Contributors

JOSEPH W. ADELSBERGER
Clinical Services Program, NCI-Frederick, SAIC Frederick,
Inc., P.O. Box B, Frederick, MD 21702-1201

JOHN ALTMAN
Emory Vaccine Center, 954 Gatewood Rd., Atlanta, GA 30329

BURT E. ANDERSON
Dept. of Medical Microbiology and Immunology, University of
South Florida College of Medicine, MDC Box 10, 12901
Bruce B. Downs Blvd., Tampa, FL 33612

GRANT J. ANHALT
Dept. of Dermatology, Johns Hopkins School of Medicine,
Ross Research Bldg., Room 771, 720 Rutland Ave., Baltimore,
MD 21205

AFTAB A. ANSARI
Dept. of Pathology and Laboratory Medicine, Emory
University School of Medicine, Atlanta, GA 30322

MARY D. ARI
Meningitis and Special Pathogens Branch, Division of
Bacterial and Mycotic Diseases, National Center for Infectious
Diseases, Centers for Disease Control and Prevention,
Atlanta, GA 30333

WILLIAM M. BALDWIN, III
Transplantation Laboratory, Dept. of Pathology, Johns Hopkins
School of Medicine, Ross Research Bldg., Room 659B, 720
Rutland Ave., Baltimore, MD 21205-2196

MICHAEL W. BASELER
Applied and Developmental Research Program, SAIC-
Frederick, Inc., P.O. Box B, Bldg. 469-6, NCI-FCRDC,
Frederick, MD 21701

LEE ANN BAXTER-LOWE
Immunogenetics & Transplantation Laboratory, University
of California, San Francisco, Box 0508, San Francisco,
CA 94143-0508

MAURO BENDINELLI
Dept. of Experimental Pathology and Retrovirus Center,
University of Pisa, 37, Via San Zeno, I-56127 Pisa, Italy

DEBORAH L. BIRX
U.S. Military HIV Research Program, Walter Reed Army
Institute of Research, 13 Taft Court, Rockville, MD 20850

GUY BOIVIN
Centre de Recherche en Infectiologie, Centre Hospitalier
Universitaire de Québec, and Dept. of Medical Biology, Laval
University, Québec City, Quebec G1V 4G2, Canada

GRAHAM H. BOTHAMLEY
NE London TB Network, Homerton University Hospital,
Homerton Row, London E9 6SR, United Kingdom

ARTHUR R. BRADWELL
Dept. of Immunology, The Medical School, University
of Birmingham, Vincent Drive, Birmingham B15 2TJ,
United Kingdom

RICHARD A. BRONSON
Dept. of Obstetrics and Gynecology and Dept. of Pathology,
Health Science Center, State University of New York, Stony
Brook, NY 11794-8091

MARY B. BROWN
Dept. of Pathobiology, College of Veterinary Medicine,
University of Florida, Gainesville, FL 32611-0880

C. LYNNE BUREK
Dept. of Pathology, Johns Hopkins University School of
Medicine, 648 Ross Research Building, 720 Rutland Ave.,
Baltimore, MD 21205

ANDREW W. O. BURGESS
Dept. of Medical Microbiology and Immunology, University of
South Florida College of Medicine, MDC Box 10, 12901
Bruce B. Downs Blvd., Tampa, FL 33612

RUFUS W. BURLINGAME
INOVA Diagnostics, Inc., San Diego, CA 92131-1638

LEE ANN CAMPBELL
Dept. of Pathobiology, Box 357238, Room F-161F, Health
Sciences Bldg., 1959 N.E. Pacific St., University of
Washington, Seattle, WA 98195

KAI CAO
CW Bill Young Marrow Donor Recruitment and Research
Program and Dept. of Oncology, Georgetown University
Medical Center, E404 Research Bldg., 3970 Reservoir Rd.,
NW, Washington, DC 20057

MARY CARRINGTON
Laboratory of Genomic Diversity, SAIC-Frederick, Inc.,
National Cancer Institute, Frederick, MD 21702

CHI-CHAO CHAN
Immunopathology Section, Laboratory of Immunology, National Eye Institute, National Institutes of Health, Building 10-Room 10N103, Bethesda, MD 20892

DANIEL W. CHAN
Dept. of Pathology, Division of Clinical Chemistry, Johns Hopkins University School of Medicine, 600 North Wolfe St., Meyer B-121, Baltimore, MD 21287-7065

EDWARD K. L. CHAN
Dept. of Oral Biology, University of Florida, P.O. Box 100424, Gainesville, FL 32610-0424

CHUNG-CHE (JEFF) CHANG
Dept. of Pathology, Methodist Hospital/Baylor College of Medicine, 6565 Fannin, MS 205, Houston, TX 77030

STEPHEN J. CHANOCK
Pediatric Oncology Branch and Advanced Technology Center, National Cancer Institute, 8717 Grovemont Circle, Bethesda, MD 20892-4605

KEVIN CHESTERTON
Immunogenetics Laboratory, Dept. of Medicine, Johns Hopkins University School of Medicine, 2041 E. Monument St., Baltimore, MD 21205-2222

MARIAN S. CHIN
Immunology & Virology Section, Laboratory of Immunology, National Eye Institute, National Institutes of Health, Building 10-Room 10N248, Bethesda, MD 20892

IAN CHIN-YEE
The London Health Sciences Centre, London, Ontario N6A 4G5, Canada

A. BERNARD COLLINS
Dept. of Pathology, Massachusetts General Hospital and Harvard Medical School, 32 Fruit St., Boston, MA 02114

ROBERT B. COLVIN
Dept. of Pathology, Massachusetts General Hospital and Harvard Medical School, 32 Fruit St., Boston, MA 02114

MARY ELLEN CONLEY
Dept. of Pediatrics, University of Tennessee College of Medicine, and Dept. of Immunology, St. Jude Children's Research Hospital, 332 N. Lauderdale, Memphis, TN 38105

LINDA COOK
Molecular Virology Laboratory, Seattle Cancer Care Alliance, Fred Hutchinson Cancer Research Center, Seattle, WA 98109

ROSS L. COPPEL
Dept. of Microbiology, Monash University, Clayton, Victoria, Australia

JOSEPHINE H. COX
U.S. Military HIV Research Program, Henry M. Jackson Foundation for the Advancement of Military Medicine, 13 Taft Court, Rockville, MD 20850

NANCY J. COX
Influenza Branch, Division of Viral and Rickettsial Diseases, National Center for Infectious Diseases, Centers for Disease Control and Prevention, 1600 Clifton Rd., Mail Stop G16, Atlanta, GA 30333

LETA K. CRAWFORD-MIKSZA
Food and Drug Laboratory Branch, California Dept. of Health Services, 850 Marina Bay Parkway, Richmond, CA 94804

JOHN T. CURNUTTE
Schering-Plough Biopharma, 901 California Ave., Palo Alto, CA 94304-1104

JEFFREY R. CURRIER
Henry M. Jackson Foundation, 13 Taft Ct., Suite 200, Rockville, MD 20850

DARSHANA DADHANIA
Division of Nephrology, Dept. of Medicine, Weill Medical College of Cornell University, and Dept. of Transplantation Medicine and Extracorporeal Therapy, New York-Presbyterian Hospital, New York, NY 10021

M. R. DAHA
Dept. of Nephrology, C3P-29, Leiden University Medical Center, Albinusdreef 2, 2333 ZA Leiden, The Netherlands

DEREK A. DAMIN
Private Practice, Kentuckiana Allergy, PSC, Louisville, KY 40222

INGER K. DAMON
Poxvirus Program, Division of Viral and Rickettsial Diseases, Centers for Disease Control and Prevention, 1600 Clifton Rd., Mail Stop G-43, Atlanta, GA 30333

RICHARD T. DAVEY, JR.
Office of Clinical Research, National Institute of Allergy and Infectious Diseases, National Institutes of Health, Bethesda, MD 20892

STEPHEN DEALLER
Pathology Dept., Royal Lancaster Infirmary and University of Lancaster, Lancaster LA1 4RP, United Kingdom

MARK DESOUZA
U.S. Military HIV Research Program, Armed Forces Research Institute of Medical Sciences, 315/6 Rajvithi Rd., Bangkok 10400, Thailand

BARBARA DETRICK
Immunology Laboratory, Dept. of Pathology/Meyer B125, Johns Hopkins University School of Medicine, 600 N. Wolfe St., Baltimore, MD 21205

NICOLETTE C. DEVORE
Center for Biologics Evaluation and Research, U.S. Food and Drug Administration, 29 Lincoln Dr., Bethesda, MD 20892

ROBIN L. DEWAR
Clinical Services Program, NCI-Frederick, SAIC Frederick, Inc., P.O. Box B, Frederick, MD 21702-1201

STEVEN D. DOUGLAS
Division of Allergy-Immunology, Clinical Immunology Laboratories, The Children's Hospital of Philadelphia, Dept. of Pediatrics, University of Pennsylvania School of Medicine, 3615 Civic Center Blvd., Abramson Bldg., Rm 1208, Philadelphia, PA 19104-4318

BRUCE E. DUNN
Dept. of Pathology, Medical College of Wisconsin, 8700 W. Wisconsin Ave., Milwaukee, WI 53226, and Veterans Integrated Service Network 12, Clement J. Zablocki VA Medical Center, 5000 W. National Ave., Milwaukee, WI 53295-1000

PAUL H. EDELSTEIN
Dept. of Pathology and Laboratory Medicine and Dept. of Medicine, University of Pennsylvania School of Medicine, Philadelphia, PA 19104-4283

TAREK ELBEIK
Dept. of Laboratory Medicine, University of California, San Francisco, and San Francisco General Hospital, Bldg. NH, Room 2M35, 1001 Potrero Ave., San Francisco, CA 94110

MELISSA E. ELDER
Division of Immunology, Rheumatology, and Infectious Diseases, Dept. of Pediatrics, University of Florida Health Sciences Center, 1600 SW Archer Rd., R1-118, Gainesville, FL 32610-0296

ANDREW L. FELDMAN
Laboratory of Pathology, Center for Cancer Research, National Cancer Institute, and FDA-NCI Clinical Proteomics Program, Bethesda, MD 20892

HEINZ FELDMANN
Special Pathogens Program, National Microbiology Laboratory, Public Health Agency of Canada, and Dept. of Medical Microbiology, University of Manitoba, Winnipeg, Manitoba R3E 3R2, Canada

NINGGUO FENG
Division of Gastroenterology and Hepatology, Stanford University School of Medicine, 300 Pasteur Dr., Stanford, CA 94305-5187

GUIDO FERRARI
Dept. of Surgery, P.O. Box 2926, Duke University Medical Center, Durham, NC 27710-2996

BOURKE L. FIRFER
Dept. of Pathology, Stroger Hospital of Cook County, Rosalind Franklin University of Medicine and Science, Chicago, Illinois

DAVID M. FLEISCHER
Dept. of Pediatric Allergy and Immunology, Johns Hopkins Hospital, CMSC 1102, 600 N. Wolfe St., Baltimore, MD 21287

THOMAS A. FLEISHER
Dept. of Laboratory Medicine, Clinical Center, National Institutes of Health, Bethesda, MD 20892-1508

CARL E. FRASCH
Laboratory of Bacterial Polysaccharides, Center for Biologics Evaluation and Research, Mailstop HFM-428, 1401 Rockville Pike, Rockville, MD 20852

GIULIA FREER
Dept. of Experimental Pathology and Retrovirus Center, University of Pisa, 37, Via San Zeno, I-56127 Pisa, Italy

MARVIN J. FRITZLER
Dept. of Biochemistry and Molecular Biology, University of Calgary, HRB 410B, 3330 Hospital Dr. NW, Calgary, Alberta T2N 4N1, Canada

MIHAELA GADJEVA
New Research Building, Brigham and Women's Hospital, 77 Louis Pasteur, Room 652, Boston, MA 02115

DENNIS GALANAKIS
Dept. of Pathology, State University of New York at Stony Brook, Stony Brook, NY 11794

CHARLOTTE A. GAYDOS
Division of Infectious Diseases, School of Medicine, Johns Hopkins University, Baltimore, MD 21205

M. ERIC GERSHWIN
Division of Rheumatology/Allergy and Clinical Immunology, School of Medicine, University of California at Davis, Davis, CA 95616

SMITA A. GHANEKAR
BD Biosciences Immunocytometry Systems, 2350 Qume Dr., San Jose, CA 95131

PATRICIA C. GICLAS
Clinical Reference Laboratories, Complement Laboratory, Dept. of Pediatrics, Division of Allergy and Immunology, National Jewish Medical and Research Center, 1400 N. Jackson, Denver, CO 80206-2761

JAMES A. GOEKEN
Dept. of Pathology, University of Iowa Healthcare, 5231-G RCP, 200 Hawkins Dr., Iowa City, IA 52242-1009

JUDITH A. GOODSHIP
Institute of Human Genetics, University of Newcastle upon Tyne, Newcastle upon Tyne NE1 3BZ, United Kingdom

TIMOTHY H. J. GOODSHIP
Institute of Human Genetics, International Centre for Life, University of Newcastle upon Tyne, Central Parkway, Newcastle upon Tyne NE1 3BZ, United Kingdom

PETER D. GOREVIC
Division of Rheumatology, The Mount Sinai Medical Center, Annenberg Building, Room 5-207M, Box 1244, 1425 Madison Ave., New York, NY 10029-6574

JAN GRATAMA
Dept. of Medical Oncology, Erasmus MC - Daniel den Hoed Cancer Center, Rotterdam, The Netherlands

ALLEN GROLLA
Special Pathogens Program, National Microbiology Laboratory, Public Health Agency of Canada, Winnipeg, Manitoba, Canada

PAULETTE HAHN
Division of Rheumatology & Clinical Immunology, University of Florida, P.O. Box 100221, Gainesville, FL 32610-0221

SCOTT A. HALPERIN
Dept. of Pediatrics and Dept. of Microbiology & Immunology, Dalhousie University and the IWK Health Centre, 5850/5980 University Ave., Halifax, Nova Scotia, Canada B3K 6R8

ROBERT G. HAMILTON
Johns Hopkins University School of Medicine, Johns Hopkins Asthma & Allergy Center, DACI Reference Laboratory, 5501 Hopkins Bayview Circle/Room 1A20, Baltimore, MD 21224-6801

RONALD J. HARBECK
Dept. of Medicine and Immunology, Clinical Laboratories, National Jewish Medical and Research Center, 1400 Jackson St., Denver, CO 80206

CHOLI HARTONO
Division of Nephrology, Dept. of Medicine, Weill Medical College of Cornell University, and Dept. of Transplantation Medicine and Extracorporeal Therapy, New York-Presbyterian Hospital, New York, NY 10021

KARIM E. HECHEMY
Division of Infectious Disease, Wadsworth Center, New York State Dept. of Health, 120 New Scotland Ave., Albany, NY 12208

RICHARD L. HENGEL
Infectious Disease Solutions, 35 Collier Rd., Suite M245, Atlanta, GA 30309

PAUL G. HEYWORTH
Schering-Plough Biopharma, 901 California Ave., Palo Alto, CA 94304-1104

JEANETTE HIGGINS
Clinical Services Program, NCI-Frederick, SAIC Frederick, Inc., P.O. Box B, Frederick, MD 21702-1201

HELENE C. HIGHBARGER
Clinical Services Program, NCI-Frederick, SAIC-Frederick, Inc., P.O. Box B, Frederick, MD 21702-1201

BRIAN HJELLE
Depts. of Pathology, Molecular Genetics & Microbiology, and Biology, University of New Mexico School of Medicine, MSCO8 4640, 1 University of New Mexico, Albuquerque, NM 87131

RICHARD L. HODINKA
Dept. of Pediatrics and Dept. of Pathology, Clinical Virology Laboratory, Children's Hospital of Philadelphia, and University of Pennsylvania School of Medicine, Abramson Research Center, Rm 716D, 3615 Civic Center Blvd., Philadelphia, PA 19104-4399

ALEX R. HOFFMASTER
Meningitis and Special Pathogens Branch, National Center for Infectious Diseases, Centers for Disease Control and Prevention, 1600 Clifton Rd., MS G34, Atlanta, GA 30333

AKI HOJI
Dept. of Infectious Diseases and Microbiology, University of Pittsburgh Graduate School of Public Health, Pittsburgh, PA 15261

STEVEN M. HOLLAND
Laboratory of Clinical Infectious Diseases, National Institute of Allergy and Infectious Diseases, National Institutes of Health, Bldg. 10, CRC B3-4141, MSC 1684, 10 Center Dr., Bethesda, MD 20892-1684

JOHN J. HOOKS
Immunology & Virology Section, Laboratory of Immunology, National Eye Institute, National Institutes of Health, Bldg. 10, Room 10N248, Bethesda, MD 20892

D. CRAIG HOOPER
Center for Neurovirology, Dept. of Microbiology and Immunology, Thomas Jefferson University, 1020 Locust St., Room 454, Philadelphia, PA 19107-6799

GLEN L. HORTIN
Dept. of Laboratory Medicine, Warren G. Magnusson Clinical Center, National Institutes of Health, 10 Center Dr., MSC 1508, Bethesda, MD 20892-1508

JULIE A. HOUP
Immunogenetics Laboratory, Dept. of Medicine, Johns Hopkins University School of Medicine, 2041 E. Monument St., Baltimore, MD 21205-2222

C. ALAN HOWARD
National Marrow Donor Program, Minneapolis, MN 55413

ERIC D. HSI
Depts. of Anatomic and Clinical Pathology, Cleveland Clinic Foundation, L-11, 9500 Euclid Ave., Cleveland, OH 44195

PATRICIA A. HUGHES
Dept. of Pediatrics, Section of Infectious Disease, Albany Medical Center, Room A-615, MC 88, 47 New Scotland Ave., Albany, NY 12208

RICHARD G. HUGHES
The Binding Site Ltd., P.O. Box 11712, Birmingham B14 4ZB, United Kingdom

LANCE HULTIN
Dept. of Medicine, Cellular Immunology and Cytometry, University of California, Los Angeles, 12-236 Factor Bldg., 10833 Le Conte Ave., Los Angeles, CA 90095-1745

PATRICIA HULTIN
Dept. of Medicine, Cellular Immunology and Cytometry, University of California, Los Angeles, 12-236 Factor Bldg., 10833 Le Conte Ave., Los Angeles, CA 90095-1745

RICHARD L. HUMPHREY
Johns Hopkins Hospital, Meyer B121C, 600 N. Wolfe St., Baltimore, MD 21287-7021

CAROLYN KATOVICH HURLEY
CW Bill Young Marrow Donor Recruitment and Research Program and Dept. of Oncology, Georgetown University Medical Center, E404 Research Bldg., 3970 Reservoir Rd., NW, Washington, DC 20057

HIROMI IMAMICHI
Clinical Services Program, NCI-Frederick, SAIC-Frederick, Inc., P.O. Box B, Frederick, MD 21702-1201

TOMOZUMI IMAMICHI
Clinical Services Program, NCI-Frederick, SAIC-Frederick, Inc., P.O. Box B, Frederick, MD 21702-1201

ELAINE S. JAFFE
Hematopathology Section, Laboratory of Pathology, National Cancer Institute, 10 Center Dr., Bldg. 10, Room 2N110, MSC-1500, Bethesda, MD 20892-1500

PETER B. JAHRLING
U.S. Army Medical Research Institute of Infectious Diseases, Fort Detrick, Frederick, MD 21702

HAL B. JENSON
Baystate Health and Tufts University School of Medicine, Western Campus, Springfield, MA 01199

BARBARA J. B. JOHNSON
Div. of Vector-Borne Infectious Diseases, National Center for Infectious Diseases, Centers for Disease Control and Prevention, Fort Collins, CO 80522

ANDRÉ A. KAJDACSY-BALLA
Dept. of Pathology, University of Illinois Medical Center at Chicago, 1819 West Polk St., Room 446, Chicago, IL 60612-7335

EDWARD KAPLAN
Dept. of Pediatrics, University of Minnesota Medical School, World Health Organization Collaborating Center for Reference and Research on Streptococci, 420 Delaware St., S.E., Minneapolis, MN 55455

KEVIN L. KAREM
Poxvirus Program, Division of Viral and Rickettsial Diseases, Centers for Disease Control and Prevention, 1600 Clifton Rd., Mail Stop G-43, Atlanta, GA 30333

A. R. KARIM
Dept. of Neuroimmunology, The Medical School, Edgbaston, Birmingham, United Kingdom

JACQUELINE M. KATZ
Influenza Branch, Division of Viral and Rickettsial Diseases, National Center for Infectious Diseases, Centers for Disease Control and Prevention, 1600 Clifton Rd., Mail Stop G16, Atlanta, GA 30333

JERRY A. KATZMANN
Protein Immunology Laboratory, Mayo Clinic College
of Medicine, 210F Hilton Bldg., 200 First St. SW, Rochester,
MN 55905

MICHAEL KEENEY
The London Health Sciences Centre, London, Ontario N6A
4G5, Canada

DAVID F. KEREN
Warde Medical Laboratory, 300 West Textile Rd., Ann Arbor,
MI 48108-9548

THOMAS S. KICKLER
Dept. of Pathology, Johns Hopkins University School of
Medicine, Weinberg Bldg. Room 2337, 600 N. Wolfe St.,
Baltimore, MD 21205

THOMAS J. KIPPS
Dept. of Medicine, Division of Hematology/Oncology, Moores
Cancer Center, University of California-San Diego School of
Medicine, 9500 Gilman Dr., La Jolla, CA 94093-0663

ALEXANDER I. KLIMOV
Influenza Branch, Division of Viral and Rickettsial Diseases,
National Center for Infectious Diseases, Centers for Disease
Control and Prevention, 1600 Clifton Rd., Mail Stop G16,
Atlanta, GA 30333

AMY D. KLION
Laboratory of Parasitic Diseases, Bldg. 4, Room 126, National
Institute of Allergy and Infectious Diseases, National Institutes
of Health, 4 Center Dr., Bethesda, MD 20892-0425

MEGHAVI KOSBOTH
Division of Rheumatology & Clinical Immunology, University
of Florida, P.O. Box 100221, Gainesville, FL 32610-0221

PAUL KROGSTAD
David Geffen School of Medicine at UCLA, Dept. of
Pediatrics and Dept. of Molecular and Medical Pharmacology,
University of California, Los Angeles, 10833 Le Conte Ave.,
Room 22-442 MDCC, Los Angeles, CA 90095

NIELS KRUSE
Institute for Multiple Sclerosis Research, Medical Faculty,
University of Göttingen, and Gemeinnützige Hertie-Stiftung,
Waldweg 33, D 37073 Göttingen, Germany

JIACHUN X. KUNG
Dept. of Clinical Pathology, Cleveland Clinic Foundation
L-11, 9500 Euclid Ave., Cleveland, OH 44195

CHO-CHOU KUO
Dept. of Pathobiology, Box 357238, Room F-161A, Health
Sciences Bldg., 1959 N.E. Pacific St., University of
Washington, Seattle, WA 98195

ROBERT A. KYLE
Mayo Clinic College of Medicine, 628 Stabile Bldg., 200 First
St. SW, Rochester, MN 55905

ROBERT S. LANCIOTTI
Arboviral Diseases Branch, Division of Vector-Borne
Infectious Diseases, National Center for Infectious Diseases,
Centers for Disease Control and Prevention, P.O. Box 2087,
Fort Collins, CO 80522-2087

MARIE LOUISE LANDRY
Dept. of Laboratory Medicine, Yale University School of
Medicine, P.O. Box 208035, New Haven, CT 06520-8035

ANA M. LAZARO
CW Bill Young Marrow Donor Recruitment and Research
Program and Dept. of Oncology, Georgetown University
Medical Center, E404 Research Bldg., 3970 Reservoir Rd.,
NW, Washington, DC 20057

HOWARD M. LEDERMAN
Division of Pediatric Allergy & Immunology, Johns Hopkins
Hospital - CMSC 1102, 600 N. Wolfe St., Baltimore,
MD 21287-3923

MARY S. LEFFELL
Immunogenetics Laboratory, Dept. of Medicine, School of
Medicine, Johns Hopkins University, 2041 E. Monument St.,
Baltimore, MD 21205

DIANE S. LELAND
Dept. of Pathology and Laboratory Medicine, Indiana
University School of Medicine, Riley Hospital, Room 0969,
702 Barnhill Dr., Indianapolis, IN 46202

RICHARD A. LEMPICKI
Clinical Services Program, NCI-Frederick, SAIC Frederick,
Inc., P.O. Box B, Frederick, MD 21702-1201

MARTHA L. LEPOW
Dept. of Pediatrics, Section of Infectious Disease, Albany
Medical Center, Room A-615, MC 88, 47 New Scotland Ave.,
Albany, NY 12208

PATRICK S. C. LEUNG
Division of Rheumatology/Allergy and Clinical Immunology,
School of Medicine, University of California at Davis, Davis,
CA 95616

PAUL N. LEVETT
Provincial Laboratory, Saskatchewan Health, 3200 Albert
St., Regina, Saskatchewan, Canada S4S 5W6

MYRON M. LEVINE
Center for Vaccine Development, Dept. of Medicine and Dept.
of Pediatrics, University of Maryland School of Medicine, 685
W. Baltimore St., Rm 480, Baltimore, MD 21201

MARK D. LINDSLEY
Mycotic Diseases Branch, Division of Bacterial and Mycotic
Diseases, National Center for Infectious Diseases, Centers for
Disease Control and Prevention, 1600 Clifton Rd., N.E.,
Mailstop G-11, Atlanta, GA 30333

STEPHEN E. LINDSTROM
Influenza Branch, Division of Viral and Rickettsial Diseases,
National Center for Infectious Diseases, Centers for Disease
Control and Prevention, 1600 Clifton Rd., Mail Stop G16,
Atlanta, GA 30333

LANCE A. LIOTTA
Center for Applied Proteomics and Molecular Medicine,
George Mason University, Manassas, VA 20110

VLADIMIR N. LOPAREV
Centers for Disease Control and Prevention, 1600 Clifton Rd.,
MS G-18, Atlanta, GA 30333

ROBIN G. LORENZ
University of Alabama at Birmingham, Birmingham,
AL 35294

THOMAS P. LOUGHRAN
Penn State Cancer Institute, Pennsylvania State University
College of Medicine, Hershey, PA 17033

MARK LOWENTHAL
Laboratory of Pathology, Center for Cancer Research, National Cancer Institute, and FDA-NCI Clinical Proteomics Program, Bethesda, MD 20892

JULIA LUBORSKY
Endocrine Immunology, Dept. of Pharmacology and Dept. of Obstetrics and Gynecology, Rush University Medical Center, Chicago, IL 60612

DONNA P. LUCAS
Immunogenetics Laboratory, Dept. of Medicine, Johns Hopkins University School of Medicine, 2041 E. Monument St., Baltimore, MD 21205-2222

ANDREW D. LUSTER
Center for Immunology and Inflammatory Diseases, Division of Rheumatology, Allergy and Immunology, Massachusetts General Hospital, CNY 8301, 149 13th St., Charlestown, MA 02129

ROBERT LYONS
Division of Rheumatology and Clinical Immunology, Dept. of Medicine, University of Florida, P.O. Box 100221, 1600 S.W. Archer Rd., ARB R3-110, Gainesville, FL 32610-0221

KEVIN MACALUSO
Dept. of Pathobiological Sciences, School of Veterinary Medicine, Louisiana State University, Skip Berman Dr. #3213, Baton Rouge, LA 70803

HOLDEN T. MAECKER
BD Biosciences Immunocytometry Systems, 2350 Qume Dr., San Jose, CA 95131

FABRIZIO MAGGI
Dept. of Experimental Pathology and Retrovirus Center, University of Pisa, 37, Via San Zeno, I-56127 Pisa, Italy

JAMES B. MAHONY
Dept. of Pathology and Molecular Medicine, McMaster University, and the Regional Virology & Chlamydiology Laboratory, St. Joseph's Hospital, 50 Charlton Ave. E., Hamilton, Ontario L8N 4A6, Canada

VERNON C. MAINO
BD Biosciences Immunocytometry Systems, 2350 Qume Dr., San Jose, CA 95131

EUGENE O. MAJOR
Molecular Medicine and Virology Section, Laboratory of Molecular Medicine and Neuroscience, National Institute of Neurological Disorders and Stroke, Bldg 36, Room 5W21, 36 Convent Dr., MSC 4164, Bethesda, MD 20892-4164

MICHAEL P. MANNS
Dept. of Gastroenterology and Hepatology, Zentrum Innere Medizin, Medizinische Hochschule Hannover, Hannover, Germany

SUZANNE M. MATSUI
Gastroenterology Section (111-GI), VA Palo Alto Health Care System, 3801 Miranda Ave., Palo Alto, CA 94304, and Division of Gastroenterology and Hepatology, Stanford University School of Medicine, 300 Pasteur Dr., Stanford, CA 94305-5187

THOMAS W. McCLOSKEY
The Institute for Medical Research, North Shore University Hospital / New York University School of Medicine, 350 Community Dr., Manhasset, NY 11030

THERON McCORMICK
Baylor College of Medicine and Pediatric Allergy and Immunology Service, Texas Children's Hospital, 6621 Fannin St., FC330.01, Houston, TX 77030-2399

BENJAMIN D. MEDOFF
Center for Immunology and Inflammatory Diseases, Division of Rheumatology, Allergy and Immunology, and Pulmonary and Critical Care Unit, Massachusetts General Hospital, Harvard Medical School, Boston, MA 02114

JULIA A. METCALF
Office of Clinical Research, National Institute of Allergy and Infectious Diseases, National Institutes of Health, Bethesda, MD 20892

STEPHEN A. MIGUELES
Laboratory of Immunoregulation, National Institute of Allergy and Infectious Diseases, National Institutes of Health, Bethesda, MD 20892

CHRISTINE J. MORRISON
Mycotic Diseases Branch, Division of Bacterial and Mycotic Diseases, National Center for Infectious Diseases, Centers for Disease Control and Prevention, 1600 Clifton Rd., N.E., Mailstop G-11, Atlanta, GA 30333

MOON H. NAHM
University of Alabama at Birmingham, 845 19th St. South (BBRB-614), Birmingham, AL 35294

STANLEY J. NAIDES

Preface

Over the past several decades, dramatic progress has taken place in the field of immunology. As a consequence, significant advances have been realized not only in the research realm but also in the diagnostic and clinical arena.

Clinical immunology, a dynamic and ever-evolving discipline, has witnessed remarkable advances. Exciting discoveries in molecular biology, recombinant DNA and proteins, cytokine biology, and human genetics have enhanced our understanding of immune-mediated diseases and have led the way for novel therapeutics for many immunologic disorders. With these advances, clinical immunology has matured and its applications have increased extensively. Furthermore, the scope of clinical immunology, which extends to a wide and diverse group of human diseases, has become integrated into nearly every medical specialty. This widespread feature of clinical immunology may be seen in, but not limited to, disciplines such as hematology, transplantation, rheumatology, oncology, dermatology, infectious disease, allergy, and neurology. Thus, it is the clinical laboratory immunologist who serves as the interface for communication among these various disciplines, while providing leadership and knowledge for the best laboratory approaches to evaluate patients with immune-mediated diseases.

Given their strategic position in the hospital setting, it is imperative that clinical and diagnostic immunology laboratories have a blueprint to follow with regard to sound and appropriate laboratory procedures. As the field of immunology continues to explode with new discoveries and applications, the laboratory director is the key person who can harness basic immunologic research findings and translate them into useful and reliable laboratory applications. Furthermore, the immunology laboratory director serves as a consultant to the clinician regarding the interpretation of laboratory testing and as the facilitator for the exchange of basic and new concepts in immunology.

This Manual has traditionally served to assist and guide the laboratory director in immunology. For six editions, the *Manual of Clinical Laboratory Immunology* has fulfilled this mission under the excellent guidance of Noel R. Rose, editor-in-chief. In fact, for nearly 30 years, this Manual has served as the primary reference manual for clinical immunology laboratories around the world, providing up-to-date methodologies for diagnosis and monitoring of immune-mediated disorders. We now offer the 7th edition of the Manual, with the goal of following the renowned reputation of the past six editions. The 7th edition continues to provide a concise review of the basic principles underlying each procedure, detailed descriptions of the methodology, and special focus on interpretation of the laboratory findings.

In an effort to capture the exciting new dimensions in the field of immunology and to reflect the continuous evolution of clinical immunology, significant changes have been introduced into this edition. First, the name of the Manual has been modified. The new title, *Manual of Molecular and Clinical Laboratory Immunology*, reflects the tremendous impact of molecular biology on the discipline. Molecular immunology has emerged as a significant development in the field, and numerous applications are quickly moving into the clinical and diagnostic laboratories. The first section of the book delineates the varied and timely molecular applications that the immunology laboratory will be implementing in the laboratory environment. The chapter on general methods introduces this new information and the theme is continued in several other sections throughout the book.

Second, each chapter in the Manual has been substantially revised and updated to present the most current information on that topic. Just as in the previous editions, experts once again have contributed to the various chapters and included important additions to provide the most contemporary procedures. Moreover, the Manual features not only timely and current long-standing laboratory procedures but also several chapters dedicated to cutting-edge topics that may shortly be implemented in the clinical immunology laboratory. Some of these ground-breaking areas can be seen in the sections pertaining to transplantation, monitoring of cytokines and chemokines, multiple applications of flow cytometry, allergic diseases, and cancer.

Noel Rose's insightful goal for this Manual was that it must not only serve the needs of today's clinical immunology laboratory but also look to the future, where even more dramatic progress in diagnosis and treatment can be anticipated. I share that vision with him and hope that this edition will follow in that outstanding tradition.

The publication of this Manual is the joint effort of many dedicated individuals. I wish to acknowledge the tremendous support and outstanding commitment of our volume editors, section editors, and chapter authors, who as experts in their areas have contributed their extraordinary experience,

energy, and generous time to the success of this edition. In addition, I wish to express special appreciation to the editorial and production staff at ASM Press for their excellent work. In particular, I would like to thank Ellie Tupper, our senior editor, for her guidance, patience, nudging, and incredible support through the many phases of this production.

I would also like to acknowledge the valuable assistance of Jeff J. Holtmeier, Director, ASM Press, and the creative endeavors of Jennifer Adelman, Marketing Director.

BARBARA DETRICK, PH.D.

Proteomics and Genomics Methodology in the Clinical Immunology Laboratory

THOMAS A. FLEISHER

1

Major advances in proteomics and genomics have occurred since the last edition of this book, and these are further impacting the field of diagnostic and clinical immunology. The completion of the Human Genome Project has fueled the field of genomics and provided the critical database from which to expand genomic studies. This has been complemented by recognition that proteins, the products of the genome, are highly evolved and varied to carry out the work of the cell. A vast array of proteins provide a wide range of functional elements in the immune system. Expanded evaluation of these critical products should provide new insights into the biology of the immune system and pathology of immunologic disorders. The future will depend on linking genomic and proteomic studies as partners in understanding the immune response and characterizing the underlying basis of immunologic diseases.

The laboratory methods available to evaluate proteins and nucleic acids form the substance of the following four chapters. These are developed in the setting of a recognition that our current approaches leave the vast majority of the world of human proteins untouched and the reality that specific and reliable biomarkers of human disease remain an unfulfilled promise. In light of this, new strategies to expand the range of evaluating the proteome are introduced by Remaley and Hortin in chapters 2 and 3 that include multiplex immunoassays, two-dimensional gel electrophoresis, and mass spectrometry. It is likely that these and additional technologies will provide the means to measure new markers for early specific disease detection and monitoring the effectiveness of therapy. Parallel developments in the field of genomics also impact on the field of diagnostic and clinical immunology. In chapter 5 by Podzorski, a general survey is provided of methods available in the field of molecular biology. Many of these techniques have already found their way into the diagnostic laboratory, and it is likely that this trend will continue at an even faster pace. In chapter 4, by Chanock, the emerging technology of microarray analysis is summarized, an approach that has already resulted in an approved assay system for clinical laboratory use.

The information garnered by the expanding range of analytes and technologies available to evaluate the proteome and genome is fueling a new vision of scientific discovery referred to as systems biology (1). This integrated proteomic and genomic approach should afford far better understanding of the perturbations that lead to human disease. Furthermore, such a multiparametric approach applied in the evaluation of a patient should allow for the identification of disease-specific therapies and the real possibility of strategies that will ultimately prevent disease.

Introduction to Protein Analysis

GLEN L. HORTIN AND ALAN T. REMALEY

2

PROTEIN DIVERSITY AND ITS DIAGNOSTIC SIGNIFICANCE

Proteome Complexity

The complete set of human proteins in an individual, what was first termed the proteome by Wilkins in 1994, represents even greater complexity than the genome. In the stepwise flow of genetic information from approximately 25,000 genes comprising the human genome (7) to mRNAs to proteins, there is likely to be a progressive increase in complexity (Fig. 1). Alternative splicing of RNA leads to the possibility of producing several mRNAs from each gene.

There are multiple sources of variation in individual proteins and in the proteome, as outlined in Table 1. Posttranslational modifications of the primary translation products of mRNAs potentially lead to large numbers of structural variants of individual gene products. A total of more than 200 types of posttranslational modifications have been described (11, 12), including biosynthetic modifications such as glycosylation, phosphorylation, acetylation, sulfation, proteolysis, and chemical modification by reactants in the environment such as sugars, aldehydes, reactive oxygen species, and free radicals. Thus, the complete human proteome derived from typical somatic cells is likely to contain more than 1,000,000 different structures, although current technologies are able to detect only a small subset of the expected protein diversity (1–3, 9).

As proteins undergo extracellular and intracellular degradation, a complex array of peptides is generated, quite possibly even more complex than the original set of proteins. Analysis of ultrafiltrates of plasma has identified thousands of peptides (10), which are likely a small sampling of the total. Currently, there is little understanding of the complete range of peptides generated, the peptidome, although some subsets of the peptidome, such as the diverse range of peptides generated for antigen presentation on histocompatibility antigens, have been investigated and are recognized to have a critical role in directing immune responses (4, 5). Peptide splicing has recently been identified as another mechanism that may increase peptide diversity (6).

Somatic recombination and mutation of selected genes in immune cells, such as those encoding immunoglobulins, add further to the genetic and polypeptide complexity (8). Different cells within an individual encode millions of variants of immunoglobulin genes, which are expressed as even larger numbers of variant mRNAs and proteins. In practice, the complex mixtures of proteins comprising immunoglobulins usually are analyzed as a class, such as immunoglobulin G. The exception is in cases of multiple myeloma, where there is massive expansion of a clonal line expressing a single defined polypeptide sequence. Subsets of immunoglobulin molecules often are defined for diagnostic purposes by their antigen-binding specificity, although these sets generally also consist of a complex mixture of variant protein structures with subtle variations in binding specificity.

Bacteria, viruses, fungi, dietary components, therapeutic agents, and other environmental exposures contribute a diverse range of other potential protein and peptide components that may occur within the body. These components represent important immunogens, allergens, toxins, therapeutic agents, and targets for diagnostic applications.

Challenges of Proteome Analysis

Analysis of the proteome is a supremely complex and difficult problem (1–3, 9). For reasons outlined in Table 1, analysis of the proteome is substantially more complicated than analysis of genetic variation. Genes are a relatively fixed linear combination of only four nucleotides. Proteins have a primary linear structure of 20 primary amino acids that may undergo multiple modifications and form branched or cross-linked structures joined by disulfides or other cross-links. The peptide chain folds into local secondary structures, such as alpha helices and beta sheets, and then, in many cases, into globular domains that comprise the tertiary structure. Multiple polypeptide chains may come together, forming the quaternary structure of proteins with multiple subunits, and there may be multiple associations with other inorganic ions, cofactors, and ligands. Many proteins participate in complex interaction networks or assemble further into supramolecular structures, such as organelles, membranes, ribosomes, and filaments. Analysis of protein interaction networks is a challenging aspect of proteome analysis. Furthermore, proteins are distributed into all cellular and extracellular compartments, whereas the genetic material is restricted to the nucleus. In order to understand many pathophysiological processes, such as prion diseases, amyloidosis, hemoglobinopathies, and apoptotic processes, simple primary sequence analysis of proteins

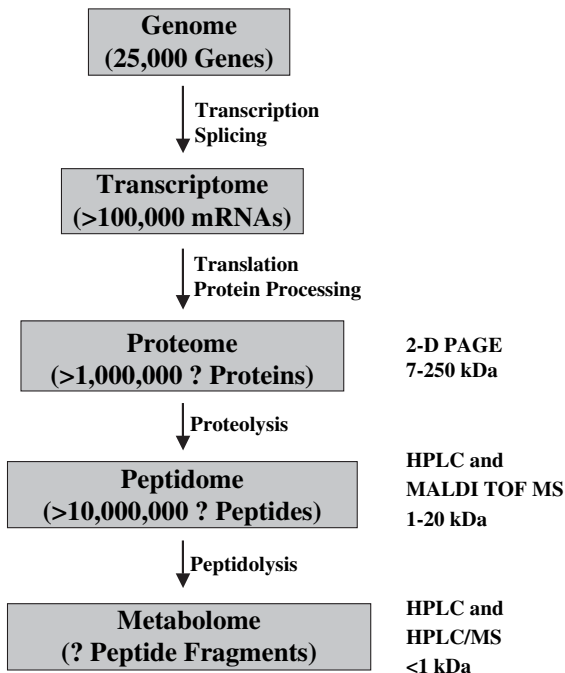
Increasing Complexity Through Steps in Expression of Genetic Information


FIGURE 1 Molecular diversity: increasing complexity through steps in expression of genetic information and common methods of analysis. 2-D PAGE, two-dimensional polyacrylamide gel electrophoresis; HPLC, high-performance liquid chromatography; MALDI TOF MS, matrix-assisted laser desorption ionization–time of flight mass spectrometry.

TABLE 1 Elements of protein diversity

Type of variation
Structural
Primary structure (amino acid sequence)
Genetic variation
RNA splicing variants
Biosynthetic modifications
Chemical modification by reactants
Secondary structure (helix and sheet formation)
Tertiary structure (folding into domains)
Quaternary structure (combination of subunits)
Formation of supramolecular structures (protein interactions): organelles, ribosomes, filaments, membranes, lipoproteins
Association with ligands: inorganic ions, cofactors, ligands
Quantitative
Changes in abundance over time
Localization
Distribution among subcellular, cellular, and tissue compartments

such as two-dimensional gel electrophoresis, have the capability of resolving only up to a few thousand components in a single analysis. Therefore, current analytical technologies permit analysis of only a small subset of the human proteome, usually only a survey of the most abundant components.

is inadequate. Often it is essential to identify not only the primary structural variation of proteins but also variation in their folding, aggregation, or abnormal localization within or outside of cells.

Two additional challenges to protein analysis that are nearly as great as structural diversity are (i) the dynamic nature of protein concentration and (ii) the wide range of protein concentrations. Unlike genes, which occur in most cells at a constant two copies per cell except during cell division, the concentrations of individual proteins change continually as an ongoing balance between synthesis and export or degradation. Since the proteome changes from moment to moment, the time of specimen collection is an important variable, and it is often necessary to perform repeated analysis to examine changing patterns of proteins during pathophysiological processes. Not only are concentrations of proteins undergoing constant change, but also the concentrations of proteins in blood vary over a huge range—from millimolar concentrations of albumin and hemoglobin down to concentrations far below any current methods for detection. Assuming that some proteins may present at concentrations as low as a few molecules per liter, the range of concentrations is more than 10^{20}-fold. Unlike the case for nucleic acids, there is no simple method for amplification of the concentration of proteins. Most methods for protein analysis have a practical analytical concentration range of only about 100- to 10,000-fold, and the highest-resolution separation methods for protein analysis,

Protein Analysis for Diagnostic Applications

ALAN T. REMALEY AND GLEN L. HORTIN

3

CLINICAL LABORATORY ANALYSIS OF COMPONENTS OF THE PROTEOME

In the context of the amazingly diverse and dynamic array of proteins in the human proteome, a relatively tiny set of proteins representing a few hundred gene products are analyzed for diagnostic purposes. This represents only about 2% of all gene products and leaves the huge realm of the other 98% of gene products remaining to be evaluated as potentially useful diagnostic markers. In most cases, current diagnostic analyses of proteins analyze a single gene product at a time and measure the sum total of many posttranslationally modified forms of an individual gene product. Until very recently, the arrays of hundreds of thousands of variant protein structures from posttranslational processing or of perhaps an even larger number of peptide fragments of proteins derived from degradation of proteins have been, for the most part, untapped universes for diagnostic analysis.

Recent refinements in methods for protein separations have led to methods for simultaneous analyses of hundreds of plasma proteins (1, 2, 12, 58). Applications of mass spectrometry to analysis of plasma peptide components over the last few years suggest that there are a large number of potential diagnostic markers among these components (10, 55, 64, 72). Mass spectrometric analyses of peptides are applicable to a variety of fluids and even to direct tissue analysis (9). Recent approaches for profiling hundreds of peptide components in a single analysis show promise for rapid discovery of potential new markers of disease and for direct diagnostic application (9, 10, 55, 64, 72). It appears that many peptide components circulate in blood bound to larger carrier proteins so that they are not cleared rapidly by filtration in the kidneys (48). Further description of analysis of proteins by two-dimensional electrophoresis and peptides by mass spectrometry are in the final section of this chapter, which describes research and potential future clinical laboratory methods.

PREANALYTICAL VARIABLES IN ANALYSIS OF PROTEINS

Approaches to Sampling of Proteins for Diagnostic Purposes

Considering that proteins are differentially distributed among cellular compartments, types of cells, tissues, and different body compartments, the sites and methods of sample collection are critical factors in what types of diagnostic information can be obtained. Potential types of diagnostic specimens are summarized in Table 1. Due to ease of access and analysis, biological fluids are the most common diagnostic specimens. Biological fluids often have both liquid and cellular components. Usually, different approaches are required for analysis of soluble components, e.g., by immunoassay, while analysis of proteins in cellular components requires either a solubilization step or methods for cellular analysis such as flow cytometry, immunohistochemistry, or tests of cellular function. Analysis of proteins in solution is useful for providing information about the concentration within a particular compartment, such as the blood circulation, and may allow analysis of structural variants of proteins. Analysis of proteins in cellular elements provides additional information about protein distribution and localization within cells and assists with classification of cells. Assays of cellular function, such as cellular adhesion, response to antigens, or metabolic responses to stimuli, simultaneously assess the function of many protein components along signaling and functional pathways. These may serve as useful screening methods to identify pathways with dysfunctional or deficient protein components.

Direct tissue sampling by biopsy provides additional information about the distribution and spatial organization of proteins within cells and about cellular abnormalities based on protein expression. Analysis of proteins in these types of specimens depends on immunohistochemistry or sampling of proteins from microdissection specimens or other extraction methods.

Functional and spatial analysis of proteins noninvasively in the intact body would offer the ideal analysis. Skin testing for allergens and a variety of other immunogens for many years has been applied as an approach for in vivo evaluation of specific protein-directed pathways (see section M of this book). A variety of endocrinological stimulation and challenge tests similarly quantitatively evaluate a number of complex protein responses in vivo. Recent progress in molecular imaging has yielded information about the function and distribution of specific proteins within the body (24, 60). These techniques offer the prospects of noninvasively evaluating the concentration and localization of specific proteins across the entire human body—or at least the compartments accessible to the molecular probes—rather than from a limited tissue or fluid sampling.

Variables in Specimen Collection and Processing

Many preanalytical variables can impact efforts to sample the diverse range of proteins for diagnostic purposes. Considering the highly dynamic nature of the concentration and distribution of proteins, timing of sampling can be a major variable in the analysis of circulating proteins. Some components undergo diurnal rhythms or respond to recent dietary intake. Physiological stresses such as exercise, psychological trauma, or physical pain can evoke complex physiological responses. For many diagnostic tests, efforts are made to collect specimens in a fasting state in order to minimize postprandial changes in components such as lipoproteins and to avoid turbidity of specimens from lipemia. Recent posture of the person undergoing sampling—recumbent, sitting, or standing—can introduce some redistribution of fluids within the body and changes in protein concentrations in the vascular compartment. Transfusions, intravenous fluids, and medications may directly or indirectly alter the composition and distribution of protein and cellular elements in the circulation. The tissue distribution and the number of circulating white blood cells and platelets may change acutely in response to a variety of stimuli, such as infection, medication, or thrombosis.

Timing of sampling in relation to ongoing disease or physiological processes can be critical. Collection of several specimens over a day is important for identifying a diagnostic pattern associated with acute injury such as myocardial infarction, whereas collection of specimens over several weeks may be required to assess a serological response to an infection.

Blood represents the most common specimen collected for protein analysis. Since blood circulates throughout the body and contacts diverse tissues, it provides a sampling of most proteins secreted by tissues or released by cellular death or injury throughout the body. Specimens usually are collected from peripheral veins, but occasionally, selected venous or arterial sampling is applied to identify local gradients of a protein such as renin or insulin to localize the site of production.

Blood commonly is fractionated into cellular and serum or plasma fractions for analysis. Cellular elements within the blood allow in situ analysis of protein components within a number of cell types, by techniques such as flow cytometry. For analysis of the components of the serum or plasma fraction, blood usually either is drawn into a collection tube and allowed to clot or is collected in syringes or tubes containing inhibitors of coagulation such as citrate, EDTA, or heparin. Following centrifugation, these procedures, respectively, yield serum or anticoagulated plasma. During the clotting process to form serum, a number of components, such as fibrinogen and clotting factors, are consumed or bound into the clot, decreasing the total protein content by about 5%. Additional peptide and protein components, such as activation peptides of coagulation factors and platelet proteins, are released into serum during clotting. Collection of blood in chelating agents such as EDTA avoids the activation of calcium-dependent proteases in the coagulation cascade and inhibits other proteases and peptidases that require metal cofactors. Use of chelating agents such as EDTA, together with rapid chilling and centrifugation of specimens, is necessary to achieve high recovery of some highly protease-sensitive proteins and peptides. Heparin serves as an alternative anticoagulant for plasma. Heparin acts by accelerating the inhibition of coagulation factors by endogenous inhibitors rather than by chelation of calcium. Plasma contains a diverse range of endo- and exopeptidases that can cleave polypeptides. Although chelating agents inhibit some of these, there is no collection procedure that will universally block protease activities.

Multiple factors in the collection process, as listed in Table 2, may affect the serum or plasma collected. The collection technique affects whether other tissue components are added from local tissue trauma and cells are ruptured by

high shear rates while flowing through collection needles. Any component contacting blood may activate clotting, adsorb selected components, or shed contaminating compounds into blood. Blood collection tubes are not simply inert containers for blood but have several constituents, including a surface coating to prevent binding of cells to tube walls, lubricants for stoppers, a reduced internal pressure to draw in blood, and, in some cases, polymeric gels to serve as a barrier between cells and serum after centrifugation (6). Either clot activators or inhibitors are added, depending on whether the device is for collection of serum or plasma. The materials of stoppers and tube walls are selected to serve as either a clot activator or an inert surface. Recent studies have found that polymeric components are released by many types of collection tubes (16) and that quantitative immunoassays in some cases can be affected unpredictably by components released from blood collection tubes (6).

Processing steps introduce additional variables. The time delay and temperature of the specimen before centrifugation influence the extent of clot formation, contraction, crosslinking, and fibrinolysis. Centrifugation time and speed influence the efficiency of separation of cells, particularly for plasma, where centrifugation speed and time affect the number of platelets remaining in specimens. The duration and conditions of storage of specimens waiting for analysis can affect the recovery of particular proteins and peptides. Freezing of specimens generally slows protein degradation, but cycles of freezing and thawing of proteins also can lead to denaturation, aggregation, and loss of function of some proteins. Selected plasma proteins may form a cryoprecipitate in samples that are frozen and thawed or stored under refrigeration, resulting in selective loss of components. Frozen specimens may require warming and extensive mixing to dissolve all components, and there may be some physical changes in components such as lipoprotein particles.

DIAGNOSTIC GOALS IN PROTEIN ANALYSIS

There are a variety of different types of diagnostic questions that are addressed by protein analysis. The simplest is the qualitative question of whether a protein serving as a physiological marker is present or absent in a particular specimen. The goal of such a test may be to identify previous exposure to or infection with an infectious agent, such as cytomegalovirus or human immunodeficiency virus, or to determine whether a woman is pregnant or to identify the presence of a specific autoantibody. These qualitative assays may be interpreted by visual inspection, and in most cases, there is little need for highly precise quantitative measurements due to the large difference between positive and negative responses.

A second qualitative question is whether there is structural variation of a protein. The diagnostic issue may be whether there is a genetic variant of a protein, change in isoenzyme distribution, or variation in posttranslational modification. Addressing these issues often requires physical separation techniques such as electrophoresis, chromatography, or mass spectrometry. Some examples of these types of analyses are analyses of genetic variants of hemoglobin and transthyretin, analysis of serum proteins by electrophoresis and immunofixation for detection of abundant monoclonal immunoglobulins rather than the usual polyclonal pattern, analysis of creatine kinase isoenzymes and isoforms as markers for myocardial infarction, analysis of glycoforms of transferrin as markers for alcohol abuse, and analysis of glycoforms of α-fetoprotein as markers for hepatic carcinoma.

More commonly, diagnostic analyses of proteins involve questions of quantitative analysis, e.g., how does the concentration of a protein component compare to a reference range or to previous values for the same patient? In these cases, reference ranges for the appropriate population and the precision of the quantitative measurements become significant issues in the interpretation of whether the values represent physiological abnormality or a change versus a previous value for the same subject. Measurements of changes for an individual patient rely on having specimens collected at the appropriate times, such as acute- and convalescent-phase specimens for serological analysis.

METHODS OF PROTEIN ANALYSIS

Functional Assays

Measurements of protein function can serve as a means to specifically measure the quantity of a single protein or of entire pathways, as in the example of complement activation assays (see section C of this book) or coagulation assays. In general, the methods for performing functional assays are relatively specific for the protein or pathway of interest.

Functional assays can serve as rapid screens for either quantitative deficiencies of a protein or functionally defective variants that may be present in normal quantities. The high specificity of many enzymes for particular substrates allows relatively simple and selective measurement of the activity of some proteins by monitoring of absorbance in reactions. Analysis of selected intracellular enzymes in serum offers a common diagnostic tool for detecting cellular injury and leakage of intracellular products from specific tissues. Activity of enzyme inhibitors, such as C1 inhibitor, can be measured indirectly through loss of activity of their target enzymes.

Binding assays represent the broadest range of functional assays for proteins in the clinical laboratory. These are used most often for identifying or quantifying subsets of immunoglobulins that recognize specific antigens. These types of assays, including serological assays, are covered below.

Immunoassay Methods

Immunoassays are among the most versatile and widely used methods for the analysis of proteins, peptides, and other molecules in the clinical laboratory. Qualitative immunoassays developed by Landsteiner and Witt for identifying red cell antigens and antibodies served as the foundation for practice of transfusion medicine (42). The first report of a quantitative immunoassay was over 70 years ago by Heidelberger and Kendall (27), who used antibodies to measure capsular polysaccharides from streptococci. Immunoassays began to be widely applied as quantitative methods following the development by Yalow and Berson of the radioimmunoassay (RIA) (79). Although myriad types of immunoassays have been developed over the years, each with their own advantages and disadvantages and sometimes cryptic acronyms, all immunoassays depend upon a few basic principles which are summarized here.

Antibodies as Immunoassay Reagents

A fundamental prerequisite for any immunoassay is to have a reagent that specifically recognizes and binds the analyte of interest. Antibodies, due to their high versatility and specificity in molecular recognition, are ideally suited as recognition elements in immunoassays. Antibodies offer high specificity and affinity, the most important features of the

recognition element, that often are sufficient to allow the measurement of low-abundance molecules in complex mixtures such as serum without any prior purification step. Other molecules, such as receptors, binding proteins, lectins, and oligonucleotide aptamers, occasionally have been substituted for antibodies as recognition elements in assays, but generally these alternatives offer more limited variation in binding specificity and lower binding affinity.

Immunoglobulins offer great diversity in binding specificities due to the millions of amino acid sequence permutations within their antigen binding domains (44). These variations result from recombination events during the differentiation of B lymphocytes between the various immunoglobulin gene segments and from somatic mutation that by clonal selection allows further affinity maturation.

Each plasma cell produces antibodies with a single antigen binding domain and, therefore, epitope specificity. During the immune response to large, complex antigens such as proteins, however, many different clones of plasma cells are stimulated to produce antibodies to different epitopes. Polyclonal antibodies from immunization of animals with a protein, therefore, represent a heterogeneous mixture of antibodies that react to many different epitopes on a protein antigen with widely different affinities. Antisera collected from animals or humans therefore represent very complex mixtures that change in antigen specificity, affinity, and titer from one batch to the next. Only a small proportion of the antibodies recognize the specific antigen of interest. To improve the specificity of antisera, adsorption procedures may be applied to remove unwanted antigen specificities or affinity purification may be applied to select antibodies with only the desired specificities.

Small molecules, such as peptides, often have low immunogenicity. Development of strong immune responses may require conjugation to an immunogenic carrier protein or chemical synthesis of peptides as branched, polyvalent structures. Development of peptide-specific antisera offers one approach for developing reagents of greater specificity for a particular segment of a protein.

Monoclonal antibodies, in contrast to polyclonal antibodies, are derived from a single plasma cell clone and, therefore, express a single antigen-binding specificity. Monoclonal antibodies are produced by fusing a single plasma cell, usually isolated from the spleen of an immunized mouse, with an immortalized B-cell myeloma cell line to produce an immortalized hybridoma cell line (40). A monoclonal antibody represents a single discrete reagent that should have a constant binding specificity for each batch of antibody produced. Monoclonal antibodies also allow the selection of an antibody directed against a single epitope; this potentially provides improved specificity of an immunoassay. Monoclonal antibodies have allowed a detailed analysis of the nature of epitopes in proteins (20, 71). Continuous sequence epitopes are defined by peptide sequences of about 3 to 7 residues in length. Conformational or discontinuous sequence epitopes depend on the folding and conformation of a protein. Some continuous epitopes may be inaccessible or masked in the native folded structure of proteins and may become accessible as the protein is unfolded or denatured, while at the same time, conformational epitopes may be lost. Some proteins may become denatured during purification, storage, freezing and thawing of solutions, or immobilization on surfaces; this introduces a complicating factor in selecting antibodies that will recognize the native protein. Screening assays for assessing antibody binding should use a form of the protein similar to that occurring in specimens.

Deciding on whether to use polyclonal or monoclonal antibodies depends on a variety of factors. Polyclonal antibodies often have overall higher affinity than individual monoclonal antibodies, and this may assist in assays of low-abundance components. Polyclonal antibodies are easier to produce, but they have substantial lot-to-lot variability. In immunoassay formats relying on aggregate formation such as radial immunodiffusion (RID), immunofixation, turbidimetry, and nephelometry, polyclonal antiserum promotes the formation of cross-linked aggregates more efficiently. Monoclonal antibodies may allow better targeting of molecular specificity. This may be advantageous where the goal is to bind only a specific molecular form of a protein, but it can be a disadvantage if the goal is to recognize the sum total of all molecular forms of a protein. Depending on the particular immunoassay application and format, either polyclonal or monoclonal antibodies or a combination of antibodies may be most favorable.

Antigen-Antibody Interaction

The interaction between an antigen and its antibody can be described by the following reaction and the equation related to it:

$$Ag + Ab \underset{K_d}{\overset{K_a}{\rightleftharpoons}} Ag - Ab$$
$$K_{eq} = K_a/K_d = (Ag - Ab)/(Ab)(Ag)$$

K_{eq}, which is the ratio of the association constant (K_a) over the dissociation constant (K_d), is called the equilibrium binding constant of the antigen (Ag)-antibody (Ab) reaction and provides an overall index of the strength of the interaction between an antigen and antibody. The equilibrium binding constant can be determined from the slope of a Scatchard plot, which is the plot of the ratio of the concentration of antibody-bound antigen to free antigen against the concentration of the antibody-bound antigen. Alternatively, application of new methods, such as surface plasmon resonance measurements, permits the continuous monitoring of antibody-antigen binding and dissociation reactions to determine the association constants (62).

The term "affinity" is formally used to refer to the binding constant for a single antigen binding domain, and the term "avidity" is used to describe the overall interaction of an antibody with its antigen, which takes into account the number of antigen binding sites, as well as the valency or number of epitopes on the antigen. For example, the avidity of immunoglobulin M (IgM) for antigens is much higher than the affinity of its individual antigen binding sites, because it forms pentamers and has a total of 10 binding sites per complex. The avidity of an antibody that is necessary for developing an immunoassay depends on the assay design and on the concentration of the antigen being measured. In general, the equilibrium binding constant for most antibodies used in immunoassays ranges between 10^8 and 10^{12} liters/mol.

Because antibodies are bivalent molecules, the molecular configuration of the antigen-antibody complex is dependent upon the molar ratio of antigen to antibody. The different types of antigen-antibody complexes that form can be broadly classified into three configurations based on the three zones of the immunoprecipitin curve (Fig. 1). When there is a vast molar excess of antibody to antigen, most of the antigen-antibody complexes will exist as a single antibody bound to a single antigen. Conversely, when there is much more antigen
FIGURE 1   Immunoprecipitin curve. At a fixed concentration of antibody, the type of antigen-antibody complex that forms is dependent upon the antigen concentration.

than antibody, the complexes that form will mostly be single antibodies that are fully saturated with two antigens. At the point of equivalence, which is usually at a molar ratio of antibody to antigen of approximately 2 to 3, large insoluble lattice-like complexes form between the antigen and antibody. This occurs because of the ability of polyclonal antibodies to bind to multiple epitopes on each protein molecule and then to form cross-linked structures bridged by antibody molecules with proteins bound at both antigen binding sites (Fig. 1). Monoclonal antibodies, because of their specificity for a single epitope, do not form large antigen-antibody complexes, unless the antigen is multivalent. The antigen-antibody complexes that form at the point of equivalence are as large as 100 nm in diameter and will increase the turbidity of a solution because of their ability to reflect light. In addition, these large immune complexes, when present in a semisolid support such as agarose gels, will self-aggregate and form visible precipitin lines. If a constant amount of antibody is used, the precipitation reactions will vary depending on the antigen concentration, and monitoring of the aggregation reaction, e.g., by turbidimetry, nephelometry, or RID, can provide a quantitative measure of antigen concentration.

Immunoassay Formats

A wide variety of different immunoassay formats have been described that vary in the formats for antigen binding and signal generation (23, 78). However, it is possible to classify the many immunoassay formats based on the immunoprecipitin curve into antigen excess, antibody excess, and antigen-antibody equivalence assays (Table 3). A further differentiation can be made between homogeneous assays, where all components are present and measurements are performed in a homogeneous mixture, and heterogeneous assays, which require physical separation of bound and free components before signal analysis is performed.

Antigen excess assays are competitive assays in which the antibody is in limiting amounts with respect to the concentration of the analyte. These types of assays are often used to measure small molecules, such as peptides, drugs, and steroid hormones, which exist in the micromolar to nanomolar concentration range. These types of assays can be further subdivided based on the type of signal detection system used

and whether the free analyte has to first be separated (heterogeneous) or not (homogeneous) from the antibody-bound analyte before signal measurement.

In antibody excess-type assays, the antibody is in molar excess relative to the concentration of the antigen. These are noncompetitive assays and usually involve the use of either one (one-site) or two different (two-site) antibodies for binding to the analyte. These assays are best suited for large antigens, such as proteins, with multiple epitopes. Antibody excess-type assays can achieve high sensitivity, with detection of low-abundance analytes in the picomolar to femtomolar concentration range.

By convention, antigen excess assays are usually named based on the signal detection system used followed by the word immunoassay, as in fluoroimmunoassay (FIA), which uses a fluorescent tag for detection. Antibody excess assays are in general termed immunometric assays, and the individual types of assays are identified by inserting the word for the signal detection system in the middle of the name. For example, the immunofluorometric assay is an immunometric assay that utilizes fluorescence for quantification. The enzyme-linked immunosorbent assay (ELISA) is a generic name for all enzyme-labeled assays that are performed on a microtiter plate and can be either an antibody excess or antigen excess assay. The surfaces of microtiter plates nonspecifically adsorb substances in a noncovalent-type interaction and are used as a solid support for binding either the antibody or antigen.

Antigen-Antibody Equivalence Assays

Antigen-antibody equivalence assays were the first type of immunoassays developed, because they do not require labeling of either the antigen or antibody or a sophisticated detection system. The antigen-antibody reaction can be interpreted visually by the formation of an aggregate or agglutination of particles such as red cells. For most of these assays to work, antigen and antibody need to be approximately at the equivalence point. If either is in large excess, a visible reaction may not occur.

Heterogeneous assay formats for antigen-antibody equivalence assays rely on a separation process to achieve the equivalence point between antigen and antibody. Gel diffusion-based assays use a transparent semisolid support, such as agar or agarose, as a diffusion medium for antibody and antigen. At the distance within the support where antigen and antibody achieve equivalence, a precipitin line is formed. There are many different variations of gel diffusion assays. One of the first to be developed and the simplest is the RID assay. In this method, a test solution containing the antigen is put in the well of a gel, and its corresponding antibody is incorporated into the gel matrix. As the antigen passively diffuses away from the well and into the gel, its concentration decreases progressively, and it forms a circular precipitin line at a distance from the well where it reaches the equivalence point with antibody in the gel. The greater the radius of the circular precipitin line, the greater the concentration of the antigen in the original test solution. Double-immunodiffusion-type assays involve the diffusion of both the antigen and antibody from separate wells in a gel in what are commonly termed Ouchterlony plates. This technique allows one to compare the antigen or antibody concentrations in two or more solutions and to test for cross-reactivity between samples.

The diffusion of antibody and or antigen in a gel can be accelerated by electroimmunoassay, in which electrophoresis drives the migration of an antigen from the sample well in one direction. The migrating antigen forms a rocket-shaped precipitin line with antibody in the gel, and the height of the rocket is related to the concentration of the antigen. Compared to other immunoassay formats, gel diffusion assays are relatively insensitive (0.1 μg/ml to 10 mg/ml), are only semiquantitative, and are also slow and cumbersome to perform. For these reasons, clinical use of these methods has declined.

Homogeneous forms of antigen-antibody equivalence assays are commonly performed as qualitative agglutination assays or as quantitative assays of aggregate formation. Agglutination assays also involve measurement of the antigen-antibody complex, but the size of the complex is enhanced by attaching either the antigen or antibody to a small particle, such as a latex bead or red blood cell. These assays can be used for measuring either antigen or antibody in a competitive or noncompetitive format. The testing for endogenous blood group antigens on red blood cells by this technique, termed the "direct hemagglutination test," is still widely used in blood banks. The attachment of antigen or antibody to a particle increases its valency, thus facilitating antigen-antibody complex formation, and the particles assist visualization of the immune complexes. The detection limits of these types of assays can be as low as 1 μg/ml. Latex agglutination tests have been used to develop simple screening tests on slides, such as for pregnancy testing (detection of urinary human chorionic gonadotropin [hCG]), although more sensitive and easier-to-use immunochromatographic lateral-flow tests (54) are replacing most agglutination tests.

Some agglutination tests have persisted, however, as screening tests for infectious agents and transfusion medicine.

Quantitative applications of antigen-antibody equivalence assays use instrumentation to measure the absorbance or light scattering of solutions during the antigen-antibody reaction by turbidimetry or nephelometry (8, 75). These tests depend upon the formation of large antigen-antibody immune complexes in the presence of a fixed concentration of excess antibody. The specimen is diluted to achieve an antigen concentration near the equivalence point with antibody. Measurement of either the rate or final endpoint change of light absorbance or scattering relates to the antigen concentration. Turbidimetry relies on spectrophotometric measurements of changes in absorbance during the antigen-antibody reaction. Nephelometry measures light scattered to the side by aggregates formed in the antigen-antibody reaction. Nephelometry generally measures a larger proportional change in signal than does turbidimetry, because the amount of scattered light at the start of a reaction is small unless the specimen is lipemic or contains particles. Therefore, nephelometry usually allows detection of lower antigen concentrations than does turbidimetry. Sample turbidity due to lipemia or other causes can serve as an interference with either type of assay.

The attachment of antibodies and antigens to particles, such as latex beads, and/or the addition of polymers, such as polyethylene glycol, promotes the formation of the immune complexes and can enhance the sensitivity of turbidimetry and nephelometry approximately 10- to 100-fold (8, 26, 27, 75). Attachment of small antigens, such as peptides or drugs, to particles also increases their size and valency to allow the application of these techniques for analysis of small molecules. Competitive assay formats, in which antigen in solution competes with particle-bound antigen for antibody binding and inhibits aggregation of particles, offer another variation in this technique (8).

Turbidimetric and nephelometric methods are readily automated because all components are in solution, no separation step is required, and simple photometric detection is used. Most automated turbidimetric and nephelometric assays perform checks for antigen excess to ensure that an acceptable ratio of antibody to antigen is achieved. Relatively abundant proteins that exist in serum or plasma in concentrations greater than 1 to 10 mg/liter, such as apolipoproteins, complement factors, fibrinogen, and immunoglobulins, are all commonly measured by clinical laboratories by automated nephelometric or turbidimetric analyzers. Turbidimetric assays are available on the routine test menus of many general chemistry analyzers.

Antigen Excess Assays

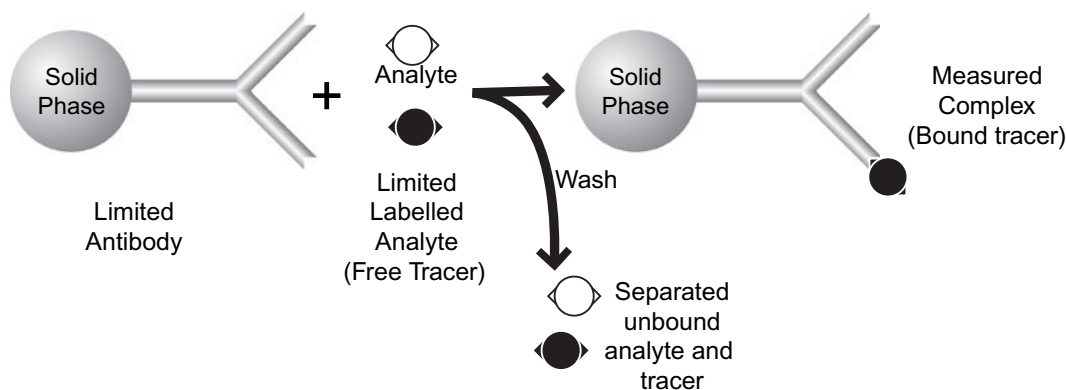
RIA (Fig. 2), as first described in the 1950s (79), is the prototypical antigen excess assay. Its development represented a major milestone in the history of quantitative immunoassays. RIA and other antigen excess assays usually are competitive assays (Fig. 2). A relatively small amount of radiolabeled antigen, the tracer, competes with unlabeled antigen in the specimen for a fixed and limited amount of antibody. The more antigen that is in the sample, the less tracer that is bound to the antibody. The amount of tracer bound to the antibody is measured after bound tracer is separated from the unbound tracer. Radioactive counts from the bound tracer are inversely related to the antigen concentration in the original sample. The detection limits of an RIA depend upon the avidity of its antibody for antigen and the specific activity of the radiolabeled tracer.


