α), IL-2, and IL-2 receptor α in 24 core needle renal allograft biopsy samples, demonstrated that acute rejection is associated with a high level of intragraft expression of granzyme B mRNA (46). In this study, the level of expression of other mRNAs examined did not distinguish acute-rejection samples from samples without acute-rejection changes. In a follow-up investigation, Lipman and colleagues utilized competitive quantitative PCR assay to measure transcripts for granzyme B, perforin, and TIA-1 in 35 renal allograft biopsy specimens (10 samples with acute rejection, 6 with chronic rejection, 9 showing both acute and chronic rejection, 9 without any rejection changes, and 1 with cytomegalovirus [CMV] nephritis) and 6 nontransplant biopsy specimens (47). Quantitation of transcript levels showed that the mRNAs for the cytotoxic attack molecules are expressed at significantly higher levels in the acute-rejection samples than in the no-rejection or chronic-rejection samples; also, in the one specimen with CMV nephritis, neither granzyme B nor perforin was detected and TIA-1 mRNA was found at a very low level.

Sharma et al. determined, with the use of RT-PCR assay, intragraft gene expression in 80 renal allograft biopsy specimens obtained from 68 recipients of renal allografts (76). From the 80 biopsies performed to resolve the basis of graft dysfunction, 42 of the samples were classified as acute rejection, 10 as chronic rejection, 11 as both acute and chronic rejection, 10 as cyclosporine (CSA) toxicity, and the remaining 7 as other, using the Banff 97 working classification (61). Measurement of intragraft mRNAs in renal allograft biopsy samples identified heightened expression of transcripts for Fas ligand and granzyme B in samples classified as acute rejection compared to all other diagnostic categories (76).

In M. Suthanthiran's investigation of intragraft expression of cytokine mRNAs in 127 renal allograft biopsy specimens from 107 patients with graft dysfunction, IL-2 mRNA was detected in 10 of 82 acute-rejection samples but in none of the 45 samples without acute rejection (91); IL-10, a cytokine with both anti-inflammatory and proinflammatory activities, was detected in 46 of 82 samples with acute rejection and in 9 of 45 samples without acute rejection (91, 100).

Strehlau et al. applied competitive quantitative PCR assay to measure transcript levels in 60 renal allograft biopsy samples and reported heightened expression of mRNAs for Fas ligand, granzyme B, perforin, IL-7, IL-10, and IL-15 during an episode of acute rejection (90). Data analysis, taking into consideration the levels of expression of granzyme B, perforin, and Fas ligand, showed that acute rejection can be predicted with a sensitivity of 100% and a specificity of 100%. Neither the levels of transcripts for IL-2 nor the levels of mRNAs for IFN-γ and IL-4 were increased in the acute-rejection samples; also, the levels of RANTES (regulated upon activation normal T-cell expressed and secreted) mRNA and IL-8 mRNA were not informative (90).

IL-15, a product of nonlymphoid cells such as macrophages, dendritic cells, and renal tubular cells, promotes the activation, growth, and differentiation of T cells, B cells, and NK cells. Pavlakis et al. investigated intragraft expression of IL-15 and IL-2 mRNA in 45 renal allograft biopsy specimens and reported the detection of IL-15 mRNA in all of the samples and in a heightened fashion in samples classified as acute rejection (60). Intragraft expression of IL-2 mRNA was a rare event; only 3 of the 45 specimens expressed IL-2 mRNAs.

The association between mRNA levels and the Banff rejection grades and the response to antirejection therapy was investigated by Nickel et al. (56). Measurement of levels of mRNAs in 22 renal allograft biopsy samples showed that the levels of mRNAs for perforin, granzyme B, and Fas ligand but not that of Fas are significantly higher in therapy-resistant acute-rejection samples ($n = 7$) than in therapy-sensitive specimens ($n = 8$).

Experimental data and emerging literature suggest that the chemokine and chemokine receptor system is a significant participant in the antiallograft response. In the study by Panzer et al. (59), intragraft expression of CXCR3 ligands IP-10 (IFN-γ-inducible protein) and I-TAC were increased 5.2- and 7.2-fold, respectively, in the renal allografts undergoing acute rejection; also, a 5.7-fold increase in the level of expression of RANTES was observed in the rejecting allograft.

Existing data support the idea that acute rejection can be diagnosed with a high degree of accuracy by noninvasive means (34). Vasconcellos and colleagues investigated whether peripheral blood cell mRNA levels predict renal allograft diagnosis (97). Transcripts for Fas ligand, granzyme B, and perforin were measured in 31 paired samples of peripheral blood cells and renal allograft biopsies (11 specimens obtained during an episode of acute rejection and 20 specimens obtained in the absence of acute rejection) from 25 recipients of renal allografts. Coordinate gene expression between peripheral blood cells and allograft biopsy samples was evident, and the levels of any two of the three mRNAs measured were highly informative; the calculated positive and negative predictive values were 100 and 95%, respectively.

The diagnostic utility of peripheral blood cell mRNA levels as predictors of allograft rejection has been extended in a number of studies. Shoker et al. reported that the levels of peripheral blood cell CD40 ligand mRNA are a correlate of the acute-rejection Banff score and the severity of intertubular capillary changes (80). Tan and colleagues, following measurement of peripheral blood cell mRNAs for cytokines in sequential samples obtained from 43 patients (15 with acute rejection and 28 without), concluded that alterations in peripheral blood cell cytokine mRNA levels predict acute rejection as well as responsiveness to antirejection therapy, and that IL-5 and IL-13 mRNA levels increase before and during an episode of acute rejection (93).

Granulysin is expressed by CTL and NK cells and induces mainly caspase-independent cell death. Sarwal and colleagues investigated granulysin expression in peripheral blood cells ($n = 61$) and in allograft biopsy samples ($n = 53$) obtained from 97 adult or pediatric recipients (67). Granulysin mRNA levels were higher in peripheral blood cells obtained during an episode of acute rejection or infection. Allograft biopsy samples classified as acute rejection ($n = 53$) showed mononuclear granulysin staining, and the intensity of staining was higher in steroid-resistant samples ($n = 25$) than in steroid-sensitive samples ($n = 28$).

Sabek et al. collected peripheral blood from 27 patients undergoing renal allograft biopsies for graft dysfunction and measured peripheral blood cell levels of mRNA encoding granzyme B, perforin, or HLA-DR with the use of real-time quantitative PCR assay (64). Granzyme B expression was increased during an episode of acute rejection, and its upregulation predicted acute rejection with a 95% specificity. Levels of HLA-DR mRNA were informative as well and predicted acute rejection with an 88% sensitivity (64).

Simon and colleagues examined whether longitudinal monitoring of peripheral blood cell gene expression in the first month of renal transplantation predicts the development of acute rejection (85). In their study of 67 recipients of renal allografts, transcripts for granzyme B and perforin

were measured with the use of real-time PCR assay. Renal allograft recipients who developed acute rejection ($n = 17$) had higher levels of granzyme B mRNA and perforin mRNA than those without acute rejection ($n = 50$). Data analysis involving receiver operating characteristic curve analysis demonstrated that gene expression levels are predictive of development of acute rejection and that peripheral blood cell perforin mRNA levels, measured in samples obtained on days 8 to 10 posttransplantation, predicted the occurrence of an episode of acute rejection with a sensitivity of 90% and a specificity of 82%; also, measurement of granzyme B mRNA levels in the samples obtained 8 to 10 days post-transplantation predicted acute rejection with a sensitivity of 87% and a specificity of 72%. In a follow-up investigation of 54 subjects (17 with rejection and 34 without), Simon et al. found that that the positive predictive values and negative predictive values are optimized to 78 to 100% and 82 to 91%, respectively, by taking into consideration the peripheral blood cell perforin and IL-18 mRNA levels together (86).

We and others developed PCR-based protocols for urinary cell mRNA profiling and investigated whether noninvasive diagnosis of acute rejection is feasible by measurement of urinary cell mRNA levels. Li et al. demonstrated that the urinary cell levels of mRNA for perforin and granzyme B are increased in patients with acute rejection compared to those without acute rejection (43). In that single-center study, which included 151 urine specimens from 85 renal allograft recipients, the levels of perforin and granzyme B mRNA, but not those of constitutively expressed cyclophilin B mRNA, were higher in urinary cells from patients with an episode of acute rejection than in those without such an episode. The level (log-transformed mean ± standard error [SE]) of perforin mRNA was 1.4 ± 0.3 fg per μg of total RNA in the patients with an episode of acute rejection (24 samples from 22 patients) and -0.6 ± 0.2 fg per μg of total RNA in the patients without an episode of acute rejection (127 samples from 63 patients) ($P < 0.001$). The levels of granzyme B mRNA were 1.2 ± 0.3 fg per μg of total RNA in the patients with an episode of acute rejection and -0.9 ± 0.2 fg per μg of RNA in the patients without an episode of acute rejection ($P < 0.001$).

The receiver operator characteristic curves, illustrated in Fig. 2, show the fractions of true-positive results (sensitivity) and false-positive results ($1 -$ specificity) for various cutoff levels of perforin mRNA, granzyme B mRNA, and cyclophilin B mRNA. The log-transformed threshold that gave the maximal sensitivity and specificity for perforin mRNA was 0.9 fg per μg of total RNA; at this threshold, the sensitivity and specificity were both 83% ($P < 0.001$). The log-transformed threshold was 0.4 fg per μg of total RNA for granzyme B mRNA; at this threshold, the sensitivity was 79% and the specificity was 77% ($P < 0.001$). The levels of cyclophilin B mRNA were not useful in identifying allografts that would show acute rejection.

In serial studies of urinary cell mRNA profiling, sequential urine samples were obtained from 37 patients during the first 9 days after transplantation. A mixed-level two-way analysis of variance was used to estimate and compare the mean levels of perforin mRNA, granzyme B mRNA, and cyclophilin B mRNA during days 1 through 3, 4 through 6, and 7 through 9 in 8 patients in whom acute rejection developed within 10 days after transplantation and in 29 patients in whom acute rejection did not develop within the first 10 days. The levels of perforin mRNA and granzyme B mRNA, but not those of cyclophilin B mRNA, were higher in urine samples obtained on days 4 through 6 and 7 through 9 from patients in whom acute rejection developed than in samples from those without acute rejection (Fig. 3).
FIGURE 2 Receiver operator characteristic curve of mRNA levels. The fractions of true-positive results (sensitivity) and false-positive results (1−specificity) for perforin mRNA levels, granzyme B mRNA levels, and cyclophilin B mRNA levels as markers of acute rejection are shown. The calculated areas under the curve were 0.86 for perforin mRNA levels, 0.86 for granzyme B mRNA levels, and 0.58 for cyclophilin B mRNA levels. A value of 0.5 is no better than expected by chance, and a value of 1.0 reflects a perfect indicator. (Reprinted from reference 43 with permission.)

A key physiological role of chemokines is to mediate the recruitment and activation of host leukocytes to sites of inflammation, including organ transplants undergoing allograft rejection (55, 73). The chemokine IP-10 (CXCL10) and its receptor CXCR3 constitute an important pathway in the rejection of vascularized allografts. We and others measured with the use of real-time quantitative PCR assay the
FIGURE 3 Levels (mean ± SE) of perforin mRNA, granzyme B mRNA, and cyclophilin B mRNA in sequential urine samples. The mRNAs were measured in urine samples obtained during the first 9 days after transplantation, using competitive quantitative PCR assay. The levels of perforin mRNA and granzyme B mRNA but not those of cyclophilin B mRNA were higher in the 8 patients in whom acute rejection developed within the first 10 days after transplantation than in the 29 patients in whom acute rejection did not develop within the first 10 days after transplantation. The respective numbers of urine samples obtained from the patients with an episode of acute rejection and those without such an episode were as follows: 6 and 43 on day 1, 2, or 3 after transplantation; 5 and 26 on day 4, 5, or 6; and 6 and 14 on day 7, 8, or 9. Means, SEs, and P values were estimated with use of a mixed-level two-way analysis of variance. In all cases, log-transformed values are shown. (Reprinted from reference 43 with permission.)

levels of IP-10 mRNA and CXCR3 mRNA in 90 urine specimens from 82 kidney transplant recipients with allograft dysfunction (94). Levels of IP-10 and CXCR3 mRNA were significantly higher in the urine of patients with acute rejection than in those with other causes of acute graft dysfunction or with stable function posttransplantation. Receiver operating characteristic curve analysis demonstrated that acute rejection can be predicted by IP-10 levels with a sensitivity of 100% and a specificity of 78% with the use of a cutoff value of 9.11 copies/μg of total RNA, and by CXCR3 levels with a sensitivity of 63% and a specificity of 83% with the use of a cutoff value of 11.59 copies/μg of total RNA (Fig. 4). Also, immunohistologic analysis of transplant biopsy samples showed that IP-10 and CXCR3 are largely absent from grafts with stable function, whereas during acute rejection IP-10 is expressed by renal tubules and infiltrating mononuclear cells, and CXCR3 is expressed by host mononuclear cells, including in areas of tubulitis (94).

CD103 ($\alpha^E\beta_7$-integrin) is displayed on the surface of alloreactive CD8$^+$ cytotoxic T cells and CD103$^+$ cells observed in renal allografts undergoing rejection (31, 63). Because intratubular localization of mononuclear cells is a feature of acute cellular rejection of renal allografts (61), we and others investigated the hypothesis that CD103 mRNA levels in urinary cells predict acute rejection (22). Eighty-nine urine specimens from 79 recipients of renal allografts were collected. RNA was isolated from the urinary cells, and CD103 mRNA levels and levels of a constitutively expressed 18S rRNA were measured with the use of real-time quantitative PCR assay. CD103 mRNA levels, but not 18S rRNA levels, were higher in urinary cells from 30 patients with an episode of acute rejection (32 biopsy samples and 32 urine samples) than in 12 patients with other findings on allograft biopsy (12 biopsy samples and 12 urine samples), 12 patients with biopsy evidence of CAN (12 biopsy samples and 12 urine samples), and 25 patients with stable graft function after renal transplantation (0 biopsy samples and 33 urine samples) (P = 0.001, one-way analysis of variance). Acute rejection was predicted with a sensitivity of 59% and a specificity of 75% using a natural log-transformed value of 8.16 CD103 copies/μg as the cutoff (P = 0.001).

Serine proteinase inhibitor 9 (PI-9) with a reactive center P1 (Glu)-P1$'$ (Cys) is a natural antagonist of granzyme B and is expressed at high levels in CTL. In view of the role of CTL in acute rejection, we and others investigated the postulate that PI-9 would be hyperexpressed during acute rejection (54). Since PI-9 can protect CTL from its own fatal arsenal and potentially enhance the vitality of CTL, we and others examined whether PI-9 levels correlate with the severity of rejection as well as predict subsequent graft function. Ninety-five urine specimens from 87 renal allograft recipients were obtained. RNA was isolated from the urinary cells, and mRNA encoding PI-9, granzyme B, or perforin and a constitutively expressed 18S rRNA were measured with the use of real-time quantitative PCR assay and the level of expression was correlated with allograft status. The levels of PI-9 (P = 0.001), granzyme B (P < 0.0001), and perforin mRNAs (P < 0.0001), but not the levels of 18S rRNA (P = 0.54), were higher in the urinary cells from the 29 patients with a biopsy-confirmed acute rejection than in the 58 recipients without acute rejection. PI-9 levels were significantly higher in patients with type II or higher acute-rejection changes than in those with less than type II changes (P = 0.01). Furthermore, PI-9 levels predicted subsequent graft function (r = 0.43, P = 0.01).

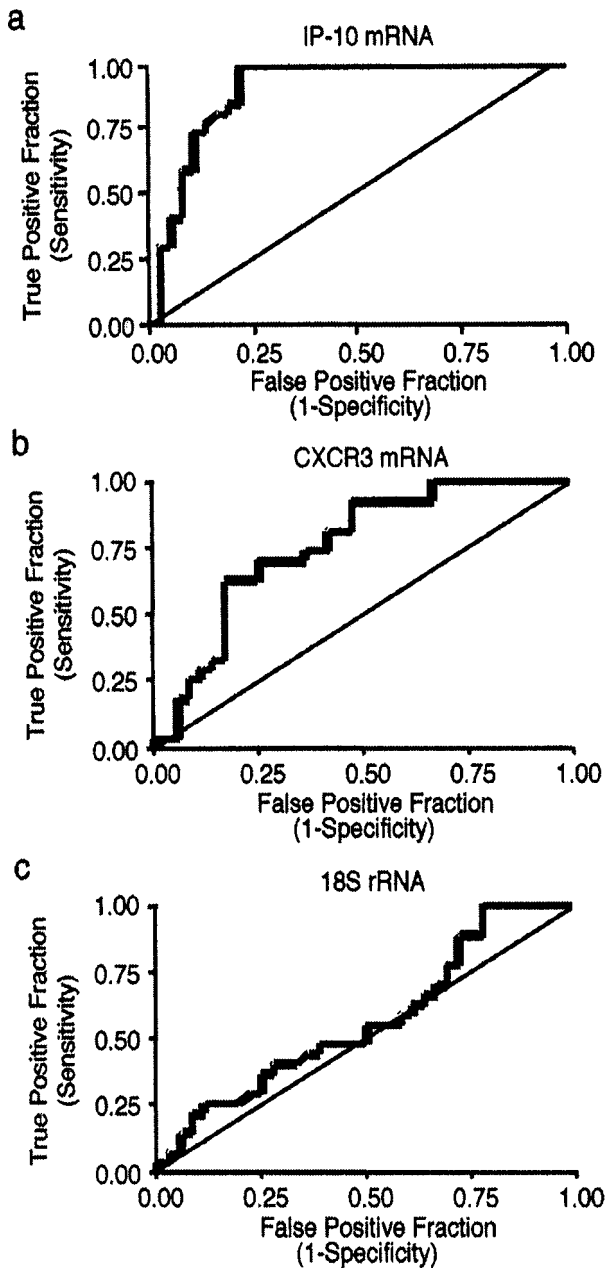
The usefulness of urinary cell mRNA profiling for the noninvasive diagnosis of early acute rejection and delayed acute rejection has been examined by Kotsch et al. (38). Urinary cell


FIGURE 4 Receiver operating characteristic curve of mRNA and rRNA levels. The fractions of true-positive results and false-positive results for IP-10 mRNA levels, CXCR3 mRNA levels, and 18S rRNA levels as markers of acute rejection are shown. Levels of mRNAs were measured with the use of real-time quantitative PCR assay. The calculated areas under the curve were 0.903 for IP-10 mRNA levels, 0.762 for CXCR3 mRNA levels, and 0.574 for 18S rRNA levels. A value of 0.5 is no better than expected by chance, and a value of 1.0 reflects a perfect indicator. (Reprinted from reference 94 with permission.)

mRNA levels were measured in 221 specimens collected from 26 recipients of renal allografts, and the transcript levels were measured with the use of real-time quantitative PCR assay. An increase in the levels of granulysin mRNA was observed in 11 of 14 acute-rejection episodes. In this investigation, levels of mRNA for granzyme B, perforin, Fas ligand, TNF-α,

RANTES, IL-2, IL-10, IFN-γ, TGF-β1, CD3, and CCR1 were less specific and sensitive in predicting acute rejection than were granulysin mRNA levels (38).

The clinical application of microarray platforms for global mRNA profiling has begun to yield novel insights regarding allograft rejection. Akalin et al. used the first-generation high-density oligonucleotide array composed of 6,800 genes (Affymetrix GeneChip) to investigate gene expression patterns of seven renal allograft biopsy samples with acute rejection and three biopsy samples without acute rejection (2). Compared to the gene expression pattern of the samples without acute rejection, 32 to 219 genes were upregulated in the acute-rejection samples; of these transcripts, only 4 (the HuMig gene, the T-cell receptor active β chain-related gene, the gene for IL-2-stimulated phosphoprotein, and the RING4 gene) were uniformly upregulated in all seven acute-rejection specimens, and 6 additional transcripts (for ISGF-3, C3, nicotinamide N-methyltransferase, MIP-3b, myeloid differentiation protein, and CD18) were upregulated in six of the seven acute-rejection samples. Moreover, upregulation of cytotoxic effector molecules in the acute-rejection biopsies was not observed, and two genes were found to be downregulated (2).

Sarwal et al. used the DNA microarray technology, pioneered at Stanford University, to investigate gene expression patterns of renal allograft biopsy samples from 50 pediatric recipients (66). Exploratory and supervised bioinformatics analyses demonstrated consistent differences in the gene expression profiles of samples classified as acute rejection, drug toxicity, CAN, and normal. Importantly, molecular heterogeneity among histologically indistinguishable acute-rejection samples was evident. Genes that were found to be highly expressed included those that are involved in T-cell activation: those for nuclear factor κB_1, IFN-γ, IL-2, and T-cell receptors. NK cells and macrophage activation were also seen, with high levels of expression of NK cell transcript 4, macrophage receptor, and macrophage matrix metalloproteinase 7. Expression levels of effector molecules such as granzyme A and chemokines such as RANTES were also elevated.

Flechner et al. (26), with the use of oligonucleotide microarrays (Affymetrix HG-U95Av2 gene chip), analyzed 31 human renal biopsy specimens (9 samples from live donor controls [normal], 7 acute-rejection samples, 5 samples from patients with renal dysfunction but no rejection [graft dysfunction], and 10 samples from patients with good transplant function and normal histology [protocol samples]). Peripheral blood lymphocytes (PBLs) that corresponded to acute rejection (7 specimens), protocol biopsies (9 specimens), and graft dysfunction (8 specimens) were also analyzed. Gene expression profiling of allograft biopsy samples showed that 96 genes were upregulated and 619 were downregulated when the acute-rejection gene expression pattern was compared with that of protocol samples, and 44 of the 96 unregulated genes were those implicated in immune and inflammatory functions. Some of the upregulated immune genes in the acute-rejection samples were those for allograft inflammatory factor 1 (AIF-1), CD2 antigen, CD14 antigen, RANTES, the C-X-C motif chemokine receptor 4, granzyme A, endothelial cell growth factor 1 (platelet derived), integrin, IP-30, and IL-10 receptors α and β. Of the 12 immune genes shown to be upregulated during comparison of samples classified as acute rejection to samples from patients with graft dysfunction but without acute-rejection changes, 7 genes corresponded to the genes that were upregulated in the acute-rejection versus stable-function group. The upregulated 7 immune genes were those for IL-10 receptor α, Src-like-adaptor, lymphocyte-specific protein tyrosine kinase, endothelial cell growth factor 1

(platelet derived), AIF-1, integrin, and adipsin. The gene expression pattern of PBLs was found to be different from that of corresponding biopsy samples. Two immune genes, those for β_2-microglobulin and immunoglobulin (Ig) κ constant, were found to be upregulated during comparison of gene expression patterns of PBLs from patients with acute rejection to the PBLs from patients with stable function. The gene expression patterns of PBLs distinguished acute-rejection biopsy samples from stable-function samples but not from biopsy samples from patients with graft dysfunction but without acute rejection.

Molecular Correlates of Chronic Rejection of Renal Allografts

The histologic hallmarks of CAN are interstitial fibrosis and obliterative vasculopathy. We and others have observed high levels of intragraft expression of TGF-β1 mRNA in biopsy samples classified as CAN (76, 91). In mRNA phenotyping studies of 127 renal allograft biopsy samples obtained from 107 recipients of renal allografts, a significant correlation was found between intragraft TGF-β1 mRNA expression and CAN (76). The investigation also showed that neither interstitial fibrosis nor CAN is predicted by intragraft expression of mRNAs for IL-2, IFN-γ, IL-4, IL-10, granzyme B, or perforin.

TGF-β1 is normally associated with latency-associated protein and becomes activated by β6 integrin (53, 77). Sawada et al. have reported heightened expression of β6 integrin in renal allograft biopsy specimens with CAN, whereas β6 integrin was not detected in normal renal allograft biopsy specimens (68). The detection of an endogenous activator of TGF-β1 in biopsy samples classified as CAN may provide a potent mechanism for the downregulation of E-cadherin and EMT.

Intragraft gene expression in transplant nephrectomy specimens has been investigated by Nocera et al. (57). Ten specimens were from patients with CAN, and three were from patients with early (<30 days) graft failure due to intrarenal hemorrhage and vascular thrombosis. Normal renal tissues from kidneys removed for neoplasm served as the control. In biopsy samples classified as Banff CAN grades 2 and 3, genes that were hyperexpressed included those for IL-6, IL-10, IFN-γ, and IL-3. The genes for IL-3 and IL-10 were not expressed in the early graft failure group (57).

Donauer et al., using microarray technology, analyzed renal biopsy specimens from 13 chronically rejected transplant kidneys, 16 normal kidneys, and 12 end-stage polycystic kidneys (23). Compared with normal kidneys and end-stage kidneys from patients with polycystic kidney disease, chronically rejected transplant kidneys displayed higher expression of 21 genes and lower expression of 6 genes. Among the 21 genes that were upregulated, 3 genes were associated with immune response (those for Ig heavy chain, MHC class I, and prostaglandin E receptor EP3 subtype), 2 genes were associated with inflammation (those for complement C1s and KIAA0201), and 3 genes were associated with signaling (those for hepatocyte growth factor activator inhibitor, ceramide glucosyltransferase, and FYN binding protein). The remaining genes that were upregulated represented transcription, protein metabolism, cytoskeleton, and adhesion/extracellular matrix (type IV collagenase). In comparison of gene expression in end-stage renal disease (polycystic kidneys and chronically rejected kidneys) with normal tissues, 11 genes were found to be upregulated whereas 37 genes were downregulated. Among the 11 genes that were upregulated, 8 were associated with immune responses (those for Ig heavy chain, Ig rearranged γ chain, CD53 glycoprotein, secreted cement gland protein, Ig κ chain, SNC73 protein, rearranged Ig heavy chain, and Ig germ line κ chain C18).

Scherer et al. analyzed histologically normal renal allograft biopsy samples obtained at 6 months posttransplantation; one group developed chronic rejection at 12 months and the other did not (70). Allograft gene expression patterns, identified with the use of Affymetrix HG-U95Av2 gene chip, revealed a set of 10 genes that potentially could serve as predictive biomarkers of chronic rejection (70). The differentially expressed genes included those for cytokeratin 15 (KRT15), Hox A7, Hox B7, prolactin receptor, OS9 (APRIL [acidic protein rich in leucines]), G-protein gamma, OBCML (opiate-binding protein-cell adhesion molecular-like), NPRL2 (tumor suppressor), DKFZp5586B1722, and W26469:32f4.

Flechner et al. investigated gene expression patterns of 41 renal allograft biopsy samples obtained from renal graft recipients treated with a regimen of cyclosporine (CSA)-basiliximab mycophenolate mofetil (MMF)-prednisone or sirolimus-MMF-prednisone (27). The biopsies were performed at 2 years posttransplantation and mRNA profiles were determined using high-density oligonucleotide arrays (Affymetrix HG-U95Av2 gene chip). mRNA profiling revealed 379 differentially expressed genes between the two treatment protocols, and 97% of the upregulated genes were observed in the CSA treatment arm. Of the upregulated genes, the top 6 of the 32 functional clusters was composed of genes implicated in transcription, fibrosis/tissue remodeling, immunity/inflammation, intracellular protein transport, signal transduction, and cell growth. In this investigation, biopsy samples classified as CAN were more frequent in the CSA group than in the sirolimus group, and 130 genes were found to be differentially expressed when gene expression patterns of samples with normal histology ($n = 18$) were compared with those of Banff CAN grades 2 and 3 ($n = 9$). The differentially expressed genes included those involved in fibrosis/tissue remodeling and immunity/inflammation.

Molecular Correlates of Acute Rejection of Cardiac Allografts

Endomyocardial biopsy samples obtained during an episode of acute ejection reveal perivascular and interstitial mononuclear cell infiltrates. In severe acute rejection, destruction of myocytes with histologic evidence of necrosis, tissue edema, hemorrhage, and vasculitis is seen (12).

Shulzhenko et al. investigated the expression of mRNAs for CD40 ligand, IFN-γ, and Fas ligand in 39 endomyocardial biopsy samples obtained from 10 adult cardiac allograft recipients within the first 6 months of transplantation and found that the transcripts for CD40 ligand, IFN-γ, and Fas ligand were all expressed at a higher level during an episode of acute rejection than with no rejection (82). Moreover, levels of IFN-γ mRNA were predictive of the development of acute rejection.

The CD27/CD70 costimulatory pathway has been shown to enhance antigen-specific CTL activity via a perforin-dependent pathway (101). Morgun and colleagues investigated with the use of quantitative competitive PCR assay the level of expression of CD27 mRNA in 120 endomyocardial biopsy samples and in 89 peripheral blood mononuclear cell samples collected from 31 recipients of cardiac allografts and reported that the levels of CD27 transcripts were higher in the biopsy samples obtained during acute rejection than with no rejection (52). Interestingly, the CD27 mRNA levels were lower in peripheral blood mononuclear cells collected during acute rejection than during rejection-free periods.

T-cell immune response cDNA 7 (TIRC7) is considered to play a critical role in T-cell signaling. With the use of quantitative competitive PCR assay to measure intragraft

and peripheral blood cell TIRC7 mRNA, Shulzhenko et al. found that intragraft expression TIRC7 was increased in endomyocardial biopsy specimens of patients with acute cardiac allograft rejection, whereas the transcript levels were decreased in the peripheral blood cells (83).

CD69 is a human leukocyte membrane protein expressed on T cells, B cells, and NK cells during the early phase of immune activation. Schowengerdt et al., with the use of flow cytometry, investigated CD69 membrane protein expression in peripheral blood T cells collected from pediatric recipients of cardiac allografts and found that CD69 expression is increased in both CD4+ T cells and CD8+ T cells during an episode of acute rejection (72).

The chemokine and chemokine receptor system is a key regulator of immune cell traffic. Melter et al. examined 169 sequential endomyocardial biopsy samples by immunocytochemistry for the expression of CCR1, CCR3, CCR5, or CXCR3 by CD3+ T cells and found a strong association among CD3+ T-cell infiltration, CXCR3 expression, and acute rejection by histology; RT-PCR analysis of 35 endomyocardial biopsy samples showed that eotaxin, lymphotactin, MCP-1, Mig, and SDF-1 (stromal cell-derived factor 1) were present in both normal and rejecting biopsy samples, whereas the CXCR3 ligand IP-10 was exclusively present in samples classified as acute rejection (51).

Fahmy and colleagues measured with the use of real-time quantitative PCR assay levels of mRNAs for chemokines and chemokine receptors in 316 serial and scheduled endomyocardial biopsy specimens from 30 cardiac allograft recipients and reported that the levels of mRNAs for IP-10, Mig, I-TAC, RANTES, CXCR3, and CCR5, but not those of MCP-1 and IL-8, are higher in samples classified as grade 2 or 3 rejection than in samples without rejection (24). In a subsequent study of gene expression patterns of 60 endomyocardial biopsy samples from 24 recipients, Fahmy et al. reported that, despite similar rejection grade by histology, the levels of IP-10, Mig, RANTES, CXCR3, and CCR5 were all higher in samples obtained between 9 and 12 months of transplantation than in samples obtained in the first 3 months of transplantation (25).

The vitronectin receptor integrin αVβ3A participates in multiple aspects of endothelial cell biology, including migration, apoptosis, and T-cell signaling. Yamani et al. investigated the expression of integrin αVβ3, fibronectin receptor α5β1, and tissue factor in endomyocardial biopsy samples and reported positive staining for integrin αVβ3 protein during acute cellular rejection of cardiac allografts but not for α5β1, or tissue factor in lymphocytic aggregates and vascular endothelial cells (102).

As in acute rejection of renal allografts, cardiac allografts undergoing acute rejection are distinguished by intragraft hyperexpression of cytotoxic attack molecules granzyme B, perforin, and Fas ligand. With the use of quantitative competitive PCR assay, Shulzhenko et al. measured levels of mRNA for granzyme B, perforin, and Fas ligand in 29 endomyocardial biopsy samples from 11 cardiac allograft recipients and reported that the levels of mRNAs for granzyme B, perforin, and Fas ligand were all higher in samples showing acute rejection than in those without rejection (84). Also, the levels of any two of the three mRNAs measured were increased in 100% of prerejection biopsy samples, in 92% of rejection samples, and in only 36% of biopsy samples without histologic changes of acute rejection. Upregulation of Fas ligand expression, during an episode of acute rejection, was also found by Oh et al. in their examination of endomyocardial biopsy specimens from 13 consecutive cardiac allograft

recipients (58), and as observed with renal allografts (75), the levels of expression of mRNA for Fas antigen were similar in biopsy samples with and without acute rejection.

Schoels et al. measured peripheral blood cell mRNA levels in 58 peripheral blood cell samples collected from 44 cardiac allograft recipients undergoing endomyocardial biopsies (71). Thirty-nine parameters, including cytokine and chemokine mRNAs, were examined, and data analysis showed that among the 39 mRNAs, peripheral blood mononuclear cell levels of mRNAs for perforin, granzyme B, CD95 ligand, RANTES, CXCR3, ENA 78, and TGF-β1 were significantly higher and the COX2 mRNA level was lower when peripheral blood samples were collected during grade 2 or higher rejection ($n = 26$) than in samples with no rejection or less than grade 2 rejection ($n = 36$). Receiver operator characteristic curve analysis showed that rejection of grade 2 or higher can be predicted with a sensitivity of 84% and a specificity of 82% with the use of levels of perforin, CD95 ligand, RANTES, COX2, and SEC7/TIC mRNAs (71).

Vascular endothelial growth factor (VEGF) is a major angiogenesis cytokine and has multiple functional attributes, including proinflammatory activity. Reinders et al. studied the expression of VEGF by immunohistochemistry in 101 endomyocardial biopsy samples from 10 cardiac transplant recipients and reported that whereas VEGF is expressed at a low level in normal endomyocardial biopsy samples, the angiogenic cytokine is induced in specimens with acute rejection and persistent expression is associated with the development of graft vascular disease (62). It was also observed that VEGF expression is associated with graft infiltration by CD3+ T cells and CD68+ monocytes and macrophages.

Molecular Correlates of Chronic Rejection of Cardiac Allografts

Cardiac allograft vasculopathy (CAV) is a form of chronic rejection in which intimal thickening leads to accelerated transplant coronary artery disease. High rejection scores on endomyocardial biopsy samples are an independent predictor of the development CAV (16).

Thrombospondin-1 (TSP-1) is a matrix glycoprotein expressed by smooth muscle cells and endothelial cells in response to vascular injury, platelet-derived growth factor, and basic fibroblast growth factor. TSP-1 stimulates the migration and proliferation of smooth muscle cells. In a study by Zhao et al., quantitative PCR assay was used to measure TSP-1 mRNA levels in endomyocardial biopsy specimens and immunochemistry was used to localize TSP-1 protein expression (108). TSP-1 mRNA levels in cardiac allografts were higher than in normal donor hearts, and cardiac allograft recipients with persistent elevations in TSP-1 mRNA levels in their sequential endomyocardial biopsy samples developed severe CAV (as determined by angiography), whereas those with transient elevations did not develop CAV; TSP-1 protein was localized primarily to cardiac myocytes and neointimal smooth muscle cells.

In a subsequent study, Zhao et al. studied the expression of CXCR3 and its ligands IP-10, I-TAC, and Mig in 133 consecutive endomyocardial biopsy samples from human cardiac allografts and in 11 normal donor hearts (107). mRNAs for IP-10, Mig, and I-TAC were detected only in cardiac allografts and not in normal hearts; sustained elevations of IP-10 and I-TAC were associated with CAV, and both IP-10 and Mig were both increased during acute rejection. CXCR3 was localized to both vascular cells and infiltrating cells, whereas IP-10 and I-TAC were found in vascular cells and Mig was detected primarily in infiltrating macrophages (107).

AIF-1 cDNA was initially cloned in a rat model (Lewis to F344) of chronic rejection, and AIF-1 mRNA and protein were both observed in neutrophils and macrophages infiltrating the cardiac allograft (95). Autieri et al. examined the association between the level of expression of AIF-1 and International Society for Heart and Lung Transplantation (ISHLT) rejection grade and CAV (6). In their study, 157 endomyocardial biopsy specimens from 26 recipients of cardiac allografts were analyzed for AIF-1 mRNA expression with the use of semiquantitative PCR assay. The authors found that the levels of AIF-1 mRNA were a correlate of ISHLT rejection grade and that the levels increase with rejection severity. Also, AIF-1 protein was localized to infiltrating cells in grade 1 specimens, whereas AIF-1 was detected in both infiltrating cells and cardiomyocytes in the biopsy samples showing grade 3 rejections (6).

The transcription factor early growth response factor 1 (Egr-1) participates in multiple immune and inflammatory pathways. Egr-1 is induced in endothelial cells and interacts with the consensus sequence GCGGTGGGCG present in the promoter region of several stress-related genes, including those for intercellular adhesion molecule 1 (ICAM-1), platelet-derived growth factor, TGF-β1, and plasminogen activator inhibitor 1 (PAI-1). Egr-1 induction may play an important role in the proliferation of vascular smooth muscle cells leading to intimal thickening and CAV. Autieri et al. investigated the role of Egr-1 in cardiac allograft rejection by examining 106 endomyocardial biopsy samples from 11 recipients of cardiac allografts (5). Immunohistochemistry and Western blotting were used to investigate Egr-1 expression in coronary arteries from patients with CAV.

Egr-1 protein was not detected in biopsy samples without rejection, and intense nuclear staining was detected in leukocytes and cardiac myocytes from samples with grade 3 rejection. Egr-1 mRNA was detected in 20% (6 of 30), 34% (20 of 58), 22% (2 of 9), and 89% (8 of 9) of the endomyocardial samples classified as ISHLT grades 0, 1, 2, and 3 (5). In this study, Egr-1 hyperexpression was found in the vascular cells of coronary arteries from patients with CAV.

Molecular Correlates of Acute Rejection of Lung Allografts

Acute rejection of lung allografts is distinguished by perivascular mononuclear cell infiltration of venules and arterioles. Various degrees of peribronchiolar mononuclear cell inflammation leading to bronchitis and bronchiolitis are also seen in allograft biopsy specimens (4, 104). Bronchoscopic lung allograft biopsy is the procedure of choice to evaluate acute rejection in lung transplantation.

An immunohistochemical study of 72 transbronchial biopsy specimens from 21 human recipients of lung or heart and lung allografts showed that the CD3+ cells are more abundant in allografts than in controls and that a positive correlation exists between histologic rejection and the number of CD3+, CD8+, CD25+, and CD16+ cells. In this study, the inverted CD4/CD8 ratio was not a correlate of rejection, and the phenotype of the cell infiltration was not predictive of CMV infection (19).

Clement et al. analyzed 31 bronchoalveolar lavage specimens for the level of expression of perforin and granzyme B and reported that their level of expression in alveolar lymphocytes is a correlate of the severity of rejection (17). Immunohistochemical analysis of transbronchial lung biopsy samples from patients with acute lung allograft rejection has shown increased expression of both CD4+ helper and CD8+ cytotoxic T cells and heightened expression of RANTES,

perforin, and Fas ligand during acute rejection (13). Intriguingly, perforin appeared to play a dual role: a cytopathic role contributing to tissue injury as well as a role in the downregulation of antiallograft immunity. Shreeniwas et al. evaluated 52 transbronchial biopsy specimens from 24 recipients of lung allografts and found by immunohistochemical staining that E-selectin expression but not the expression of ICAM-1 is a correlate of acute lung allograft rejection (81). It was also found in this study that endothelial cells displayed a high level of expression of HLA class II proteins even in the absence of acute rejection.

Murine models of acute lung allograft rejection suggest an important role for chemokines CXCL9/CXCR3 and RANTES (8, 10). The participation of the chemoattractant IP-10 and its receptor CXCR3 in lung allograft rejection was explored by Agostini et al. (1). Immunohistochemical examination of transbronchial biopsy specimens showed that acute rejection and obliterative broncholitis were associated with infiltration of cells that express CXCR3. Moreover, the T cells from the bronchoalveolar lavage specimens were positive for CXCR3. In addition to CXCR3, acute rejection was also associated with IP-10-expressing macrophages, and IP-10 levels were high in the bronchoalveolar fluid collected during an episode of acute rejection.

Shi and colleagues investigated with the use of quantitative competitive PCR assay whether the levels of mRNAs encoding IL-15 and granzyme B are diagnostic of acute rejection of lung allografts (78). As found with renal allografts, mRNAs for IL-15 and granzyme B were both expressed at a higher level in bronchoalveolar lavage-derived mononuclear cells from patients with acute lung allograft rejection than in samples from patients with stable lung function. Data analysis involving receiver operator characteristic curve analysis demonstrated that acute rejection can be predicted with a sensitivity of 94% and a specificity of 67% with the use of a cutoff value of 3.1 fg of granzyme B mRNA per μg of RNA.

Gimino et al. used microarray technology (Affymetrix GeneChip) to analyze the gene expression patterns of bronchoalveolar lavage cells of patients with and without acute lung allograft rejection (28). The bronchoalveolar lavage cell counts as well as the differential counts were similar between the two groups. The gene expression profiles, however, were strikingly different. In the acute-rejection group (n = 7 patients), 135 genes were upregulated compared to the genes in the no-rejection group (n = 27 patients), and the upregulated genes suggested seven biological pathways in the acute-rejection process. The upregulated immune response genes included those for STAT-4, CD28, chemokine (C-C motif) receptor 7, chemokine (C-X-C motif) receptor 3, CTLA-4, granzyme A, perforin 1, IFN-γ, lymphotoxin β, T-cell receptor α locus, T-cell receptor β locus, IL-2-inducible T-cell kinase, CD3ε, human Ig rearranged γ chain, Ig κ chain, and Ig λ locus. Other genes that were found to be significantly changed when specimens with acute rejection versus no rejection were compared included those regulating apoptosis (6 genes) and transcription (5 genes) and genes involved in cell signaling (10 genes).