FIGURE 2 Diagram of an antigen excess-type assay using a solid support to immobilize the antibody.

Free and bound tracers have been separated by many different techniques, such as charcoal adsorption, gel filtration, polymer or salt precipitation, and secondary antibody precipitation. The most convenient and widely used separation method involves attaching the antibody or antigen to a solid support, such as beads or the reaction tube itself. The analyte bound to the antibody can then be separated from the unbound free analyte by a simple washing step (Fig. 2). Microparticles a few micrometers in diameter are often used as a solid support; their large surface area and small size promote rapid reaction. Superparamagnetic microparticles are used in many assay formats to allow retention of particles during washing steps.

As an alternative to the method shown in Fig. 2, one can also perform an RIA by radiolabeling the antibody and immobilizing a limited amount of antigen to the solid support. The more antigen in the test sample, the less radiolabeled antibody will be bound to the antigen immobilized to the solid support. The choice of RIA format depends in part on whether the antigen or antibody is more suitable for labeling.

Many types of radioisotopes have been used to label the tracer for RIAs, but ^{125}I and ^3H (tritium) have been the most frequently used isotopic labels. Whatever radioisotope or labeling procedure is used, it is critical to determine that the chemical modification during labeling does not significantly alter the antigen-antibody interaction. A standard curve or calibration curve is typically performed with each RIA run to control for decay of the tracer and other variables. A variety of mathematical approaches have been applied for mathematical fitting of calibration curves and calculation of results (19). Because the accuracy of the final result depends upon the accuracy of assigning concentrations to calibrators, their concentrations must be carefully established, and ideally, the calibrators should be in a matrix similar to the sample. For many routine diagnostic tests, calibrator concentrations are related to certified reference materials, which are available from various government and international organizations, such as the National Institute of Standards and Technology or the World Health Organization, and contain an assigned antigen concentration.

Nonisotopic labels have largely replaced radioisotopic labels for routine use in competitive assays in the clinical laboratory (23, 78). Nonisotopic labels are more amenable to automation, are more stable, and reduce safety concerns and regulatory requirements related to the use of radioisotopes. Use of fluorescent labels to develop FIAs offers a sensitive and versatile approach for labeling tracer molecules. High background signals from endogenous fluorescent compounds are one limiting factor in the sensitivity of common fluorescent dyes such as fluorescein. Organic chelates of the rare-earth lanthanide europium serve as improved fluorescent labels due to their relatively long fluorescent lifetime and a large Stokes' shift, the difference between the excitation and emission fluorescent wavelengths (28, 34). Use of time-resolved fluorescence measurements with europium labels provides a large enhancement of signal versus background fluorescence that has been employed for what has been termed dissociation-enhanced lanthanide fluorescence immunoassay (DELFIA), with substantial enhancement in the sensitivity of detection.

Chemiluminoimmunoassays are the chemiluminescent assay equivalent of an RIA. Chemiluminescent molecules emit light after activation in a chemical reaction, usually an oxidation reaction. Chemiluminescent labels usually offer greater sensitivity than fluorescent labels, because chemiluminescence uses no light excitation source that can produce scattered light and because background signal from specimens is very low. Chemiluminescent labels, such as isoluminol, and acridinium esters have been widely applied in automated immunoassays (23, 78).

In enzyme immunoassays (EIAs), the antibody or antigen is labeled by covalently coupling it with an enzyme, which generates a signal through the catalytic action of the enzyme. Enzymes can be directly conjugated to an antibody or antigen, using various chemical cross-linkers, or can be attached to a reagent, such as a secondary antibody or streptavidin, which recognizes the primary antibody modified by biotinylation (14). A wide variety of enzymes have been used as enzyme labels, but peroxidase and alkaline phosphatase are the most common because they are relatively stable, have a very high catalytic rate, and have readily available chromogenic substrates (23, 78). EIAs are quantified by measuring the activity of the enzyme with either a chromogenic, fluorogenic, or chemiluminescent substrate. Several enzyme cascade-type reactions have also been used to further amplify the signal (67). In these reactions, the product of the covalently attached enzyme is utilized by two or more coupled reactions that continuously recycle the original product, and with each cycle more signal is generated.

A number of homogeneous formats for antigen excess assays have been developed (Table 3). Elimination of a separation step makes these assays easier and more rapid to perform, but generally they have lower sensitivity than heterogeneous assays. Fluorescence polarization immunoassay

(FPIA) was one of the first homogeneous assays developed and became widely available in the Abbott TDx analyzer (11). FPIA depends on the change in rotational movement of a small fluorescence-labeled antigen when it binds to antibody. When the fluorescent label is excited with plane polarized light, the decreased rotational movement of the bound tracer results in a greater polarization of the emitted fluorescent light. FPIAs are competitive-type assays in which the antigen in the test sample competes with the fluorescently labeled antigen for binding to a limited amount of antibody. FPIAs have been developed for many different therapeutic drugs and other small molecules and are sensitive down to the micromolar to nanomolar concentration range.

Two other homogeneous competitive immunoassays that are also commonly used to measure small antigens, such as drugs, are the enzyme multiplied immunoassay technique (EMIT) (65) and the cloned enzyme donor immunoassay (CEDIA) (29). In EMIT assays, the target antigen is covalently attached to an enzyme and when an antibody specific to the drug binds to the drug-enzyme complex, the activity of the enzyme is decreased by steric blockade of the active site. Addition of antigen in a specimen competes for antibody binding and frees up labeled enzyme molecules to have increased enzyme activity.

In CEDIA, one of two recombinant fragments of beta-galactosidase is conjugated to the antigen being measured. The two enzyme fragments normally spontaneously assemble in solution to create an active enzyme complex. However, this assembly is prevented if the reagent antibody binds to the antigen-enzyme fragment. Antigen in the test sample competes for antibody binding and frees up the antigen-labeled fragment to form active enzyme. Important practical advantages of the EMIT and CEDIA are that they require simple absorbance measurements and no separation step.

Antibody Excess Assays

Antibody excess assays, unlike competitive RIAs, employ an excess of antibody or binding reagent in a noncompetitive assay format. Although not frequently considered classic immunoassays, immunoblotting, immunohistochemistry, direct immunofluorescence, and flow cytometry, which are used to detect antigens in gel membranes, tissue sections, cell lines, and cells in suspension, respectively, are simple reactions generally with excess antibody relative to antigen.

Immunoradiometric assays (IRMAs) (29, 50, 77) are the antibody excess assay equivalent of RIAs. Generally, IRMAs use an excess of two or more antibodies (23, 78) that recognize different epitopes on the analyte and are called two-site or sandwich-type assays (Fig. 3). Unlike in competitive assays, the signal from the assay is directly proportional to the concentration of the analyte. These assays are well-suited for large protein antigens that have multiple epitopes. Reliance on the binding of antibodies to two different epitopes helps improve the specificity of these assays. Frequently, at least one of the two antibodies is a monoclonal antibody to ensure that the two antibodies recognize different epitopes and do not compete with each other. The two antibodies can be incubated with the antigen simultaneously (one-step assay) or sequentially (two-step assay), with a wash step between the two antibody steps. Typically, one of the antibodies is attached to some type of solid support and is called the capture antibody, whereas the other antibody is labeled to generate the signal and is called the signal or detector antibody. The sandwich-type complex that is formed between the two antibodies and the antigen is then separated from excess free labeled antibody by a wash step before measurement of bound signal (Fig. 3).

Like for antigen excess assays, both isotopic and nonisotopic signal detection systems can be used in these types of assays, and the name of the signal detection system is usually incorporated into the assay name (Table 3). Two-site immunometric assays are typically more sensitive than competitive-type assays and can routinely detect analytes down to the femtomolar concentration range. These assays are also usually significantly faster than competitive-type assays, because the use of excess antibody increases the rate of the reaction between the antibody and antigen. Disadvantages of the immunometric assays are the requirement for the target antigen to be large enough to have two separate epitopes without steric hindrance of simultaneous antibody binding and use of larger amounts of antibody reagent. Use of excess labeled antibody also potentially increases the background from nonspecific binding, which often becomes the major factor limiting the sensitivity of these assays. Blocking proteins,
FIGURE 3 Diagram of a two-site antibody excess-type immunometric (labeled-antibody) assay.

such as albumin, and mild detergents are frequently added to the reaction buffer and wash solutions to reduce the background from nonspecific binding.

By reversing the assay format to use antigen as a capture reagent, many serological assays to detect antibodies with particular binding specificities can be performed in reagent excess formats. Describing these assay formats as antibody excess is somewhat of a misnomer in that excess antigen replaces antibody as the capture reagent, and it would be more accurate to term these assays as reagent excess rather than antibody excess. One example of this type of assay is the radioallergosorbent test, in which allergen-specific IgE antibodies are detected by incubating the sample with a solid support coated with an excess of a specific allergen (25). After a wash step, any bound IgE is then measured after detection with a labeled secondary antibody that is specific to human IgE. Antibodies to antigens of many infectious agents, such as hepatitis viruses, human immunodeficiency virus, and many other pathogens, can be assessed by measuring binding of selected classes of immunoglobulins to immobilized antigens of the pathogen.

Automation of Immunoassays

Except for turbidimetric and nephelometric tests, which were first automated in the late 1960s (63), automated analyzers for performing most immunoassays were relatively slow to evolve compared to other kinds of laboratory testing. The discovery of nonisotopic labels and homogeneous assays in the 1970s heralded the development of fully automated immunoassay analyzers in the early 1980s for drugs and other small molecules (11). The emergence of dedicated analyzers in the early 1990s that could use a solid support for separating bound and free analytes made it possible also to automate heterogeneous immunoassays for low-abundance proteins, such as peptide hormones. Currently, there are over two dozen different types of automated immunoassay analyzers (74), and like for the rest of the clinical laboratory, automation has greatly improved both the consistency and efficiency of immunoassay testing.

Automated assays are now available for almost all common diagnostic immunoassays and have largely replaced manual testing (4, 74). Manual RIA and ELISA are primarily limited to esoteric testing and research assays. Many automated immunoassay analyzers can perform over 50 different types of tests, with a throughput over 200 tests per hour. Manual immunoassays often take several hours to a day to perform; the antigen-antibody reaction is often allowed to approach equilibrium in order to maximize the signal and to reduce any variability from subtle differences in the timing of the various steps. In contrast, analysis time for most automated immunoassays is less than 1 h; these assays are performed under nonequilibrium conditions. This is possible because automated immunoassays use sensitive signal detection systems, such as fluorescence and chemiluminescence, that generate enough signal even with short reaction times, and automation enables very precise timing of all steps in assays. As a consequence, the intra-assay and interassay variabilities of automated immunoassays are also usually much better than for manual tests.

The menu for automated immunoassay analyzers has steadily increased and has now expanded to include a wide spectrum of tests, such as drug assays, protein hormones, steroids, tumor markers, and even serological tests, which in the past may have been done by different parts of the clinical laboratory. Automated immunoassays have, therefore, improved the efficiency of clinical laboratories by facilitating

consolidation. Currently, there is also great interest and effort in developing immunoassay analyzers that can be integrated with other automated systems, such as general chemistry analyzers, to allow even greater lab integration and efficiency from full laboratory automation.

Because of the wide variety of automated immunoassay analyzers that are currently available, it is sometimes difficult to identify the best instrument for any given laboratory (4). Besides the analytical quality of the lab tests that are available on any given analyzer, there are many other factors to consider when choosing the best immunoassay platform (Table 4). The characteristics of the laboratory and how any new analyzer will fit with the operation and goals of the laboratory must be considered.

Rapid, Point-of-Care Immunoassays

Small point-of-care devices represent one of the fastest-growing forms of immunoassay testing. These types of tests allow rapid pregnancy or ovulation testing in a home or clinic setting. The menu of tests that can be performed with simple point-of-care devices includes a wide variety of tests, such as assays for rapid detection of influenza virus or streptococcal antigens, serum markers for myocardial infarction or congestive heart failure, drugs of abuse in urine, and antibodies to human immunodeficiency virus.

Point-of-care devices rely on the same basic principles as other immunoassays, but the methods for physical separation of bound and unbound components and for signal generation differ somewhat from most other applications of immunoassay methods. Most of the current generation of point-of-care immunoassays employ single-use lateral-flow devices (7, 26). A specimen is applied to a membrane strip and the specimen flows along the strip by capillary action. An early zone of the membrane contains small colored particles derivatized with a specific antibody or antigen which interacts with the specimen. As the mixture of particles and specimen continues to flow along the membrane, they pass over a zone of immobilized antibody or antigen. If the specimen contains a large antigen, such as hCG, that is targeted in the assay, it forms a sandwich between antibody-coated particles and immobilized antibodies on the membrane. This creates a visible colored line on the membrane that can be detected visually or with a photometer. If no antigen is present, the particles are not retained by the immobilized antibody and they are swept away by continued flow of the specimen, which serves as a washing and separation step. The situation described represents a typical antibody excess reaction. Some lateral-flow assays, for example, for molecules (such as drugs of abuse) that are too small to serve as bridges in sandwich-type assays, represent competitive or antigen excess formats in which a positive result is represented by a decrease in binding of particles to the zone of recognition.

Visually interpreted assays are best suited for qualitative interpretations such as positive or negative results for pregnancy or influenza virus antigen detection. However, progressive miniaturization of photometers and other components of analyzers makes it possible to perform virtually any immunoassay method with a small portable analyzer. Analysis of parathyroid hormone (PTH) by portable analyzers in operating rooms serves as one example of the feasibility of performing virtually any quantitative assay with small portable analyzers (69).

Methods for Analyzing Structural Variation in Proteins

Clinical laboratories have applied a variety of electrophoretic, chromatographic, and other separation techniques to analysis of proteins. These techniques are useful for qualitative analysis of the size, charge, associations, and other physical properties of proteins that may not be distinguished by quantitative methods such as immunoassays or functional assays.

Fractionation by Precipitation or Flotation

Centrifugation represents one of the simplest methods for separating proteins into two or more fractions, usually a precipitate and a soluble fraction. Prior to centrifugation the specimen may be incubated in the cold to allow cryoprecipitate formation, or the composition of the specimen may be adjusted with additives to change ionic strength, pH, or other properties of the solution. These simple separations have been applied to a variety of clinical applications: analysis of cryoprecipitates, identification of antibody-bound versus free proteins, separating protein-bound from free components, separating various lipoproteins by density or differential precipitation, and preparative cell and subcellular fractionations. Because these techniques generally do not have an associated method for detection other than by visual inspection, these separation techniques commonly are used as preparative steps to generate a soluble precipitate fraction that is subjected to another analytical technique.

Electrophoretic Methods

There are a large number of different electrophoretic techniques based on variation in electrolyte composition, support or separation medium, and detection method. Separations are based on the differential migration of proteins in an electric field due to variation in protein charge or size. Clinical laboratory analyses of proteins in biological fluids such as serum, cerebrospinal fluid, and urine provide quantitative analysis of specific components and qualitative identification of unusual components, such as abundant monoclonal immunoglobulins. Tiselius originally described electrophoretic separations of proteins in open columns (70). Subsequently, many variations of this technique using different support and separation media, such as paper, nitrocellulose membranes, agarose gels, and polyacrylamide gels, were described (37), and recently electrophoresis in open columns has returned as a common clinical technique in the form of capillary electrophoresis (5). These low-resolution analyses separate components into prealbumin, albumin, and one or more α, β, and γ fractions. Protein stains such as amido black visualize the distribution of all protein components. In capillary electrophoresis, all proteins are detected without staining by measurement of absorbance in the UV region as proteins migrate through an absorbance detector. Other staining procedures such as immunofixation followed by staining, use of lipid stains, or addition of enzyme substrates allow selective detection of different components. Immunofixation analysis is commonly applied to evaluate monoclonal immunoglobulins.

Isoelectric focusing is an equilibrium method in which a pH gradient is formed by the electrolyte or support medium and proteins migrate until they reach their isoelectric point (pH at which the protein has no net charge). This method provides higher resolution than the typical methods for serum protein analysis, and it is applied in the clinical laboratory to achieve higher-resolution separations of immunoglobulins for evaluation of oligoclonal bands in cerebrospinal fluid. Isoelectric focusing also is commonly applied as a first-dimension separation in two-dimensional electrophoresis, which is discussed later in this chapter.

Electrophoretic separations based primarily on protein size can be performed by using gels with a gradient of decreasing pore size or by analysis of proteins in a denaturant, such as sodium dodecyl sulfate (SDS), that dissociates proteins into individual peptide chains. These techniques have been applied clinically to analysis of the size distribution of urinary proteins and lipoproteins (45, 47). The technique described by Laemmli (41) for SDS-polyacrylamide gel electrophoresis also has been applied frequently as a research tool due to its relatively high resolution and size-based separation of polypeptides.

Chromatographic Methods

Chromatographic methods allow the separation of proteins and peptides based on size, charge, or adsorption to a variety

of hydrophobic or affinity matrices. Size separation of proteins and peptides by gel filtration or size exclusion chromatography is best suited for separating molecules or complexes that have a relatively large difference in size (76). It has been applied to analysis of a variety of antibody-antigen complexes such as macroenzymes formed by binding of an enzyme to cognate autoantibodies or by binding of a small hormone, such as insulin, to a cognate autoantibody. Gel filtration allows rapid separation of bound and free antigens in these cases based on the much smaller size of the free antigen.

Ion-exchange chromatography allows separation of proteins and peptides primarily based on differences in net charge that result in differential binding to a solid phase bearing groups with an opposite charge. An example of an application in clinical laboratories is the analysis of glycated hemoglobin (21). This technique can be used as a preparative technique such as for the preparation of a partially purified immunoglobulin fraction from serum or as part of a multistep purification of virtually any protein or peptide.

Most peptides and proteins have some affinity for hydrophobic stationary phases such as octyl (C_8) or octadecyl (C_{18}) silica (32). Differential elution of peptides and proteins can be achieved using a gradient of progressively increasing hydrophobicity such as aqueous solution with an increasing concentration of acetonitrile. This technique of reverse-phase chromatography has been of greatest utility for separations of peptides. Separations of proteins generally are less efficient due to lesser variability in their absorption characteristics and denaturation of proteins in the organic solvents.

Many different types of adsorptive phases have been used for affinity chromatography (30). Immobilized antibodies provide a highly selective phase for rapid purification of selected antigen molecules that might be eluted for analysis of molecular variation by a technique such as mass spectrometry. Lectins, streptavidin, or a variety of other affinity matrices can be used for separations of classes of molecules interacting with the affinity matrix. Binding of glycated hemoglobin to phenylboronate groups has been applied by clinical laboratories to determine the fraction of hemoglobin occurring as a glycated form.

QUALITY ASSURANCE OF TESTING

General Quality Assurance Measures

The goal of quality assurance activities is to make sure that the complete testing process is performed reliably and reported in a manner most appropriate for clinical interpretation. Usually, the central components of a quality assurance program are considered to be quality control (QC) and proficiency testing (PT) programs. However, QC and PT serve as checks only for the analytical process, and there are many other critical steps in the testing process. Some other measures that generally are necessary to monitor and ensure proper performance of the testing process include thorough evaluation of new tests, identification of any test limitations or interferences, determination of reference ranges, development of procedures and appropriate materials for patient preparation and specimen collection and processing, development of information sources and ordering procedures that help direct accurate and appropriate ordering of tests, ensuring appropriate staff qualifications and training, programs for equipment maintenance, criteria for repeat testing in the case of questionable or critical results, monitoring of turnaround times, and review of information systems and reporting processes.

QC programs evaluate testing for repeated analysis of pooled material and are designed primarily to identify systematic changes in an analytical process, such as from deterioration of a reagent over time. Consistent values for QC materials determine that a test has stable performance but do not necessarily ensure that test results are accurate. Federal regulations in the United States mandate that at least two levels of QC material be analyzed daily for each test that is performed. For qualitative tests, these would be materials representing positive and negative specimens, and for quantitative tests, these should represent high and low results. QC materials should be selected to have values that ensure appropriate performance near important clinical decision values, so for some tests, more than two levels of QC material may be desirable. The stability of test systems needs to be evaluated to determine whether QC testing should be performed daily or at more frequent intervals. Some point-of-care devices have internal procedural controls that check on the performance of each test or have electronic simulators that may check performance of an analyzer. The degree to which these measures substitute for analysis of QC materials is controversial, and laboratories need to review the extent to which regulations allow these substitutions. Another alternative process for QC of procedures is to perform statistical evaluation of patient results. This may help detect gradual shifts in testing processes or changes in the preanalytical process such as changes in patient preparation, collection devices, or specimen processing that are not monitored by traditional QC.

PT compares the analysis of the same pooled specimens by different laboratories. PT serves as a measure of test accuracy and variation in performance between laboratories. Target values for a specific test may be established by statistical analysis of all participating laboratories or, for selected tests, by analysis of specimens by reference methods.

QC and PT serve as indicators of systematic changes in a testing process, but they are not effective measures for detecting sporadic errors due to problems such as specimen dilution with intravenous fluid, hemolysis of specimens, or specimen clots or bubbles which interfere with sampling. Checks of the specimen for potential interferences such as hemoglobin or lipemia and criteria for repeat analyses based on extreme values or changes from previous values (delta checks) may identify some specimen collection problems or sporadic errors.

Troubleshooting Immunoassay

Immunoassays have several limitations which are important to recognize, particularly when interpreting unexpected or discordant test results (39, 66). One important inherent limitation of immunoassays is that they sometimes lack sufficient specificity and either endogenous or exogenous substances can affect the accuracy of the result (51). For example, many protein hormones can exist in a large variety of different structural forms, not all of which are biologically active. The biologically active form of PTH has 84 amino acids, but several inactive carboxyl-terminal proteolytic fragments of PTH can accumulate in patients to variable degrees, depending on renal function (15). The particular forms of PTH that are detected by any given assays are dependent upon which epitopes or regions of the PTH molecule the antibodies are directed against. Similarly, in the case of drug immunoassays, depending on the antibody used in an assay, an inactive catabolite of the drug, as well as the active drug, may be detected. Many parent drugs are also similar in structure and hence will often cross-react in immunoassays. Some protein

analytes may also be highly polymorphic in their primary amino acid sequence and/or in posttranslational modifications. Some of these variant forms may therefore not be detected, particularly when highly specific monoclonal antibodies are used in assays (57). The ability of an antibody to react with a protein antigen can also be affected by whether the protein is bound to another protein or other subunit, which may mask an epitope on the protein antigen and interfere with binding to an antibody. Also, some molecules seemingly unrelated in terms of overall structure may cross-react or interfere with an immunoassay, because they may still share a relatively small region or epitope. Depending on the assay design, cross-reactive substances can result in either a positive or a negative bias.

Depending on the assay design, unusually high concentrations of an analyte may paradoxically cause a falsely low result by a phenomenon called a hook or prozone effect. Those analytes that have a wide concentration range, such as hCG and tumor markers, are most likely to be affected by this problem. Two-site immunometric assays are particularly prone to hook problems when the antigen concentration is sufficiently high that different antigen molecules are bound to the capture and labeled antibodies. When this occurs a sandwich complex is not formed (Fig. 3), which results in a falsely low value. This problem can be ameliorated by performing the assay on a diluted sample or making sure that there is sufficient excess antibody even for those samples with unusually high levels of the analyte. Two-step immunometric assays that are performed in a sequential manner so that only one antibody is used per step and with a wash step between antibodies also reduce the likelihood of hook effect problems.

Heteroantibodies are another important cause of immunoassay problems (39, 43, 66). Heteroantibodies are nonreagent antibodies that come from the test sample and, depending on the assay design, can cause a positive or negative bias, by reacting with the antibody reagents or the analyte. For example, autoantibodies, such as rheumatoid factor, which binds IgG, can interfere with immunoassays by blocking the reagent antibody from reacting with the analyte or by cross-linking the reagent antibody. Autoantibodies that are induced as a consequence of the administration of a therapeutic recombinant protein may also interfere with the immunoassay of that protein by competing with the reagent antibody. Heterophile antibodies, which are a group of poorly defined antibodies that react with a wide range of antigens, are the most common source of heteroantibody problems. Human anti-mouse antibodies are heterophile antibodies that react with mouse immunoglobulins, and they frequently interfere with immunoassays by binding to mouse monoclonal antibody reagents. Heterophile antibodies may develop due to environmental exposure to different animal immunoglobulins, but they may also develop in patients after the intravenous administration of a therapeutic or diagnostic mouse monoclonal antibody. In order to reduce interference from heterophile antibodies, immunoassay reagents frequently contain mouse and other animal serum or excess nonimmune animal immunoglobulins to compete for the binding of heterophile antibodies.

Various preanalytical factors can also affect immunoassays. Similar to other laboratory tests, hemolysis, lipemia, and bilirubinemia often adversely affect immunoassays. Radioisotopes and fluorescent contrast material given to patients for various radiological imaging procedures can also create problems, depending on the immunoassay label. Some immunoassays are also incompatible with the various blood collection tube additives. For example, EDTA in plasma collection tubes will often interfere with assays that use alkaline phosphatase, because it will chelate Zn from the reaction mixture, which is a necessary cofactor for the enzyme. Many protein analytes are labile and are prone to proteolysis and must, therefore, be processed quickly and properly stored to get accurate results. Finally, in the case of drugs and those analytes that show a large diurnal variation, the specimen must be collected at the appropriate time in order to properly interpret the result.

As with all diagnostic assays, it is critical that the clinical laboratory assess the analytical performance of its immunoassays with a QC program. Immunoassays are particularly prone to drift between lots of reagents because of subtle differences in the binding properties of the antibody reagents. It is also required for clinical laboratories to participate in an external PT program, such as the one offered by the College of American Pathologists. An overall quality assurance program should also be implemented to ensure that the immunoassays are meeting the medical needs of the ordering physicians. Because of the complexity in interpreting many immunoassays, it is especially important for the laboratory to monitor, in conjunction with the ordering physicians, that their immunoassay results are being interpreted and utilized correctly.

RESEARCH APPLICATIONS AND FUTURE DEVELOPMENTS FOR PROTEIN ANALYSIS

Advances in Immunoassay Technologies

There has been ongoing progress in immunoassay methods since their inception over 70 years ago. These provide incremental improvements in sensitivity down to attomolar (10^{-18} M) or zeptomolar (10^{-21} M) limits of detection and progressive miniaturization and acceleration of analyses. Some more fundamental potential changes in immunoassay techniques are (i) the application of new specificity elements such as single-chain antibodies, imprinted polymers (38), or RNA aptamers (36) which may provide chemically defined recognition elements with a different range of specificities and (ii) applications of nanotechnology that offer potential dramatic miniaturization of assays (35) and new detection technologies with high sensitivity such as immuno-PCR, which uses PCR as the reporter system for an immunoassay (52).

Multiplex Immunoassays

Another fundamental change in immunoassay technology is presented by multiplex immunoassays, which measure many components in a single assay rather than one component at a time. Small panels of tests in a single lateral-flow immunoassay device are in common use for applications such as detection of markers for myocardial infarction or for screening for a panel of drugs of abuse (7). However, technological advances in multiplex assays offer the possibility of analyzing a much larger number of components in a single analysis. At present, multiplex assays are in two basic forms—surface based and particle based. In surface-based multiplex assays, an array of spots of different antigens or antibodies is prepared on a surface such as a silica chip, a glass slide, or the well of a microtiter plate (13). Binding of components in a specimen to each spot is analyzed as a separate reaction, using a labeled antigen or antibody component applied after the specimen. Particle-based assays rely on the ability to distinguish particles based on size, color, or other properties (17). This allows the simultaneous analysis

of addressable beads derivatized with different antigens or antibodies. Following incubation with specimen and a labeled detection reagent, the signal attached to beads can be analyzed by flow cytometry. Multiplex immunoassays offer the advantages of being able to measure a large number of components simultaneously and to perform replicate analyses of individual components as an internal quality assurance measure. However, there are major challenges in ensuring reproducibility of multiplex assays, in optimizing assays for each of multiple components, and in analyzing the large amount of data generated. As the number of results from a multiplex assay grows, the interpretation of results may need to rely increasingly on sophisticated informatics tools.

Two-Dimensional Gel Electrophoresis and Chromatography

Sequentially combining two separation technologies with different principles of separation allows separation of many more components than either technique alone. The most widely used approaches have been variations of the technique described by O'Farrell (53), which employs isoelectric focusing in the first dimension in the presence of denaturants and nonionic detergents and SDS-polyacrylamide gel electrophoresis in the second dimension. This technique can provide resolution of more than 1,000 components in a single analysis. Two-dimensional electrophoresis has served as a valuable research tool, but clinical use has been limited by low throughput, labor-intensiveness, and complexity in standardization and interpretation of data. Completion of sequencing of the human genome and improvement in mass spectrometric methods for peptide analysis have greatly advanced the ability to identify components separated in two-dimensional gels. The number of plasma components that can be analyzed by two-dimensional gels also has been increased by recent applications of immunosubtraction methods to remove the most abundant plasma components such as albumin, transferrin, and immunoglobulins, which otherwise overload the capacity of the method and limit detection of low-abundance components (22, 59). Considering the large number of potential protein components in plasma, even the highest-resolution methods for two-dimensional gel analysis probably evaluate only a small subset of the most abundant components in plasma.

Two-dimensional gel electrophoresis will fail to detect proteins and peptides that are more basic or acidic than the pH range of the isoelectric focusing analysis and that are smaller than about 7,000 Da. Two-dimensional chromatography offers a separation technology for components that may not be observed by two-dimensional gel electrophoresis, such as small peptides. Two-dimensional or multidimensional chromatography combines complementary separation methods such as chromatofocusing or ion-exchange chromatography with reverse-phase chromatography (73). The first dimension is run in a series of steps that are collected as fractions that are each analyzed by the second mode of separation. This technique has been coupled to detection by tandem mass spectrometry to allow sequence analysis of a thousand or more peptide components in a single run.

Mass Spectrometric Methods

The Nobel Prize in Chemistry was awarded in 2002 to Fenn and Tanaka for the development of two major advances—electrospray ionization and matrix-assisted laser desorption/ionization–time of flight (MALDI-TOF)—in mass spectrometric analysis of proteins (18, 46). These methods have provided new tools for the analysis and identification of proteins and peptides. In the technique of electrospray ionization, a solution containing proteins or peptides is sprayed into fine droplets which, after solvent evaporation, yield individual multiply charged protein molecules. The protein ions are analyzed in a vacuum by a mass spectrometer. This technique uses a liquid specimen so that it can be linked directly to the outflow from liquid chromatography. A single protein tends to generate a number of peaks due to different forms of the protein. Thus, it is difficult to analyze complex mixtures of proteins by this technique. Usually, it is applied to samples enriched for a single protein or to mixtures of peptides that are analyzed by liquid chromatography linked to electrospray ionization mass spectrometry. A recent example is the analysis of molecular variants of transthyretin that are related to hereditary amyloidosis (3).

MALDI-TOF mass spectrometry uses a laser to vaporize a small amount of solid specimen that consists of protein specimens dried with a light-absorbing compound that then serves as the sample matrix. Vaporization of the sample by the laser tends to release predominantly intact polypeptide molecules with a single charge. The charged polypeptides are analyzed in a vacuum by accelerating them in an electric field and measuring how long it takes them to reach a detector (time of flight). Lighter peptides reach a higher speed; analysis of the time of flight allows accurate determination of polypeptide mass. MALDI-TOF mass spectrometry is complementary to electrophoretic methods in that it has highest resolution and detection sensitivity for small peptides. It is possible to analyze large proteins as well, although there is progressive loss of resolution and detection sensitivity as protein size increases. MALDI-TOF mass spectrometry also allows the analysis of profiles of complex mixtures of peptides such as those occurring in biological fluids, resolving up to hundreds of different peaks. It serves as a relatively rapid and simple method of analysis that could find clinical applications. Some processing or fractionation of specimens prior to analysis is required to avoid suppressive effects of salts and abundant protein components. A variation of this technique in which fractionation of the specimen is performed using specimen target plates with a modified surface has been termed surface-enhanced laser desorption/ionization–time-of-flight mass spectrometry (33, 49). In this method, the target surface serves as a selective capture surface that is analyzed by MALDI-TOF mass spectrometry. This technique has generated both excitement as a discovery tool for potential markers of disease (10, 56) and controversy with regard to how to analyze complex sets of data (61) and to achieve acceptable reproducibility for clinical use (31, 68). It is not clear yet whether mass spectrometry will find common clinical laboratory use as a diagnostic tool or whether it will be used primarily as a discovery tool for potential new markers that will then be analyzed by methods such as immunoassay.

Genomics and Chip Technology

STEPHEN J. CHANOCK

4

The genomics revolution has ushered in a new age in scientific research which has notably expanded the paradigm of scientific investigation. Until recently, genetic studies examined individual gene expression by Northern blotting or single polymorphisms by gel-based restriction fragment length polymorphism analysis, but with new high-throughput technologies, it is possible to survey the expression of all transcripts in a cell in parallel or analyze thousands of sequence variants at once. This shift towards examining expression patterns in a single genome has been possible because of the technical advances in microchips and bead arrays. Incidentally, the same technologies can interrogate thousands of genetic variants in one individual genome.

The genomic age has tremendous potential to explore the interactions between a host and either its environment or pathogens. The genomic paradigm becomes more complex as the analysis incorporates genomic observations derived from both host and pathogen. Still, the near future promises to see the realization of patterns of genes integral to disease susceptibility and outcomes, which can be used to develop new drug targets or preventive strategies (7). Already, we have seen examples in pharmacogenomics, such as the association of drug efficacy in lung cancer patients receiving the targeted therapy gefitinib in subjects with a particular type of somatic mutation in the tumor (16).

As a consequence of the high-throughput analytical platforms, there has been an explosion in the generation of data, particularly in public databases (17). Accordingly, analytical capabilities for these ambitious large-scale studies have lagged behind the generation of genomic data. The creation of common databases replete with search tools has made this staggering amount of data available to many investigators, some of whom will undoubtedly continue to forge novel analytical approaches. In turn, validation can easily be based on analysis of existing data and the robustness of a new approach can be judged against current standard practices and previous publications. In a short period, the genomics age has shifted a substantial proportion of study to the search for patterns or profiles of expression or genetic variants in specific diseases. Eventually, it will be necessary to refine the paradigm so that the transition from research observation can seamlessly move into clinical practice under standards agreed upon by all.

DNA MICROARRAY EXPRESSION

There are two different techniques for spotting known DNA sequences in microarray expression analyses; either cDNA clones or synthesized oligonucleotides (notably, the length of oligonucleotides has increased over the past decade) are spotted as DNA probes on a solid support, such as a glass microscope slide. All genes expressed in an organism or cell type can be spotted onto a surface using robotics and an informatic grid that locates the precise position of each DNA probe. Annotated double-stranded cDNA clones, usually presequenced for validation, are PCR amplified, purified, and spotted in a predetermined array pattern. Oligonucleotides can be synthesized as short (25 bp) or long (50 to 75 bp) and directly printed on a glass surface or synthesized onto the glass or silicon surface. Photolithography technology has emerged as a standard technology for spotting oligonucleotides on array surfaces, which, incidentally, is the same technology as used for computer microchips (15).

Microarray analysis interrogates total RNA or mRNA purified from cell or tissue sources. If a sufficient quantity of RNA is available, reverse transcription can be performed directly, but if there is limited RNA, protocols for amplification of the cDNA can faithfully represent the target RNA with a modicum of variance (24). cDNA is labeled with either dUTP-biotin or a conjugated fluorescent dye, such as Cy3 or Cy5, which is easily detected with a fluorescent scanner. Depending on the study design, the labeled probes are singly or in combination hybridized to the microarray slides prior to scanning for digital imaging. The coordinates for each spot and known duplicates guide the collection of data and permit facile determination of individual gene expression profiles.

The prospect of developing more accurate diagnostic profiles of diseases represents a major goal of microarray technology applied to gene expression. In one experiment, one can assess the relative differences in expression of all transcripts in a cell type or tissue, providing a snapshot of what is turned on and off. Harvest of total RNA or mRNA is critical; technical problems or degradation fatally undermines the interpretation of expression data. Hence, the timely extraction of RNA from fresh or carefully frozen tissue is a requirement for performing expression array analysis.

Naturally, the quality control steps for ensuring that RNA is not degraded must be established, and in circumstances in which insufficient RNA is available, careful amplification of RNA can be performed during the generation of cDNA (24). It is notable that expression studies do not establish the absolute expression level but, instead, when conducted carefully, an accurate assessment of the differential expression of all genes in a particular cell type.

Global analysis of gene expression using microarrays can be applied to many research questions. Distinct expression profiles can be used as molecular signatures of diseases (12, 14). In some cases, this approach in population-based studies can identify profiles of genes that subtype a disease, such as breast cancer or non-Hodgkin's lymphoma (1, 8). Moreover, the clustering of specific genes in breast cancer portends outcome and is beginning to be used in studies to determine therapeutic intervention (8, 19, 21). Certainly, additional prospective studies are needed to fully address these critical issues. Intense effort has been directed at applying expression profiles to therapeutic response (e.g., pharmacogenomics); in some cases, studies have sought to identify signature expression patterns that correlate with response or toxicity. Conversely, microarray studies have identified suitable genes or pathways for development of novel drug targets. In this regard, sequence analysis of genes altered in expression in breast cancer have led to the characterization of a new tumor suppressor gene, GATA3 (22).

Once the hybridization steps are completed, sophisticated scanning technology is required to capture images of differences in signal. The immense collection of raw data can be mined according to distinct analytical algorithms. With so many data points, the standard visualization tool is a pseudo-color coding of the ratio between the expression of two samples hybridizing to the same DNA sequence. Background noise can be reduced by filtering raw data prior to visualization steps.

An analytical plan seeks to reduce the complexity of ratios and seek patterns or profiles of gene expression which, in turn, reflect biologically significant observations. Some investigators choose not to supervise the analysis and thus with no prior knowledge define relationships between samples. Many investigators utilize a supervised analysis in which a training set is validated in an independent data set; the purpose of this approach is to discover markers that are specific to each group. Furthermore, some have stated that to navigate immensely dense data sets, an artificial intelligence program can provide sophisticated analyses. For instance, each of the following has been successfully used to classify biologically confirmed sets: artificial neural networks, advanced clustering, and support vector machines (3). Alternatively, others choose to conduct standard statistical tests, such as *t* tests, and classify on the basis of classical statistics. The classification of data includes determination of gene ontogeny, which is usually drawn from one of several public databases, and the clustering of data is intended to visualize the data. Both dendrograms and multidimensional scaling are used to visualize the relationship between expression patterns in a graphic representation that reflects a presumed biological relationship between sets of samples that differentiates two or more subsets.

Recently, the microarray platform has been used to perform comparative genomic hybridization to identify regions of allelic loss or amplification. Instead of using cDNA generated from harvested RNA, DNA extracted from tissue, including archived material, is hybridized to DNA chips. Currently, most studies have used cDNA or oligonucleotide-based arrays to identify regions of loss of heterozygosity or gene amplifications (2, 6).

MICROARRAY ANALYSIS OF SEQUENCE VARIATION

There are several substantive differences between the analyses of gene expression patterns and germ line genetic variants. Unlike the study of expressed transcripts, which utilizes a technique that captures all known transcripts by priming with the poly(A) tail, common and rare genetic variants have to be interrogated base by base. Since there is no common handle to capture sequence variants, analysis has to specifically examine unique regions by PCR amplification. This requires detailed knowledge of flanking sequence and amplification conditions for each region of interest. Therefore, for large-scale analysis, large-scale multiplex analysis has been developed and has several limitations: single-nucleotide polymorphisms (SNPs) in close proximity are difficult to assay; selected regions, often high in GC content, do not faithfully amplify both alleles; and random drop-out of assays occurs, though, with optimization, at a tolerable level that does not significantly undermine the ability to estimate haplotype structure from unphased genotype data (18). There are probably over 10 million common SNPs in the human genome (with a mean allele frequency of more than 5% in at least one studied population). Furthermore, SNP frequencies can vary substantially by population.

Chip technology was initially applied to single-base pair mutation detection, using a similar hybridization technology but with genomic DNA as a template. Modifications of laying SNPs on microchips quickly progressed from a single-SNP analysis to analysis of thousands of SNPs (11). Currently, there are four commercial technologies available for large-scale, high-throughput genotype analysis (Table 1). For each technology, substantial effort and cost must be expended to optimize the panel of SNPs, which are fixed prior to analysis. As the International HapMap Consortium completes its first phase of genotype analysis, it will be possible to analyze the structure of genetic variation across the genome in a more comprehensive manner (13). This strategy, known as whole-genome scanning, is based on the observation that there is linkage disequilibrium across any gene or region and estimates the haplotype structure of a region. Since SNPs are inherited in units, haplotype blocks can vary in size according to the region of the genome and the population under study (10). These blocks can decrease the complexity and permit analysis of a subset of SNPs, known as

TABLE 1 Current high-throughput genotype technologies

Technology
Affymetrix: simplification of the genome by restriction digestion, and addition of universal adapting linkers, which are amplified prior to fragmentation and labeling. SNPs are assayed on a microchip using an address system.
ParAllele: allele-specific primer extension followed by ligation and amplification prior to reading on a bead or microarray platform
Illumina: allele-specific gap fill followed by ligation and amplification prior to readout on a microarray or microchip system
Perlegen: a PCR-based sample preparation that targets amplification across the genome. High-density oligonucleotide arrays consisting of short DNA probes are synthesized on a glass surface and used to determine genotypes with great redundancy. The technology is vendor based and not exportable to academic or government labs.

haplotype tagging SNPs, which captures a high proportion of ancestral haplotypes. These facts underscore the dynamic history of selection and adaptation of genetic variation in response to differential challenges, such as diet, pathogens, and climate. In some regions of the genome, there is little linkage disequilibrium, requiring an alternative analysis plan with a more dense collection of neighboring SNPs.

With these new technologies, the search for genetic contributions to disease susceptibility and outcomes can systematically evaluate all genes as well as the intergenic regions of the genome. Because most SNPs are silent and have no apparent functional consequence, the challenge is to identify the set of informative SNPs that are "causal."

Laboratory analyses (e.g., in vitro or animal work) will be necessary to investigate the basic mechanism of an SNP or haplotype, which alters either expression or function. The laboratory component continues to be outpaced by the advances in technical capabilities in genomics. For instance, we can now consider analyzing a large set of common SNPs across the genome, chosen on the basis of haplotype structure in the search for germ line genetic risk factors for disease or outcome (including toxicity or efficacy associated with therapeutic intervention) (9).

The new technologies for SNP detection will enable studies to look at genetic variation across all genes of a pathway or biological process as well as across the entire genome (which comes at a formidable cost). Similar to the analytical challenges of the microarray expression studies, analytical approaches will continue to evolve in SNP research (4). Since SNPs are low penetrance and impact risk, the challenge of finding the informative SNPs for a disease or outcome is daunting. Innovative strategies coupled with sufficiently large population-based studies will minimize false positives and improve the probability of obtaining findings that can be replicated, a central requirement for SNP studies (5, 23).

FUTURE DIRECTIONS IN SEQUENCE TECHNOLOGIES

One of the major goals of the coming decade is the development of high-throughput sequence technologies. Sequence analysis across a region or gene captures all of the common and rare variants. Since neighboring SNPs can undermine the fidelity of a genotype SNP assay, large-scale sequence analysis should be more accurate. When sequencing platforms are cost-effective, perhaps an entire genome can be sequenced for a reasonable cost—the so-called "$1,000 genome." At this point, it will be possible to examine common and uncommon genetic variants in large population-based studies. However, these developments are not imminent, so there is adequate time to begin to consider the analytical challenges ahead, namely, identifying rare variants that lead to significant phenotypes (20). Since most rare variants are probably not causal, interpretation of rare genetic variants will require corollary functional data or detailed family pedigree analysis to establish a critical relationship with disease outcome.

Introduction to Molecular Methodology

RAYMOND P. PODZORSKI

5

The genomics revolution involving chip technology is overviewed in chapter 4. This chapter is intended to provide a more detailed discussion of the molecular techniques and equipment that are available, or under development, for use in the clinical laboratory. While sufficient detail is provided to understand the design and strengths and weaknesses of the various techniques, this chapter is not intended to provide complete step-by-step instructions for each molecular diagnostic procedure. The reader is encouraged to investigate other chapters of this manual or other sources for more detailed descriptions of these procedures and their applications (see references).

MOLECULAR SPECIMENS

Prior to performing a molecular assay on a specimen, DNA or RNA of interest must be available and in a functional form for testing. The specimen processing component of a molecular assay involves liberating the nucleic acid from the target of interest to remove or inactivate potential inhibitors of nucleic acid amplification or hybridization and concentrate the nucleic acid prior to analysis. In many instances, the most labor-intensive portion of a molecular assay is specimen processing. The labor costs alone associated with specimen processing can determine whether a particular molecular assay is worth being run in-house.

The actual amount of manipulation that will be required prior to placing an aliquot of the specimen into a molecular assay depends upon a number of factors. These include the specimen type, or types, the sensitivity required, and the volume of specimen anticipated. Types of specimens differ considerably in terms of the difficulty in isolating functional nucleic acids. Specimens such as cerebrospinal fluid, whole blood, serum, or plasma are typically more amenable to relatively uncomplicated specimen processing protocols compared to specimens such as tissue, bone, sputum, or stool. In addition, it is well known that microorganisms differ in terms of the relative ease of nucleic acid extraction. For example, mycobacteria and many fungi are relatively difficult to process, while viruses are typically far easier to process for a nucleic acid sample.

When contemplating bringing molecular diagnostics in-house, it is a common concern that the assays will be so labor-intensive, complicated, and procedurally foreign to the technologists that it will be difficult to maintain a high level of competency with the assays. Fortunately for those in the market for molecular testing, the days of having to make all your nucleic acid extraction reagents are effectively over. Because of the tremendous growth in the number of specimen processing reagents, kits, and instruments available today, it is beyond the scope of this chapter to present any meaningful evaluation or comparison of these products. However, it would be very prudent for those pondering bringing molecular assays into their laboratories to give considerable thought to their specimen processing requirements. In certain instances there may be little flexibility in terms of how specimen processing can be done. For example, molecular-assay-based kits that have been approved by the U.S. Food and Drug Administration (FDA) typically come with specimen processing reagents and/or procedures designating which specimen types the kit is designed for, how the specimens must be processed, and what reagents should be used. However, when developing and using homebrew molecular assays, or assays using an analyte-specific reagent (ASR), individualized specimen processing protocols may provide considerable latitude in terms of protocol options.

A particularly important point to note is that for some molecular assays, complex processing procedures are not required. Some nucleic acid amplification-based assays require only "boil-and-go" processing. This type of processing involves heating a small aliquot of the specimen at 100°C for a short period, cooling and spinning the aliquot at 10,000 to 15,000 $\times g$ for 2 to 3 min to pellet any insoluble material, and taking the supernatant and using it directly in the assay. Specimens that are less likely to contain strong inhibitors of nucleic acid amplification tests and are known to consistently contain a certain amount of the target nucleic acid are good candidates for boil-and-go processing. When more elaborate specimen processing procedures are required, relatively recent advances in semiautomated and automated specimen processing instruments are changing the landscape of nucleic acid extraction in the clinical laboratory. The use of specimen processing instruments, coupled with real-time amplification technology discussed below, and the availability of FDA-approved kits, or ASRs, for molecular assays have markedly reduced the complexity of many molecular procedures. While the first automated specimen processing instruments that came onto the market were large and expensive, a number of new, smaller, and less costly specimen processing instruments have been introduced recently and initial evaluations of these instruments have

been encouraging. These instruments automate many, or all, of the steps involved in nucleic acid isolation, minimizing the demands of manual processing procedures that were common a few years ago. Semiautomated or automated specimen processing instruments are now within reach of most clinical laboratories and allow the laboratory to more easily maintain a level of quality, proficiency, and competency in their nucleic acid extractions over a range of specimen types and instrument users. However, the performance of automated specimen processors has been reported to vary. Some users have found that additional up-front steps are required with some specimens to reach the same DNA extraction efficiency seen with manual procedures. Discussing the performance of an automated processing instrument of interest with an experienced user, or doing an in-house evaluation of the instrument, before purchasing it is strongly suggested.

CLASSICAL MOLECULAR DIAGNOSTIC TESTING

Molecular testing in the clinical laboratory consists of two major areas: (i) the use of DNA probes to directly detect or characterize a specific target and (ii) the use of nucleic acid amplification technologies to detect or characterize a specific target DNA or RNA. The use of DNA probe technology is discussed first; nucleic acid amplification technology and nucleic acid sequencing are discussed later, followed by molecular arrays, a more elaborate application of probe technology. The procedures for use of DNA probes are now well standardized and frequently simpler than those for nucleic acid target or probe amplification assays. However, the sensitivity that can be attained with many probes is still lower than that of nucleic acid amplification procedures, and this remains the main drawback of more widespread use of probe technology directly on patient specimens (79). Classical molecular techniques that are DNA probe based can be divided into three general categories: solid-phase hybridization, solution-phase hybridization, and in situ hybridization. Each type of probe hybridization assay is discussed individually, as are probe amplification procedures.

Solid-Phase Hybridization

In the slot or dot blot DNA probe hybridization procedure, intact cells are lysed and the DNA is denatured, brought into direct contact with a nylon membrane by vacuum aspiration in a dot or slot configuration, and then fixed onto the membrane (9, 22). Nucleic acids bound to solid supports such as nylon membranes are still available to participate in hybridization reactions. The membrane is immersed in a hybridization solution containing the DNA reporter probe and allowed to hybridize. In solid-phase assays the hybridization reaction is very slow and typically requires an overnight incubation to complete. Following hybridization, the unbound reporter probes are washed away and the bound probe is detected by one of several methods. Dot or slot blots are especially useful for the processing of multiple specimens at one time, since numerous specimens can be screened on a single filter. A variation on the dot or slot blot utilizes sandwich or capture hybridization (70, 85, 118). This procedure utilizes two probes that bind to different sites on the target nucleic acid. One probe is attached to the membrane and serves to capture the target nucleic acid in the sample. The second probe is labeled and serves as the detector. This system was developed to circumvent the direct binding of target DNA to the membrane. In some cases, sandwich hybridization has been found to be more sensitive than standard membrane hybridization.

The Southern blot is a solid-phase hybridization assay that allows size determination of DNA fragments bound by the reporter probe (8, 22, 99). The Northern blot, a variation on the Southern blot, is a molecular assay to detect RNA instead of DNA (10, 88). These procedures generally require purified DNA or RNA. In the Southern blot, sample DNA is isolated and digested with a restriction endonuclease, and the fragments are separated by size using agarose gel electrophoresis. In the Northern blot, total sample RNA is isolated and separated by size using denaturing agarose gel electrophoresis. In both types of blots the nucleic acids are then transferred to a nylon membrane for hybridization with a specific probe. These assays typically require 2 to 3 days to complete because the transfer of the nucleic acid to the membrane is usually done overnight and the probing of the membrane is also done overnight. A very well-known molecular assay that involves Southern blot analysis is testing for T-cell receptor gene rearrangements.

Solution-Phase Hybridization

Some commercially available DNA probe kits for use in the clinical laboratory are based on solution-phase hybridization, or some variant, in which both the target nucleic acid and the probe are free to interact in an aqueous reaction mixture (7, 59, 114, 115). The free target-probe interaction in the aqueous environment has very rapid hybridization kinetics, typically requiring just 1 h or less to complete, a considerably shorter time than the overnight hybridization frequently required in a solid-phase hybridization reaction. The key to solution-phase hybridization is that the nucleic probe must be single stranded and not hybridize with itself.

In the clinical laboratory, one popular method for detecting probe hybridization in solution is a bacterial and fungal culture confirmation procedure that utilizes the hybridization protection assay (HPA) (3, 67). In HPA, an acridinium ester-labeled DNA probe is hybridized to target rRNA. After 15 min the hybridization reaction mixture is treated with alkali. After an additional 15 min, the reaction mixture is placed in a luminometer, peroxides are added, and the acridinium ester emits detectable light. In HPA, hybridization of the acridinium ester-labeled DNA probe protects the acridinium ester from alkaline hydrolysis, and upon addition of peroxides, the acridinium ester will emit detectable light. However, if the acridinium ester-labeled DNA probe is not hybridized, the acridinium ester is not protected from alkali and is hydrolyzed to a form that does not emit light; thus, the quantity of light emitted is a reflection of the degree of hybridization. HPA can be performed in a few hours and does not require removal of excess unbound acridinium ester-labeled DNA probe. Because HPA is proprietary technology of Gen-Probe, it has seen little use outside of various kits offered by Gen-Probe.

Another solution-phase hybridization method suited for use in the clinical laboratory is a reverse hybridization assay using free detection probes and tethered (but with considerable mobility) capture probes. Following sample extraction the DNA is denatured, mixed with free biotinylated detection probes, and placed in a microtiter plate with capture oligonucleotide probes tethered to the wells. The solution is incubated for about 1 h. The capture probes bind to areas of the target DNA that are unique from those sites bound by the detection probes. Following hybridization, unbound material is washed away and an alkaline phosphatase-conjugated antibiotin antibody is added. After the appropriate incubation, the wells are washed again and the substrate is added. The bound alkaline phosphatase can be detected using either a colorimetric or chemiluminescent substrate (51, 82).

In Situ Hybridization

In situ hybridization assays involve the same general principles as solid- and solution-phase hybridizations. However, in situ hybridization occurs within the morphological context of individual cells or a tissue sample (31, 101). When considered in conjunction with tissue morphology and host response, the results of these assays confirm that specific DNA or RNA targets are present in the specimen under study and provide additional information regarding distribution and abundance. In clinical settings, formalin-fixed paraffin-embedded tissue sections frequently form the starting material for in situ hybridization assays. In situ hybridization requires that target nucleic acid be made accessible for hybridization while the cellular morphology is preserved for subsequent interpretation and analysis. Therefore, the tissue processing must be delicate enough to preserve the cellular structure while denaturing the nucleic acids in the cell to make them accessible to the DNA probe. The sensitivity of in situ hybridization is limited by the accessibility of target nucleic acids within the cell. Because of the accessibility limitations associated with mammalian cells, it has been found that relatively small probes (500 bases or less) are optimal to favor tissue penetration (104).

Signal Amplification Schemes

Several ingenious signal amplification schemes have been developed in recent years to increase the sensitivity of probe-based assays (24, 45, 91, 117). Unlike nucleic acid target amplification or probe amplification procedures, signal amplification procedures are designed to increase the signal generated by the probe hybridized to a specific sequence of target

DNA or RNA. The fact that signal amplification procedures do not involve nucleic acid target or probe amplification is a theoretical advantage, because it makes these amplification procedures less prone to the contamination problems that are of concern in enzyme-catalyzed amplification procedures. However, a relative lack of sensitivity compared to nucleic acid amplification procedures is still a drawback to some of these procedures. While some assays have sensitivities to below 100 nucleic acid targets per ml (16), other signal amplification procedures require a minimum of 10^3 to 10^5 nucleic acid targets (depending upon specimen processing) (44), which is well below the sensitivity of highly optimized nucleic acid target or probe amplification procedures. The chief limitation of some signal amplification systems is the background noise due to nonspecific binding of reporter probes. Problems with high backgrounds have led to modifications such as incorporating gray zones into the interpretation of the assay when the result is close to the positive cutoff and procedural modifications, such as the use of target capture probes and isonucleotides, to reduce the background noise levels associated with some signal amplification procedures (16, 37).

bDNA

One of the most well-known signal amplification systems is the branched DNA (bDNA) probe system (Bayer Corporation), which utilizes multiple probes together with multiple reporters (16, 95, 109). This system utilizes a specific target capture step for isolation of the nucleic acid sequence of interest followed by hybridization with unlabeled label extender and preamplifier probes (Fig. 1). One
FIGURE 1 bDNA-based signal amplification. Target nucleic acid is released by cell disruption and captured to a solid surface via multiple contiguous capture extender probes. Label extender probes hybridize with adjacent target sequences and contain additional sequences homologous to the preamplifier probes. Preamplifier probes bind multiple bDNA (amplifier) probes. Enzyme-labeled oligonucleotides bind to the bDNA by homologous base pairing, and the enzyme-probe complex is measured by detection of chemiluminescence.

region of the label extender is complementary to the target nucleic acid, and another part of the label extender is capable of hybridizing with the preamplifier. The preamplifier and bDNA amplifier are the keys to the amplifying power of this technique. The bDNA amplifier is chemically synthesized with a comb-like backbone made from a branching nucleoside analog that is incorporated at regular intervals along the oligonucleotide. The bDNA binds many labeled probes, providing a significant boost in signal. Depending upon the specific version of bDNA kit used, over 10,000 reporter molecules can be incorporated onto each target sequence. The most recent bDNA probe system has high specificity because both capture and target probes must bind before the signal amplification can take place, and the use of nonnatural bases, isocytidine and isoguanosine, decreases nonspecific hybridization. In this bDNA probe system, nonspecific hybridization rarely results in hybridization of both capture and target probes to the same nontarget sequence. Because bDNA probe systems provide quantitative detection over a range of several orders of magnitude, such assays are very useful for monitoring therapeutic responses during disease therapy. The determination of responses to therapy has been demonstrated to be useful in assessing the need for further therapy or for adjusting doses of therapeutic agents for certain infectious diseases (human immunodeficiency virus type 1 and hepatitis C virus [HCV]).

Hybrid Capture

The most commonly used technology for human papillomavirus (HPV) testing of cervical specimens is Digene's hybrid capture (4, 26, 35, 38, 102). This is a signal amplification system that is based upon the binding of multiple alkaline phosphatase-conjugated antibodies that are specific

for DNA-RNA hybrids (Fig. 2). Isolated target DNA is denatured and hybridized to a complementary RNA probe at 65°C for 1 h. The DNA-RNA hybrids are transferred to a capture microtiter plate with wells that are coated with polyclonal antibodies that are specific for DNA-RNA hybrids and incubated at room temperature for 1 h with rotary shaking. The hybridization solution is discarded, and alkaline phosphatase-conjugated antibodies specific for DNA-RNA hybrids are added to the capture plate and incubated at room temperature for 30 to 45 min. These antibodies have the same specificity as the capture antibodies on the plate and bind to open epitopes on the captured DNA-RNA hybrids. The plate is rigorously washed, and a chemiluminescent substrate is added to the plate, which is incubated in the dark for 15 to 30 min at room temperature and then read in a luminometer.

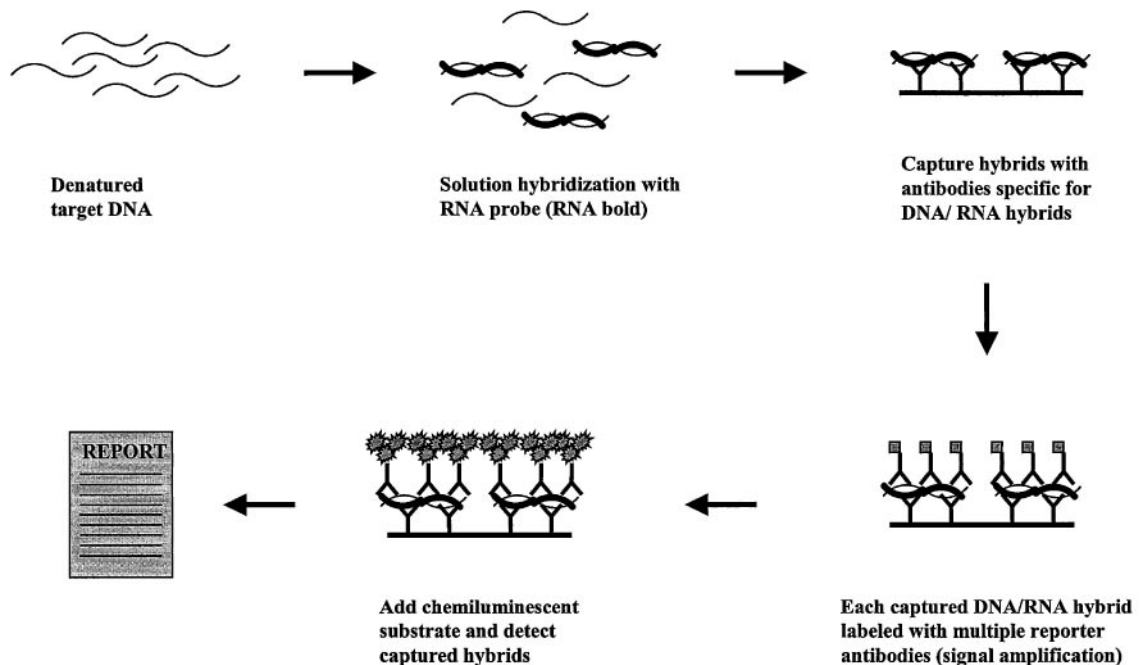
The sensitivity of hybrid capture for HPV is reported by the company to be 1.08 pg/ml (product insert). Based upon a genome size of about 8,000 bp for HPV, this translates to approximately 134,000 DNA copies/ml of specimen. This sensitivity closely compares to what Digene has reported for this technology in a quantitative HBV assay that is under development (142,000 copies/ml of blood) (44). However, up-front ultracentrifugation of specimens for HBV testing by hybrid capture increases the sensitivity to approximately 4,700 DNA copies/ml. This sensitivity is below what would be expected for a target amplification assay such as PCR. Use of a signal amplification assay raises a concern about the signal-to-noise ratio on samples with a low target DNA copy number. For the HPV assay, Digene defines a gray zone for weakly positive specimens because the signal amplification specificity is suspect for samples with signals just above the positive breakpoint. A new version of the assay that is under


FIGURE 2 Hybrid capture. Target DNA is released by cell disruption, denatured, and allowed to hybridize to specific RNA probes. Double-stranded DNA-RNA hybrids are captured to a solid surface via antibodies specific for the hybrids. Multiple reporter antibodies specific for the hybrids bind each captured DNA-RNA hybrid, setting the stage for signal amplification. A chemiluminescent substrate is added and the reporter antibody-hybrid complex is measured by detection of chemiluminescence.

development attempts to improve the specificity of the assay by incorporating avidin-coated wells which bind to specific single-stranded biotinylated oligonucleotide capture probes (11). The single-stranded capture probes capture the desired DNA-RNA hybrids in a sequence-specific fashion. This modification lowers the possibility of nonspecific DNA-RNA hybrids being captured by the polyclonal anti-DNA-RNA antibodies. Digene is looking to use hybrid capture as a basic platform for a number of assays. In addition to the HPV test, a number of additional assays are available or under development (quantitative cytomegalovirus, HBV, chlamydia, and *Neisseria gonorrhoeae* tests).

Invader

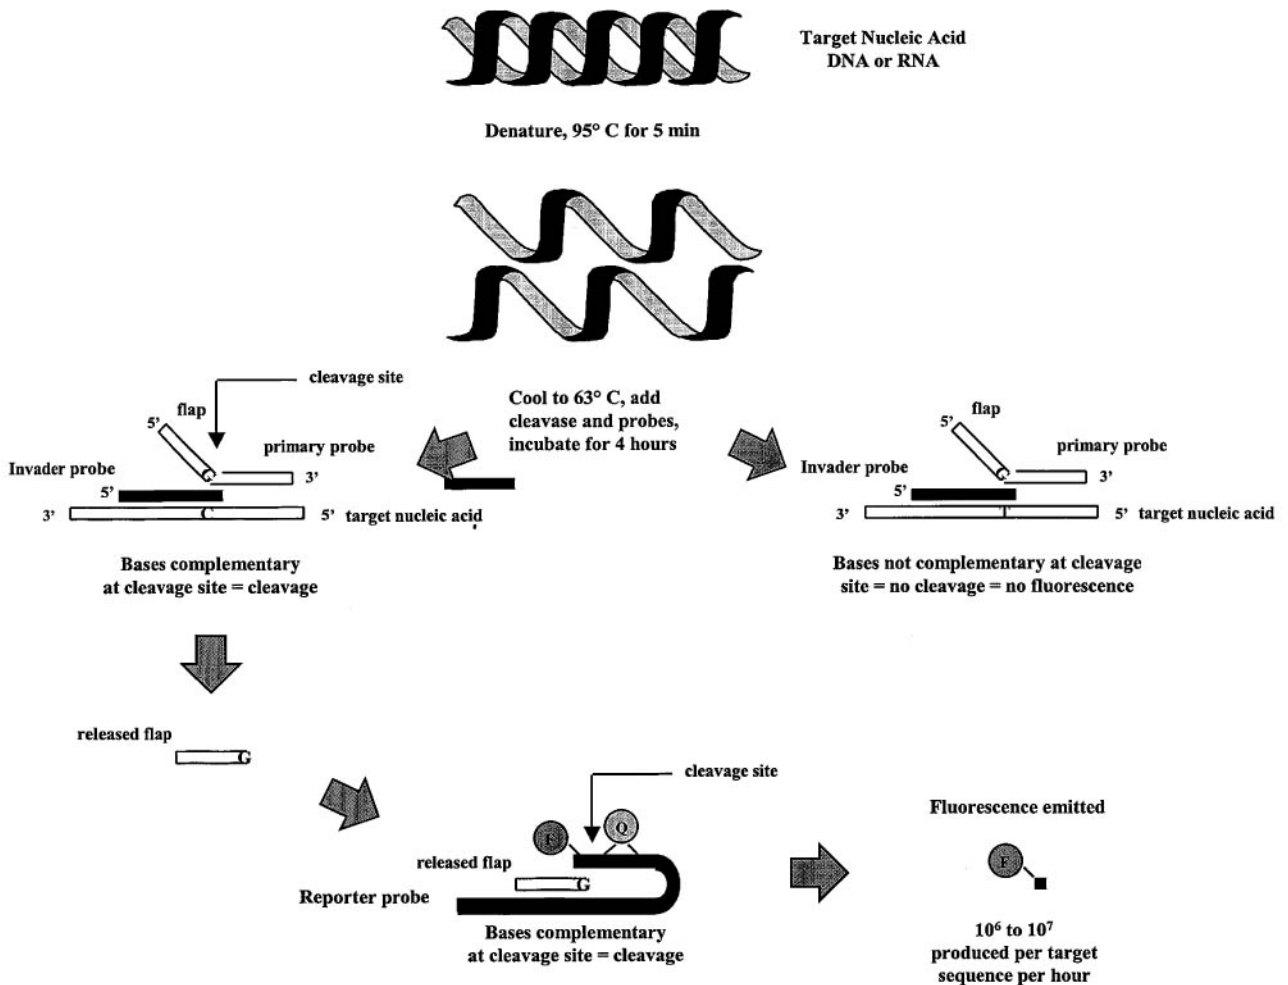
Invader technology (Third Wave Technologies, Inc., Madison, Wis.) is a signal amplification procedure that generates large numbers of reporter probes from a single target-bound DNA probe (45, 91). This procedure is isothermal and done in a microtiter format, and the results are read on a fluorescence plate reader. The assay utilizes two major components: (i) a cleavase enzyme that specifically cuts a bound probe and (ii) three oligonucleotide probes, i.e., a primary probe, an "invader" probe, and a reporter probe. The primary probe and invader probe are designed so the Invader assay will interrogate one specific base in the target nucleic acid (Fig. 3). In the primary reaction, the invader oligonucleotide probe and primary probe bind together to the target nucleic acid sequence, creating a structure with a 1-bp overlap and a nonhybridized flap on the 5′ end of the primary probe. The cleavase enzyme recognizes this overlapping structure and cleaves the 5′ flap off the primary probe. Each time the correct structure forms, the cleavase enzyme cuts the 5′ flap off the primary probe. The reactions are deliberately carried out at temperatures near the denaturation temperature of the primary probe. This results in a dynamic hybridization reaction allowing multiple uncleaved primary probes to bind to the same nucleic acid without temperature cycling, and in linear signal amplification because 1,000 to 10,000 5′ flaps are


FIGURE 3 Invader. A primary probe, with a 5′ flap, and an invader probe bind to the target nucleic acid and form a 1-bp overlap. Cleavase recognizes this substrate and cleaves the 5′ flap from the primary probe. The free 5′ flap acts as secondary invader probe with the reporter probe. Cleavase cleaves the fluorescein (F) from the 5′ end of the reporter probe, separating it from the quencher dye (Q), allowing a fluorescent signal that can be detected. If the target region of the primary probe and the invader probe do not match perfectly with the target DNA, the proper substrate is not formed and the cleavase will not cleave the 5′ flap from the primary probe (right panel).

being cleaved from primary probes per hour for each target molecule in the reaction. When the primary probe and the target nucleotide do not complement each other perfectly, the correct overlapping structure does not form and the cleavase enzyme will not cut the primary probe.

The accumulating 5′ flaps released from the cleaved probes participate in the secondary detection reaction. The free 5′ flaps are designed to act as secondary invader probes, and the reporter probe acts as both the secondary probe and the target. Each reporter probe, regardless of the target in the primary reaction, has the identical sequence and is designed to fold over on itself to mimic a probe hybridized to a target and make a 5′ flap. The principle of the reporter probe used in the Invader assay is fluorescent energy transfer. The reporter probe contains a fluorescein at the 5′ end and a quencher dye attached nearby in the sequence. When the two dyes are proximal to each other, no fluorescence is produced. Once a free 5′ flap binds to the reporter probe, the two form the overlapping structure recognized and cut by the cleavase enzyme. When the cleavase enzyme cuts the fluorescein off the 5′ end of the reporter probe, the dyes are separated and a fluorescent signal can be detected. Under the conditions of the assay, 5′ flaps readily cycle on and off the reporter probes. Every time a 5′ flap and uncleaved reporter probe form the correct overlapping structure, the cleavase cuts the 5′ fluorescein off the reporter probe. Each free 5′ flap can cause the cleavage of 1,000 to 10,000 reporter probes in 1 h. As a result, the primary and secondary reactions work together to produce a 1 million- to 10-million-fold linear amplification of the signal from a single target gene. Because of its linear signal amplification, Invader technology is inherently quantitative and can be employed in quantitative and qualitative assays. Currently the maker of Invader assays has a number of hemostasis testing ASRs available; these include tests for Factor V Leiden, Factor II, and MTHFR, as well as many others (49). Invader reagents for infectious disease testing are relatively few, with ASRs for HCV genotyping and an HPV assay available.