Molecular Correlates of Chronic Rejection of Lung Allografts

Chronic rejection of lung allografts is a major diagnostic and therapeutic challenge and a significant contributor to morbidity and mortality. It is manifested by the development of bronchiolitis obliterans syndrome (BOS) (36). BOS is not common in the early posttransplantation period, but its incidence progressively rises to involve 60 to 70% of lung transplant recipients within 5 years of transplantation. Histologically,

bronchiolitis obliterans is characterized by fibroproliferative growth engulfing airway lumens and obliterating blood vessels. The prognosis is dismal after BOS is diagnosed, with mortality reaching 40% in the 2 years following the diagnosis (4). Acute rejection is the leading cause of BOS (15).

Belperio et al. investigated the role of CXC chemokines Mig, IP-10, and I-TAC in the pathogenesis of bronchiolitis obliterans. With the use of enzyme-linked immunosorbent assay to analyze bronchoalveolar lavage fluid obtained from healthy lung transplant recipients and those who developed BOS, the investigators found that the levels of Mig, IP-10, and I-TAC are all elevated in patients who progress from acute rejection to chronic rejection (9).

Molecular Correlates of Acute Rejection of Liver Allografts

A consensus document, the Banff schema for the grading of liver allograft rejection, has been published (21). Not dissimilar to the histologic criteria used to classify renal allograft rejection, the grading schema for acute liver rejection is based upon the degree and severity of infiltration/inflammation by mononuclear cells of the portal triad, bile duct, and venous endothelium.

Krams et al. investigated intrahepatic expression of granzyme B using semiquantitative RT-PCR (39). Allograft biopsy samples obtained during an episode of acute rejection showed heightened expression of granzyme B mRNA compared to biopsy specimens without rejection, with resolution of rejection, or with only preservation injury.

The levels of expression of granzyme B as well as granzyme A have been examined in fine-needle aspirates of liver allografts, and the levels of both granzymes B and A were significantly higher in the aspirates obtained from grafts undergoing acute rejection than in aspirates from the liver grafts not showing acute rejection, but not higher than in aspirates obtained from patients with CMV infection (40).

Hyperexpression of chemokine receptors CXCR3, CXCR4, and CCR5, at the protein level, has been observed in graft-infiltrating lymphocytes as well as in circulating cells (30). It has been reported that CXCR3 ligands, IP-10, Mig, and I-TAC are all highly expressed on liver allograft endothelium and that the expression of SDF, a ligand for CXCR4, is restricted to biliary epithelium CCR3, and CCR5 is overexpressed in activated Kupffer cells (30).

Bartlett et al. investigated intrahepatic expression of costimulatory molecules CD80, CD86, and CD154 in 44 orthotopic liver allografts, at the levels of mRNA (with the use of semiquantitative RT-PCR) and protein (immunohistochemistry), and observed that intragraft expression of CD80 and CD154, at the protein but not at the mRNA level, is a correlate of acute rejection (7).

Liver allografts undergo acute rejection despite effective suppression of IL-2 expression, suggesting that additional growth factors, such as IL-15, contribute to the rejection process. Support for this hypothesis is provided by the observation of Conti et al. that in situ expression of IL-15 is elevated in patients with acute liver allograft rejection, especially during steroid-resistant rejection, and chronic rejection (18).

High-density microarray analyses, carried out by Sreekumar and colleagues, have begun to yield gene expression patterns that distinguish acute rejection from recurrent hepatitis C virus infection of the liver allograft (88). In their study, liver allograft biopsy samples from patients with acute rejection showed overexpression of genes associated with MHC class I and class II antigens, complement components, T-cell activation, and apoptosis compared to gene expression patterns of recurrent hepatitis C virus infection. Additional genes hyperexpressed during an episode of acute rejection included those for granzyme B, TNF-related apoptosis-inducing ligand, TNF-α-converting enzyme, TNF-α-inducible protein A20, TNF-α, TGF-β1 and insulin-like growth factor 1, transcription factor ISGF-3, IFN-γ-responsive transcription factor, and heat shock protein 70.

Molecular Correlates of Chronic Rejection of Liver Allografts

Compared to that for all other solid organ allografts, the incidence of chronic liver rejection is low; it is reported to be about 5% (20, 99). Also, contrary to the case with other vascularized solid organs, the incidence of chronic liver rejection usually decreases over time. Chronic rejection is typically seen in liver transplant recipients with persistent unresolved acute rejection and can lead to end-stage liver disease within the first year after transplantation.

Vasculopathy of hepatic arteries and terminal venules with loss of bile ducts are the distinguishing histologic features. Patients present with a cholestatic picture with blood tests indicating elevation of γ-glutamyl transpeptidase and alkaline phosphatase.

Van der Leij et al. investigated, with the use of RT-PCR and by immunocytochemistry, the expression of the TGF-β1-induced antiapoptotic factor (TIAF) gene in chronic liver allograft rejection and found that whereas this gene is not expressed in normal liver, its expression is upregulated in liver biopsy specimens with chronic rejection (96).

Molecular Characterization of Acute Rejection of Pancreatic Islet Allografts

Human islet cell transplantation has become a viable clinical therapeutic approach for the treatment of type 1 diabetes (74). The inability to diagnose rejection of islet cell graft prior to the development of hyperglycemia complicates clinical management of the islet graft recipient. Han et al. developed quantitative real-time PCR assays for the measurement of rhesus and cynomolgus monkey mRNAs for perforin, granzyme B, and Fas ligand and investigated whether heightened expression of peripheral blood cell mRNAs for cytotoxic attack molecules precede and/or are diagnostic of islet graft rejection in nonhuman primates (33). Four rhesus monkeys with long-term islet allograft function were studied following discontinuation of anti-CD154 monoclonal antibody therapy; in all four recipients, elevations in the level of expression of mRNAs encoding cytotoxic proteins were observed to precede islet graft rejection, and among the CTL genes, alterations in the levels of granzyme B mRNA were the best predictor of rejection (33).

Han et al. have translated their preclinical observations to the clinic (32). In their study cohort of 13 islet graft recipients with insulin independence, 8 subsequently became insulin dependent. Longitudinal measurement of peripheral blood cell mRNA levels showed that elevations in the levels of mRNAs for perforin, granzyme B, and Fas ligand precede islet graft failure and hyperglycemia. As previously observed by Han and colleagues in the nonhuman primate model (33), alterations in the levels of granzyme B mRNA were the best predictor of islet graft failure. Upregulation of CTL genes was also noted during episodes of infection, but the combination of elevations in CTL transcript levels and cellular sensitization, as identified with the use of mixed leukocyte reaction assay, was observed only in the patients who lost their islet grafts and in not those with infection.

TABLE 1 Noninvasive diagnosis of acute rejection of allografts

Type of allograft	Cell type	Molecular correlate of acute rejection	Reference
Renal	Peripheral blood	Granzyme B↑, perforin↑, Fas ligand↑	97
Renal	Peripheral blood	CD40 ligand ↑	80
Renal	Peripheral blood	IL-5 and IL-13 ↑	93
Renal	Peripheral blood	Granulysin ↑	67
Renal	Urinary	Granzyme B ↑, perforin ↑	43
Renal	Peripheral blood	Granzyme B ↑, HLA-DR ↑	64
Renal	Peripheral blood	Granzyme B ↑, perforin ↑	85
Renal	Urinary	CD103 ↑	22
Renal	Urinary	PI-9 ↑	54
Renal	Peripheral blood	IL-18 ↑	86
Renal	Urinary	IP-10 ↑, CXCR3 ↑	94
Renal	Urinary	Granulysin ↑	38
Heart	Peripheral blood	TIRC 7 ↓	83
Heart	Peripheral blood	CD27 ↓	52
Heart	Peripheral blood	Granzyme B ↑, perforin ↑, CD95 ligand ↑, RANTES ↑, CXCR3 ↑, ENA 78 ↑, COX2 ↓	71
Lung	Bronchoalveolar lavage	Granzyme B ↑, perforin ↑	17
Lung	Bronchoalveolar lavage	CXCR3 ↑, IP-10 ↑	1
Lung	Bronchoalveolar lavage	Granzyme B ↑, IL-15 ↑	78
Islet	Peripheral blood	Granzyme B ↑	32

CONCLUDING REMARKS

We have reviewed data regarding molecular correlates of rejection of human renal, cardiac, lung, liver, and pancreatic islet cell allografts. Nucleic acid-based strategies have proven useful for the detection and quantification of gene expression in the clinic. Recent refinements have paved the way for devising noninvasive molecular diagnostic tests for acute rejection of allografts (Table 1). Global expression profiling with technologies such as microarrays will add to our knowledge and provide further insights into molecular pathways, and several pathways are likely to be responsible for the rejection process. Future challenges will include sorting out the vast genomic data and identifying of critical pathways and targetable nodal points. We envision molecular studies to be of value not only from a diagnostic perspective but also in the development and application of mechanism-based therapeutics. The ultimate objective, personalized medicine for the transplant recipient, is an accomplishable goal.

Human Natural Killer Cell Receptors

DOLLY B. TYAN AND MARY CARRINGTON

140

Natural killer (NK) cells are one of the first lines of defense of the innate immune system. Typically described as large granular lymphocytes and sharing a common progenitor with T cells (24), they function both prior to initiation of the adaptive immune response and when the latter system is subverted, as happens in some viral infections and cancer. They respond early and rapidly after infection by producing gamma interferon from prestored transcripts before T cells in the adaptive immune system have had time to expand and differentiate in response to antigen. Likewise, they express granzymes and perforin and their lytic reactions can be triggered in minutes without requirement of transcription, translation, or proliferation (27, 29). In a mature immune response, they can sense varying levels of HLA class I or other ligands on target cells that the adaptive immune system does not see and perform spontaneous target cell killing of virally infected or transformed cells.

Regulation of NK cytolytic activity is a function of engagement of one or more NK surface receptors that may be activating or inhibitory. Unlike receptors in the adaptive immune system, NK receptors are in germ line configuration and do not rearrange (24). Two of the primary sets of receptors present on human NK cells are called the killer immunoglobulin (Ig)-like receptors (KIR; previously known as the killer inhibitory receptors) and the CD94/NKG2 lectin-like receptors. These sets each correspond to a family of genes with exceptionally interesting features in terms of both their genetics and their signaling. The KIR genes (15 genes and 2 pseudogenes) have enormous genetic diversity generated by a combination of variable gene content, alternative splicing, and allelic polymorphism, and they recognize a limited set of HLA class I molecules or epitopes, whereas the more ancestral CD94/NKG2 genes (four genes plus NKG2D) have less diversity but an intriguing array of unconventional HLA class I-like target ligands. These two receptor gene families and their roles in the immune response are the topic of this chapter. Other NK receptor gene families (e.g., leukocyte Ig-like receptor [LIR] and natural cytotoxicity receptor [NCR] genes) also present on some NK cells (4, 35, 56) will not be discussed here.

KIR GENETICS

The KIR genes occupy about 150 kb of the leukocyte receptor complex located on chromosome 19q13.4 (24) residing in a region comprising several families of leukocyte receptor genes (Fig. 1). They encode type I glycoproteins (extracellular amino terminus) with either two or three external Ig-like loop domains, a stem region, a transmembrane (TM) region, and either a short or a long cytoplasmic tail (CYT). The nomenclature is descriptive: the first three-letter designation indicates the gene family (KIR), the number and letter following (2D or 3D) indicate the number (i.e., two or three) of external Ig-like domains present, the letter following (L or S) indicates the presence of a long or short CYT, and the last digit indicates a gene variant with similar organization but >2% sequence difference (Fig. 2). For example, KIR2DL1 is the first variant in a series of KIR (KIR2DL1, KIR2DL2, etc.) with two external domains (i.e., 2D) and a long CYT (i.e., L). KIR exist as monomers with the exception of KIR3DL, which can also form homodimers (24). KIR are found primarily on NK cells but also on NKT cells (a subset of memory T cells with NK receptors), where they may modulate the adaptive immune response by competition with the T-cell receptor for ligand or by modulation of the response depending on which KIR genes are present (56).

A prototype KIR gene (KIR3DL1) has nine exons, as shown in Fig. 3 (8, 33, 56), and all of the other KIR genes can be derived from it by alternative splicing and subsequent mutation. Most KIR have two external Ig-like domains and are of two types. Type 1 KIR2D genes have functional exons 4 (D1) and 5 (D2), but exon 3 (D0) is a pseudoexon that is shorter by one codon and is spliced out even with the correct splicing sites and the correct reading frame (56). Type 2 KIR2D genes have exons 3 (D0) and 5 (D2) present but have spliced out >2 kb containing the fourth exon (D1). Figure 3 portrays the usual variants, but additional splicing variants also exist that are relatively unique (reviewed in references 54 and 56).

The TM and CYT of the KIR are of paramount importance for the function of NK cells because signaling occurs through these portions of the molecule. In general, KIR with long CYTs are inhibitory and those with short CYTs are activating. The long CYTs contain ITIM motifs [immunoreceptor tyrosine-based inhibitory motifs: sequence, $(V/I)XYXX(L/V)$] (29, 35, 49) which when phosphorylated become docking sites for the SHP-1 protein tyrosine phosphatase involved in inhibitory signaling (31). KIR with a charged residue (Lys) in the TM and short CYTs are generally activating. The short CYTs lack the ITIM motifs, and the charged TM residues interact with adaptor molecules containing ITAM
FIGURE 1 HLA class I and KIR gene loci: functionally related gene clusters that exhibit extreme polymorphism. The HLA class I genes map within the MHC at 6p21.3, and the KIR genes map within the leukocyte receptor complex (LRC) at 19q13.4. The KIR gene order is shown for the two distinct KIR haplotypes that have been sequenced in their entirety. Chr., chromosome; ILT, Ig-like transcript; LAIR, leukocyte-associated Ig-like receptor; FCaR, FCα receptor; GPVI, glycoprotein VI.

motifs [immunoreceptor tyrosine-based activation motifs; sequence, D/EXXYXXL/IX$_{(6-8)}$YXXL/I] connecting them to protein tyrosine kinase (PTK) activation pathways (31). KIR2DL4 may be divergent in that it appears to be activating despite its long tail due to the presence of a charged residue (Arg) in the TM domain and a substitution of Cys for Tyr in the CYT ITIM domain (56). KIR CYTs can also have different lengths despite similar exon lengths and sequences due to point substitutions in the exons that lead to premature stop codons (e.g., KIR3DS1) (50). The multiple examples of shortened

CYTs suggest that the generation of activating KIR is evolutionarily important (56). Finally, KIR with similar extracellular domains can have CYTs with opposite signaling motifs that may dictate the ultimate effector function of the NK cell.

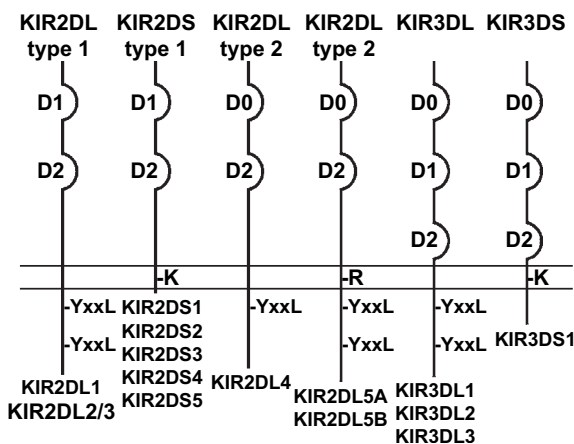
In addition to the variations in splicing and CYT composition, most of the KIR genes are known to be polymorphic (56). The polymorphism varies by gene locus and is thought


FIGURE 2 The basis of KIR nomenclature: domain structure of the KIR molecules. KIR genes express molecules with either two or three extracellular Ig-like domains. The cytoplasmic domains of the inhibitory receptors are long and contain ITIM (I/VXYXXL/V) sequences, whereas a charged amino acid residue, which facilitates interaction with the adaptor molecule DAP12/KARAP, is located in the TM of the short-tailed activating receptors. KIR2DL4 contains signature sequences of both activating and inhibitory receptors. (This figure was adapted from http://web.ncbi.nlm.nih.gov:2441/books/bookres.fcgi/mo no_003/ch1d1.pdf.)
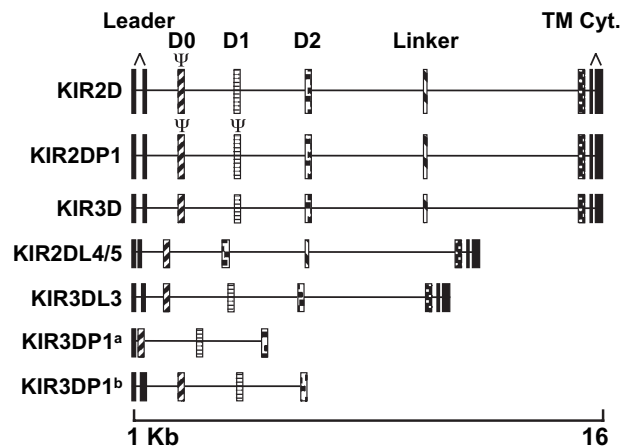

FIGURE 3 Exon-intron structure of the KIR genes. Exons 1 and 2 correspond to the leader (signal) sequence; exons 3 to 5 correspond to the Ig domains D0, D1, and D2, respectively; exons 6 and 7 correspond to the linker and TM regions, respectively; and exons 8 and 9 correspond to the cytoplasmic domain. All exons are design coded. The genes for type 1 two-domain KIR genes, KIR2DL1, KIR2DL2 and -3, and all 2DS genes, have a genomic organization identical to that of the genes encoding KIR molecules with three Ig domains, but exon 3 (encoding D0) of the genes for two-domain KIR is a pseudoexon (ψ). Exon 3 is also a pseudoexon in the KIR2DP1 gene, which also contains a pseudoexon 4. The genes encoding type 2 two-domain KIR, which include KIR2DL4, KIR2DL5A, and KIR2DL5B, are characterized by the absence of exon 4. (This figure was adapted from http://web.ncbi.nlm.nih.gov:2441/books/bookres.fcgi/mo no_003/ch1d1.pdf.)

to be a result of point mutations and homologous recombination. The full extent of the polymorphism has not yet been established and is just beginning to be understood as new populations are studied. The polymorphic sites lie along the entire length of the gene (as opposed to HLA genes where there are "hot spots" of variability) but frequently occur in the Ig-like loop domains, suggesting that the polymorphisms contribute to the interactions with KIR ligands (56).

One of the most intriguing features of the KIR system is that individuals have haplotypes (genes linked on one chromosome) with variable gene content. Multiple examples of unequal recombination exist within the KIR region (reviewed in reference 56), giving rise to gene duplication or, in some cases (e.g., the KIR3DL1 and KIR3DS1 genes), to genes with the same binding capacities but different signaling potentials where these genes segregate as alleles. The arrangement of KIR loci is given in Fig. 4 (8). There are three framework genes, the KIR3DL3, KIR2DL4, and KIR3DL2 genes, present in most individuals. However, individuals have varying numbers of the remaining genes. In general, there are considered to be two supertypic haplotypes, called A and B. The A haplotypes are missing many of the activating genes and generally have KIR2DS4 as their only activating receptor. The B haplotypes contain more genes and have more activating receptors while retaining many or all of the inhibitory ones. Variation in the A haplotypes results from allelic polymorphism, whereas that in the B haplotypes results from both allelic diversity and the variable number of genes present. There is a growing array of haplotypes (at least 37) that have been identified as different populations have been studied (Fig. 4). Since all individuals inherit both a paternal and a maternal haplotype, this serves to increase the diversity of KIR genes present in any one individual (e.g., a person may inherit two different B haplotypes or one A and one B haplotype). One of the difficulties in typing individuals for their KIR genes stems from the inability to distinguish homozygosity from hemizygosity for any given gene.

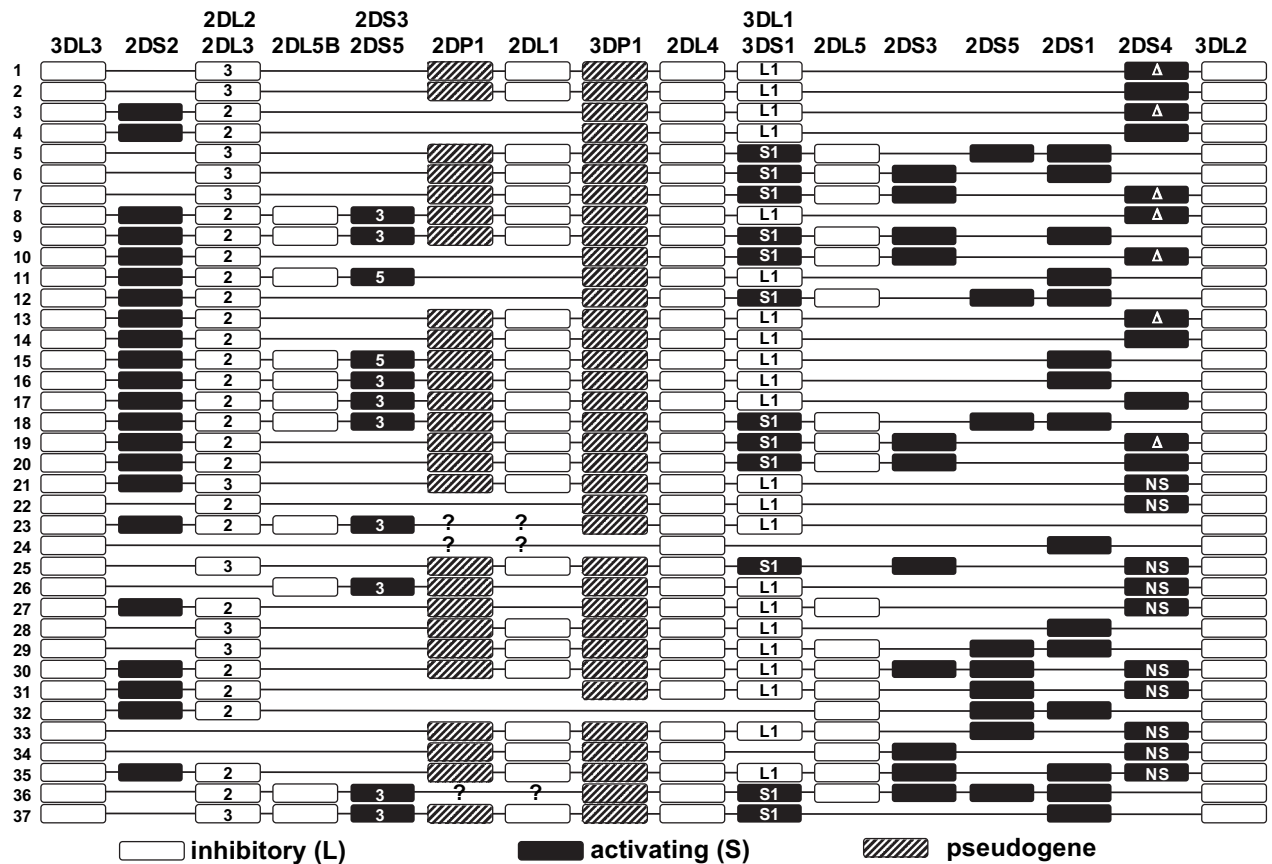
NK cell function in recognizing abnormal cells or those in which there is selective downregulation of HLA class I genes is dependent on the expression of the KIR genes present and the relative numbers of inhibitory versus activating receptors. With minor exceptions in some individuals with promoter polymorphisms, all of the KIR genes present in any given individual are transcribed and would be found in the whole population of their NK cells collectively. However, the number and types of receptors (inhibitory or activating) present on any individual NK cell or clone are variable, and different cells would express only some of the encoded KIR genes. Determining which genes are expressed appears to be a stochastic process but one in


FIGURE 4 KIR haplotypes identified by segregation analysis. Segregation analysis was used to determine the haplotypes shown, many of which are not yet definitive, since it is not always possible to determine gene copy number precisely, even when using family material (14, 19, 46, 52). KIR2DS4 alleles with the 21-bp deletion are indicated by Δ, and those that were not subtyped are marked NS. (This figure was adapted from http://web.ncbi.nlm.nih.gov:2441/books/bookres.fcgi/mono_003/ch1d1.pdf.)

which the expression is stable over time (56). Allelic exclusion may occur in a clonally specific manner but is not a requirement, and both alleles can be expressed on the same NK cell or in the NK cell population as a whole (56). Every NK cell will have at least one inhibitory receptor expressed that recognizes self class I ligands in order to avoid autoimmunity. No additional NK receptor is essential. However, the expression of as many as six additional activating genes has been observed (56). Even given this diversity of receptor expression on individual cells, it is conceivable that one could have a combination of KIR haplotypes and HLA genes that would not yield a single inhibitory pair. Despite the presence of the inhibitory receptor CD94/NKG2A (see below), the resulting diminished inhibitory capability could theoretically lead to autoimmunity and/or pathogenesis. As was mentioned above, the function of the NK cell depends on the array of receptors it expresses and is the sum of the signaling potentials of the activating and inhibiting receptors. Determination of the ultimate effector function of a given NK cell requires that these activating and inhibiting receptors reside on the same cell. Additionally, the stimulating antigen and relevant major histocompatibility complex (MHC) must be present on the same cell to avoid killing of normal bystander cells (28).

Taken together, the variable gene content of haplotypes, the alternative splicing of exons, the allelic polymorphism, and the ethnic distributions contribute to a system with enormous diversity, perhaps beginning to approximate that seen for HLA.

KIR LIGANDS

The ligands for the KIR are the HLA classical class I molecules A, B, and C and the nonclassical class I molecule HLA-G. HLA class II does not appear to be involved (27). The best-known interaction occurs between inhibitory KIR and HLA-C (35, 37, 38). HLA-C has a dimorphism at position 80 (Asn/Lys). KIR2DL1 recognizes C locus molecules with Lys at this position (Cw2, Cw4, Cw5, and Cw6; group C2), whereas KIR2DL2 and KIR2DL3 (products of alleles recognizing the same ligands [36]) recognize those with Asn at this position (Cw1, Cw3, Cw7, and Cw8; group C1). The dichotomy in recognition of the C locus molecules is also dependent on a dimorphism at position 44 in the D1 domain of the KIR2DL proteins, where KIR2DL1 has Met but KIR2DL2 and KIR2DL3 have Lys.

KIR2DS1 (activating) can also recognize C locus molecules with Lys80, but substitution of Lys for Thr at position 70 lowers the affinity compared to that of KIR2DL1 (56). In the case of KIR2DS2, on the other hand, substitution of tyrosine for phenylalanine in one of the loops enhances the affinity for C (Asn80) compared to that of KIR2DL2 (56). In general, high-affinity ligands for the activating genes are unknown, but differences in affinities between inhibitory and activating receptors are key to the ultimate cytolytic signal, or lack thereof, given to the NK cells.

Other KIR genes recognize other class I molecules. KIR3DL1 receptors recognize an epitope on HLA-B molecules that also differs in the region around position 80 (56). This region (positions 77 to 83) gives rise to a peptide dimorphism, known as Bw4 or Bw6, found on all B locus molecules, and each B locus gene has a predictable Bw4 or Bw6 epitope. Because one or the other of these epitopes occurs on every B locus protein, they have very high frequencies in the population. The Bw4 epitope can also be present on some HLA-A locus molecules (e.g., A23, A24, A25, and

A32). KIR3DL1 can distinguish Bw4 from Bw6 and delivers an inhibitory signal when the Bw4 epitope is present on the target cell. While KIR3DL1 appears to be specific to Bw4-positive HLA-B allotypes, KIR3DL2 apparently has a much more restricted set of ligands recognizing HLA-A3 and HLA-A11 (56), although A3 is a moderately high frequency antigen at least in the Caucasian population (3). Lastly, KIR2DL4 recognizes HLA-G (7, 40), which is found preferentially on human extravillous cytotrophoblast (EVT) cells at the maternal-fetal interface. It was originally thought to mediate inhibition of decidual NK cells (56), but as noted above, KIR2DL4 is different from the other KIR with long CYTs and can also be an activating receptor. Other data suggest that the response depends on the activation state of the effector cells (18). In any case, the interaction of HLA-G and KIR2DL4 is likely to be involved in supporting proper maternal-fetal interactions (39, 40). The fact that the KIR2DL4 gene is unique among the KIR genes in being conserved in humans and Old World primates (56) and ubiquitously expressed suggests that its role is important evolutionarily.

CD94/NKG2 RECEPTORS

In addition to the KIR family, another family of receptors belonging to the C-type lectins exists on NK cells. This is the family of CD94/NKG2 receptors (35, 56) encoded by the NK gene complex located on chromosome 12p12.3–p13.1 (24). These receptors are type 2 membrane glycoproteins (intracellular amino terminus), and each subunit has an extracellular C-type lectin domain connected by a stalk region of 25 to 75 residues to the TM and CYT domains. CD94 is the product of a single monomorphic gene, whereas the NKG2 family is a limited family of receptors encoded by the NKG2A gene (and its splice variant the NKG2B gene) and the NKG2C, NKG2E, and NKG2F genes. The NKG2A, -C, -E, and -F molecules have only limited polymorphism but are structurally diverse, suggesting differences in ligands and signaling (24). With the possible exception of the NKG2F gene, which encodes an orphan receptor (21), all of these NKG2 genes encode receptors that are functional only as heterodimers with CD94 (35). CD94 appears to be required for cell surface expression of the NKG2 molecules and may act as a chaperone (24). CD94 can also homodimerize. NKG2A and NKG2B have long CYTs, whereas NKG2C and NKG2E have short CYTs. As with the KIR, those with the long CYTs are inhibitory and those with the short CYTs are activating. There is another gene in the same NK cluster, but only distantly related, called the NKG2D gene (9). Its product does not require CD94, can homodimerize, and is an activating receptor found also on all CD8$^+$ T cells (27). It is relatively nonpolymorphic, and no inhibitory form of it has been detected. Further, cells activated through NKG2D are relatively resistant to inhibition by inhibitory KIR engaged through HLA class I except when inhibitory KIR are present in high abundance or when the ligand is HLA-G (see below) (9). NKG2D has been extensively studied, and its ligand binding has revealed novel mechanisms by which viruses can subvert the immune system to escape killing.

CD94/NKG2 AND NKG2D LIGANDS

Unlike those of the KIR, the CD94/NK2 and NKG2D ligands are generally HLA class Ib molecules (for which there was previously no known function) or atypical class I-like molecules. NKG2A binds the class Ib molecule HLA-E (6).

In contrast to the usual class Ia peptides bound in the groove, HLA-E presents the leader sequence peptides from the other class Ia genes (including the leader from HLA-G) (23). NKG2D, on the other hand, binds to stress-inducible nonclassical HLA class I-like molecules (9). These include the MICA (MHC class I-related chain A) and MICB (9) proteins as well as the UL16 binding proteins (ULBP), also named the retinoic acid-inducible transcript proteins (RAET). These ligands are induced by cellular stress such as heat shock, transformation, and viral or bacterial infection (e.g., UL16 is a protein derived from cytomegalovirus [CMV]) (41). MICA and ULBP are expressed in lipid rafts at the cell surface (12), which may be relevant for signaling. MICA and MICB have the heavy chain of a classical HLA class I molecule but lack beta-2 microglobulin and peptide. The ULBP have only the alpha-1 and -2 domains of a classical HLA class I molecule, lacking both the alpha-3 domain and beta-2 microglobulin, and have glycosylphosphatidylinositol anchors instead of the traditional TM and CYT domains. Levels of these ligands can be modulated both transcriptionally and posttranslationally, and release of soluble forms of MICA or ULBP can contribute to pathogenesis.

PATHOGENESIS

Viruses

Because killing by NK cells is dependent on the strength of signal resulting from the inhibitory-activating receptor competition, pathogenesis can result when either the levels of the signals or the ligands are perturbed. CMV is instructive in this regard but is by no means the only viral type in which NK cells play a putative role. CMV expresses proteins that trap class I heavy chains in the endoplasmic reticulum (US3) or translocate them to the cytosol for degradation (US2, US11). Another (US6) downregulates the expression of HLA class I genes by interfering with peptide transport via TAP (transporter associated with antigen processing) and trapping the class I proteins inside the cell (31, 53). In addition, UL18 produced by CMV mimics an HLA class I molecule and may act as a decoy. CMV also subverts the NKG2D (activating) pathway by producing UL16, a CMV-encoded TM glycoprotein that binds to MICB (but not MICA) and to ULBP. UL16 causes upregulation of ULBP but causes the binding of UL16 to MICB, ULBP1, and ULBP2 to occur inside the endoplasmic reticulum (43, 59). This impedes or prevents the transit of these ligands to the cell surface, thus reducing the surface ligand density necessary to deliver the NKG2D activation signal. Further, in vitro studies have shown that at least one retinoic acid-inducible transcript protein can be secreted from transfected CHO cells (9).

Thus, one could envision a scenario in which the KIR and the CD94/NKG2 inhibitory receptors would have no ligands on a CMV-infected cell and the NK cell would receive an unopposed activating signal. However, if the activating KIR or NKG2D also had no ligand or bound to soluble ligand(s), no cytolysis would ensue, either because the NK cell received no signal at all or because the soluble ligand acted as a decoy away from the infected cell. Additionally, since NKG2D is a coreceptor for CD8$^+$ T cells (9, 48, 56), this arm of the immune system would also not function. Viral replication would then proceed. Clearly, multiple evasion strategies have developed in CMV to subvert both the innate and adaptive immune systems, strategies demonstrated to be highly successful for viral replication and spreading.

KIR genes also have been implicated in viral pathogenesis. Patients infected with hepatitis C virus (HCV) can be subdivided into two basic groups: those who clear the virus and resolve the infection and those who have chronic HCV infection. The affinities of inhibitory KIR2DL proteins for their respective ligands proceed as follows: KIR2DL1 >KIR2DL2>KIR2DL3 (58). Patients who are homozygous for both KIR2DL3 and its cognate HLA-C1 ligands, a receptor-ligand combination that theoretically provides the weakest inhibitory signal, have a significantly better chance of resolving HCV infection than patients who have the KIR2DL1-HLA-C2 or KIR2DL2-HLA-C1 receptor-ligand combinations (20). These data suggest that weak inhibitory receptor-ligand signaling, such as that provided through KIR2DL3-HLA-C1 interactions, may be relatively easily overcome by competing activating signals, resulting in the eliminations of HCV-infected targets. For human immunodeficiency virus (1, 34), individuals with KIR3DS1 in combination with Bw4-positive HLA-B molecules having Ile at position 80 (Bw4-80I) have delayed progression to AIDS when infected with the virus. This delay is dependent on having both KIR3DS1 and Bw4-80I because the presence of one without the other shows no protection. In fact, having two copies of KIR3DS1 in the absence of Bw4-80I is associated with more rapid progression to AIDS. Taken together, these data support an interaction between the products of these genetic determinants in AIDS progression.

Autoimmune Disease

Activating KIR, especially KIR2DS1 and KIR2DS2, have been implicated in autoimmune diseases such as rheumatoid arthritis and psoriatic arthritis (PsA) (36). Since the affinity of the HLA-C group ligand binding is higher for the inhibitory KIR2DL1 and KIR2DL2 and -3 than it is for the activating KIR2DS1 and KIR2DS2, disease appears to ensue when the balance is disrupted. For PsA, it appears that disease susceptibility is a function of the sum of the activating and inhibitory KIR-ligand combinations that are present, where genotypes corresponding with strong activating potential increase the risk of developing disease. Thus, the particular array of KIR present on any given cell will dictate the response of that cell, and the sum of the population of cells will dictate the susceptibility to PsA.

Pregnancy and Recurrent Spontaneous Abortions

Large numbers of NK cells having NKG2A (inhibitory), NKG2C (activating), and a subset of the KIR (e.g., KIR2DL4) are present on maternal NK cells at the fetal-maternal interface with the EVT cells (7, 15). In addition, HLA-C, -E, and -G are expressed on the EVT cells (22), suggesting a balance between activation and inhibition to ensure an appropriate level of fetal trophoblast invasion (in order for proper transfer of essential nutrients and gases from the mother to the fetus) while preventing rejection of the fetal cells. A study of recurrent spontaneous aborters demonstrated that these women have fewer inhibitory KIR (55) than women without pregnancy loss. Along the same lines, HLA-G is the ligand for the inhibitory receptor KIR2DL4. The HLA-G leader sequence can be presented in the context of HLA-E as a ligand for NKG2A. HLA-G has been shown to overcome the signal of the activating receptors and inhibit killing by the NK cells when present in high enough density (32, 39). Further, HLA-G can be present as complexes or in soluble form (15) and either potentially divert the activation of NK cells as described above for

CMV or possibly saturate the inhibitory receptors when present in increased concentrations. HLA-C is the only polymorphic class I molecule expressed by extravillous trophoblast cells, and combinations of maternal KIR on uterine NK cells and fetal HLA-C genotypes expressed on the trophoblast may confer a range of uterine NK cell effects, from relatively strong activation to strong inhibition. Combinations of maternal KIR and fetal HLA-C ligands were tested for their potential effects on the risk of developing preeclampsia. The frequency of possessing two A haplotypes (i.e., those encoding either 0 or 1 expressed activating KIR) was high among preeclamptic mothers relative to that among mothers with healthy pregnancies, specifically when the baby carried at least one HLA-C group 2 allele (17), a receptor-ligand combination that is likely to convey strong inhibitory signals on the uterine NK cells. These data suggest that NK cell activation at the maternal-fetal interface is necessary for maternal and fetal health during pregnancy.

Blood Dyscrasias and Cancer

For lymphoproliferative disease of granular lymphocytes, there is an increase in the number of activating genes with increased production of anti-KIR antibody (13). Pure red-cell aplasia is thought to have an NK cell component in which the inhibitory receptors lack any self ligand and thus destroy autologous $CD34^+$ stem cells via a CD94/NKG2A mechanism (16). These data, together with the situation described earlier, where the NK inhibitory receptors potentially lack any of their ligands, suggest that autoreactive NK cells exist in otherwise healthy individuals.

Many tumors downregulate HLA class I (10). In mice, the upregulation of NKG2D ligands occurring in tumor cells leads to potent rejection of the tumors and conversion to T-cell immunity against the original tumor line (NKG2D ligand negative). In humans, NK cells from colorectal cancer patients lack NKG2D expression due to internalization while soluble MICA is elevated (11). In vitro studies have shown that when soluble MICA is present, NKG2D is internalized within 4 to 24 hours and tumor growth occurs. When soluble MICA is absent from the serum, NKG2D expression is upregulated and the NK cells are tumoricidal, retarding tumor growth in SCID mice. Likewise, MICA-positive leukemia cells are lysed by NKG2D-positive NK cells (45). Leukemia patients, but not healthy donors, were found to have elevated soluble MICA and MICB in their sera, suggesting that the presence of the soluble MIC (shedding) has a regulatory effect on NKG2D either by downregulating it or by acting as a decoy as described above for CMV. The shedding of MIC has also been implicated as instrumental in the progression of prostate cancer (60).

BONE MARROW TRANSPLANTATION

In a landmark paper in 2002 (44), it was shown that donor versus recipient NK alloreactivity could significantly eliminate leukemia relapse and graft rejection and protect acute myelogenous leukemia (AML) patients against graft-versus-host disease (GVHD). The basis for this is as follows: lethally conditioned patients have MHC antigens expressed on their residual cells. MHC differences between donor and recipient can cause failure to engraft due to these residual cells, including mismatches for HLA-C, the ligand for the subset of KIR described above. Conversely, donor cells in the graft, including T cells, can become activated posttransplant by the disparate MHC, setting the stage for GVHD. T cells in the graft are desirable, however, since they both hasten engraftment and enhance the graft-versus-leukemia effect in those surviving any GVHD. The goal of enhancing engraftment and the graft-versus-leukemia effect while reducing or eliminating GVHD (cf. reference 38) has become the holy grail of bone marrow transplantation.

NK cells are among the transplanted donor cells. In a mismatched allogeneic setting, it is possible that the appropriate KIR ligand (class I) might be missing from the recipient cells and trigger NK cell activation and host cell killing. In the study mentioned above, when recipients were stratified according to whether ligand for the donor inhibitory KIR was present or absent, it was found that recipients were totally protected against rejection, GVHD, and AML relapse when the ligands were absent (i.e., transplanted with alloreactive or incompatible NK cells). The probability of event-free survival at 5 years was 60% in the group where the ligands were absent versus 5% in the group where they were present. Multivariate analysis showed that this difference was due strictly to KIR ligand incompatibility in the GVHD direction. This is thought to be due to the killing of the dendritic cells and antigen-presenting cells which predispose to graft failure and GVHD (38). Further studies with mice demonstrated that large numbers of incompatible NK cells do not cause GVHD and that subsequent infusions of alloreactive NK cells into mixed chimeras convert recipients into full donor chimeras. Moreover, infusions of alloreactive NK cells into sublethally conditioned recipients convert them to fully myeloablated status without the need for additional conditioning. The same is not true for patients with acute lymphocytic leukemia (ALL), in whom NK cells are known by in vitro experiments not to be effective (38, 44). Others have had varying levels of success in replicating these findings, but the findings offer an exciting new avenue for improving success in bone marrow transplantation.

SIGNALING

Signaling in NK cells occurs through a variety of receptors, the most well known of which is CD16 (Fc gamma RIII). The following discussion applies only to signaling through the NKG2 and KIR pathways, however, and the reader is referred to the review by Lanier (24) for details of signaling through CD16.