NUCLEIC ACID AMPLIFICATION TECHNIQUES

The primary objective of nucleic acid amplification techniques is to improve the sensitivity of assays based on nucleic acids and to eventually simplify these assays by development of automated assay formats such as real-time detection. The technology behind nucleic acid amplification methods is highly diverse and constantly changing. Because of this complexity, it is useful to assign such methods to one of three general categories: (i) target amplification systems such as PCR, nucleic acid sequence-based amplification (NASBA), transcription-mediated amplification (TMA), and strand displacement amplification (SDA); (ii) probe amplification systems, which include the ligase chain reaction; and (iii) signal amplification systems (described above), in which the signal generated from each probe molecule is increased by using compound probes or branched probes, or by generation of large numbers of reporter probes. Ligase chain reaction is not discussed in this edition of this manual; readers are referred to the previous edition for an in-depth discussion of this technology.

PCR

PCR is based upon the ability of DNA polymerase to copy a strand of DNA by elongation of complementary strands initiated from a pair of closely spaced oligonucleotide primers (64, 65, 66). Theoretically, each cycle of the reaction will double the amount of target DNA, resulting in millionfold levels of amplification.

PCR can be used on all types of specimens (2, 5, 23, 60, 74, 79, 80, 93, 98, 110, 116). As with all the nucleic acid target amplification procedures, some knowledge of the target sequence must be available in order to design the two single-stranded DNA oligonucleotide primers that will be used to amplify target DNA (Fig. 4). These PCR primers, each about 20 to 25 nucleotides long, can be synthesized by using an automated DNA synthesizer or ordered from a commercial supplier. PCR has high sequence specificity because the two unique primers must hybridize in relatively close proximity to each other on the target DNA sequence under stringent temperature and reaction conditions before exponential amplification can occur.

A commonly used set of cycling temperatures includes denaturation of double-stranded DNA at 94°C for 10 to 30 s, hybridization of oligonucleotide primers at 52°C for 10 to 30 s, and extension (polymerase-mediated complementary strand synthesis) from the primers at 72°C for 15 s to 1.5 min (Fig. 4) (93). These three steps are repeated for 25 to 45 cycles. In the early cycles of the reaction, the initially synthesized strands of new DNA are variable in length depending upon the processivity of the DNA polymerase. However, after a few cycles the primers begin to use the newly synthesized strands of DNA as templates, and the predominant product of PCR becomes a double-stranded DNA sequence, the length of which is the sum of the lengths of the two primers plus the intervening target DNA. PCR is an exponential amplification reaction such that after n cycles there is $(1 + x)^n$ times as much target as was present initially, where x is the mean efficiency of the reaction for each cycle. Theoretically, as few as 20 cycles would yield approximately 1 million times the amount of target DNA initially present. In practice, however, the theoretical maxima are never reached, and more cycles are necessary to achieve such a level of amplification.

NASBA

The first non-PCR nucleic acid amplification technique was a transcription-based amplification system (TAS) developed in 1989 by Kwoh et al. (46). In TAS, amplification of RNA is based upon a repeated two-cycle reaction of cDNA synthesis followed by transcription of the cDNA template into multiple copies of RNA. A major drawback to TAS was that heat was needed to denature the RNA-DNA intermediate formed during each cycle of the reaction. Heating inactivated the enzymes used in TAS, requiring their replenishment at the end of each cycle. During the development of TAS, it was discovered that the addition of *Escherichia coli* RNase H to the reaction resulted in degradation of the RNA template within the double-stranded RNA-DNA intermediates, allowing the cycling reaction to proceed under isothermal conditions (29). One variation of this nucleic acid amplification reaction is known as NASBA (also called 3SR for self-sustained sequence replication) and has been patented by Organon Teknika (17, 89).

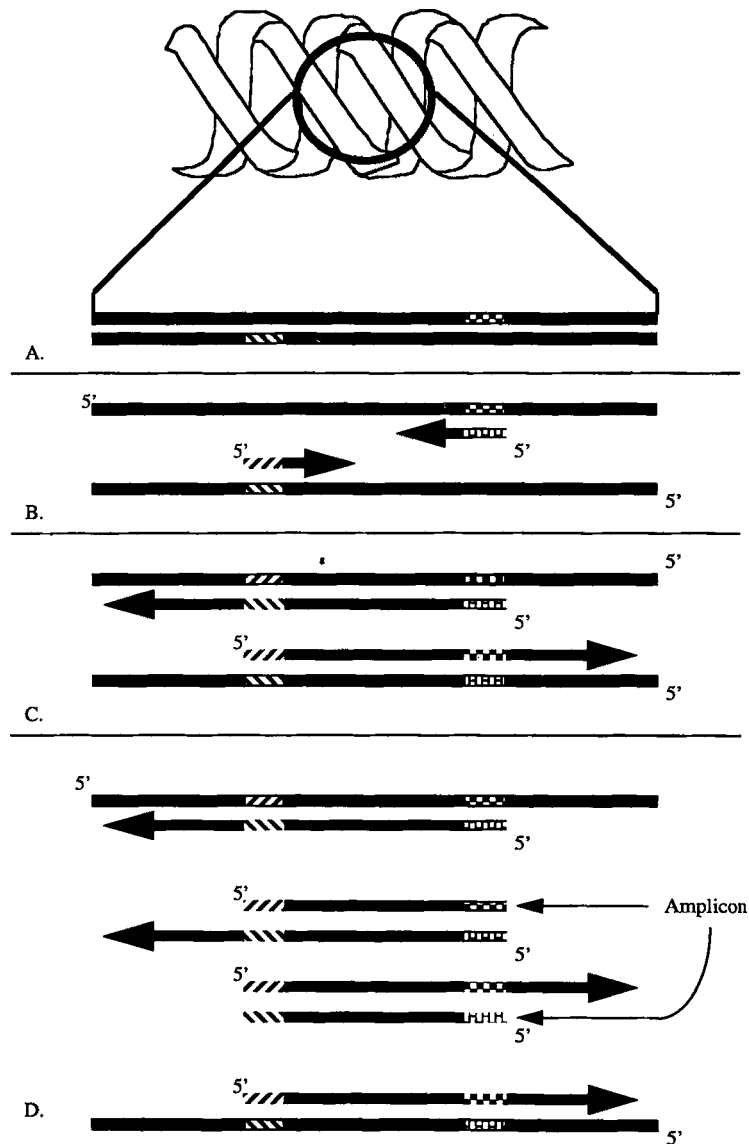
NASBA utilizes the collective activities of three enzymes (avian myeloblastosis virus reverse transcriptase, RNase H, and bacteriophage T7 DNA-dependent RNA polymerase) to isothermally amplify an RNA target (Fig. 5). The initial steps in the reaction involve the formation of cDNAs from the target RNA using specific oligonucleotide primers; one of the primers contains a T7 RNA polymerase binding site at its 5′ end. The RNase H in the reaction


FIGURE 4 PCR. (A) In the first cycle, a double-stranded DNA target sequence is used as template, with the primer binding sites indicated by the hatched lines. (B) The two DNA strands are separated by heat denaturation, and two synthetic oligonucleotide primers (complementary cross-hatched lines) anneal to their recognition sites in the 5′ to 3′ orientation when the reaction cools. Note that the 3′ ends of the primers (arrowheads) are facing each other. (C) *Taq* DNA polymerase initiates synthesis at the 3′ end of each primer. Extension of the primer via DNA polymerization (synthesis) results in new primer binding sites. The net result after one round of polymerization is one copy of each (two total) strand of the original target DNA of unspecified length. (D) In the second cycle, each of the four DNA strands shown in panel C anneals to primers (present in excess) to initiate a new round of DNA polymerization. Of the eight single-stranded products, two are of a length defined by the distance between and including the primer annealing site. This amplification product (amplicon) accumulates exponentially in subsequent cycles.

degrades the initial strands of target RNA in the RNA-DNA hybrids after they have served as templates for the first primer. The second primer binds to the newly formed cDNA and is extended, resulting in the formation of double-stranded cDNAs with one strand capable of serving as a transcription template for T7 RNA polymerase. It is reported that approximately 10 million-fold amplification occurs after a 1- to 2-h incubation, with an initial rate of amplification of 10-fold every 2.5 min for the first 10 min. Organon Teknika has developed an electrochemiluminescence-based solid-phase sandwich hybridization system to automate the detection of the amplified product from NASBA. This is a generic detection system so it can be used to detect the amplified product from Organon Teknika-supplied kits or can be used to detect the product from in-house-developed NASBA assays.
FIGURE 5 TAS. The initial steps in the reaction involve formation of cDNAs from the target RNA by using oligonucleotide primers, one of which contains a T7 binding site. RNase H activity (a separate enzyme in NASBA, associated with the reverse transcriptase in TMA) degrades the initial strands of target RNA in the RNA-DNA hybrids after they have served as templates for the initial primer. The second primer then primes the initial single-stranded cDNAs, resulting in the formation of double-stranded cDNAs with one strand capable of serving as the transcription template for T7 RNA polymerase. This results in the synthesis of numerous copies of RNA. These RNAs serve as templates for synthesis of more cDNA intermediates. These cDNAs lead to the synthesis of more copies of RNA which then reenter the cycle.

Although NASBA involves several enzymes and a complex series of reactions, individual steps in the reaction are invisible to the user. Advantages of NASBA include very rapid kinetics and an isothermal environment of 41°C. NASBA is especially useful for the amplification of single-stranded RNA targets. PCR amplification of mRNA requires isolation of RNA and/or pretreatment of the samples with DNase prior to the reverse transcription and amplification. With NASBA, because reaction conditions are maintained at temperatures that do not extensively denature DNA, the DNA is largely inaccessible to the NASBA machinery, and no pretreatment steps are necessary. While NASBA is well suited for amplification of single-stranded RNA, it is a more complicated procedure when it comes to the amplification of double-stranded DNA. For DNA amplification, heat denaturation steps are required in the initial stages of the reaction in order to generate the necessary amplification intermediates. Despite this potential shortcoming, NASBA has been used successfully to amplify DNA targets (32).

TMA

TMA is an RNA amplification system developed and patented by Gen-Probe (48). The procedure is very similar to

NASBA, with the exception that only two enzymes are involved. The procedure is an isothermal reaction that uses one oligonucleotide primer, with an RNA polymerase binding site, to a specific target sequence of rRNA. This primer and a reverse transcriptase together generate cDNA molecules (Fig. 5). RNase H activity inherent in the reverse transcriptase degrades the RNA template from the cDNA, leaving a single-stranded cDNA. A second oligonucleotide primer initiates copying of the cDNA strand by the reverse transcriptase to made a double-stranded DNA template. The double-stranded DNA molecules produced act as intermediates in the TMA process. RNA polymerase binds to the polymerase binding site at one end of the cDNA intermediate and transcribes one strand of the molecule into thousands of RNA copies. These RNA copies feed back into the reaction, leading to more cDNA intermediates which in turn lead to thousands more RNA copies (Fig. 5). Detection of the amplified rRNA is done in solution using a labeled DNA probe via Gen-Probe's chemiluminescence-based HPA. The level of RNA-DNA hybrids formed is determined using a instrument to detect the light emitted during the chemiluminescence reaction. TMA is widely used for the direct detection of *Mycobacterium tuberculosis* in respiratory specimens (25, 39).

In this assay, sonication is used to lyse the mycobacteria and 12- by 75-mm tubes are used for amplification and detection. Because of all the handling involved, the M. tuberculosis TMA kit does not work as easily with large numbers of specimens as some other nucleic acid amplification assays, and it may be prone to cross contamination between specimens. Great care in the performance of the assay must be exercised in order to prevent cross contamination and possible false-positive results. TMA is a procedure that can potentially be applied to many molecular diagnostic assays, not just for M. tuberculosis and Chlamydia trachomatis, in the clinical laboratory (41).

SDA

SDA was developed and patented by Becton Dickinson, Inc., in 1991 (54, 111, 112). SDA is an isothermal DNA amplification procedure that uses specific primers, a DNA polymerase, and a restriction endonuclease to achieve exponential amplification of the target. Published reports claim ≈10^7-fold amplification of the target following a 2-h reaction (111). The key technology behind SDA is the generation of site-specific nicks by the restriction endonuclease BsoBI. The site-specific nicks are utilized by an exonuclease-deficient DNA polymerase (Bst DNA polymerase) to displace the nicked strand of DNA, generating a single-stranded DNA target for synthesis primers. At the same time, Bst DNA polymerase utilizes the remaining template strand to generate a new strand of DNA. Normally, restriction enzyme cleavage produces double-stranded DNA products, which would not be the proper template for SDA. However, if α-thio-substituted nucleotides (dCTPαS; one of the oxygen molecules in the triphosphate moiety has been replaced with sulfur) are used to synthesize a double-stranded, hemiphosphorothioated DNA recognition site for restriction enzyme cleavage, the restriction enzyme is capable of cleaving only the unmodified strand, while the hemiphosphorothioated strand remains unbroken. dCTPαS is the key base in SDA because it is responsible for transforming the original target sequence into the hemiphosphorothioate form, which is resistant to restriction endonuclease cleavage. This results in a nick being formed in the unmodified primers used to initiate SDA, with the hemiphosphorothioated strand serving as a template for DNA synthesis by Bst DNA polymerase at the site of the nick (Fig. 6). SDA can be thought of as a two-part reaction (111). The initial rounds of the reaction transform the original target sequence into the hemiphosphorothioate form with nickable BsoBI sites at each end. The second part of the reaction involves the exponential amplification of the transformed target sequence.

Although the SDA reaction is a complex one, individual reaction steps occur simultaneously and do not require attention once the reaction has been initiated. With the exception of the initial 95°C denaturation step, SDA is isothermal and requires no specialized laboratory equipment other than a controlled environment of 37°C. In addition, SDA can be applied to either single- or double-stranded DNA. With SDA, a limit to the size of the target DNA that can be efficiently amplified has been observed. For Becton Dickinson's FDA-approved C. trachomatis and N. gonorrhoeae SDA assay, the DNA targets are both around 100 bp in length (54). While this may not result in a serious functional limitation of SDA, it may complicate postamplification decontamination procedures if these are utilized (75).

POSTAMPLIFICATION DETECTION

One of the reasons nucleic acid-based amplification assays are becoming more commonplace in the clinical laboratory is that more convenient methods for detecting the reaction products are being developed. Although several different procedures are available for the detection of the products from these assays, the choice of a postamplification detection procedure depends upon several factors, including (i) the type of amplification system used, i.e., target, probe, or signal amplification; (ii) the extent of heterogeneity in the sample being detected; (iii) the need for detection of rare sequence variants in the amplified product; (iv) the requirement for sequence confirmation of the amplification product; and (v) the equipment required (72, 116). Target amplification procedures probably provide the simplest products for postamplification detection. Not only are there frequently large amounts of product, but also the sequence of product is homogeneous, reducing the complexity of detection and allowing the use of less stringent hybridization conditions than would be required if there were other sequences at similar concentrations in the mixture. Less stringent hybridization conditions may be critical to the detection of targets that contain multiple sequence variants.

In this edition of the manual there is no discussion of agarose gel and blotting-based amplification product detection procedures. These procedures are obsolete for most clinical laboratory assays and have been replaced by more rapid and less labor-intensive product detection methods that are discussed below. Those who are interested in these procedures can review earlier editions of the manual and other references (77). In addition, dedicated procedures for the detection of amplified products following nucleic acid amplification, such as reverse dot blots, are discussed only briefly because these methods are being replaced with real-time nucleic acid amplification assays where the product is detected concurrently with the ongoing amplification. Real-time nucleic acid detection systems are discussed below.

Amplification Product Capture—Reverse Dot Blot

The amplification product capture procedure is based on a modified solution-phase hybridization technique that incorporates the use of amplification primers biotinylated on their 5′ ends (116). This type of amplification product detection procedure is frequently called a reverse dot blot because, unlike a dot blot where the nucleic acid to be probed is immobilized to a solid support and the probe is free in solution, the probe itself is actually attached to a solid support and the nucleic acid to be probed is free in solution (94). In systems commonly used in the clinical laboratory, capture probes specific for a certain amplified target nucleic acid are attached to the wells of a 96-well microtiter plate or to magnetic beads (14, 56). However, unlike in typical solid-phase hybridization, the capture probes are only tethered at one end and have considerable freedom to twist and turn in the hybridization buffer. Because of the freedom of movement available to the capture probes, hybridization reactions can occur at rates that rival those of true solution-phase hybridizations. Amplified DNA with its biotinylated 5′ end is allowed to hybridize to the capture probes. After the unbound DNA is washed away, avidin-horseradish peroxidase is added, and it binds to the biotin incorporated into amplified DNA. A chromogenic substrate is then added to detect the amplified DNA colorimetrically.

DNA detection systems of this type are attractive for use in the clinical laboratory because no radioactive isotopes are involved and often microtiter plates or magnetic bead-based systems are used that depend on familiar laboratory instrumentation. In addition, capture systems of this type can be developed to allow simultaneous assaying with multiple

A. TARGET GENERATION

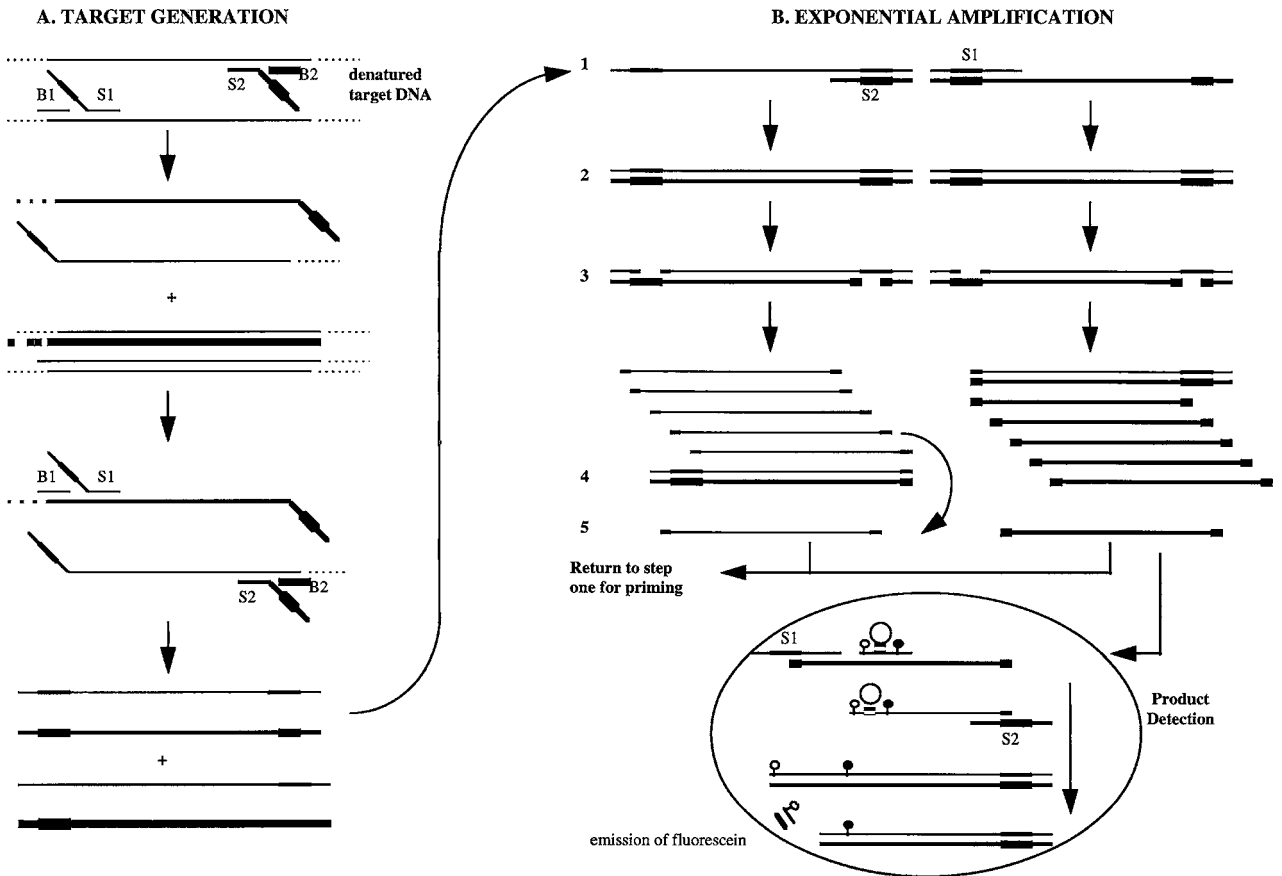
B. EXPONENTIAL AMPLIFICATION


FIGURE 6 SDA. The initial rounds of the reaction (A) transform the original target sequence into the hemiphosphorothioate form with nickable BsoBI sites at each end that enter into the second part of the reaction (B), which involves exponential amplification of the transformed target sequence. In reaction part A, sample DNA is denatured at 95°C in the presence of an excess of four specific primers that define the target sequence. Two primers, S1 and S2, contain unmodified BsoBI recognition sites at their 5′ ends and specific target-binding sequences at their 3′ ends. S1 and S2 bind opposite strands of DNA flanking the target region. The other two primers, B1 and B2, are target-binding primers only, without a restriction endonuclease recognition sequence, and bind opposite strands of DNA immediately upstream of primers S1 and S2. The incorporation of primers B1 and B2 concomitantly generates a product with defined ends during the reaction and eliminates the need for restriction enzyme cleavage of the sample DNA prior to SDA. Following the addition of the primers, the reaction mixture is allowed to cool to 37°C, and Bst DNA polymerase and BsoBI are added in excess together with dATP, dGTP, dTTP, and dCTPαS. The Bst DNA polymerase activity now extends all four primers simultaneously (A). Primers S1 and S2 form complementary strands of modified DNA that contain unmodified BsoBI sites at their 5′ ends. B1 and B2 prime the same strands and displace the newly synthesized strands primed with S1 and S2, producing new strands of DNA with defined ends that start immediately upstream of the S1 and S2 binding sites. Now S1 and B1 bind to the displaced strand initially primed with S2, while S2 and B2 bind to the displaced strand initially primed with S1 (A). Extension and displacement reactions on these templates produce two defined fragments with a hemiphosphorothioate BsoBI site at each end. Copies of the original target DNA containing hemiphosphorothioate BsoBI ends have now been generated (A, bottom). These copies now enter the second, and prominent, part of the SDA reaction (B). Following priming and extension from S1 and S2, a double-stranded fragment of a specific size that contains a BsoBI site on each end that is susceptible to nicking (remember that S1 and S2 primers contain unmodified BsoBI recognition sites at their 5′ ends) is generated. Repeated cycles of nicking, Bst DNA polymerization and strand displacement, and priming of the displaced strands with S1 and S2 result in exponential amplification of target DNA. For product detection, the fluorogenic probe (large circle) binds to one strand of amplified DNA and its 3′ end is extended simultaneously with the amplification (S1) probe for that strand. The extended fluorogenic probe is displaced by the product from the amplification (S1) probe. The extended fluorogenic probe is now bound by the opposite-strand primer (S2) and is copied. The copying of the fluorogenic probe forces the stem-loop structure apart and creates a double-stranded BsoBI site, which is flanked by both FAM (small open circle) and ROX (small solid circle). The BsoBI site in the fluorogenic probe lacks the dCTPαS at the nucleotide position of BsoBI cleavage. As a result, BsoBI cuts clean through the two strands of DNA and liberates FAM from the quencher. Now fluorescent emission from FAM can be detected.

probes, which avoids the need to use separate amplification reactions for multiple probings.

HPA

HPA detection systems are based on the use of a chemiluminescent DNA probe and hold considerable promise (67, 81). HPA is a proprietary procedure from Gen-Probe which is used to detect the amplified product from their TMA assay. In HPA, an acridinium ester-labeled DNA probe that is hybridized to amplified target RNA is protected from alkaline hydrolysis and upon addition of peroxides will emit detectable light. However, in its unhybridized form, the attached acridinium ester is not protected and is hydrolyzed to a form that does not emit light. HPA does not require the binding of amplified RNA to a solid support by RNA capture or other means, it can be performed in about an hour, the excess unbound DNA probe does not need to be removed, and it has a sensitivity of 10^{-16} to 10^{-18} mol (10^4 to 10^7 copies) of target RNA. However, because HPA is proprietary technology, it is not widely available.

Real-Time Product Detection

While the detection systems described below could be read following PCR (or some other nucleic acid amplification technique) by using a fluorescent plate reader, the true power of the technology is realized when it is done using an instrument that is capable of real-time detection of the PCR product (27, 33, 92). Real-time detection is when the fluorescence emission of the reporter probe (driven by the PCR product accumulation, for example) is monitored cycle by cycle. Real-time PCR utilizes one instrument (thermal cycler/signal detector) for both amplification and product detection. There is no transferring of the PCR products into a plate to be read in a fluorescence reader, and there is no agarose gel or other post-amplification product detection system to run. A very important advantage of real-time detection is that once the amplification reactions have been prepared, each tube remains closed throughout the PCR amplification and detection process. The closed system associated with real-time detection greatly reduces the risk of laboratory contamination with PCR products. Additional advantages of real-time detection over older methods include the ability to quantitate a wider concentration of target, increased precision, increased accuracy, reduced hands-on time, fewer reagents and instruments required, and shorter turnaround times. The advantages real-time detection offers compared to other postamplification product detection systems in use today are so overwhelming that they cannot be ignored.

Fluorescent resonance energy transfer (FRET), or some close facsimile of this, is the principle behind the real-time detection technology in use today (19, 55, 103). FRET is an energy transfer between two dye molecules in close proximity, one acting as a donor and the other acting as an acceptor. The acceptor molecule can be either another fluorescent dye molecule or a nonfluorescent dark quencher molecule. These molecules used in real-time amplification assays are attached to short DNA probes specific for the target sequence of interest. The efficiency of energy transfer between the dyes depends upon the physical distance between them and the degree of overlap between the emission spectrum of the donor dye and the absorption spectrum of the acceptor dye/quencher. When the molecules are close, following excitation with the appropriate wavelength of light, energy is transferred from the donor dye to an acceptor dye/quencher without the emission of fluorescence. As a result, the donor dye fluorescence is quenched, and the acceptor dye/quencher

is excited, resulting in either fluorescent light of a different emission wavelength than the donor dye or heat. When the dyes are distant, following excitation with the appropriate wavelength of light, energy transfer is sharply reduced or eliminated and the donor dye emits the energy via a specific wavelength of fluorescent light that differs from that of the acceptor dye/quencher. Real-time DNA probes incorporating dark quenchers have become very popular because they have a broad absorption spectrum with lower background fluorescence. These characteristics lead to assays with increased sensitivity and allow the use of multiple reporter dyes with the same dark quencher. There are numerous fluorescence-based real-time detection systems available today. Only a few of the more popular ones are discussed below.

TaqMan

The $5' \rightarrow 3'$ exonuclease-based detection assay developed by Holland et al., now called TaqMan, allows real-time PCR detection of the target sequence (34). This method employs the $5' \rightarrow 3'$ exonuclease activity of *Taq* to generate a specific detectable product concomitantly with amplification (69) (Fig. 7). Fluorescent energy transfer is the principle behind TaqMan detection technology (19, 55, 103). A special reporter probe designed to hybridize within the target sequence is added to the PCR amplification mixture. The reporter probe contains 6-carboxyfluorescein (FAM) as a reporter dye covalently linked to the 5' end. A quencher dye, such as 6-carboxytetramethylrhodamine (TAMRA) or a nonfluorescent dark quencher, is covalently linked close to the 3' end of the probe. This probe is not involved in the amplification reaction and is phosphorylated on its 3' end to prevent extension by *Taq*. Because of the close proximity of the quencher dye to the reporter dye, the reporter dye fluorescence is suppressed. Annealing of this reporter probe to one of the PCR product strands during the course of amplification generates a target-specific substrate suitable for exonuclease cleavage. During DNA extension from a PCR primer, the $5' \rightarrow 3'$ exonuclease activity of *Taq* cleaves 5'-terminal nucleotides off the bound reporter probe in essentially a nick translation reaction and frees the FAM reporter from the quencher (50). The free FAM reporter now emits fluorescence. The cleavage of the reporter probe does not affect the emission of the quencher (if it has any). Even in a high background of genomic DNA, labeled-probe degradation occurs only in a target-specific fashion. Since the exonuclease activity of *Taq* acts only if the fluorogenic probe is annealed to the target, the increase in fluorescence is proportional to the amount of PCR product produced and because of this proportionality, this system is readily capable of performing quantitative determinations of the amount of target nucleic acid in the amplification reaction.

This detection system differs from a traditional PCR procedure only by the addition to the amplification reaction of a fluorogenic reporter probe. One requirement for this detection method is that the reporter probe must bind to target before extension from a PCR primer blocks the binding site. If the annealing temperature of the reporter probe is close to or below the annealing temperature of the upstream amplification primer, there is a greater chance that the amplification primer will be extended before the reporter probe has bound to the target. This would result in inefficient label release and could lead to a false-negative result. This problem may be overcome by varying the relative concentrations of amplification primers and reporter probe, by manipulating the sequence and length of the reporter probe, or by using more stable base analogs.
FIGURE 7 TaqMan. Annealing of the reporter probe to one specific strand of the PCR product during the course of amplification generates a target-specific substrate suitable for exonuclease cleavage. During DNA extension from a PCR primer, the 5′ → 3′ exonuclease activity of *Taq* cleaves 5′-terminal nucleotides off the bound reporter probe and frees the FAM reporter (F) from the TAMRA quencher (Q). The free FAM reporter now emits fluorescence.

Molecular Beacons

Another popular way to realize real-time PCR detection in a nucleic acid amplification assay is through the use of molecular beacons (107, 108). Like in TaqMan, a "FRET-like" transfer is the key to molecular beacons. Molecular beacons are single-stranded DNA hairpin-shaped reporter probes with an internally quenched reporter dye whose fluorescence is restored when the probe binds to a target nucleic acid (Fig. 8). Molecular beacons are designed so the loop portion of the molecule is the probe sequence complementary to PCR product. The stem is formed by the annealing of the complementary sequences on the ends of the probe
FIGURE 8 Molecular beacons. During the denaturation step of PCR, the target DNA and the stem-loop of the molecular beacon denature. As the temperature is lowered to allow annealing of PCR primers, the molecular beacon hybridizes to one specific strand of the PCR product. This conformational change that occurs during hybridization forces the stem apart and causes the fluorescent dye (F) to move away from the quencher (Q), leading to fluorescence. When the temperature is raised for primer extension, the molecular beacons dissociate from their targets and do not interfere with PCR.

sequence. The fluorescent dye is attached to the end of one arm and a quencher is attached to the end of the other arm. The stem keeps these two moieties in close proximity to each other, causing the fluorescence to be quenched by energy transfer. In molecular beacons the quencher is typically a nonfluorescent molecule, such as 4-([4′-dimethylamino-phenyl]azo)-benzoic acid, that serves as a universal quencher for many fluorescent dyes used in molecular beacons. The quencher emits the energy that it receives from the fluorescent dye as heat so the probe is unable to fluoresce. During the denaturation step of PCR, the molecular beacons assume a random coil configuration and fluoresce. As the temperature is lowered to allow annealing of PCR primers, stem-loop structures form rapidly, preventing fluorescence. However, when the molecular beacon hybridizes to a target molecule, it forms a structure that is longer and more stable than the stem-loop structure of the unhybridized probe. This conformational change forces the stem apart and causes the fluorescent dye to move away from the quencher, leading to fluorescence. When the temperature is raised for primer extension, the molecular beacons dissociate from their targets and do not interfere with PCR. A new hybridization takes place in the annealing step of every PCR cycle, and the intensity of the resulting fluorescence indicates the amount of accumulated PCR product. Like TaqMan, molecular beacons can detect multiple targets in the same solution when different-colored fluorescent dyes are used on the probes (107). Unlike a TaqMan probe, molecular beacons fluoresce specifically only when the probe is hybridized (annealing step of a PCR cycle) to its target molecule.

The selection of a DNA sequence to be used in a molecular beacon depends upon several parameters. For best results, molecular beacons should be targeted to the middle of the PCR product of interest. The length of the stem sequences should be chosen so that a stem is formed at the annealing temperature of the specific PCR in which the molecular beacon is to be used. The stem sequences should hybridize only to each other and not to the probe portion of the molecular beacon. The length of the loop sequence should be chosen so that the probe-PCR product hybrid is stable at the annealing temperature of the specific assay. Owing to their stem-loop structure, the recognition of targets by molecular beacons is more specific than traditional DNA probes, so single-nucleotide differences between probe targets can be readily detected using melting-curve analysis (6). Since molecular beacons remain intact throughout the amplification process, unlike TaqMan probes, they can be utilized in melting-curve analysis. Following completion of target amplification, melting-curve analysis is done by slowly raising the temperature to 95°C and measuring the decrease in fluorescence as the molecular beacon is "melted off" the target. Melting-curve analysis is a very simple way to detect mutations in the target DNA. Molecular beacons melt away at higher temperatures when they match the target DNA perfectly and at a lower temperature when there is even just a single-base mismatch between the probe and target DNA.

Hybridization Probes

The probe system used in many molecular assays built for the Roche LightCycler real-time PCR instrument is called hybridization probes. This system involves two separate individually labeled DNA probes that both target a region of one strand of the amplified product. Specific binding of these two probes places them next to one another in a tail-to-head arrangement (Fig. 9). The 5′ probe is the donor probe and has a fluorescein reporter dye at its 3′ end. The 3′ probe is the acceptor probe and has a LightCycler Red reporter dye at its 5′ end and is phosphorylated at its 3′ end to prevent elongation during PCR. During the denaturing step of a PCR cycle, the hybridization probes (just like the PCR primers) are free in solution. During the annealing step, the probes will hybridize to an internal sequence of one specific stand of the amplified product and be positioned next to one another. This results in the reporter dyes being brought into very close proximity with each other. The fluorescein reporter dye is specifically excited and the excitation is transferred (FRET) to the acceptor LightCycler Red reporter. The fluorescein emission is quenched by the close LightCycler Red dye. The LightCycler Red reporter dye becomes excited and emits a red fluorescence that is measured by the instrument at the end of each annealing step. When the temperature is raised for the extension step of the assay, an exonuclease-deficient thermostable DNA polymerase starts elongation from the PCR primer on the strand that the hybridization probes are bound to and the hybridization probes are displaced. At the end of the elongation phase, the PCR product is double stranded again and the hybridization probes are back in solution. A new hybridization by the hybridization probes takes place in the annealing step of every PCR cycle, and the intensity of the resulting fluorescence indicates the amount of accumulated PCR product. Like TaqMan and molecular beacons, hybridization probes can detect multiple targets in the same solution when different-colored fluorescent dyes are used on the probes (107). Since hybridization probes remain intact throughout the amplification process, they can be utilized in melting-curve analysis to detect mutations in the target DNA.

Because each probe has only a single label, hybridization probes are frequently touted as being easier to synthesize, purify, and characterize than dually labeled probes. However, there are several factors that must be considered when contemplating the use of these probes. Cost is something to keep in mind. You are paying for synthesis, labeling, and purification of two probes that are typically 20 to 30 bases each. Also, instead of working out the sequence requirements and annealing conditions for one reporter probe, you have to work it out for two. The melting temperature (T_m) of the hybridization probes should be 5 to 10°C higher than the T_m of the PCR primers. The optimum T_m between the two hybridization probes depends upon how they are used. For basic detection of an amplified product, the T_ms of the probes should be within 2°C of each other. For detection of mutations in the amplified product, the best results are obtained when the difference between the T_ms of the hybridizations probes is 5 to 10°C. The probe with the lowest T_m (called the sensor probe when detecting a mutation) should be the donor probe and should be positioned directly over the mutation of interest. In addition to calculating the T_ms for the probes, you have to determine how far apart from one another the hybridization probes should bind. The distance required between donor reporter dye and acceptor reporter dye for efficient FRET depends upon the fluorophores that are used to make the hybridization probes. Typically the hybridization probes are designed so that they hybridize from 1 to 5 nucleotides apart. However, some studies suggest that the probes should be a minimum of 5 nucleotides apart to prevent close contact quenching and to maximize emission from the acceptor probe (57).

Real-Time Detection Used in SDA

The real-time detection system utilized in Becton Dickinson's *C. trachomatis*/*N. gonorrhoeae* SDA kit is a hybrid with some
FIGURE 9 Hybridization probes. Two separate fluorescently labeled probes (the donor probe is labeled at the 3′ end with fluorescein [probe D] and the acceptor probe is labeled at the 5′ end with LightCycler Red 640 [probe A]) are juxtaposed tail to head upon specifically binding to one strand of the PCR product during the annealing phase of PCR. An excitation wavelength of light specific for the donor probe only is produced during annealing. The acceptor probe absorbs resonance energy from the donor probe and emits fluorescence, with emission collection only being done in the acceptor range.

features of molecular beacons, some features of TaqMan, and some features found in both (54). Like for TaqMan and molecular beacons, fluorescent energy transfer is the principle behind SDA real-time detection (55). The SDA reaction contains a single-stranded DNA fluorogenic probe with FAM as a reporter dye covalently linked to the 5′ end. A quencher dye, rhodamine (ROX), is covalently linked close to the middle of the fluorogenic probe. The area between the two dyes includes a stem-loop structure, making the fluorogenic probe similar in conformation to a molecular beacon (Fig. 6). The loop contains the recognition sequence for the BsoBI restriction endonuclease used in SDA. However, the BsoBI recognition sequence in the fluorogenic probe contains dCTP, not dCTPαS. The fluorogenic probe also contains a target-specific sequence 3′ to the ROX. In its native form, the FAM and ROX dyes are proximal to each other such that excitation of FAM leads to transfer of the emitted energy to ROX. The result is that very little emission from excited fluorescein is detected. As SDA product accumulates, the fluorogenic probe binds to one strand of amplified DNA and its 3′ end is extended simultaneously with the amplification (S1) probe for that strand. The extended fluorogenic probe is displaced by the product from the amplification (S1) probe. The extended fluorogenic probe is now capable of being bound by the opposite-strand primer (S2) and is copied. The copying of the fluorogenic probe forces the stem-loop structure apart and creates a double-stranded BsoBI site, which is flanked by both FAM and ROX. The BsoBI site in the fluorogenic probe

lacks the dCTPαS at the nucleotide position of BsoBI cleavage. As a result, BsoBI cuts clean through the two strands of DNA and liberates FAM from the quencher (mechanism similar to TaqMan). Now fluorescence emission from FAM can be detected. The detection steps occur simultaneously with SDA, making a real-time detection process similar to TaqMan and molecular beacons. Real-time detection in the C. trachomatis/N. gonorrhoeae kit is very important because no SDA product inactivation system is included. Real-time detection allows the amplification reactions to remain closed throughout the SDA procedure. The closed amplification reactions significantly reduce (but do not totally eliminate) the risk of contamination of the laboratory with amplified product. This detection system will undoubtedly be utilized in other SDA assays developed by Becton Dickinson.

Real-Time PCR Instruments
To realize the full potential of real-time PCR, an instrument is required that can do the thermal cycling as well as the concurrent amplification product detection. As described above, fluorescence-based product detection is typically how real-time PCR is done. Currently, there are numerous instruments on the market that are capable of doing real-time PCR. They differ markedly in terms of cost, complexity, capability, cycling speed, utility in the clinical laboratory, and space requirements. It is beyond the scope of this chapter to provide a detailed comparison of the many real-time PCR instruments available today. However, Table 1 lists some of

the more popular real-time PCR instruments that are available in the United States today and compares some of their basic features. All of these instruments are capable of doing basic real-time PCR, using some or all of the real-time detection systems listed above, and graphically displaying the results. The fluorescent dyes supported by the real-time PCR instruments vary depending upon the manufacturer. In addition, features such as the ability to custom select excitation and emission filters depend upon the manufacturer. All of the instruments in Table 1 are capable of doing conventional PCR; however, the ease of recovery of the amplified product varies depending upon the amplification tube used by the manufacturer. Some of the instruments listed in Table 1 may be better suited than others for use in the clinical laboratory. Roche and Cepheid both produce real-time PCR instruments that are being extensively marketed for use in the clinical laboratory. In addition, both of these companies have some FDA-approved diagnostic kits available for use in the clinical laboratory as well as an ever-expanding number of ASRs. The reader should check with representatives of these companies for the latest information on the availability of kits and reagents.

The basic design is similar among real-time PCR instruments (Fig. 10). They consist of a computer and software to run the instrument and analyze the data, a thermal cycler for nucleic acid amplification, and an optical system to excite the fluorescent reporter molecules together with an emission detector. The optical systems used by the various manufacturers of real-time PCR instruments do vary. It is important

for potential buyers to determine which instrument best fits their needs. One nice thing about these machines is that the space requirements for real-time PCR instruments have decreased significantly as new instruments have been introduced. They now should be able to be accommodated by all but the most crowded of clinical laboratories. However, when considering space requirements for the instrument, remember that a computer is required to run the instrument and a printer may be needed to generate hard copies of the results.

DNA SEQUENCE ANALYSIS IN THE CLINICAL LABORATORY

The application of nucleic acid sequencing technology to problems in medicine is starting to come of age (40). The utilization of sequencing to aid in the diagnosis and management of disease will be a major growth area in the clinical laboratory in the coming years. As the utility of sequencing information becomes more appreciated, and the sequencing hardware and software become more readily available and easier to use, more and more laboratories will incorporate this technology into their routine testing.

Sanger's dideoxy chain termination procedure has become the most popular sequencing method in use today (96). This procedure takes advantage of two properties of DNA polymerases: (i) their ability to synthesize faithfully a complementary copy of a single-stranded DNA template and (ii) their ability to use 2′,3′-dideoxynucleoside triphosphates as bases. 2′,3′-Dideoxynucleoside triphosphates resemble

TABLE 1 Comparison of basic features of five real-time PCR instruments

Feature	Roche LightCycler 2.0	Cepheid SmartCycler II	Stratagene Mx3000P	Applied Biosystems 7500	Bio-Rad iCycler iQ
Tube	Glass capillary tube	Proprietary reaction tube	Conventional 0.2-ml PCR tube	Conventional 0.2-ml PCR tube	Conventional 0.2-ml tube
Optics	Blue LED excitation, photohybrid detection, detects six different spectral bands	High-intensity LED excitation, silicon photodetectors, filters to excite/detect four different spectral bands	Tungsten halogen lamp excitation, scanning photomultiplier tube detector, user-selected filters to excite/detect four different spectral bands	Tungsten halogen lamp excitation, charge-coupled device camera detector, filters to excite/detect five different spectral bands	Tungsten halogen lamp excitation, filters to excite/detect five different spectral bands
Probe capability	SYBR Green I, TaqMan, Molecular beacons, Hybridization probes	SYBR Green I, TaqMan, Molecular beacons	SYBR Green I, TaqMan, Molecular beacons	SYBR Green I, TaqMan, Molecular beacons	SYBR Green I, TaqMan, Molecular beacons

2′-deoxynucleoside triphosphates except that they lack a 3′-OH group (Fig. 11). They can be added to an extending strand of DNA, but they cannot be added onto and therefore serve as chain terminators. Initiation of DNA synthesis requires a primer (short single-stranded piece of DNA) that binds to the strand of DNA to be copied, resulting in the copy strand of DNA being synthesized downstream from the primer. One commonly used version of the Sanger DNA sequencing protocol is carried out in a single tube in the presence of four 2′-deoxynucleoside triphosphates (dA, dC, dG, and dT), specific primer, single-stranded template DNA, and DNA polymerase. Also included in the mixture is a limiting amount of four 2′,3′-dideoxynucleoside triphosphates (ddA, ddC, ddG, and ddT), each coupled to a different-colored fluorescent dye (28). The concentration of the 2′,3′-dideoxynucleoside triphosphates is much lower than the concentration of 2′-deoxynucleoside triphosphates. The 2′,3′-dideoxynucleoside triphosphates randomly terminate the extending DNA fragments at one of the four nucleotides. When the sequencing reaction is finished, the reaction tube contains a population of partially synthesized DNA molecules, each having a common 5′ end (designated by the DNA primer used) but each varying in length to a base-specific 3′ end. The sequencing mixture is then cleaned up to remove any unincorporated dye terminators, and the DNA fragments are denatured and then separated by electrophoresis in a sequencing gel or by capillary gel electrophoresis. The labeled DNA bands are revealed by laser light. Each dye attached to a terminator 2′,3′-dideoxynucleoside triphosphate emits light at a different wavelength when excited by the laser; thus, all four colors (and therefore all four bases) can be distinguished in a single gel lane or capillary tube. The sequence is read directly from

the gel in the sequencing instrument, starting with the fastest-moving (smallest) fragment at the bottom and moving up the gel. As you move up the gel each fragment is one base longer than the preceding fragment, thus revealing the DNA sequence. In capillary gel electrophoresis the sequence is read as the fragments reach the end of the capillary, starting with the fastest-moving (smallest) fragment. The sequencing information is then loaded directly into a computer. Direct electronic entry of sequence data eliminates the tedious and error-prone entry of the DNA sequence by manual methods. Review and editing of the DNA sequence generated by the computer can be easily done by evaluating the electropherograms generated by the sequencing analysis software.

Sanger's dideoxy sequencing protocol requires a single-stranded DNA template (96). In traditional DNA sequencing the fragment of DNA to be sequenced is inserted into the polycloning region of the M13mp series of vectors (62). M13mp is a genetically engineered *E. coli* bacteriophage that contains a single-stranded circular molecule of DNA. Growing up M13mp with the inserted DNA to be sequenced generates large quantities of single-stranded DNA template. While M13mp has been used for many years, and is still used today for the generation of single-stranded template DNA for sequencing, it is much too cumbersome for routine use in the clinical laboratory. A much simpler procedure for DNA sequencing combines features of PCR with the Sanger dideoxy sequencing procedure. This procedure has been termed "cycle sequencing" and allows ready sequencing of double-stranded PCR products (76, 86, 87). Today, when sequencing is done in the clinical laboratory, cycle sequencing is most often the procedure used. Cycle sequencing involves linear amplification of DNA using one specific

Normal deoxynucleoside triphosphate

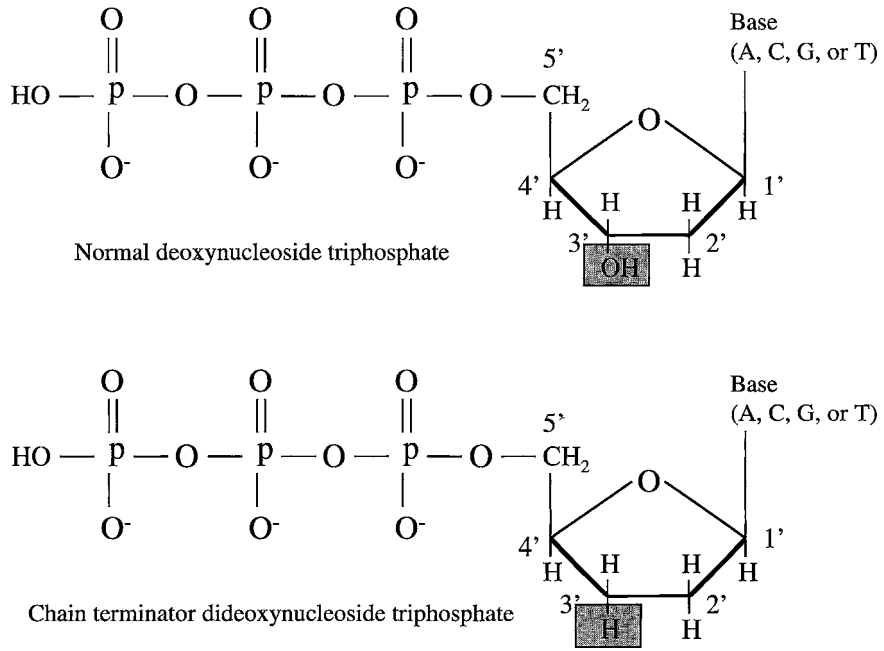
Chain terminator dideoxynucleoside triphosphate


FIGURE 11 Bases used in Sanger's dideoxy chain termination procedure.

primer targeted to a region of the PCR product to be sequenced. Cycle sequencing is typically carried out as described above, with the exceptions that a double-stranded PCR product serves as template DNA and a thermostable DNA polymerase is used for DNA synthesis (76, 86, 87). The reaction mixture is subjected to 20 to 40 cycles of denaturation, annealing, and extension, resulting in the synthesis of new DNA from the sequencing primer. During the denaturation phase of the cycle the double-stranded DNA template is denatured to single-stranded fragments. Cooling the reaction to the primer annealing temperature allows the

sequencing primer to bind to one of the strands of target DNA. Raising the temperature to the extension temperature allows the thermostable DNA polymerase to extend the copy strand of DNA. During extension, the $2',3'$-dideoxynucleoside triphosphates randomly terminate the extending DNA fragments at one of the four nucleotides. Following the sequencing reaction, the sequencing mixture is cleaned up to remove any unincorporated dye terminators, and the DNA fragments are denatured and then separated by electrophoresis in a sequencing gel or by capillary gel electrophoresis (Fig. 12). The labeled DNA bands are identified

Electrophoretic separation of DNA fragments
FIGURE 12 Cycle sequencing-based procedure. DNA or RNA to be sequenced is extracted from the sample of interest, and PCR is used to amplify the target to be sequenced. Once the target has been cleaned up it is used as template in a dideoxy-based cycle sequencing reaction. An automated sequencer determines the composition of the sequence template based upon different-colored fluorescent chain terminators and directly enters the sequence data into a computerized workstation, where data analysis is completed.

using a laser light source and detector system as described above. Depending upon the template DNA, cycle sequencing reactions routinely extend 200 to 600 bases from the primer. The major advantage of cycle sequencing is that it permits direct sequencing of double-stranded DNA without many of the inconveniences associated with conventional DNA sequencing (cloning DNA to be sequenced and isolating single-stranded M13 DNA). Several additional advantages are also associated with cycle sequencing. The elevated reaction temperature used in cycle sequencing reduces false stops induced by template secondary structure and decreases background caused by nonspecific primer binding because of the higher-stringency conditions. In addition, high-G+C-content DNA is sequenced with greater accuracy because of the higher temperatures associated with cycle sequencing. The denaturation step also frees template DNA from newly synthesized cDNA strands, making them available as templates for subsequent rounds of priming and extension; thus, less DNA is required in cycle sequencing than in a standard dideoxy sequencing reaction.

Very thin polyacrylamide gels formerly were used to separate DNA fragments and determine the sequence of template DNA. However, their use is very time-consuming and labor-intensive. Although 36 to 96 sequencing reactions can be run on a single gel, a new gel is required for each run of sequencing reactions. Capillary gel electrophoresis systems eliminate the need for repeated pouring of gels and many other sequencing gel-associated preparation steps (20, 43, 83). Capillary systems are replacing many polyacrylamide gel-based systems in use today. Because of the inherent difficulty in loading specimens into small capillaries, these instruments come with autoloaders. The capillary systems used in these sequencing instruments differ among manufacturers. Some capillary systems automatically inject fresh separation material into the capillary before each run, while other systems reuse the capillaries after a regeneration cycle has been completed. For ease of setup and operation, capillary electrophoresis instruments have become standard platforms in most laboratories. Until relatively recently, the cost of the capillary sequencing instruments was quite high, and some had only had one capillary. However, there are several models of capillary instruments available today, covering a wide range of prices. Depending upon your needs, you can purchase capillary instruments with from 8 to 96 working capillaries. The system that can run 96 sequencing reactions at once utilizes a 96-well thermal cycler microplate format. The 96-well format provides an easy interface between the thermal cycler, where cycle sequencing is done, and the capillary sequencing instrument. Another concern voiced about some capillary electrophoresis systems is that the length of DNA that can be analyzed is shorter than that obtained from the same type of reactions sequenced using polyacrylamide gels (63). However, with improvements that have been made to the capillary systems and the gel matrix used for DNA fragment separation there is now little, if any, difference in the read length between polyacrylamide gels and the capillary electrophoresis systems.

MOLECULAR ARRAYS

Molecular arrays are ordered sets of unique DNA probe molecules attached to a solid support (99). Arrays consist of a few different probes to hundreds of thousands of different DNA probes. Each individual probe goes on the array at a precisely defined location on the substrate. The identity of the DNA molecule fixed to each substrate never changes.

Molecular arrays evolved from Southern's work in the 1970s that demonstrated that labeled DNA molecules (called probes today) could be used to interrogate DNA molecules attached to a solid support (100). The Southern blot was a very simple molecular array utilizing one DNA probe. The strategy of the molecular arrays today parallels that of a reverse dot blot, because the probe is immobilized, not the target as in a Southern blot. In general, molecular arrays are described as macroarrays or microarrays, the difference being the size of the DNA probe spots. Macroarrays contain probe spot sizes of about 300 μm or larger and can be easily imaged by existing gel and blot scanners. Microarrays have probe spot sizes typically less than 200 μm in diameter, and these arrays usually contain thousands to hundreds of thousands of probes. Two commonly used methods to produce microarrays are "printing" (spotting) and in situ synthesis procedures such as photolithography, ink-jet, or maskless array synthesis (1, 12, 13, 21, 30, 36, 52, 53, 68). With printed microarrays, about 10,000 DNA probes (PCR products from cDNAs) can be printed onto a microscope slide using high-speed robotics (Fig. 13) (13, 21). Microarrays synthesized by in situ procedures can contain up to 400,000 distinct DNA probes, each in its own 20-μm^2 region, depending upon the technology used. Unlike printed microarrays, in situ microarrays utilize short DNA probes (oligonucleotides typically 8 to up to 90 bases in length) and not PCR products from cDNAs (12, 30, 36, 52, 53, 68).

Two key innovations have led to the practical use of microarrays. First, the use of nonporous substrates, such as glass or silica, has facilitated miniaturization and fluorescence-based detection (99). The second innovation was the development of methods for high-density spatial synthesis of short DNA probes, such as photolithography, ink-jet technology, and maskless array synthesizers (36, 53, 68). Glass or silica has a number of practical advantages over porous membranes such as nylon or nitrocellulose for use in microarrays. Because liquid cannot penetrate the surface of glass or silica, target nucleic acids can find immediate access to the probes without diffusing into pores, thus speeding the rate of hybridization. The washing step which follows hybridization is also unimpeded by diffusion, speeding up the procedure and improving reproducibility. The flatness, rigidity, and transparency of glass or silica improve image analysis, as the locations of the probes can be much better defined than they are on a nylon membrane. High image definition is critical because of the very small scale associated with microarrays. The physical rigidity associated with glass or silica allows their incorporation into cartridges or flow cells for automated processing, which is essential for development of high-throughput assays. Microarrays, with their thousands of probes that determine cDNA binding, allow enormous amounts of data to be collected in a single experiment.

Microarrays are used for two major applications: (i) determination of DNA sequences and mutation detection and (ii) genome-scale determination of gene expression. For DNA sequence analysis it is important that the hybridization between target and probe is able to discriminate a single mismatched base pair; this high degree of discrimination is possible only with short probes (12, 30, 53, 71). Precise sequence discrimination is less important for gene expression microarrays, but in this case, quantitative measurement of gene expression over a wide dynamic range is important. Printed microarrays and high-density spatial microarrays are both commonly used for gene expression assays, while sequencing assays have largely been the province of high-density spatial

FIGURE 13 Expression array schema. Templates for genes of interest are obtained from DNA clones and amplified by PCR. Following purification, the aliquots (≈5 nl) are "printed" on glass microscope slides using a high-speed computer-controlled robot that draws the capture probes from a microtiter plate (left side of figure). Total RNA synthesized from test cDNA (stimulated T cells, for example) and control cDNA (unstimulated T cells) is labeled with different-colored fluorescent dyes during a single round of reverse transcription (right side of figure). The labeled test RNAs are pooled and allowed to hybridize under stringent conditions to the capture probes on the microarray. Laser excitation of the fluorescent dyes yields an emission of known spectra, which is measured using a scanning confocal laser microscope. Data from a single hybridization experiment are viewed as a normalized ratio comparing the intensity of the signal between the two dyes. Significant deviations from background are indicative of increased or decreased levels of gene expression relative to the control sample.

oligonucleotide microarrays. Genome-scale gene expression microarrays are the most commonly used today. An experiment with a single microarray can provide researchers information on thousands of genes simultaneously or thousands of bases of DNA sequence—a dramatic increase in throughput from methods previously available. Today, researchers are able to purchase arrays with probes to thousands of human or mouse genes as well as expression arrays covering the complete genomes of hundreds of different bacteria. The challenge is no longer in the development of microarrays, but in developing experimental designs to exploit the full power of microarrays. Microarray technology has the potential to be as revolutionary to biological research as PCR technology. The potential for microarrays seems virtually limitless (42, 113).

An ingenious microarray that is finding utility in the clinical laboratory today is manufactured by Affymetrix, Inc.,

using their proprietary, light-directed chemical synthesis process called photolithography (Fig. 14) (12, 30, 52, 53, 58, 106). This process combines solid-phase chemical synthesis with photolithographic synthesis techniques employed in the semiconductor industry. Short DNA probes are generated in situ on a glass substrate by combining standard DNA synthesis protocols with phosphoramidite reagents modified with photolabile 5′-protecting groups. Spatially addressable synthesis is accomplished through selective photodeprotection of substrate areas, utilizing a photolithographic mask set in a process similar in principle to that utilized in computer chip manufacturing. These deprotected areas are then activated for chemical coupling. Selective deprotection of multiple areas containing a distinct DNA sequence allows for the simultaneous stepwise synthesis of numerous different short probes. Any probe can be synthesized at any discrete, specified

A.

B.

FIGURE 14 Photolithography. (A) A 1.2- by 1.2-cm glass substrate with photoprotected linker groups. Areas of the glass substrate are selectively illuminated by light passing through a photolitho-graphic mask. Deprotected areas are activated. (B) With nucleoside incubation, chemical coupling occurs at activated positions. This process is repeated until the desired set of probes is obtained. This type of microarray is called a GeneChip. The microarray is placed into a cartridge to facilitate its use in a hybridization assay.

location in the array, and any set of probes composed of the four nucleotides can be synthesized in a maximum of $4N$ cycles where N is the length of the longest probe in the array. For example, the entire set of 10^5 20-nucleotide probes, or any desired subset, can be synthesized in only 80 coupling cycles. Multiple high-density microarrays are synthesized simultane-ously on a large glass wafer. The wafers are then punched out into individual microarrays that are packaged in plastic car-tridges. The cartridges protect the array from the environ-ment and serve as flow cells for automated hybridization and laser scanning. Affymetrix has termed their high-density microarrays GeneChips. Each GeneChip contains from 10,000 to 400,000 different short DNA probes on a 1.2- by 1.2-cm glass wafer. The number of probes that can be put on a chip is limited only by the physical size of the array and the achievable photolithographic resolution (12). The number of probes needed on a chip depends upon the function of the chip. It is staggering to comprehend that the precise sequence and location of each probe on a GeneChip microarray are known. Following hybridization the chip is scanned using a laser scanner (Fig. 15). The fluorescent reporter groups emit light that is proportional to the stringency of hybridization at each probe. Probes with nothing bound emit no light, while probes bound with a perfectly matching target nucleic acid emit 5 to 35 times more light than probes bound with a target nucleic acid that is mismatched by only one base (53). Currently, an Affymetrix GeneChip (Roche AmpliChip CYP450) is FDA approved and available for human cytochrome P450 gene mutation analysis (15). The

Affymetrix instrument on which the cytochrome P450 GeneChip is run has also been FDA approved. Other GeneChips for clinical use are in development.

UTILIZATION OF MOLECULAR TESTS IN THE CLINICAL LABORATORY

Just a few years ago, DNA probes and nucleic acid amplifica-tion techniques were used only in a relatively few high-volume microbiology, histocompatibility, and human genetics laboratories. In these early years molecular tests typically occupied their own niche in the laboratory and did not replace any conventional procedures. Because of their cost and complexity they were only used where they could pro-duce results that could not be duplicated by any other method. However, the application of molecular procedures has become far more common in recent years and will con-tinue to expand rapidly in the coming years. This virtual explosion of molecular utilization is fueled by many factors. These include more readily available reagents, both FDA-approved reagents and ASRs, the shift to real-time amplifi-cation technologies, more choices of automated specimen processing instrumentation, competition leading to decreases in the costs of reagents, the advent of more choices of ampli-fication technology, the virtual elimination of the need for radioactive nucleotides for reporter probes, the scaling up of molecular procedures allowing high-volume analysis, and the volumes of scientific literature demonstrating that these pro-cedures are the "gold standard" for diagnosing many types of

FIGURE 15 Protocol for using the GeneChip. Target DNA or RNA is amplified by PCR using primers with a T3 RNA polymerase promoter sequence in one and a T7 RNA polymerase promoter sequence in the other. The PCR product is transcribed (DNA → RNA) using T7 or T3 RNA polymerase in the presence of fluorescein-labeled rUTP. The fluorescein-labeled RNA is fragmented by heating (95°C for 30 min) in the presence of 30 mM MgCl$_2$. The labeled and fragmented RNA is hybridized to the GeneChip and then analyzed by laser scanning and computer analysis of the resulting fluorescence.

infections and diseases. Today we see molecular tests replacing more conventional technology in the clinical laboratory, and this trend will only continue. *C. trachomatis* and *N. gonorrhoeae* testing is an excellent example of nucleic acid amplification-based testing replacing more conventional technology in the clinical laboratory. The competitive price, superior sensitivity, and relatively easy procedures have led to widespread use of amplification-based testing for *C. trachomatis* and *N. gonorrhoeae* (18, 97, 105).

At this writing, the number of nucleic acid amplification-based procedures that have been approved for use by the FDA exceeds 40 and continues to grow. The number of available ASRs is also growing very fast. A new landmark in molecular diagnostics was reached in early 2005 with FDA approval of the first microarray-based diagnostic test (Roche AmpliChip CYP450). Because of the widespread applicability of molecular technology to many areas of laboratory testing, it is certain that many more commercial molecular kits and reagents of all types will continue to be developed at a rapid pace. It is difficult to compare molecular technology with conventional immunology procedures such as enzyme immunoassay, immunoprecipitation, immunohistology, and flow cytometry with regard to such parameters as ease of use, cost, and appropriateness. This is because one rarely is faced with choosing a method for a particular test where all the available procedures produce the same result with equivalent sensitivity, specificity, accuracy, and precision. Certainly,

more costly molecular diagnostic procedures should not be used to replace procedures currently in place that have been proven to be cost-effective, rapid, sensitive, and reliable. It is important to remember that despite all their sensitivity and speed, nucleic acid amplification procedures will not replace conventional immunological procedures in all situations. This is because the results from nucleic acid amplification procedures mean different things than those from many immunology-based tests. For example, nucleic acid amplification procedures determine if DNA or RNA from a particular organism is present in the specimen. They reveal nothing about the viability of the organism (nucleic acid amplification techniques are capable of detecting DNA from dead organisms) or whether the organism is involved in an infectious process. Serology that clearly demonstrates a rise in titer of antibody to a specific organism strongly suggests involvement in infection.

When making the decision to utilize molecular diagnostic procedures, the institution must take into consideration all the benefits that the new technology may offer (90). The decision should not be based solely on a laboratory price comparison between the conventional assay and a molecular assay. Instead, the decision should take into account the impact new diagnostic technology will have on clinical practice and patient management and the cost savings associated with it. For example, the direct detection of *C. trachomatis* in poor-quality specimens using amplification technology

would lead to more positive results than conventional procedures and better patient management (18). The costs saved by selecting the appropriate antibiotic therapy and preventing infectious complications associated with untreated *C. trachomatis* infections are part of the cost-benefit equation that must be considered when evaluating the use of molecular diagnostic assays. In some cases, in order for the benefits of molecular testing to outweigh their inherent costs, the procedures must be integrated into the assessment of the total patient management picture to realize the impact they have on clinical and financial outcomes. Major financial and patient outcome benefits are achievable because of the ability of molecular tests to replace or reduce the use of less sensitive and less specific tests and cause a decrease in the use of unnecessary diagnostic procedures and ineffective therapies.

FUTURE OF MOLECULAR TECHNOLOGY IN CLINICAL IMMUNOLOGY

Nucleic acid probes, amplification technology, sequencing technology, and microarrays represent some of the greatest advances in the clinical immunology laboratory since the introduction of the flow cytometer. As molecular diagnostics become more widely available, their use in the immunology laboratory will only increase. In the near term, the major application of molecular techniques will be for diagnosis and monitoring the progression of hematological diseases and in histocompatibility testing. In addition, clinical studies have demonstrated that molecular techniques provide prognostic information that directly influences treatment choices in acute leukemia cases. Looking further out into the future, the use of molecular tests will probably lead to further subdivision of the neoplasms that are presently being diagnosed and generate more clinically useful information. The advent of gene therapy will make the identification of specific molecular targets (e.g., the type of junctional species in the *bcr/abl* gene translocation) particularly important so the appropriate therapy can be selected. These applications of molecular technology will only proceed at greater speed in the coming years due to advanced automated analysis using microarrays.

For nucleic acid amplification technology, the most significant challenge that must be addressed with these techniques is false positivity due to contaminating nucleic acids (61, 72, 73, 74, 75, 78). It is absolutely essential that the issue of contamination control be addressed and the integrity of the amplification assay results be ensured. "An ounce of prevention is worth a pound of cure" is especially applicable here; once clinicians have lost faith in a laboratory procedure it can be very difficult to regain. The availability of well-established amplification product inactivation procedures and, especially, the use of closed real-time product detection systems have smoothed the way for more widespread use of this technology in the clinical laboratory (47, 75).

The ability to partially or fully automate molecular diagnostic procedures is another key factor in determining how large a role these procedures will play in the near future (72). Because of their complexity, the high cost of reagents, and the amount of labor involved, many molecular-biology-based tests were very expensive to perform. However, these limitations are rapidly declining because of the production of more automated instrumentation at lower costs by more manufacturers, the availability of more FDA-approved kits, and greatly simplified procedures through the use of real-time target amplification instrumentation. The use of target amplification technology coupled with microarrays will lead to entire assays being done on a small chip. The aim of these miniaturized systems is to create devices that will perform the same assays as are currently carried out in large molecular laboratories much more simply, faster, and at lower cost. Early versions of this all-in-one system can be found in the Gen-Probe Tigris DTS, the Cepheid GeneXpert, and the IQuum Liat System. For a limited number of assays these instruments do the specimen processing, nucleic acid amplification, and product detection (84). Instruments such as these greatly simplify molecular analysis, leaving the operator to just make sure that the appropriate specimen and reagents are being used for the test. In many ways the early years of molecular assays in the clinical laboratory are very similar to early years of immunoassays in the clinical laboratory. The first immunoassays were laborious, expensive, and used exclusively in the research laboratory. But as advances were made in the technology that simplified and automated the procedures, immunoassays became a commonplace in the clinical laboratory.

An especially important challenge that lies ahead for molecular technology in the clinical laboratory is in the area of education (73). Clinical laboratory science training programs at all levels will need to provide more in-depth instruction in molecular diagnostic procedures. Clinical immunologists must be willing to acquire new skills or they may relinquish control of diagnostic molecular biology to laboratory sections that are perceived by some to be more technology oriented, but with little vested interest in immunology. For example, some DNA probe-based tests for infectious diseases are currently being performed in chemistry laboratories. This is due in part to the perception by the manufacturers and laboratory administrators that microbiologists and immunologists are unfamiliar with performing tests based upon nucleic acid chemistry and so they believe that this testing should fall within the realm of the clinical chemist. Undoubtedly, the clinical chemists will be glad to fill this role. The American Association for Clinical Chemistry, through its American Board of Clinical Chemistry, is now offering board certification in molecular diagnostics. Only through education and the ability to meet new challenges will clinical immunologists be able to control the use of molecular techniques and practice of molecular diagnostics in the clinical immunology laboratory.

Introduction

DAVID F. KEREN

<div align="center">6</div>

Section B examines the topics of immunoglobulin production by gene rearrangements, the measurement of immunoglobulins, identification of monoclonal protein products by serum protein electrophoresis and immunofixation, detection of oligoclonal bands in cerebrospinal fluid, and characterization of cryoglobulin, cryofibrinogen, and pyroglobulins.

The chapter by Kipps (chapter 7) examines the genes that code for immunoglobulins. Immunoglobulin heavy-chain constant-region exons, heavy-chain variable-region genes, and light-chain gene complexes are each described. Immunoglobulin gene rearrangements are then discussed in detail, with a focus on their expression in ontogeny and the mechanisms of heavy-chain class switching that generate antibody diversity. Detection methods for immunoglobulin gene rearrangements involving PCR methods and an anchored-reverse transcriptase PCR–enzyme-linked immunosorbent assay are overviewed in the final section of this chapter.

Warren (chapter 8) overviews how the immunoglobulin structure is related to its function and the utility of serum viscosity evaluations. Practical methods for the measurement of immunoglobulins in the clinical laboratory are then described, with a focus on nephelometry, immunoturbidimetry, and the more classic radial immunodiffusion and Laurell rocket techniques. A new method is presented that uses affinity-purified antibodies in a nephelometric format to measure serum free light chains. This method has been useful in detecting light-chain myeloma, AL (light-chain-associated) amyloidosis, and nonsecretory myeloma. The clinical uses of these techniques to identify patients with congenital or acquired humoral immunodeficiency and polyclonal and monoclonal increases in gamma globulin are reviewed. Finally, the ability of high-molecular-weight immunoglobulins to increase viscosity is discussed, along with currently available viscometers.

In chapter 9, Keren and Humphrey review the technical details and clinical applications of serum and urine protein electrophoresis. First, the relevance of protein structure to migration of immunoglobulins and other proteins in an electrophoretic field is discussed. This is followed by an overview of techniques used for gel electrophoresis and capillary zone electrophoresis on serum and urine, complete with details for specimen processing, quality control, and quality assurance. Descriptions of the major proteins identified are presented along with several case examples—including possible causes for false-positive and false-negative results. Finally, detection and measurement of monoclonal proteins in the serum and urine are reviewed in detail.

Katzmann and Kyle (chapter 10) present a thorough review of characterization of monoclonal gammopathies in serum and urine by immunofixation and immunosubtraction. They describe the use of isoelectric focusing with immunoblotting as a useful technique to evaluate cerebrospinal fluid for the presence of oligoclonal bands. They provide details of the methodological background of these techniques and a practical approach to interpret monoclonal gammopathies that takes into account the type and amount of the monoclonal protein present as well as the background of nonmonoclonal immunoglobulins. Artifacts that can cause false-positive results are described. Newer methods such as immunosubtraction and Penta gel (Sebia, Norcross, Ga.) immunofixation are presented as possible alternatives to standard immunofixation. The Mayo Clinic database is used to provide definitive information on the occurrence of the monoclonal gammopathies.