The signaling pathways are dependent upon the family of NK receptor and upon whether the receptor is activating or inhibitory. For the activating receptors (except KIR2DL4 [27]), the KIR associates with the disulfide-linked homodimer DAP12/KARAP (killer cell-activating receptor-associated protein) (25–27, 31, 35, 47). The association occurs due to a Lys in the TM domain of the KIR forming a salt bridge with the ITAM-containing DAP12. When the ligand for the KIR is engaged, tyrosine phosphorylation of the ITAM occurs, causing recruitment of Syk and ZAP70 (tyrosine kinases) through their SH domains, and downstream activation occurs through the Jun N-terminal protein kinase (JNK) and extracellular signal-regulated kinase (ERK) pathways, although the JNK activation may be independent of DAP12. In studies with ULBP activation of NK cells (51), the downstream activation occurred through JNK2, STAT5, ERK, mitogen-activated protein kinase (MAPK), and AKT. The end result was gamma interferon production resulting in CD25 expression, Ca^{2+} influx, increased FasL expression, tyrosine phosphorylation of STAT1, cytokine and chemokine production, degranulation, and cytotoxicity (2, 27, 30). CD94/ NKG2C and CD94/NKG2E also associate through a Lys residue with Asp in the TM segment of DAP12 (25). Antibodies to CD94 have been shown to induce

activation of tyrosine kinase and phospholipase C gamma (PLC-γ) and to generate inositol phosphates (24). In contrast, NKG2D associates with DAP10, also through a salt bridge. DAP10 does not have an ITAM but instead has an essential YXXM motif. Activation after ligand binding is through the phosphatidylinositol 3-kinase pathway and involves Vav1 and Rho family GTPases and PLC. The activation is independent of Syk or ZAP70 (5, 27). The YXXM motif is important because it is the binding site for the p85 regulatory subunit of phosphatidylinositol 3-kinase and recruits Grb2 (9).

For the inhibitory genes, ligand binding to the KIR causes tyrosine phosphorylation of the ITIM and the subsequent recruitment of SHP-1 and SHP-2 (tyrosine phosphatases). The latter prevent pp36 binding and inhibit the activation through Vav, PLC-γ, Grb2, Syk, and ZAP70 (24, 26, 27, 29, 35, 42, 54). CD94/NKG2A functions in a similar manner to block signaling. Interestingly, inhibitory KIR which have docking sites for SHP-1 are found in the center of lipid rafts where activation signals accumulate. The rafts increase in size in cytolytic responses and disappear rapidly when the inhibitory response predominates (57).

KIR TYPING

The involvement of KIR genes in viral infections and potentially in bone marrow transplantation suggests that KIR typing may have wider application in the future. For this reason, KIR typing by molecular methods is becoming standardized through an ongoing external quality control program (UCLA Tissue Typing Laboratory, Los Angeles, Calif.). Testing is variably done by sequencing, PCR-sequence-specific priming (PCR-SSP), or PCR-sequence-specific oligonucleotide probing (PCR-SSOP). Because of the high homology among the genes, sequencing can yield erroneous results and should be used only as a means for typing on a restricted level. Individual labs have their own primer-probe sets for assignment of types, but now a commercial kit (KIR Genotyping SSP Priming Kit) is available from Dynal/Pel-Freez (Brown Deer, Wis.) and is in widespread use among those labs performing KIR typing. In general, 16 genes can be defined: the 2DL1, 2DL2, 2DL3, 2DL4, 2DL5, 3DL1, 3DL2, 3DL3, 3DS1, 2DS1, 2DS2, 2DS3, 2DS4, 2DS5, 2DP1, and 3DP1 genes. The kit further distinguishes two alleles each for the 2DL5, 2DS4, and 3DP1 genes. (The DP designation indicates a pseudogene.) This basic typing strategy allows the definition of genes that are present or absent but does not distinguish between homozygotes and hemizygotes at any gene locus. Validation of KIR typing can be done either by using the external quality control program already in place or by requesting DNA from the CEPH (Centre d'Etude du Polymorphisme Humain) families that were tested at the 13th International Histocompatibility Workshop (http://www.ihwc.org). Additional polymorphism is detectable using allele-specific primers (e.g., reference 46), but these primers are not commercially available. It is clear that additional polymorphisms will be discovered, and thus typing for alleles is currently incomplete. Typing for the NKG2 system is not routinely done since the genes appear to be minimally polymorphic and NKG2D is present on all NK cells. Should typing be desirable, monoclonal antibodies are available that detect each of the members of the family.

SUMMARY

NK cells form the first line of immune defense in innate immunity. A complex system of cell surface receptors exists on NK cells. These receptors can be activating or inhibitory and are derived from multiple gene families, including the KIR and the CD94/NKG2 families discussed above. Their ligands are the HLA class I and class I-like molecules. Current data suggest that the effector response of the individual NK cell is determined by competition between the activating and inhibitory receptors and depends on the strength of the overall strongest signal. We are beginning to appreciate the role of NK cells in viral infections, autoimmune disease, cancer, and bone marrow transplantation, and methods to type the KIR genes are now available.

Detecting Chimerism after Blood and Marrow Transplantation

LEE ANN BAXTER-LOWE

141

In medicine, "chimerism" describes the coexistence of cells that are derived from different zygotes. This term is derived from Chimera, the name of a fire-spitting monster with a lion's head, a goat's body, and a serpent's tail, which is described in Greek mythology. Hematopoietic chimerism has been reported in association with allogeneic transplantation, blood transfusion, and pregnancy (with the condition occurring in mothers and offspring). This chapter discusses fundamental aspects of laboratory assessment of hematopoietic chimerism after blood and marrow transplantation. Clinical indications for chimerism testing in blood and marrow transplantation include posttransplant monitoring of engraftment kinetics and stable mixed chimerism as well as detecting relapse and graft loss. Additional applications include detecting cells engrafted from a third party (e.g., through blood transfusion) and distinguishing monozygotic and dizygotic twins.

Chimerism testing detects the presence of donor cells, preferably providing quantification (e.g., the percentage of donor cells). This objective is accomplished by detecting genetic polymorphism or distinguishing the products of polymorphic genes. Chimerism testing is routinely used after allogeneic blood and marrow transplantation to monitor the status of the allograft and to detect relapse (2, 7, 20). This testing has also become important for guiding certain posttransplant interventions, such as donor lymphocyte infusions. Microchimerism testing, which is usually defined as detecting cells of donor origin when they account for <1% of total cells, is currently used predominantly in research settings. Microchimerism has been reported after solid-organ transplantation (31), blood transfusion (22), and pregnancy (11). The clinical significance of microchimerism remains controversial.

METHODS FOR CHIMERISM TESTING

In the early years of bone marrow transplantation, chimerism testing was primarily limited to use for monitoring donor engraftment. Most donors were HLA-identical siblings, and engraftment of donor cells was often detected using erythrocyte antigens that differed between donor and host. Although flow cytometry and agglutination methods for detecting erythrocyte antigens could detect admixtures of 0.1 to 0.5% for approximately 80% of sibling pairs, transfusions could confound the results and engraftment of other

lineages could not be determined (12). Another technique which was used to monitor engraftment was conventional cytogenetic analysis of metaphase chromosomes. Cytogenetic approaches have several limitations, including the lack of an informative marker for many donor-recipient pairs, the necessity for metaphase chromosomes, and substantial labor requirements. For HLA-mismatched donor-recipient pairs, serological HLA typing was also used to monitor engraftment. Limitations included poor sensitivity, qualitative results, and cross-reactivity of reagents, which confounded data interpretation.

In the 1980s, some of the limitations associated with these historical methods were overcome by new methods that detected polymorphism in genomic DNA. One of the earliest of these new methods detected restriction fragment length polymorphism by using gel electrophoresis to separate DNA fragments based upon size and Southern blotting followed by probe hybridization to detect specific fragments (32). There were informative markers for most donor-recipient pairs, but this labor-intensive procedure has since been supplanted by more convenient methods that use DNA amplification.

Another DNA-based method uses in situ hybridization with probes that are specific for sex chromosomes or autosomal markers. This method can be sensitive, specific, and quantitative. For sex-mismatched transplants, fluorescence in situ hybridization is still used today because single cells can be analyzed and counting large numbers of cells allows high precision and sensitivity (30). Methods that detect only Y chromosome markers, inferring that negative cells are of female origin, are subject to errors in overestimation of female cells caused by age- or disease-related loss of the Y chromosome as well as several technical factors that diminish hybridization. These limitations are overcome by procedures that use different chromophores to distinguish probes hybridized to X and Y chromosomes. With the use of both X and Y probes, the false-positive rate for female and male cells is less than 1% (13). This method can be used only for sex-mismatched transplants.

Today, the most widely used methods for chimerism testing detect polymorphic differences in the numbers of tandem repeats of perfect or slightly imperfect sequence motifs in genomic DNA (see Fig. 1). These motifs are generally referred to as variable-number tandem repeat (VNTR) sequences. For a particular VNTR locus, the number of tandemly repeated sequence motifs in each allele shows
FIGURE 1 STR alleles. Two STR alleles that are distinguished by the numbers of tandem repeats of the sequence motif AAAG are depicted at the top of the figure. The solid black sections represent conserved sequences which are located in the flanking regions of the STR. Oligonucleotides labeled 5′ P and 3′ P anneal to these flanking regions to selectively prime DNA synthesis in the PCR. In this example, the 5′ P primer is labeled with a fluorescent dye molecule. The products of the PCR can be separated using slab gel electrophoresis (bottom left), and the fluorescence is often displayed as an electropherogram (bottom right).

codominant Mendelian inheritance. VNTR loci with sequence motifs of 2 to 8 bp (also called microsatellites) are usually described as short tandem repeats (STR). The acronym VNTR can describe any locus with a repeated sequence motif but is sometimes used to distinguish repeats of long sequence motifs (>8 bp pairs) from STR.

CHIMERISM TESTING USING STR LOCI

In 2005, the predominant methods for chimerism testing involve amplification of STR loci. STR polymorphism is detected using test systems that employ PCR to selectively amplify a target locus (Fig. 1). The assay requires genomic DNA from the test sample and control DNA samples, which can be isolated from any source (e.g., blood, bone marrow, and tissue). PCR primers are designed to specifically anneal to conserved flanking regions of the repeat unit. The PCR products are usually fluorescently labeled and resolved by electrophoresis on capillary or slab gels that can resolve single-nucleotide differences. The size and quantity (i.e., the area under the peak) of each allele are determined and used to calculate the relative proportions of each allele in the test sample.

Most laboratories begin by amplifying a panel of STR loci to determine the sizes of the STR alleles for the host and donor. Alleles that differ between the donor and recipient are referred to as informative alleles. As shown in Fig. 2, there are several possible observations: host and donor alleles are identical (not informative); at least one host and one donor allele is unique (host and donor informative); there is a unique host allele but the donor allele is also present in the host (host informative); or there is a unique donor allele but the host allele is also present in the donor (donor

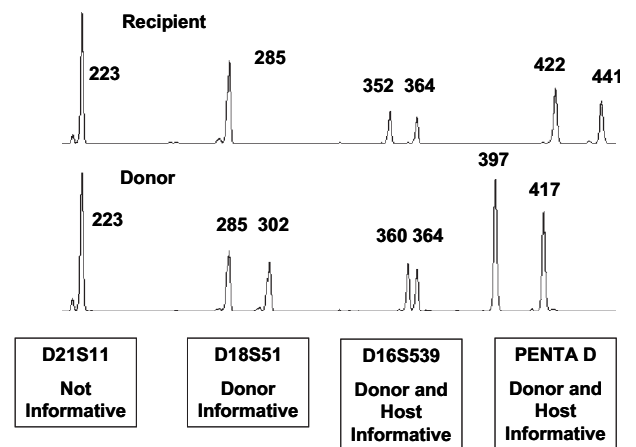
informative). Thiede et al. compared the frequencies of informative alleles for 27 STR markers in 203 recipients and their HLA-matched related donors (33). Penta E, SE33, D2S1338, and D18S51 were the most frequently informative,


FIGURE 2 Electropherograms for a donor-recipient pair. Electropherograms for multiplex reactions for four loci are shown. For D21S11, the donor and recipient are homozygous for the same allele (223 bp). For D18S51, the recipient is homozygous for an allele with 285 bp. The donor shares this allele and has an additional informative allele (302 bp). For D16S539, the donor and recipient share the 364-bp allele, and there are informative alleles for the donor (360 bp) and recipient (352 bp). For Penta D, there are two informative recipient alleles (422 and 441 bp) and two informative donor alleles (397 and 417 bp).

with each being informative for both the donor and recipient in 25 to 50% of the pairs. The frequency of detecting informative alleles was correlated with the degree of heterozygosity ($r = 0.86$; $P = 0.0001$) but not with the total number of alleles observed for the locus.

For posttransplant specimens, the goal is to estimate the relative proportions of donor and recipient alleles in the sample. These are determined by measuring the areas under the informative peaks for the donor and host. Data from admixtures containing increasing quantities of DNA are shown in Fig. 3. For posttransplant specimens, the results are typically reported as the percentage of donor alleles in the specimen. The percentage of donor alleles (% D) is calculated using the following equation:

$$\% \, D = (D_1 + D_2)/(D_1 + D_2 + H_3 + H_4)$$

where D_1 and D_2 represent the areas under donor-informative peaks 1 and 2 and H_1 and H_2 represent the areas under host-informative peaks 3 and 4. If the host and donor share an allele, the shared allele is eliminated from the equation. Calculations for more complex patterns have been summarized by Nollet et al. (25).

There are two approaches for PCR for posttransplant specimens, (i) multiplex PCR using a panel of primers for many STR loci or (ii) individual PCR using one or two loci that have the most favorable characteristics. Advantages of multiplex test systems include availability of commercial reagents, ease of use, and minimal DNA requirements (25). One drawback of the multiplex approach is that amplification conditions are optimized for the primer mixture rather than a particular locus,

which limits the sensitivity that can be achieved. In addition, inadequate correction for spectral overlap of dyes can increase background variation and sometimes affect quantification of informative alleles (29). An alternative which overcomes some of these limitations is to select one or two loci for posttransplant testing and to perform amplification under conditions that are optimal for each locus (27). Improving the efficiency of the PCR and diminishing background variation are beneficial for achieving maximal sensitivity.

Unfortunately, the area under the peak for each PCR product is not always directly proportional to the quantity of the allele in the genomic DNA template. Factors that contribute to deviations include (i) preferential amplification, (ii) stutter peaks, (iii) artifacts related to spectral overlap, and for slab gels, (iv) artifacts related to lane tracking (27, 29). There are several approaches to overcome these limitations, including (i) determining the mean values for many loci (i.e., multiplex methods), (ii) selecting loci and reaction conditions to minimize these factors, and (iii) using standard curves generated by admixtures of donor and host DNA to adjust for deviations from linearity (25, 27).

Preferential amplification is illustrated in Fig. 2 (for Penta D), where the peak for the smaller allele (397 bp) is approximately 14% larger than expected for equivalent amplification of each donor allele and the peak for the larger allele (417 bp) is 14% smaller than expected. Preferential amplification is influenced by a variety of factors, including the number and the relative size difference of the alleles, amplification efficiency, concentration of reaction components (e.g., DNA, polymerase, and magnesium), and differences in sequence motifs that affect the DNA polymerase (27).
FIGURE 3 Admixtures of control DNA for a donor-recipient pair. The electropherogram for the homozygous recipient is shown in the top panel. The small peak to the immediate left of the main peak is a stutter peak. The panel labeled "100% Donor" shows the alleles from the control DNA from the donor. The small peak to the immediate left of the two large peaks is a stutter peak. Presumably, the stutter peak from the larger of the donor alleles comigrates with the smaller allele. The next panels show the amplification products of admixtures of donor and recipient DNA. Arrows show the host peak in the admixtures.

Preferential amplification can be minimized by selecting loci with informative alleles that have small differences in length.

Stutter peaks can occur during the PCR if the polymerase is dissociated during extension of the new strand of DNA (35). When another polymerase molecule associates with the DNA, loops can form in the template or extending strand which can cause loss or addition of one or more repeat units in the final PCR product. The resulting products, which differ by one or more repeat units, serve as templates during subsequent cycles, creating additional copies of alleles with aberrant lengths. Stutter peaks are also referred to as shadow bands or DNA polymerase slippage products. Examples of stutter peaks are provided in Fig. 3 and 4. Stutter peaks can be included in determining the area for the associated allele. If stutter peaks comigrate with an informative peak, it is necessary to make appropriate adjustments by estimating the contribution of the stutter peak by using admixtures of control DNA or making corrections using a standard curve (27).

MIXED CHIMERISM

There are many situations in which there is coexistence of donor and host hematopoietic cells, and this phenomenon is referred to as mixed chimerism. In patients with mixed chimerism, the proportion (percentage) of donor cells can change, and this condition is described as increasing mixed chimerism if the percentage of donor cells is increasing or decreasing mixed chimerism if the percentage of donor cells is decreasing. Sometimes there are lineage-specific differences in levels of donor cell engraftment. For example, certain patients with severe combined immunodeficiency (SCID) syndrome have T cells that are of donor origin while all other cells remain of host origin. This situation is referred to as split chimerism.

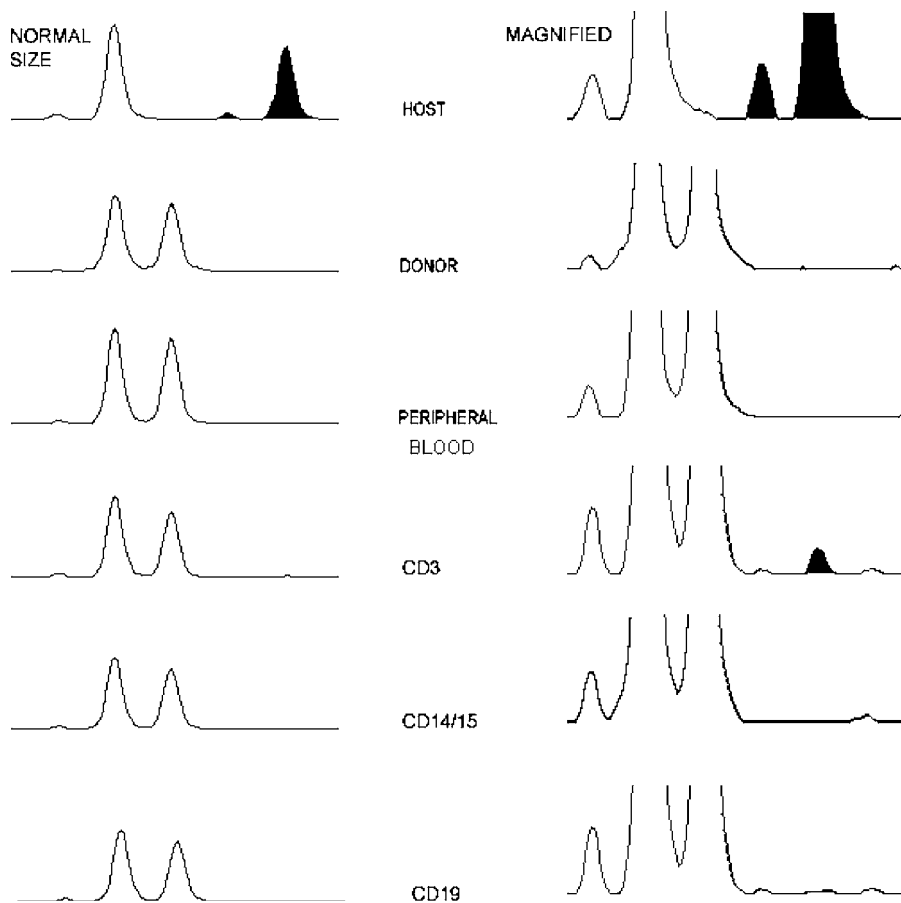
For patients with mixed chimerism, it is important to understand underlying dynamic processes. Changes in percentages of donor cells may be caused by alterations in engraftment levels for all lineages or in the relative numbers of cells of lineages that have different levels of donor chimerism. Thus, increases in percent donor chimerism do not necessarily indicate improved donor cell engraftment. For example, in a SCID patient with split chimerism, T cells may proliferate during an infection, causing the percentage of donor cells in peripheral blood to increase. This is not an indication of additional donor cell engraftment but rather selective expansion of donor-derived T cells. After the infection subsides and the T cells die, the percentage of donor cells in peripheral blood will decrease.


FIGURE 4 Testing of cell subsets to increase sensitivity. The two upper left panels show the electropherograms of the host alleles and donor alleles. The host allele is undetectable in electropherograms for peripheral blood, CD14/15, and CD19 subsets using the standard scale and an expanded scale (right). For the CD3 subset, the host allele is barely detectable in the standard scale but is clearly evident in an expanded scale. Subset analysis not only provides increased sensitivity but also shows the lineage of the autologous cells.

For mixtures of donor and recipient alleles, it is preferable to (i) select loci that have informative alleles for the donor as well as the host, (ii) avoid loci that have alleles with substantial differences in size, because this often results in preferential amplification of the smaller allele, and (iii) avoid loci with informative alleles that comigrate with stutter peaks (± 1 or more core units of the sequence motif) of other alleles. If preferential amplification and/or comigration with stutter peaks occurs, it is possible to correct for deviations from expected rates of amplification by making adjustments according to a standard curve which is determined using admixtures of donor and host DNA (27). Another alternative for diminishing contributions from loci that deviate from normal distribution is to determine the mean percentage of donor cells for many loci.

SENSITIVITY

If only donor alleles are detected in a posttransplant specimen, the condition is described as complete donor chimerism or full donor chimerism. In this situation, the sensitivity of the assay is extremely important because there may be autologous cells in the sample that are present at levels that are below the detection limits of the assay. For example, complete donor chimerism (100% donor cells) may be reported using an assay with 5% sensitivity but a more sensitive technique may detect low levels of residual autologous cells (e.g., a result of 96 to 99% donor cells). Transplant recipients who have become complete donor chimeras can subsequently become mixed chimeras due to proliferation of autologous cells that were previously present at undetectable levels.

If the specimen is predominantly of donor or host origin, sensitivity becomes the most important factor for selecting optimal STR loci. In this situation, the following characteristics are important: (i) preferential amplification of the informative allele(s) for the minority population is advantageous because it improves sensitivity, (ii) low background variation is beneficial because it enhances the ability to detect very small informative peaks, and (iii) separation of peaks allows for avoidance of comigration with stutter peaks, which diminishes sensitivity. With careful selection of loci, sensitivity of at least 0.1% can be achieved with this technique.

Sensitivity can also be increased by testing subsets of cells (2, 24). For example, following allogeneic transplantation, T cells may account for only 10% of peripheral blood leukocytes and 3% of bone marrow cells. If the sensitivity of the method for detecting host cells was 1% and 20% of the T cells were of host origin, 98% of cells in unseparated peripheral blood would be determined to be of donor orgin and 100% of those in unseparated bone marrow would be determined to be of donor origin. For isolated T cells, results of chimerism testing would be reported as 80% donor cells for subsets isolated from peripheral blood or bone marrow. If the sensitivity for the informative host allele was 3% rather than 1%, unfractionated peripheral blood would be reported as 100% donor. The usefulness of testing subsets of cells is shown in Fig. 4, in which host cells are detectable only in the T-cell subset. In patients with transplants for hematological malignancies, chimerism testing of a subset of cells that expresses a tumor marker is sometimes used as an indirect test for minimal residual disease.

NEW TECHNIQUES

Real-time PCR assays that detect single-nucleotide polymorphisms (SNPs) have been applied to chimerism testing.

A report on 11 biallelic SNPs described informative alleles for 90% of the donor-recipient pairs and sensitivity of 0.1% (1). One drawback of the real-time PCR techniques is that the coefficient of variation is 30 to 50% (1, 23), in comparison with approximately 5% for STR systems (7, 17, 21, 27). One factor contributing to this variation for real-time PCR is that the cycle threshold for a positive reaction is typically plus or minus one cycle and a difference in one cycle translates into a twofold difference in the number of copies of the target allele. Thus, real-time PCR assays are very useful for applications requiring high levels of sensitivity but are not optimal for quantifying differences in mixed chimerism that are readily detected by STR or in situ hybridization methods. Real-time PCR methods play an important role in detecting microchimerism, because these assays can reach a sensitivity of 1:100,000 cells.

Pyrosequencing, which is a rapid and quantitative sequencing technology, has also been applied to chimerism testing. Hochberg et al. were able to identify at least one informative SNP locus in each of 55 patients with HLA-identical donors by using pyrosequencing to measure donor and recipient alleles for 14 SNPs with high allele frequencies (18). This approach overcomes many of the limitations of STR analysis (e.g., preferential amplification and stutter peaks), and the assays are easier to perform. However, in the current format, sensitivity is inferior to that obtained with STR methods (5%).

CLINICAL INDICATIONS

For blood and marrow transplantation, chimerism analysis has become an important component of posttransplant monitoring. In the peritransplant period, chimerism testing is used to monitor engraftment, rejection, and graft failure. Engraftment kinetics may be important. Rapid engraftment has been associated with increased risk for acute graft-versus-host disease (2, 9). Under certain conditions, persistence of autologous cells of particular lineages (e.g., CD3 and NK cells) has been associated with increased risk for relapse of malignant disease (9). These investigations have provided the foundation for certain treatment interventions, such as donor lymphocyte infusions and modifications in immunosuppressive therapy (5, 6).

For patients receiving transplants for hematological malignancies, detection of persisting or recurrent autologous cells may be an indication of residual disease and/or the presence of normal hematopoietic cells. The risks associated with persistence of residual disease are straightforward. It has been suggested that the persistence of normal autologous cells is also an important risk factor for relapse, because these cells are indicative of tolerance, which may diminish graft-versus-tumor effects (7, 8). Chimerism analysis of subsets of cells can increase the sensitivity for detecting autologous cells and provide an indirect assay to screen for possible recurrent disease. Trends in donor chimerism have also been shown to be important for certain patients. Decreasing donor chimerism in longitudinal specimens has been associated with disease relapse, and patients who have rapid decreases in donor chimerism have the highest risk of relapse (3–6, 10). Reports of these trends have provided the foundation for several clinical trials to prevent disease relapse by using chimerism analysis to prescribe preemptive immunotherapy such as withdrawal of immunosuppression or infusions of donor cells (7). Other investigators have reported correlations by using cells with particular markers (e.g., CD34) or suggested certain thresholds that are associated with relapse (e.g., 75% CD34 cells of donor origin) (28, 34).

There have been many observational studies suggesting that chimerism testing may be useful for prognosis, but contradictory results have created considerable controversy in the field. It is likely that many factors have contributed to apparently discordant observations, including differences in disease, transplant regimens, sampling, and characteristics of chimerism testing (e.g., sensitivity and accuracy). For example, one study reported that mixed chimerism in T cells and NK cells was associated with leukemia relapse in children but not adults (16). Overall, serial and quantitative analysis of chimerism can be useful for identifying patients who are at highest risk for relapse. The frequency of testing is an important factor, because the time between onset of mixed chimerism and relapse can be short for some patients.

Chimerism monitoring can be particularly important for transplant regimens that are associated with delayed or gradual engraftment, such as reduced-intensity conditioning regimens (9, 15). In this setting, measuring the levels of donor chimerism of the peripheral blood cell subset might allow early therapeutic interventions to prevent graft rejection or disease progression.

Transplantation of umbilical cord blood is associated with increased rates of graft failure and delays in engraftment relative to transplantation of cells derived from living donors. One approach that has had early success in overcoming these obstacles is transplantation with multiple cord blood units. For these transplants, chimerism testing must distinguish cells from the host from those from multiple donors. The general principles provided in this chapter apply to this situation, but interpretation of the data can be very complicated due to sharing of alleles. Early reports have suggested that multidonor hematopoietic chimerism gradually evolves into survival of cells derived from a single unit. The importance of engraftment kinetics in this complex setting remains to be determined.

In addition to the indications described above, chimerism testing can be used to test for the presence of third-party cells derived from blood transfusions (14), maternal cell engraftment in immunocompromised children (19), and maternal cell contamination of umbilical cord blood units (26). The STR loci which are used for engraftment testing are also used for identity testing and can be used to distinguish between monozygotic and dizygotic twins.

SUMMARY

The zygotic origin of cells can be determined using a variety of methods. In 2005, the prevalent technique for chimerism testing involves quantification of the products of PCR amplification of highly polymorphic STR loci. These assays have not yet been standardized, and there can be substantial variation in the sensitivity and accuracy. After hematopoietic cell transplantation, chimerism assays are routinely used to monitor donor engraftment and autologous recovery. Analysis of lineage-specific chimerism can improve sensitivity for detecting residual host cells and can be useful for assessing prognostic risks for graft-versus-host disease, rejection, or recurrent malignancy.

Clinical Immunology Laboratory Accreditation, Licensure, and Credentials

LINDA COOK AND RONALD J. HARBECK

142

It was once possible to perform testing on hospital and clinic patient samples by simply setting up a laboratory and going to work. Many of today's excellent clinical immunology laboratories were spawned in the leading research laboratories across the country as new assays were evaluated and developed by leading researchers and clinicians. Many currently used immunology tests were originally designed, validated, and performed by research technicians, graduate students, or postdoctoral fellows. However, in today's hospital and reference laboratory environment, many government regulations and professional guidelines mandate the education levels of individuals who perform and oversee the testing, recommend test procedures, and define acceptable ordering, result reporting, and billing practices. The U.S. Department of Health and Human Services division of the CMS (formerly the HCFA), which regulates billing practices, has also had a significant impact on the way laboratories must be structured and managed. Today's successful clinical immunology laboratory practitioners must educate themselves about existing guidelines and regulations and keep abreast of the constant changes in order to ensure compliance and professionalism in all areas of the laboratory. This chapter provides a broad overview of the major agencies and regulations which have had an impact on laboratory practices. Laboratory personnel must keep constantly updated by reading appropriate professional articles and reviewing the appropriate Web pages of the responsible agencies and organizations for the latest information.

Various governmental agencies, regulations, organizations, etc., are referred to in this chapter. To assist the reader, a list of abbreviations follows. In addition, an extensive list of websites is provided in Table 1 to help the reader obtain further information regarding specific agencies, regulations, and programs.

Abbreviations. AAAAI, American Academy of Allergy, Asthma and Immunology; **AACC,** American Association of Clinical Chemistry; **ABHI,** American Board of Histocompatibility and Immunogenetics; **AMA,** American Medical Association; **AMLI,** Association of Medical Laboratory Immunologists; **ASCP,** American Society of Clinical Pathologists; **ASHI,** American Society for Histocompatibility and Immunogenetics; **ASM,** American Society for Microbiology; **CAP,** College of American Pathologists; **CDC,** Centers for Disease Control and Prevention; **CLEP,** Clinical Laboratory Evaluation Program; **CLIA,** Clinical Laboratory Improvement Amendments; **CLSI,** Clinical and Laboratory Standards Institute (formerly National Committee for Clinical Laboratory Standards); **CMS,** Centers for Medicare and Medicaid Services (formerly the Health Care Financing Administration [HCFA]); **CPA,** Clinical Pathology Accreditation Ltd.; **CPT,** Current Procedural Terminology; **DRG,** diagnosis-related group; **FDA,** Food and Drug Administration; **GLP,** good laboratory practice; **HCPCS,** HCFA Common Procedure Coding System; **HMO,** health maintenance organization; **ICD,** International Classification of Diseases; **ISO,** International Organization for Standardization; **JCAHO,** Joint Commission on Accreditation of Healthcare Organizations; **LOINC,** Laboratory Observation Identifier Names and Codes; **OIG,** Office of the Inspector General; **WHO,** World Health Organization.

REGULATORY ISSUES AND AGENCIES OF THE FEDERAL GOVERNMENT

CLIA

In 1965 the federal government enacted Public Law 89-97, which created Medicare and Medicaid under the Social Security Act of 1939. As a result of this law, the Department of Health, Education and Welfare developed standards for clinical laboratories operating in inpatient and outpatient settings. The Department of Health, Education and Welfare appointed JCAHO to set standards and survey the laboratories for accreditation. However, Congress became concerned that significant problems existed in the quality of laboratory testing for Medicare recipients provided by laboratories engaged in interstate commerce. Therefore, in 1967 Congress passed the CLIA (CLIA '67) mandating licensure for laboratories providing testing on more than 100 out-of-state specimens per year in major testing categories such as microbiology, chemistry, serology, and hematology. A letter of exemption could be obtained from the CDC for those laboratories receiving fewer than 100 out-of-state specimens per year.

In 1987 the *Wall Street Journal* published an article which again raised concerns among the public about the quality of laboratory testing, especially cytology (1, 2). This prompted Congress and many state health departments to closely review the operations of the nation's clinical laboratories. This review resulted in Congress passing Public Law 100-578, or the CLIA of 1988 (CLIA '88) (12). In 1992 the final rules for CLIA '88

were published (13, 16). CLIA '88 replaced CLIA '67 and the separate Medicare/Medicaid regulations that were in effect up until this time. CLIA '88 required that all facilities performing examinations on materials obtained from the human body for the purpose of providing information for the diagnosis, prevention, or treatment of any disease or impairment of, or the assessment of the health of, human beings were subject to CLIA standards. The sites included in these new regulations were doctors' offices, clinics, health departments, hospitals, and reference laboratories. These requirements mandated additional procedures, reviews, and proficiency testing for all laboratories whether or not they were directly associated with

health care institutions. Laboratories exempt from CLIA '88 include those that are subject to the rules published and enforced by the Veterans Administration and by the Department of Defense (for personnel drug surveillance and enforcement purposes). In addition, laboratories licensed by approved state licensure programs, law enforcement agencies that determine the legal status of individuals, laboratories performing forensic testing, and those performing research testing where the results are not reported for clinical use are also exempt from CLIA '88 regulations.

As part of the CMS's mandates, it is responsible for the administration of the Medicare and Medicaid programs. It is

the responsibility of the Division of Outcomes and Improvement within the CMS to ensure that medical laboratories provide quality testing results. This is achieved through a survey and certification program (14). As of August 2005, the Division of Laboratory Services of the CMS reports that 192,533 laboratories are registered, while 104,994 physician office laboratories are registered. Approximately 38,000 labs are authorized to perform high- or moderate-complexity testing. There are 10 regional offices located throughout the United States with at least one laboratory consultant in each office who is a medical technologist.

Many medical laboratories may not be directly affected by the CMS surveys. CMS has granted "deemed" status to several organizations. In other words, the CMS has the authority to establish and oversee a program that allows private, national accreditation organizations to "deem" that a laboratory is in compliance with Medicare requirements. These organizations include the CAP, JCAHO, the American Association of Blood Banks, the American Osteopathic Association, ASHI, and the Commission on Office Laboratory Accreditation. In addition, two states, Washington and New York, are exempt from CLIA regulations since their programs were found to be equal to or exceed Medicare compliance requirements.

CLIA has established four categories of testing,: waived, moderate complexity, provider-performed microscopy, and high complexity. The waived tests are those considered simple laboratory examinations and procedures that pose insignificant risk of producing an erroneous laboratory test result. Laboratories with a certificate of waiver are not subject to inspection for certification. However, it is expected that the laboratory will abide by all quality control measures as specified by the manufacturer of the kits in use. CLIA '88-waived tests include those performed in bacteriology (includes urine catalase, *Helicobacter pylori* test kits, and group A streptococcus antigen detection kits), endocrinology (includes urine human chorionic gonadotropin and ovulation tests by visual color comparison), general chemistry (includes some cholesterol, creatinine, fecal occult blood, fructosamine, gastric occult blood, glucose, microalbumin, and triglyceride tests), hematology (erythrocyte sedimentation rate, hematocrit, hemoglobin, and prothrombin times), toxicology and therapeutic drug monitoring (ethanol and nicotine and/or metabolites such as cotinine), and urinalysis (urine dipsticks). For the immunology laboratory, tests for bladder tumor-associated antigen and antibodies against *H. pylori* and Epstein-Barr virus (infectious mononucleosis) and respiratory syncytial virus have been approved as of August 2005 as waived tests. The FDA maintains a website which contains frequent updates of waived tests (Table 1).

Tests included in the moderately complex category require some basic scientific and technical knowledge of the various analytical phases of the testing. In addition, basic training and experience are required to perform the test. The tests generally are not fully automated and require some monitoring, timing, or simple calculations. Independent technical skill, decision making, or intervention by the analyst may be required. Before the results of a moderately complex test are released, interpretation and judgment by the analyst may be required.

The moderately complex testing category contains one subcategory of provider-performed microscopy. Tests included in this category are procedures which utilize a microscope in which the test specimen is labile or if the test

is delayed could compromise the accuracy of the results. They include wet-mount preparations of vaginal, cervical, or skin specimens; KOH preparations; pinworm examinations; fern tests; postcoital examinations of vaginal or cervical mucus; urine sediment examination; nasal smears for eosinophils; fecal leukocyte examination; and examination of semen for the presence or absence of sperm and motility. Tests included in this category must be performed during a patient's visit only by licensed physicians, dentists, or podiatrists or by mid-level practitioners, including nurse practitioners, nurse midwives, and physician assistants.

Highly complex testing involves a manual procedure with multiple steps in the sample or reagent processing or automated procedures requiring significant operator intervention. These tests require specialized scientific and technical knowledge as well as appropriate training and experience in order to perform all phases of the analytical process. Reagents used in these tests may be labile and may require special handling or preparation. The operational steps involved in performing the tests may be complex, requiring manual manipulation and monitoring. A high level of troubleshooting abilities, decision making, intervention, interpretation, and judgment are required. Many tests performed in the clinical immunology laboratory are included in this category.

CLIA '88 has specified the training needed of individuals based on the complexity of the testing. For a laboratory performing moderately complex testing, the directors may include pathologists, M.D.'s, D.O.'s, or Ph.D.'s with appropriate experience and training or individuals with a master's or bachelor's degree in science with appropriate experience and training. For high-complexity laboratories a pathologist, other M.D., or D.O. with 1 year of laboratory training during residency or 2 years' experience directing or supervising high-complexity testing may direct the laboratory. In order for a Ph.D. to direct a high-complexity laboratory, he or she must be certified in one of the laboratory specialties, e.g., by the American Board of Medical Laboratory Immunology, or until September 1994 have had 2 years' laboratory training or experience. At the end of the 2 years the individual must (i) become board certified, (ii) be serving as a laboratory director and qualified on or before 28 February 1992, (iii) be qualified under 14 March 1990 CLIA '67 rules, or (iv) be qualified under state law to direct a laboratory in the state on or before 28 February 1992. Further information regarding the requirements for a laboratory director and updates of requirements can be located at http://www.phppo.cdc.gov/clia/regs/subpart_m.aspx#493.1405.

In addition to the laboratory director, specific qualifications are required for technical supervisors, general supervisors, clinical consultants, and cytotechnologists. The CLIA regulations require that the laboratory employ one or more individuals who are qualified by education and either training or experience to perform the responsibilities of a technical supervisor. For diagnostic immunology the requirements range from board-certified pathologists to individuals with a bachelor's degree in science with 4 years of training in high-complexity testing. For histocompatibility and clinical cytogenetics, individuals must be an M.D., D.O., or Ph.D. with 4 years of training or experience. The CLIA requirements for a general supervisor are an M.D., D.O., or Ph.D., a master's or bachelor's degree in science with 1 year of training or experience in high-complexity testing, or an associate degree in laboratory science or medical laboratory technology and 2 years of training or experience in high-complexity testing. One should refer to the CAP website for additional

requirements for education and training for supervisors and testing personnel (http://www.phppo.cdc.gov/clia/regs/toc.aspx).

Reimbursement Issues

Receiving payment for the tests performed in the laboratory has become a very complex issue. Regulations concerning how much will be paid for which tests now rarely match the fee chosen by an individual laboratory. Different billing and reimbursement practices are set by a variety of entities, including private insurance companies, HMOs, the CMS, and a variety of regional carriers who determine local medical review policies. Beginning in 1997 the task of attempting to standardize these policies throughout the country was given to the CMS, a federal agency that is tasked with oversight of the federal program. The CMS created a negotiated rulemaking committee with members consisting of representatives from laboratory organizations, physician groups, and other interested parties. In an ongoing effort, the committee has been tasked to define national reimbursement policies for many lab tests and tries to define through a consensus process policies that reflect good laboratory utilization of testing. National policies are available on the CMS website (http://cms.hhs.gov/coverage). Because of the myriad of reimbursement strategies, each laboratory must establish its own policies and procedures based on information from each of these entities. Because the CMS reimbursement policies have the largest impact on laboratories, a brief review of the most important CMS issues follows. Many other carriers use the CMS policies as guides to set their individual policies. For these reasons, a clear understanding of CMS procedures and guidelines is important. It may also be important for each lab to investigate other agencies and insurance companies when they constitute a significant percentage of the testing population.

Current billing practices for the CMS separate tests into two major types, inpatient and outpatient testing. For inpatient testing, reimbursement is in the form of a single lump payment based on the diagnosis of the patient and any subsequent problems which occur during a hospital stay. The payment system is based on categorization of the patient's disease into a DRG. DRGs consist of 495 groups in 23 major diagnostic categories. The conversion of U.S. hospital billing practices to this billing system occurred in October of 1983 and led to the conversion of hospital laboratories from revenue centers to cost centers. Because hospitals receive the same money for a single patient with a particular disease, the onus is on physicians and laboratory directors to ensure appropriate laboratory utilization by all individuals who order laboratory tests on patients.

Outpatient tests, for which the patient is usually seen in a clinic setting, are being reimbursed per test by Medicare or Medicaid. Payments are subject to a variety of rules and regulations. Many of these issues are dealt with by hospital billing departments, but laboratory directors and managers are responsible for ensuring compliance with the CMS regulations. The most important of these is the selection of the appropriate CPT-4 billing code for each test being performed. Because of the perceived success of the DRG inpatient billing system, a similar system has been designed for outpatient billing. The regulations for outpatient billing have their foundation in the Ambulatory Payment Classification system for coding of procedures and tests. This funding program and associated regulations are administered by the Medicare Outpatient Prospective Payment System, which became functional as of 1 August 2000. The Ambulatory Payment Classification system has 451 groups of outpatient services that must be coded. The Outpatient Prospective Payment Program regulations currently do not include laboratory billing, with the exception of allergy skin testing and some immunopathology testing. This system may in the future be expanded to include all laboratory tests.