Gorevic and Galanakis (chapter 11) present the state of the art for detecting and measuring cryoglobulins, cryofibrinogenemia, and pyroglobulins. This timely chapter includes details on the importance of hepatitis C virus in both type II and III cryoglobulins. Many practical suggestions are made about the importance of proper handling in the identification and characterization of these temperature-critical samples. The discussion of cryofibrinogens emphasizes their heterogeneity and reviews the clinical indications for their detection. Lastly, pyroglobulins that lack the clinical manifestations of cryoglobulins but can confound laboratory findings in heat-based assays such as those used to inactivate complement are overviewed.

Immunoglobulin Genes

THOMAS J. KIPPS

7

IMMUNOGLOBULIN MOLECULES

Introduction

Immunoglobulins are a heterogeneous group of glycoproteins produced by B lymphocytes and plasma cells. A single person can synthesize 10 million to 100 million different immunoglobulin molecules, each having distinct antigen-binding specificities. This great diversity in the so-called humoral immune system allows us to generate antibodies specific for a variety of substances, including synthetic molecules not naturally present in our environment. Despite the diversity in the specificities of antibody molecules, the binding of an antibody to an antigen initiates a limited series of biologically important effector functions, such as complement activation and/or adherence of the immune complex to receptors on leukocytes (32). Resolution of immunoglobulin structure has revealed how these molecules can have such great diversity in antigen-binding activities while maintaining conserved effector functions, such as complement activation.

Basic Immunoglobulin Structure

The basic unit of the immunoglobulin molecule is composed of two identical heavy chains and two identical light chains. These four polypeptides are held together by disulfide bonds and noncovalent interactions (15, 89). The amino-terminal domains (110 to 120 amino acids) of the heavy and light chains are designated the variable regions, because their primary structures vary markedly among different immunoglobulin molecules (33). The carboxy-terminal domains, however, are referred to as constant regions, because their primary structures are the same among immunoglobulins of the same class or subclass. The amino acids in the light- and heavy-chain variable regions interact to form an antigen-binding site (15, 25). Each four-chain immunoglobulin basic unit has two identical binding sites. The constant-region domains of the heavy and light chains provide stability for the immunoglobulin molecule. The heavy-chain constant regions also mediate the specific effector functions of the different immunoglobulin classes (Table 1) (31).

There are two classes of immunoglobulin light chains, the κ and λ light chains, that differ in the amino acid sequences of the constant-region domains. The ratio of κ to λ chains in adult plasma is 2:1. The main purpose of the light-chain constant region may be to allow for proper assembly and release of an intact immunoglobulin molecule. Soon after synthesis, the antibody light-chain constant region associates with the nascent immunoglobulin heavy chain, releasing the latter from the immunoglobulin-binding protein, or BiP. BiP is a heat shock protein that, in the absence of antibody light chain, binds the first constant-region domain of the newly synthesized heavy chain, thereby retaining the heavy-chain polypeptide in the cell's endoplasmic reticulum (45).

Heavy-Chain Isotypes

Five major classes of immunoglobulin molecules—immunoglobulin G (IgG), IgA, IgM, IgD, and IgE—correspond to the five classes of heavy-chain isotypes (γ, α, μ, δ, and ε). The immunoglobulin molecule of each isotype can contain either a κ or a λ light chain but not both. The physical properties of each of these classes of immunoglobulin molecules are summarized in Table 1.

IgG

IgG is the most abundant of immunoglobulins found in adult plasma, accounting for approximately 80% of the total immunoglobulin. IgG is the predominant antibody produced during a secondary immune response. IgG molecules can penetrate extravascular spaces and cross the placental barrier to provide immunity to the fetus. These molecules have a four-chain 150-kDa immunoglobulin structure with a hinge region that can be attacked by proteolytic enzymes such as papain and pepsin, allowing for separation of the antigen-binding fragment(s), Fab or $F(ab)_2$, from the crystalizable or constant fragment (Fc) of the antibody molecule. Receptors for the Fc (FcR) allow effector cells to recognize target cells coated with a specific antibody (68).

There are four subclasses of IgG: IgG1, IgG2, IgG3, and IgG4. Each subclass has a particular heavy-chain constant region and has different effector functions (31). The most abundant class is IgG1, which accounts for approximately 65% of the total IgG in the plasma. Of the IgG subclasses, IgG1 binds best to FcRI (CD64) and FcRII (CD32), with affinities (K_d) of 10^{-8} M and 5×10^{-7} M, respectively. IgG1 and IgG3 bind equally well to FcRIII (CD16), with a K_d of 2×10^{-6} M. FcRIII is the FcR expressed by natural killer cells (NK cells, or K cells) that mediate antibody-dependent cell-mediated cytotoxicity. Proteins of the IgG4 or IgG2 subclass bind poorly to FcRI (CD64) or FcRII (CD32) and do not bind to FcRIII (CD16) at all. The average half-life of circulating IgG molecules is about 21 days.

TABLE 1 Physical properties of human immunoglobulins

Heavy-chain class (isotype)	Heavy-chain subclasses	No. of heavy-chain domains	Secretory form(s)	Molecular mass (Da)	Antigen-binding valency	Concn (mg/ml) in serum	% of total immunoglobulins
IgG (γ)	$\gamma1, \gamma2, \gamma3, \gamma4$	4	Monomer	150,000	2	8–16	80
IgA (α)	$\alpha1, \alpha2$	4	Monomer, dimer	160,000 (monomer)	2 (monomer)	1.4–4.0	13
				400,000 (secretory protein)	4 (secretory protein)		
IgM (μ)		5	Pentamer	900,000	10	0.5–2.0	6
IgD (δ)		4	Monomer	180,000	2	0–0.4	1
IgE (ε)		5	Monomer	190,000	2	17–450	0.002

IgA

The IgA molecules constitute 13% of the total plasma immunoglobulins. There are two major classes of IgA molecules, designated IgA1 and IgA2, with IgA1 being the more abundant (85% of total IgA in plasma). The half-life of IgA molecules is about 6 days.

IgA antibodies are synthesized during a secondary immune response and contribute to mucosal immunity (9, 43, 54). IgA antibodies are the primary antibodies in saliva, tears, and colostrum and in the fluids of the gastrointestinal, respiratory, and urinary tracts. These secreted immunoglobulins consist of an IgA dimer bound to the joining (J)-chain polypeptide and a secretory protein with a molecular mass of 70 to 80 kDa. The J chain is required for proper hepatic transport of IgA (59). The secretory component is actually part of an FcR for dimeric IgA that is synthesized not by B cells but rather by epithelial cells of organs such as the intestine. This protein facilitates the transport of the IgA protein across the epithelial cell and may protect the secreted IgA molecule from proteolytic digestion by enzymes in the intestinal lumen. Since these molecules do not cross the placenta barrier and do not easily bind to cell surfaces, their main role may be to prevent foreign substances from binding to mucosal surfaces and entering the blood.

IgM

The IgM immunoglobulins comprise about 6% of the immunoglobulins in adult plasma. These molecules have very high molecular weights (thus, they are called macroglobulins), and they are formed by the linking of five identical immunoglobulin units by disulfide bonds and a J chain. IgM is the predominant class found during a primary immune response. The IgM molecules do not cross the placenta and do not enter into extravascular spaces; however, they fix complement more efficiently than the monomeric IgG molecules. The half-life of IgM molecules in plasma is approximately 6 days. In addition, monomeric IgM is the main immunoglobulin expressed on B cells.

IgD

The IgD molecules constitute only 1% of the plasma immunoglobulins and they are expressed on B cells with IgM. These immunoglobulins do not cross the placenta and do not easily penetrate extravascular spaces. However, IgD molecules are found in relatively high concentrations in umbilical cord blood. IgD molecules are thought to function as B-cell membrane receptors for antigens and may help in the recruitment of B cells for specific antigen-driven responses (70).

IgE

IgE has been called a reaginic antibody to denote its association with immediate hypersensitivity. IgE antibodies constitute a very small percentage of the total plasma immunoglobulins (0.002%). Although four human IgE isoforms can be produced by alternative splicing of the epsilon primary transcript (47), the isoforms appear to have similar functions. Plasma IgE levels may increase (5 to 20 times the baseline) in parasitic infections and children with atopic diseases. The Fc portion of the IgE molecule can bind to high-affinity receptors on the surfaces of basophils and mast cells. The cross-linking of IgE antibody by an allergen can induce the release of vasoactive amines; proteases; lipid-derived inflammatory mediators; and cytokines such as tumor necrosis factor alpha, gamma interferon, and interleukins 1, 3, 4, 5, and 6 (see section M, this volume). Studies indicate that the microenvironment of mucosal tissues in allergic disease favors class switching to IgE (21).

IMMUNOGLOBULIN GENE COMPLEXES

Immunoglobulin Heavy-Chain Gene Complex

Immunoglobulin Heavy-Chain Constant-Region Exons

The heavy-chain gene complex is located at band q32 on the long arm of chromosome 14 (39). This complex is composed of approximately 50 functional heavy-chain variable-region genes (V_H genes), more than 120 nonfunctional V_H pseudogenes, 25 functional diversity (D) segments, 6 functional heavy-chain J-region (J_H) minigenes, and exons encoding the constant regions (C genes) for each of the immunoglobulin heavy-chain isotypes (37, 51, 72). The order ($5'{\rightarrow}3'$) of the genes encoding each of the immunoglobulin heavy-chain isotypes is C_μ, C_δ, $C_\gamma3$, $C_\gamma1$, $C_\varepsilon2$ (a nonfunctional pseudogene), $C_\alpha1$, C_γ (a nonfunctional pseudogene), $C_\gamma2$, $C_\gamma4$, $C_\varepsilon1$, and $C_\alpha2$ (Fig. 1). The exons encoding the heavy-chain constant regions and each associated intronic switch region are as depicted in Fig. 1. These exons are labeled and pseudogenes are also indicated in the figure.

Immunoglobulin V_H Genes

The V_H gene segments map within a region of approximately 1,100 kb in size that is telomeric to the J_H and constant-region exons (Fig. 1). Each V_H gene can be assigned to one of seven V_H gene subgroups. Each subgroup comprises V_H genes with more than 80% nucleic acid sequence homology. Genes of the V_H1, V_H5, and V_H7 subgroups have similarities

Telomere

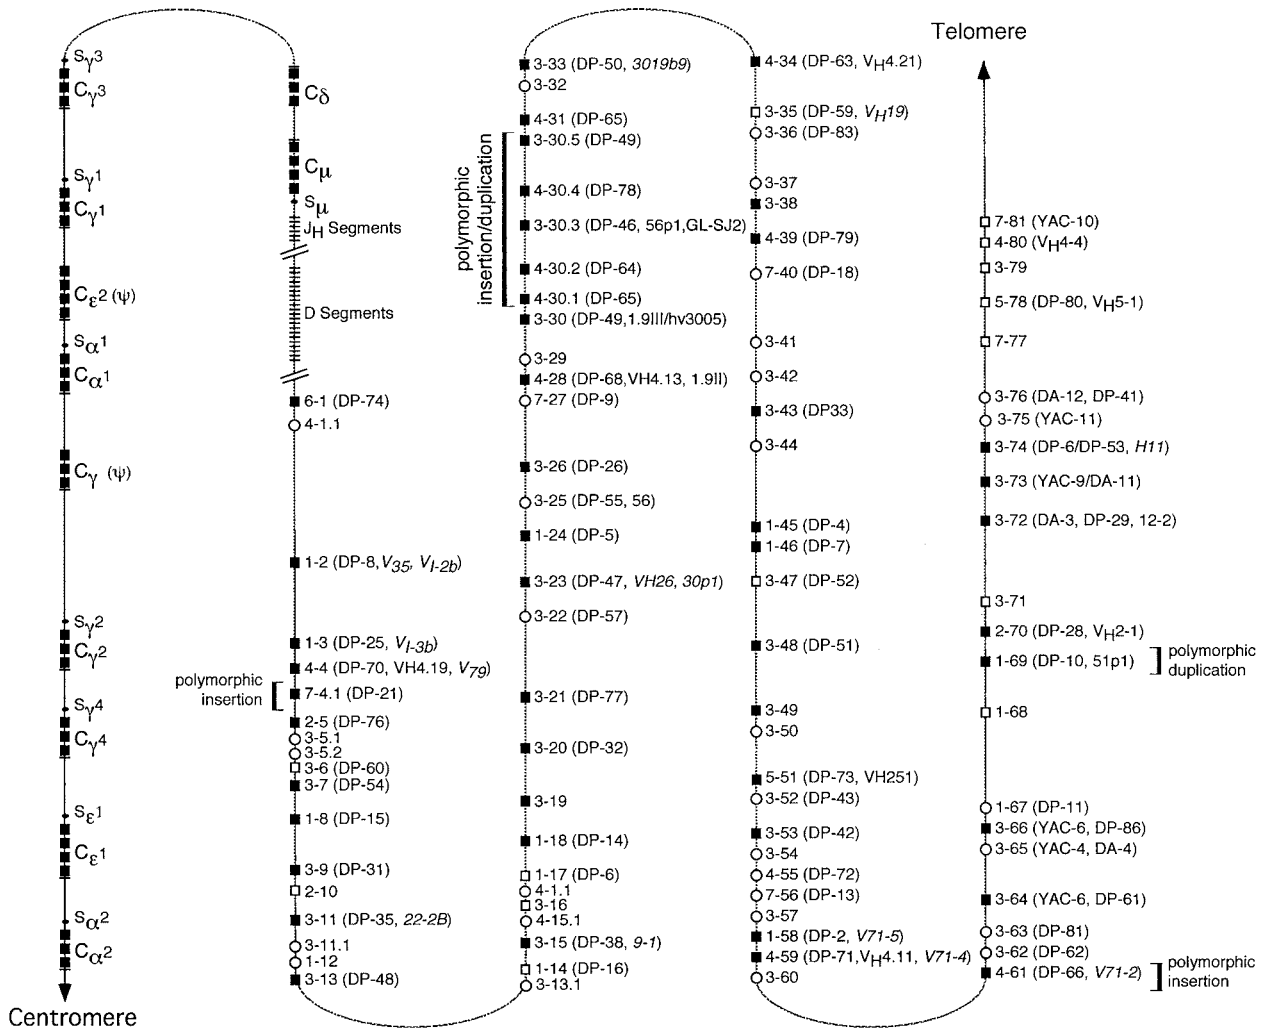
Centromere


FIGURE 1 Immunoglobulin heavy-chain gene complex. The heavy-chain exons encoding the constant regions are represented by black boxes, and the associated intronic switch (S) regions are indicated by lines. A ψ next to the heavy-chain isotype designation indicates that the gene is a pseudogene. J$_H$ segments and D segments are indicated by lines. Each V$_H$ gene locus is labeled on the right of each symbol. Identified polymorphic insertions and/or duplications are indicated with brackets. Black squares represent V$_H$ gene loci that are known to be functional. White circles represent V$_H$ pseudogenes. At the ends of the line connecting the symbols are arrows that indicate the direction to the centromere or the telomere. The white boxes denote loci that apparently are functional V$_H$ genes but that rarely, if at all, are expressed into protein. The arrows indicate the direction of transcription of the gene segments.

in primary structure, suggesting a common ancestral origin in evolution, whereas the V$_H$2, V$_H$4, and V$_H$6 families share similarities that allow them to be classified into a different clan (7, 38). The V$_H$3 genes constitute their own discrete clan.

The immunoglobulin V$_H$ genes of each subgroup, except the immunoglobulin V$_H$6 gene, are interspersed throughout the immunoglobulin heavy-chain locus. By convention, the loci of each of the various V$_H$ genes are assigned a number corresponding to the V$_H$ gene subgroup followed by a hyphen and then the rank order distance from the heavy-chain D segments on chromosome 14 (Fig. 1). The immunoglobulin V$_H$6 subgroup has only one functional V$_H$

gene. Since this is the first V$_H$ gene telomeric to the D segments, this gene is called V$_H$6-1 (Fig. 1). There are an additional 50 loci that have been identified as functional V$_H$ genes (83) (Fig. 1). The largest subgroup is V$_H$3, with 22 to 24 functional genes. The next largest are the V$_H$1 and V$_H$4 subgroups, each with 8 to 11 functional genes. The V$_H$2, V$_H$5, and V$_H$7 subgroups each have one to three functional genes. Of the 51 functional V$_H$ genes, there are four V$_H$ loci that may have noncoding-region defects that preclude their translation into protein and/or have V$_H$ genes that are expressed at very low frequency relative to other V$_H$ genes (Fig. 1). Also, interspersed among the functional V$_H$ genes are several nonfunctional pseudogenes (Fig. 1).

The extent of identified genetic polymorphism varies among the different immunoglobulin V_H gene loci. Some immunoglobulin V_H gene loci, e.g., V_H6-1, V_H5-51, and V_H4-34, are highly conserved (65, 73). Indeed, the single-copy immunoglobulin V_H6 gene, V_H6-1, is conserved even among higher primates (52). Other loci have been used to identify genetic polymorphic variations. These allelic variations are of two different types. The first type of genetic polymorphism is the classic form in which there are two or more alleles at a single locus, each differing from one another in one or more nucleotide bases. For example, 1.9III and hv3005 differ from each other at several nucleotide bases and have only 98.8% overall homology (98.3% coding-sequence homology), but are alleles of locus V_H3-30. The second type of allelic variation results from duplications, insertions, and/or deletions of whole segments of immunoglobulin V_H genes within the immunoglobulin heavy-chain gene complex. Duplication of an immunoglobulin V_H gene(s) results in some haplotypes' having identical immunoglobulin V_H genes belonging to distinct loci, each possibly differing from their respective alleles by one or more nucleotide base substitutions. For example, there may be an insertion in and about locus V_H3-30, in part consisting of another copy of this gene. As a result, alleles of V_H3-30, e.g., 1.9III and hv3005, also may be alleles of locus V_H3-30.5 in haplotypes containing this insertion. On the other hand, some haplotypes are missing gene loci altogether. For example, allele frequencies for hv3005 (V_H3-30b) and 1.9III (V_H3-30) in the Caucasian population are 0.19 and 0.72, respectively (56). An additional haplotype(s) with an allele frequency of 0.08 lacks either 1.9III or hv3005 and thus apparently is a blank haplotype for this locus. Genetic disequilibrium also is noted for certain groups of V_H genes in a given haplotype. For example, 56p1 (V_H3-30.3) is an insertion or deletion element that has been observed only with haplotypes carrying one or two copies of 1.9III. The V Base website (http://vbase.mrc-cpe.cam.ac.uk/), the international ImMunoGeneTics information system (http://imgt.cines.fr:8104/), and the international ImMunoGeneTics project of the European Bioinformatics Institute (http://www.ebi.ac.uk/imgt/) provide Internet databases and listings of V_H gene maps and alleles.

The relative expression level of each functional V_H gene is not uniform. Certain V_H genes, e.g., V_H3-23, V_H4-34, and V_H1-69, are overexpressed relative to other V_H genes (56, 74). Each of seven V_H3 genes (V_H3-23, V_H3-30, V_H3-30b, V_H3-30.3, V_H3-33, V_H3-15, and V_H3-11) accounts for 8 to 20% of the V_H3 gene rearrangements, whereas the remaining functional V_H3 genes contribute to less than 3% of the rearrangements. Some of the V_H genes that encode a disproportionate share of the immunoglobulin expressed by normal adults also are polymorphic. For example, the V_H genes V_H4-31 and, to a lesser extent, V_H30.4 are deleted in some persons but, when present, encode a significant proportion of the heavy-chain repertoire (56).

Immunoglobulin Light-Chain Gene Complexes

κ Light-Chain Complex

The κ light-chain gene complex is contained within band p12 on the short arm of chromosome 2 (Fig. 2). This gene complex consists of approximately 40 functional κ light-chain variable-region genes (V_κ genes), more than 30 nonfunctional V_κ pseudogenes, 5 J_κ segments, 1 constant-region exon, and 1 κ-deleting element (Kde) (Fig. 2) (34, 82).

The V_κ genes in the κ light-chain gene complex are found in two regions centromeric to the J_κ and C_κ exons,

each region spanning approximately 500 kb. Approximately 800 kb separates the two regions (Fig. 2). The region proximal to J_κ and C_κ, designated the p region, contains 40 V_κ gene segments (B3 → B1, L13 → L1, A30 → A15, and O18 → O11), and the distal region, designated the d region, contains 36 gene segments (O1 → O10, A1 → A14, and L14 → L25). Thirty-two of the 76 V_κ genes are pseudogenes (Fig. 2). The d region apparently arose through duplication of a large portion of the p region (47). Consequently, there are 33 pairs of V_κ genes that have 95 to 100% nucleic acid sequence homology, accounting for 66 of the 76 V_κ genes in the κ light-chain complex (92). The V_κ genes can be grouped further into four clusters, A, B, L, and O, three of which (A, L, and O) are duplicated and found in both the J_κ-proximal p region and the J_κ-distal d region. The B cluster, containing V_κ genes B1, B2 (EV15), and B3 (DPK26), is found only in the J_κ-proximal p region.

The V_κ genes in the κ light-chain gene complex can be categorized into three main subgroups (1 to 3) and several smaller subgroups (4, 5, 6, and 7) based on nucleotide sequence homology (28, 44). The largest subgroup is V_κ1, with 21 functional genes (Fig. 2). The next largest subgroups are V_κ2, with 11 functional genes, and V_κ3, with 7. There are three functional genes in the V_κ6 subgroup, and one each in the V_κ4 and V_κ5 subgroups. The V_κ7 subgroup has only one nonfunctional pseudogene.

As in the V_H locus, there are several prominent alleles identified in the V_κ gene locus. The V_κ genes coding for segments O12, L4, and L16 (humkv328/humkv328h2) each have several alleles, some with open reading frames and others with stop codons (10, 41). Moreover, the V_κA2 gene also is polymorphic, with some alleles having defective promoters that preclude their translation into protein. Inheritance of such defective V_κA2 alleles has been associated with an increased risk for serious infection with type b *Haemophilus influenzae*, suggesting that the polymorphic variations in the germ line repertoire can influence the susceptibility to infectious disease (16).

As with the immunoglobulin V_H genes, the expression of V_κ genes is not uniform. Eleven of the nearly 30 known functional V_κ genes encode most of the κ light-chain variable regions expressed in the normal adult repertoire (10). Moreover, of the 44 genes that are potentially functional, only 28 have been found commonly to encode κ light-chain variable regions (Fig. 2) (10, 41). This raises the possibility that some of the potentially functional V_κ genes have defects that preclude their ability to undergo light-chain gene rearrangement or to be translated into protein. Alternatively, these genes may have an extremely low expression frequency.

λ Light-Chain Gene Complex

The λ light-chain gene complex is located at band q11.12 on the long arm of chromosome 22. These λ constant-region genes are telomeric to the λ variable-region genes. Originally, the isotypes they encoded were designated Mcg$^+$, Ke$^-$ Oz$^-$, Ke$^-$ Oz$^+$, and Ke$^+$ Oz$^-$, depending on their reactivity with Mcg, Kern, and Oz antisera that were raised against λ Bence Jones proteins of patients with multiple myeloma (26). These isotypes are now designated C_λ1, C_λ2, C_λ3, and C_λ7, respectively. In total, there are 7 to 10 C_λ genes telomeric to the V_λ genes, depending on the haplotype (20, 87). Each C_λ gene is associated with its own J_λ segment. The most prevalent haplotype contains four functional C_λ genes (C_λ1, C_λ2, C_λ3, and C_λ7, encoding the Mcg, Ke$^-$ Oz$^-$, Ke$^-$ Oz$^+$, and Ke$^+$ Oz$^-$ isotypes, respectively) and three pseudogenes (C_λ4, C_λ5, and C_λ6) (Fig. 2) (11, 87).

FIGURE 2 Immunoglobulin light-chain gene complexes. The left panel depicts the κ light-chain gene complex on chromosome (Chr) 2p11-12. The black rectangles in this figure represent the Kde or the $C_κ$ constant-region exon as indicated to the right of each rectangle. The $J_κ$ segments are indicated by lines labeled "$J_κ$." The κ light-chain enhancer (labeled E) is located between the $J_κ$ segments and the $C_κ$ exon. The $V_κ$ genes that can encode functional κ light-chain variable regions are represented by black boxes, and the $V_κ$ pseudogenes are indicated by white boxes. Immediately adjacent to and to the right of each box is a Roman numeral that denotes the subgroup to which the respective $V_κ$ gene belongs, followed by its designated name. The arrows indicate the direction of transcription of the gene segments. A *p* is used to label the proximal arm of the $V_κ$ gene complex, and *d* is used to label the distal arm. The right panel depicts the λ light-chain gene complex on chromosome 22q11.2. The black boxes represent functional $J_λ$-$C_λ$ exons, whereas white boxes represent $J_λ$-$C_λ$ pseudogenes. Each of the $J_λ$-$C_λ$ exon pairs is indicated to the right of each symbol. Each $V_λ$ gene is represented by a black box. To the right of each box is a tentative designation indicating the subgroup (first number) followed by a number indicating the rank order of the particular $V_λ$ in the λ light-chain gene complex. The $V_λ$ genes are organized into three clusters, designated A, B, and C, that are indicated to the left of each cluster. The gene encoding VpreB is located near the C cluster. The direction to the telomere or the centromere is as indicated at the top. The arrows indicate the direction of transcription of the gene segments.

There are about 41 functional V_λ genes and more than 30 nonfunctional V_λ pseudogenes that are arranged into 10 subgroups (35, 64, 91). Each subgroup comprises V_λ genes with more than 75% nucleotide sequence homology (6, 64) (Fig. 2). Like that of the κ light-chain locus, the sequence organization suggests that large DNA duplications contributed to the generation of the germ line repertoire of V_λ gene segments (35). The V_λ genes are clustered into three large DNA segments located within 860 kb of the J_λ and C_λ genes (18, 35, 91). The cluster most proximal to the J_λ-C_λ exons, designated cluster A, comprises 18 functional V_λ genes, belonging mostly to the $V_\lambda2$ and $V_\lambda3$ gene subgroups, designated 3-1 (3r, DPL23) through 2-33 (2f, DPL14) in Fig. 2. The next cluster, cluster B, contains 15 functional V_λ genes of the $V_\lambda1$, $V_\lambda5$, $V_\lambda7$, and $V_\lambda9$ gene subgroups, designated 1-36 (1a, DPL1) through 5-52 (5b). The third cluster, cluster C, contains six functional V_λ genes of the $V_\lambda4$, $V_\lambda6$, $V_\lambda8$, $V_\lambda10$, and $V_\lambda11$ gene subgroups, designated 10-54 (10a) through 4-69 (4b) (Fig. 2). As in the other immunoglobulin gene complexes, there are multiple nonfunctional pseudogenes interspersed between these functional V_λ genes in all three clusters. Also, located on the telomeric end of these clusters is the exon encoding VpreB.

As noted for the relative expression of individual V_H and V_κ genes, the expression of individual V_λ genes appears to be nonrandom. V_λ genes of the $V_\lambda1$ and $V_\lambda3$ subgroups are used most frequently. These subgroups encode approximately 44 and 40%, respectively, of the λ light-chain immunoglobulins in normal adult sera (1). This proportionate representation apparently is not observed in B-cell plasmacytic disorders. Although the $V_\lambda2$ subgroup was identified for 3% of the λ light-chain immunoglobulins in normal adult sera, it accounted for 40% of the λ Bence Jones proteins and 60% of the λ macroglobulins from patients with Waldenström macroglobulinemia in one survey (1).

IMMUNOGLOBULIN GENE REARRANGEMENT

Immunoglobulin Gene Rearrangement and Expression in Ontogeny

As B cells develop, they generally first rearrange their immunoglobulin heavy-chain genes (84). One or more D segments rearranges to become juxtaposed with a single J_H element. This generates a D-J_H complex that then may rearrange with any one of some 50 functional V_H genes.

Subsequently, gene rearrangements occur within the light-chain gene complexes. One of the 40 functional V_κ genes rearranges with any one of five J_κ segments. Should these gene rearrangements fail to generate a functional V_κ-J_κ exon, the Kde generally rearranges to a site in or immediately downstream of the V_κ-J_κ exon, thus deleting the κ light-chain constant-region exon (22). Many of the V_κ genes in the *p* region are in the orientation opposite that of the J_κ segments, thus requiring that the V_κ exons in this region undergo inversion during immunoglobulin gene rearrangement (Fig. 2). Subsequent to κ light-chain gene rearrangement, one of the functional V_λ exons can rearrange with any one of the four functional J_κ-C_λ exons to generate a gene that can encode a λ light chain (Fig. 3) (87).

Precursor B cells that have only D and J_H elements rearranged are referred to as progenitor B cells, or pro-B cells. The term pre-B cells is reserved for precursor B cells that have completed immunoglobulin heavy-chain gene rearrangement and have a functional V_H-D-J_H complex.

Both pro-B cells and pre-B cells generally have immunoglobulin light-chain loci in the germ line configuration.

Nevertheless, pre-B cells express small amounts of immunoglobulin μ chains in association with "surrogate" λ light chains. One of these surrogate λ light chains is called λ_5. λ_5 has similarity with known C_λ light-chain domains (53). Another surrogate λ light chain is called VpreB, because it resembles a variable-region domain but bears an extra N-terminal protein sequence. Both proteins are encoded by genes located on chromosome 22. The λ_5 gene is situated within a λ-like locus that is telomeric to the true λ light-chain locus. The VpreB gene is located within the cluster of immunoglobulin V_λ genes defined by breakpoints of chromosomal translocations found in a few leukemias and lymphomas (53). VpreB and λ_5 pair with the μ heavy chains to form a primitive immunoglobulin receptor that may be expressed on the surface membrane of the developing pre-B cell together with CD79a and CD79b (80). Monoclonal antibodies that recognize λ_5 or VpreB specifically bind to pre-B cells and can react with B-lineage acute lymphocytic leukemias (86).

Expression of the surrogate light chains plays a critical role in normal B-cell development. This is underscored by studies on transgenic mice that lack functional λ_5 genes (40). In these mice, B-cell development in the marrow is blocked at the pre-B-cell stage, thereby markedly reducing the numbers of functional mature B lymphocytes in the blood and lymphoid tissues (8). Similarly, humans that have inactivating mutations in the λ_5 genes on both alleles of chromosome 22 have agammaglobulinemia and markedly reduced numbers of B cells (57).

Under normal conditions, a B lymphocyte or plasma cell synthesizes only one species of light chain and heavy chain, even though the cell has two different sets of each of the immunoglobulin gene complexes that initially undergo seemingly independent immunoglobulin gene rearrangements. This is achieved by limiting each B-cell clone to the expression of only one immunoglobulin heavy-chain allele and one light-chain allele. This phenomenon is called allelic exclusion. Although some B-cell leukemias may lack allelic exclusion and express both immunoglobulin alleles (66), allelic exclusion generally is observed with most B-cell tumors.

Genetic Basis for Immunoglobulin Gene Rearrangement

Each germ line V gene, D element, and J segment is flanked by recognition sequences that are required for site-specific recombination. These sequences typically consist of a conserved palindromic heptamer (e.g., 5′ CACAGTG 3′), a nonconserved spacer of 12 or 23 bp, and an A/T-rich nonamer (5′ ACAAAAACC 3′) (46). Joining occurs between segments flanked by recognition sequences with unequal spacers (19, 77, 84). This is referred to as the 12/23 joining rule. Because all segments of a particular type (e.g., V gene segments) are flanked by one type of signal sequence and all the segments to which they should be joined (e.g., J segments) are flanked by the opposite type of signal sequence, the 12/23 rule ensures that the joining will be restricted to events that could be biologically productive. Although each spacer varies in sequence, the length of each spacer is conserved and corresponds to one or two turns of the DNA double helix. Each spacer serves to bring the heptamer and nonamer sequences to the same side of the DNA helix, where they both can be bound by a protein complex that catalyzes recombination. These heptamer-spacer-nonamer sequences are often called recombination signal sequences, or RSS (19, 77).

HEAVY CHAIN
KAPPA CHAIN
LAMBDA CHAIN
FIGURE 3 Immunoglobulin gene rearrangement. Diagonal double lines indicate that there is a large distance between flanking genes depicted as rectangular boxes (not drawn to scale). Depicted on the left side of each immunoglobulin gene complex are exemplary immunoglobulin V_H genes (V_H', V_H'', and V_H'''), immunoglobulin κ light-chain genes (V_κ', V_κ'', and V_κ'''), or immunoglobulin λ light-chain genes (V_λ', V_λ'', and V_λ'''). D designates the diversity gene segments of the antibody heavy-chain locus. J_H, J_κ, and J_λ indicate the joining gene segments of the antibody heavy chain, κ light chain, and λ light chain, respectively. C_μ and C_δ are the constant-region exons of the μ and δ heavy chains, respectively. Below each is a possible immunoglobulin gene rearrangement comprising a V_H-D-J_H segment for the antibody heavy-chain gene or a V_κ-J_κ or a V_λ-J_λ segment for the κ or λ light-chain gene, respectively. Below the representative λ constant-region loci in row C are listed the names of the lambda nonallelic genetic markers, Mcg, Ke^- Oz^-, Ke^- Oz^+, and Ke^+ Oz^-, on $C_\lambda1$, $C_\lambda2$, $C_\lambda3$, and $C_\lambda7$, respectively. As indicated, $C_\lambda4$, $C_\lambda5$, and $C_\lambda6$ are pseudogenes (ψ gene) that do not encode protein.

Somatic V-region gene recombination involves introduction of double-stranded DNA breaks at RSS, juxtaposition of the broken ends, and then religation through a process called nonhomologous DNA end joining (NHEJ). The commonest mode of recombination involves the looping out and deletion of the DNA between two gene segments on the same chromosome. The 12- and 23-mer-spaced RSS are brought together by interactions between proteins that specifically recognize the length of the spacer between the heptamer and nonamer signals, thus accounting for the 12/23 joining rule (19, 77). The two DNA molecules then are broken and religated (23). The ends of the heptamer sequences are joined precisely in a head-to-head configuration to form a signal joint in a circular piece of DNA that then is lost from the genome when the cell divides. However, when the RSS are oriented in the same direction along the chromosome, the segments undergo recombination via inversion, in which case the intervening DNA is retained.

The first cleavage step requires a specialized heterodimeric endonuclease encoded by *RAG-1* and *RAG-2* (60, 61). The RAG-1 endonuclease has sequence similarities to bacterial topoisomerases that catalyze the breakage and rejoining of DNA. *RAG-1* and *RAG-2* are coexpressed normally only in developing lymphocytes that are undergoing receptor gene rearrangement. Mice with either of these genes knocked out cannot undergo immunoglobulin or T-cell receptor gene rearrangements and consequently fail to produce mature B or T lymphocytes (75). Mutations that impair but do not completely abolish the function of *RAG-1* or *RAG-2* in humans result in a form of combined immune deficiency called Omenn syndrome (88).

The RAG-1/RAG-2 endonuclease recognizes either the 12-mer-spaced or the 23-mer-spaced RSS and then introduces double-stranded DNA breaks. After introducing these breaks, the RAG-1/RAG-2 complex remains bound to the DNA. Mutations that affect the ability of the RAG proteins to bind and to maintain the broken ends in a stable postcleavage complex can lead to misrepair of the double-stranded breaks, thereby enhancing the risk for oncogenic chromosomal aberrations (29, 85). Involved in the processing and juxtaposition of these double-stranded breaks are several proteins, including the high-mobility-group proteins 1 and 2 (HMG1 and HMG2). HMG1 and HMG2 are widely expressed, abundant nuclear proteins that bind and bend DNA without sequence specificity, thereby playing an important role in the assembly of nucleoprotein complexes involved in DNA repair and transcription (81). HMG1 may facilitate the bending of the DNA to allow for the components of one double-stranded break-RAG complex to bind and to cleave the DNA at a different RSS, thus bringing together two disparate RSS in accordance with the 12/23 joining rule (19, 77).

The double-stranded break-RAG complex also binds at least six other proteins, including Ku70, Ku80, DNA-dependent protein kinase (DNA-PK), XRCC4, DNA ligase IV (Lig4), and Artemis (48). DNA-PK is a serine-threonine protein kinase that is activated by DNA double-stranded breaks and is essential for the normal repair of DNA breaks induced by ionizing radiation, chemical agents, or VDJ recombination (49, 79). Mice that are deficient in DNA-PK can make only trivial amounts of immunoglobulin or T-cell receptors and are called severe combined immunodeficiency mice, or SCID mice (36). Mice deficient in Artemis have a "leaky" SCID phenotype and develop some T and B cells in later life (79). Ku-deficient mice also are deficient in T and B cells but have small stature and other nonimmunologic defects, suggesting that the Ku proteins also play important roles in normal development (24, 63). Defects in mice resulting from mutations in either Ku, XRCC4, Lig4, Artemis, or DNA-PK genes predispose to lymphoma (2, 4).

The process of recombination allows for the generation of junctional diversity in the sequences of the rearranged gene segments. DNA ends generated by the RAG-1/RAG-2 endonuclease cleavage reaction are each fused by the NHEJ pathway involving the proteins listed in the preceding paragraphs. The hairpinned termini of gene segments that give rise to the coding joint are each subsequently cleaved at random sites by an endonuclease. Cleavage of a hairpin away from its apex generates an overhanging flap, which, if incorporated into the joint, results in the addition of palindromic nucleotides that contribute to junctional diversity. The opened hairpin ends can be modified further by nucleases that can remove a self-complementary overhang or cut further into the original coding sequence. In addition, a lymphocyte-specific enzyme, terminal deoxynucleotidyl transferase, can add non-template-encoded nucleotides (42). Finally, additional junctional diversity comes from the nucleolytic activities that remove potential coding-end nucleotides prior to the final ligation of the DNA breaks into one intact recombination joint (23).

Heavy-Chain Class Switching

During differentiation, a single B lymphocyte can synthesize heavy chains with different constant regions coupled to the same variable region (76). As pre-B cells develop into mature B cells, intact IgM monomers are inserted into the plasma membrane, followed by IgD molecules with the same antigen-binding specificity. The IgM and IgD constant-region genes are closely linked in embryonic DNA and may be transcribed together. The differential splicing of the transcript allows the simultaneous synthesis of the two immunoglobulin heavy chains from a single species of RNA.

The switch from IgM to IgG, IgA, or IgE requires active transcription of the downstream constant-region exons encoding the switched immunoglobulin isotype. This requires prior interaction of B lymphocytes with an antigen or mitogen and ligation of CD40 via the ligand for CD40 (CD154) expressed by activated T cells. Patients with inherited defects in CD40 or CD154 have an immune deficiency syndrome (hyper-IgM syndrome type I) characterized by normal to high serum levels of IgM and extremely low serum levels of other immunoglobulin isotypes (14, 17). Interleukins provided by antigen-reactive T lymphocytes strongly influence (i) which B cells differentiate into IgM-secreting plasma cells and (ii) which B cells switch their immunoglobulin heavy-chain isotype, e.g., to IgG or IgA (3, 76).

Immunoglobulin class-switching recombination (CSR) occurs in or near the α switch region upstream of the μ gene and any one of the switch regions of the other heavy-chain isotype genes (Fig. 1). The μ switch region, designated S_μ, consists of approximately 150 repeats of the sequence $(GAGCT)_n(GGGGGT)$, where n is generally three but can be as many as seven. The sequences of the other switch regions (S_γ, S_α, and S_ε) are similar in that they also contain repeats of the GAGCT and GGGGGT sequences. The switch in heavy-chain classes results from DNA recombination between S_μ and S_γ, S_α, or S_ε accompanied by the deletion of intervening DNA segments and the apposition of the previously rearranged variable-region gene next to the new constant-region gene.

In contrast to VDJ recombination, which occurs mostly in the G_0 and/or G_1 stage of the cell cycle, CSR seems to require DNA replication. Also, unlike VDJ recombination, CSR also requires expression of activation-induced deaminase (AID), an enzyme expressed in activated B cells that also is required for somatic hypermutation (see "Generation of Antibody Diversity," below) (27, 58). Patients with inherited defects in AID have an immune deficiency syndrome (hyper-IgM syndrome type II) characterized by relatively high serum levels of IgM, and negligible serum levels of other immunoglobulin isotypes (69). AID is expressed in germinal centers of the lymph nodes and spleen, the sites where CSR takes place in B cells activated in response to an antigen (50). AID most likely deaminates the closely positioned cytosines (dC) in the S-region DNA, converting the dC into uracils (dU), which in turn are removed by uracil-DNA glycosylase (UNG). The importance of UNG is underscored by patients who have inherited defects in this enzyme, resulting in an autosomal recessive form of the hyper-IgM

immune deficiency syndrome similar to that of patients with inherited defects in AID (30, 33). The abasic sites generated by UNG are cleaved by apurinic/apyrimidinic endonuclease, resulting in closely positioned staggered nicks in the DNA that may result in double-stranded DNA breaks (5). The end-processing, repair, and joining mechanisms for these DNA breaks apparently involve mechanisms and proteins similar to those involved in NHEJ used for VDJ recombination. Because the CSR occurs in the intron between the variable-region exon and the exon encoding the first constant-region domain, this process does not generate mutations in the regions encoding the variable or constant regions of the newly generated immunoglobulin heavy chain (90).

GENERATION OF ANTIBODY DIVERSITY

Several mechanisms contribute to the generation of diversity among immunoglobulin polypeptide variable regions (84). These are (i) the presence in the germ line of multiple V, J, and D gene segments; (ii) the random joining of these DNA segments to produce a complete variable-region exon; (iii) uncorrected errors made during the recombination process; (iv) the coming together of the heavy- and light-chain polypeptides to produce a complete immunoglobulin monomer capable of binding an antigen; and (v) somatic mutations within the rearranged DNA segments themselves. The last of these occurs through a process called somatic hypermutation.

Somatic hypermutation is not active in all B cells and cannot be triggered merely by mitogen-induced B-cell activation. However, during discrete stages of B-cell differentiation, expressed immunoglobulin V genes can incur new mutations at rates as high as 10^{-3} base changes per base pair per generation over several cell divisions, particularly during the secondary immune response to an antigen. Hypermutations begin on the 5′ ends of rearranged V genes downstream of the transcription initiation site and continue through the V gene and into the 3′-flanking region before tapering off. As such, the mutations are clustered in the region spanning from 300 bp 5′ of the rearranged variable-region exon to approximately 1 kb 3′ of the rearranged minigene J segment. Mutations frequently are clustered around hot spots defined by the primary DNA sequence. The sequence RGYW (R, purine [A or G]; Y, pyrimidine [C or T]; W, A or T) and its complement, for example, are hot spots for mutation that are conserved among species (55, 71).

Somatic hypermutation requires the activity of AID through a process that has some similarity to CSR (13). In addition to having the hyper-IgM immune deficiency syndrome type II, patients that have inherited defects in AID have B cells that lack the capacity to undergo somatic hypermutation (58). As with CSR, somatic hypermutation requires active transcription of the genes undergoing mutation. AID most likely deaminates the dC in the region encompassing the rearranged variable-region gene, converting the dC into dU, which are converted into T after DNA replication, giving rise to CG-to-T or -A transitions. Alternatively, the dU are removed by UNG, resulting in abasic sites that subsequently may be cleaved by apurinic/apyrimidinic endonuclease. The removal of uracil generates staggered nick cleavage of the DNA. Repair of these staggered nicks may involve low-fidelity DNA synthesis, giving rise to frequent mutations. DNA-cleaving enzymes and DNA repair enzymes (e.g., mismatch repair enzymes, base excision repair enzymes, proteins involved in NHEJ, etc.) form a complex called the mutasome that also apparently binds the target DNA to reduce

its tendency to incur complete double-stranded DNA breaks. As a consequence of this process, mostly transitional mutations are introduced at high frequencies into the expressed immunoglobulin V genes, as well as into other transcriptionally active genes with hot spots that can serve as a substrate for AID, UNG, and the mutasome (55, 78). Subsequent selection of the B cell and its daughter cells that express mutated V genes encoding an immunoglobulin variable region with improved fitness for binding antigen allows for "affinity maturation" of the antibodies expressed during the immune response to antigen (62). Such selection enhances the frequency of nonconservative base substitutions in the DNA sequences encoding the complementarity-determining regions that serve as the contact sites for antigen binding (12).

DETECTION OF IMMUNOGLOBULIN GENE REARRANGEMENTS

Analysis for immunoglobulin gene rearrangements can detect clonal immunoglobulin gene rearrangements. Immunoglobulin gene rearrangement irreversibly alters the genomic DNA of the developing B cell and its descendant daughter cells. Because of the many different immunoglobulin gene rearrangements possible, a B cell's particular type of immunoglobulin gene rearrangement can serve as a clonal marker.

Southern Blot Hybridization

The Southern blot hybridization technique frequently is used to examine for clonal immunoglobulin gene rearrangement secondary to an abnormal expansion of cells from a single B-cell clone. In this technique, genomic DNA is cleaved at specific sites with a restriction enzyme(s) to generate restriction fragments of various sizes that can be resolved with respect to length via agarose gel electrophoresis. After electrophoresis, the DNA fragments inside the gel are denatured and then blotted onto a nitrocellulose or nylon membrane. The membrane then is hybridized to a ^{32}P-radiolabeled probe specific for a region of the immunoglobulin gene of interest. Polyclonal B-cell populations reveal nonrearranged germ line bands in Southern blot analysis, as each B-cell clone contributes to only a small fraction of the total genomic DNA isolated from normal lymphoid tissue. However, if the population is monoclonal, non-germ line bands will be observed using probes specific for sites contiguous to the site of recombination (i.e., the J_H region). Such non-germ line bands indicate that the lymphoid tissue contains an expansion of one B-cell clone.

PCR

More-sensitive methods for detecting immunoglobulin gene rearrangements, such as PCR, can be used to examine for residual cells of a malignant B-cell clone following antitumor therapy. PCR using sense-strand oligonucleotide primers corresponding to an immunoglobulin V gene subgroup (Table 2) together with antisense-strand oligonucleotide primers corresponding to the relevant J-region or constant-region exon can amplify the rearranged V gene in genomic DNA or cDNA, respectively.

Because these gene segments are separated by large stretches of intervening DNA in germ line DNA, PCR with genomic DNA and primers specific for a V gene subgroup and the J gene segment(s) will fail to amplify any immunoglobulin genes unless the genes have first undergone rearrangement. However, after immunoglobulin gene rearrangement, the variable-region gene leader sequence

[a]Positions at which either of two nucleotides is used to represent most, if not all, of the V genes in a given subgroup are indicated in parentheses.

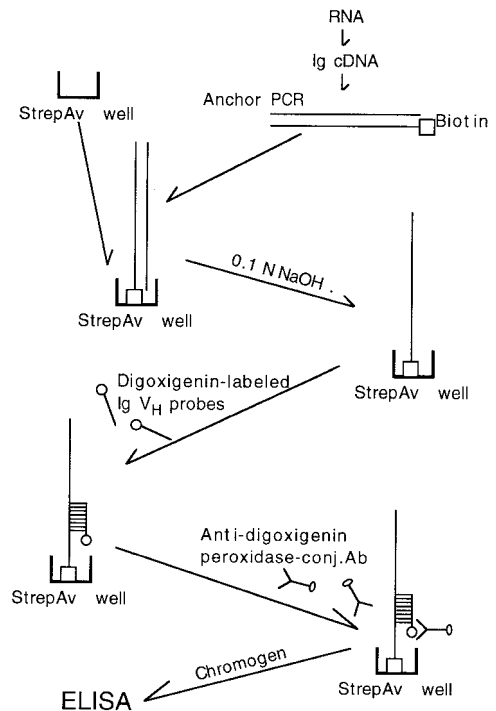
primers and J primers anneal to sites that are separated by fewer than 400 bp, making PCR straightforward. It should be noted that PCR on genomic DNA with primers specific for a V gene subgroup and a constant-region exon will not amplify rearranged immunoglobulin genes because the distance between the J segment and the immunoglobulin constant-region exon is too large. Such primer pairs are better suited for amplifying cDNA derived from the immunoglobulin transcripts from which the intron separating the J region and the constant-region exon are deleted through RNA processing and splicing.


FIGURE 4 Schematic representation of the PCR-ELISA technique. Following anchored PCR, a nested PCR attaches a biotin molecule (white box) to the antisense strand of the PCR product. This allows the strand to bind to streptavidin (StrepAv)-coated wells of an ELISA plate. The sense strand is removed by alkaline wash, allowing for hybridization of the tethered antisense strand with digoxigenin-labeled immunoglobulin V_H oligonucleotide probes (represented by the ball and stick figures). Hybridized and bound oligonucleotides then are detected using peroxidase-conjugated antidigoxigenin antibodies (anti-digoxigenin peroxidase-conj. Ab). The peroxidase-conjugated antibodies are developed with chromogen, and the plates are read using an ELISA plate reader.

Resolution of the junctional sequences in the rearranged immunoglobulin genes expressed by a tumor can provide a specific tumor marker. This marker can be used to examine for any tumor-derived immunoglobulin gene fragments amplified by PCR performed on genomic DNA of lymphoid tissue. Such methods are highly sensitive, allowing for detection of minimal residual disease in lymphoid tissue that otherwise harbors no detectable pathologic or immunophenotypic trace of a residual tumor.

Anchored Reverse Transcriptase PCR-ELISA

Another method for assessing immunoglobulin V gene expression is the anchored reverse transcriptase PCR–enzyme-linked immunosorbent assay (ELISA). This method can be used to assess the expressed immunoglobulin repertoire of monoclonal or polyclonal B-cell populations (67). With this technique, the expressed genes are amplified uniformly regardless of polymorphism and/or somatic mutations, since the cDNA is G tailed and used in a primary PCR with a poly(C) anchor sense primer and an immunoglobulin constant-region antisense primer. The amplified cDNA then is used as the template for a secondary nested PCR that increases the specificity of the overall PCR and that generates a final PCR product having a biotin molecule attached to the 5' end of

the antisense strand. This allows the antisense strand to become tethered to avidin-coated polystyrene ELISA plates. Digoxigenin-labeled oligonucleotides specific for subgroup or V gene consensus sequences of the sense strand of the PCR product are used to probe the tethered and alkali-denatured antisense strand. Because of the digoxigenin label, the probe that hybridizes with the tethered antisense strand can be detected using alkaline phosphatase-conjugated antidigoxigenin antibodies. The latter can be detected by adding a chromogen and then by reading the change in optical density of the reaction mixture with an ELISA plate reader (Fig. 4). The frequency of each gene or gene subgroup then can be calculated by dividing the concentration of each immunoglobulin gene product by the total concentration of immunoglobulin V genes.

Immunoglobulin Quantification and Viscosity Measurement

JEFFREY S. WARREN

8

Quantification of intact immunoglobulins has proven useful in the evaluation of patients with suspected immunodeficiency syndromes, B-cell and plasma cell neoplastic diseases, allergic conditions, and chronic inflammatory and autoimmune disorders. The armamentarium of quantitative immunoglobulin assays was initially extended by the development of immunoglobulin light-chain assays and more recently by the development of free (unbound) immunoglobulin light-chain assays. Despite important advances in immunoglobulin and light-chain quantification methods, there remain technical complexities that can influence proper clinical usage. Equally important, even when measurements are straightforward, is the need for a thorough understanding of the clinical indications for, and limitations to, immunoglobulin measurement.

Viscosity is the resistance of a fluid to flow. A wide variety of clinical conditions can affect the viscosity of blood (25). While abnormalities of the formed elements of blood (e.g., polycythemia and extreme leukocytosis) can result in clinically significant hyperviscosity, the overwhelmingly most common explanation for hyperviscosity is an abnormality in structure and/or concentration of immunoglobulin. There are several methods available for the measurement of whole-blood, plasma, and serum viscosity. It is important to understand the uses and limitations of whole-blood, plasma, and serum viscosity measurements and how each is reported.

This chapter is divided into three sections. The first section provides a brief review of immunoglobulin structure, important because of its direct relevance to quantitative immunoglobulin measurement. The second section provides a review of assay methods, issues related to quality control and assurance, and test validation, as well as a brief discussion of the clinical application of immunoglobulin measurements. A new development since the 6th edition of this manual has been the advent of free-light-chain assays. Finally, the third section addresses both technical and clinical aspects of viscosity measurement.

IMMUNOGLOBULIN STRUCTURE

Knowledge of immunoglobulin structure is important to understanding measurements of intact immunoglobulins and free light chains as well as in clinical viscometry. Basic antibody function (i.e., antigen binding) was recognized for years before the elucidation of immunoglobulin structure (1).

Early studies of antibody binding to highly purified carbohydrate antigens led to the deduction that antibody was composed of protein. The development of clinical electrophoresis led to the further recognition that antibody migrated largely within the gamma region of serum proteins, hence the names "gamma globulin" and "immunoglobulin" (34). In 1952, Colonel Ogden Bruton, a pediatrician, used serum protein electrophoresis to evaluate a boy suffering from recurrent bacterial infections (6). Recognition that the gamma fraction of protein was absent, coupled with the boy's favorable response to injections of gamma globulin from healthy humans, supported the conclusion that this serum fraction was important in host defense and led to the definition of a specific immunodeficiency syndrome (Bruton's agammaglobulinemia). Recognition of monoclonal immunoglobulins as the uniform product of clonal proliferations of neoplastic B lymphocytes and plasma cells was important in the understanding of such diseases as multiple myeloma and Waldenström's macroglobulinemia.

In contrast to serum alpha and beta globulins, which are composites of structurally homogeneous proteins (e.g., alpha-1 antiproteinase, transferrin, and complement protein 3), immunoglobulins are structurally heterogeneous (11, 17). This structural heterogeneity is accounted for at several levels. There are five major immunoglobulin classes, each different in both structure and function (Table 1). Subclasses within immunoglobulin G (IgG) (Table 2), IgA, and IgM also contribute to immunoglobulin heterogeneity, as do allotypic variations in both heavy- and light-chain structure. Overwhelmingly, however, the great heterogeneity of structure reflects the vast array of different amino acid sequences within the variable and hypervariable regions of immunoglobulin molecules. One of the pivotal scientific advances in the history of immunology was the elucidation of the molecular mechanisms responsible for the generation of antibody and immunoglobulin diversity (35) (see chapter 7). It is important to remember these different levels as contributors to the structural heterogeneity of immunoglobulins because they warrant consideration both in the quantitation of polyclonal immunoglobulins by class (e.g., total IgG or IgM) and in the quantitation of monoclonal immunoglobulins (e.g., in patients with multiple myeloma). The general structure of an intact immunoglobulin molecule includes two heavy chains (gamma, alpha, mu, delta, or epsilon), two light chains (kappa or lambda) (Table 1),

TABLE 1 Characteristics of immunoglobulins

Nomenclature	IgG	IgA	IgM	IgD	IgE
Heavy-chain class	Gamma	Alpha	Mu	Delta	Epsilon
Heavy-chain subclasses	1, 2, 3, 4	1, 2	1, 2		
Light-chain types	Kappa and lambda	Kappa and lambda	Kappa and lambda	Kappa and lambda	Kappa and lambda
Physical characteristics					
Molecular mass (Da)	143,000–160,000	159,000–447,000	900,000	177,000–185,000	187,000–200,000
Sedimentation coefficient (Svedberg units)	6.7–7.0	7.5–9.0	18–19	6.9–7.0	7.9–8.0
Functional characteristics					
Serum half-life (days)	7–23	5–6	5	2–8	1–5
Complement fixation[a]	+	−	+ +	−	−
Placental transfer[a]	+	−	−	−	−
Reaginic activity[a]	±	−	−	−	+ +

[a] ±, borderline; +, present; + +, strong activity; −, no activity.

and bridging disulfide bonds (chapter 7). Within each heavy and light chain are N-terminal variable and hypervariable (antigen-binding) domains and C-terminal constant domains. Antibody structure is best understood in the context of the genetic and molecular bases for structural and functional diversity (chapter 7).

Pioneering studies of antibody structure, carried out in the 1950s and 1960s (11, 28, 30), provided important insight into antibody function and resulted in immunoglobulin subunit nomenclature that is still in use. In 1958, Porter (30) digested rabbit gamma globulin with the enzyme papain. Separation of the digestion products on the basis of charge density revealed two identical antigen-binding fragments (Fab) and one fragment that could be crystallized (Fc). The Fab fragments had sedimentation coefficients of 3.5S. The fact that the Fc fragment could be crystallized provided evidence that it was biochemically homogeneous. Digestion of purified antibody with pepsin yielded a different set of fragments. The largest, which has a sedimentation coefficient of 5S, had an antigen-binding valence of 2, hence its designation, F(ab′)$_2$. Reduction of the disulfide bonds that held F(ab′)$_2$ fragments intact led to the formation of two fragments that resembled Fab. In 1961, Edelman and Poulik reported that reduction of intact immunoglobulin molecules led to the formation of two so-called "heavy" chains and two so-called "light" chains (11).

As noted above, the Fab domains of immunoglobulin molecules are structurally variable and responsible for antigen binding. In contrast, the Fc domain determines the biological function of a given immunoglobulin molecule. As summarized in Table 1, the biological functions of immunoglobulins are diverse, including such characteristics as complement fixation (e.g., IgG and IgM), placental transfer (IgG), high-affinity

cytophilic binding to mast cells (IgG4 and IgE), etc. (28). IgM generally circulates as a pentamer that consists of five covalently linked IgM monomers with an antigen-binding valence of 10. IgA occurs as a monomer in serm weighing 160,000 Da with a valence of 2. In secretions, IgA can occur as a multimer, usually a dimer.

Light chains (kappa and lambda) each possess an N-terminal 110-amino-acid variable region and a C-terminal 107-amino-acid constant domain. By analogy, heavy chains (gamma, alpha, mu, epsilon, and delta) each possess a 110-amino-acid N-terminal variable region and, depending on the particular class, >330-amino-acid constant regions. Structurally apposed light- and heavy-chain variable regions form an antigen-binding site. It is useful to think of the antigen-binding (Fab) region of an immunoglobulin molecule as a hand that grasps a uniquely shaped doorknob (antigen). Finally, as alluded to above, the genetic and molecular bases for immunoglobulin structure and antibody diversity have been studied intensively (chapter 7) (15, 35). Kappa light chains are encoded on chromosomal band 2p11, lambda light chains are encoded on 22q11, and the heavy-chain loci are encoded on chromosome 14. A highly regulated series of DNA recombination and splicing steps are required to generate intact immunoglobulin molecules (15, 35). Immunoglobulins are produced only by B lymphocytes and plasma cells.

IMMUNOGLOBULIN CLASSES

IgG is the predominant class of serum immunoglobulins. More than 60% of circulating IgG is IgG1, with IgG2, IgG3, and IgG4, in that order, present in decreasing concentrations (Table 2) (31). Except for IgG3, which has a serum half-life of 1 week, the IgG subclasses have half-lives of 2 to 3 weeks. IgG antibodies comprise the most important effector class of molecules in a secondary or anamnestic humoral immune response. Among large populations of B lymphocytes that express different cell surface IgG molecules, high-avidity antigen binding provides a selective advantage for clonal proliferation (14). As a result, as a humoral immune response "matures," higher proportions of IgG antibodies exhibit a high degree of antigenic specificity.

IgA is the most important immunoglobulin in the mucosal host defense system. Mucosal IgA exists chiefly as dimers covalently linked by J chains (14). A 60-kDa peptide called the secretory piece is necessary for IgA to be secreted by the various types of epithelial cells that line the mucosa.

TABLE 2 Characteristics of IgG subclasses

Property	IgG1	IgG2	IgG3	IgG4
Concn in serum (g/liter)	1.8–7.8	1.0–4.6	0.3–1.4	0.08–1.8
Half-life (days)	14–23	14–23	7–8	14–23
Complement fixation	Strong	Weak	Strong	None
Phagocyte binding (via Fc receptors)	Yes	No	Yes	No
Associated with allergies	No	No	No	Yes

IgA, like all immunoglobulins, is produced by B lymphocytes and plasma cells but is transported across mucosal epithelial layers (from the abluminal to the luminal side). As noted in Table 1, IgA exists as IgA1 and IgA2, the former being present in a higher concentration in serum and each having a half-life of 4 to 5 days.

Serum IgM circulates chiefly in the form of pentamers. Each monomeric subunit includes two mu heavy chains, which in turn each possess an extra constant-region domain. As a result, pentameric IgM has a molecular mass of approximately 900 kDa. IgM is the first immunoglobulin class to be expressed on B cells during lymphocyte development, and it is the predominant immunoglobulin class in a primary humoral response (14).

IgD circulates in very low concentrations. Like IgM, B-cell surface IgD is expressed early in lymphocyte development (14). Monomeric IgD consists of two heavy chains (each 62 kDa) and two identical kappa or lambda light chains. The biological role of serum IgD is unknown, and clinical measurement of IgD has no value except for the rare patient with either an IgD-secreting neoplasm (e.g., multiple myeloma) or the equally rare patient with a familial hyper-IgD fever syndrome.

The clinical use of IgE measurements is discussed in greater detail in section M, which describes allergic diseases. Serum IgE molecules circulate as monomers that consist of two epsilon chains that each weigh 70 kDa and two identical kappa or lambda light chains. Like IgM, IgE contains an extra constant-region domain. While IgE is normally present in low concentrations, elevated IgE concentrations are seen in a wide variety of allergic and autoimmune diseases. In contrast to total IgE measurements, antigen-specific IgE measurements are widely used in the evaluation and management of patients with specific atopic disorders. Cytophilic IgE binds to mast cells and basophils via very high affinity Fcε receptors. Activation of such cells via IgE-specific antigen binding results in the rapid release of vasoactive mediators that can cause localized swelling and/or a generalized, sometimes life-threatening reaction (anaphylaxis) (14, 16).

MEASUREMENT OF IMMUNOGLOBULINS

Quantification of IgG, IgA, and IgM in clinical laboratories is currently almost exclusively performed by automated nephelometric or immunoturbidimetric assay systems (8). Application of nephelometry and immunoturbidimetry to immunoglobulin measurement represents a trend away from more labor-intensive manual methods such as radial immuno-diffusion (RID) and the Laurell rocket technique (18). Likewise, most serum kappa and lambda light-chain measurements and total IgE measurements are also carried out using automated nephelometric or dedicated immunoturbidimetric assay systems (9). In contrast, more than 20% of clinical laboratories that participated in the 2004 College of American Pathologists proficiency testing survey program used a RID method for IgG subclass measurements, and nearly all laboratories that measured total IgD employed a RID assay (8).

Nephelometric assays are based on rate reactions in which antigen, in this case an immunoglobulin such as IgG, is injected into a reaction chamber with an antigen-specific antibody (13). As antigen-antibody complexes form in suspension, they are interrogated with an intense light source. Photons are reflected (30° to 90°) from the immune complexes, where they are quantified with a photomultiplier tube. The rise in light signal intensity as a function of time

(in milliseconds) is determined by the concentrations of antigen and antibody. Rate nephelometers are sophisticated instruments that perform duplicate assays, can exhibit high throughput, and are programmed to employ multiple dilutions of antigen or antibody, thus allowing for a near-optimal precipitin-forming rate reaction. While rate nephelometers are quite accurate, abberant results can occur as the result of antigen excess effects. This may be particularly pronounced when measuring an analyte that has a relatively low normal concentration (e.g., IgG4 subclass). Such antigen excess effects can fail the instrument-derived antigen excess check. When measuring IgG subclasses it is a useful check to add up the concentrations of all four subclasses to see if their total approximates the total IgG concentration. Immunoturbidimetric assays are formatted similarly, but rather than relying upon the quantitation of reflected light, they rely on the blockade light transmission (180°) through the suspension of immune complexes being formed by antigen and reagent antibody (29, 33).

Nephelometric and immunoturbidimetric assay systems have had a large economic impact on clinical laboratories because they are automated, can be used to assay many different analytes with a single platform, and allow higher throughput. As a result, employment of these methods yields a lower cost per test in laboratories that process significant volumes.

RID assays entail addition of reagent antibody to warm (50°C) agarose while it is in the liquid state (12, 27). Liquefied antibody-containing agarose is poured into a flat plastic container and allowed to cool to room temperature. Wells are then cut into the solidified agarose. Standard dilutions of known concentrations of antigen, in this case, immunoglobulin such as IgG, are placed into multiple wells. Serum samples that contain patient IgG to be measured are placed in other wells. As the antigen (IgG) diffuses in all directions from the wells, a visible antigen-antibody precipitin reaction forms where antigen and antibody reach equivalence. The concentration of the unknown analyte, in this case serum IgG, can be calculated by comparing the diameter of the precipitin ring to those of the standard curve generated by the serially diluted known concentrations of antigen added to different wells. Typically, a 5-$\log_{10}$ dilution standard curve is employed (12, 29). The diameters measured from precipitin rings formed by patient samples can be interpolated from the standard curve. RID offers the advantages that it is simple and requires very little equipment. The major disadvantages are that RID assays are manual, take 16 to 48 h to run, and are often very expensive. Technical artifacts attributable to lipids or monomeric IgM or IgA can lead to inaccurate results. When reagent antibody is monoclonal, as in the many IgG subclass assays, the per-test cost can be extraordinarily high. Inherent in RID immunoglobulin assays are higher coefficients of variation than those observed for nephelometric and immunoturbidimetric methods (greater than 10% versus less than or equal to 7.9%).

The Laurell rocket technique is very similar to RID except that the diffusion phase of the assay is accelerated from hours (typically 16 to 48) to minutes by the application of an electrophoretic field (26). While the end point is still the formation of a precipitin line (antigen-antibody complexes in agarose), the geometry is changed from a circle to that of a rocket-shaped arc, hence the designation "rocket." With the Laurell technique, the height of the precipitin rocket is proportional to the antigen concentration. As in the RID technique, a standard curve is constructed by running multiple known dilutions of a standard antigen preparation. Again, immunoglobulin concentrations in patient

samples are calculated based on interpolation from the standard curve. While Laurell rocket electrophoresis is faster than RID, the remaining shortcomings still apply.

FREE-LIGHT-CHAIN MEASUREMENT

The detection of free monoclonal immunoglobulin light chains in serum and/or urine is fraught with technical and practical challenges. Identification of free monoclonal light chains in the serum of patients with multiple myeloma or light-chain (AL)-type amyloidosis is limited, especially early in the course of the disease, because these proteins, by virtue of their low molecular mass (less than 25,000 Da), are filtered by the glomerulus and subsequently reabsorbed by the proximal tubular epithelial cells. Accordingly, serum protein electrophoresis may reveal no apparent abnormality. The diagnostic yield is increased substantially by also screening urine for such Bence Jones proteins (monoclonal free light chains). Again, low concentrations of Bence Jones proteins may be missed early in disease because proximal tubular reabsorption of such clonal proteins is relatively efficient either until the quantities of protein increase and exceed the reabsorptive capacity of the tubular epithelium or until tubular damage (acquired Fanconi syndrome) occurs and there is increased excretion of Bence Jones proteins.

Bradwell et al. (4) developed a highly sensitive immunoassay for the quantification of free immunoglobulin light chains in both urine and serum. Affinity-purified antibodies that react specifically with free light chains, but not bound light chains, are linked to the surface of latex particles which in turn form aggregates when incubated with free light chains. Employment of such particles in automated immunoturbidimetric analyzers has led to the development of a robust assay system that can be used in clinical practice. Because free kappa and lambda (polyclonal) light chains are normally present in serum and urine, it is necessary to report results of the free-light-chain assay in terms of a ratio of free kappa to free lambda. The existence of a significant clonal increase in either free kappa or free lambda light chains will distort this ratio.

The serum and urine free-light-chain assays have been proposed to be useful as a screening test, as a means to monitor response to therapy, and as a means to assess disease progression and/or relapse (3). In addition, a recent study suggests that this assay yields an abnormal free kappa/lambda ratio for most patients with nonsecretory myelomas (10). Finally, the presence of Bence Jones proteins (clonal free light chains in urine) in patients with monoclonal gammopathy of undetermined significance has been reported to predict a greater risk of progression to myeloma (2).

The addition of sensitive and specific free-light-chain assays to the armamentarium of laboratory tests available for the diagnosis and management of patients suspected to have myeloma, Waldenström's macroglobulinemia, monoclonal gammopathy of undetermined significance, B-cell leukemias and lymphomas, and AL-type amyloidosis is an exciting prospect. It will be critical for clinical studies to address specific potential applications of these assays. Particular attention will need to be paid to comparisons between free-light-chain assays and optimally used "traditional" assays. For example, it will be appropriate to compare sensitivities and specificities of free-light-chain assays to those of serum *and* urine immunofixation assays, not serum *or* urine immunofixation assays. Likewise, it will be important to assess the impact of sensitive free-light-chain assays on outcomes for patients. Serum and urine free-light-chain assays are Food and Drug Administration cleared for use in the diagnosis and monitoring of patients with B-cell and plasma cell neoplasms and collagen vascular diseases such as systemic lupus erythematosus (3). However, important utilization questions remain to be answered.

CLINICAL ASPECTS OF IMMUNOGLOBULIN MEASUREMENT

Serum immunoglobulin concentrations vary widely in children and adults (19). Very low concentrations of IgG, IgA, and IgM are observed in the sera of healthy infants approximately 6 months after birth. Immunoglobulin concentrations in a newborn are nearly equal to those observed in adults as a result of transplacental passage from the mother. These immunoglobulin concentrations then decline to a nadir at approximately 6 months of age. Normal ranges of immunoglobulins rise progressively until adult concentrations are reached during adolescence. It is important to apply age-specific reference ranges when one interprets quantitative immunoglobulin measurements in prepubertal children.

There are a variety of congenital and acquired immunodeficiency disorders that are characterized by hypogammaglobulinemia (14). Depending upon the underlying etiology and accompanying abnormalities, humoral immunodeficiency syndromes are often accompanied by specific clinical findings and/or manifestations. In general, patients with humoral immunoglobulin deficiencies are at risk for bacterial infections caused by high-grade encapsulated bacteria such as *Streptococcus pneumoniae* and *Haemophilus influenzae* (23). Detailed discussion of humoral immunodeficiency syndromes is beyond the scope of this chapter. Children suspected of suffering from Bruton's (X-linked) agammaglobulinemia and adults suspected of suffering from common variable immunodeficiency will typically exhibit markedly subnormal concentrations of IgG, IgA, and IgM in serum. The most common congenital humoral immunodeficiency disorder is selective IgA deficiency, which affects approximately 1 in 700 adults (14). Many of these patients are asymptomatic, but some suffer from recurrent mucosal infections and/or autoimmune phenomena. A subset of selective IgA deficiency patients exhibit concomitant IgG subclass deficiency. Aggressive treatment of patients with various neoplastic and autoimmune diseases has resulted in many individuals with acquired humoral immunodeficiencies. Like patients with congenital humoral immunodeficiency disorders, these individuals are at risk of high-grade bacterial infections. Likewise, multiple myeloma is frequently accompanied by both the presence of a monoclonal immunoglobulin spike (M protein) and suppression of polyclonal gamma globulin (see below).