Regulations also exist for laboratories which service skilled nursing facilities, kidney dialysis centers (end-stage renal disease regulations), and physicians' office laboratories. In addition to these specialized situations many state governments also have regulations which impact billing practices.

Finally, with the transition of many patients into HMOs, much of the outpatient laboratory services became a capitation system in which the laboratory receives a predetermined amount of money for each covered individual regardless of the number of tests which are done. It is important for individuals responsible for laboratory testing for HMOs to maximize the efficient use of laboratory services and have an accurate idea of test expenses.

Compliance Issues

The OIG within the Department of Health and Human Services is responsible for issuing and monitoring billing regulation for the federal government. The OIG has issued three different regulatory documents which describe the compliance programs for hospital billing departments and clinical laboratories. These can be found on the OIG website under the date of issue; the initial hospital compliance program was issued in 1998 (2/23/98), with supplemental guidelines issued in 2005 (1/27/05); the compliance guidelines for clinical laboratories were issued in 1998 (8/24/98). These documents must be read by individuals responsible for ordering, performing, and billing for laboratory tests so that all laboratory practices are consistent with the regulations. The purpose of these plans is to assist clinical laboratories in developing effective internal controls that will promote adherence to federal and state law, and the program requirement of federal, state, and private health plans (15). The key elements listed in the compliance program should address the following: (i) the development of written standards of conduct that address specific areas of potential fraud, e.g., marketing schemes, CPT coding issues, improper diagnosis coding, and improper claim submissions; (ii) the designation of a chief compliance officer or other appropriate bodies who are charged with the responsibility of operating and monitoring the compliance program and reporting to the chief executive officer and the governing body; (iii) the development and offering of education and training programs to all affected employees; (iv) the maintenance of a process to receive complaints and the adoption of procedures to protect the anonymity of complainants and whistleblowers; (v) the development of a system to respond to allegations of improper and illegal activities and the use of disciplinary action against employees who have violated internal compliance policies or applicable laws or who have engaged in wrongdoing; (vi) the use of audits and/or other evaluation techniques to monitor compliance and ensure a reduction in identified problem areas; and (vii) the investigation and remediation of identified systemic problems and the development of policies addressing the nonemployment or retention of sanctioned individuals.

Each institution and all laboratories must comply with these regulations in order to ensure lack of fraud and abuse in Medicare and Medicaid billing. Immunology laboratories should play a role in the development of laboratory and institutional procedures and policies and ensure that all systems and employees are in compliance with the OIG documents.

Regulations exist which mandate communication between laboratories and the physicians who utilize them. In the OIG compliance documents, the responsibility is placed on the laboratory to inform physicians on a regular basis of the CPT-4 coding and Medicare reimbursement amounts for all tests. This is especially important for tests billed as multiple CPT-4 codes. For example, billing for immunoglobulin quantitations—immunoglobulin G (IgG), IgA, and IgM—could be billed as "3 × 82374, Gammaglobulins, each." The laboratory has the responsibility to inform all patients ordering immunoglobulin quantitations that they are ordering three billable tests in this example. Physician information is also important if "reflex" testing is done. Reflex testing, or the automatic addition of a second test based on the results of the first test, can only be done when the physicians and institution have established the process based on clear medical necessity. All physicians must be aware and agree with any reflex testing strategies being used by the laboratory. This includes all immunofluorescent tests, antinuclear antibodies (ANAs), antimitochondrial antibodies, etc., in which one bill is generated for the initial screen and a second bill is issued for the further analysis of a positive result, e.g., the titration of a positive ANA test.

Another aspect of Medicare and Medicaid billing is that each test must be considered medically necessary. As a part of this determination, each request for laboratory test billing must contain information concerning the diagnosis for the patient. If the test is ordered as part of a panel, all the tests within the panel must also be medically necessary. The diagnostic information for each patient is conveyed using a coding system of diseases termed the ICD-9. ICD-9 was initially published in January of 1979 and is currently the system in use. A federal coordination and maintenance committee meets on a regular basis to examine the ICD-9 code system and adds to or modifies the codes as needed. As this is a federal coding system, it is available in its current form on the CMS website. This disease system is used in both inpatient and outpatient services to code and classify morbidity data for medical records, medical care review, and basic health statistics. The National Center for Health Statistics at the CDC is the WHO collaborating center for North America.

Procedure Coding

In addition to the disease coding, each laboratory test must be coded to indicate the actual test performed. There are over 150 known coding systems that have been developed. The one that is most applicable to U.S. clinical laboratories is the CPT code. CPT coding was developed by the AMA in 1966 and is updated annually (http://www.ama-assn.org). The CPT-4 system has thousands of codes that define a wide variety of medical procedures, including a section for pathology and laboratory medicine. Each test analyte is defined by a five-digit code. Medicare payments have been divided into Part A (the professional component) and Part B (the technical component). Laboratory tests that require significant professional interpretation skills, such as direct skin biopsy immunofluorescent studies or flow cytometry leukemia analysis, can be billed for both a professional and a technical component. The professional component is billed by adding the additional code (-26) modifier onto the five-digit code for the test performed. The reimbursement amount for each technical component (Part B) for each CPT-4 code is published yearly on the CMS website (Table 1) for all CPT-4 codes and for each U.S. state. Part A reimbursements vary widely and should be determined for each local medical carrier. All laboratories should review their CPT-4 coding each

year to ensure the appropriate coding for all laboratory tests. In addition to the CPT-4 coding system, CPT-5 is under development.

Two other coding systems are used, the HCPCS and the LOINC. The HCPCS is referred to as a national code and is approved and maintained jointly by the CMS, the Health Insurance Association, and the Blue Cross and Blue Shield Association. The HCPCS system uses five-position alphanumeric codes for nonphysician procedures and for injectable drugs and their administration. The LOINC was developed by an ad hoc group of clinical pathologists, chemists, and laboratory service vendors. Their goal was to create universal test codes for laboratory tests and procedures.

Advanced Beneficiary Notice

Under Section 1862 (a)(I)(A) of the Medicare Law, Medicare will pay only for services that it determines to be "reasonable and necessary." If the service is not determined to be reasonable and necessary, the beneficiary is not responsible for payment of the service unless prior to the service being rendered, the patient has been notified in writing that Medicare will likely deny payment of the service for his or her specific condition. By signing the advanced beneficiary notice, the patient agrees to assume financial responsibility for the service. The reason given must be specific to the services under consideration. An advance written notice to the beneficiary can protect the provider from liability.

GLP

Clinical laboratories have been increasingly involved in pharmaceutical and diagnostic companies' evaluation of new drugs or diagnostic products. In the 1970s the FDA published regulations governing the conduct of the safety tests on regulated products (GLP regulations, 21 CFR part 58). Compliance with these regulations is intended to ensure the quality and integrity of the safety data prior to the marketing and/or clinical testing of the regulated product. Products that must have evidence of safety include human and animal drugs, human biological products, medical devices, and diagnostic products. The regulations address such issues as the protocol, personnel, facilities, equipment, operations, testing, and controls. The FDA conducts regular inspections and data audits to monitor a laboratory's compliance with GLP requirements. This process is rather detailed and thorough. Before undertaking a GLP project, it is important to consult with a quality assurance professional familiar with GLP regulations. Table 1 lists websites that provide more detailed information on GLP.

ASR

In 1997, the FDA issued a Final Rule regulating analyte-specific reagents (ASR) that are sold for clinical diagnostic applications (Federal Register, 21:8, revised 1 April 2004, 21CFR809.3 and 21CFR809.10). They are defined by the FDA as "antibodies, both polyclonal and monoclonal, specific receptor proteins, ligands, nucleic acid sequences, and similar reagents which, through specific binding or chemical reactions with substances in a specimen, are intended for use in a diagnostic application for identification and quantification of an individual chemical substance or ligand in biological specimens" (6). This rule has made it easier for manufacturers of diagnostic products to develop and market products. The burden of responsibility for the performance of an ASR is on the laboratory. This regulation mandates that each report generated by a laboratory in which an ASR was used must state, "This test was developed and

its performance characteristics determined by [*laboratory name*]. It has not been cleared or approved by the U.S. Food and Drug Administration." A laboratory may elect to include additional, clarifying information along with this statement. The CAP has developed some sample statements to go along with the required statement (5). For example, the following statements have been suggested. (i) "The FDA has determined that such clearance or approval is not necessary." (ii) "This test is used for clinical purposes. It should not be regarded as investigational or for research." (iii) "This laboratory is certified under the Clinical Laboratory Improvement Amendments of 1988 (CLIA) as qualified to perform high-complexity clinical testing. Pursuant to the requirements of CLIA, this laboratory has established and verified the test's accuracy and precision." Since the implementation of the ASR regulations, difficulties have surrounded the application of the regulations, so the FDA began a series of hearings beginning in 2005 to improve the process. Revised regulations may be issued in the future to deal with some of these issues.

STATE CERTIFYING PROGRAMS

The CMS has recognized certain states as being exempt from their certifying program. These states can carry out their own laboratory surveillance and issue their own certifications. These states currently include Washington and New York. Prior to 1 January 2000 the laboratories in Oregon were exempt.

Washington State

In 1989 the state legislature passed the Medical Test Site Licensure law, which allowed the state to regulate clinical laboratory testing. In 1993, Washington's program was judged to be equivalent to CLIA and Washington became the first state in the country to be granted deemed status. In 1997 the CMS extended Washington's exempt status under the CLIA program for all laboratories. Washington retains its regulatory activity at the state level, where it claims the process is more accessible and responsive to local needs.

Under the Washington State program, approximately 2,600 test sites are issued licenses or certificates of waiver. Biennial on-site surveys of approximately 600 nonwaived testing sites are conducted. This survey examines quality control and patient records, test performance, test reporting, management policies, and quality assurance programs. Although the state does not offer its own proficiency testing program, testing sites must participate in a program that is approved by the CMS. The state monitors proficiency test results for acceptability.

New York State

In 1996 New York received exempt status under the CLIA program for independent and hospital laboratories. Prior to this New York became the first state, in 1965, to initiate a certification and licensing program for clinical laboratories operating within the state. Since then the program has expanded, and now, through the Clinical Laboratory Evaluation Program (CLEP), it monitors the quality of testing from all clinical laboratories and blood banks within the state of New York as well as all out-of-state facilities that accept clinical specimens obtained from within New York State. In very rare situations, an unusual test can be granted an exception and performed in a lab without a license. CLEP issues permits to over 1,000 laboratories across the nation and 600 patient service centers in New York State.

The three objectives of the CLEP program are "1) to monitor, improve, and broaden the clinical capabilities of participating laboratories and blood banks; 2) to provide guidelines, quality control standards, and procedures to be used by permit-holding clinical facilities; and 3) to expand the clinical and educational background of medical technologists, laboratorians, and other personnel involved in the operation of clinical laboratories through training and remediation programs."

Standards for New York State accreditation can be found at http://www.wadsworth.org/labcert/clep/Survey/standards-menu.htm. To obtain a New York State laboratory permit, the laboratory must complete an application, submit the required fees, designate a laboratory director and assistant directors, if applicable, and obtain certificates of qualification in all permitted categories for which the laboratory has applied. Currently approximately 2,300 certificates of qualification have been issued to individuals to serve as directors or assistant directors of clinical laboratories and blood banks. In addition, the laboratory must successfully participate in two successive New York State proficiency testing events for all applied categories and subcategories and for all analytes for which New York State proficiency testing is offered, submit standard operating procedures and validation data for department review and approval, complete a successful on-site inspection, and submit an acceptable plan of correction for any deficiencies cited during the inspection. An out-of-state laboratory seeking a New York State permit shall pay to the department an on-site survey fee calculated by the department, which shall consist of a transportation expense and a per-diem expense. Details concerning certification of labs and tests and a request form for a nonlicensed exemption can be found at http://www.wadsworth.org/labcert/clep/clep.html.

The specific technical categories and subcategories for tests that relate to a clinical immunology laboratory are listed in Table 2.

California

The California section of Laboratory Field Services (LFS) is responsible for licensing clinical laboratory personnel, including clinical laboratory scientists (formally titled clinical laboratory technologists), bioanalysts, specialty directors, specialty scientists, and cytotechnologists, through an application process and examination. The program also approves training schools for clinical laboratory personnel, including schools that provide instruction in phlebotomy. Finally, the program conducts complaint investigations which may include on-site inspection processes.

California requires all laboratories to participate in proficiency testing programs that have been approved by the California Department of Health Services and the federal government. Currently, proficiency testing is performed three times per year with five specimens to test per analyte.

ACCREDITATION AND LICENSURE OF LABORATORIES

The CLIA regulations issued by the federal government have mandated that all laboratories performing clinical testing must undergo regular inspections by an agency or organization with deemed status, e.g., the CAP, JCAHO, or New York State. These agencies all have detailed requirements which include acceptable education and training for all personnel, content of procedure manuals, documentation of quality control and preventive maintenance procedures, verification of new procedures, ordering and result reporting

TABLE 2 New York State Department of Health technical categories and subcategories [a]

Technical categories and subcategories	Description
Cellular immunology	
Lymphoid function assays (formerly Limited I)	Analysis of lymphocyte functions by in vitro assays, e.g., antigen-induced proliferation, alloantigen-stimulated proliferation, mitogen-stimulated proliferation, cytolytic assays, and cytokine or immunoglobulin production. For determinations of cytokines in serum, plasma, or CSF, refer to "Cytokines" below.
Lymphoid/T-lymphocyte immunophenotyping (formerly Limited IIA and IIB)	Lymphoid immunophenotyping (formerly Limited IIA) is for laboratories that perform tests for any markers in addition to CD3/CD4 and CD3/CD8. T-lymphocyte immunophenotyping (formerly IIB) is for laboratories performing only CD3/CD4 and CD3/CD8 testing.
Nonlymphoid immunophenotyping (formerly Limited III)	Quantification of nonmalignant cells other than lymphocytes, e.g., stem cell analysis, PNH, or LAD
Malignant leukocyte immunophenotyping (formerly Limited IV)	Use of flow cytometry to identify and characterize leukemias or lymphomas in blood and tissue specimens based on cell phenotype, including cell surface and cytoplasmic antigens, with or without ploidy analysis
Diagnostic immunology	Diagnostic services serology subcategories: (i) serological tests for autoantibodies except antibodies to blood cells and spermatozoa; (ii) serological tests for specific markers of infectious diseases or exposure to such diseases, excluding HIV; (iii) tests for nonspecific indicators of infectious diseases or exposure to such diseases; and (iv) IgA, IgE, IgG, IgM, C3, C4, and alpha-1 antitrypsin
	Donor services serology subcategory: for donor banks and laboratories under contract to donor banks that perform any tests on donors of human organs, tissues, and/or blood for transfer, transfusion, or transplantation
HIV	For laboratories performing serological or molecular tests for HIV for diagnostic or prognostic purposes. This category encompasses three subcategories: (i) screening tests only, (ii) general, and (iii) viral identification.
Histocompatibility	Identification of HLA antigens
General	Laboratories performing all phases of histocompatibility testing for organ or tissue transplantation, including MHC class I and class II antigen typing, HLA antibody screening, and, when necessary, cross-matching hold a permit for this category.
HLA typing	This category is for laboratories offering only HLA antigen typing, HLA antibody screening, and/or mixed-lymphocyte cultures. This category would apply to those laboratories performing histocompatibility testing or initial antigen typing for transplant purposes. Laboratories that perform HLA antigen typing for parentage testing only and not as a diagnostic test need only hold a permit in the category of parentage/identity testing only.
Transplant monitoring	This category is for laboratories performing testing for STR to monitor the success of engraftment following the transplantation of hematopoietic progenitor cells (e.g., bone marrow) or other molecular tests to monitor the success of transplant procedures.
Cytokines	This category includes the quantification of cytokines in serum, plasma, or CSF.

[a] Other categories related to a clinical immunology laboratory include fetal defect markers and immunohematology. Abbreviations: CSF, cerebrospinal fluid; PNH, paroxysmal nocturnal hemoglobinuria; LAD, leukocyte adhesion deficiency; MHC, major histocompatibility complex; STR, short tandem repeats.

procedures, and many other details which are necessary for the documentation of appropriate laboratory practice. The requirements by these agencies are equal to or, in most cases, greater than those mandated by CLIA.

LAP

The Laboratory Accreditation Program (LAP) of the CAP has been in existence since 1962 and since that time has developed into the world's largest single voluntary clinical laboratory improvement program. The LAP has been granted deemed status by CMS and is recognized by JCAHO as an equivalent program in JCAHO-accredited institutions. There are currently over 6,000 laboratories accredited by the CAP in the United States and abroad. The focus of the LAP is the use of an educational, peer

review inspection process using teams of laboratory professionals as inspectors. The CAP gives working laboratorians an opportunity to participate in the inspection process. By visiting and inspecting peer laboratories a significant educational component is added to the accreditation process. The CAP selects a team of inspectors of practicing pathologists, laboratory scientists, and medical technologists who are matched to the laboratory's profile as closely as possible. All aspects of the laboratory's operation are evaluated in this process, from sample acquisition to general laboratory management.

The process to become accredited by the CAP begins with the submission of an application. The CAP then forwards to the laboratory checklists for each of the laboratory sections. The checklists are developed and approved by CAP

committees and address each laboratory discipline. There are frequent revisions of the checklists to reflect the ever-changing profile of laboratory testing and regulations. It is advisable to check the CAP website (Table 1) to review the current checklists. Since the checklists that are sent to the labs are the checklists that the inspectors use during the on-site visit, the laboratory should review all items and address any deficiencies or problem areas prior to the inspection. The major areas that are covered in the checklist include proficiency testing, quality control and quality improvement (e.g., supervision, procedure manuals, specimen collection and handling, reporting of results, reagents, calibration, controls and standards, instruments, and equipment), personnel, physical facilities, and laboratory safety. Next, the CAP selects an inspection team, and a mutually acceptable date is set for the inspection. However, in 2006, the CAP will conduct unannounced inspections. During the inspection process the inspectors conduct a thorough inspection of each phase of the laboratory's operation using the checklists as guides. After the inspection, the inspectors meet with the laboratory staff for a summation conference to review the findings. The inspectors leave a copy of the final summation report, and the laboratory must correct any deficiencies and provide any requested documents to the CAP. If the deficiencies are corrected to the satisfaction of the CAP, the laboratory is accredited for a 2-year cycle but conducts a self-inspection at the 1-year mark using the most current checklists.

JCAHO

More than 19,000 health care organizations are accredited by JCAHO in the United States and in several foreign countries. JCAHO began evaluating hospital laboratory services in 1979. In 1995 JCAHO's standards were deemed to be certifiable under CLIA '88.

Generally a medical technologist surveyor is assigned to review the laboratory's activities and policies. During the on-site survey, the surveyor will look at administrative, technical, safety, and infection control policies and procedures as well as proficiency testing records. In addition, surveyors will meet with laboratory directors and managers to determine their involvement in the operation of the organization. Specifically, they will be seeking information on the communication between the clinical staff, administrators, and other departments; reviewing in-services; and evaluating the oversight of the laboratory testing and quality assessment and improvement activities. While visiting each laboratory section, the surveyor will review section-specific policies and procedures, infection control and safety practices, preventive maintenance, quality control, and proficiency testing results. The surveyor will also visit patient care areas to assess the processes for testing, specimen collection, and requesting and reporting of results and blood transfusions.

ASHI

ASHI has set standards for histocompatibility testing for many years. The standards include the following areas: general policies, personnel qualifications, quality assurance, HLA antigens, serological typing—HLA class I and II antigens, mixed-leukocyte culture tests, antibody screening, renal transplantation, non-renal organ transplantation, marrow transplantation, platelet and granulocyte transfusion, disease association, parentage testing, nucleic acid analysis, flow cytometry, and enzyme-linked immunosorbent assays. ASHI

maintains these standards and conducts inspections of laboratories for licensing as well as assisting in the certification of technologist and director level individuals (Table 1).

Proficiency Testing

A significant ongoing requirement of all accrediting agencies is the regular performance of testing on blinded samples. Testing should be done in a manner identical to that for patient samples and the results then sent to be compared to those from other laboratories performing testing in a similar manner. Laboratories must show evidence that they are enrolled, participate in a regular proficiency testing process, and regularly review results and make corrections to problems and errors discovered in the process of the testing. In addition, a subset of tests are "regulated analytes" in which a continuing good performance is necessary in order for the laboratory to be able to bill Medicare and Medicaid for these tests. Regulated tests in the immunology laboratory include a number of assays usually performed by nephelometry (IgG, IgA, IgM, IgE, C-reactive protein [CRP], C3, C4, haptoglobin, and alpha-1 antitrypsin) and a few serology tests, including tests for rheumatoid factor, infectious mononucleosis, rubella, and ANA. Any tests performed by laboratories in which proficiency testing is unavailable must be shown to be performing correctly in some other manner. This may include trading samples with other laboratories, regular review of clinical appropriateness, or other strategies.