A vast array of chronic inflammatory and infectious diseases is accompanied by polyclonal increases in immunoglobulin concentration. In these settings there is usually value in specific quantitative measurements of IgG, IgA, or IgM. Serum protein electrophoresis, accompanied by a densitometric measurement of the total gamma globulin concentration, will usually suffice as a means to assess the humoral immune system and to rule out the possibility of an underlying monoclonal gammopathy.

The great majority of patients with multiple myeloma and Waldenström's macroglobulinemia have monoclonal increases in immunoglobulins in serum, urine, or both (21). Serum and urine protein electrophoresis and immunofixation are important in the establishment of the presence of such an M protein (19–22, 24). Typically, smaller paraprotein immunoglobulin spikes are frequently seen in patients with B-cell lymphoproliferative conditions (e.g., chronic lymphocytic leukemia), monoclonal gammopathy of undetermined significance, AL-type amyloidosis, M-protein-associated

peripheral neuropathy, and posttransplantation lymphoproliferative disorder. In many cases, the presence of a monoclonal protein will be obvious when serum or urine protein electrophoresis is performed. Performance of serum and/or urine immunofixation allows maximal sensitivity and will allow identification of the M protein. It is important to remember that many patients with light-chain-type myeloma will not exhibit a serum M-protein spike but will possess urine Bence Jones proteins (18, 21, 24). Once an M protein is identified and characterized, densitometric quantification of the spike remains the best available means by which to monitor the monoclonal protein (7, 22). As discussed above, the precise clinical roles for free monoclonal light-chain assays remain to be clearly defined.

VISCOSITY MEASUREMENT

Viscosity is the resistance of a fluid to flow. Abnormalities of the formed elements of blood (e.g., increased red blood cell mass, decreased red blood cell deformability, and changes in properties and/or numbers of white blood cells) or abnormalities in plasma proteins (e.g., increased immunoglobulin concentration) can cause hyperviscosity. While emerging technologies such as laser Doppler velocimetry and mass-detecting sensors (32) promise to change clinical viscometry, most laboratories continue to employ either Ostwald, Wells-Brookfield, or falling-drop viscometers.

Ostwald viscometers are based on the relationship between fluid viscosity and the rate of flow through a fixed wall narrow-bore tube. The greater the viscosity of either anticoagulated whole blood, plasma, or serum, the lower the rate of flow. Typically, the flow rate of the sample of interest is compared to a standard (e.g., that of water). The Wells-Brookfield viscometer employs a stationary plate (sample cup) and a cone (needle) that is rotated within the cup by an electric meter at a constant speed and temperature (5). The fluid sample is placed in the cup in which the cone rotates. The greater the viscosity of the fluid, the greater the torque generated. In turn, the torque is measured with a torque meter and translated into "viscosity." Falling-drop viscometry is based on the fact that particulates fall more slowly through a viscous fluid than through a less viscous fluid. Viscosity of biological samples is typically reported in centipoise; normal plasma viscosity is approximately 1.35 to 1.85 cP. Water exhibits a viscosity of 1.0 cP at 37°C. Whole-blood viscosity can also be expressed as "equivalent hematocrit of whole blood viscosity," which is the viscosity equivalent to that exhibited by anticoagulated whole blood at the given hematocrit. Clinical interpretation of "equivalent hematocrit" requires an actual hematocrit measurement for comparison. For example, a patient with hyperviscosity due to a high concentration of a monoclonal paraprotein might exhibit a hematocrit equivalent of 55% and an actual hematocrit of 40%. In this case the "excess" viscosity would be attributable to the paraprotein. Conversely, a patient with polycythemia and hyperviscosity might exhibit a hematocrit equivalent of whole-blood viscosity of 55% and an actual hematocrit of 55%. In this case, the "excess" viscosity would be attributable to the increase in red blood cell mass. Charts are available that display the mathematical relationship between hematocrit and viscosity of whole blood (5).

CLINICAL ASPECTS OF VISCOSITY MEASUREMENT

The most common cause of hyperviscosity is the presence of a paraprotein. More than 80% of cases of hyperviscosity are associated with Waldenström's macroglobulinemia and an IgM paraprotein. IgM molecules have a high molecular weight as well as a shape that increases their intrinsic viscosity. IgA paraproteins, less commonly, IgG paraproteins, and, rarely, monoclonal light chains can also result in hyperviscosity (25). Increases in red blood cell mass (e.g., polycythemia), abnormal deformability of red blood cells (e.g., hemoglobinopathies), and very high white blood cell counts (e.g., chronic lymphocytic leukemia) can result in increases in whole-blood viscosity. As alluded to above, hyperviscosity attributable to a paraprotein would increase both whole-blood and plasma or serum viscosity, while abnormalities of formed elements affect whole-blood viscosity but not plasma or serum viscosity.

Symptoms and signs of hyperviscosity include fatigue, blurred vision, headache, tinnitus, decreased hearing, vertigo, paresthesias, segmental dilation of retinal veins, retinal hemorrhage, mucosal bleeding, nystagmus, ataxia, somnolence, stupor, and coma (25). Individual patients exhibit different thresholds, but symptoms and signs of hyperviscosity typically occur when whole-blood viscosity exceeds 4 cP. Serum protein electrophoresis, immunofixation, a complete blood count with differential, and review of a peripheral blood smear will nearly always elucidate the underlying cause of hyperviscosity. In the great majority of cases of clinically significant hyperviscosity, the underlying etiology has previously been established (e.g., Waldenström's macroglobulinemia and multiple myeloma).

Clinical Indications and Applications of Serum and Urine Protein Electrophoresis

DAVID F. KEREN AND RICHARD L. HUMPHREY

9

Serum and urine protein electrophoreses are performed to detect and measure monoclonal gammopathies (M proteins). In effect, serum and urine protein electrophoreses provide an immunochemical "biopsy" of the humoral immune system. However, a wide variety of other clinically relevant information is also available from examination of the proteins demonstrated from these studies. This chapter reviews basic principles of electrophoresis, the types of apparatus that are available, quality control and quality assurance procedures, and costs involved with the procedure and provides a wide variety of patterns with recommended interpretations.

BACKGROUND ON PROTEIN STRUCTURE

Electrophoresis of serum and urine in the clinical laboratory takes advantage of the fact that each protein has its own unique structure. Proteins are composed of amino acids, each of which contain a basic amino group ($-NH_2$), an acidic group ($-COOH$), and a sequence that is specific to each amino acid, referred to as an R group (Fig. 1). The R groups may be acidic or basic and vary in size from a single hydrogen atom, to linear or branched hydrocarbon chains, to a complex double-ring structure. The complex structural and charge characteristics of these amino acids and the unique amino acid sequence of each protein determine the position that the protein migrates to upon electrophoresis (15).

The primary structure of a protein results when amino acids connect to one another by linking the amino group of one amino acid to the carboxyl group of the next. While this covalent peptide bond is formed, a water molecule is released (Fig. 2). The resulting linear chain of amino acids is a polypeptide containing a free amino group at one end (N terminus) and a free carboxyl group at the other end (C terminus). The amino acid composition of each protein is determined by the information encoded in the individual's DNA.

As the polypeptide chains of amino acids form, a simple secondary structure is created by folding along one dimension and is held together primarily by hydrogen bonds. These may take the form of random coils, an alpha-helix, or a beta sheet. A three-dimensional tertiary structure forms as a result of several types of attachment: hydrogen bonds, disulfide bonds, van der Waals forces, and hydrophobic bonds. In more complex molecules, such as immunoglobulins, a quaternary structure forms when several polypeptide chains link together. For instance, consider the immunoglobulin M (IgM) molecule. Though classified as a single protein, it consists of 10 identical heavy chains, 10 identical light chains, and 1 joining chain, combining for a molecular mass of about 900 kDa. Finally, many proteins have carbohydrate groups attached (glycosylated) covalently. These carbohydrate groups stabilize the protein's conformation and in some circumstances help to protect it from digestion (13, 15).

Following synthesis of the protein, posttranslational modifications which convey heterogeneity to the protein may occur. These include phosphorylation, N-terminal acylation, side-chain acylation, sulfation of tyrosine, C-terminal α-amidation of glycine, and γ-carboxylation of glutamic acid (15). The ability of electrophoretic techniques to detect subtle changes in charge is illustrated by the second band that is seen in heterozygotes for α_1 antitrypsin variants due to substitution of a single amino acid of a different charge (Fig. 3).

The charge on the protein molecule and, consequently, its migration on serum and urine protein electrophoresis are determined both by its constituent amino acids and by the pH of the buffer used for the electrophoresis. Each protein may be defined by its isoelectric point (pI), the pH at which its positive and negative charges are equal and hence migration does not occur. At the pH of agarose gel electrophoresis, the algebraic sum of the protein's positive and negative charges determines the protein's migration. This allows the laboratory to separate the major proteins into unique bands and fractions that can be used to identify a wide variety of clinical conditions.

PRINCIPLES OF PROTEIN ELECTROPHORESIS

The first studies of serum protein electrophoresis were performed entirely in a fluid-based system devised by Arne Tiselius, winner of the 1948 Nobel Prize in Chemistry, called moving boundary electrophoresis (25). In that regard, it is similar to the most recently available technique of capillary zone electrophoresis (CZE). In his system, Tiselius layered a mixture of proteins on a buffer in a U-shaped tube with electrodes at each end of the U. The migration of the proteins through the electrical field was detected by a sensitive Schlieren band optical system. With this technique, the major protein fractions of albumin, alpha, beta, and gamma globulins were defined.
$$H_2N - \underset{\underset{R}{|}}{\overset{\overset{H}{|}}{C}} - COOH$$

FIGURE 1 General structure of an amino acid.

Zone Electrophoresis

In the late 1930s, to improve separation and allow direct visualization of the major protein fractions, filter paper was deployed as the first support medium. The filter paper was placed between two reservoirs of buffer with electrodes at each end. The protein solution was carefully applied to the filter paper, and after electrophoresis the major bands were visualized by use of a protein dye. However, the addition of this support medium introduced new variables, such as the texture of the medium, which provided resistance (that would vary according to the brand and lot) to protein migration, as well as charge effects due to endosmotic flow (19). The latter reflected the fact that the support medium itself contained a net negative charge that could not migrate, and as a consequence, the positive buffer ions would flow toward the cathode. The result was that weakly anionic proteins were pulled cathodally from the application point.

The use of cellulose acetate and agarose, which started in the 1950s and was vastly improved in the 1970s with the development of techniques with higher resolution, began techniques that are used today. These clear support media allow rapid electrophoresis, crisp separation of major protein fractions, and densitometric scanning to measure the protein fractions (18).

The simplicity of separation in a fluid-based system has been revisited in the past decade with the development of CZE. In this procedure, instead of a large, glass U-shaped tube, thin fused silica capillaries, about 25 μm in diameter, are the vessels through which the proteins pass. The narrow

$$\downarrow$$

$$H_2N - \underset{\underset{R1}{|}}{\overset{\overset{H}{|}}{C}} - \overset{\overset{O}{\|}}{C} - \underset{\underset{H}{|}}{\overset{\overset{H}{|}}{N}} - \underset{\underset{R2}{|}}{\overset{}{C}} - COOH \quad + \quad H_2O$$
FIGURE 2 Peptide bond formation between two amino acids.

capillaries create a huge negatively charged surface area that results in a strong endosmotic flow toward the cathode. At a strong alkaline pH, the proteins are pulled by the endosmotic flow past a UV detector (using a 200- or 215-nm wavelength) that records the amount of each protein fraction on an electropherogram (resembling a densitometric scan) and is able to convert the values to a virtual gel image (6, 14, 20, 21).

Unfortunately, while this mode of detection is efficient, it also detects other substances that absorb at those UV wavelengths. So far, the most frequent causes of false-positive deflections in the electropherogram have been radiocontrast dyes and occasionally antibiotics (3, 7, 8, 10). Radiocontrast dyes and some antibiotics can produce suspicious bands anywhere from the transthyretin (prealbumin) area through the γ region (Table 1).

One key feature of the evolution in electrophoresis systems has been the improvement in resolution. With the development of clear cellulose acetate gels in the 1950s, densitometric scans could distinguish five major protein fractions, with the bands in each fraction being relatively

diffuse. Further improvements enhanced the ability to distinguish small M proteins or genetic variants (such as α_1 antitrypsin) that were difficult or impossible to see by previous techniques (Fig. 4). Improvements have included enclosed systems that prevent evaporation of buffer, helping to keep the ionic concentration of the buffer constant; the addition of calcium lactate to buffer; the use of thin gels; and the use of cooling devices to control heat production.

Guidelines for the diagnosis of monoclonal gammopathies recommend use of electrophoretic systems that provide crisp separation of the β_1 from the β_2 region and which are able to recognize M proteins at concentrations as low as 0.05 gm/dl in the γ region (2, 16).

With currently available manual agarose systems, excess moisture needs to be removed from the surface of the gel prior to application of the sample. After blotting, in most

manual systems, 3 to 5 µl of sample is applied to uniform narrow slits in a plastic template. However, with semiautomated systems, the samples may be placed in a well connected to special paper that wicks the sample to its sharp edge, which is applied directly to the surface of the gel. With some urine samples with particulate matter and serum with IgM monoclonal gammopathies, there have been reports of poor application (7, 17). The manufacturer recommends centrifuging the urine in such cases and observing that the paper moistens all the way to the sharp edge. In addition, we recommend always comparing the total protein value with the observed migration to help in preventing false negatives.

Laboratories should establish their own reference ranges when adopting these techniques. While the different methods provide similar numbers, significant differences have been reported (Table 2) (9). The largest differences between the agarose gel technique and CZE occur in the α_1 region for both men and women. These differences in part reflect the considerable improvement in detection of α lipoprotein and α_1 acid glycoprotein (orosomucoid) by CZE. Nonetheless, as long as the appropriate ranges are established for each technique, there should be good agreement in the interpretation of the results obtained (22).

QUALITY CONTROL AND QUALITY ASSURANCE

Specimen Requirements for Serum

For serum testing, the blood sample should be drawn into a Vacutainer tube without anticoagulant. After clotting, the serum is separated and stored at 4°C for up to 72 h. Although serum can be used after 72 h, C3 will deteriorate, changing the quantity of protein in the β_2 region of the electrophoresis. If the sample is to be held longer than 72 h before electrophoresis, freezing the sample at −20°C preserves the C3 for future study.

Proper samples are important because interferences can provide special problems for interpretation. Hemolysis will provide a broadly migrating band in the α_2-β region reflecting the presence of hemoglobin-haptoglobin complexes. This may obscure or even mimic an M protein in this region. Lipemic samples may not absorb effectively into a gel and may not be taken up by the thin capillaries used in CZE. Centrifuge and insert the pipette below the floating lipid
FIGURE 4 Serum protein electrophoresis on the semiautomated Sebia Hydragel 30 β_1-β_2 gel demonstrating sharp bands and a crisp separation of the β_1 (transferrin) band from the β_2 (C3) band. Samples 6, 13, 14, 24, and 25 have suspicious bands that all proved to be M proteins by immunofixation. In sample 24, the M protein (an IgA κ) migrated in the same location as the C3 (β_2) band. By comparing this band to the other C3 bands on this gel, the increase becomes more obvious.

TABLE 2 Comparison of serum protein intervals by agarose gel electrophoresis and CZE[a]

Group and fraction	Protein concn range (g/dl)	
	Agarose gel electrophoresis	CZE

layer to procure the sample. To prevent interference from lipemic samples, the patient should be fasting.

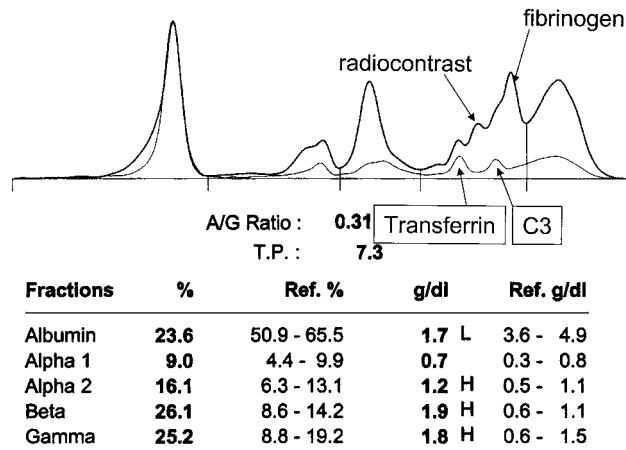
Specimen Requirements for Urine

An early-morning void collected into a container without preservative is adequate for screening for the presence of monoclonal free light chains (MFLC, or Bence Jones protein) (11). The urine should be stored at 4°C until electrophoresis. Prior to electrophoresis, the sample should be concentrated to optimize the detection of MFLC. The amount of concentration necessary depends on the protein concentration of the urine. Usually, a 50- to 100-times concentration is sufficient for urine samples with relatively small amounts of protein. One approach is to place the urine sample into a commercial ultrafiltration concentrating device and allow it to be concentrated for a set period of time (one of our laboratories uses 4 h). Samples with small amounts of protein will be concentrated more rapidly, up to 100 times, whereas samples with high protein concentration will be concentrated much less. If the patient is known to have an M protein in the serum and/or an MFLC in the urine, a carefully timed 24-h urine sample should be collected in a container without preservative. Collection of the sample is key to obtaining accurate and reproducible information about the M protein. Patients should be instructed to note the time when they are ready to start their collection, to empty their bladder, and to discard this first voiding. All subsequent voidings are then saved and added to the collection. The next day, at the same time, finish the collection by including the final bit of urine in the 24-h sample. While this seems excessively compulsive, if the first sample is included, it may be including urine that has been in the bladder for as long as 8 h (effectively making this a 32-h collection). The container should be refrigerated at 4°C during the collections and until the collection is delivered to the laboratory to minimize deterioration of proteins and growth of microorganisms. The 24-h collection is needed in order to quantify the amount of MFLC, which is used in the estimation of tumor burden and the response to therapy.
Internal Controls

Each protein electrophoresis gel should have an internal control sample run on it. The percentage of protein in each fraction should be recorded and compared day to day. Even

with urine protein electrophoresis, serum controls are recommended because normal urine contains only trivial amounts of protein and would not serve as an adequate estimation of the migration of proteins on the gel. The controls should be evaluated for migration positions of the major bands and for the amount of protein in each region. One convenient way to do this is by using a Levey Jennings chart (Fig. 5). For CZE systems, each channel should have such samples performed, because the separation characteristics will differ slightly from one capillary to the next.

Avoiding False-Positive Results

Unexplained bands from the α through the γ region may represent an M protein. However, before they are interpreted as being M proteins, this diagnosis should be secured by immunofixation (see chapter 10). As mentioned above, in CZE, interference from radiocontrast dyes and some antibiotics gives deflections that may be misinterpreted as M proteins (Fig. 6). Some of these, such as sulfamide sulfamethoxazole, produce a small deflection at the anodal end of albumin which should not be confused with an M protein (8, 10). Others, such as piperacillin-tazobactam (Tazocin; Wyeth), can produce a peak in the γ region. These interfering substances may be removed by desalting or use of activated charcoal (3, 5). In both CZE and gel-based electrophoresis, other proteins can produce bands that are not immunoglobulins but which do mimic an M protein. Fibrinogen, C-reactive protein, C3 variants, transferrin variants, hemoglobin-haptoglobin complexes, and markedly elevated levels of β lipoprotein can all be confused with an M protein. We recommend that all bands suspected of being M proteins be confirmed by immunofixation or immunosubtraction (see chapter 10) before being reported. One inexpensive way of ensuring that the suspected M protein is an immunoglobulin and not another interfering protein or radiocontrast dye is to use a single-lane pentavalent (anti-IgG, -IgA, -IgM, -κ, -λ) in the same serum (15). If the suspected band does not precipitate (forming an immunofixed band) with that reagent, it is not consistent with an immunoglobulin or M protein (Fig. 7).


When performing immunofixation, the specificity of the reagent antisera needs to be confirmed with each new lot. The study of the antisera should include both serum and plasma. Even though plasma is not the specimen that is

FIGURE 5 Levey Jennings charts for albumin for the month of September 2004 (top) and the α_1 fraction for the same run (bottom). More variation is seen in the α_1 fraction because of the smaller percentage of proteins present in this fraction. Nonetheless, no sample is beyond 2DS (2 standard deviations) and no trend of high or low values is evident. V.M., median value.

recommended for use, occasionally fibrinogen will be present due to the presence of anticoagulation therapy, inadequate time for the specimen to clot before the serum was removed from the clot, or drawing of the sample into a tube containing an anticoagulant. If the reagent antiserum against immunoglobulin contains reactivity for fibrinogen, a false-positive result may be recorded (23).

Good quality assurance requires coordination of all available laboratory information for the patient. A file is set up for the patient the first time that an M protein is detected in the serum or in the urine. The patient's current sample should be correlated with previous studies by using this file, for several reasons. First, the migrations of the M protein should be compared. If there is any change in migration, identification of

FIGURE 6 A complex electropherogram pattern with a normal pattern underlaid to show the normal positions of the β-region bands. The abnormal serum shows hypoalbuminemia and anodal slurring of albumin, and the four peaks in the β region are labeled. The fibrinogen was identified by immunofixation, and the radiocontrast dye was indicated by both the lack of a band in that region by immunofixation for IgG, IgA, IgM, κ, and λ and a telephone call indicating that the patient had been given a radiocontrast dye (Table 1). Ref., reference; T.P., total protein; A/G, albumin/globulin.

the patient sample should be confirmed. If this matches, the identification of the M protein should be confirmed immunologically (by immunofixation or immunosubtraction). When a new and different M protein from that seen in the original study is identified, the clinician should be contacted to determine if the patient has had extensive chemotherapy and/or stem cell transplantation. Occasionally, new M proteins can appear in the context of these events. Otherwise, the appearance of a new M protein is distinctly unusual, so we recommend another sample to confirm that a mislabeling at the time of the sample draw has not occurred.

If the migration of the M protein matches that of the previous serum or urine sample, the amount of the M protein should be measured. The amount of the M protein is recorded on the report along with a statement as to whether it has increased, decreased, or remained unchanged since the previous sample.

Comment is also made about the remaining normal gamma globulins (Fig. 8). Suppression of the gamma globulins can be a negative prognostic indicator and, if severe enough, may predispose the patient to infections, possibly requiring gamma globulin replacement therapy (26). If the
FIGURE 7 Results for three serum samples. For each sample, there are two lanes; the lane on the left is a serum protein electrophoresis fixed with acid, and the lane on the right is an immunofixation with antipentavalent antisera (anti-IgG, IgA, IgM, κ, and λ). The sample in lane 8 shows a band (arrow) that does not react with antipentavalent antisera; it is fibrinogen.

M protein is in the gamma globulin region, our laboratory subtracts the M-protein value from the total gamma region. If the remaining gamma globulin is 0.25 g/dl or less, we comment that the normal gamma globulins are suppressed. This number derives from earlier data noting that patients with common variable immunodeficiency disease have clinical problems when the gamma globulin region is below this level. If the M-protein is in another region (α or β), the total gamma globulin is looked at to see if it is below 0.25 g/dl.
The patient's file is reviewed to see if the patient has had a recent urine sample. If the patient has a known MFLC, a follow-up urine sample is indicated periodically (depending on the aggressiveness of the process and/or therapy) to monitor the tumor burden and to help estimate the degree of damage to the nephron. Patients with monoclonal gammopathy of undetermined significance should have periodic urine and serum electrophoresis, depending on clinical judgment.

Recently, the availability of free light-chain (FLC) testing in serum and urine has been shown to be useful both in the initial detection of MFLC and in monitoring of patients with light-chain disease. The measurement of the FLC may be able to replace the 24-h urine collection to follow tumor burden in such cases after demonstration of the clonality of the process by immunofixation.

The use of external quality assurance proficiency testing is essential to compare the results from one laboratory with those of others who are using the same system in the detection of M proteins, and also to allow gauging of the effectiveness of one manufacturer's electrophoretic system to correctly identify an abnormality versus the systems provided by other manufacturers.

Cost-Effectiveness of Testing

Cost is related mainly to the number of samples assayed per day and selection of the most appropriate type of equipment used for the number of tests performed. For laboratories with relatively small volumes (two to four serum samples per day), it may be worthwhile to consider sending the test to a reference laboratory and using the resources of the laboratory for higher-volume testing or required stat testing. Laboratories

Fractions	%	Ref. %	g/dl	Ref. g/dl

FIGURE 8 An electropherogram with a prominent M-protein spike and suppression of the normal gamma globulin. The spike measures 1.9 g/dl, and the total gamma globulin is 2.0 g/dl. Only 0.1 g/dl is accounted for by the gamma globulin not measured in the M-protein spike. T.P., total protein; A/G, albumin/globulin; Ref., reference.

with larger volumes (5 to 10 per day) may wish to use a manual assay. Although this testing is relatively inefficient, it would allow for a more rapid turnaround time. With a volume of about 20 samples per day, a semiautomated method would decrease technologist time. At volumes of 40 or more samples per day, the bar-coded, automated CZE systems are highly efficient, with excellent resolution.

## PROTEINS IDENTIFIED IN SERUM PROTEIN ELECTROPHORESIS

By use of agarose or acetate electrophoresis, serum proteins were classified as the five major regions identified by electrophoresis: albumin, α_1, α_2, β, and γ. However, we now can recognize several specific major proteins by electrophoresis (Fig. 9).

A tiny transthyretin (formerly named prealbumin) band may be seen in systems with superior resolution (Fig. 9). It is a 55-kDa protein that is used mainly to assess the nutritional status of patients with protein calorie malnutrition. The normal concentration in serum (20 to 40 mg/dl) is too low to be reliably evaluated by serum protein electrophoresis; therefore, measurements are usually performed by nephelometry.

Albumin is the main serum protein. It is a 69-kDa protein that is responsible for the osmotic effect of serum proteins and serves as a transport protein for a wide variety of molecules. An innocuous variant, bisalbuminemia, is occasionally seen. Analbuminemia is a rare condition in which patients do surprisingly well. Occasionally, the latter patients require diuretics to control mild edema, and some have had elevated cholesterol levels.

α_1 lipoprotein (high-density lipoprotein) is better evaluated by specific biochemical methods, but it may be seen on serum protein electrophoresis. In gel-based techniques, it usually accounts for the faint, diffusely staining broad band between the α_1-antitrypsin band and albumin. By CZE, it migrates in the α_1 region.

α_1 acid glycoprotein is a heavily glycosylated acute-phase reactant protein that migrates just anodal to α_1 antitrypsin. With its usual concentration of 50 to 150 mg/dl and heavy glycosylation, it is either barely visible or not seen on normal samples. However, with acute-phase reactions, it is seen on the anodal side of α_1 antitrypsin. Because the glycosylation
FIGURE 9 Serum electropherogram with major protein bands noted, as well as globulin regions.

interferes with protein staining, it is not seen well by gel-based methods; however, CZE methods show it to advantage as an anodal shoulder to the α_1 antitrypsin band in patients with an acute-phase reaction.

α_1 antitrypsin is a 52-kDa protein that is a member of the serine protease inhibitors (serpins) that function to inhibit a wide variety of proteases, including trypsin. This important protease inhibitor (PI) is usually present as PIMM (the normal homozygous type). However, there are several genetic variants. The Z variant and S variant are secreted in decreased amounts and are ineffective in inhibiting proteases. These variants in their homozygous form predispose the patient to emphysema and cirrhosis. The α_1 region must be carefully inspected to be certain that the α_1 antitrypsin band is present with appropriate migration (Fig. 10).

α_2 macroglobulin is a huge, 720-kDa molecule that is a member of the thiol ester plasma proteins and functions as a protease inhibitor. Despite this, it is not an acute-phase protein. Its level is elevated in patients with nephrotic syndrome due to its large size and increased synthesis in those patients.

Haptoglobin is the other major α_2-region protein. It binds free hemoglobin and exists in various forms that have a mass of between 86 and 900 kDa. The 1-1 genotype protein migrates slightly anodal to α_2 macroglobulin, the 2-1 genotype protein completely overlaps α_2 macroglobulin, and the 2-2 protein is slightly cathodal to α_2 macroglobulin. It is decreased in hemolysis and increased as an acute-phase reactant.

Transferrin, the major β_1-region molecule, is a 76.5-kDa protein that transports nonheme ferric iron. During acute-phase reactions, this protein decreases in concentration. In serum it contains two complex carbohydrate chains, each of which has a sialic acid residue. Cerebrospinal fluid contains both this form of transferrin and one that lacks the sialic acid residues. The latter fraction of transferrin migrates in the β_2 region and has been used to distinguish leakage of cerebrospinal fluid from nasal or aural secretions.
β_1 lipoprotein (low-density lipoprotein) is better evaluated by specific biochemical methods, but it may be seen in the β region (with gel-based systems) or α region (by capillary zone methods). It is an enormous molecule, with a mass of 2,750 kDa.

C3, the third component of complement and the only one readily visualized by serum protein electrophoresis, is the major β_2-region molecule. It consists of a 110-kDa α-chain and a 75-kDa β-chain. The level of C3 becomes elevated late in an acute-phase reaction. As mentioned above, if the sample is not stored properly, it is the first serum protein to break down.

Fibrinogen is the 340-kDa protein present in plasma but not in normal serum (Fig. 6 and 7). However, if the patient is anticoagulated, the sample is drawn into a tube containing an anticoagulant, or the serum is separated before clotting is completed, the sample may have enough residual fibrinogen to give a band in the β-γ region that can be confused with an M protein.

C-reactive protein is a 135-kDa protein that migrates in the γ region. Its name derives from its ability to react with the capsular polysaccharide of *Streptococcus pneumoniae*. It is an early indicator of an acute-phase reaction, best measured by nephelometric techniques.

Immunoglobulins migrate mainly in the β and γ regions. IgG is the main serum immunoglobulin (700 to 1,600 mg/dl). It is a 160-kDa protein, typically with a γ migration. It consists of four subclasses: IgG1, IgG2, IgG3, and IgG4. A polyclonal increase in the IgG4 subclass on occasion may mimic an M protein (Fig. 11). Such polyclonal increases can be

distinguished from M proteins by performing an immunofixation. IgM migrates in the β-γ region (40 to 230 mg/dl). It is a 900-kDa molecule that exists as a pentamer. It is the earliest immunoglobulin to respond to antigenic stimulation but does not appear to have a memory response. IgA in the serum exists mainly as a 160-kDa monomer (70 to 400 mg/dl), but in mucosal secretions it exists mainly as a dimer attached to a secretory component (380 kDa). IgD is present mainly on the surface of lymphocytes and is present only in small quantities in the serum (0 to 8 mg/dl). IgE is present mainly on the surface of mast cells and basophils. Serum concentrations are measured only for patients with allergies and in the extremely rare cases of IgE myeloma (see chapter 107).

PATTERN INTERPRETATION FOR SERUM

Although the main purpose of serum protein electrophoresis is the detection of M proteins, several other protein patterns that can be detected may be of clinical use. Some of these findings were mentioned above with regard to each major protein; however, others that depend upon a pattern of reactivity are reviewed here.

Liver Disease Pattern

In patients with cirrhosis, synthesis of hepatocyte-derived proteins such as albumin and transferrin is decreased. As shown in the capillary zone electropherogram in Fig. 12, this usually forms a stepwise increase from the α_2 region through the γ region. However, due to inflammation and rerouting of blood around the liver, the levels of other proteins may be increased. Typically, the serum demonstrates hypoalbuminemia (there may be anodal slurring of the albumin band if the bilirubin level is increased). There is β-γ bridging due to a polyclonal

increase in IgA, and a broad increase in the γ region reflecting the polyclonal increase in IgG.

Protein Loss Patterns

With nephrotic syndrome, loss of protein occurs through damaged glomeruli. The serum shows hypoalbuminemia, low or low-normal levels of α_1 globulin, and elevated levels of α_2 globulin due to retention of its large molecules (α_2 macroglobuin and haptoglobin) in the serum; the β region may be increased due to elevated levels of β_1 lipoprotein, and there may be low-normal gamma globulin levels or hypogammaglobulinemia due to loss of IgG into the urine (Fig. 13).

In protein-losing enteropathy, damage to the gastrointestinal tract such as occurs in gluten-losing enteropathy (celiac disease), the serum demonstrates findings similar to those of the nephritic syndrome with hypoalbuminemia, hypogammaglobulinemia, and occasionally elevated levels of α_2 macroglobulin.

Milder patterns of protein loss may result in only decreased albumin and gamma globulin. Because most serum protein electrophoresis is performed for patients for whom an M protein is in the differential diagnosis, when we see these findings, we recommend performing a urine immunofixation to rule out MFLC.

Acute-Phase Pattern

Acute-phase reaction is the result of recent damage that may occur due to disease such as infection and inflammation, or it may result from therapeutic measures such as surgery. In the serum, largely due to the effect of interleukin-6, there is a decrease in albumin and transferrin (β_1 globulin) with an increase in α_1 acid glycoprotein (orosomucoid), α_1 antitrypsin, and haptoglobin. In the mid- to fast-γ region, depending on the electrophoresis system being used, the C-reactive protein band may be seen. Later in the course of the inflammation, C3

increases. A somewhat similar pattern is seen in pregnancy and in patients receiving estrogen therapy, except that in the estrogen effect pattern a normal albumin level and an elevated transferrin level accompany the increase in α_1 antitrypsin and haptoglobin.

Hypogammaglobulinemia is never normal in an adult. When the total γ-region value falls below the normal range of 2 standard deviations set in our laboratories, we note that hypogammaglobulinemia is present. This may be seen in a variety of conditions, such as common variable immunodeficiency

disease, chronic lymphocytic leukemia, well-differentiated lymphocytic lymphoma, light-chain disease, and nonsecretory myeloma, and in patients who are receiving chemotherapy. The patient should have a urine protein electrophoresis and immunofixation performed to rule out the presence of MFLC. Amyloid AL (light-chain-associated amyloid) can sometimes be seen in cases of hypogammaglobulinemia. Measurement of the serum FLC has been shown to help in detecting both cases of AL and cases of nonsecretory myeloma (1, 12). Hypogammaglobulinemia is not a normal finding in the elderly.

Detection of M Proteins in Serum

Most M proteins belong to the IgG subclass and migrate in the γ region (Fig. 4, samples 13 and 25). Since the normal IgG migrates broadly throughout the slow β and γ region, even small M proteins at as low as 0.05 to 0.1 g/liter (especially in the presence of hypogammaglobulinemia) can be detected in systems with high-quality resolution (Fig. 14). Identification of the M protein requires immunologic demonstration that the M-protein band is made up of only one heavy-chain type and one light-chain type. Immunofixation and immunosubtraction are the two methods we recommend for this (see chapter 10).

M proteins, especially those of the IgA (Fig. 4, sample 24) and IgM (Fig. 4, sample 6) classes, are commonly detected in the β region. These can be more challenging to detect because of the presence of the three major proteins in that region: β1 lipoprotein (in gel-based methods), transferrin, and C3. This is when electrophoresis systems of high-quality resolution can be especially helpful. When we see protein level elevations in the β region on densitometry (or electropherogram, in the case of CZE) that are unexplained by β-γ bridging (such as in the cirrhosis pattern), immunofixation or immunosubtraction is indicated to rule out an M protein. Occasionally, M proteins will appear as a shoulder to one of the other bands, or even migrate directly on top of the band, producing an aberrantly large C3 or transferrin band.

Rarely, M proteins may migrate in the α_2 region. These are very difficult to detect because of the higher concentration of the proteins that normally migrate there. This is one reason why a negative serum protein electrophoresis does not rule out the presence of a detectable serum M protein. When serum protein electrophoresis is negative for a patient for whom having an M protein is strongly suspected, an immunofixation of the serum and urine should be performed.
Measurement of Serum M Proteins

With the better-resolution systems, the lower limit of detection of M proteins has been estimated at about 50 mg/dl (4, 24). Detection of small M proteins can be clinically significant. These proteins may indicate early detection of what will prove over time to be a typical myeloma. Differentiation between myeloma and monoclonal gammopathy of unknown significance requires careful follow-up of the patient by the clinician and period laboratory studies. Small M proteins may be seen in patients with light-chain myeloma, IgD myeloma, IgE myeloma, amyloid AL, and other B-cell lymphoproliferative processes such as chronic lymphocytic lymphoma or well-differentiated lymphocytic lymphoma. Once an M protein has been detected and characterized immunologically, it should be measured to allow follow-up. For M proteins that are clearly distinguishable from other proteins, we recommend measuring the M-protein band itself by densitometry (for gel-based systems) or by use of the electropherogram (for CZE). We place the demarcation for the M protein at the notch it forms with the normal immunoglobulins (Fig. 14). For M proteins that migrate in the β or α_2 regions, where other proteins are present, it is a judgment call as to whether the M protein is distinguishable from the other proteins in the region. If one can make this distinction, this measurement will usually be better for monitoring of patients with M proteins than a measurement by nephelometry of the total immunoglobulin of that class. The M-protein measurement excludes most of the polyclonal immunoglobulins, whereas the nephelometric measurement will include them, obscuring to some degree changes in the M protein on subsequent measurements.

PATTERN INTERPRETATION FOR URINE

In 50- to 100-fold-concentrated urine samples, albumin in small amounts may be seen in a variety of conditions. Normally, up to 150 mg of total protein (mostly albumin) may be detected during 24 h. The amount may be increased following strenuous exercise and in patients with diabetes.

Mild glomerular damage will demonstrate the moderate-size major serum proteins that normally do not pass effectively through the glomerular barrier (Fig. 15). As long as the tubular reabsorptive function is intact, no, or little, faintly staining protein will be seen in the α_2 and β regions. When the capacity for the tubules to reabsorb 1 g of protein in 24 h is exceeded, small bands will be seen in these regions, along with faintly staining γ region. With severe nonselective renal disease, a pattern that resembles that of serum

FIGURE 15 Several urine protein electrophoretic patterns for concentrated urine samples.

protein electrophoresis excluding, to a lesser extent, the large molecules in the α_2 region is found.

If only the tubules are damaged, the large amounts of small serum proteins that pass through the glomerulus will not be reabsorbed and will appear in the urine. Typically, one will find a small amount of albumin and numerous bands of various sizes in the α_1, α_2, and β and γ regions (Fig. 15). After the interpreter gets used to the usual bands of tubular proteinuria, if a band is found in a different location an immunofixation should be performed to rule out the presence of MFLC.

When a large excess of a relatively small molecule is present, such as in a patient with myoglobinuria, if the amount excreted is greater than the tubular reabsorptive capacity, an overflow proteinuria pattern is seen. This situation must be studied by immunofixation to rule out the possibility that the band represents an M protein.

Detection of M Proteins in the Urine
MFLC (Bence Jones proteins) typically occur as monomers (22 kDa) and dimers (44 kDa), both of which pass into the urine. Uncommonly, they exist as tetramers that are too large to pass through the normal glomerular capillaries and into the glomerular filtrate.

An early-morning void or a 24-h urine sample is the best specimen in which to look for MFLC. Alternatively, or in addition, measurement of FLC in serum via new nephelometric techniques may also be able to detect MFLC (see chapter 8). Once MFLC have been demonstrated by electrophoresis and documented by immunofixation or FLC measurements, they should be monitored by measuring the MFLC peak on the densitometric scan of a 24-h urine collection. Because urine immunofixation electrophoresis can be informative even when the spike cannot be seen by urine protein electrophoresis, some laboratories use a semiquantitative method of comparing very small quantities of MFLC by grading the density of the band on a scale of 1 to 4. Alternatively, FLC measurements have been suggested as a possible technique. These have the advantage that serum measurements can be made, avoiding the necessity to collect a 24-h urine sample. However, FLC measurements are a relatively new technique and need to be related to the immunofixation results for each case.

Although CZE techniques to detect MFLC have been described, they are not yet commonly used in clinical laboratories. Therefore, this discussion will focus on gel-based results.

MFLC and M proteins may migrate anywhere from the α through the γ region on urine protein electrophoresis (Fig. 15). Once one becomes familiar with the common patterns of glomerular and tubular proteinuria discussed above, unusual bands will become apparent. This is more difficult with tubular proteinuria and its many bands from small proteins which are not reabsorbed than with glomerular proteinuria.

For optimal detection of MFLC, we recommend performing immunofixation and urine protein electrophoresis on all samples. For the initial detection of MFLC, we review our files on the patient to see if there is a known M protein in the serum. If so, that information is used to determine the antisera we use to evaluate the urine. We always use anti-κ and anti-λ but would in addition use antisera of the heavy-chain isotype demonstrated in the serum (γ, α, μ, δ, or ϵ).

Commonly, both the intact M protein and the MFLC can be found in the urine of a patient with multiple myeloma. The urine immunofixation is compared to the urine protein electrophoresis to determine which band is the MFLC. This band is measured by densitometry of the urine protein electrophoresis. The concentration of the total protein in the urine is used with this measurement and the volume of 24-h urine to determine the amount of the MFLC per 24 h as follows: MFLC/24 h = (total protein concentration [mg/ml]) × (ml/24 h) × % MFLC by densitometry.

The record of the urine protein electrophoresis and immunofixation is stored in a file with the serum protein and immunofixation results. This allows correlation of the current results with previous results and on occasion can catch a mislabeled sample.

CLINICAL APPLICATIONS
Serum and urine protein electrophoreses are not general screening techniques. They are employed to detect M proteins in patients suspected of harboring plasma cell and B-lymphocyte proliferative disorders. We recommend that both urine and serum be studied for patients suspected of having an M protein.

In addition to M proteins, however, performance of serum and urine protein electrophoresis often detects a wide variety of other abnormalities that can provide useful clinical information, as described above. Therefore, attention to all regions of the electrophoretic pattern is needed, and such abnormalities are included in the final report.

The presence of a band suspected of being an M protein requires immunological characterization (see chapter 10). Also, measurement of the immunoglobulin isotype, and in some cases the FLC, may be useful for monitoring of the patient (see chapter 8).

Immunochemical Characterization of Immunoglobulins in Serum, Urine, and Cerebrospinal Fluid

JERRY A. KATZMANN AND ROBERT A. KYLE

10

The characterization of immunoglobulins spans a spectrum of methods, including molecular analysis of gene usage and rearrangement; quantitation of immunoglobulin heavy chains as well as intact and free light chains; qualitative assessment and characterization of clonality; and identification of abnormalities that may be clinically significant, such as hyperviscosity syndrome, cryoglobulinemia, and amyloidosis (AL). This chapter focuses on qualitative methods for the assessment and characterization of clonality. The methods include nondenaturing agarose gel electrophoresis (AGE) with immunofixation, capillary zone electrophoresis (CZE) with immunosubtraction, and isoelectric focusing with immunoblotting. All three methods can be used to identify monoclonal, oligoclonal, and polyclonal immunoglobulin populations and to identify the heavy and/or light chains contained in the population. Immunofixation electrophoresis (IFE) and immunosubtraction electrophoresis (ISE) are diagnostic tools used for the identification of monoclonal gammopathies and, conversely, for the confirmation of polyclonal hypergammaglobulinemia. Isoelectric focusing with immunoblotting is a cerebrospinal fluid (CSF) diagnostic test for the identification of oligoclonal bands (OCB) in multiple sclerosis (MS).

MONOCLONAL GAMMOPATHIES

The monoclonal gammopathies (dysproteinemias or paraproteinemias) are characterized by the proliferation of a single clone of plasma cells that produces an immunologically homogeneous protein commonly referred to as a monoclonal protein or a paraprotein. It is important to identify monoclonal proteins and to be able to distinguish between increases in monoclonal and polyclonal immunoglobulins (19–21). Monoclonal immunoglobulins are associated with a clonal process that is malignant or potentially malignant, whereas an increase in polyclonal immunoglobulins is due to an inflammatory or reactive process (22).

All immunoglobulins are products of clonal plasma cells. In a normal immune response, each of the thousands of immunoglobulin clonotypes produced by the plasma cell clones is present in relatively small proportion. The normal immune response is therefore described as polyclonal. Monoclonal gammopathies are a group of disorders that include plasma cell and B-lymphoid proliferative disorders and are defined by the expansion of a plasma cell clone. The

secreted immunoglobulin from the expanded plasma cell clone results in a detectable monoclonal immunoglobulin (12). The monoclonal gammopathies include a spectrum of diseases, from ones that may have little clinical significance to ones that may be rapidly fatal. These include multiple myeloma (MM), Waldenström's macroglobulinemia, smoldering MM, monoclonal gammopathy of undetermined significance (MGUS), primary systemic AL, lymphoproliferative diseases, and plasmacytomas. The distribution of these diseases in the Mayo Clinic practice from 1960 through 2003 is listed in Table 1. During this interval, our dysproteinemia practice identified 31,479 monoclonal gammopathies. The most common of the monoclonal gammopathies is MGUS, but the hallmark monoclonal gammopathy is MM. MM is a malignant plasma cell disorder that resides in the bone marrow and causes multiple osteolytic lesions. Patients often present with bone pain or fractures due to these bone lesions. The monoclonal immunoglobulin produced by the malignant plasma cell clone was one of the first serological tumor markers. The identification of a monoclonal immunoglobulin in serum (or urine) is an indicator of the expansion of the clone of plasma cells and, depending on the clinical presentation, triggers a series of additional laboratory tests to confirm the diagnosis of a monoclonal gammopathy. In addition to monoclonal immunoglobulin being a diagnostic tool for the identification of monoclonal gammopathies such as MM, the amount of monoclonal immunoglobulin can be quantitated and used as a surrogate marker to monitor the plasma cell population.

METHOD BACKGROUND

Analysis of serum or urine for monoclonal proteins requires a sensitive, rapid, and simple screening method that detects the presence of a monoclonal protein and also requires a specific assay to confirm the clonality and identify the heavy-chain class and light-chain type. High-resolution agarose gel protein electrophoresis (PEL) and CZE fulfill the requirements for a screening procedure for detection of monoclonal proteins (17, 18, 20). IFE in agarose or ISE with CZE is needed to confirm the presence of the monoclonal protein and determine its type.

Nondenaturing PEL systems such as cellulose acetate, agarose gel, and CZE separate proteins on the basis of charge and size. Five serum fractions have traditionally been identified

**TABLE 1** Distribution of plasma cell proliferative disorders at Mayo Clinic, 1960 to 2003[a]

Type of monoclonal gammopathy	% of cases
MGUS	61
MM	17

by PEL: albumin, α_1, α_2, β, and γ. In a normal serum separated by agarose gel PEL, the γ fraction will have a broad, Gaussian distribution (Fig. 1). The distribution of immunoglobulins through the γ fraction is predominantly due to charge differences on the different immunoglobulin clono-

types. In the IFE results illustrated in Fig. 1, it can be seen that the immunoglobulin G (IgG) migration pattern corresponds to the PEL γ fraction. In the serum of a patient with a monoclonal gammopathy, the increased monoclonal immunoglobulin migrates in a restricted area of migration in the electrophoresis pattern (Fig. 2). All patients with a localized band on PEL require IFE or ISE to confirm the monoclonal protein and to determine its heavy-chain class and/or light-chain type. The IFE reactivity in Fig. 2 indicates that the restricted electrophoretic migration is due to an IgG (γ) heavy chain and an associated λ light chain. It is this restricted heavy-chain migration on the gel and the associated migration of only one light-chain type that identify and characterize the monoclonal immunoglobulin heavy- and light-chain types. The monoclonal fraction (M-spike) from the serum PEL quantitates the amount of the monoclonal protein.

Plasma cells produce immunoglobulin heavy and light chains which are assembled into the intact immunoglobulin molecules. In order to ensure proper assembly, there is an approximately 40% excess of light chain produced. Unlike
FIGURE 1 PEL and IFE of normal serum. (Top) PEL gel scan and electrophoretogram with the albumin (Alb), α_1, α_2, β, and γ fractions. (Bottom) IFE gel scan. Lanes were immunofixed with antisera to γ (G), α (A), μ (M), κ (K), and λ (L). The distribution of normal serum immunoglobulins is illustrated.
FIGURE 2 PEL and IFE of a serum containing a monoclonal protein. The PEL indicates that the M-spike equals 7.2 g/liter, and the IFE indicates that it is a monoclonal IgG λ protein. The γ and λ bands are sharp and comigrate. There is very little polyclonal immunoglobulin in this serum sample. Alb, albumin; lanes G to L, as defined in the legend to Fig. 1.

the secreted intact immunoglobulins, the free light chains are rapidly cleared from serum (32, 33). The light chains are cleared and metabolized by the kidneys within hours of secretion. In healthy individuals, the light chains are catabolized and are not readily apparent by urine PEL. As patients become proteinuric, however, both heavy and light chains can be detected by PEL and IFE. In patients with monoclonal gammopathies, the excess monoclonal free light-chain production may often be detected in urine. In IgG myeloma, for example, approximately three-fourths of patients have an excess of light chains that are excreted and detected in the urine as Bence Jones proteinuria (24). The immunofixation assay for urine studies is identical to the serum assay except that urine samples with low protein content need to be concentrated to increase the detection sensitivity.

IFE and ISE are required for confirmation and characterization of monoclonal proteins identified by PEL. In addition, it should be emphasized that even when PEL is negative, IFE may detect small monoclonal proteins. In the absence of a localized band on serum and/or urine PEL, IFE should still be performed if MM, macroglobulinemia, AL, solitary or extramedullary plasmacytomas, or a related disorder is suspected.

MONOCLONAL PROTEINS

Most patients with monoclonal gammopathies have a detectable monoclonal heavy and light chain in the serum, and some have a detectable monoclonal urinary protein as well. In some patients, however, heavy chains are not produced by the plasma cells. Table 2 lists the distribution of monoclonal serum proteins detected in the Mayo Clinic practice from 1960 through 2003. During this time, 28,249 monoclonal proteins were detected. Most of the monoclonal proteins were IgG, IgM, and IgA molecules, and there were a small number of monoclonal IgD and IgE immunoglobulins. There were, however, significant numbers (5%) of serum monoclonal proteins in which monoclonal light chains were detected but which had no associated heavy chain. Because the free light chains are so readily cleared from the serum, patients with these disorders often show small or undetectable M-spikes on serum PEL. The monoclonal free light-chain diseases, however, represent very significant disorders. Although monoclonal free light chains represented 5% of all the monoclonal gammopathies, light-chain MM (LCMM) accounted for 20% of the MM cases (Table 3). This overrepresentation of free light chains in MM (20%) versus all monoclonal gammopathies (5%) emphasizes the importance of confirming small serum PEL abnormalities by IFE. It can also be seen in Table 3 that

TABLE 2 Monoclonal serum proteins detected at Mayo Clinic, 1960 to 2003[a]

nearly 3% of MM patients have no detectable monoclonal heavy chain or light chain (6, 30, 35). These nonsecretory-MM patients have large numbers of plasma cells in the bone marrow, and most of these patients have clonal plasma cells with cytoplasmic κ or λ light chain, indicating a secretory defect. A small number of these nonsecretory-myeloma patients, however, have no detectable cytoplasmic immunoglobulin in their plasma cells and are nonproducers. Although not listed in Table 3, there are also rare monoclonal gammopathy patients who produce a portion of the heavy chain but no light chain. These disorders include γ, α, and μ heavy-chain disease.

One final point should be taken from Table 2. Four percent of the detected monoclonal gammopathies are biclonal gammopathies. In these patients, there are two separate expanded clones of plasma cells. The PEL may show two M-spikes, and the immunofixation will show two different heavy and light chains with different mobilities (Fig. 3). The presence of two monoclonal proteins is clinically no different
FIGURE 3 PEL gel scan and IFE of a serum containing a biclonal gammopathy. The PEL gel contains two discrete bands in the γ fraction. The IFE indicates that there is a γ band with a corresponding κ band plus a μ band with a corresponding κ band. The biclonal gammopathy contains a monoclonal IgG κ and a monoclonal IgM κ protein. Lanes G to L, as defined for Fig. 1.

from a monoclonal gammopathy (25). Above 50 years of age, monoclonal gammopathies are detected in the general population at a rate of 3% (26). If a monoclonal protein occurs in 3% of the population over age 50, we can expect that 3% of these individuals will have a second "monoclonal" protein. In addition, we can predict that 0.09% of monoclonal gammopathies will actually be triclonal gammopathies.

IFE

IFE is the composite of the two separate procedures of PEL and immunofixation. Proteins are first separated by electrophoresis in a nondenaturing agarose gel, and then an antiserum is applied to precipitate the proteins of interest. Soluble proteins are washed away, and the immunoprecipitate is visualized with a protein stain. There are a number of reagent sets that are available from commercial vendors. These assay kits provide agarose gels, diluent, electrophoresis buffer, antisera, wash buffer, stain, and destaining solution as well as the application system for applying sample and antisera to the gel. In a single assay, the patient serum or urine is usually applied to six lanes of the gel and electrophoresed so that all six lanes have the proteins separated in an identical manner. Fixative solution is added to a single lane to precipitate all the proteins. This is the PEL lane and serves as the reference lane for all the proteins. The remaining five lanes are overlaid with antiserum to γ, α, μ, κ, or λ chains in order to precipitate the specific immunoglobulins. The soluble proteins are washed out of the gel, and the immunoprecipitated proteins are visualized with acid violet stain and compared to the reference lane. In the IFE shown in Fig. 1, it can be seen that the IgG migration pattern corresponds almost exactly to the shape of the γ fraction, whereas the IgA and IgM immunoglobulins migrate predominantly in the fast-γ region and the interface of the β and γ fractions. Because IgG is normally present in serum in much higher concentrations than IgA or IgM, the distribution of the κ and λ light-chain reactivity corresponds to the distribution of the IgG population. In addition, the κ lane appears denser than the λ lane as a reflection of the increased concentration of κ immunoglobulins compared to λ. The commercial reagent sets are available in gel configurations that allow the analysis of samples from one, two, four, or nine patients on a single gel. The entire process from sample application to stained IFE gel takes approximately 1.5 h.

Serum IFE

Serum samples should be collected and stored refrigerated until analyzed. Refrigerated samples are stable for at least 2 weeks and can be stored frozen indefinitely. Serum samples are often diluted for application to the IgG lane, and a lesser dilution is used for the other gel lanes. In the Sebia Hydragel system, the serum for the IgG lane is diluted 1:6 and the sera for the other five lanes (PEL, α, μ, κ, and λ) are diluted 1:3. If the serum is hypogammaglobulinemic (γ fraction or total immunoglobulins, <0.5 g/dl), the IFE may need to be performed with undiluted serum applied to the gel in order to sufficiently visualize the immunoglobulins. Conversely, if the serum has marked polyclonal hypergammaglobulinemia (γ fraction or total immunoglobulins, >4 g/dl), the serum may need to be diluted further in order to see through the dense protein stain.

The evaluation of PEL and IFE gels is a qualitative skill that takes experience for correct interpretation. The agarose gels should always be examined directly by the interpreter. As illustrated in Fig. 1, normal serum samples show broad, homogeneous staining in all the lanes. Perhaps most importantly, the κ and λ lanes show identical staining distributions. Some monoclonal proteins have a broad distribution on PEL and can be confused with a polyclonal immunoglobulin pattern, but the light-chain distribution shows only κ or λ associated with the increased heavy-chain staining pattern. Conversely, large increases in polyclonal immunoglobulin concentrations may appear to have restricted migration on PEL and may be confused with a monoclonal gammopathy. Large polyclonal increases in immunoglobulins may occur in patients with chronic active hepatitis, connective tissue disorders, or chronic lymphoproliferative disease. The distribution of κ and λ migration on IFE should always be examined carefully.

Patients with hypogammaglobulinemia will have faintly staining γ fractions, and those with polyclonal hypergammaglobulinemia will have darkly staining γ fractions. Because undiluted hypogammaglobulinemic sera may be applied to the gels, the gels may have an artifact at the point of application that represents material that does not enter the agarose. This type of artifact is recognized by noting that all lanes contain stained material at the point of application. Because of the high protein content of polyclonal hypergammaglobulinemic sera as well as the potential for rheumatoid factors in these sera, they may also exhibit a point-of-application artifact. In addition, these polyclonal hypergammaglobulinemic samples often contain multiple faint, fuzzy areas of nonhomogeneous distribution in many of the lanes. These most likely represent the "tips" of the polyclonal responses. The presence of these multiple bands in polyclonal hypergammaglobulinemic sera should be interpreted as artifact and not reported as small monoclonal proteins.

Most monoclonal protein bands are straightforward to identify and interpret (Fig. 2). The bands are dark and narrow, and there is a heavy-chain band and either a κ or λ light-chain band but not both. The IFE bands have the same migration as the band in the PEL lane. The most difficult samples to interpret are sera that contain very small, fuzzy heavy- and light-chain bands within a polyclonal background (Fig. 4). Because all immunoglobulins are clonal products and because our analytic procedures have become very sensitive, we can identify small clones that may have no clinical significance. If a serum free light-chain assay and/or urine IFE has ruled out a monoclonal free light chain, it is better to report these diffuse bands as unable to rule out a small monoclonal protein. If the small monoclonal protein is clearly present (as in Fig. 4) but is too small to fractionate as an M-spike on PEL, our laboratory reports the result as a small monoclonal protein within a polyclonal background. This makes it clear to the clinician that the monoclonal protein is too small to be quantitated and is not equal to the quantitation of the γ fraction.

In our practice, approximately 90% of the monoclonal proteins identified by IFE contain a single monoclonal heavy chain and corresponding light chain (Table 2). In 4% of the identified monoclonal gammopathies, there is a second monoclonal protein identified (biclonal gammopathy). In the biclonal gammopathy illustrated in Fig. 3, the IFE contains a γ heavy-chain band and a μ heavy-chain band, and each has a corresponding κ light-chain band. If, however, the two heavy-chain and the two light-chain bands are identical, they should not be reported as a biclonal gammopathy unless migration of one is cathodal and that of the second is anodal. If the bands are identical IgM molecules, they are most likely monomeric and pentameric IgM (7S and 19S), and if they are identical IgA or IgG molecules, they are most likely
FIGURE 4 PEL and IFE of a serum containing a small monoclonal IgG κ protein. The protein is too small to be fractionated and quantitated as an M-spike. The γ fraction contains mostly polyclonal immunoglobulin, and the PEL electrophoretogram shows a small bump on top of the γ fraction. The PEL gel scan contains a small, fuzzy band corresponding to the asymmetry in the electrophoretogram, and the IFE shows some corresponding increased, restricted reactivity in the γ and κ lanes. Lanes G to L, as defined for Fig. 1.

monomers and dimers. The biclonal gammopathies are clinically identical to the monoclonal gammopathies, and most of these patients will be diagnosed with biclonal gammopathy of undetermined significance. The size of each individual M-spike should be separately monitored for disease activity. In the case of a monoclonal protein that circulates as a monomer and polymer, the sum of the peaks should be used to monitor disease activity.

Monoclonal free light chains represent the other 5% of the monoclonal gammopathies. Sera with monoclonal light chains will show a discrete κ or λ band on IFE, and there will be no corresponding γ, α, or μ heavy chain (Fig. 5). Although IgD monoclonal proteins are uncommon and IgE monoclonal proteins are very rare, any monoclonal free light-chain result should be confirmed by retesting the sample by IFE using antisera to δ and ε in the lanes usually reserved for γ, α, and μ (Fig. 6). Monoclonal free light chains usually do not accumulate in the serum and may

have a small M-spike or no M-spike (Fig. 5). In spite of this small serum abnormality, monoclonal free light chains are often associated with serious disease. The light-chain diseases include LCMM, AL, and light-chain deposition disease. Although monoclonal free light chains represent 5% of all monoclonal proteins identified in our practice, they account for 20% of the monoclonal proteins found in MM patients. Monoclonal free light chains are uncommon in MGUS and are associated predominantly with MM or AL. The recognition and reporting of a monoclonal free light chain should therefore be done cautiously. If the light-chain band on IFE is very faint and fuzzy or if the light-chain band is distinct but has a corresponding faint, fuzzy heavy-chain band, the report should suggest that a small monoclonal protein or a monoclonal free light chain cannot be excluded. Follow-up tests of urine IFE and serum free light chains should be recommended.

Serum IFE Clinical Significance

The identification of a serum monoclonal protein suggests the possibility of a diagnosis of a number of monoclonal gammopathies. Most of these are clinical diagnoses, but the
FIGURE 5 PEL and IFE of a serum specimen from a patient with LCMM. Although this patient has myeloma, there is no obvious PEL abnormality. The IFE, however, clearly shows a discrete λ band with no corresponding γ, α, or μ reactivity. Lanes G to L, as defined for Fig. 1.
FIGURE 6 PEL and IFE of a serum from a patient with an IgD myeloma. The PEL contains a small M-spike that has a corresponding λ band as determined by IFE. The IFE was repeated with antisera to κ, λ, δ (D), and ε (E) and indicated that the monoclonal protein is an IgD λ immunoglobulin. Lanes G to L, as defined for Fig. 1.

laboratory may want to suggest the possible clinical significance of the PEL and IFE results. If the monoclonal protein is an intact immunoglobulin (IgG, IgA, or IgM) but is too small to be fractionated as an M-spike on PEL, our laboratory does not associate a potential diagnosis with the report. These small abnormalities are reported as small monoclonal proteins within a normal (or polyclonal hypergammaglobulinemic, hypogammaglobulinemic, or β-fraction)

background. In addition, we suggest that the studies be repeated in 6 to 12 months. Repeat testing allows the identification of those cases in which a very early monoclonal process was present during the initial PEL and IFE, and a significant increase in the M-spike will be detected in the second sample.

If the monoclonal protein is an IgG or IgA and is a quantifiable M-spike that is <3 g/dl, our laboratory reports that the result is consistent with MGUS, early myeloma, or AL. The order of the report indicates the relative frequency of each group of diseases, and the three diseases represent three categories of monoclonal gammopathies that the clinician needs to consider: (i) diseases such as MGUS or smoldering myeloma that should be observed but not treated; (ii) malignant diseases such as MM, lymphoma, plasma cell leukemia, or plasmacytomas; and (iii) diseases of protein structure such as AL, light-chain deposition disease, or cryoglobulinemia. If the IgG or IgA M-spike is >3 g/dl, the result is consistent with MM.

If the monoclonal protein is an IgM that is <3 g/dl, our laboratory reports that the result is consistent with MGUS, early macroglobulinemia, or lymphoproliferative disease. If the IgM M-spike is >3 g/dl, the IFE result is consistent with Waldenström's macroglobulinemia.

If the monoclonal protein is an IgD or free κ or λ light chain, our laboratory reports that the result is consistent with MM or AL. A 24-h urine monoclonal protein study should be suggested for any patient who has a serum monoclonal free light chain or monoclonal IgD, as well as for IgG, IgA, or IgM M-spikes >1.5 g/dl (21). Some laboratories suggest urine monoclonal protein studies for all patients with a monoclonal serum protein.

Serum Artifacts

As described above, sera with very low or very high immunoglobulin concentrations or γ fractions may need to be retested at different dilutions in order to evaluate the IFE.

The presence of fibrinogen or hemoglobin may cause the artifactual identification of an M-spike on PEL. Fibrinogen migrates in the fast-γ region and has the appearance of an M-spike on PEL. Analysis by IFE, however, shows no monoclonal immunoglobulin corresponding to the PEL band (Fig. 7). If a fast-γ band is identified in a patient with no previous history of a fast-γ monoclonal protein, the PEL report should be delayed until the sample is tested for fibrinogen and/or the IFE results are known. Samples can be checked for fibrinogen by the addition of 10 μl of thrombin (topical USP, 1,000 U/ml) to 200 μl of serum and incubation of the sample for 15 min at 37°C. If a fibrin clot forms, the supernatant should be retested by PEL. Some samples have sufficient anticoagulant that addition of thrombin will not remove the entire fibrinogen peak. In addition to reporting no monoclonal protein detected by IFE, the report should indicate that the γ fraction may be increased due to the presence of fibrinogen. Depending on the particular AGE system, hemoglobin-haptoglobin complexes migrate in the β or α fractions. If a fuzzy extra β/α band is identified on PEL, the sample should be examined for hemolysis (Fig. 8).

The presence of a very sharp band in each lane at the point of application indicates nonspecific staining that is due to protein not entering the agarose gel. This point of application may represent immunoglobulin aggregates or cryoglobulins, and the sample should be retested after treatment of the sample with a reducing agent such as dithiothreitol (DTT) and warming. A 0.5 M solution of DL-DTT in water
can be stored up to 1 year at −20°C. Twenty microliters of the DTT solution is added to 80 μl of serum, and the mixture is vortexed and incubated at 37°C for 15 min. The reduced serum sample should be retested.

Very large M-spikes are sometimes difficult to completely wash out of the gel. A large IgG κ monoclonal protein, for example, may have dark, sharp bands in the γ and κ lanes but may also cause fuzzy, faint reactivity in the α, μ, and λ lanes due to the inability to remove the large amount of soluble protein in the narrow region of the M-spike. In addition to causing this "shadow" artifact, large IgG peaks (>3 g/dl) may migrate so sharply on PEL that the binding of stain in the center of the peak is saturated. The quantitation of the M-spike by PEL will be lower than the quantitative immunoglobulin measurement and thus may not reflect changes in concentration due to therapy or progression. Nephelometry should be suggested to assist in patient monitoring (Fig. 9).

FIGURE 7 PEL and IFE of a sample containing fibrinogen. The PEL contains a fast-γ peak that is indistinguishable from a small monoclonal protein. The IFE shows no corresponding heavy- or light-chain bands. Lanes G to L, as defined for Fig. 1.

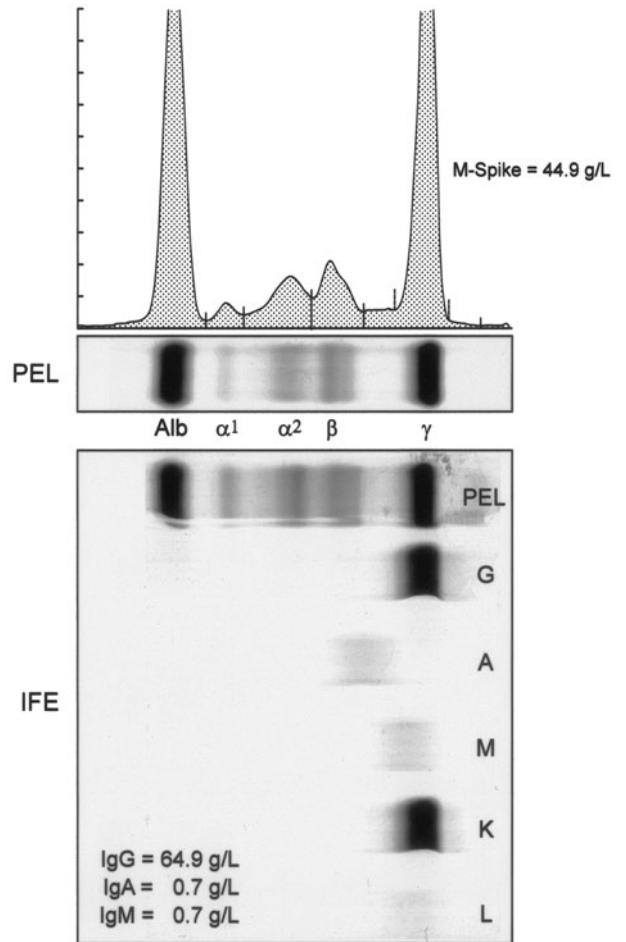

FIGURE 8 PEL of a hemolyzed serum sample. The gel scan appears to contain a small monoclonal protein in the α₂-β region. Alb, albumin.

FIGURE 9 PEL, IFE, and quantitative immunoglobulins of a serum sample that contains a large IgG κ M-spike. The large, narrow IgG band has saturated the amount of stain in the PEL agarose gel. The M-spike is 44.9 g/liter, whereas the IgG nephelometric quantitation is 50% higher at 64.9 g/liter. Alb, albumin; lanes G to L, as defined for Fig. 1.

Quality Control

New reagent lots should be tested against sera with known monoclonal proteins before being used for routine testing. In addition, antisera should be tested with a plasma sample to ensure no cross-reactivity with fibrinogen. A sample containing a monoclonal protein of known immunotype should be tested each day. If a patient sample that has been previously immunotyped is part of the workload, that sample may serve as a daily control. The gels should be reviewed with respect to the sharpness of the AGE bands and the correlation of the IFE bands with the AGE M-spike. IFE gels that are too faint or too dense should be repeated with the appropriate dilution. The IFE gels are reviewed in our laboratory by two independent observers.

In addition to the internal laboratory controls, external proficiency challenges are available for identification and characterization of monoclonal proteins. The College of American Pathologists proficiency program supplies challenges on a quarterly basis, and its summary reports allow laboratories to compare their performance with that of other laboratories as well as with those of other methods and reagents from different manufacturers.

Urine IFE

Because light chains may accumulate in the urine, the presence of a monoclonal immunoglobulin light chain in the urine may be seen in almost any of the monoclonal gammopathies. For patients with LCMM, urine PEL and IFE are the major diagnostic and monitoring assays. Patients for whom a monoclonal light chain in the serum, a monoclonal IgD, or any intact monoclonal immunoglobulin M-spike that is >1.5 g/dl is detected should have 24-h urine monoclonal protein studies ordered. Although urine IFE is recommended for patients with a serum M-spike of >1.5 g/dl (21), patients with smaller serum M-spikes may have a large amount of light-chain immunoglobulin in the urine. Many laboratories perform urine monoclonal protein studies for all patients with a serum monoclonal protein. In addition, urine IFE should be performed for patients in whom MM, Waldenström's macroglobulinemia, AL, or light-chain deposition disease is suspected, even if the routine urinalysis is negative for protein. It is not uncommon for the urine to have a normal total protein result and no abnormality on urine PEL but still have a monoclonal light chain detected by IFE. Conversely, patients for whom a monoclonal protein is identified in the urine should have serum studies ordered.

The assessment of urine samples by IFE is similar to serum IFE. The major difference is the need to concentrate urine samples to achieve an appropriate protein concentration. Because of the very large range of urine protein concentrations, the urine IFE test has more stringent sample preparation requirements than serum IFE. Final concentrations of urine protein should ideally be between 2,000 and 8,000 mg/dl. This means that samples with protein concentrations of <16 mg/dl should be maximally concentrated (200×). Centrifugal concentrators allow rapid concentration of urine samples with minimal loss of protein. Our laboratory uses Vivaspin concentrators which are centrifuged at 5,000 rpm until the urine specimens reach final concentration. The polyethersulfone membrane has a 10,000-molecular-weight cutoff and retains most urinary proteins. Urine samples collected with acetic acid, hydrochloric acid, or sodium carbonate should not be accepted for analysis, and samples collected in toluene should have the toluene aspirated before concentration.

Urine samples should be collected and stored refrigerated until analyzed. Urine specimens that are collected with no preservatives are stable for 3 days at room temperature and for 14 days refrigerated or frozen. Urine samples collected with toluene or thymol as a preservative are stable at room temperature for 7 days. Most of the observed instabilities relate to urine samples with low protein content and monoclonal proteins that are at the detection limit of the assay. Large monoclonal protein peaks will be detectable beyond these limits. The limit of detection for urinary monoclonal proteins is 0.5 to 2.6 mg/dl. These limits are 10- to 20-fold lower than the detection limit for serum, and the difference is a reflection of the lack of polyclonal background in many urine samples and of the urine concentration step.

The evaluation of urine IFE gels is similar to that of serum gels. In urine specimens with low protein concentration and with no monoclonal proteins, we may see sufficient staining to identify broad κ and λ reactivity with identical staining distribution. If the gels are too light to visualize any κ and λ reactivity and the urine is already concentrated 100 to 200 times, the assay result should be reported as no monoclonal protein detected. If the gel is too densely stained to evaluate whether there is restricted migration, the assay should be repeated with a lower concentration of the urine sample. As for serum, small abnormalities within a polyclonal background are the most difficult to interpret. Small bands may be less distinct in urine than in serum, and it is important to compare the κ and λ reactivities for differences in distribution. As in serum, however, identification and characterization of most monoclonal proteins in urine is usually straightforward on IFE (Fig. 10). Many samples with monoclonal proteins in the urine have a single monoclonal light-chain band with no corresponding heavy-chain band. Two discrete light-chain bands of either the κ or the λ type may be present, and these are due to the presence of monomers and dimers of the monoclonal light chain. Often, however, there is a second, small monoclonal light-chain band with a corresponding heavy-chain band. Our laboratory reports these results as a monoclonal light chain plus an immunoglobulin fragment. The paired heavy and light chains usually have the same migration as the serum monoclonal protein and are most likely intact immunoglobulin.

Urine IFE Clinical Significance

A urinary monoclonal light chain in an M-peak of >1 g/24 h is consistent with a diagnosis of MM or macroglobulinemia (Fig. 10). In patients with MM, there are a large number of monoclonal plasma cells in the bone marrow and a large amount of monoclonal protein is usually produced. Any excess free light chain that is produced has a short half-life in serum and accumulates in the urine. The amount of excess free light chain is, of course, most dramatic in LCMM. In patients with LCMM, the serum may have a small M-spike, whereas the urine will contain a large M-spike and very little other protein.

A small amount of monoclonal light chain in the presence of proteinuria (>3 g/24 h) which is predominantly albumin is consistent with AL or light-chain deposition disease (Fig. 11) (23). In these diseases, there are usually small numbers of monoclonal plasma cells in the bone marrow and a small amount of monoclonal light chain is produced. The monoclonal free light chains, however, may be deposited as amyloid fibrils or may deposit in the glomerulus, causing light-chain deposition disease. The resultant organ damage results in proteinuria that is predominantly albumin and contains only a small amount of monoclonal light chain.
FIGURE 10   PEL and IFE of urine from a patient with LCMM. The PEL shows a large M-spike in the β fraction. The IFE shows a dense λ band corresponding to the M-spike. In addition, there are small amounts of additional λ reactivity in the γ fraction that most likely represent multimers of the monoclonal λ protein. Alb, albumin; lanes G to L, as defined for Fig. 1.

Urine Artifacts

As described above, inadequate concentration of urine specimens may result in false negatives, and overly concentrated urine samples will give high background staining if large amounts of polyclonal immunoglobulins are present. This makes interpretation impossible.

Interfering substances are more commonly identified in urine than in serum by PEL. As in serum, the presence of hemoglobin will result in a band in the α region on PEL, and as with sera, these samples should be examined for their red color. If hemoglobin is present, the report should indicate hemolysis. Other reported interfering substances have included radiographic dyes, antibiotics, and proteins such as myoglobin, lysozyme, and β_2 microglobulin. Reports of newly identified monoclonal protein bands on PEL should be delayed until confirmed by IFE.

Artifacts at the point of application are more common in urine than in serum. These are usually caused by insoluble material other than immunoglobulin aggregates. The shadow artifacts caused by large M-spikes are also more common in urine than in serum and need to be recognized as such (Fig. 10).

FIGURE 11   PEL and IFE of urine from a patient with primary systemic AL. The urine contains 5 g of protein per 24-h collection. The PEL shows mostly albumin and no apparent monoclonal protein. The IFE shows a faint λ band in the fast-γ region. Alb, albumin; lanes G to L, as defined for Fig. 1.

Because monoclonal gammopathies are uncommon in people under the age of 40, IFE of urine is rarely indicated for patients <30 years of age. In addition, IFE of urine specimens is not useful for general screening without a clinical suspicion of plasma cell dyscrasia.

SERUM ISE

Because of increased sensitivity and shorter turnaround time, IFE has replaced immunoelectrophoresis as the preferred method for characterization of monoclonal proteins. CZE been shown to be a rapid procedure that can be automated for the clinical laboratory, and because of its high resolution, it is slightly more sensitive than AGE (2, 3, 13, 16, 18). CZE may therefore eventually replace AGE as a method of screening for serum M-spikes. The ISE procedure is an addition to the basic CZE method.

The small sample volume required for CZE makes ISE possible for routine characterization of M-spikes. Like CZE, ISE is rapid and automated, but it is not as sensitive as IFE. ISE detects only abnormalities that are apparent on PEL. In the ISE procedure, an M-spike is identified by CZE, the serum is

then incubated with various antisera, and the sample is reanalyzed by CZE to determine which specific antiserum removed the electrophoretic abnormality. In addition to ISE being automated and rapid, it may show which light chains are associated with which heavy chains in sera in which two monoclonal proteins comigrate. The disadvantage of ISE is that in order to "immunosubtract" an abnormality, there must first be an abnormality detected by CZE. Small monoclonal proteins that are not detected by electrophoresis but which would be detected by IFE are therefore not able to be identified by ISE. Because some small serum abnormalities may represent very serious clinical disease, ISE cannot be the only method used by a laboratory for detection and characterization of monoclonal proteins.

Almost a decade ago, Beckman introduced a clinical laboratory CZE instrument that was dedicated to PEL and ISE. The Paragon CZE 2000 has seven capillaries and an automated loader for patient serum samples and has been evaluated for its use in the detection of monoclonal proteins. In a comparison study of 1,518 serum samples, we found that agarose gel PEL had a sensitivity and specificity for monoclonal protein detection of 91 and 99%, respectively, whereas CZE had a sensitivity and specificity of 95 and 99%, respectively (16). The increased sensitivity was due to increased resolution in the β region as well as increased resolution of small monoclonal proteins within a polyclonal background. The increased resolution included sera from a small number of patients with monoclonal free light chains that were positive by IFE but negative by agarose PEL. In spite of the increased resolution and sensitivity, the specificity appears to be the same for the two procedures. Recently, Sebia has also introduced a CZE system for PEL in the clinical laboratory.

Because of the automation and the small volumes passing through the capillary tubes, it is feasible to use this method for ISE. The Beckman system uses solid-phase reagents that are packaged for use on the Paragon instrument. The process uses solid-phase beads that are either bare or coupled with antisera that are specific for either γ, α, μ, κ, or λ chains. The beads are contained in a reaction chamber that has six wells (one for each bead type). The loader aliquots patient serum into each well, incubates the reaction chamber, aspirates the supernatants, and then performs CZE on each supernatant. The electrophoretograms from the original serum sample and from the absorbed samples are compared to determine which antiserum removed the abnormality. The Sebia instrument and reagent set employs a similar approach except that the antisera are modified to migrate on CZE in an area that is outside the standard serum fractions. Any patient immunoglobulin that combines with the antisera will therefore be removed from the electrophoresis pattern. These ISE reagent sets are not configured to identify IgD or IgE monoclonal proteins, nor are they configured for analysis of urine samples.

The ISE patterns for a normal serum sample are illustrated in Fig. 12. The PEL pattern shows the resolution of the β fraction into two distinct peaks. This increased resolution allows the identification of some abnormalities that are hidden in the AGE β fraction. The "subtraction" of IgG results in almost total removal of the γ fraction except for the fast-γ region where IgA and IgM migrate. The anti-κ and anti-λ reagents decrease the γ fraction by approximately two-thirds and one-third, respectively. The use of anti-IgA and anti-IgM decreases the background under the β fraction and the β/γ region, respectively. Results for an abnormal serum sample are shown in Fig. 13. The anti-IgG reagent

FIGURE 12 ISE of a normal serum sample. The CZE pattern is shown in the upper left panel (SPE, serum protein electrophoresis). The upper right panel shows the CZE pattern after subtraction of IgG from the sample. Except for the remaining IgM and IgA near the β fraction, almost the entire γ fraction is removed. The IgA panel shows the CZE after subtraction of IgA, and the troughs surrounding the β fraction now appear closer to the baseline. The κ and λ panels show the reduction in the γ fraction after removal of the immunoglobulins that contain κ or λ light chains.

removes the M-spike as well as the polyclonal portion of the γ fraction. The anti-κ reagent removes the M-spike as well as a portion of the polyclonal γ fraction. The ISE procedure works well when an abnormality is detected by capillary electrophoresis. In addition to being rapid and automated, the method is not subject to point-of-application artifacts and can detect biclonal gammopathies that comigrate on IFE. γ, κ, and λ bands that comigrate on IFE, for example, may represent IgG κ and IgG λ proteins or may represent an intact IgG monoclonal protein plus a monoclonal free light chain. The ISE procedure or a free light-chain assay will clarify this type of IFE result.

The most important limitation of ISE is that small monoclonal proteins that are not identified by electrophoresis are not able to be characterized. If ISE is used to immunotype monoclonal proteins identified by PEL, an IFE procedure must also be used to screen sera that have normal electrophoretic patterns but for which IFE has been ordered. In addition, IFE for δ and ε heavy chains needs to be performed on samples with a newly identified monoclonal free light chain.

The use of the Sebia Hydragel IF Penta for normal PEL patterns is one approach to complementing the use of CZE with ISE. Although serum samples with normal electrophoretic patterns require IFE for monoclonal gammopathy screening, there will be a low incidence of monoclonal proteins in these samples. The Penta-gel system uses antisera that are a blend of the five specificities used in IFE (anti-γ, -α, -μ, -κ, and -λ). If the single-lane Penta IFE shows a restricted band, then the IFE must be repeated for the sample with all five antisera in separate gel lanes. Depending on

AGE

CE/IS
FIGURE 13 Immunosubtraction of a serum sample from a patient with an IgG κ monoclonal protein. The M-spike is apparent by AGE and CZE. After subtraction, the M-spike is removed with antiserum to IgG and κ. Note that the polyclonal portion of the γ fraction is also removed by the IgG reagent and is reduced by the κ and λ reagents. CE/IS, capillary electrophoresis/immunosubtraction; SPE, serum protein electrophoresis.

the volume and mix of cases, this approach may be an efficient approach for identifying and characterizing monoclonal proteins by ISE and IFE.

Quality Control

New reagent lots should be tested against sera with known monoclonal proteins before being used for routine testing. A commercial triclonal control is supplied by Beckman. A sample containing a monoclonal protein of known isotype should be tested each day. If a patient sample that has been previously isotyped is part of the workload, that sample may serve as a daily control. The electrophoretograms for each patient should be reviewed to ensure that all the capillaries gave consistent patterns.

HEAVY-CHAIN DISEASE

Although rare, there are monoclonal immunoglobulins that are composed of truncated heavy chains and contain no immunoglobulin light chain (9, 31, 35). These are often Fc regions with molecular masses that range between 27 and 49 kDa. The serum IFE will show a heavy-chain band, but there is no corresponding light-chain abnormality. Because the heavy-chain peptide is truncated, the heavy chain is also detected in the urine. When immunoelectrophoresis was the common method for characterization of monoclonal proteins, the lack of sensitivity made it necessary to use other methods to confirm the absence of the light chain. As a group, these methods were termed immunoselection (10, 34). In these procedures, antisera to κ and λ are incorporated into an AGE gel prior to sample application. When the serum sample is applied, any molecules containing light chains will be precipitated near the application point and only free heavy chains will electrophorese away from the origin. In normal serum, IFE with anti-heavy-chain specificity will then result in reactivity near the origin, but for heavy-chain disease patients there will be an additional band that has migrated away from the origin. As IFE procedures have replaced

immunoelectrophoresis, the increased sensitivity has made immunoselection unnecessary. Although a monoclonal protein in heavy-chain disease is not always apparent on PEL, ISE is an immunoselection method that can be used for heavy-chain disease samples that contain a visible electrophoretic abnormality. The monoclonal band in γ heavy-chain disease is often broad and not clearly localized on PEL. Localized PEL bands have never been seen in α heavy-chain disease, and hypogammaglobulinemia is often the only prominent feature on PEL of μ heavy-chain disease.

CSF OLIGOCLONAL BANDING

The diagnosis of MS is based predominantly on clinical and radiological findings, but CSF laboratory tests are used to support the diagnosis and are especially useful for patients with unusual presentations (11, 28). The concentration of immunoglobulins is increased in the CSF of patients with inflammatory diseases of the central nervous system, such as MS, neurosyphilis, and acute inflammatory polyradiculoneuropathy (15, 29). This increase in gamma globulins in the CSF of MS patients is due to increased intrathecal synthesis of immunoglobulins (5). Because serum proteins cross the blood-brain barrier, it is important to ascertain whether the gamma globulins are synthesized in the CSF or are derived from the serum. The two most commonly used laboratory tests for CSF-specific immunoglobulin synthesis in MS are oligoclonal banding and the CSF IgG index. OCB have been reported to be positive for 75 to 90% of patients with MS, and the CSF IgG index is positive for 70 to 80% (4, 7, 14, 27). The use of both tests increases the sensitivity to 90 to 95% (27). Although these tests are not specific for MS, they provide useful supportive data when MS is part of the differential diagnosis and when the presentation is unusual.

As described above, the normal polyclonal migration pattern of serum gamma globulins on AGE results in a homogeneous, Gaussian distribution, and monoclonal proteins migrate as a distinct, discrete band. The repertoire of
FIGURE 14 IEF with IgG immunoblotting of paired CSF-serum samples. (A) Positive oligoclonal banding result for an MS patient. The CSF contains more than four IgG OCB that are not seen in the serum. (B) Negative result with no IgG bands detected in the CSF or serum. (C) Negative result with no IgG bands that are CSF specific. (D) Banding pattern obtained with a sample that contains a monoclonal protein.

immunoglobulins within the CSF of patients with MS, however, is of such restricted heterogeneity that the electrophoretic pattern does not show a normal continuous distribution. The γ region contains multiple faint bands reflecting the limited number of plasma cell clones. The detection of these OCB within the CSF (but not in a paired serum sample) is interpreted as representing increased CSF-specific immunoglobulin synthesis and is supportive of the diagnosis of MS.

Isoelectric focusing with immunoblotting has been reported to be more sensitive than high-resolution AGE for OCB detection in MS patients (1, 28). In our own studies comparing isoelectric focusing with IgG immunoblotting to high-resolution AGE, the isoelectric focusing had a sensitivity and specificity of 90 and 94%, respectively, compared to a sensitivity and specificity of 60 and 96%, respectively, for AGE (8). It is this increased diagnostic sensitivity that has led to the switch from AGE to isoelectric focusing.

Our laboratory uses gels and reagents from Helena Laboratories for isoelectric focusing and IgG immunoblotting detection of OCB. The isoelectric focusing agarose gel has a pH gradient from 3 to 10. Five microliters of serum diluted 60-fold and 5 μl of unconcentrated CSF are each applied to the gel. After electrophoresis, the separated proteins are transferred to a nitrocellulose membrane and blotted with an anti-IgG peroxidase conjugate. The OCB that are visualized in this assay are much fainter and less distinct than monoclonal bands detected in serum or urine by IFE. A band is considered positive if it is detected in the CSF but not in the serum. Many laboratories interpret two or more CSF-specific bands as consistent with MS. Our validation studies have indicated that most patients with MS have eight or more CSF-specific bands in this reagent system, whereas most non-MS patients have three or fewer CSF-specific bands. We therefore interpret four or more bands as consistent with MS. Results for a paired CSF and serum sample from an MS patient are shown in Fig. 14A. The CSF has more than 10 IgG bands, and the serum contains no discrete IgG bands. Two negative results are shown in Fig. 14B and C. The first CSF-serum pair has no IgG bands. The second CSF-serum pair has no CSF-specific IgG bands, since the banding pattern for the CSF is exactly mirrored by the serum banding pattern. Results for a CSF-serum paired sample from a patient with a monoclonal gammopathy are

shown in Fig. 14D. The monoclonal protein is detected in the serum and CSF, and the laddered pattern is typical for the distribution of a monoclonal protein on isoelectric focusing.

Although OCB are difficult to interpret and count, the isoelectric focusing procedure results in sharper bands that are easier to identify than OCB on AGE. In addition, positive CSF samples usually have only two CSF bands as determined by AGE but more than eight CSF bands as determined by isoelectric focusing. The higher number of CSF bands in positive samples makes the interpretation of the gels easier.

Quality Control

Every gel should contain a positive CSF sample with a known number of bands. The gel is acceptable if band resolution, separation, and staining allow identification of the appropriate number of bands. The number of bands detected in the control should be within one band of the target. All gels should be read independently by two readers. If the two readers do not agree on the test interpretation (e.g., positive versus negative), then a third reader should be consulted. Because of the difficulty in interpreting these gels, all members of the laboratory should participate in periodic blind challenges to standardize gel interpretation.

Cryoglobulins, Cryofibrinogenemia, and Pyroglobulins

PETER D. GOREVIC AND DENNIS GALANAKIS

11

CRYOGLOBULINS

Background

Cryoglobulinemia is one of a group of syndromes which are characterized by the induction of clinical and/or laboratory abnormalities by cold. Cryoglobulins are immunoglobulins (Igs) that precipitate out of solution below core body temperatures, either as a single isotype (simple cryoglobulins) or as immune complexes in which both antibody and antigen are Igs (mixed cryoglobulins). In some instances, cryoglobulinemia may coexist with other related but usually distinct forms of cold hypersensitivity, such as Raynaud's phenomenon, cold agglutinin activity, or cold-dependent activation of complement (14).

Simple cryoglobulins may be either an intact Ig or a cryoprecipitable Ig light chain (type I cryoglobulins) and are always clonal in terms of electrophoretic mobility or variable-region amino acid sequence. In mixed cryoglobulins, the antibody is almost always IgM (occasionally IgA), which may be monoclonal (type II) or polyclonal (type III) (5). The antigen in mixed cryoglobulins is usually polyclonal IgG, though in some instances the IgG may be oligoclonal when analyzed as to subclass or as revealed by immunoblotting, immunofixation, or two-dimensional gel electrophoresis (24). Mixed cryoglobulins are therefore cold-precipitable rheumatoid factors (RFs), with the serum often being positive when standard assays for IgM antiglobulin activity are used. Many type II RFs have a predilection for the Cγ2-Cγ3 interface of the Fc portion of IgG and react with the binding site for staphylococcal protein A. The complexing of the two isotypes of Ig in mixed cryoglobulins is prerequisite for in vitro cryoprecipitation; the binding affinity of the IgM RF and stoichiometry of complexes formed by mixed cryoglobulins are significantly influenced by temperature (4, 23). The relative frequencies of the different types of cryoglobulins seen in a clinical immunology laboratory will vary significantly with the type of diseases sampled or referred for analysis, and depending on how carefully sera are processed prior to study; the latter is particularly of concern in screening for type III cryoglobulins, which are generally present only at low levels and may require larger volumes of serum for analysis (Table 1).

Concept

The decision to test a serum sample for cryoglobulins may be based on the knowledge that the patient has a specific known or suspected disease, be dictated by the evaluation of a particular clinical manifestation, or be carried out to clarify other abnormalities that have been uncovered in the course of a laboratory evaluation for another purpose. Type I cryoglobulinemia may be suspected in the presence of a known plasma cell dyscrasia (e.g., multiple myeloma or Waldenström's macroglobulinemia), immunochemical evidence of a monoclonal Ig (M-spike) or Ig light chain (Bence Jones protein) in serum and/or urine (see chapters 9 and 10), or clinical evidence of hyperviscosity or ischemic vasculopathy. Type II cryoglobulinemia should be considered in B-cell neoplastic states that may be associated with RF and other autoimmune phenomena, in Sjögren's syndrome, and in chronic inflammatory liver diseases, particularly due to infection by hepatitis C virus (HCV) (7). Type III cryoglobulins have been associated with a wide variety of chronic infectious and autoimmune diseases, many of which are characterized by hyperimmunization and/or hyperglobulinemia. The presence of mixed cryoglobulins may be suggested by purpura or documented cutaneous vasculitis, clinical findings of or biopsy-proven glomerulonephritis, unexplained neuropathy or hepatitis, a positive RF in serum, or markedly depressed C4 levels (14) (Table 2).

Other laboratory abnormalities may be consequences of the physicochemical properties of the cryoglobulins or reflect polyclonal B-cell activation or clonal B-cell proliferation often associated with these disorders. Since cryoprecipitation does not occur at core body temperatures and may begin within minutes of the cooling of serum, it is especially important to consider ex vivo artifacts in the interpretation of laboratory data for patients affected by these syndromes. Most important of these is the handling of the serum before separation, which can significantly affect quantitation, especially when the endpoint is to assess the effect of therapy by comparison of serial specimens. Others may be introduced in the handling of biopsy specimens, during measurements of serum viscosity (9), or by cooling of anticoagulated blood in processing for the Coulter Counter (Table 3). The first

TABLE 1 Classification of cryoglobulins

Type	Frequency (%)	% at concn of:		
		<1 mg/ml	1–5 mg/ml	>5 mg/ml
Simple (type I)	5–38	10	30	60
IgG, IgM, or IgA				
Ig light chain				
Mixed				
Monoclonal (type II)	14–72	20	40	40
Polyclonal (type III)	23–54	80	20	0

clinical description of cryoglobulinemia in a patient with multiple myeloma in 1933 by Wintrobe was based on the recognition of an apparently copious buffy coat fraction in an individual known to be cytopenic due to bone marrow replacement. In more recent experience, failure to recognize pseudoleukocytosis or pseudothrombocytosis due to a high-thermal-amplitude cryoglobulin during treatment with cytotoxic agents can significantly compromise care (11) (Fig. 1).

Procedures

Proper handling of blood samples is the single most important variable determining the success rate for identifying cryoglobulinemia and the most difficult to achieve. In our experience, the best results have been obtained when the screen for cryoprecipitation is carried out by the individual in direct contact with the patient (i.e., physician, house staff, or technician) and proper attention is given to the importance of separating serum from whole blood at 37°C. Although less sensitive and specific than other tests for gammopathy or immune-complex disease, analysis of serum for cryoprecipitation has the advantage of simplicity, requires minimal equipment, and is therefore very cost efficient. It is also an excellent teaching instrument for students and other trainees, as all that is required is a "warm heart" (to keep the sample close to core body temperature and minimize ex vivo cryoprecipitation before separation), a refrigerator (in which to observe the sample overnight), and a source of warm running water (to prove that any precipitate that forms can be redissolved on warming). Since cryoglobulins often come out of solution within 24 to 48 h, many sera can be efficiently screened within 1 or 2 days of collection, allowing the clinician to rapidly make further decisions regarding additional workup.

Isolation, Quantitation, and Characterization of Cryoglobulins

1. Collect 10 to 20 ml of blood (2 red-top tubes) and keep at 37°C for 30 to 60 min prior to separation. To ensure that cryoprecipitation does not occur ex vivo, the blood may be placed in a thermos kept at this temperature or put into a 37°C water bath prior to centrifugation. Patients previously found to have high levels of cryoglobulin may require smaller volumes for serial studies, and those suspected of having type III cryoglobulins may require larger volumes for analysis. Occasionally, gel formation in the syringe or Vacutainer tube may occur as the initial manifestation of cryoprecipitation (see also below). Serum is separated from the clot by centrifuging the clot warm for 10 min at 2,500 rpm ($1,500 \times g$). Following separation, it should be carefully inspected for lipemia, which may complicate the visual inspection of the sample for cryoprecipitation over the several hours following collection. Serum thus collected antiseptically, or to which a drop of sodium azide (0.1 g/liter) is added to prevent bacterial overgrowth, may be safely sent by overnight mail (even at room temperature) to a reference laboratory for detailed characterization.

2. Cryoglobulins are grossly apparent on visual inspection down to the range of 50 to 100 µg/ml, depending on the volume of the serum sample submitted for analysis. Type I cryoglobulins are often apparent as flocculent, occasionally crystalline precipitates that are usually observed within 24 h of separation. Cryocrystalglobulins can be characterized by light microscopy, using Giemsa or hematoxylin and eosin stains, as dense-structured inclusions or extracellular material on staining with osmium and uranyl acetate for electron microscopy, or as non-Congo red-binding birefringence visualized by polarizing microscopy. Type III cryoglobulins are

TABLE 2 Disease, clinical,[a] and laboratory associations

Type of cryoglobulin	Associations		
	Disease(s)[b]	Clinical	Laboratory
I	Macroglobulinemia, myeloma, idiopathic	Necrosis, Raynaud's phenomenon, acrocyanosis	M-spike, increase in viscosity, cryocrystals
II	HCV infection, Sjögren's syndrome, CLL, lymphoma, macroglobulinemia	Purpura, neuropathy, keratoconjunctivitis	RF, nephritis, hepatitis, decrease in C4
III	Chronic infections, autoimmune disease	Vasculitis	RF, nephritis

[a] Reversible cyanosis of the helices of the ears and livedoid vasculitis are characteristic of IgG type I cryoglobulinemia, whereas purpura due to leukocytoclastic angiitis is characteristic of type II IgMκ-IgG cryoglobulins.
[b] Idiopathic, no apparent underlying disease; CLL, chronic lymphocytic leukemia.

**TABLE 3** Laboratory abnormalities in cryoglobulinemia

Abnormality
Direct effects
Cryoprecipitation
Cryogel formation
Cryocrystalglobulins
Hyperviscosity
Present only with cooling
Accentuated by cooling
Immunochemical findings
Normal (frequent with type III)
Hyperglobulinemia
Diffuse elevation or M-spike on serum protein electrophoresis
Elevation of a specific isotype (IgG, IgA, or IgM) or subclass (type I)
Increased high (19S)- and low (7S)-molecular-weight IgM (type II)
Skewing of the normal (2/1) κ:λ ratio of Ig light chains (types I and II)
Hypoglobulinemia
Diffuse (occasionally with type II)
Noncryoglobulin isotypes (type I)
Clonal markers of B cells
Monoclonal gammopathy
Clonal populations of B cells revealed by surface Ig
Peripheral blood (heavy- and light-chain determinants)
Lymphoid aggregates in bone marrow (type II)
Evidence of Ig gene rearrangement
Antibody activity and immune complex formation
19S IgM antiglobulins (RFs) (types II and III)
IgA (type II) or IgG (type I) RF
Elevated levels of circulating immune complexes, especially assays based on C1q binding activity
Antinuclear antibodies (see chapters 112–115)
Antiviral antibodies (Epstein-Barr virus, HBV, HCV)
Hypocomplementemia
Classical or alternative pathway activation as a manifestation of specific diseases (e.g., lupus)
In vivo/ex vivo activation by cryoprecipitates
Selective depression of C4
Cold-dependent activation independent of cryoprecipitation
Ex vivo artifacts (avoid by testing at 37°C)
Increased erythrocyte sedimentation rate
Pseudoleukocytosis
Pseudothrombocytosis
Cryoprecipitation in biopsy material

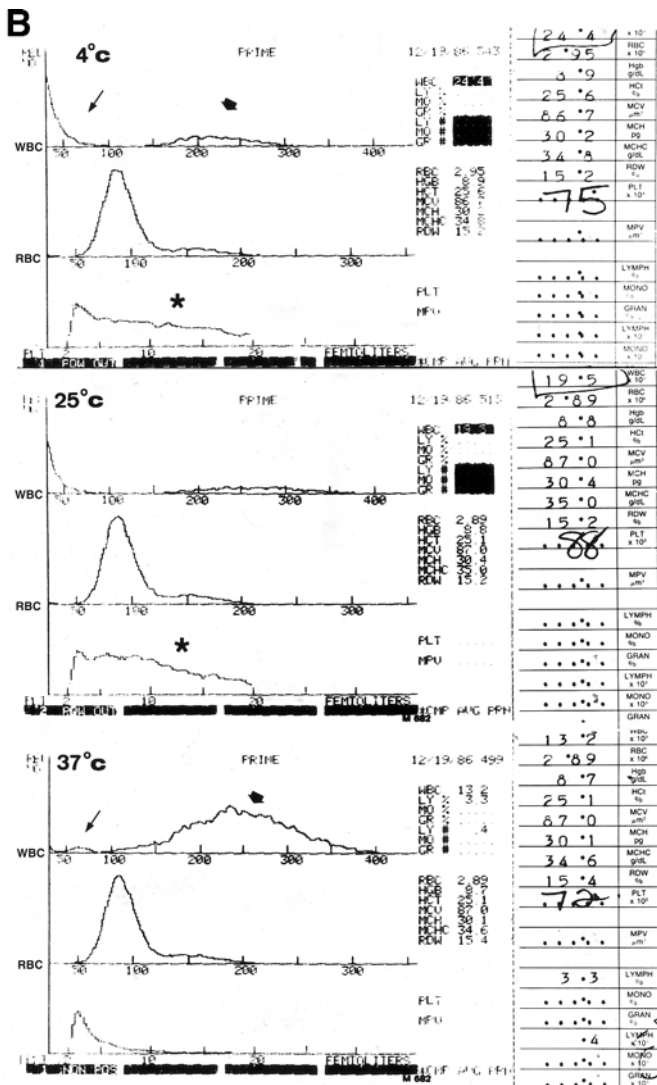
usually gelatinous and may take up to a week to be fully apparent. Consequently, serum samples are observed at 4°C for 7 days after collection. This analysis may be facilitated by measurement of turbimetry (e.g., using a jacketed spectrophotometer cuvette at 630 nm) at 15-min intervals or by cryoprecipitation from hypotonic media. The kinetics of cryoprecipitation are quite variable, depending on the individual sample and the concentration of cryoglobulin present (10). This may reflect in part different mechanisms for cryoprecipitation, including lag periods overcome by nucleation events (14, 15). We have observed little variability when the kinetics of cryoprecipitation of serum, plasma, or isolated cryoglobulins have been compared by turbimetric analysis (Fig. 2).

3. Positive sera are spun down in a refrigerated (4°C) centrifuge (Sorvall) at 3,000 rpm for 15 min, and the supernatant is removed for further analysis. The pellet is vortexed six times with 5 to 10 ml of ice-cold 0.15 M saline, each time spinning out the precipitate for 15 min at 3,000 rpm; contaminating red blood cells may be lysed hypotonically. Finally, the sample is suspended in warm saline (1/10 to 1 volume of the initial serum) and incubated at 37°C for 1 h. Ideally, there should be complete dissolution of the precipitate with shaking. If this does not occur, the presence of fibrin or bacterial contamination should be considered; warm-insoluble precipitate should be spun out at 37°C (3,000 rpm for 10 minutes) and the supernatant should again be cooled to 4°C and observed for cryoprecipitation.

4. The concentration of cryoglobulin can be determined as a cryocrit or as an absolute concentration of protein back-calculated for the initial volume of serum. Cryocrits are appropriate for serial measurements in individual patients (provided that the method is carefully reproduced between samples) and for the purposes of general comparison. Exact protein


measurements are more accurate and can be compared to quantitation of specific Ig isotypes in serum, isolated cryoglobulins, and serum supernatant obtained following cryoprecipitation. To obtain a cryocrit, an aliquot of the initial warm serum is used to fill a disposable Wintrobe tube to the 10-mm mark. The tube is kept vertical at 4°C for the time determined above for cryoprecipitation and then centrifuged cold at 2,000 rpm (2,000 × g) for 30 min; the percent total volume occupied by the pellet is then obtained by visual inspection. The total protein content of isolated cryoglobulin (rigorously washed as described above) is determined in our laboratory by the Bradford method, using the Coomassie protein assay (Pierce bicinchoninic acid protein assay). In some instances, repeated warming and cryoprecipitation lead to significant loss of material, and therefore quantitation is defined in terms of the initial isolation protocol for consistency.

5. Warmed dissolved cryoprecipitate is characterized by immunochemical analysis, in our laboratory first by double diffusion in agar (Ouchterlony plates) and then by agarose gel immunofixation electrophoresis (IFE) (see chapter 9). In addition to defining type I cryoglobulins, immunofixation may reveal the clonality of the IgM component, or the oligoclonality of the IgG components, of mixed cryoglobulins. Since the monoclonal components of type II cryoglobulins are almost invariably IgM(κ), the percent contribution of clonal IgM to total IgM present in a mixed cryoglobulin can either be estimated by correlating the contribution of a clonal band to total immunoreactive IgM on a strip developed with anti-μ antiserum with one developed with anti-κ antiserum by visual inspection or be more formally quantitated by densitometry.

6. Other modalities which have been utilized include the following. (i) Immunoblot analysis with anti-heavy-chain or anti-light-chain antisera of cryoglobulins separated under nondenaturing conditions on 4% polyacrylamide gels (which can also be used to demonstrate 7S IgM in serum) or on composite agarose polyacrylamide gels. Immunoblotting combined with IFE can be performed on as little as 10 μg of material, can distinguish type II from type III mixed cryoglobulins, and may be particularly effective for the demonstration of the oligoclonality of each component of the complex. (ii) Two-dimensional gel electrophoresis, run under denaturing and reducing conditions in order to dissociate mixed cryoglobulins and separate Ig heavy and light chains by molecular weight and isoelectric focusing point. Two-dimensional polyacrylamide gel electrophoresis (PAGE) may be more sensitive than IFE for the demonstration of B-cell clonality in patients with cryoglobulinemia and has been combined with Fourier transform-ion cyclotron resonance mass spectrometry for the high-resolution analysis of cryoglobulin constituents (8, 24). (iii) Capillary zone electrophoresis,

which has been adapted in some laboratories for the rapid characterization of cryoprecipitates, may be particularly useful for type III cryoglobulins because of the sensitivity of the technique. Subtraction analysis of the gamma globulin curve before and after cryoprecipitation can be used as an alternative to protein and Ig determinations for quantitation (16).

7. The relative contributions of the different components of mixed cryoglobulins may be determined immunochemically by standard techniques (i.e., radial immunodiffusion or, more commonly, nephelometry) if sufficient material is available (see chapter 8). This may be used to confirm the nature of mixed cryoglobulins and to show selective enhancement of specific antibody activity in cryoprecipitates compared to that in serum but is rarely of clinical significance. The power of this type of analysis has been significantly expanded in research studies through the use of capture enzyme-linked immunosorbent assays (ELISAs) that employ both isotype- and idiotype-specific antibodies (21). Since most mixed cryoglobulins remain cryoprecipitable in the pH range of 5.0 to 8.5, they can be dissociated under, e.g., acid conditions, and IgM can be separated from IgG and quantitated after ion-exchange chromatography or passage through specific immunoabsorbents (e.g., protein G columns) or size fractionated by high-pressure liquid chromatography or fast protein liquid chromatography.

Assays for Specific Antibody Activities, Antigens, or Detection of Nucleic Acid

1. Mixed cryoglobulins contain IgM RF activity when tested by either standard assays or more sensitive techniques (e.g., binding of radiolabeled aggregated IgG). Unlike rheumatoid arthritis, cryoglobulin RF activity, particularly in HCV-associated disease, is not associated with antibodies to cyclic citrullinated peptide. Although both cryoprecipitable and noncryoprecipitable RF activity can be detected, occasional testing of RF activity in serum may be invalid because it has been lost due to cryoprecipitation of a high-thermal-amplitude (i.e., one that rapidly cryoprecipitates above room temperature) mixed cryoglobulin (Fig. 1).

2. Individual case reports and small series have shown enrichment of a number of specific antibody activities, including binding to antigens such as IgG or HCV recombinant proteins, in cryoglobulins associated with specific disease states (14). Most of these antibodies (e.g., HCV antibodies [HCVAbs]) are associated with the IgG fraction of mixed cryoglobulins and can be quantitated by ELISA, which should be normalized for total IgG quantitated in cryoglobulin relative to serum (21, 23). In some instances, we have found that a specific antibody activity was in fact not concentrated in the isolated cryoglobulin, as was the case for a patient with a type 1 IgG(κ) cryoglobulin without

---

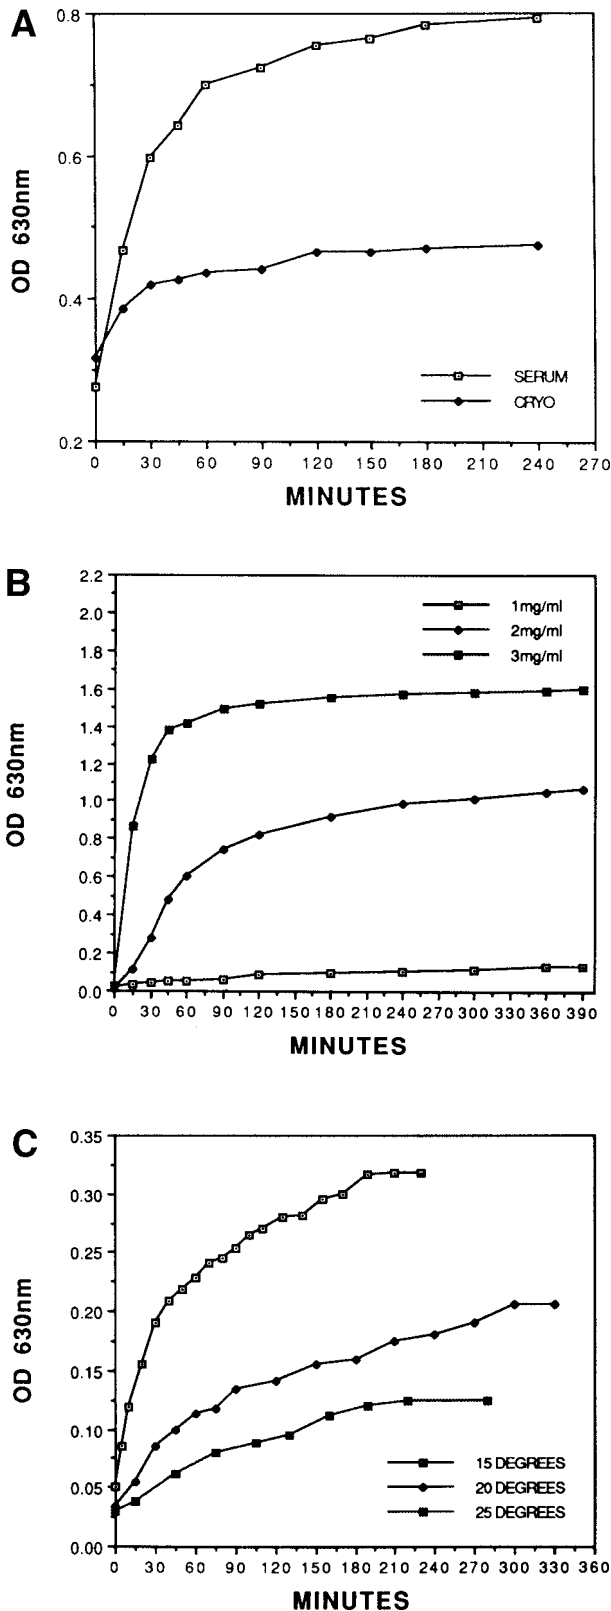
FIGURE 1 Cryoglobulinemia was initially missed in a patient with cutaneous vasculitis documented by biopsy of a purpuric lesion on the right second digit (A, left panel). Because of deteriorating status, including renal failure, she was treated with high doses of steroids and then cytotoxic agents, with apparently poor response in terms of an expected drop in leukocyte count. One weekend, while still in the intensive care unit, the patient was noted to have developed nasal purpura in the distribution of a cold-air oxygen mask (A, right panel). The Coulter histograms obtained at 4, 25, and 37°C (B) display the leukocyte (top), erythrocyte (middle), and platelet (bottom) panels. The leukocyte panel shows small lymphocytes to the left (thin arrow) and larger polymorphonuclear leukocytes and monocytes to the right (thick arrow), with the ordinate displaying percent total cells; the platelet panels at 4 and 25°C are unusual in having a long tail (∗) after the expected narrow peak. Pseudoleukocytosis and pseudothrombocytosis are revealed at 37°C, which shows (i) all the leukocytes to be polymorphonuclear, with few lymphocytes, as expected for a patient on high-dose corticosteroids; and (ii) a narrow platelet peak. Both findings are reflected in the manual counts (B, right). Recognition of this artifact led to identification of a type II cryoglobulin with RF activity, with restricted IgM and κ arcs by immunoelectrophoresis (C, arrowheads) and a high thermal amplitude of cryoprecipitation (D). OD, optical density.


FIGURE 2 Kinetics of cryoprecipitation, assessed by turbimetric analysis, for a type II cryoglobulin, comparing serum and isolated cryoglobulin (A), different concentrations of isolated cryoglobulin (B), and different temperatures of cryoprecipitation (C). OD, optical density.

instrinsic HCVAb activity who developed HCV infection during the course of his illness.

3. The nature of mixed cryoglobulins as immune complexes in chronic infection by HBV and HCV is indicated by reports of selective enrichment of both antigens (e.g., HBV surface and HCV core antigens) and specific antibody activity in some isolated cryoprecipitates (14). Current experience is that 60 to 80% of type II cryoglobulins in patients with the syndrome of mixed cryoglobulinemia (purpura, arthralgias, and renal disease) are associated with evidence of HCV infection, assessed by anti-HCV antibody activity and/or amplification of specific nucleic acid by PCR following reverse transcription (RT) (1). In our laboratory, HCVAb activity is assessed by recombinant immunoblot assay and the presence of HCV RNA is determined initially by RT-PCR using nested primers framing conserved sequences in the 5′ untranslated region of the viral genome. The recombinant immunoblot assay for HCVAb measures primarily IgG antibody to HCV antigens. Controls include known positive and RF-positive, HCVAb-negative sera; RT-PCR is also carried out with positive and negative samples, with care taken to control for carryover contamination (see chapter 83). HCV copy number can be more accurately determined by commercially available quantitative assays, including those using competitive PCR (e.g., the Roche Amplicor system) or direct capture of viral RNA by complementary branched DNA (Chiron). The lower limits of detection for these assays are 600 and 615 IU of HCV RNA per ml, respectively. Quantitative assays may be used to demonstrate selective enrichment of HCV RNA in cryoprecipitates (reported as being more frequent than enrichment of HCVAb), in some instances when the serum supernatant is negative or below the level of detection of the particular assay, and to follow the clinical course and the effect of therapy with alpha interferon (IFN-α) (20). HCV genotype analysis is commercially available and may be used as one variable to anticipate the efficacy of therapy with IFN-α; however, its value for the evaluation of mixed cryoglobulinemia and other autoimmune manifestations of chronic infection is uncertain (12).

New HCV assays are likely to enhance the sensitivity and specificity of measurements of cryoglobulins associated with extrahepatic diseases associated with chronic infection. These include the quantitation of hepatitis core antigen (18) and real-time PCR assays for HCV RNA and replicative intermediate (negative strand) (17). The former may be assayed by ELISA (Chiron-Ortho Clinical Diagnostics) and has been found to be concentrated in isolated cryoprecipitates (22); the latter may prove to be a more sensitive marker for occult HCV infection in cryoglobulinemia (6) and as a criterion for productive infection by virus in extrahepatic sites.

Complement Measurements in Cryoglobulinemia

Sera from type II mixed cryoglobulinemia patients typically have low antigenic levels of the early components of complement (see chapter 12), with relatively normal levels of C3 and factor B. Measurements are best made at 37°C in order to minimize artifacts introduced by ex vivo cryoprecipitation or activation by other complexes that may occur over time at 4°C. Serial studies have shown that hypocomplementemia correlates only poorly with symptomatology or cryoglobulin levels. Most patients with type I cryoglobulinemia have normal complement levels, though occasional instances in which complement activation occurs and has been shown to be directly due to cryoprecipitate formation have been well

described. In type III cryoglobulinemia, complement measurements may reflect abnormalities prevalent in the underlying disease (e.g., lupus erythematosus) or among the subset of patients predisposed to develop cryoglobulinemia (e.g., rheumatoid vasculitis or primary Sjögren's syndrome).

In sera manifesting cold-dependent activation of complement (CDAC), a similar profile of low 50% hemolytic complement value and poorly hemolytic C4 with normal hemolytic C5 to C9 is seen at 4°C, with normal values being obtained for EDTA-treated plasma and for serum kept at 37°C. In contradistinction to cryoglobulinemia, C1q and C4 antigenic levels are normal. CDAC may be consequent to HCVAb-monoclonal RF complexes with differing stoichiometry, may be present in sera that do not contain detectable cryoprecipitates, and appears to correlate somewhat with liver damage and response to treatment with IFN-α (25). CDAC, RF, cryoglobulinemia, and elevated levels of IgM-containing immune complexes are all prevalent in HCV infection.

Conclusions

Although many clinical laboratories offer cryoglobulin determinations, rarely is testing rigorously carried out, and there is considerable interlaboratory variability. The most common sources of error are (i) false-negative results due to loss of cryoprecipitate during storage and (ii) false-positive results, usually due to residual fibrin in the sample and failure to demonstrate redissolution of material with warming. In most instances, cryoglobulins are readily apparent by visual inspection of the specimen at 1 to 3 days. Many have thermal amplitudes characterized by 10^3- to 10^4-fold decreases in solubility occurring over a relatively restricted (<10°C) temperature range, which may be significantly influenced by the level of cryoprotein in the sample. Detailed characterization can be achieved by using standard immunochemical techniques modified to be carried out above the temperature of cryoprecipitation.

Intralaboratory Quality Control and Interlaboratory Proficiency Testing

1. Serum must be obtained from blood that is clotted at body temperature; whole blood that is allowed to cool or placed at 4°C before separation should not be accepted.

2. A sample size of 1 to 3 ml of serum may be adequate to screen for type I or II cryoglobulins but is inadequate for type III cryoglobulins; for type III, 5 to 10 ml of serum should be required. Smaller sample volumes should be rejected, especially if a protocol that requires aliquoting of the specimen is followed.

3. Serum samples obtained from patients who are receiving heparin or other anticoagulants are not acceptable for cryoglobulin determinations (see below).

4. Complement and HCV RNA measurements should not be performed on serum that has been allowed to cryoprecipitate; they should be carried out on parallel samples of blood appropriately processed for these determinations.

5. A positive cryoprecipitate formed at 4°C may be defined by complete solubilization when warmed to body temperature or by comparison to a sterile aliquot of the same specimen kept at this temperature.

6. Whereas a cryocrit determination may be made for a centrifuged aliquot of serum cooled in a calibrated hematocrit tube, reflex cryoglobulin characterization requires rigorous washing of the cryoprecipitate.

7. Reflex testing may include immunofixation, Ig quantitation, and nephelometric evaluation for RF activity.

CRYOFIBRINOGENS

Background

In the older literature, the term "cryofibrinogenemia" was used to describe a related phenomenon of cryoprecipitation in plasma that is distinct from cryoglobulinemia but which may be associated with thromboembolic disease, vasculopathy, and occasionally connective tissue diseases. Whereas cryoglobulins precipitate in both cooled plasma and serum, cryofibrinogens are seen only in plasma. A more accurate description of this phenomenon might be abnormal or pathologic fibrinemia, which is observed as a precipitate when citrated plasma is left at 4°C for several or more hours or overnight and reflects the presence of abnormal levels of soluble fibrinogen-fibrin complexes; such cryoprecipitates often redissolve at higher temperatures (e.g., 37°C) and contain, in addition, major amounts of fibronectin, in and of itself a cryoprecipitable protein (Fig. 3). Thus, cryofibrinogenemia is a misnomer and actually describes cold-precipitable complexes of fibrin and fibrinogen which also contain fibronectin. These may occur (i) when blood drawing is slow, allowing thrombin generation ex vivo; (ii) in any condition in which increased levels of fibrin occur (e.g., chronic intravascular coagulation); or (iii) in certain dysfibrinogenemias, because the fibrin generated in these conditions is poorly or not at all coagulable at ambient or physiologic temperatures but may polymerize in the cold. This last occurrence is rare and can be ruled out by the presence of a normal plasma thrombin time.

Concept

The decision to test a plasma sample for cryofibrinogenemia may be suggested by clinical features of severe cold intolerance (e.g., Raynaud's phenomena or cold urticaria) or evidence of thrombotic vasculopathy that cannot be explained by antiphospholipid autoantibodies, clotting factor deficiencies, or relevant mutations (see chapter 118). It may be part of a more general evaluation for causes of purpura, disseminated thrombohemorrhagic coagulopathy, or other thromboembolic disorders; in major surgery or trauma during the intraoperative or immediate postoperative period; or evaluation of skin necrosis, chronic leg ulcers, or gangrene. Cryofibrinogenemia may be associated with neoplastic states (notably, multiple myeloma, various solid malignancies, and leukemia) and IgA nephropathy and is rarely familial; it has also been described in the absence of clearcut underlying disease and in about 3% of random blood samples from hospitalized patients or asymptomatic healthy blood donors (2).

Two examples of pathologic fibrinemia follow.

Case 1

A 14-year-old girl was evaluated for cold-sensitive vasculitic purpura, mainly of the extremities. The condition had become so severe that she required home tutoring throughout the year to avoid cold exposure. Her condition was monitored by measuring her plasma cryocrit, the column of insoluble material formed when citrated plasma was incubated at 4°C and centrifuged. This value rose markedly during exacerbations of her disease and decreased following each plasmapheresis treatment. Cryoprecipitate that formed when plasma was frozen and thawed at 4°C was also measured as another indicator of cryoprecipitable plasma protein. Relative to those of healthy donors, and to other patient plasmas with similarly elevated fibrinogen levels, her level of cryoprecipitable protein was at least threefold higher during a quiescent period. Her isolated fibrinogen was functionally normal, as was that obtained from her parents. Her protease-free serum, alone or with added
FIGURE 3 Isolated washed cryofibrinogen (arrows) visualized by agarose gel electrophoresis (left) and immunofixation (right). Gel electrophoresis reveals some residual albumin toward the anode, fibronectin in the β region, an origin artifact, and fibrinogen, compared to serum samples in the upper and lower lanes. In the immunofixation on the right, an origin artifact is seen in all lanes due to precipitation on the cold gel. However, the antifibrinogen lane shows increased precipitate, thereby characterizing this as fibrinogen. (Figure generously provided by D. Keren.)

fibrin-depleted fibrinogen isolated from her plasma or from that of a normal donor, did not form a cryoprecipitate.

Case 2

A 42-year-old man was referred for cryogel formation, occurring each time blood was drawn by venipuncture (Fig. 4). He was known to have chronic hepatitis due to HCV and had achieved only limited response to various regimens of IFN-α and ribavirin. Other significant clinical features were visual changes; purplish blotching, notably involving the forehead; and erectile dysfunction. The initial coagulation profile disclosed a prolonged thrombin time and only partial correction when equal volumes of his plasma and normal donor plasma were mixed. Serial plasma dilutions yielded

FIGURE 4 Reversible cryogel formation at 4°C (tube inverted) and 37°C (liquid).

abnormally increasing thrombin times, consistent with the acquired dysfibrinogenemia of hepatic disorders. There was no family history of dysfibrinogenemia.

Repeated evaluations showed that drawn blood rapidly formed a gel-like material at 4°C that did not fully dissolve when rewarmed to 37°C; this gel did not contain significant Ig as determined by either Ouchterlony analysis or sodium dodecyl sulfate-PAGE. After removal of this gel, no further cryoprecipitation was observed; similarly, when plasma was clotted by addition of thrombin at 37°C and the clot was synerized and removed after several hours, his serum formed no additional cryoprecipitate when left at 4°C. By contrast, the level of citrated plasma cryoprecipitate obtained by conventional freeze-thawing was approximately threefold higher than that of normal controls.

All of the patient's symptoms improved following plasmapheresis but recurred progressively within 2 weeks or so, requiring repeat treatments. During the first few plasmaphereses, the intravenous line to the cell separator, as well as the plasma line to the disposal container, began to occlude with visible strands of clot; frequent flushing of the lines with normal saline was only partially successful in overcoming this obstacle. The problem was solved by incorporating 6 to 10 U of heparin/ml in the citrate anticoagulant solution used during the procedure. The patient's plasma formed abnormally increased amounts of precipitate when left at 4°C overnight, whether obtained before plasmapheresis or after the procedure from the removed plasma. For testing, his serum was rendered protease-free by addition of hirudin (20 U/ml), aprotinin (50 U/ml), and phenylmethylsulfonyl fluoride (100 μM); soluble fibrin was depleted by incubation of fibrinogen solutions at 4°C, pH 6.4, and an ionic strength of 0.1 overnight followed by removal of formed precipitates by centrifugation at 4°C. Such protease-free serum formed no cryoprecipitate with or without added fibrinogen that had been depleted of its soluble fibrin.

In subsequent weeks, the patient was placed on coumadin, and heparin was stopped; plasmapheresis was

continued uneventfully over several months and eventually stopped without recurrence of symptoms.

Interpretation

In the first patient, pathologic fibrinemia was clearly related to the inflammatory vascular lesions and could be used as an index to follow the activity of the disease and response to treatment. In the second patient, fibrinemia may have resulted from the delayed clearance of activated coagulant factors that is prevalent among patients with chronic liver disease. Paradoxically, dysfibrinogenemia may have contributed to the abnormal levels of circulating fibrin by allowing higher levels of soluble fibrinogen-fibrin complexes to accumulate, as fibrin monomers are normally soluble in high fibrinogen excess under physiologic conditions. Whether dysfibrinogenemia is congenital or acquired, such plasma often has a greater maximal capacity for soluble fibrin owing to defective coagulability or incoagulability of abnormal fibrinogen molecules.

Procedures

1. To screen for cryofibrinogenemia, simultaneous normal and patient plasma samples are collected in citrate, ideally containing an added inhibitor of thrombin generation ex vivo (see below), at 37°C and allowed to stand overnight at 4°C. It is important *not* to collect plasma in EDTA, because this agent will inhibit cryoprecipitation of fibrin-fibrinogen complexes. Also important, blood should *not* be collected in heparin unless its concentration is ≤2 U/ml of collected plasma, since much higher concentrations can induce cryoprecipitation. This is related to heparin-fibronectin interactions with some fibrinogen and fibrin in the cryoprecipitate (see step 6 below). Blood should be collected rapidly, and sufficient anticoagulant (e.g., 3.8% sodium citrate) should be added to avoid in vitro induction of fibrin formation. For best results, low concentrations of heparin (see below) or hirudin (1 to 5 U/ml) should be added to the citrate before blood collection in order to inactivate any thrombin following collection. Since cryoglobulins will also precipitate out of plasma, the presence of a cryofibrinogen will be suggested by the absence of a comparable precipitate in a paired sample of serum (13).

2. To evaluate fibrinemia (cryofibrinogenemia), procedures involving EDTA-collected blood should not be used (see specific recommendations below). The essential reason is that EDTA prevents fibrinogen-fibrin cryoprecipitation. Soluble fibrin in plasma can be measured by using commercially available kits; those using either tissue plasminogen activator-based or monoclonal antibody-based assays are increasingly used, the latter being technically more convenient. A double-antibody assay (Organon Teknika) which uses a fibrin-specific antibody directed to γ-chain residues 312 to 324 and another antibody specific for the carboxy-terminal end of the α chain or another similar test is preferred. Since the latter epitope is lost when fibrin is degraded, this assay also distinguishes between intact and degraded forms. Care must be taken to draw blood so as to avoid ex vivo fibrin formation (see above), as specified in the manufacturer's instructions. In one report, levels of 13 to 105 ng/ml were found in healthy individuals of widely differing ages.

3. Two alternative methods may be used to measure cryoprecipitable protein. One is to allow citrated plasma to remain undisturbed overnight (or at least 6 h and preferably >24 h) on ice or at 4°C, centrifuge the plasma cold, and measure the insoluble column as a percentage of the total volume (cryocrit). This method, though imprecise, is useful when fibrinemia is pronounced. The second option is to freeze the platelet-poor plasma shortly after harvesting in a self-defrosting freezer (−8 to 20°C) overnight (or at least 6 h) and then thaw it at 4°C overnight. Centrifugation at cold temperatures yields insoluble material, which can then be suspended in ice-cold buffered saline and washed several times to remove noncryoprecipitable proteins. More exhaustive washing may progressively remove fibronectin as well. The final pellet is solubilized at 37°C or in 6 M urea; protein content is determined by diluting an aliquot in 6 M urea and measuring the absorbance at 280 nm, which is compared to a control. For conversion to milligrams of protein, an extinction coefficient (1%, 1 cm, 280 nm) of 14 or 15 can be used, since the two major proteins (i.e., 80 to 90% of the total content), fibrinogen-fibrin and fibronectin, have coefficients of 15.5 and 14, respectively (5).

4. Fibrin-fibrinogen complexes in most, if not all, dysfibrinogenemic individuals can be quantified by harvesting the cryoprecipitate obtained from frozen and thawed plasma. The exception may be the very rare homozygous individuals with dysfibrinogenemia whose fibrinogen is incoagulable. In such an instance, plasma may not form cryoprecipitate, and measurement of fibrinogen antigen or activity is useful. This is best done by using a clotting and/or an antigen-based assay, as high Ig levels may significantly affect heat precipitation, clot mass, or turbidity-based assays for fibrinogen. Though little information other than case reports is available, it seems likely that paraproteinemias can significantly affect heat-based fibrinogen assays and that fibrinemia may complicate the interpretation of heat-based assays for Ig (see below).

5. Commonly not appreciated is the ex vivo fibrinemia resulting from the use of blood cell separators in which the standard anticoagulant is citrate. By measuring cryoprecipitate content, which is fibrin concentration dependent, we observed up to five times more fibrin in plasmapheresis plasma than in plasma from a blood donation which was harvested and frozen within 2 h. Similarly, a very slow withdrawal of blood dramatically increases cryoprecipitable protein relative to that in rapidly drawn blood. If serum is harvested from such samples prematurely, it will subsequently form cryoprecipitates (i.e., at 4°C) which may be erroneously interpreted as cryoglobulins. Its failure to redissolve at 37°C is a strong clue that this is cross-linked fibrin gel rather than cryoglobulin. A reasonable precaution is to allow whole blood to clot for at least 6 h at 37°C, remove the clot, and observe for another hour or so to ascertain that no further clot forms before serum is harvested to be tested for cryoglobulins. To confirm that no fibrinogen remains, one can perform a commercially available fibrinogen assay with the patient serum and a normal control serum, preferably a pool from several or more donors.

6. If cryoglobulin analysis is carried out for patients who are receiving heparin anticoagulation, or on samples collected during plasmapheresis in which heparin has been administered, it is also important to be aware of the possibility of cryoprecipitation due to complexes between heparin and fibronectin, if heparin is present in sufficient concentration; in addition, fibronectin itself is cold insoluble. Thus, heparin induces or enhances cryoprecipitate formation. Here, the presence of fibrinogen in the complexes is a secondary and variable event; the relative content of fibrinogen and fibronectin in isolated cryoprecipitates can be assessed by immunoblot analysis using monospecific antisera to these proteins (3). Although at in vivo therapeutic concentrations (i.e., <1 U of heparin/ml) this effect may be negligible, the heparin content of blood samples may range up to 5 or more U/ml, at which level it can significantly induce cryoprecipitation.

Conclusions

Cryofibrinogenemia may result from elevated levels of fibrin-fibrinogen complexes in plasma, be a manifestation of dys-fibrinogenemia, be secondary to cold insolubility of fibronectin, or, rarely, result from complexing with monoclonal antifibrinogen antibodies; in addition, fibronectin can form cold-insoluble complexes with Ig in various disease states (e.g., fibrillary glomerulonephritis). A search for cryofibrinogenemia may be dictated by unexplained thrombo-hemorrhagic coagulopathy or cold-dependent purpura; it may also be dictated by the finding of characteristic pathology, occurring in various affected organs, as for example an occlusive thrombotic diathesis due to eosinophilic deposits within vessel lumina, extending into the intima, which may be associated with a granulomatous vasculitic component. Cryofibrinogenemia can be screened by cryoprecipitating or freeze-thawing plasma collected in citrate that contains an inhibitor of thrombin generation and is most convincing in the absence of coexisting cryoglobulinemia. It is important not to collect blood in EDTA or in high concentrations of heparin (see below), since the former interferes with cryoprecipitate formation and the latter (depending on the heparin concentration in plasma) may enhance cryoprecipitate formation; this needs to be carefully considered in the performance of serial studies to assess the effect of treatment in individual patients.

Anticoagulant-Related Recommendations

An optimal tube for collecting plasma for cryofibrinogen determination is not commercially available. Consequently, the clinical utility of this test is limited because of lack of sensitivity. In the practice setting, it could be argued, for example, that a cryofibrinogen determination might potentially be useful in detecting only markedly positive patients (e.g., cold-sensitive vasculitis) and for monitoring such a patient's clinical course or a therapeutic response.

1. A thrombin or thrombin generation inhibitor should inhibit ex vivo thrombin activity but not enhance cryoprecipitation. To achieve this, the usual citrate tube can contain the added inhibitor (e.g., low concentrations of heparin). It is important that blood be collected and mixed rapidly with this citrate-inhibitor solution. If such a heparin-citrate mix is used, the heparin concentration in harvested plasma should be ~0.5 to 2 U/ml. For this calculation, it can be assumed that most, if not all, blood heparin will remain in the plasma.

2. Always collect a control serum sample from the same draw.

3. Commercially available tubes: citrate tubes can be used with the knowledge that they have the disadvantage of unpredictable ex vivo thrombin generation and therefore falsely enhanced or positive cryoprecipitate formation. This is particularly so in a prolonged blood draw. EDTA tubes should not be used. Heparin tubes: a currently popular 7-ml-capacity tube has 90 U of heparin (Vacutainer; Becton Dickinson). The resulting concentration in collected plasma is approximately 20 U/ml, far too high, and should not be used. It may cause heparin-induced cryoprecipitate formation that is not fibrin or fibrinogen related.

4. Validation: to institute and validate such a test, an analytical second step is needed. Among the choices (vide supra), immunofixation is a reasonable analytical procedure.

5. Volumes of plasma to be observed at 4°C for 3 days must be at least 3 ml.

PYROGLOBULINEMIA

Background

Pyroglobulins are Igs that precipitate irreversibly as a gel when serum is heated to 56 to 60°C for 30 min; by contrast, heat precipitation of Bence Jones proteins under similar conditions is reversible. Pyroglobulins are invariably single-component proteins and constitute <1% of monoclonal gammopathies overall and ~6% of Waldenström's macroglobulins.

Concept

Pyroglobulins of every Ig isotype (including IgD and IgE) have been reported in association with multiple myeloma, lymphoproliferative diseases, and plasma cell leukemia. Unlike the case for cryoglobulins, their occurrence has not been associated with specific clinical manifestations, although high levels of these proteins may also cause hyperviscosity or coagulopathies.

Procedure

1. Pyroglobulins precipitate when warmed to 56°C and do not redissolve on heating to 100°C. They are usually apparent as an M-spike on serum protein electrophoresis which significantly decreases, or completely disappears, after pyroprecipitation. Serum immunofixation will thus define the specific monoclonal component forming the pyroglobulin, and this can be confirmed by sodium dodecyl sulfate-PAGE of the isolated material.

2. As noted above, fibrinogen and fibrin and their core proteins are also heat precipitable at these temperatures. Any remaining fibrinogen and/or fibrin due to dysfibrinogenemia or an incompletely clotted blood sample and their split products (typically containing the thermally sensitive D domain) will also form irreversible precipitates at 56°C. To control for this, serum can be treated with 2 or more μU of thrombin per ml and allowed to stand for 1 to 2 h at 37°C; any clots formed can be removed by syneresis before heating to 56°C.

3. Unlike cryoglobulins, pyroglobulin formation is usually not significantly inhibited by the pH range 3 to 9 or by changes in the ionic strength of the solution. Similarly, the effects of reducing (e.g., 2-mercaptoethanol) or dissociating (e.g., Triton X-100) agents on this phenomenon are variable. Occasionally, single patients have been described to have both cryoglobulins and pyroglobulins.

Conclusion

Recognition of the laboratory phenomenon of pyroglobulinemia has importance as a potentially confounding factor for heat-based assays used to inactivate complement or to measure fibrinogen levels. Proper identification of a pyroglobulin as being a monoclonal component may in turn lead to the diagnosis of macroglobulinemia or plasma cell dyscrasia.

Analysis of Complement in the Clinical Laboratory

PATRICIA C. GICLAS

12

The serum complement system represents an important effector arm of the innate, or "nonspecific," immune response in vertebrates. Complement provides a fast-acting mechanism for the identification and removal of foreign substances before the more specific arms of the adaptive immune system can come into play. Among other important roles of complement is the clearance of immune complexes, effete cells, and the cellular debris that results from damaged tissues. Complement activation contributes to many of the symptoms associated with inflammation, including local changes in blood flow and the influx of inflammatory cells into the affected area. If uncontrolled, complement activation presents a danger that can result in tissue damage and loss of function or death. Learning the reason for a patient's low complement is becoming easier with the advent of more specific methods of evaluation, including the ability to differentiate between acquired and inherited deficiency.

Many clinical laboratories have shied away from the analysis of complement, due in large part to the lability of the system and the special handling that samples require if the results are to be reliable. Although with overnight shipping of frozen specimens and more commonly available ultracold freezer storage (−60°C and below) mishandling of specimens is not a major problem in today's laboratory, care should still be taken to ensure that the referring laboratory has the appropriate information for sample collection and preservation. The previous editions of this manual included methods for analysis of complement that remain valid and are a source of methods not described in this volume. The chapters to follow provide information about some methods of analysis to be used for screening tests that are necessary to perform before deciding which specific tests are required for diagnosis of a complement deficiency.

ACTIVATION PATHWAYS

The classical pathway (CP) was the first to be discovered and the first for which the action of its components was described. The alternative pathway (AP) is more primitive in the evolutionary sense and includes a unique "amplification loop" that enables far more C3 cleavage than is possible with the other pathways. The lectin pathway (LP) bypasses C1 of the CP but makes use of C4 and C2 to form a C3-cleaving enzyme. As can be seen from comparing these pathways in Fig. 1, they share the same terminal, or late, components (C3 and C5 to C9) as well as many similar proteins in the activation mechanisms. After an initial pathway-specific "recognition" event, activation occurs in an enzyme cascade that results in production of physiological effects. The key event in complement activation is deposition of C3b on the activator's surface, the central event in all of the activation pathways.

Activation seldom involves only one pathway. If enough C3b is deposited on the activator or other surfaces in the area by the CP or LP, the AP will also become involved. Small immune complexes that bind C1q are the usual activators of the CP, but large, insoluble ones activate the AP. There are other substances that also bind and activate C1q, such as lipid A of bacterial lipopolysaccharide, monosodium urate crystals, subcellular membranes, and some enveloped viruses. CP activation can also occur through interaction of C1q and C-reactive protein that is complexed with pneumococcal C polysaccharide. The binding of the pattern recognition lectins, mannose-binding lectin, or ficolin to the appropriate sugar residues on bacterial surfaces leads to activation of the LP. Complex polysaccharides such as yeast cell walls (zymosan), high-molecular-weight inulin, Sephadex, cellulose acetate, and bacterial cell walls provide appropriate surfaces for AP activation. Even without the involvement of the complement pathways, cleavage of C3 or C5 by enzymes of the contact coagulation system (e.g., XIIa and Kallikrein), from inflammatory cells (e.g., elastase and cathepsin G) or from bacteria, can produce active C3a and C5a, and presumably deposit C3b that could initiate the amplification loop of the AP.

MEASUREMENT OF COMPLEMENT

In the previous edition of this manual, I discussed the value of performing the CH50 and AH50 assays as the first step in complement analysis when a deficiency is suspected. Chapter 14, by Seelen et al., describes functional assays for CP, AP, and LP activity that can be done at the same time, thus adding an additional dimension to the screen. Once it has been determined that a defect in one pathway is present, the appropriate tests can be done to determine whether a single component is missing (e.g., genetic deficiency) or several components are affected (e.g., depletion by activation). The function of mannose-binding lectin can be evaluated more extensively by the
FIGURE 1 CP, LP, and AP of the human complement system, showing the control steps and where some of the biologically active split products are produced.

method described in chapter 15, by Gadjeva and Thiel. For other tests to quantitate individual components of any of the pathways, the reader should consult the previous editions of this manual.

BIOLOGICAL ACTIVITIES OF COMPLEMENT FRAGMENTS

The symptoms of inflammation associated with complement activation are due to a limited number of biologically active complement split products that are produced by the enzymatic cascade. The anaphylatoxins C3a and C5a can interact with their specific receptors on many cell types. Some of their effects include alterations in local blood flow through increased dilation and permeability of small vessels and smooth muscle contraction (e.g., guinea pig ileum and tracheal rings and estrous rat uterus) as well as upregulation of adhesion molecules on endothelial and white blood cell surfaces. Systemic effects on blood pressure, heart rate, and oxygen perfusion have been noted in animal models of complement activation. Neutrophils, monocytes, macrophages, eosinophils, and mast cells can be enticed to perform many of their tricks (e.g., chemotaxis and mediator and enzyme release) by these complement fragments. An inactivator of the anaphylatoxins, serum carboxypeptidase N, rapidly cleaves the C-terminal arginase from C3a and C5a, rendering them unable to interact appropriately with their receptors. $C5a_{desArg}$ retains some chemotactic activity, but neither $C3a_{desArg}$ nor $C5a_{desArg}$ has the ability to induce enzyme release or the other functions associated with anaphylatoxin activity. The assays available for measurement of these peptides are directed against the desArg forms since these are the ones that are found in the circulation. It should be noted that C4a, once grouped with the anaphylatoxins, has not been found to interact with either the C3a or C5a receptor, and a specific C4a receptor has not been found to date.