The CAP is the proficiency test supplier with the largest range of test samples supplied. Details of the surveys available and the analytes contained in each survey are available on the CAP website (Table 1). Many other organizations, including ASHI, the CDC Model Performance Evaluation Program, and certain state programs also supply proficiency materials. A variety of manufacturers of reagents and instruments also produce proficiency testing or quality control materials with which results from labs are compared to each other.

INTERNATIONAL ISSUES AND AGENCIES

While U.S. medical laboratories are required to follow guidelines established by CLIA, laboratories outside of the United States have, in many cases, developed systems for assessment of quality that follow international standards. One such organization is the ISO, headquartered in Geneva, Switzerland. The ISO is a nongovernmental federation of national standards bodies from over 100 countries worldwide. Established in 1947, the mission of the ISO "is to promote the development of standardization and related activities in the world with a view to facilitating the international exchange of goods and services, and to developing cooperation in the spheres of intellectual, scientific, technological and economic activity." During the 1970s and 1980s, with an increase in the global economy, companies found a wide variation in the quality of the goods and services they purchased from sources all over the world. From this the ISO developed internationally accepted standards to ensure product quality. In 1987, the ISO published the ISO 9000 series of international standards and guidelines on quality management and quality assurance. For clinical laboratories, document ISO/TC 212, CD 15189, addresses standardization and guidance in the field of laboratory medicine and in vitro diagnostic test systems. In addition to quality management areas discussed in this document, pre- and postanalytical procedures, analytical performance, laboratory safety, reference systems, and

quality assurance are included. Certification by the ISO is a voluntary activity.

In addition to the ISO, other nongovernmental organizations are involved in laboratory quality assurance at the international level (8). These include the International Federation of Clinical Chemistry and Laboratory Medicine (IFCC) and the WHO. The IFCC interacts with several international professional organizations involved in laboratory medicine, including the International Union of Immunological Societies and the World Association of Societies of Pathology and Laboratory Medicine. Among the national organizations are the CLSI (formerly the National Committee for Clinical Laboratory Standards) in the United States and the Institute for Standardization and Documentation in Medical Laboratory in Germany. Regional organizations include the Asian Pacific and Latin American Federation of Clinical Biochemists. In addition to Germany, many other countries in Europe and several clinical

laboratory professional organizations have been actively involved in quality systems and accreditation issues. Among these are the European Communities Confederation of Clinical Chemistry and Laboratory Medicine (7, 10) and External Peer Review Techniques. Further information about the activities of these organizations can be found on their websites (Table 1).

A peer review system for the accreditation of pathology laboratory services in the United Kingdom was inaugurated in 1992. The CPA (Table 1) is associated with the Royal College of Pathologists, the Association of Clinical Pathologists, the Association of Clinical Biochemists, the Institute of Biomedical Science, the Independent Healthcare Association, and the Institute of Health Services Management. The operation functions in a manner similar to that of the CAP in the United States. There are advisory committees that define and review standards, assess applications, recommend inspectors, and advise on decisions after inspection. Survey

TABLE 3 Credentialing agencies and programs[a]

Level	Certifying agency or program	Organization	Education level required	Examination frequency	Website
Director	American Board of Medical Laboratory Immunology	ASM	Ph.D. or M.D. and appropriate experience	Annual	http://www.asm.org
Director	American Board of Medical Microbiology	ASM	Ph.D. or M.D. and appropriate experience	Annual	http://www.asm.org

Technician	ASCP—MLT (General)	ASCP	Associate degree and appropriate experience	Annual	http://www.ascp.org

[a] See text for abbreviations.

teams of voluntary inspectors, each with expertise in the laboratory's specific disciplines, conduct on-site inspections. The inspectors are drawn from practicing pathologists and clinical or biomedical scientists. A recent paper discusses the accreditation process (3).

For a laboratory to become accredited, the process begins with the laboratory assessing itself against the relevant CPA standards, making application, and being subjected to an on-site inspection in order to determine compliance with the standards. After the relevant advisory committee has reviewed the inspectors' assessment, a report is sent back to the laboratory. If there are no problems with the on-site inspection of the laboratory, the board issues a 12-month certificate. If deficiencies are found, accreditation is withheld until the deficiencies have been corrected to the satisfaction of the CPA. When the laboratory has major deficiencies, approval is withheld until the deficiencies have been corrected. In this case reapplication is required. Accreditation is valid for 4 years, with the CPA reserving the right to reinspect at any time without notice. There is a requirement for an annual reregistration and a self-declaration stating continuing compliance with the standards.

CREDENTIALING

A number of organizations are involved in issuing credentials or licenses for individuals who demonstrate technical and management skills in clinical immunology. These programs generally include two components, one which establishes guidelines for training programs and a second which creates and administers the examination process. It is important for all individuals involved in clinical immunology laboratory practice to obtain appropriate certification. These programs encourage professionalism for their members and provide core groups of exceptionally qualified leaders in laboratory immunology. A list of professional societies which provide credentialing programs is shown in Table 3.

LABORATORY STANDARDS

Several professional and voluntary organizations have developed standards for the testing of clinical specimens and provide reagents for the standardization of assays. Among those organizations that have developed procedural standards is the CLSI. The CLSI is a professional volunteer organization that creates standards documents for the testing of clinical samples. A committee of experts develops a document that describes GLP for a test or analyte. After the committee creates a draft, the documents go through three stages, a "proposed" status in which a wide and thorough review takes place, then in some cases a "tentative" stage when the document needs a thorough field evaluation period or when specific data need to be collected, and finally "approved" status when the guideline has achieved wide consensus in the field. Although these are not mandatory guidelines, they are

[b]dsDNA, double-stranded DNA; RF, rheumatoid factor; ASO, anti-streptolysin O; TPO, thyroid peroxidase; HCV, hepatitis C virus; IFN, interferon; IL, interleukin; LIF, leukemia inhibitory factor; G-CSF, granulocyte colony-stimulating factor; GM-CSF, granulocyte-macrophage colony-stimulating factor; M-CSF, macrophage colony-stimulating factor; TGF, transforming growth factor; TNF, tumor necrosis factor.

[c]ENA, extractable nuclear antigen.

useful documents and in some cases are used as the basis for acceptable performance on inspection checklists for laboratory certification agencies such as the CAP. Table 4 contains a list of available CLSI guidelines for immunology tests. Additional information can be found at the CLSI website (Table 1). Occasionally agencies such as the CDC have published guidelines for the performance of laboratory testing of importance to the clinical immunology laboratory. For example, in 1997 the CDC published guidelines for CD4$^+$-cell determination in persons infected with human immunodeficiency virus (HIV) (4).

The Standards Committee of the AMLI has recently provided an autoantibody reference preparation of 10 sera (http://amli.org/standards.htm). The antibody specificities represented on the panel include double-stranded DNA, SS-A, SS-B, Sm, ribonucleoprotein, Scl-70, centromere, Jo-1, and two negative sera. The Standards Committee has also begun to evaluate and produce other serum panels for detection of cardiolipin, neutrophil cytoplasmic, ribosomal P, thyroid peroxidase, thyroglobulin, tissue transglutaminase, and gliadin autoantibodies. The CDC and the Arthritis Foundation have also described a similar panel of reference sera (11). The IFCC provides serum reference materials for several assays that are performed in the clinical immunology

laboratory, including assays for C3, C4, CRP, IgG, IgA, IgM, and prostate-specific antigen (PSA). The Association of the Teaching of Immunology of the French Language Universities maintains a website where reference serum preparations are discussed (http://www.assim.refer.org/serumr~1.htm). In addition, a complete list of national and international reference preparations for the clinical immunology laboratory has recently been published (9). Finally, several companies provide reference serum preparations. For example, Zeus Scientific Company (Raritan, N.J.) provides reference sera for enzyme-linked immunosorbent assay procedures. For further information on available standards and reference materials, see Table 5.

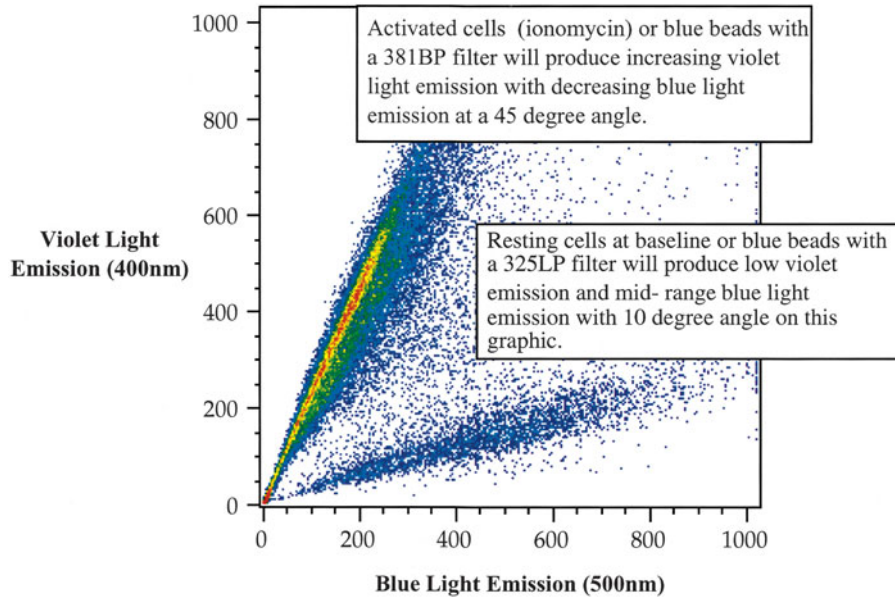
Subject Index

COLOR PLATE 1 (chapter 23)   A standard approach to analyzing flow cytometry data from tetramer-stained whole blood. Whole blood from an individual who was HLA-B7+ and seropositive for EBV was stained with anti-CD3, anti-CD8, anti-CD11a, and an HLA tetramer composed of the HLA-B*0701 heavy chain and a well-characterized B7-restricted CD8+ T-cell epitope from EBV (RPP, for the first three amino acids in its peptide sequence). The same hierarchical gating procedure is shown in panels A and B. (A) Data displayed in pseudo-color dot plot format; (B) contour plot format, with the show-outliers option turned on for the third panel to show the low-frequency tetramer-positive population.
COLOR PLATE 2 (chapter 23)   Use of overlay plots to show the phenotype of a tetramer-positive population with two markers. In this example, whole blood from the same donor as in Color Plate 1 was stained with anti-CD8, anti-CD38, anti-HLA-DR, and the B7/EBV.RPP tetramer. After gating on lymphocytes and CD8hi cells (two left-hand panels), CD8hi cells are plotted as forward scatter versus tetramer, and a gate on the tetramer-positive cells is set. Finally, an overlay plot is created where all CD8+ cells are shown in orange (as a zebra-plot format), while the tetramer-positive cells are presented as an overlay of blue dots.


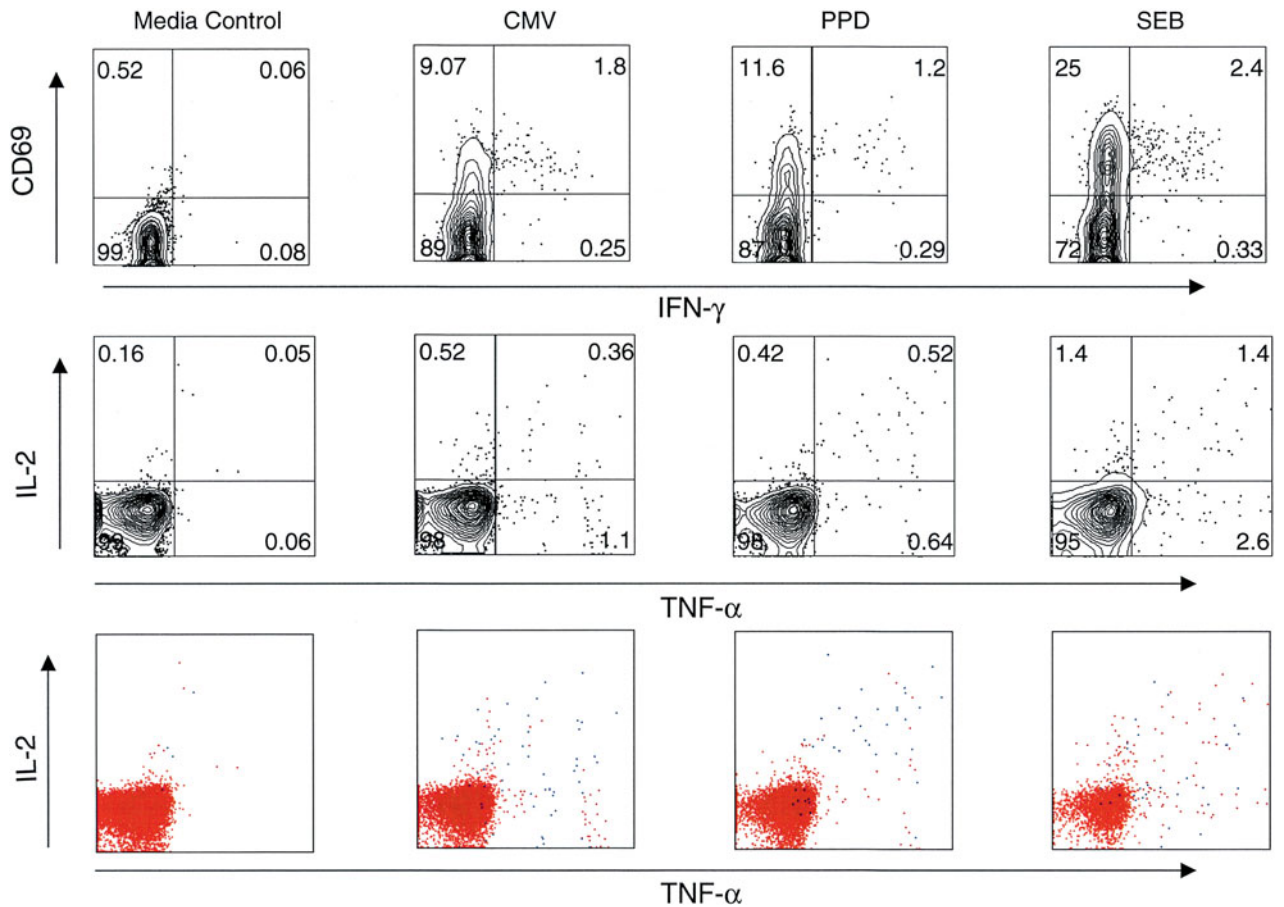
COLOR PLATE 3 (chapter 36)   Blue light emission versus violet light emission as measured by INDO-1-loaded cells or control blue beads. Control positions of blue beads used in the alignment and UV detection of the calcium method can produce either a 45° angle or a 10° angle depending on the light filters used. The expected positions of simulated (free calcium release) and resting cells at baseline are indicated.

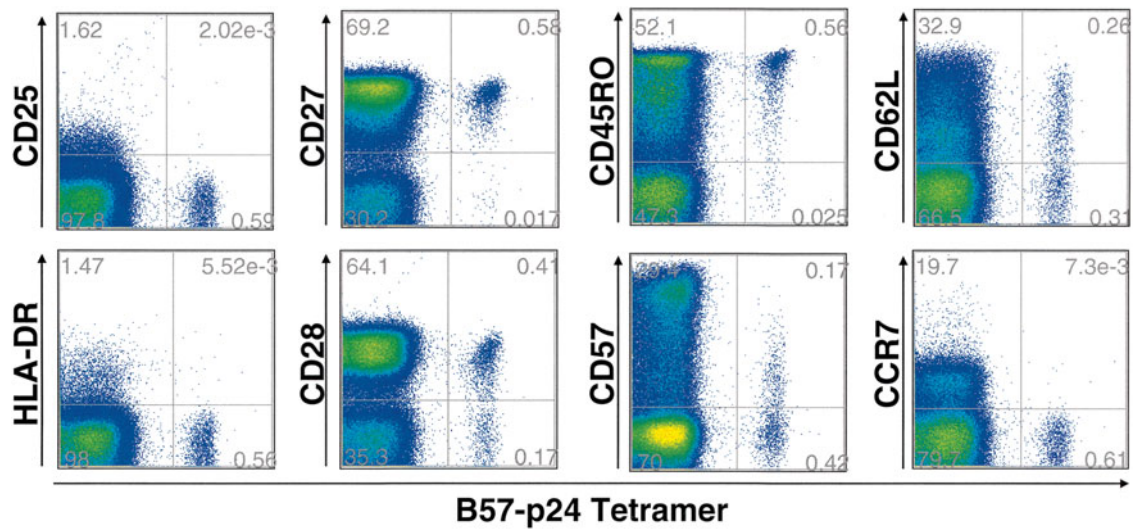
COLOR PLATE 4 (chapter 48)   Direct immunofluorescence of a frozen section from a renal biopsy specimen from a patient with IgA nephropathy, stained with FITC–rabbit anti-human IgA and showing diffuse granular staining in the glomerular mesangium.
COLOR PLATE 5 (chapter 48) Direct immunofluorescence of a frozen section from a renal biopsy specimen from a patient with membranous glomerulonephritis, stained with FITC–rabbit anti-human IgG and showing diffuse granular deposits of IgG along the glomerular basement membrane.

COLOR PLATE 6 (chapter 48) Direct immunofluorescence of a frozen section from a renal biopsy specimen from a patient with anti-GBM disease, stained with FITC–rabbit anti-human IgG and showing diffuse linear staining along the glomerular basement membrane.
COLOR PLATE 7 (chapter 58) Mantoux test. Intradermal injection of tuberculin raises a weal with a characteristic peau d'orange appearance.

COLOR PLATE 8 (chapter 58) Multipuncture Heaf test. This grade 1 reaction is commonly seen in healthy subjects who have received BCG vaccination.

COLOR PLATE 9 (chapter 68) Detection of influenza A virus in columnar respiratory epithelial cell by using a respiratory screen reagent. (Immunofluorescent staining; magnification, ×400.)

COLOR PLATE 10 (chapter 68) Detection of influenza A virus infection in R-mix cells by immunofluorescent staining at 24 h postinfection. (Courtesy Caroline Fong; magnification, ×200.)
COLOR PLATE 11 (chapter 68) Detection of CMV pp65 antigen in PBL nuclei by immunofluorescent staining. (Magnification, ×400.)


COLOR PLATE 12 (chapter 97) Whole blood from an individual with untreated latent *Mycobacterium tuberculosis* infection was analyzed to determine the frequency of immediate cytokine-producing *M. tuberculosis*-specific CD4$^+$ T cells. Whole blood was stimulated with PPD for 20 h, the final 4 h in the presence of brefeldin A. CD4$^+$ T cells were analyzed on a flow cytometer (gating strategies not shown) for expression of various intracellular cytokines after stimulation with medium control, CMV, PPD, and SEB antigens (as shown across the top panel). In the first row of dot plots, with CD4$^+$ T cells expressing both CD69 (a marker of short-term activation) and IFN-γ, it is shown that 1.2% of CD4$^+$ T cells express both markers after stimulation with PPD antigen. By subtracting the 0.06% background frequency measured after stimulation with medium control antigen, the proportion of *M. tuberculosis* (really PPD)-specific CD4$^+$ T cells is 1.14%. In the second row of dot plots, parallel tubes demonstrate the frequency of CD4$^+$ T cells expressing both TNF-α and IL-2 under the same conditions. In the third row of dot plots, the events (cells) enumerated in the second row are visualized but color coded (gating strategy not shown) to indicate cells expressing all three cytokines of interest (i.e., the blue dots indicate CD4$^+$ T cells expressing IFN-γ, with TNF-α and/or IL-2 or neither, while the red dots indicate expression of TNF-α and/or IL-2 or neither).


COLOR PLATE 13 (chapter 97) PBMCs from an HIV-infected long-term nonprogressor were surface labeled with MAb to cell surface molecules and an HLA class I tetramer (HLA57 tetramer loaded with a peptide from the p24 protein). Cell frequencies from each of four quadrants from each of the eight dot plots representing the surface molecules tested are on the y axis (CD25, HLA-DR, CD27, CD28, CD45RO, CD57, CD62L, and CCR7), while tetramer staining is shown on the x axis. The data show that the frequency of antigen-specific CD8$^+$ T cells in this individual was ~0.59% of all CD3$^+$ T cells (gating strategy not shown). In addition, the data show that these antigen-specific cells found in the peripheral blood were nearly all CD25$^-$, HLADR$^-$, CD45RO$^+$, CCR7$^-$, and heterogenous for the other markers measured. These data illustrate how HLA tetramers can help tease apart antigen-specific T-cell responses, particularly if immunophenotyping (shown here) is coupled with functional assays (e.g., CFSE proliferation assays and/or intracellular cytokine responses).