Complement split products (C4a, C3a, C5a, iC3b, C4d, SC5b-9, and Bb, as well as others) can be measured by enzyme immunoassay or radioimmunoassay methods or by changes in electrophoretic mobility or size. These tests are very sensitive and can pick up activation of less than 1% of the parent component. Analysis of complement split products, including $C3a_{desArg}$ and $C5a_{desArg}$, can give valuable insight into pathological processes taking place during a disease state. These assays are extremely useful in determining whether complement activation is occurring and by which pathway(s), thus providing information about the underlying pathological mechanism. Chapter 16, by Baldwin, describes the application of complement analysis in diagnosing acute and chronic transplant rejection.

In addition to the enzymes and other components of the activation pathways, there are a number of important proteins that control the cascade. Among these, C1-esterase inhibitor is responsible for stopping the uncontrolled activation of the CP and also acts as a control for certain enzymes of the coagulation system. Deficiencies of this protein result in the condition of hereditary or acquired angioedema, and a number of new therapies are being developed to specifically treat the acute symptoms of hereditary and acquired angioedema. The major control of the AP occurs through the action of two proteins that stop the cleavage of C3. Another important control protein is factor H, which binds to C3b in either the classical or alternative C3 convertase enzyme and is required before factor I can cleave and inactivate the C3b. While the gross absence of either of these proteins has long been associated with severe depletion of C3 and subsequent pyogenic infections in the affected individual, more recently, subtle changes in the protein structure of factor H and its cell-associated counterpart, membrane cofactor protein (CD46), have been associated with atypical hemolytic-uremic syndrome. The analysis of these proteins and their genes in this devastating disease is discussed in chapter 13 by Strain et al.

It should be noted that complement is appearing daily in the literature of immunology in many contexts that were once considered the domain of the cellular immunologist, e.g., interactions with B-cell and T-cell functions as basic as the induction of antibody responses and memory cell retention. Its involvement in such diverse processes as asthma, early pregnancy loss or low birth weight, and age-related macular degeneration makes us realize how little we know about this ancient and intriguing system. No doubt additional interactions will be discovered in the coming years and give even more importance to the laboratory evaluation of the complement system.

Molecular and Clinical Evaluation of Atypical Hemolytic Uremic Syndrome

LISA STRAIN, JUDITH A. GOODSHIP, AND TIMOTHY H. J. GOODSHIP*

13

ATYPICAL HUS

The hemolytic uremic syndrome (HUS) consists of the triad of a microangiopathic hemolytic anemia, thrombocytopenia, and acute renal failure (43). Most commonly, this is associated with a preceding diarrheal illness, often due to infection with *Escherichia coli* O157 (19). Less frequently, there is no preceding diarrheal illness, and hence this form of the disease is known as atypical HUS. This can be either sporadic or, when more than one member of a family is affected, familial. In both sporadic and familial HUS, the disease can be recurrent. The clinical features of the syndrome are due to the development of platelet-rich microthrombi in small vessels. This particularly affects the glomeruli of the kidney, causing acute renal failure. Recovery of renal function is uncommon in atypical HUS, and many patients require long-term renal replacement therapy. While dialysis is often successful, recurrence of the disease in renal allografts is seen in approximately 50% of patients (21).

ATYPICAL HUS AND COMPLEMENT FACTOR H

Recent findings for both the familial and the sporadic forms of the disease suggest that atypical HUS is a disease of complement dysregulation. Familial HUS was first described in 1956; both autosomal dominant and recessive forms of inheritance have been reported (2, 12, 13). In 1998, linkage to a cluster of genes on chromosome 1 (the so-called regulators of complement activation [RCA] cluster) that encode proteins important in the control of complement activity was established. Warwicker et al. studied three families with HUS and established linkage in the affected individuals to the RCA cluster (44). The first RCA gene examined in these families was the gene for factor H. This is because there had been previous reports of an association between familial HUS and factor H deficiency (24, 28, 33, 39). Factor H shares a basic structure with other proteins encoded by the genes of the RCA cluster. Such proteins consist largely of multiple contiguous homologous modules called complement control protein modules (CCPs), also known as short consensus repeats or sushi domains (reviewed in reference 14). Each factor H CCP is approximately 60 amino acids in length and possesses 10 to 18 highly conserved residues. Four cysteines form two disulfide bridges to give the CCP a loop-within-a-loop characteristic structure. The CCPs house the sites for interaction with C3b and C4b and thus complement regulation.

Warwicker et al. found a mutation in the exon encoding CCP 20 in one of the families but not in the other two (44). Since then, there have been a series of reports documenting the association between atypical HUS and factor H mutations (3, 4, 7, 21, 26, 31, 45). These studies show that between 15 and 30% of patients with atypical HUS (both familial and sporadic) have a factor H mutation. The majority of the mutations, especially in adults, are missense, with a normal factor H level. These mutations tend to cluster in the C-terminal region of the molecule, an area known to be important for binding to C3b and anionic surfaces (27) (Fig. 1A). Such mutations result in impaired protection of host surfaces against complement activation (17, 25, 35). Other mutations in factor H predisposing to HUS are associated with either complete or partial factor H deficiency, and they are distributed throughout the gene (Fig. 1B).

Three pieces of evidence suggested that other complement genes apart from the gene for factor H were involved in the pathogenesis of atypical HUS.
1. Only 15 to 30% of patients have a factor H mutation.
2. Two of the original three families whose defect mapped to the RCA cluster (44) did not have a factor H mutation.
3. In our HUS panel, several patients who exhibited evidence of overactivity of the alternative complement pathway, such as a low C3 level, did not have a factor H mutation (31).

To take this further, other candidate genes involved in the regulation of complement activation have been examined, including those for membrane cofactor protein (MCP) (CD46) and factor I.

MCP

MCP is widely expressed on the surface of almost every human cell except erythrocytes (8, 10, 11, 18, 20). Together with serine protease factor I, it degrades C3b and C4b bound to the cell surface (1, 6, 15, 23, 37, 38). This proteolytic event is known as cofactor activity.

Structurally, MCP consists of four alternatively spliced isoforms that coexist on most cells (5, 16, 30, 34). The extracellular domain is composed of four CCPs. Following this is an

FIGURE 1   Factor H mutations associated with HUS are identified above the corresponding CCP. (A) Missense mutations with normal factor H levels. (B) Mutations associated with factor H deficiency (Fr, frameshift; X, premature stop codon; Δ, deletion). The amino acid numbering includes the 18-amino-acid signal peptide.

O-glycosylated region rich in serines, threonines, and prolines, the STP region, which is alternatively spliced. There are either 14 or 29 amino acids in the STP region, depending on the splicing in or out of STP exon B. The STP region is followed by a juxtamembranous region of 12 amino acids of unknown function, which is followed by a hydrophobic transmembrane domain and cytoplasmic anchor. The cytoplasmic tail of MCP is also alternatively spliced (the 16-amino-acid CYT-1 and the 23-amino-acid CYT-2) and mediates signaling events (16). The MCP gene is located within the RCA cluster on chromosome 1 with 14 exons spanning ~43 kb.

Because MCP lies within the RCA cluster on chromosome 1, it was considered as a candidate gene in the two families from Warwicker's original linkage study in which a factor H mutation had not been found (44). In one family, mutation screening showed no abnormality. In the other, a heterozygous 6-bp deletion (GACAGT) in the exon encoding CCP4, resulting in the loss of two amino acids (ΔD237/S238), was detected in affected individuals (32). In this family, three male siblings were affected at the ages of 27, 31, and 35 years (29). C3 levels at presentation were normal, and there was no recovery of renal function. Subsequently, all three received a cadaver renal transplant, with no recurrence of HUS in the allograft. Fluorescence-activated cell sorter (FACS) analysis of peripheral blood mononuclear cells (PBMCs) from an affected individual demonstrated reduced expression of MCP, and C3b binding studies of PBMC lysates revealed ~50% reduction in C3b binding. Mutant MCP constructs were evaluated after

transfection into Chinese hamster ovary (CHO) cells. Western blot, flow cytometry, cell surface labeling (biotinylation), and pulse-chase analysis all showed that the mutant protein was retained intracellularly. Noris et al. have also described a family in which two siblings were affected by HUS (22). The female patient was first affected at the age of 16 months and had recurrent episodes of HUS, eventually resulting in end-stage renal failure requiring dialysis. Her brother had two episodes of HUS at the age of 9, from which he made a complete recovery. Mutation screening in both revealed a heterozygous 2-bp deletion in MCP exon 7, which encodes CCP4. This results in a premature stop codon and was associated with reduced expression of MCP on PBMCs (22). The functional effect of this mutation is therefore similar to the deletion mutation and results in half of the normal level of cell surface expression of MCP.

Following the finding of the MCP deletion mutation (ΔD237/S238), a panel of other HUS families in whom a factor H mutation had not been found (31) were examined. In two families, a transition (T822C) resulting in a serine-to-proline change, S206P, in the exon encoding CCP4 was found. In one family, two brothers were affected at the ages of 8 and 15. In both, renal function recovered. The two affected individuals in this family were heterozygous for the S206P substitution. In the other family, one male and one female sibling were affected. Again, both made a complete recovery. The affected individuals in this family were homozygous for the substitution, their parents being first-degree relatives. For the affected individuals from both families, FACS analysis

revealed that the levels of MCP expression in PBMCs were normal. C3b binding was ~50% reduced in affected heterozygotes and undetectable in affected homozygotes. The functional consequences of the S206P substitution were studied in CHO cells expressing this mutant. All the studies undertaken showed that the mutant protein's ability to interact with C3b was severely impaired (32). Cells bearing the mutation demonstrated less inhibition of C3b deposition. The mutant protein exhibited almost total loss of reactivity to the MCP monoclonal antibody GB24 that blocks C3b binding. C3b binding was diminished, and C3b cofactor activity was abolished. However, C4b binding and cofactor activity were unaffected. This mutation, therefore, had a very specific effect on alternative pathway regulation.

FACTOR I

Besides abnormalities of soluble and membrane-bound RCA, mutations in factor I in atypical HUS have recently been described. Factor I is a soluble regulatory serine protease of the complement system which cleaves three peptide bonds in the alpha-chain of C3b and two bonds in the alpha-chain of C4b, thereby inactivating these proteins. The protein is a heterodimer with a molecular weight (MW) of about 88,000 which consists of a noncatalytic heavy chain (MW, 50,000) which is linked to a catalytic light chain (MW, 38,000) by a disulfide bond. The protein is synthesized as a single-chain precursor of 565 amino acids, predominantly in the liver. Four basic amino acids are then excised from the precursor prior to secretion of the heterodimer. Like many of the complement proteins, factor I has a modular structure. The heavy chain contains two low-density lipoprotein receptor domains, a CD5 domain, and a module found only in factor I and complement proteins C6 and C7. The factor I gene is located on chromosome 4q25 and spans 63 kb (40). It comprises 13 exons, and there is a strong correlation between the exonic organization of the gene and the modular structure of the protein. The light chain of factor I, which is the serine proteinase region of the molecule, is encoded in five exons. The genomic organization of the enzymatic part of factor I is similar to that of trypsin. The gene structure is unusual in that the first exon is small, 86 bp, and it is separated from the rest of the gene by a large first intron of 36 kb. Factor I deficiency has been described previously in approximately 30 kindreds and is usually associated with a predisposition to pyogenic infection (41, 42). Fremeaux-Bacchi et al. have recently described three mutations in factor I in atypical HUS (9). They screened the coding sequence of factor I in 6 familial and 19 sporadic cases of HUS. In two cases, heterozygous nonsense mutations led to a premature stop codon (G456X and W528X). Both of these had approximately half-normal antigenic factor I levels, and in the third, which had normal factor I levels, there was a heterozygous missense mutation in exon 13 (A1600T) which leads to the substitution of an aspartic acid residue by valine (D506V). Factor I levels were normal. D506 is a highly conserved residue in the catalytic site of factor I, and its substitution is likely to be functionally significant.

CLINICAL EVALUATION OF THE PATIENT WITH ATYPICAL HUS

The diagnosis of HUS should be suspected for any patient presenting with the aforementioned triad of a microangiopathic hemolytic anemia, thrombocytopenia, and acute renal failure. The same triad is also a feature of thrombotic thrombocytopenic purpura (TTP), a syndrome in which neurological and systemic manifestations such as fever are also seen at presentation. Distinction of the two is based on the predominant presenting feature, renal involvement in HUS versus neurological involvement in TTP. The triad of presenting features can also be seen as a secondary manifestation of systemic lupus erythematosis, systemic sclerosis, antiphospholipid antibody syndrome, malignant hypertension, cobalamin C disease, and human immunodeficiency virus infection. Appropriate investigations should be undertaken to exclude these. An evaluation of complement activation should be undertaken as outlined above. However, it has been shown that factor H and MCP mutations can be present without evidence of complement activation. Consideration should therefore be given to undertaking mutation screening of the genes for factor H, MCP, and factor I.

MOLECULAR EVALUATION OF FACTOR H, MCP, AND FACTOR I

Table 1 summarizes the methods that can be used to detect mutations within or near the genes for factor H, MCP, and factor I. The two techniques most frequently used for mutation scanning are denaturing high-performance liquid chromatography (DHPLC) and single-strand conformation polymorphism (SSCP). DHPLC is based on heteroduplex analysis in which mutant and wild-type sequences present in a PCR product are heated and allowed to reanneal slowly. This results in the formation of four species of DNA: two heteroduplexes and two homoduplexes. These DNAs have altered mobility compared to the wild-type sequence, and this is seen as a time shift or variant pattern on DHPLC. In SSCP, the PCR amplicon is denatured, snap-cooled, and electrophoresed in a nondenaturing polyacrylamide gel. The single-stranded DNA assumes a three-dimensional conformation which is dependent on the primary sequence and secondary structure, and this results in altered migration patterns compared to the wild-type pattern. The disadvantages of these scanning methods are that neither can detect homozygous changes and the sensitivity is not greater than 95%. In addition, all variant patterns have to be sequenced to fully characterize the nature of the change. Sequencing PCR amplicons directly without prior mutation scanning can be costly, but the sensitivity of detection approaches 100%. With the wide availability of automated fluorescent sequencers and robotic liquid handling, direct sequencing is increasingly becoming the method of choice for mutation detection. If the exon-specific primers have a 5′ N13* (N13 forward GTAGCGCGACGGCCAGT, N13 reverse CAGGGCGCAGCGATGAC) (modified M13) tag, then all sequencing reactions can be carried out with a common forward primer and a common reverse primer. Genomic DNA is sequenced, with each exon being amplified with approximately 20 bp of flanking intron. Care has to be taken in designing primers to amplify the exons coding for the C-terminal exons of factor H because of the close homology with the factor H-related proteins (46). Genomic DNA is extracted from peripheral blood by standard methods and then amplified by PCR with exon-specific primers and annealing temperatures as reported previously (9, 31, 32). PCR products are purified by use of magnetic microparticles (AMPure; Agencourt Biosciences) to remove unincorporated deoxynucleoside triphosphates, primers, and salts. Sequencing reactions are carried out by dye terminator cycle sequencing using either exon-specific primers or N13 primers, purification with magnetic microparticles

TABLE 1 Methods for mutation detection[a]

Method	Advantage(s)	Disadvantage(s)
Southern blot, hybridize to cDNA probe	Only way to determine major deletions and rearrangements	Laborious, expensive Needs several μg of DNA
Sequencing	Detects all changes Mutations fully characterized	Expensive
Heteroduplex gel mobility	Very simple Cheap	Sequences of <200 bp only Limited sensitivity Does not reveal position of change
DHPLC	Quick, high throughput Quantitative	Expensive equipment Does not reveal position of change
SSCP	Simple, cheap	Sequences of <200 bp only Does not reveal position of change
DGGE	High sensitivity	Choice of primers is critical Expensive primers Does not reveal position of change
Chemical mismatch cleavage	High sensitivity Shows position of change	Toxic chemicals Experimentally difficult
PTT	High sensitivity for chain-terminating mutations Shows position of change	Chain-terminating mutations only Expensive, difficult technique Usually needs RNA
Quantitative PCR	Detects heterozygous deletions	Expensive
Microarrays	Quick High throughput Might detect and define all changes	Expensive Limited range of genes

[a]DGGE, denaturing gradient gel electrophoresis; PTT, protein truncation test. Reproduced with permission from *Human Molecular Genetics* (38a).

(CleanSeq; Agencourt Biosciences), and then electrophoresis on a fluorescent 16-capillary sequencer (Beckman CEQ 8000). The resulting electropherograms are checked for homozygous and heterozygous base changes by use of an automated sequence analysis package (Mutation Surveyor [50]; SoftGenetics LLC). This program has a trace difference component in which the test electropherogram is subtracted from the normal electropherogram and base changes are seen as peaks rising above the background. One disadvantage of both sequencing and mutation scanning, however, is that large deletions and duplications or other large-scale rearrangements will not be detected, so some method of dosage analysis is required. MLPA (multiplex ligation-dependent probe amplification) is a relatively new method for detecting deletions and duplications in a simple two-stage procedure and gives dosage information for up to 45 exons in one test (36). Conventional dosage analysis can also be carried out with a fluorescent multiplex PCR, but a limited number of exons can be tested in this way.

An Enzyme-Linked Immunosorbent Assay-Based Method for Functional Analysis of the Three Pathways of the Complement System

M. A. SEELEN, A. ROOS, J. WIESLANDER, AND M. R. DAHA

14

BACKGROUND

The complement system has a crucial role in innate immune defense against invading microorganisms and can be activated by the classical pathway (CP), the alternative pathway (AP), and the mannose-binding lectin (MBL) pathway (MP) (8). Initiation of the complement system generates a cascade of enzymatically activated proteins and is associated with the initiation of the terminal complement pathway and formation and deposition of the terminal C5b-9 complement complex, also termed the membrane attack complex. Furthermore, activation of the complement system generates opsonic components of complement, facilitating the phagocytosis of microorganisms by phagocytes (1).

The CP is activated by binding of C1q to, e.g., immunoglobulins present on microorganisms or by direct binding to apoptotic cells. The AP can be directly activated by invading microorganisms. The MP is also directly activated, via carbohydrate moieties present on the surface of invading microbes.

For assessment of the functional activity of the classical and alternative pathways, hemolysis of erythrocytes by complement activation via either the CP (CH50) or the AP (AP50) is used in most laboratories. Functional enzyme-linked immunosorbent assay (ELISA)-based procedures for the classical and alternative pathways have been developed on the basis of previously reported methods (2, 7). Also, for assessment of the functional activity of the MP, hemolytic assays have been developed.

Direct hemolysis of erythrocytes coated with mannan and indirect hemolysis of chicken erythrocytes, as innocent bystander cells, have been used (3, 4). In both assays, exogenous mannan-binding-lectin-associated serine proteases (MASP) and/or additional complement factors have to be added to the assay system to permit erythrocyte lysis. Furthermore, both types of assays are difficult to perform on a routine basis for clinical use and do not exclude participation of the CP in the assay. Petersen et al. (6) introduced an ELISA-based assay with mannan-coated plates to evaluate the activity of the MBL-MASP complex. In this assay, sera are incubated in high-ionic-strength buffer to prevent interference from CP activation by antimannan antibodies. The activity of the MBL-MASP complex is assessed in a second step with exogenously added purified C4. In clinical practice, it would be helpful to assess the functional activity of the whole MP, from MBL through to C9, without the use of additional complement sources. Such ELISA-based procedures using mannan-coated plates have been developed (5, 7), and it has been recently demonstrated that the contribution of the CP in such an assay can be prevented by addition of an inhibitory antibody directed against C1q (7).

A combination ELISA has been developed at Wieslab (Lund, Sweden), in collaboration with European academic partners, to assess the functional activity of the CP, AP, and MP.

ASSAY

The methods to assess pathway activity of the CP, AP, and MP are ELISA based. All three assays are delivered as one ELISA system. Strips of wells for CP evaluation are precoated with immunoglobulin M, strips for AP determination are coated with lipopolysaccharide, and strips for the MP are coated with mannan. Sera should be diluted 1/101 for the CP and MP assays and 1/18 for the AP assay. Specific buffers containing Mg^{2+} and Ca^{2+} for the CP and MP and a buffer containing Mg-EGTA for the AP are used to ensure that activation of only one of the pathways can occur. Activation of the CP in the MP assay, by naturally occurring antibodies directed against mannan, is inhibited by specific anti-C1q antibodies.

SAMPLES

Samples: Blood samples are to be collected under sterile conditions in red-top tubes, without serum separator. A minimum of 5 ml of whole blood is recommended. Allow blood to clot for 60 to 65 min at room temperature (20 to 25°C). Centrifuge clotted blood samples in a refrigerated centrifuge, and transfer cell-free serum to a clean tube. Sera should be handled in such a way that in vitro complement activation is prevented. Sera should be frozen at -70°C in tightly sealed sterile tubes for extended storage and should be frozen and thawed preferably only once but at most three times and should not be older than 1 year. Plasma samples cannot be used. A 30-µl serum sample is required for the assay of all three pathways.

MATERIALS AND REAGENTS

Kit components and storage of reagents:

A foil pack with a desiccation sachet including four blue-colored ELISA well strips for the CP, coated with

human immunoglobulin M; four green-colored strips for the MP, coated with mannan; and four red-colored strips for the AP, coated with lipopolysaccharide

10 ml of diluent CP, labeled blue

10 ml of diluent MP, labeled green

10 ml of diluent AP, labeled red

13 ml of conjugate alkaline phosphatase-labeled antibodies to C5b-9 (blue)

13 ml of substrate solution, ready to use

30 ml of wash solution, 30× concentrated

0.2-ml negative control, containing human serum

0.2-ml positive control, containing freeze-dried human serum

The reagents should be stored at 2 to 8°C. The positive control should be stored at −20°C.

Washing solution: A 30× concentrated washing solution is provided. A 30-ml volume of solution should be diluted in 870 ml of distilled water. When stored at 2 to 8°C, the diluted wash solution is stable until the date of expiry of the kit. Before use, the solution should be at room temperature.

EQUIPMENT AND INSTRUMENTS

Precision pipettes with disposable tips

Water bath at 37°C

Ice bath

Washer for strips, absorbent tissue, tubes, and timer

Microplate spectrophotometer with 405-nm filter

PREPARATION OF SAMPLES

Positive control: A positive control is provided in the kit. Gently tap down all lyophilized material to the bottom of the vial and remove the cap. Immediately add 200 μl of distilled water and replace the cap. Allow the vial to stand on ice for 5 min and gently shake or vortex occasionally until completely dissolved. The reconstituted positive control can be stored for 4 h prior to use if kept at 2 to 8°C or on ice. It can be frozen at –70°C and thawed once.

Serum samples: Partially thaw frozen sera by briefly placing them in a 37°C water bath with gentle mixing. After partially thawing, immediately place the tubes in an ice bath and leave them on ice until the dilution step.

Procedure 1: Dilution of Samples

CP
Dilute the serum samples, positive control, and negative control 1/101 with diluent for CP, provided in the kit in a vial with a blue label (500 μl + 5 μl of serum). The diluted serum can be left at room temperature for 60 min before analysis.

MP
Dilute the serum samples, positive control, and negative control 1/101 with diluent for MP, provided in the kit in a vial with a green label (500 μl + 5 μl of serum). The diluted serum *must* be left at room temperature for >15 min before analysis but not longer than 60 min.

AP
Dilute the serum samples, positive control, and negative control 1/18 with diluent for AP, provided in the kit in a vial with a red label (340 μl + 20 μl of serum). The diluted serum can be left at room temperature for 60 min before analysis.

Procedure 2: Incubation of Samples
In duplicate, pipette 100 μl of the following per well:

Diluent alone, as a blank

Positive control

Negative control

Patient serum

The best order of sample addition to the plate is shown in Table 1. Incubate the plate for 60 to 70 min at 37°C with a lid.

Procedure 3: Washing
Empty all wells and wash the plate three times with 300 μl of washing solution, filling and emptying the wells each time. After the last wash, empty the wells by tapping the strip on an absorbent tissue.

Procedure 4: Adding Conjugate
Add 100 μl of conjugate to each well, and incubate the plate for 30 min at room temperature. The conjugate, containing alkaline phosphatase-labeled antibodies to C5b-9, is used for all three pathways.

Procedure 5: Washing
See procedure 3.

TABLE 1 Diagram for placement of the diluted sera from patients and controls in the assay plate

Row	Contents of indicated column[a]											
	CP				MP				AP			
	1	2	3	4	5	6	7	8	9	10	11	12

[a] BL, blank; PC, positive control; NC, negative control; PS, patient serum.

Procedure 6: Addition of Substrate

Add 100 µl of substrate solution to each well, and incubate the plate for 30 min at room temperature. Read the absorbance at 405 nm on a microplate reader. (A 100-µl volume of 5 mM EDTA per well can be used as stop solution. Read the absorbance of the wells within 60 min.)

Procedure 7: Calculation of Result

Subtract the absorbance of the blank from all other samples. The absorbance of the positive control should be >1, and that of the negative control should be <0.2.

The negative and positive controls can be used in a semiquantitative way. Pathway activity can be calculated as follows: activity = $100\% \times$ (mean A_{405} of sample − mean A_{405} of negative control)/(mean A_{405} of standard serum − mean A_{405} of negative control).

It is recommended that each laboratory establish its own reference level and cutoff value for deficiencies.

PREANALYTICAL CONCERNS

Collection and Storage of Samples

With the combined assay, the functional activity of the three pathways of complement activation can be assessed. Because the functional activity is being assessed, it is important that no in vitro complement consumption occurs when the samples are collected. Serum should be stored at −70°C in tightly sealed tubes and not be frozen and thawed more than once. Storage at −70°C for more than one year can influence functional activity.

Storage of Assay

The complement kit should be stored at 2 to 8°C and not be used after the expiry date. The positive control, provided as lyophilized material, should be stored at −20°C.

All solutions should be equilibrated to room temperature (20 to 25°C) before analysis.

ANALYTICAL CONCERNS

The positive control serum should be stored at −20°C. After thawing, serum samples should be kept on ice during performance of the assay. Serum samples from patients should be stored at −70°C and thawed only just before the test is performed and should not be frozen and thawed more than once. Sera diluted for one test should not be used again. Let all solutions equilibrate to room temperature (20 to 25°C).

The diluted serum sample for the MP must be left at room temperature for >15 min and no longer than 60 min prior to analysis. The time periods for the different incubations should be kept accurately.

POSTANALYTICAL CONCERNS

The controls are intended to monitor for substantial reagent failure. It is recommended that each laboratory establish its own reference level and cutoff value for deficiencies. The individual patient complement pathway activity cannot be used as a measure of disease severity, as it may vary from patient to patient. The test results are dependent on the quality of the serum samples.

TEST VALIDATION

Sera from healthy blood donors were tested in the three assays (n = 120). The intra-assay variation for the three pathways was below 7%, whereas the interassay variation was below or equal to 20%. The normal reference range in the sera was calculated for the CP, AP, and MP. Because of the limited variation of complement activity between different sera, particularly in the CP but also in the AP, a cutoff value for normal pathway activity could be defined as the mean value of activity minus two times the standard deviation. This approach resulted in 2.5% of the healthy population falling below the cutoff value for normal complement activity. The cutoff value for the CP was calculated to be 74%, and that for the AP was calculated to be 39%. Because of the variation in MBL concentration in the normal healthy population, which is mainly genetically determined, there is a large variation in MP activity. Therefore, an arbitrary minimum level for normal MP activity was set at 10% of the standard, which corresponded to MBL concentrations below 300 ng/ml.

PITFALLS AND TROUBLESHOOTING

Because collection and storage of samples are of crucial importance in functional complement assays and the handling is not always correct, the in-house accuracy results should always be used in combination with clinical symptoms. When inappropriate handling of serum samples is suspected, the test should be repeated. Tests with results just above or below the cutoff value are best repeated.

INTERPRETATION OF RESULTS

The level of complement activity evaluated by functional assays takes into account the rate of synthesis, degradation, and consumption of complement components. Decreased functional activity can be the result of a complement deficiency or an ongoing process leading to complement consumption. With the use of this combined ELISA system, the three pathways for complement activation can be assessed at the same time. The possible deficiencies of components leading to reduced functional activity can be detected by using the combined test results of the three pathways (Table 2). For further evaluation of deficiency of a single complement component, other assays are available.

CONCLUSION

For clinicians suspecting a deficiency in innate immunity in patients with, for example, recurrent severe infections or systemic autoimmune diseases, analysis of the complement system is important. The ELISA-based kit presented in this chapter provides the tools to screen the three pathways of

TABLE 2 Determination of possible complement deficiency by combination of the test results from the three assays

[a] Decreased (↓) or normal (=) functional pathway activity.

complement activation for possible deficiencies. By using the results from the three assays, it is possible to detect the possible complement components responsible for reduced functional activity. The levels of these individual components can subsequently be evaluated.

Evaluation of the Mannan-Binding Lectin Pathway of Complement Activation

MIHAELA GADJEVA AND STEFFEN THIEL

15

Mannan-binding lectin (MBL) activates the complement system and therefore triggers an innate antimicrobial defense mechanism. Events in the MBL pathway of complement activation involve the binding of MBL to patterns of carbohydrate structures presented on the surface of microorganisms and the following activation of the proenzymes of the complement system. MBL selectively binds to sugars, e.g., mannose, glucose, L-fucose, and N-acetylglucosamine, with low affinity. To obtain physiologically relevant high-avidity interaction with MBL they must be clustered, e.g., as binding occurs on the surface of the microorganisms. In circulation, MBL is found in complex with serine protease zymogens: MASP-1 (MBL-associated serine protease-1), MASP-2, and MASP-3. The MBL-MASP complex also contains a nonenzymatic protein, MAp19. The functions of the different MASPs remain to be determined, but there is some knowledge as to the function of MASP-2. Upon binding of the MBL complex to its ligands, MASP-2 autoactivates and then proteolytically cleaves complement components C4 and C2 to generate the C3 convertase C4bC2b.

TECHNOLOGY

The protocols described here are useful for routine quantification of MBL and evaluation of the MBL pathway activity in clinical samples. The assays are based on the robust, highly sensitive and reproducible time-resolved immunofluorometric assay (TRIFMA). TRIFMAs are similar to enzyme-linked immunosorbent assays (ELISAs), with the only difference being the type of labeling of detecting molecules. Instead of enzyme-linked antibodies or streptavidin, Eu^{3+} is used to label antibodies or streptavidin. In the ELISA, a colorimetric reaction is monitored, while in the TRIFMAs, fluorescence is detected. The assay can easily be changed to an ELISA format by changing the label of the developing reagent to the relevant enzyme; e.g., if an ELISA setup is preferred, enzyme-linked streptavidin can be used instead of Eu^{3+}-labeled streptavidin. This step is followed by use of the relevant substrate solution.

QUANTIFICATION OF MBL

Different approaches have been used to measure the MBL concentration in plasma or serum (11, 12, 26). The recommended assays in this chapter focus on two approaches. The first is based on a modification of the conventional sandwich ELISA, in which microtiter wells are coated with anti-MBL antibody and then incubated with dilutions of plasma or serum and the amount of bound MBL is measured by using europium-labeled anti-MBL antibody (MBL antigen assay) (Fig. 1A). The second assay quantifies MBL on the basis of its lectin-binding activity (lectin assay), in which microtiter wells are coated with mannan instead of anti-MBL antibody (Fig. 1B) (27). The two assays produce comparable results ($r = 0.97$); however, the sensitivities of the assays differ. The MBL antigen assay is more sensitive (down to 2 ng of MBL/ml of plasma) than the lectin assay (10 ng/ml). Both assays demonstrate a high degree of reproducibility.

MBL ANTIGEN ASSAY

Sample Requirement

Both serum and plasma (EDTA, citrate, or heparin) samples may be used because the high NaCl concentration in the sample buffer inhibits coagulation. If serum is used, the blood is allowed to coagulate at room temperature (RT) for 2 h before centrifugation and removal of the serum. Serum aliquots are stored at $-80°C$ until use. The assay is not influenced by possible variations of other serum factors, e.g., complement factor C4, C1q, or C1 inhibitor. The assay can be performed with commercially available reagents.

Materials and Reagents

96-well microtiter plates (437958; FluoroNunc, Kamstrup, Denmark)

Coating anti-MBL antibody of choice (e.g., monoclonal antibody [MAb] 131-1; Immunolex, Copenhagen, Denmark)

Detection antibody: biotinylated anti-MBL antibody of choice (e.g., MAb 131-1 [Immunolex], biotinylated by using reagents from, e.g., Pierce [Lausanne, Switzerland])

Streptavidin-Eu^{3+} (Wallac Oy/Perkin Elmer, Turku, Finland)

Time-resolved fluorometer, e.g., 1232 DELFIA fluorometer (Wallac Oy)

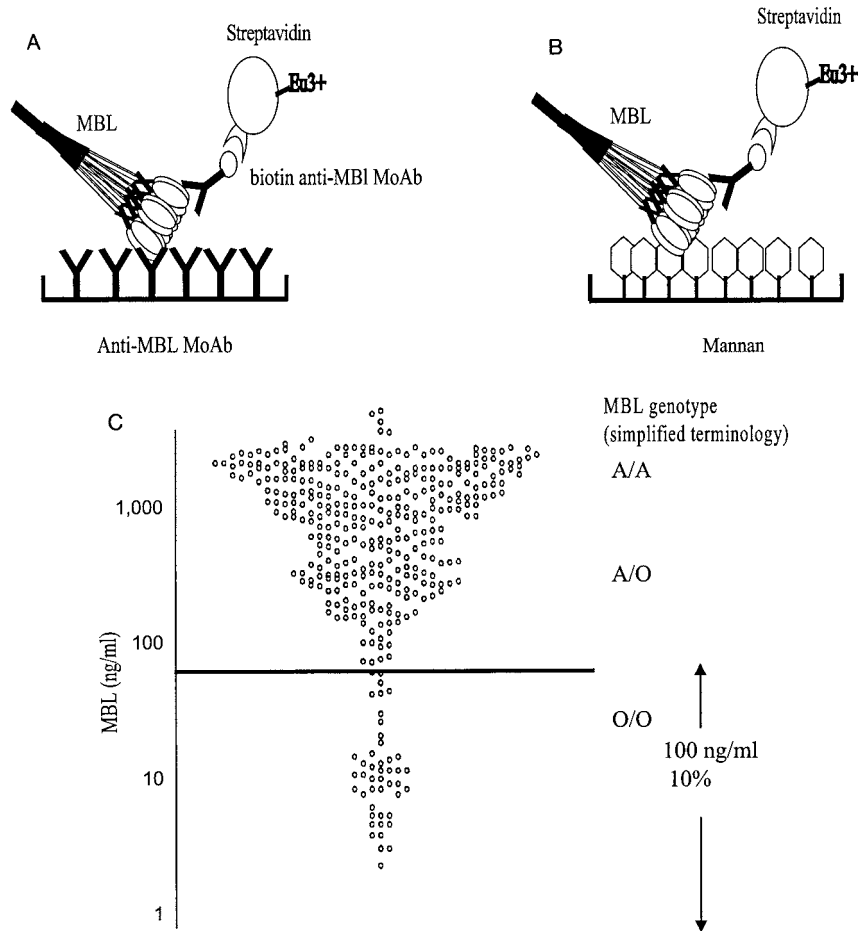
Phosphate-buffered saline (PBS): 0.23 g of NaH_2PO_4 (anhydrous; 1.9 mM), 1.15 g of Na_2HPO_4, 9 g of NaCl. Adjust the pH to 7.4 and the volume to 1 liter.


FIGURE 1 Quantification of MBL. (A) Quantification by the antigen assay. MBL is captured in the microtiter well by anti-MBL MAb and then detected by a biotinylated anti-MBL MAb. (B) Quantification by the lectin assay. MBL is captured in the microtiter well by mannan (high-affinity ligand for MBL) and is detected by biotinylated anti-MBL MAb. In both the antigen and the lectin assays, the biotinylated anti-MBL MAb step is followed by incubation with Eu^{3+}-labeled streptavidin. (C) Histogram showing levels of MBL in plasma. MBL levels correlate with MBL polymorphisms. For illustrative purposes, the genotypes are given in a simplified form, as follows: A/A, wild-type gene, excluding XA/XA; A/O, heterozygotes for the mutations in exon 1 and in the promoter region, including also XA/XA; and O/O, homozygote mutants and compound heterozygote mutants. Individual MBL levels are represented as circles. Approximately 10% of the population appears to have MBL levels below 100 ng/ml, which can be recognized as deficiency.

MBL binding buffer: 20 mM Tris, 1 M NaCl, 0.05% Triton X-100, 10 mM $CaCl_2$, 15 mM NaN_3, 1-mg/ml human serum albumin (HSA) or bovine serum albumin, 100 μg of heat-aggregated human immunoglobulin G (IgG)/ml. Adjust pH to 7.4. Store at RT. The heat-aggregated human IgG is made by heating a solution of human IgG (at 10 μg/ml) at 63°C for 30 min and then subjecting it to centrifugation at 1,000 × g; the supernatant is used as heat-aggregated IgG.

Blocking buffer: dissolve 1 mg of HSA per ml in 10 mM Tris–145 mM NaCl–15 mM NaN_3 (pH 7.4). Store at 4°C.

Washing buffer: 10 mM Tris, 145 mM NaCl, 0.05% Tween 20, 5 mM $CaCl_2$. Adjust pH to 7.4. Store at RT.

Enhancement solution: mix 5.7 ml of CH_3COOH with potassium hydrogen phthalate to reach a pH of 3.2. Add 1 ml of Triton X-100, and adjust the volume to 1 liter with distilled H_2O. Store at 4°C. Before use, add 2 μl of 15 μM 2-naphthoyltrifluoracetate (2-NTA)–50 μM tri-o-octylphosphine oxide (TOPO) per ml of CH_3COOH–potassium hydrogen phthalate (pH 3.2). Store at 4°C.

Protocol

1. Coat the wells of the microtiter plate with 0.5 μg of anti-MBL MAb 131-1 per ml in 100 μl of PBS and incubate at 20°C overnight in a moist chamber.

2. Empty the wells and block the wells with 200 μl of *blocking buffer* per well. Incubate the plate for 1 h at 20°C. After incubation, wash the plates three times with Tris-buffered saline (TBS) (100 mM Tris-Cl [pH 7.5], 0.9% NaCl)–0.05% Tween 20.

If the plates are to be stored for later use, add 200 μl of TBS per well and store them at 4°C in a moist chamber.

3. Dilute samples in *MBL binding buffer* and incubate in a moist chamber overnight at 4°C. Wash three times with *washing buffer.*
Usually 100-fold sample dilution is sufficient.
4. Detect with biotinylated anti-MBL antibody 131-1. Dilute the biotinylated antibodies in *washing buffer* (use 100 μl/well) and incubate for 1 to 2 h at 20°C in a moist chamber. Wash the wells three times with *washing buffer*.
5. Develop with streptavidin-Eu^{3+} by diluting streptavidin-Eu^{3+} appropriately in TBS–0.05% Tween 20–25 μM EDTA and incubate the plates for 1 to 2 h at 20°C in a moist chamber. After incubation, wash the plates three times in *washing buffer.*
6. Read the plate on a DELFIA fluorometer after you have added 200 μl of enhancement solution per well and shaken the plate for 5 min before reading.

LECTIN ASSAY

The lectin assay protocol describes the quantification of MBL as a lectin. It involves a modification of the previous protocol, in which the coating of the plate with anti-MBL MAb is substituted by coating with mannan.

Additional Materials and Reagents

Mannan (M7504; Sigma, St. Louis, Mo.)
Coating buffer: 15 mM Na$_2$CO$_3$, 35 mM NaHCO$_3$, 15 mM NaN$_3$. Adjust the pH to 9.6. Store at RT.

1. Coat a FluoroNunc 96-well plate with 100 μl of mannan per well at 10 μg/ml diluted in *coating buffe*r and incubate at 20°C overnight in a moist chamber.
2. Follow steps 2 to 6 from the main protocol.
Note that MBL is a calcium-dependent lectin; thus, all buffers for dilution or washing contain 5 mM CaCl$_2$. The only solution that does not contain calcium is the buffer for the dilution of the Eu^{3+}-labeled reagent (step 5, main protocol), which contains 25 μM EDTA to lower the background in the assays due to traces of free europium in the Eu^{3+}-labeled reagents.

MBL-MASP COMPLEX ACTIVITY ASSAY

The MBL-MASP complex activity assay permits determination of the MBL complex activity in serum or plasma samples and may therefore be used to evaluate the clinical implications of MBL pathway-mediated complement activation (Fig. 2) (21). The assay determines the ability of the serum to lead to deposition of C4b onto a mannan-coated surface.

Additional Materials and Reagents

Human complement C4 (A402; Quidel, San Diego, Calif.). Note that complement C4 can be easily purified from human plasma by conventional laboratory techniques as described elsewhere (3).
Biotinylated anti-human C4 antibodies, e.g., rabbit anti-human C4 (DAKO, Glostrup, Denmark). The biotinylation is carried out by using reagents from, e.g., Pierce.
The contents of the *coating buffer, blocking buffer, washing buffer,* and *MBL binding buffer* are similar to the ones described for the two assays above.
TBS

1. Coat the wells with 10-μg/ml mannan (100 μl/well diluted in *coating buffer*) and incubate the plate at 20°C overnight in a moist chamber.
FIGURE 2 MBL pathway activity assay. (A) Schematic representation of the MBL-MASP pathway activity assay. MBL-MASP complexes bind to the mannan-coated microtiter wells. MASP-2 cleaves C4, splitting it into C4a and C4b. The C4b covalently deposits on mannan, and the bound C4b can be detected by use of biotinylated anti-C4 antibodies followed by streptavidin-Eu^{3+}. (B) Relationship between C4 deposition activity and the MBL concentration in 100 normal plasma specimens. The genotypes of each individual are indicated. Linear regression, $r = 0.96$.

2. Block the plate with 200 μl of *blocking buffer* per well. Incubate for 1 h at 20°C. After incubation, wash the plates three times with *washing buffer.*
If the plates are to be stored for later use, add 200 μl of TBS per well and store them at 4°C in a moist chamber.
3. Dilute samples in *MBL binding buffer* and incubate in a moist chamber overnight at 4°C. Wash three times with washing buffer.
Usually 200-fold sample dilution is adequate.
4. Add 0.5 μg of human C4 per ml diluted in *washing buffer*, incubate the plates for 1.5 h at 37°C, and then wash the plates three times with washing buffer.
5. Detect with 0.2-μg/ml biotinylated anti-human C4 diluted in washing buffer by incubating the plate for 1 h at RT.
6. Follow steps 5 and 6 from the main protocol.

QUANTIFICATION OF MASP-2

Activation of the complement system through the MBL pathway relies on the activity of MASP-2. MASP-2 is capable of activation of C4 and is found in circulation in complex

with MBL or ficolins (L-ficolin and H-ficolin). Here, we describe an assay for quantification of plasma or serum MASP-2 (Fig. 3A) (16).

Sample Requirements

EDTA-plasma, heparin-plasma, or serum samples can be used in the assay.

Materials and Reagents

96-well microtiter plates (437958; FluoroNunc)

Coating anti-MASP-2 antibody (e.g., MAb 85B, from the Department of Medical Microbiology and Immunology, University of Aarhus [16])

Detection antibody: biotinylated anti-MASP-2 antibody (e.g., MAb 6G12, from the Department of Medical Microbiology and Immunology, University of Aarhus [16], biotinylated with reagents from, e.g., Pierce)

Streptavidin-Eu^{3+} (Wallac Oy)

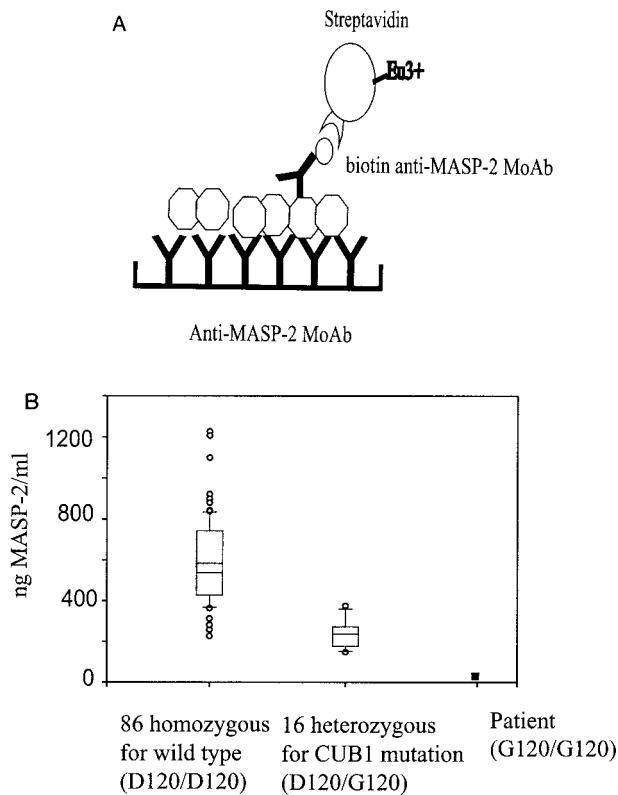
Time-resolved fluorometer, e.g., 1232 DELFIA fluorometer


FIGURE 3 Quantification of MASP-2. (A) Schematic representation of MASP-2 assay. MASP-2 is captured on the anti-MASP-2 MAb-coated microtiter wells and detected by biotinylated anti-MASP-2 MAb. (B) Concentrations of MASP-2 in 100 healthy individuals. The individuals were genotyped for the presence of the MASP-2 D120G mutation and grouped according to the allele. A total of 86 individuals carried the wild-type allele, and the concentration of MASP-2 varied between 200 and 1,200 ng/ml. The 16 heterozygous individuals had less MASP-2 (between 50 and 400 ng/ml). While both the wild-type and the heterozygous groups consisted of healthy blood donors, the single individual homozygous for the G120 polymorphism was a patient (24) who had no detectable levels of MASP-2.

MASP-2 binding buffer: 10 mM Tris, 1 M NaCl, 0.05% Tween 20, 10 mM EDTA, 15 mM NaN$_3$, 0.01% heat-aggregated human IgG. Adjust pH to 7.4. Store at RT. TBS

1. Coat the wells of the microtiter plate with 0.5-μg/ml anti-MASP-2 MAb (8B5) in 100 μl of PBS and incubate the plate at 20°C overnight in a moist chamber.

2. Empty the wells and block the wells with 200 μl of *blocking buffer* per well. Incubate the plates for 1 h at 20°C. After incubation, wash the plates three times with TBS–0.05% Tween 20.

If the plates are to be stored for later use, add 200 μl of TBS per well and store them at 4°C in a moist chamber.

3. Dilute plasma or serum samples in *MASP-2 binding buffer* and incubate in a moist chamber overnight at 4°C. Wash the plates three times with *washing buffer*.

The MASP-2 binding buffer contains a high salt concentration (1 M NaCl) and EDTA to ensure the dissociation of MBL-MASP and MBL-ficolin complexes.

4. Detect with 1 μg of biotinylated anti-MASP-2/MAp19 antibody (6G12) per ml. Dilute the biotinylated antibody in TBS–0.05% Tween 20–5 mM CaCl$_2$–0.01% heat-aggregated human IgG–0.01% (vol/vol) bovine serum. Use 100 μl/well, and incubate the plates for 1 to 2 h at 20°C in a moist chamber. Wash the wells three times with *washing buffer*.

5. Develop with streptavidin-Eu^{3+} by diluting streptavidin-Eu^{3+} appropriately in TBS–0.05% Tween 20–25 μM EDTA, and incubate the plates for 1 to 2 h at 20°C in a moist chamber. After incubation, wash the plates three times in TBS–0.05% Tween 20–5 mM CaCl$_2$.

6. Read the plate on a DELFIA fluorometer after you have added 200 μl of enhancement solution per well and shaken the plate for 5 min before reading.

COMMENTARY

Quantification of MBL

The quantification of MBL based on the described antigen assay and lectin assay is highly reproducible. It is advisable to include internal standards as controls in each assay. We usually use samples of plasma with known high (e.g., 1,586 ng of MBL/ml), medium (e.g., 224 ng of MBL/ml) and low (e.g., 17 ng of MBL/ml) MBL concentrations. We also include fivefold dilutions of standard plasma for the calibration curve. We have calculated the interassay coefficients of variation for the lectin assay to be 15, 9, and 12%, respectively, for high-, medium-, and low-MBL concentration internal standards, whereas for the antigen assay the the interassay coefficients of variation are 8, 8, and 11%, respectively.

The possible influence of rheumatoid factor, which may bind to IgG-coated wells and increase the background of the assay by cross-linking the capture and development antibodies, is eliminated by the inclusion of heat-aggregated IgG in the relevant buffer.

Note that at least three commercially available MBL antigen quantification assays exist, e.g., from HyCult Biotechnology, Uden, The Netherlands; Immunolex; and Dobeel Corp., Seoul, Korea.

MBL levels in plasma vary between 0 and 5 μg/ml (Fig. 1A). The MBL deficiency, often defined as circulating MBL levels below 100 ng/ml, is a common complement deficiency (Fig. 1C). In Caucasians, the frequency of MBL deficiency is between 5 and 10%. The level of MBL in the blood is influenced by single-nucleotide polymorphisms (SNPs) in the

MBL gene (*mbl2*) (28), e.g., in the promoter region (X or Y) and in exon 1 (B, C, and D; A is the wild type). The mutations in exon 1 lead to disruption of the Gly-Xaa-Yaa pattern of the collagen region. Such a disordered collagen helix appears to act like a dominant feature and results in decreased circulating levels of MBL. Due to linkage disequilibrium between the SNPs, seven distinct haplotypes exist in humans, four of which (YB, YC, YD, and XA) dictate low serum MBL levels (Fig. 1C) (13). Individuals with structural gene mutations have profoundly low levels of MBL, individuals heterozygous for the mutations have normal to low levels, and wild-type individuals have normal levels. The TRIFMAs, described here, yield data that correlate well with the MBL genotyping. Similar results may be obtained by ELISA (15).

MBL is a pattern recognition molecule which binds numerous bacteria, viruses, and fungi and activates the complement cascade. The MBL deficiency can be an important modulator in a disease setting or may by itself cause disease. A few examples of low MBL levels modulating disease progression are presented below. For a more extensive review, please see, e.g., reference 4. Pediatric patients with infections and with suspected immunodeficiencies have increased frequencies of MBL variant alleles (8, 25). Since patients with a suppressed cellular immune system, e.g., due to chemotherapy treatment, have higher numbers of infections and since some of those patients tend to suffer from uncommon bacterial infections, such patient groups have been studied for associations between infections and MBL levels. Bacteremia and pneumonia were associated with decreased MBL levels in chemotherapy-treated hematology patients (22), and a correlation between longer periods of fever and lower levels of MBL were noted among children with hematologic malignancies (18). Similarly, the presence of alleles giving rise to low MBL levels was found to be associated with bacterial, viral, and fungal infections in patients after treatment with myoablative bone marrow transplantation conditioning regimens (17).

Another group of patients whose immune system may be suppressed is critically ill patients admitted to the intensive care unit (ICU). Systemic inflammatory response syndrome (SIRS) may render the patients partly immunocompromised and may in some cases progress to sepsis and septic shock. When the frequencies of variant alleles in such patients were compared, it was concluded that higher levels of MBL may be important for avoiding sepsis and septic shock (6). Lower MBL levels were observed in the group of nonsurvivors than in those who survived admission to ICUs (9). Among the patients of the pediatric ICU, the MBL gene polymorphisms with low levels in serum were associated with a greatly increased risk of developing SIRS and of progression from infection to sepsis and septic shock (5).

Regarding MBL levels and viral infections, conflicting data on the associations with human immunodeficiency virus (HIV) infections have been published, showing either significantly more cases of MBL deficiency among HIV-infected patients (7, 19, 23) or a lack of correlation between MBL levels and susceptibility to HIV infection (10, 14). Regarding fungal infections, reduced levels of MBL were correlated with recurrent vaginal candidiases (1). MBL avidly binds *Aspergillus fumigatus*, and chronic necrotizing aspergillosis has been shown to be associated with polymorphisms of the MBL gene, as there was a significant increase in MBL-D allele carriers among the patient group (2).

Among systemic lupus erythematosus (SLE) patients, the presence of variant alleles is associated with increased disease activity and increased risk of infection, and homozygosity for variant alleles increases the risk for arterial thrombosis in SLE patients (20).

MBL Pathway Activity Assay

The activity of the MBL pathway is measured by C4 deposition on mannan-coated wells (Fig. 2). The C4 deposition is triggered by the formation of active MBL-MASP complexes, which cleave C4 and lead to exposure of the internal thioester bond in the C4 molecule, followed by covalent deposition of C4 on the mannan. The classical pathway activity, which can also result in C4 activation, is inhibited by the high-ionic-strength buffer used in the assay, as the binding of C1q to immune complexes is inhibited and proteases C1r and C1s are eluted from C1 complex. The activation of C4 by MASP-2 is inhibited by the high ionic strength, and therefore the assay requires subsequent incubation with purified C4 in an isotonic buffer. Published evidence indicates that the MBL pathway activity determined with this assay reflects the activity of MASP-2 in the MBL-MASP complexes. The specific activity of the lectin pathway may be determined as the ratio of milliunits of MBL per milliliter, with a standard serum set to 1,000 mU/ml. If both the MBL levels and the MBL pathway activity are measured, the specific activity can be determined as a ratio of milliunits of MBL per microgram. The deposition of C4 correlates with the deposition of MBL (Fig. 2B). This is observed when plasma from individuals who are homozygous for the wild-type MBL allele A or plasma from individuals heterozygous for the MBL polymorphisms is tested for C4b deposition and MBL concentration (Fig. 2B). The only obvious deviation from the regression line appears when plasma from individual homozygotes for the structural mutations is tested.

Quantification of MASP-2 Assay

On the basis of the MASP-2 assay described above, the MASP-2 levels in 97 healthy Danish blood donors were determined (16). The MASP-2 levels ranged from 170 to 11,196 ng/ml, with a mean of 530 ng/ml. Unlike MBL deficiency, which is fairly common, the MASP-2 deficiency appears less frequent. A polymorphic structural variant of the MASP-2 gene was described for a patient with recurrent bacterial infections and SLE manifestation (24). The mutation led to diminished MASP-2 levels in circulation (Fig. 3B). Since MASP-2 forms complexes with ficolins, it is possible that the consequences of the MASP-2 deficiency will be more severe than those of the MBL deficiency. We recommend testing for MASP-2 deficiency in patients with recurrent bacterial infections, for whom the contribution of the MASP-2 deficiency to the susceptibility to infection may be crucial.

Complement in Transplant Rejection

WILLIAM M. BALDWIN III

<div style="text-align:center">16</div>

Better reagents have led to an increased appreciation of the association between complement activation in transplants and poor outcome (7, 19). As diagnostic markers, products of complement activation have two attractive attributes related to the fact that activation of complement proceeds through a series of enzymatic steps resulting in multiple cleavage products. First, each enzymatic step is capable of amplifying the number of molecules that are cleaved. Second, the cleavage process reveals cryptic epitopes that allow the activated products to be distinguished from the unactivated precursors. In addition, activation products from two complement components, namely, C4 and C3, have the unusual property of covalently binding to protein and carbohydrate substrates. All of these properties distinguish complement activation products from some of the molecules that activate complement, such as antibodies. Antibodies themselves are not readily detected in tissue sections because only transient binding of a small number of antibodies to tissue is required to activate exponentially larger amounts of complement.

This chapter will examine the advantages and disadvantages of various reagents to complement as applied to the diagnosis of different types of rejection in transplants.

SELECTION AND INTERPRETATION OF DIAGNOSTIC REAGENTS TO COMPLEMENT IN ALLOTRANSPLANTS

Deposits of Complement in Tissue Biopsies

Examination of biopsies from organ transplants provides the most direct assessment of pathological processes jeopardizing the transplant. Stains for complement components in the organ transplant offer direct evidence of the location, distribution, and extent of complement activation at the site of injury. The different components of complement that have been used as markers of antibody-mediated rejection in transplants will be discussed in their order of activation by antibodies as shown in Fig. 1.

Polyclonal and Monoclonal Antibodies to C1q

The activation of complement by antibodies occurs primarily through the classical pathway. Because C1 is the first component of the classical pathway of complement activation, it has long been used as a marker of antibody activation of complement. Polyclonal and monoclonal antibodies to detect C1q, the subcomponent of C1 that actually binds to antibodies, are available (Fig. 1). These are frequently applied in renal pathology and dermatopathology to detect immune complexes. There are several drawbacks to C1q as a marker of rejection, however. The most serious drawback relates to sensitivity. In order to bind, one C1q molecule requires at least a pair of immunoglobulin G (IgG) antibodies (Fig. 1A). This means that there are actually fewer C1q molecules than IgG molecules to detect. Moreover, the C1q molecules that are bound to antibodies depart when antibodies release from antigen or are shed from a cell surface (Fig. 1C).

In addition to sensitivity, there are theoretical problems of specificity. It is now clear that antibody is not the only ligand that is bound by C1q. C1q can also bind to phosphatidylcholine and sphingomyelin, which are exposed on plasma membranes of apoptotic or ischemic cells, or to the surface of virally infected cells. The presence of receptors for C1q on endothelial cells raises the possibility that immune complexes containing C1q could result in antigen-independent deposition of C1q on endothelium. However, these reactions are usually less diffuse, and in the case of immune complexes, the pattern is usually granular rather than linear.

As predicted by these theoretical considerations, C1q has not proved to be a sensitive marker of antibody-mediated rejection in practice.

Polyclonal and Monoclonal Antibodies to C4d

The tissue-bound split products of C4 are significantly more sensitive than C1q as a marker of antibody-mediated inflammation. Because each activated C1 molecule can enzymatically cleave many C4 molecules, more C4 split products are available to be detected. One study found that for each C1 molecule there were about 28 C4b fragments deposited on the cell membrane (16). The covalent binding of C4b and its further-split products to tissues results in extended half-lives (Fig. 1C). The result of greater quantities and longer half-lives is that C4b and its further-split product C4d are detected more easily than C1q or antibodies in biopsies. Another advantage that results from the enzymatic cleavage of C4 is that neo-epitopes are exposed on the split products. Monoclonal antibodies produced to these neoantigens are specific for the activated split product and not the intact precursor.

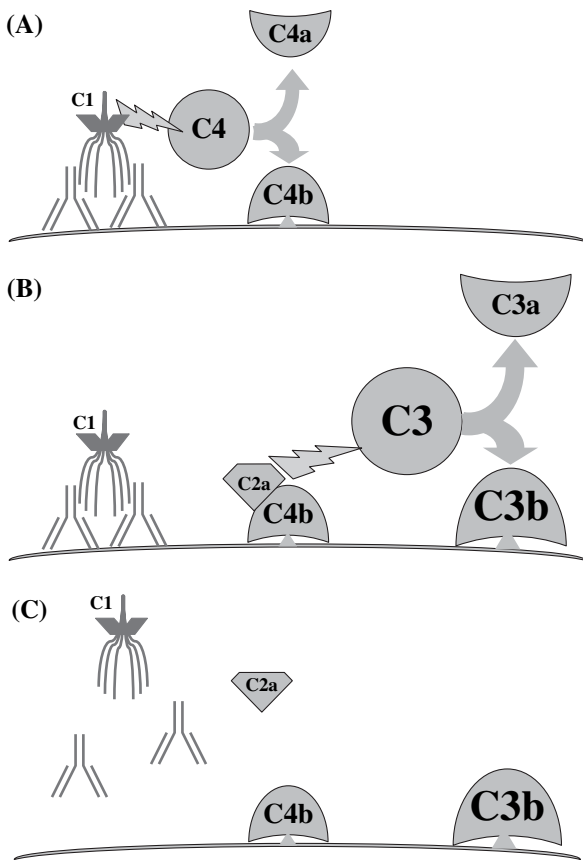
C4d, the final split product of C4, has been the most widely reported marker for humoral immune responses to


FIGURE 1 Activation of the early complement components by antibodies. (A) A pair of IgG antibodies is bound by C1 through the C1q subcomponent, and the enzymatic C1r and C1s subcomponents are activated to cleave C4 into C4a and C4b. C4b can bind covalently to a membrane protein and provide an anchor for C2, which is then cleaved. (B) The complex of C4bC2a enzymatically cleaves C3 into C3a and C3b. C3b is structurally homologous to C4b and can bind covalently to a membrane protein. (C) The covalently bound split products of C4 and C3 remain attached to the cell membrane after the antibody, C1, and C2a have dissociated from the membrane. (The sizes of the symbols for C4b and C3b are intended to reflect the potential for larger quantities of C3 than C4 activation products.)

transplants (7, 19). Therefore, the mechanism that produces C4d is worth reviewing. C4d represents the end product of a regulatory mechanism that evolved to prevent damage to autologous tissues during complement activation. The small C4d fragment results when factor I cleaves C4b twice, once on either side of the covalent bond. Factor I requires a cofactor, such as membrane cofactor protein (MCP) (CD46) or complement receptor 1 (CR1), to cleave C4b (Fig. 2). MCP is widely distributed on cells, including leukocytes and vascular endothelial cells. In contrast, CR1 is expressed on erythrocytes and leukocytes, including neutrophils and macrophages. The fluid-phase complement regulatory protein, C4-binding protein (C4bp), can also interact with cell-associated C4b and may also be found in regions of coagulation through its ability to bind to protein S. The rapid enzymatic cleavage of C4b by factor I makes C4d a more stable marker of complement activation than C4b. In fact, the monoclonal antibody used to detect C4d (Quidel, San Diego, Calif.)

actually detects an epitope expressed on C4b as well as C4d. As a result, both C4d and any remaining C4b are detected by this reagent.

The use of the monoclonal antibody to C4d has been limited to frozen tissue sections. This limitation has been circumvented by the development of a polyclonal antibody that can be used in formalin-fixed and paraffin-embedded tissues (available from Biomedica Gruppe, Vienna, Austria). The polyclonal antibody was produced by immunizing a rabbit with a synthetic 15-amino-acid peptide that coincides with a loop segment of C4d that is not shared by C3d (20). This reagent has proved to be very useful in biopsies for which no frozen tissue is available. However, detection of C4d in fixed tissues is less sensitive than in frozen sections. In addition, there are difficulties with high background and nonspecific staining of the edges of the biopsies ("edge effects").

The pattern and strength of staining are important for the interpretation of the results (Fig. 3). In biopsies from renal transplants, antibodies to major histocompatibility antigens (HLA in humans) or major blood group antigens are associated with diffuse, linear staining of the peritubular capillaries (7, 8, 13, 15, 19, 23). Arterial endothelial cells are variably involved. This pattern may reflect in part the distribution of both the target antigens and complement regulatory proteins. For example, class II major histocompatibility antigens, such as HLA-DR, are expressed constitutively on capillary and venous endothelium, but not arterial endothelium. However, HLA-DR
FIGURE 2 Regulation of C4b and C3b by circulating factor I and leukocytes expressing CR1. (A) CR1, which is expressed by leukocytes, associates with C4b or C3b, allowing factor I to cleave C4b and C3b. (B) The first enzymatic cleavage leaves iC4b or iC3b attached to the cell membrane. (C) Factor I then enzymatically cleaves iC4b or iC3b, and C4d and C3d remain covalently bound to the cell membrane. (As in Fig. 1, the sizes of the symbols for C4b and C3b are intended to reflect the potential for larger quantities of C3 than C4 activation products.)
FIGURE 3 Examples of C4d and C3d deposition in organ transplants. (a) Immunofluorescent stain for C3d in an endomyocardial biopsy from a human heart transplant (magnification, ×64). The capillaries have diffuse linear staining. (b) Immunoperoxidase stain for C4d in an experimental cardiac allograft in a rat (magnification, ×16). C4d is deposited in an artery (arrowhead) as well as all of the capillaries (small arrows point to examples). (c) Immunoperoxidase stain for C4d in an experimental lung allograft in a rat (magnification, ×16). The alveolar (Alv) capillaries are stained, as are the endothelial cells of arteries (A), capillaries, and veins adjacent to the bronchiole (Br). (Fluorescein isothiocyanate signal appears white and immunoperoxidase signal appears black in these black-and-white photographs.)

antigens are upregulated by arterial endothelial cells as well as by tubular epithelial cells in sites of inflammation (15).

Fewer studies of C4d have been reported for other organ transplants. In cardiac transplants, antibody-mediated rejection is associated with strong linear staining of capillaries for C4d, but this staining pattern has also been found in patients without detectable antibodies to HLA or clinical evidence of cardiac dysfunction (1).

Although C4d is frequently proposed to be a specific marker for antibody-mediated activation of complement, C4 is also activated by mannose-binding lectin (MBL). MBL activates complement in the innate immune system by recognizing carbohydrate structures on pathogens, but it can also bind to plasma membranes of apoptotic or ischemic cells (9).

The most rigorous criteria for diagnosing antibody-mediated rejection do not rely exclusively on C4d as a marker. Rather, these criteria include three additional parameters: (i) detection of circulating antibodies to donor antigens, (ii) demonstration of marginated neutrophils or macrophages in the capillaries of the transplant, and (iii) correlation with clinical evidence of graft dysfunction (19).

Polyclonal and Monoclonal Antibodies to C3 Split Products

Because C3 and C4 are both members of the alpha 2-macroglobulin family (5), the activation and regulation of C3 produce split products that are homologous to C4 split products (Fig. 2). C3d is the final membrane-bound split product of the regulation of C3b by factor I and a cofactor such as factor H, CR1, or MCP. C3d has been compared to C4d as a marker of complement activation (1). Like C4d, C3d is covalently bound to tissues. Monoclonal antibodies to C3d are also specific for activated C3 because the epitope recognized is cryptic in uncleaved C3.

There are two major theoretical advantages of C3d as a marker for complement activation. The first is that quantitatively more C3 than C4 can be activated because there is more substrate available and there is an amplification loop that sustains C3 activation. About twice as much C3 as C4 is present normally in the circulation (1.3 and 0.6 mg/ml, respectively), and these levels can be doubled by increased hepatic production in response to acute-phase reactions. In inflammatory sites, macrophages can produce additional C4 and C3. Once C3 is activated by any mechanism, a large supply of C3 is available as a substrate for an amplification loop, in which C3b activates more C3 through factor B (see Fig. 1 in chapter 12).

The second advantage of C3d as a marker is that the split products of C3 have more biological activities than their C4 counterparts. C3b, iC3b, and C3d are the primary ligands for CR1, CR3, and CR2, respectively. Like CR1, CR3 is expressed on neutrophils, macrophages, and subsets of T lymphocytes. CR2 is part of a major second signaling pathway for antibody production by B lymphocytes. Although C4b is also a ligand for CR1, C4d does not bind CR2 (22). Therefore, the regulation steps for C4b that result in C4d deposition could terminate the complement cascade without activation of C3 or proinflammatory consequences. As a result, cases in which C4d is deposited in the absence of significant activation of C3 would be predicted to be associated with little or no complement-mediated injury (1, 18). In fact, this situation may account for the striking amounts of C4d found in well-functioning major-blood-group-incompatible renal transplants (8, 23). The capacity of renal transplants to function well in the presence of circulating antibodies has been termed "accommodation" (10). The demonstration that C4 is activated indicates that the circulating antibodies do bind to the transplant and initiate activation of complement. Therefore, C3d might be a particularly valuable marker in evaluating the progress of complement activation in blood-group-incompatible renal transplants.

There are practical and theoretical reasons that C4d has been advocated as a better marker for antibody-mediated rejection than C3d. The practical advantage of C4d is that normal renal tissue contains less C4d than C3d. In healthy kidneys, C3d is found in the tubular basement membrane and mesangium, particularly in biopsies from older animals or humans. In spite of this extraneous staining, C3d has been found to be a useful marker in some studies of renal transplant biopsies (12). Although prominent staining of the media of arterioles for C3d occurs frequently in endomyocardial biopsies (1), this does not present a diagnostic problem.

The theoretical assertion that has been advanced for C4d as a marker for antibody-mediated responses is that it decreases false-positive reactions due to complement activation by the alternative pathway. However, in antibody-mediated immunity, the alternative pathway serves fundamentally as an amplification loop for the classical pathway, and this is one of the reasons that C3 split products can be deposited in larger amounts than C4 split products.

Polyclonal and monoclonal antibodies to other split products of C3 have also been applied in the diagnostic evaluation of tissue biopsies, but these reagents have disadvantages. The intermediate split product iC3b has the disadvantage of being short-lived. Moreover, iC3b may be more involved with down regulation of immune responses through its function as the primary ligand for CR3 on T lymphocytes as well as macrophages (reviewed in reference 10).

The use of antibodies to C3c offers even fewer advantages because C3c is the portion of iC3b that is cleaved away to produce C3d (Fig. 2C). As such, C3c does not remain bound to the membrane after being cleaved.

Polyclonal and Monoclonal Antibodies to C5b-9

The terminal five components of complement attach to each other in succession to form the membrane attack complex (MAC), which increases cell permeability. Polyclonal and monoclonal antibodies to neoantigens that are created as the complex is formed have been produced. MAC should be the best indicator that enough complement has been activated to exceed the multiple regulatory proteins capable of truncating the complement cascade after C4 or C3 activation. With currently available reagents, however, MAC has proven to be an insensitive indicator (2). This lack of sensitivity is probably related to the fact that MAC is deposited in limited quantities and sublytic amounts of MAC can be cleared rapidly from cell membranes. Regulatory proteins, such as CD59, limit the assembly of MAC on the surface of endothelial cells. Clearance of sublytic amounts of MAC occurs through an endocytic and exocytic response that removes the segments of membrane containing MAC.

Quality Control of Complement Assays Related to Tissue Biopsies

Quality controls have to be performed on the tissue substrate as well as on the reagents and methods used for the detection of complement. The extremely small tissue samples that are obtained from transplants by percutaneous needle biopsy procedures or biotomes on catheters can be inadequate, quantitatively or qualitatively. The biopsies may provide inadequate amounts of parenchyma or may contain tissue damaged during procurement. Hematoxylin and eosin stains of adjacent

tissue sections are useful to control for the quality of the tissue. The use of isotype-matched control antibodies is helpful to determine artifactual staining due to crushed tissue or edge effect. The small size of the transplant biopsies precludes their use as routine controls for the quality or dilution profiles of reagents. Larger specimens from kidneys with deposits of immune complexes can be used to establish optimal dilutions for the primary and secondary antibodies. For this purpose, renal specimens from patients with systemic lupus erythematosis can be useful as positive controls.

Soluble Products of Complement Activation in Serum, Urine, or Bronchoalveolar Lavage Specimens

Activation of the complement cascade produces many split products that do not bind to tissues or that are released from tissues. These fluid-phase products can be detected in plasma, serum, urine, and bronchoalveolar lavage samples. Enzyme-linked immunosorbent assay kits are available to quantitate soluble split products in fluids (Quidel, San Diego, Calif.). C3a, C3c, soluble C4d (sC4d), sC3d, and soluble C5b-8 or -9 (sC5b-8 or -9) are among the most frequently measured soluble complement products. C4a, C3a, and C5a are fluid-phase reactants that are produced by the enzymatic activation of C4, C3, and C5, respectively (Fig. 1B). Regulation of C3b by factor I produces the soluble split product C3c (Fig. 2C). Excess C4b and C3b that fail to bind to protein are hydrolyzed and can be the source of soluble split products, such as sC4d and sC3d. Activation through the amplification loop of the alternative pathway results in the presence of Bb in the plasma. Finally, various forms of MAC that fail to insert into plasma membranes can be detected as sC5b-8 or -9.

Plasma

Diagnostic tests that require only blood samples are appealing because they are much less invasive than biopsies from organ transplants. Theoretically, this approach might also circumvent the sampling error inherent in taking minute pieces of tissue from organs, in which the rejection process may not be diffuse. Finally, avoiding repeated trauma to the transplant could reduce nonspecific inflammation in the organ.

The major disadvantage of testing plasma is the lack of specificity. Many confounding variables can alter the levels of markers in the circulation. In the first decades after transplantation became a successful therapeutic modality, elevated levels of complement split products were detected in the serum as the result of infection as well as rejection (6). More recent studies have confirmed this finding. One study of patients with renal transplants identified C4b, C4d, C3b, and C3d bound to C-reactive protein in the first days after transplantation (26).

Testing of serum can lead to even more sources of artifact. Coagulation enzymes can cleave C3, C4, and C5 and generate excess fragments in a relatively unpredictable fashion (24). Moreover, ex vivo activation of complement occurs frequently in samples containing immune complexes, certain drugs, or other contaminants. This is especially true of cryoglobulins that are barely detectable by other methods. Therefore, it is recommended that samples be collected as EDTA-plasma and frozen as soon after centrifugation as possible.

Urine

Urine provides a sample that reflects the inflammatory events in renal transplants more directly. Several reports have indicated that elevated levels of soluble complement split products can be detected in the urine during rejection episodes (2). Obviously, these assays cannot be applied during periods of anuria or oligurea, such as when there is delayed graft function after transplantation. Nonetheless, this is an approach that deserves further investigation.

Bronchoalveolar Lavage

Currently, most lung transplants are evaluated by periodic bronchoscopic exams that include an infusion and retrieval of saline referred to as bronchoalveolar lavage. This procedure is invasive, but the sample is focused on the most susceptible tissue in the transplanted lung. Elevated levels of split products of complement are found during rejection (14). However, the appropriate method of accounting for effects of dilution has not been established (4).

TYPES OF COMPLEMENT-MEDIATED INJURY IN ALLOTRANSPLANTS

Hyperacute Rejection

Hyperacute rejection is the most unambiguous example of complement-mediated injury to transplants. This type of rejection was first recognized in renal transplants by three groups of investigators between 1966 and 1969 (11, 17, 25). This devastatingly rapid type of rejection occurs within minutes to hours after blood flow is restored to the grafted kidney. Immunohistological studies demonstrated that antibodies and complement components were deposited in the transplant. Consequently, hyperacute rejection was quickly attributed to the action of antibodies and complement.

After early reports established a link between antibodies and hyperacute rejection, a "crossmatch test" was devised by Patel and Terasaki to test for the offending antibodies (17). The screening method consisted of mixing leukocytes from the prospective donor with serum from the prospective recipient and then adding a source of complement to demonstrate lysis. After the institution of this test, hyperacute rejection of allografts was almost eliminated.

In hyperacute rejection, complement activation is initiated by large amounts of antibody binding to antigens on the endothelial cells of the transplanted organ. The most characteristic features of hyperacute rejection can be predicted from our knowledge of complement. Prominent inflammatory manifestations of complement activation in hyperacute rejection include (i) recruitment and activation of numerous neutrophils, (ii) disruption of vascular integrity resulting in edema and hemorrhage, and (iii) activation of coagulation leading to fibrin deposition and thrombosis. The relative intensities of these features depend upon the quantities and qualities of the antibodies and their target antigens. Both antibodies to major histocompatibility complex antigens (HLA in humans) and antibodies to the major blood group antigens (A and B) can cause hyperacute rejection because these antigens are expressed in high concentrations on vascular endothelial cells.

Acute Rejection

Until recently, acute rejection was often cited as an example of pure cell-mediated immunity. This classification was based largely on experimental animal studies, but the vast majority of experimental transplants are performed with young, healthy (even pathogen-free) donor and recipient animals. Unless specifically under study, previous surgical interventions, blood transfusions, trauma, and prolonged ischemia are all avoided or introduced under highly controlled

and isolated circumstances. Unfortunately, in clinical transplantation, the recipient by definition is suffering from the final stages of organ failure, and the organ most often comes from a donor who has died from a traumatic injury. Therefore, the recipient has frequently undergone previous surgical interventions or blood transfusions, the donor has experienced major trauma, and the organ has been subjected to ischemia. All of these variables can affect the function and survival of transplants adversely by increasing the initial recognition of the transplanted organ through complement-mediated processes. More recent animal experiments have provided evidence to support the clinical observations that complement contributes to the rejection process (1, 21).

Antibodies to major histocompatibility complex antigens can be elicited by previous blood transfusions, pregnancies, or transplants. If this sensitization is below the threshold of the crossmatch test used, then hyperacute rejection may be avoided, but the risk of antibody-mediated rejection is increased. Sensitization from previous pregnancies is especially pertinent when a kidney is transplanted to a wife from her husband or to a mother from her child. In these cases, complement deposition can be a prominent feature of the rejection process (3). Obviously, the incidence of antibody-mediated immunity will be related to the composition of the population of patients selected for transplantation. In some studies, a majority of the "steroid-resistant" acute rejections may have an antibody-mediated component (13). These acute rejection episodes often occur within the first weeks or months after transplantation in presensitized patients. In unsensitized patients, acute rejection episodes can occur years after transplantation (1, 15).

Chronic Rejection

Chronic loss of graft function is not due solely to immune causes. Instead, the chronic lesions in organ allografts represent repair and remodeling processes that are the final common response to many types of tissue injury. For example, the proliferative vascular lesions that characterize chronic dysfunction of renal and cardiac allografts have some similarities to ordinary arteriosclerosis. The vascular lesions in transplants are generally more extensive and uniform in distribution than in ordinary arteriosclerosis, but this may just represent the more widespread injury of the immunologically incompatible tissue. Both types of vascular lesions are currently thought to involve inflammatory processes.

The use of C4d and C3d as markers for diagnosis or prognosis of chronic graft dysfunction is under investigation. It is evident already that these markers are not as closely associated with chronic pathology in transplants. This is not unexpected, because the events that initiate chronic repair and remodeling may be resolved and even the covalently bound complement split products can be cleared from the membrane of endothelial cells before the repair processes impair organ function.

SUMMARY

Complement can be a useful adjunct in diagnosing and directing treatment of transplant rejection. Currently, the tissue-associated final split products of C4b and C3b, namely, C4d and C3d, are the most useful markers of antibody-mediated rejection. Both C4d and C3d offer the advantages of being produced in large amounts and binding covalently to tissues. Monoclonal antibodies to neoantigens on C4d and C3d that are not accessible in the unactivated precursors are available. Although these markers have provided significant diagnostic advances for organ transplantation, appropriate interpretation

requires additional information, including testing for circulating antibodies to donor antigens and correlation with clinical evidence of graft dysfunction.

Introduction

MAURICE R. G. O'GORMAN

17

Since the last edition of the *Manual of Clinical Laboratory Immunology* (6th edition, 2002), clinical flow cytometry has grown and evolved significantly in three general areas: (i) established flow cytometry applications have improved in their efficiency and proficiency; (ii) new applications have been developed and adopted; and (iii) a whole new field of molecular-based flow cytometry applications has emerged and several applications are rapidly evolving towards use in the clinical and diagnostic laboratories. In an effort to capture the burgeoning field of clinical flow cytometry, the chapters presented here are divided into two sections. The first is current application, which encompasses updates in established procedures as well as new procedures that have been recently adopted. The second section is more innovative, with applications combining molecular methodologies and flow cytometry. Below is a brief summary of the chapters in this section as well as a quick review of clinical flow cytometry applications that were not addressed in this edition of the *Manual*.

FLOW CYTOMETRY

The opening chapter in this section, compiled by Lance and Patricia Hultin, provides a general introduction to clinical flow cytometry as well as up-to-date information on reagents, instrumentation, safety, quality control, and the procedures utilized for measurement of absolute T-lymphocyte subsets in human immunodeficiency virus (HIV)-infected patients. Instrument and reagent quality control, single-platform absolute counting, and novel markers in HIV infection are a few of the areas addressed. The next chapter, by Jiachun Kung and Eric Hsi, describes new "nontraditional" clinical flow procedures that have been developed for the diagnosis of paroxysmal nocturnal hemoglobinuria and the assessment of circulating fetal red cells, T-cell receptor Vβ repertoire, and various platelet markers. The chapter on immunophenotyping of leukemia and lymphoma, written by Brent Wood, provides detailed information required to perform multicolor immunophenotyping, descriptions of normal and abnormal expression of surface markers, lists of antibodies used in the diagnosis of leukemia and lymphoma, and histograms exemplifying the specific principles and practices reviewed in the chapter.

Stem cell transplant is no longer a rare procedure performed only at highly specialized institutions. With the advent of cord blood banking, new safer stem cell transplant protocols, and numerous new clinical trials, accurate enumeration of stem cells in a variety of products has become an essential procedure for an increasing number of institutions. Robert Sutherland and coauthors complete the current clinical applications with an up-to-date review of the standards for the enumeration of hematopoietic stem cells.

The second part of this section presents new and emerging techniques in flow cytometry. The chapter by Elisabeth Paietta reviews the status of currently recognized phenotypic correlates of genetic abnormalities in leukemia and lymphoma. The recognition of specific phenotypic patterns that correlate with genetic abnormalities ultimately improves both the accuracy and speed of diagnosis. The development of reagents containing specific peptide antigen in the context of the antigen-presenting molecules has led to an entirely new tool for the measurement of antigen-specific lymphocytes. John Altman describes many of the practical details with respect to flow cytometric applications of tetramers for the detection of antigen-specific T cells. In addition to a general staining protocol, sample and instrument requirements, reagent availability, reagent providers, etc., this chapter presents the reader with a comprehensive introduction to this rapidly emerging application. In the last chapter, Bruce Patterson provides the background, technology, and clinical applications of several promising new procedures that combine molecular biology technologies (for the detection of specific targets) and flow cytometry (for the specific detection of the cell population harboring the target). This area is currently practiced by only a few highly specialized laboratories but has significant potential as the individual applications are validated and the process becomes more standardized.

OTHER APPLICATIONS

As part of this introduction, I would like to review briefly two applications that are currently being performed in clinical flow cytometry laboratories but, due to space limitations, were not covered in specific chapters in this volume.

Flow Cytometry for the Diagnosis of X-Linked Hyper IgM Syndrome

The X-linked hyper immunoglobulin M (IgM) syndrome is a combined immune deficiency resulting from mutations in

the genes encoding the CD40 ligand (CD154). Clinically, the disease presents with infections usually associated with humoral immune deficiency, although there is some evidence of cellular immune deficiency, as most patients suffer from pneumonia caused by *Pneumocystis carinii*. The CD40 ligand is expressed primarily on activated CD4-positive T cells and is responsible for inducing immunoglobulin class switching in B lymphocytes from IgM to IgG, IgA, and IgE. Patients' immunoglobulin levels often reveal elevated IgM with very low to absent detection of all other immunoglobulin classes.

A diagnostic flow cytometry screening test has been developed for the rapid detection of CD40 ligand expression abnormalities (9). Briefly, whole blood is stimulated with a phorbol ester and a calcium ionophore (the up-regulation of CD40 ligand is strongly dependent on calcium) for 4 h, after which the sample is labeled with a cocktail of monoclonal

antibodies to detect T-helper cells (CD3 and CD8) using a negative gating strategy. (Since the CD4 molecule is modulated off of the cell surface with this stimulation protocol, the CD4$^+$ T cells are analyzed by setting the gate around the CD3$^+$CD8$^-$ population.) The level of expression of CD40 ligand on the activated T cells is then assessed. This assay has been used routinely in our laboratory for the diagnosis of hyper IgM patients (see Fig. 1), to investigate CD40 ligand expression in HIV-infected children (8), and to assess functional immune reconstitution following bone marrow transplant (7) of hyper IgM patients (Fig. 2).

Flow Cytometry Applications in Allergy

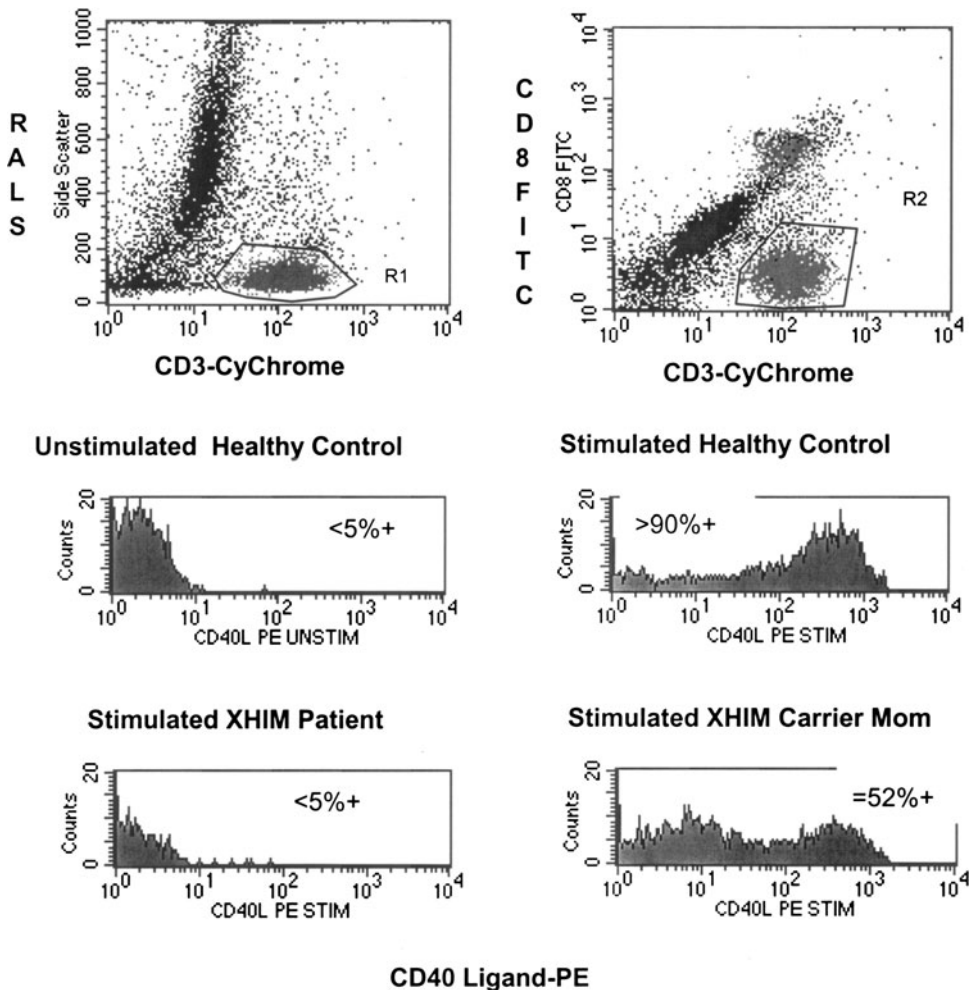
Currently, the most commonly utilized laboratory methods for laboratory diagnosis of allergy involve the detection of allergen-specific IgE. Although the latter test methods have become very popular (and many have been cleared by the


FIGURE 1 Measurement of CD40 expression on CD4$^+$ T cells. CD4$^+$ T cells are gated indirectly by first gating (R1) on CD3$^+$ T cells (in the histogram of right-angle light scatter [RALS] versus CD3 and then gating (R2) on CD3$^+$CD8$^-$ T cells. The level of expression of CD40 ligand is then measured on the events that satisfy both of these gates (R1 and R2) as percent positive (number of events expressing fluorescence above an isotype control antibody). Shown below are the results on CD40 ligand expression levels of resting CD4$^+$ T cells in whole blood from a healthy control and on vitro-activated CD4$^+$ T cells in whole blood obtained from a healthy control, a patient diagnosed with the hyper IgM (XHIM) syndrome, and an XHIM carrier mother as labeled above.
FIGURE 2 CD40 ligand expression on CD4$^+$ T cells, illustrating functional immune reconstitution in an XHIM patient transplanted with peripheral blood stem cells from an HLA identical donor sibling. Transplant date was 14 October 2004. Gating was performed as illustrated in Fig. 1.

U.S. Food and Drug Administration for in vitro diagnostic use), they do not indicate a functional relationship between allergen and disease. The skin test remains the "gold standard" for the detection of a functional allergic response; however, flow cytometry, specifically the assessment of basophil activation markers, is rapidly emerging as a viable alternative. The basis of the procedure is very simple. If basophils are sensitized in vivo with allergen-specific IgE, exposure to the allergen in vitro will initiate basophil degranulation (activation) which can be assessed by the increased expression of either CD63 or CD203c on the cell surface. Numerous publications have documented the validity of these methods (1) as well as their utility in the detection of latex allergy, insect venoms, local foods, and pollens (2–6, 10). The availability of a kit (Orpegen, Heidelberg, Germany) that includes buffers, the appropriate antibodies, and a mixture of grass pollens and food allergens has provided a platform for several laboratories to develop additional allergen-specific tests. The method is relatively simple. Briefly: whole blood is incubated for a specified amount of time with the allergen(s) of interest

as well as a negative control (buffer only). The activation process is stopped by completing the remainder of the procedure on ice. Whole blood is labeled with CD63 (activation marker) and anti-IgE (used to detect basophils). Another marker that has been utilized by several investigators due to its more restricted circulating leukocyte expression (on basophils only) is CD203c. This marker is constitutively expressed, and its level is increased upon activation of the basophils. Ronald Harbeck of the National Jewish Center in Denver, Colo. (personal communication), has recently exploited this phenomenon to detect functional antibody in patients with idiopathic chronic urticaria. Some (approximately 40%) patients with a diagnosis of chronic urticaria have a circulating antibody (IgG) which reacts with the high-affinity IgE receptor (or the IgE molecule) expressed on mast cells and basophils. Detection of this antibody has traditionally been via the autologous serum skin test (injection of the patient's serum causes a characteristic wheal and flare response) or the histamine release assay. In Harbeck's laboratory, patient serum is incubated with appropriate donor

basophils, and the change in cell surface CD203c expression is assessed relative to negative (buffer only), strong positive (anti-Fc$_\varepsilon$ receptor), and moderate positive (f-Met-Leu-Phe) controls. In chronic urticaria patients, up-regulation of basophil cell surface CD203c expression in this flow cytometry assay indicates a significant correlation with both the histamine release assay and the autologous serum skin test (presented in part at the 16th annual meeting of the Association of Medical Laboratory Immunology, Denver, Colo., 2005). Improved standardization of the allergens used for in vitro testing combined with improvements in the procedures will lead to an increased adoption of this testing modality in the near future.

Two other broad areas involving flow cytometry were not specifically addressed in this section. The use of flow cytometry in "array" testing, or so-called "multiplex" testing, is addressed in the chapter by Daniel Remick, "Multiplex Cytokine Assays" (chapter 39), where the advantages and technical aspects of multiplex testing by flow cytometry are elegantly covered. The other area not included in this section is DNA ploidy and cell cycle analyses. The excellent coverage of DNA content flow cytometry in the previous edition of the *Manual* and the lack of significant new developments in this field justified the omission of this subject from the present edition.

It was not long ago that the clinical flow cytometry community was worried that the emergence of quantitative viral loads in HIV would replace CD4 T-cell enumeration and lead to a decrease in clinical applications involving flow cytometry. This section should convince you that a decrease in clinical flow cytometry application was never realized. In fact, quite the opposite has developed, as several novel applications are being developed and are poised for adoption in clinical diagnostic laboratories.

Flow Cytometry-Based Immunophenotyping Method and Applications

LANCE HULTIN AND PATRICIA HULTIN

18

The immunophenotype of a cell describes the collection of antigens expressed on or inside the cell. Flow cytometry is a very efficient immunophenotyping tool because it can measure multiple antigens simultaneously, rapidly providing accurate measures of the percentage of cells with a particular phenotype and the absolute number of these cells per volume of blood, and can be used to quantify the number of antigens on a per-cell basis. The reactivity of specific monoclonal antibodies (MAbs) to cell surface antigens is used to subtype leukocytes into distinct lineages and differentiation and activation states. There are numerous applications, including leukemia and lymphoma typing, enumerating CD34-positive stem cells, evaluating immune reconstitution, and monitoring cancer therapies and immunodeficiency diseases. These applications are discussed throughout this manual.

The field of human immunodeficiency virus (HIV) disease in particular has broadened our understanding of the immune system and has driven many of the improvements in immunophenotyping methods. HIV type 1 (HIV-1) infection causes a rapid, profound decrease in CD4 T-cell numbers and an expansion of CD8 T-cell levels during the first 12 to 18 months of HIV-1 disease (9, 27). Some donors continue to lose CD4 T cells rapidly and progress to AIDS, while others maintain relatively stable CD4 T-cell numbers and remain AIDS free for years. During this chronic phase of HIV-1 disease the decline in CD4 T-cell numbers can be slow: it can last more than 10 to 15 years. Homeostatic mechanisms maintain relatively stable T-cell numbers during this time. Prior to the development of AIDS, homeostatic mechanisms fail and there is further decline in CD4 T cells accompanied by a decline in CD8 T-cell numbers on average 2 years prior to the onset of AIDS (18). CD4 T-cell levels are used to stage HIV disease progression, are prognostic for the development of AIDS, and are used to monitor responses to antiretroviral therapy. Centers for Disease Control and Prevention (CDC) guidelines stage HIV-1 disease by CD4 T-cell level into three groups: >500 CD4 cells/mm³, or >28% CD4 cells within lymphocytes; 200 to 500 CD4 cells/mm³, or 14 to 28% CD4 cells; and <200 CD4 cells/mm³, or <14% CD4 cells (3).

The goal of this chapter is to provide a broad description of the principles of flow cytometric immunophenotyping; to provide specific methods for lymphocyte enumeration, with particular emphasis on CD4 T-cell counting; and to review quality assurance issues that improve the accuracy and reproducibility of overall immunophenotyping results.

PRINCIPLES OF FLOW CYTOMETRY

A flow cytometer is an instrument that measures the scattered and fluorescent light derived from cells as they pass via a fluid stream through the intersection of a light source. The light source is typically a laser beam operating at one specific wavelength (e.g., 488 nm), suitable for exciting dye molecules. Scattered laser light characterizes the size and granularity of the cell, enabling the operator to distinguish the smaller, less granular lymphocytes from the other leukocytes found in whole blood. This process is called scatter gating. The fluorescent light is derived from dye molecules (fluorochromes) conjugated to MAbs that bind very specifically to cell surface antigens.

Samples for immunophenotyping are prepared by incubation with fluorochrome-labeled MAbs, and red blood cells are removed by lysis to prepare the sample for analysis on the flow cytometer. The cytometer draws up the cell suspension and injects the sample inside a carrier stream of isotonic saline solution to form a laminar flow. The sample stream is constrained by the carrier stream and thus hydrodynamically focused so that the cells pass single file through the intersection of the laser light source. For clinical flow cytometers, this process happens inside a flow cell or cuvette. At this time detectors collect the scattered and fluorescent light. The forward scatter (FSC) detector is placed in the direct path of the light source. Larger cells scatter more light than smaller cells. The remaining light is usually collected orthogonally (90°) from the light source (25). This side scatter (SSC) and fluorescent light is collected through a microscope objective (fluorescence collection lens) that focuses the light to the fluorescent detectors. Some newer systems use fiber optic cables to direct the light to these detectors. The collected light is passed through optical filters to direct specific wavelengths of light to the appropriate detectors. The filters are designed to maximize collection of light derived from a specific fluorochrome while minimizing collection of light from the other fluorochromes used to stain the cells. For example, a 530- ± 30-nm band-pass filter is used to collect the fluorescence emission of fluorescein isothiocyanate (FITC) and minimize contaminating light from phycoerythrin (PE), which has a maximum emission at 575 nm.

147

The detectors are photomultiplier tubes (PMT). When the fluorescence light reaches the PMT, it creates an electrical current that is converted to a voltage pulse. How the voltage pulse is processed from this point on varies depending on the manufacturer and the age of the instrument. Subsequently, the magnitude of the voltage output from the PMT is quantified and digitized for collection and storage by the computer system. It is important to note that the magnitude of voltage pulse is related not only to the amount of light reaching the PMT but also to the voltage setting of the PMT. The voltage setting of the PMT is a critical step of instrument setup, as discussed below. Clearly, if the sample stream is too wide, the flow cell is dirty, or the laser light source or collection lenses are not focused properly, the light measurements derived from the cells may be reduced and more variable. This is why proper daily instrument setup and daily quality control are important aspects of flow cytometry.

MAbs

MAbs are created by the fusion of B-cell tumors and primary B cells previously selected to make antibodies to only one epitope of a specific antigen. These hybridomas, as they are called, then produce large quantities of epitope-specific antibody. The specificity of MAbs greatly improved the accuracy and reproducibility of immunophenotyping compared to those obtained with polyclonal antisera and thus facilitated the rapid expansion of flow cytometry studies to elucidate the association of cellular phenotype and immune diseases. The nomenclature used to define the reactivity of MAbs is the cluster of differentiation (CD) nomenclature (7). Different MAb clones that bind to the same antigen are designated with the same CD name (e.g., all CD3 MAbs bind to the T-cell receptor).

Many cell surface molecules are responsible for specific functional activities, explaining the association of cellular phenotype with the lineage or differentiation state of the cell. There is an ever-increasing availability of MAbs directly conjugated to a variety of fluorochromes that will provide more in-depth analysis of leukocyte subsets. Useful fluorochromes are constrained by the availability of a reliable excitation source. The 488-nm laser line is most commonly used for excitation of FITC, PE, PerCP, and the tandem fluorochromes PE-Cy5, PE-Texas red, and PE-CY7. A second laser, operating at ~635 nm, is available on some clinical flow cytometers and is used to excite allophycocyanin and allophycocyanin-CY7.

With this vast array of MAb and fluorochrome choices, it is important to recognize potential sources of variation.

Different clones may differ in staining or variably affect cellular function because they may bind to different epitopes on the antigen. The same MAb clone conjugated with two different fluorochromes may yield disparate results. This is especially true for weakly staining markers. In multicolor experiments, some MAb fluorochrome combinations can interfere with the fluorescence emission of another dye molecule and can even turn a positive reactivity into a negative one. Tandem conjugates are especially prone to show interaction with other fluorochromes. T-cell subsetting panels provided by manufacturers for in vitro diagnostic work are designed to avoid these issues. However, when developing a specific research panel in the laboratory, a thorough review of the published literature is perhaps the most important first step prior to undertaking new studies.

Precise identification of most lymphocyte subsets requires the combination of at least two different MAbs, each conjugated with a different dye molecule. Table 1 lists the accepted antibody combinations used to define the main lymphocyte subsets assessed in HIV-infected patients. The table is arranged into categories of two-, three-, and four-color MAb combinations. The number of colors simply means the number of different fluorochromes that the cytometer is capable of measuring simultaneously.

INSTRUMENTATION

Current clinical flow cytometry equipment includes less expensive two-color instruments dedicated to absolute counting, three- and four-color cytometers capable of utilizing bead-based, single-platform (SPT) absolute-counting methodology, and, finally, five- and six-color instrumentation which permits more in-depth immunophenotyping and the ability to perform multiple assays in one tube, saving time and reagents while using less cellular material. Cytometer selection therefore depends on which types of clinical assays will be performed and on whether the cytometer will be used for more complex research studies. A cytometer with at least three-color capability is recommended because it allows addition of the pan-leukocyte antibody CD45 to the original two-color basic immunophenotyping panel. Four-color cytometers permit simultaneous enumeration of CD4 and CD8 T-cell subsets or simultaneous measurement of T-, B-, and NK-cell subsets. Advanced five- and six-color cytometers permit in-depth measurement of naïve, memory, and activated lymphocyte subsets and improve studies of rare cell types, such as enumeration of antigen-specific T cells in HIV-1 vaccine studies, NK T-cell studies, and dendritic-cell studies. At this point, it is not yet clear whether such detailed immunophenotyping

TABLE 1 MAb panels for HIV immunophenotyping

Recommended MAb(s) for panel type[a]			Result
Two color[b]	Three color[c]	Four color[c]	
Isotype control			Background staining
CD45 and CD14			Lymphocyte purity and recovery
CD3 and CD4	CD3, CD4, and CD45	CD3, CD4, CD8, and CD45	CD4 T cells
CD3 and CD8	CD3, CD8, and CD45		CD8 T cells
CD3 and CD19[d]	CD3, CD19, and CD45[d]	CD3, CD19, CD16/CD56, and CD45[d]	B cells
CD3 and CD16/CD56	CD3, CD16/CD56, and CD45		NK cells

will lead to improved clinical care. The most recent advance in modern five- and six-color cytometers is digital signal processing. With replacement of logarithmic amplifier signal processing with more linear digital signal processing, the within-laboratory fluorescence should more accurately reflect changes in antigen density that may accompany disease or treatment and fluorescence standardization between laboratories should also improve. This is especially true for studies that utilize markers that stain dimly or markers that are not clearly bimodal, like the activation markers CD38, HLA-DR, CD95, and CD45RA, a marker used for enumerating naïve T cells. However, proper utilization of modern five- and six-color digital cytometers is not a trivial endeavor and requires an increased diligence in antibody fluorochrome selection and instrument quality control procedures.

IMMUNOPHENOTYPING PROCEDURES

The goal of a flow cytometry laboratory is to develop methods that generate accurate, reproducible immunophenotyping results that are comparable across laboratories. The sections below describe the general sample preparation, instrument setup, sample acquisition, analysis, and quality control procedures used to achieve this goal. Stepwise protocols are provided for running the preferred three- and four-color basic immunophenotyping panel using lyse/no-wash (LNW) sample preparation. The LNW method also permits SPT absolute counting. A second protocol is provided for laboratories that perform more advanced immunophenotyping (Table 2), using MAbs that must be used in lyse/wash (LW) sample procedures prior to running on the cytometer.

Specimen Collection and Storage

Whole blood is collected into tubes containing EDTA, the anticoagulant of choice for samples processed within 30 h of collection. Heparin and acid-citrate-dextrose can also used for immunophenotyping but have not been validated for all methods. Heparin is preferred when the sample age exceeds 30 h. Blood should be stored at room temperature (20 to 25°C) prior to specimen staining. The blood specimen must be well mixed (5 min on a rocker) before being pipetted into the staining tubes. Hemolyzed or clotted specimens are rejected (4, 20).

Biosafety

Universal precautions outlining safe practices for the handling of blood are widely available and should be consulted (2). Practices relating to the biosafety of processing samples for flow cytometry have been published and are recommended (23). Briefly, laboratory personnel should wear lab coats and gloves. The use of sharps and glass should be avoided to the extent that is possible. Specific to processing samples for flow cytometry, the following hazards should be guarded against. Aerosols are created during the numerous vortexing and centrifugation steps throughout specimen processing. Working within a biosafety cabinet and attaching the safety lids to centrifugation buckets will protect against these hazards. Be sure to uncap centrifuge buckets in the safety cabinet! The use of a sample handling device which can be loaded with sample tubes inside the biosafety cabinet and attached to the flow cytometer for automated processing reduces sample handling and samples can be safely vortexed throughout sample acquisition. All of the lysing procedures outlined below include fixation, shown to inactivate HIV, but other hazards, such as hepatitis virus, may still exist. It is generally recommended that flow cytometer waste tanks be treated with bleach so that when full, the bleach will comprise 10% of the final volume. When disposing of waste, be aware that sodium azide is contained in most commercially available antibodies and staining buffer preparations

TABLE 2 Expanded T-cell panels for HIV immunophenotyping

Cell type	Phenotype(s)	MAb combination	Comments
Naïve CD4 T cells	CD45RA$^+$CD27$^+$ CD45RA$^+$CD28$^+$	CD45RA/CD27/CD3/CD4 CD45RA/CD28/CD3/CD4	CD3$^+$ excludes CD4^{dim} monocytes. CD27$^+$ or CD28$^+$ improves naïve purity by excluding CD45RA$^+$ CD27$^-$ CD28$^-$ cells.
RTE[b] enriched naïve CD4 T cells	CD45RA$^+$CD31$^+$	CD45RA/CD31/CD3/CD4	CD31 subset naïve CD4 T cells.
Peripheral expanded CD4 T cells	CD45RA$^+$CD31$^-$	CD45RA/CD31/CD4/CD27	CD27$^+$ improves naïve purity.
Naïve CD8 cells T cells	CD45RA$^+$CD27$^+$ CD45RA$^+$CD28$^+$	CD45RA/CD27/CD3/CD8 CD45RA/CD28/CD3/CD8	CD3$^+$ excludes CD8^{dim} NK cells. Naïve cells are bright for CD45RA; CD45RA$^+$CD27$^+$CD28$^+$ can improve purity.
CTL[c] enriched CD8 T cells	CD28$^-$, CD57$^+$	CD28/CD3/CD8 CD57/CD3/CD8	Perforin$^+$ cells are primarily CD28$^-$.
Senescent CD4 and CD8 T cells	CD28$^-$, CD57$^+$	CD57/CD3/CD4/CD8 CD3/CD28/CD4/CD8	Cultured CD57$^+$ cells fail to replicate. Shorter telomeres in CD28$^-$ and CD57$^+$ cells.
Activated CD4 T cells	HLA-DR$^+$CD38$^+$ HLA-DR$^+$CD38$^-$	HLA-DR/CD38/CD3/CD4	Elevated mostly in late HIV-1 disease; prognostic in late HIV-1.
Activated CD8 T cells	HLA-DR$^+$CD38^{bright}	HLA-DR/CD38/CD3/CD8	Elevated throughout HIV-1 disease.
Activated memory CD8 T cells	CD38^{bright} CD45RO$^+$	CD3/CD38/CD8/CD45RO	Prognostic in early and late HIV-1; quantifying CD38 improves power.

Recommended MAbs for panel type[a]

[a]Recommended panels of MAbs to subset differentiation/activation state of CD4 and CD8 T cells.
[b]RTE, recent thymic emigrant.
[c]CTL, cytotoxic T lymphocyte.

and can become explosive if left to accumulate in drainage pipes, so it is necessary to flush well with water after disposal. A notebook of material safety data sheets that is easily available for reference should be maintained. Most importantly, laboratories must have clear protocols outlined for personnel to follow in the event of exposure to potentially hazardous material.

Basic Immunophenotyping Panel with Three- and Four-Color LNW Sample Preparation and Bead-Based SPT Absolute Counting

CD4 T-cell levels are important measures for staging HIV-1 disease and predicting disease progression. In HIV-1-infected adults the CD4 T-cell absolute count is the most useful measure of disease progression, while in children CD4 T-cell percentage is preferred because of high variability in lymphocyte counts (6). The conventional method for determining the absolute CD4 T-cell count (CD4 T cells per cubic millimeter of blood) is referred to as a dual-platform method because it is obtained by multiplying the absolute lymphocyte count (lymphocytes per cubic millimeter), derived from a hematology analyzer, by the CD4 T-cell percentage, derived from the flow cytometer. The variation in hematology-derived absolute lymphocyte counts across different analyzers and the inability to produce reliable counts for aged samples (>24 h old) have led to development of SPT absolute-count methods. SPT refers to flow cytometry methods that do not require a hematology analyzer. The Centers for Disease Control and Prevention guidelines for performing CD4 T-cell determinations using the dual-platform (1997) and SPT (2003) methodologies are published (4, 5).

The CD45 gating method is used for the basic three- and four-color immunophenotyping panels. The addition of the pan-leukocyte marker, CD45, to the original two-color immunophenotyping panel has greatly improved the precision of the lymphocyte gate for the clinical laboratory (24). Refer to Table 1 for approved staining panels. The CD45 lymphocyte gating method permits the use of LNW sample preparation methods. CD45 gating combined with the LNW method improves lymphocyte recovery compared to that of the older light scatter gating methods. The LNW sample preparation method does not utilize a centrifugation step and therefore avoids two main pitfalls of older methods: cell loss and formation of cellular aggregates. LNW methods also allow for SPT absolute counting. Pipetting precision is critical when absolute counts are to be determined. Variability can be greatly reduced by use of reverse pipetting. Reverse pipetting is a technique in which more sample is drawn up into the pipette tip than the measured amount to be dispelled. Pipettes must be maintained and calibrated to ensure accurate results (5). Below are two commercially available SPT protocols.

Method 1: FACS Lysing Solution Used With or Without TruCOUNT Tubes Containing Lyophilized Bead Pellet

1. Add 20 µl of premixed Becton Dickinson (San Jose, Calif.), Tritest (three color) or Multitest (four color) reagent cocktail to a standard 12- by 75-mm tube or, when absolute counts are desired, to a TruCOUNT tube.
2. Add 50 µl of well-mixed whole blood, vortex gently, and incubate for 15 min at room temperature (RT) in the dark.
3. Add 450 µl of 1× FACS lysing solution, gently vortex, and incubate for 15 min at RT in the dark. Keep samples at RT in the dark prior to running the test. Vortex well just prior to acquisition on the cytometer.

Method 2: Coulter IMMUNOPREP Lysing System With or Without FlowCount Beads

1. Add 100 µl of well-mixed whole blood to the bottom of a 12- by 75-mm tube.
2. Add 10 µl of CYTO-STAT MAb reagent to the blood and vortex.
3. Incubate for approximately 10 min at RT in the dark.
4. Prepare stained specimens with the IMMUNOPREP reagent system utilizing Q-Prep, TQ Prep, Multi Q-Prep, or FP 1000 processing according to the manufacturer's directions for the removal of red blood cells and fixation.
5. When performing SPT absolute counting, pipette 100 µl of FlowCount fluorospheres to each tube just prior to acquisition on the flow cytometer.

Establishing LNW Instrument Settings

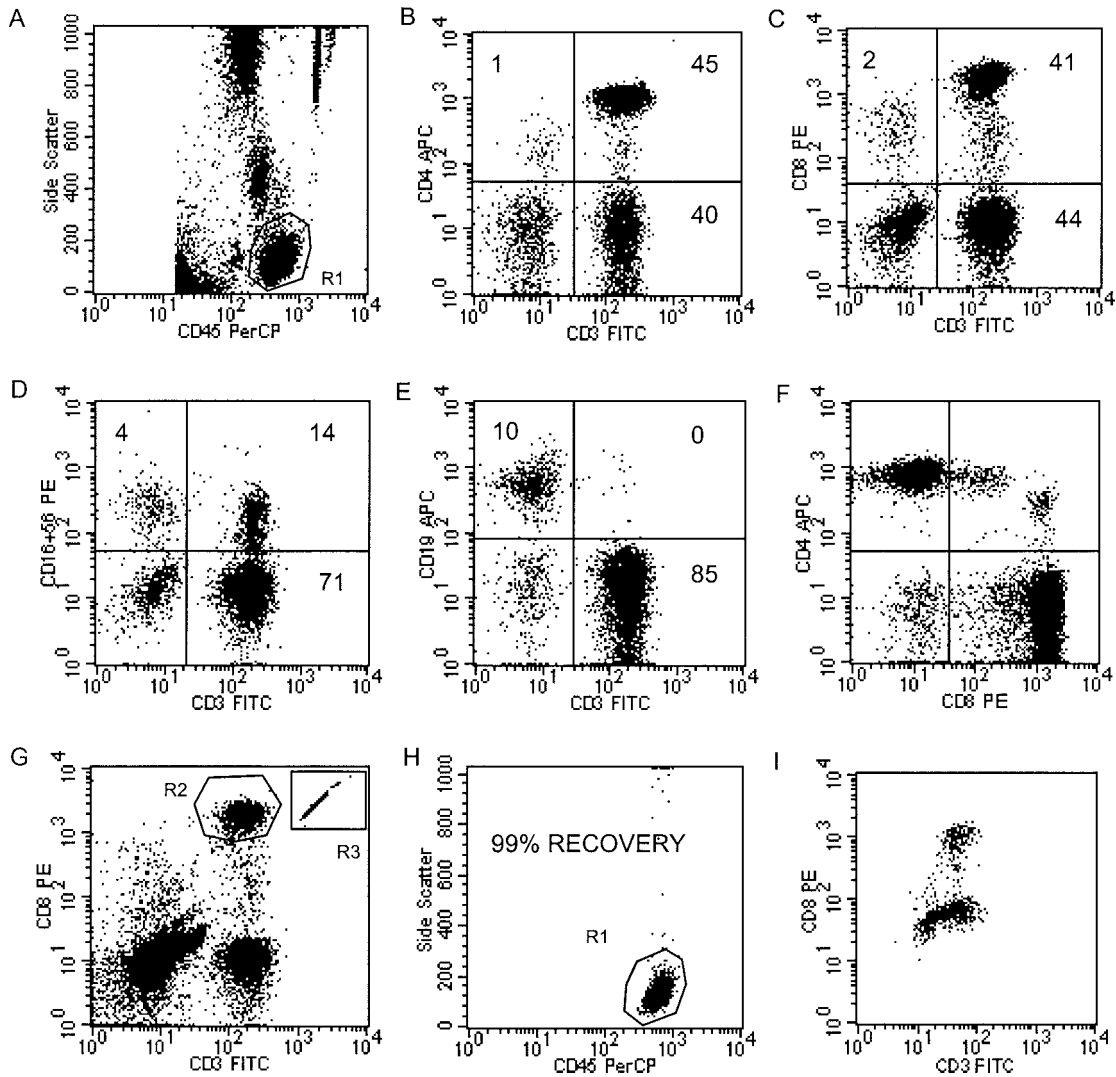
Cytometer manufacturers provide easy, software-driven procedures for determining initial instrument settings and daily quality control and compensation settings for performing basic whole-blood immunophenotyping specific for either LNW or LW sample preparation procedures. Briefly, dye-labeled and unlabeled beads are run on the cytometer. PMT voltages are automatically adjusted to place the fluorescence of the unlabeled bead into the manufacturer-established target channel, and then the fluorescence intensity of the dye-labeled beads is determined to validate that a minimum separation of the positive and negative beads exists. The software also measures the noise level of scatter signals to verify that the number of nonbead debris events is low and will not interfere with leukocyte scatter resolution. The software program adjusts compensation and flags results that are below manufacturer specifications. What is compensation? Each fluorescence detector is assigned to measure light from a particular fluorochrome that is defined by the optical filters; however, light emitted by other fluorochromes may also be detected. This spillover of fluorescence is often referred to as spectral overlap, and the removal of the nondesired fluorescence is referred to as compensation. For example, fluorescent light from fluorochrome one (FITC) can reach the detector designed to measure fluorochrome two (PE). This is because the fluorescence emission spectrum of FITC extends out beyond a wavelength of 600 nm and thus overlaps into the detection range assigned to PE, ~562 to 588 nm. Compensation subtracts the percentage of fluorescence derived from spectral overlap from the total amount of fluorescence that reaches the detector. The percentage of FITC fluorescence that reaches the PE detector, for instance, is usually around 20%. It is recommended that scatter settings and compensation be fine-tuned with a stained whole-blood sample. For use of manufacturer-derived instrument settings with LNW samples, visual confirmation that the relevant stained lymphocyte populations are retained within the appropriate analysis region is usually all that is necessary. For example, confirm that the CD3$^+$ CD4$^-$ population is retained within the lower right analysis region and that the CD3$^+$CD4$^+$ population is retained within the upper right region as shown in Fig. 1B. Perform similar examinations of the lymphocyte clusters for each MAb combination and refer to Fig. 1. Notice how the CD3$^+$CD8$^-$ population (lower right region) in Fig. 1C has an amount of PE fluorescence similar to that of the CD3$^-$ CD8$^-$ population (lower left region). Accurate, reproducible basic immunophenotyping


FIGURE 1 LNW sample preparation. Plot A demonstrates optimal CD45 lymphocyte gating with SSC adjusted to reveal distinct leukocyte populations. Plots B, C, D, and E show lymphocyte subsets with the R1 gate applied and cursor settings guided by the negatively stained populations. Results would be reported as follows: CD4 = 45%, CD8 = 41%, NK cells = 4%, and B cells = 10%. The total T-cell percentage (CD3) is 85% in both tubes sampled, providing confidence in the overall result. Plot F is gated on CD45$^+$ CD3$^+$ lymphocytes, illustrating the additional information available when the four-color immunophenotyping panel is used. Plot G is an ungated display of FL1 versus FL2 used for two different applications. The R3 gating region enumerates counting beads for SPT absolute-count determinations. The R2 gating region includes all CD8$^+$ stained events, which are then backgated through the original lymphocyte gate (R1) in plot H to determine recovery for quality assurance. Finally, plot I shows a sample that bound antibody nonspecifically. This staining artifact was successfully corrected for reporting subset percentages by restaining an aliquot of washed blood.

results are produced when manufacturer-defined instrument setup is combined with the manufacturer-supplied MAb and the LNW sample preparation procedure. These methods are highly recommended, as they have been extensively validated. It is important to record the instrument's PMT voltages each day to spot changes in instrument performance. These data are graphed in a Levey-Jennings plot. Time is plotted on the x axis and PMT voltages are plotted on the y axis for each detector. Upper and lower boundaries are usually set 5% above and below the mean PMT voltage for each detector. When PMT voltages drift beyond the established boundaries, the cytometer should be serviced to correct the problem and preclude absolute instrument failure or compromised immunophentyping results. Some laboratories also monitor the coefficients of variation (CVs) using highly uniform particles with known low CVs. Elevated CVs may indicate more subtle performance issues, such as fluidic problems in the absence of large PMT changes. For a more detailed description of instrument setup consult the individual manufacturer's procedures.

Data Acquisition

The data acquisition screen for LNW, CD45 gated sample preparations should display the leukocyte populations using a CD45-versus-SSC plot. Optimal leukocyte resolution is verified and an analysis region is set on the CD45-positive, low-SSC lymphocyte population. A stop counter is set to collect a minimum of 2,500 lymphocytes. An ungated plot of FL1 versus FL2 is created to monitor absolute-counting beads, if applicable. If TruCOUNT beads are used, the instrument threshold must be set on the FL3 detector since the beads are smaller than lymphocytes and risk being excluded when an FSC threshold is applied. Additional plots of the relevant stained lymphocyte populations, e.g., CD3 versus CD4 or CD3 versus CD8, are gated on the lymphocytes and displayed to review the staining quality. An example of identifying poor staining is shown in Fig. 1I. The sample had to be restained using a prewash in phosphate-buffered saline to remove a serum component that interferes with staining.

Data Analysis

The basis of accurate lymphocyte analysis is the establishment of a valid lymphocyte gate. Two important criteria for determining the quality of a lymphocyte gate are purity and recovery. Purity is the percentage of cells in the gate that are lymphocytes. Contamination of the lymphocyte gate is most often caused by monocytes and basophils. Recovery describes the proportion of all lymphocytes that have been included in the lymphocyte gate. Poor recovery is often caused by formation of cellular aggregates or by creating a lymphocyte gate that is too small. Small or "tight" lymphocyte gates frequently exclude dim CD45-staining B cells. A small lymphocyte gate may achieve high purity at the cost of low recovery.

Step-by-Step Three-Color Analysis

1. To simplify the description of analysis steps, the MAb combination of CD3-FITC, CD4-PE, and CD45-PerCP is used as an example. Display an ungated plot of CD45 versus SSC and set an analysis region around the CD45-positive, low-SSC cluster (Fig. 1A). The gate should be set to capture all lymphocytes, including any dim CD45 B cells and more granular NK lymphocytes. Non-CD45-staining debris should easily be excluded from the lymphocyte gate, and effective purities should approach 100%.

2. Display a plot of CD3 versus CD4 that includes only those cells within the CD45 lymphocyte gate (Fig. 1B). Set quadrant cursors (analysis regions) to separate the lymphocyte populations into distinct positive and negative clusters to derive the percentage of $CD3^+$ $CD4^+$ T cells. Record cell counts when performing SPT counting.

3. The CD3-versus-CD4 tube is used to assess the $CD3^-$ $CD4^{dim}$ monocyte contamination. Monocyte contamination should be adjusted to $\leq 3\%$.

4. Display the relevant plots for the remaining tubes in the panel gated on lymphocytes (CD3 versus CD8, CD3 versus $CD16^+$ CD56, and CD3 versus CD19). Quadrant markers may need to be adjusted slightly between tubes to effectively separate the populations, since the positions of stained clusters may vary slightly. Example plots of the complete basic immunophenotyping panel are shown in Fig. 1A to E.

Backgating and Other Quality Assurance Procedures

Purity for the CD45 gating method is estimated as 100% minus the monocyte contamination. An estimate of lymphocyte recovery is a little trickier for CD45 lymphocyte gating. Some investigators suggest that recovery can be estimated by adding the percentages obtained for the major lymphocyte markers, T cells plus B cells plus NK cells; however, this method does not prove that all lymphocytes were included in the gate. If a restrictive gate is drawn that excludes dim CD45 B cells, for example, the B-cell percentage will obviously be lower and the T-cell and NK-cell percentages will be correspondingly higher, with the sum of T cells plus B cells plus NK cells still approaching 100%. An effective method to confirm recovery of T-cell and B-cell populations is called "backgating." Backgating is the practice of projecting a lineage-gated population back through the original lymphocyte gate. An example of backgating $CD3^+$ $CD8^+$ T cells is shown in Fig. 1. Figure 1G shows an ungated display of CD3 versus CD8. A lineage gate is set on the CD8 T-cell cluster and is projected back through the CD45 lymphocyte gate (Fig. 1H). This method should be used to confirm the recovery of CD4 and CD8 T cells and $CD19^+$ B cells. The method is not effective for NK cells because the NK cell marker CD16 is also expressed by monocytes and granulocytes. Backgating methods can reveal other problems, such as cellular aggregates, dying cells, and blast cells.

Four-Color Analysis

The four-color T-cell panel uses the MAb combination CD3, CD4, CD8, and CD45. The staining and analysis are performed the same as for the three-color method described above. In addition to reducing the panel from two tubes to one, saving sample processing time, reagents, and expense, the T-cell subsets, if desired, are resolved with additional information. By displaying a CD8-versus-CD4 plot that is gated on $CD3^+$ T cells, three novel T-cell types and one staining artifact might be resolved (Fig. 1F). The additional T-cell subsets are the $CD4^-$ $CD8^-$ $CD3^+$, $CD4^{bright}$ $CD8^{dim}$ $CD3^+$, and $CD4^{dim}$ $CD8^{bright}$ $CD3^+$. Cell sorting experiments can demonstrate that the $CD8^{bright}$ $CD4^{bright}$ $CD3^+$ cells are mostly cellular aggregates of CD4 and CD8 T cells. Four-color analysis can therefore be used to validate quality control checks that flag samples where the CD4 and CD8 T cells do not add up to the total frequency of CD3-positive lymphocytes (22).

Despite the improved clarity achieved with four-color immunophenotyping, T-cell subset percentages are reported the same way as in two- and three-color analysis, namely, $CD3^+$ $CD4^+$ lymphocytes are graded as CD4 T cells and $CD3^+$ $CD8^+$ lymphocytes are graded as CD8 T cells.

Absolute-Count Determinations

Follow the above steps for three- and four-color analysis. Create an ungated plot of either CD3 versus CD4 or CD3 versus CD8, and draw a gate around the bead population (Fig. 1G). Display statistics to determine the number of beads counted.

The absolute count is calculated as the ratio of analyzed cellular events to bead events multiplied by the ratio of total bead count to blood sample volume. For example, (8,400 CD4 T cells/10,000 beads) $\times$ (51,225 beads/50 µl) = 860 CD4 cells/mm³.

SPT versus Dual-Platform Absolute Counting

The interlaboratory CD4 T-cell count CV for the TruCOUNT bead method (Becton Dickinson) was reported as 9%, compared to 16% for the dual-platform method, and the interlaboratory CV for CD4 T-cell counts was 10% for the TetraOne method (Beckman Coulter, Miami, Fla.), compared to 18% for the dual-platform method. These reports

also indicated that the intralaboratory variation was slightly lower (CV, 1 to 3% lower) for SPT (1, 21, 24). Absolute counts for overnight samples appear to be more stable, and fewer samples fail to meet quality control criteria using the SPT. Therefore, SPTs are more suitable for quality assurance testing that relies on samples shipped overnight. There can also be bias in absolute counts between the SPT and dual-platform methods depending on which hematology analyzer is used, so comparative studies should be performed. The SPT bead methodology is less variable and is preferred, especially for interlaboratory studies. Many of the published reports demonstrating higher variation for dual platform versus SPT used older sample preparation and lymphocyte gating methodologies for generating the T-cell percentage portion of the dual-platform absolute count. These older methods, discussed below, include the LW staining method and scatter gating, which clearly contribute to the overall variability of the dual-platform method. Generating the CD4 T-cell percentage portion of the dual-platform method using newer LNW and CD45 lymphocyte gating should reduce the overall variability in absolute counting using the dual-platform method; however, this approach clearly does not control for variation across hematology analyzers. The dual-platform method is still very valuable, especially for laboratories that process samples in less than 24 h, because the intralaboratory variation is relatively low and the counting beads add a significant cost to the assay. *The bead-based methods have been independently validated in multicenter studies and are Food and Drug Administration cleared for in vitro diagnostic use.*

Alternate LW Staining Methods

The LW procedure is used primarily for research studies that use novel panels of MAbs that are not specifically titrated for the LNW procedure. An example is the enumeration of naïve or memory T cells and activation marker expression on various lymphocyte subpopulations. The panel should include appropriate isotype-matched controls and a tube (CD45 and CD14) to assess the quality of the FSC-versus-SSC lymphocyte gate. The LW method uses excess MAb to ensure saturation of antigen and then removes the excess unbound dye-labeled MAb by washing to reduce background fluorescence, thereby optimizing the resolution of stained cells from unstained cells. The LW method can also be used for dual-platform absolute counts when appropriate reagents are not available.

LW Staining Procedures

A. Part one: antibody incubation
1. Add appropriate amounts of MAb to 12- by 75-mm round-bottom tubes (typically 5 to 20 μl depending on fluorochrome conjugate and manufacturer).
2. Add 100 μl of whole blood and vortex tubes, watching for proper mixing and blood droplets that may remain unmixed on the sides of the tubes.
3. Incubate for 30 min in the dark at RT.
4. Next, the stained samples are lysed, washed, and fixed. The procedures for lysing and fixing vary depending on the erythrocyte lysing method; two methods are provided.

B. Part two: erythrocyte lysing and fixation procedures
1. For FACSlyse erythrocyte lysing/fixing reagent
    a. Add 2 ml of 1× FACSlyse, vortex immediately (~5 s), and incubate for 10 min in the dark (do not exceed 12 min).

b. Centrifuge cells at $300 \times g$ for 5 min (Becton Dickinson recommends RT) and aspirate the supernatant, taking care not to aspirate cells.
c. Vortex pellet gently, add 2 ml of wash buffer, and spin at $300 \times g$ for 5 min.
d. Aspirate supernatant, vortex gently, and add 0.5 ml of 1% formaldehyde solution. Vortex cells again.

2. For alternate ammonium chloride erythrocyte lysing reagent
    a. Add 2 ml of 1× ammonium chloride lysing solution, vortex immediately (~5 s), and incubate for 5 min in the dark.
    b. Centrifuge cells at $300 \times g$ for 5 min (use centrifuge temperature of 4°C to inhibit lysing) and aspirate supernatant, taking care not to aspirate cells.
    c. Repeat steps a and b, except reduce second lysing to 3 min.
    d. Aspirate supernatant, vortex gently, and add 0.5 ml of protein-free phosphate-buffered saline with 1% formaldehyde (pH 7.2). Vortex cells again; allow fixation to stabilize for 10 min. Store samples in the dark at 4°C, if not processing samples immediately.

The LW protocols are suitable for the majority of research antigens routinely assayed in the clinical laboratory; however, some antigens may require specific modifications of the basic methods. Variations in staining of problem antigens (chemokine receptors and adhesion molecules) may include choice of blood anticoagulant, blood storage time, prewashing of the blood prior to staining to remove serum factors, MAb concentration, time and temperature of MAb incubation, and selection of fluorochrome (10).

Establishment of Initial LW Instrument Settings and Daily Quality Control

Initial instrument detector settings can be established with stained whole-blood samples. FSC and SSC detector settings are adjusted to optimize leukocyte resolution. A lymphocyte gate is set and the fluorescent plots are displayed for each fluorescence detector. Cells stained with fluorochrome-labeled CD4 MAb can be used to optimize PMT voltages for each detector. Voltages are set to place the unstained cells on scale and in the first decade of the scale. Voltages are adjusted to maximize the separation of the negative and positive median fluorescence intensities (signal-to-noise ratio). PMT voltages must not be too low or the PMT will not function linearly. PMT voltages that are too high can increase the CVs of the fluorescence distribution and effectively reduce the cytometer's ability to resolve dimly staining populations. Once optimal PMT voltages are established using CD4 T-cell staining, it is recommended to validate sensitivity using a dimly staining marker like CD56. The next step is to run a stable fluorescent particle such as chicken red blood cells (BioSure, Grass Valley, Calif.) at the same PMT voltages to establish target channels for daily instrument setup. On subsequent days the particles are run and PMTs are adjusted to place the median fluorescence into the established target channel. The CV and PMT voltages are recorded for each detector on a log sheet and plotted as a Levey-Jennings plot to monitor instrument stability. Finally, compensation is set using stained biological controls at these exact fluorescence PMT settings. More extensive descriptions of instrument performance and quality control issues are available in *Current Protocols in Cytometry* (12).

Setting Compensation

Compensation is dependent on a number of factors, particularly PMT voltage settings, fluorescence emission spectra, and optical-filter combinations, and therefore must be performed after setting PMT voltages. Compensation for LW samples is typically set using a series of single-stained samples stained with one of each fluorochrome being used for the research panel. The brightest-staining MAb (such as CD8) is typically used to avoid the possibility of under compensation.

The stepwise procedure is as follows.

    1. A sample stained with CD8-FITC is gated on lymphocytes and displayed on a plot of FITC versus PE.

    2. Analysis regions are set (quadrants) to separate the positive and negative populations. The median PE fluorescence is measured for the negative and positive populations.

    3. Compensation is adjusted so that the amount of PE fluorescence in the FITC-positively stained cells is equal to PE fluorescence in the negatively stained cells.

    4. This process is repeated for each fluorochrome.

Sample Acquisition

Samples are typically acquired with the threshold set on FSC to exclude residual red cells and debris. An FCS-versus-SSC plot is displayed to assess sample condition by observing the three distinct white blood cell populations of lymphocytes, monocytes, and granulocytes, as seen in Fig. 2A. The FSC and SSC instrument settings should be adjusted to maximize this distinction. A stop counter should be set to collect sufficient numbers of the population of interest, e.g., CD4 or CD8 T cells (typically 2,500). Additional plots with the lymphocyte gate applied should be displayed to validate the quality of staining for all MAbs being measured.

Data Analysis

Analysis begins with evaluating the quality of the lymphocyte gate and setting the positive and negative analysis regions with an isotype control. An example of enumerating naïve CD4 T cells is provided.

A. Step 1: measuring the purity and recovery of the lymphocyte gate
    1. To measure purity, set an FSC-versus-SSC lymphocyte gate as displayed in Fig. 2A, R1. Lymphocytes have low FSC and low SSC.
    2. Display a plot of CD45 versus CD14; set analysis regions (quadrants) to enumerate the CD45^{bright} CD14^{negative} lymphocyte population to determine the lymphocyte purity (Fig. 2B). Maintain monocyte contamination at ≤3%. Optimize purity at ≥95%.
    3. To measure recovery, display a second plot of CD45 versus CD14 that is ungated, creating an analysis region around the CD45^{bright} CD14^{negative} lymphocyte population (Fig. 2C, R2).
    4. Display a second plot of FSC versus SSC that displays the original lymphocyte region, R1, but that is gated on cells in analysis region 2 (Fig. 2D). To determine lymphocyte recovery, create a statistical view to enumerate the percentage of bright CD45$^+$ CD14$^-$ cells contained within the R1 scatter gate.
    5. The scatter gate is then adjusted to optimize recovery to ≥95%.
    6. The lymphocyte gate is optimized for recovery and purity with the CD45 CD14 tube. This gate is used for analysis of the remaining tubes in the panel.

B. Step 2: setting cursors with isotype controls to establish negative staining region
    1. Display plots for each of the relevant markers to be measured with the region 1 lymphocyte gate applied.
    2. Set analysis regions to measure ≥99% in the negative quadrant (quadrant 3). Occasionally, binding will occur nonspecifically in the isotype control tube, indicating that it may also occur with the corresponding MAbs in the panel. In this event the nonspecific staining observed in the isotype control tube can then be subtracted from that in the corresponding tubes.

C. Step 3: sample analysis using the example of CD45RA/ CD27/CD4/CD3 four-color-stained sample
    1. Create an FSC-versus-SSC plot and apply the lymphocyte gate optimized in step 1 above.
    2. Create a plot to display CD3 versus CD4 gated on lymphocytes.
    3. Create an analysis region to select the CD3$^+$ CD4$^+$ T cells. This region must be combined with the lymphocyte gate to establish a gate that includes only CD3$^+$ CD4$^+$ lymphocytes (G2).
    4. Create a second plot of CD45RA versus CD27 gated on CD3$^+$ CD4$^+$ lymphocytes.
    5. Set quadrant markers as established in step 2 above and as shown in Fig. 2H. The naïve CD4 T cells are in the upper right region (CD45RA$^+$ CD27$^+$).

Backgating and Other Quality Assurance Issues

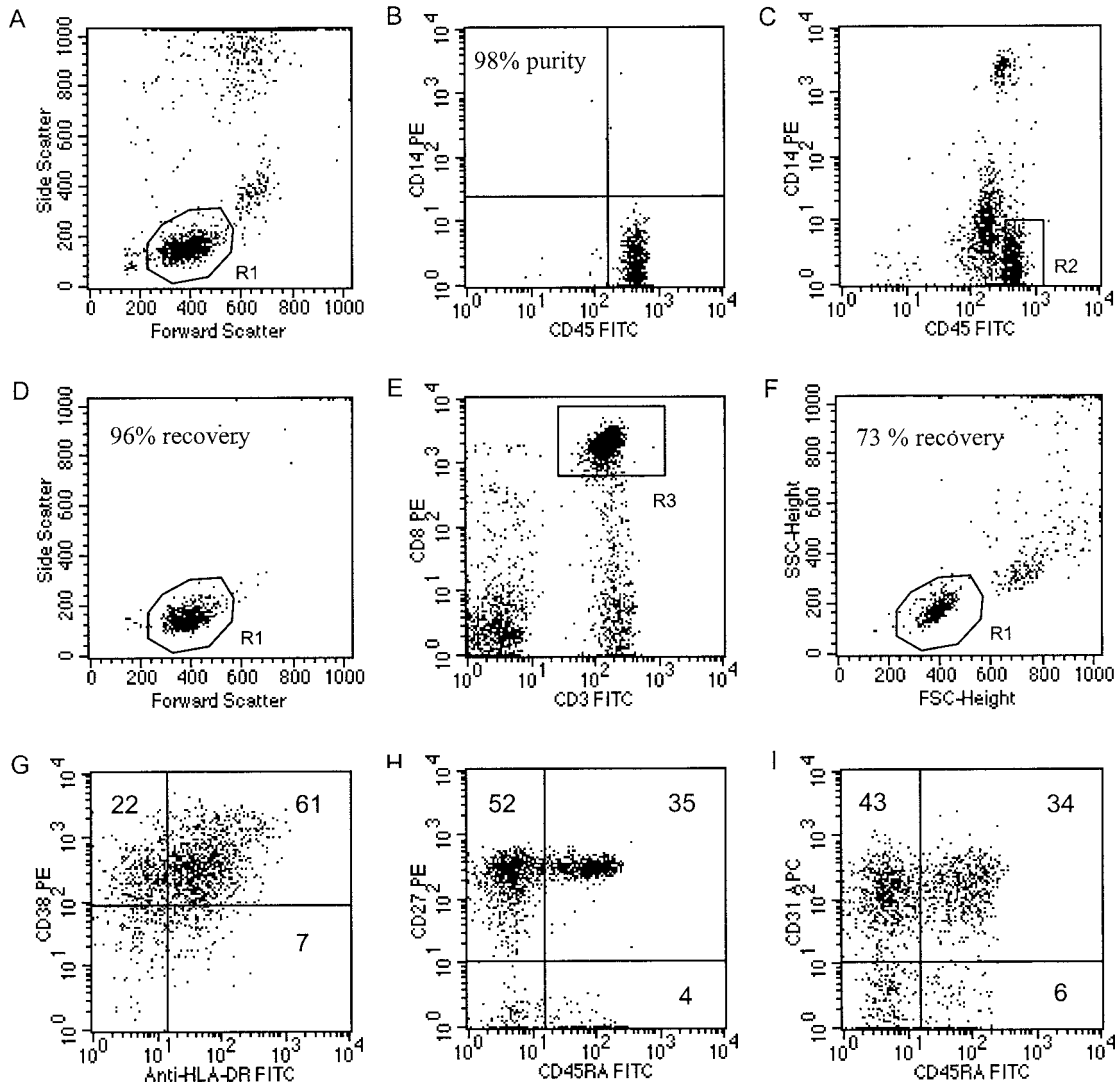
Scatter gating and LW sample preparation are much more likely to produce suboptimal lymphocyte purities and recoveries than are CD45 gating and the LNW sample preparation. Minimum purity standards for LW methods are recommended at 90%; however, in practice 95% purities are achievable with good sample preparation (4). Samples that do not meet these standards should be retested. Monocytes (CD45^{dim} CD14$^+$), basophils (CD45^{dim} CD14$^-$) and red cell debris (CD45$^-$) are the usual contaminants of the lymphocyte gate. Samples with elevated numbers of lysing resistant or nucleated red blood cells can result in substandard purities that cannot be improved by repeated staining. In this event, it may be necessary to correct all lymphocyte subset percentages from this specimen based on the purity of the lymphocyte gate. For example, if the original CD4 T-cell percentage is 20% and the lymphocyte purity is 86%, the corrected CD4 T-cell percentage would equal 20% divided by 0.86, or 23%. Correcting data by lymphocyte purity is problematic because it assumes that the lymphocyte gate is not biased toward exclusion of a particular lymphocyte subset and that the purity and recovery are the same for all tubes in the panel. This is often NOT the case. For example, in a sample where the correlated light scatter profiles do not reveal a distinct lymphocyte population, the tendency is to set a restrictive lymphocyte gate in the area of the debris, which tends to bias recovery toward T cells and away from smaller B cells. Backgating CD19$^+$ B cells can confirm this bias. In other samples the backgating technique identifies a cell preparation artifact called "escapees" (10). Escapees are aptly named because they are made up of cell aggregates, often CD8 cells that due to their high SSC signal escape from the original lymphocyte gate (Fig. 2E and F). For these reasons it is recommended that only samples with purities below 92% be corrected. Backgating the relevant lineage markers in the research panel will ensure their inclusion in the lymphocyte gate and is a preferred practice. Elevated


FIGURE 2 LW sample preparation. Plots A, B, C, and D are analyzed together to establish an FSC-versus-SSC lymphocyte gate with the highest purity and recovery of lymphocytes. Plots E and F show poor backgating of CD8$^+$ stained events due to cell clumping (escapees). Plot G measures elevated coexpression of HLA-DR versus CD38 gated on CD3$^+$CD8$^+$ lymphocytes from an HIV-1-infected donor. Plots H and I use CD45RA in combination with either CD27 (H) or CD31 (I) to define CD4$^+$ naïve cells.

numbers of dead cells that have higher SSC can also be identified with this method.

Alternate SPT Absolute-Count Methods

The FACSCount system (Becton Dickinson) is a unique bead-based method that uses a no-lyse procedure. The interlaboratory CV in CD4 T-cell counts is reported to be less than 10% (17). The FACSCount is ideal for some laboratories because it does not require flow cytometry experience and is less expensive. It is a dedicated absolute counter that does not provide the versatility of MAb panels and cannot determine percentages within the lymphocyte population required for pediatric samples. The volumetric methodology was previously validated against dual-platform methods using the OrthoCytoron flow cytometer, which is no longer commercially available. At least two new volumetric systems have recently been developed, the Guava PCA system,

primarily for use in resource-poor countries, and the Partec CyFlow. These systems have not yet been approved in the United States for in vitro diagnostic use, and publications from independent multicenter studies are not currently available. Data for the Guava system have been submitted to the Food and Drug Administration for approval. Absolute counting is facilitated by use of a precision syringe-driven pump to accurately determine the volume of prepared sample that is measured. The blood sample is stained with a cocktail of CD4-PE and the tandem conjugate CD3-PE-CY5, and erythrocytes are removed using an LNW method. Precise measurement of all reagents is critical because the dilution of blood to lysing reagent (1:20) is used for calculation of the absolute count. The instrument uses a green diode laser to excite the dyes PE and PE-CY5 and to generate FSC measurement. The system does not currently derive the percentage of CD4 or CD8 T cells within the lymphocyte

population; however, this capability is under development using the MAb combination of CD45 and CD4.

The CyFlow system by Partec can generate absolute counts by a novel electrode method. When the sample volume in a tube containing the stained cells drops below the upper electrode in the tube the counting begins, and when the sample dips below the lower electrode the counting stops. The precise volume of sample between electrodes is 200 μl, so the absolute count can be generated based on a dilution factor.

T-CELL ALTERATIONS IN HIV-1 DISEASE

There are phenotypic changes in CD4 cells through the chronic phase of HIV-1 disease that may include a slight decrease in expression of CD45RO, CD28, and CD27, with slight increases in the expression of CD45RA, CD57, and HLA-DR; however, these phenotypic changes do not appear to contribute prognostic power beyond the enumeration of CD4 T-cell numbers alone and do not reflect the profound decrease that is observed in assays of CD4 T-cell function. More pronounced phenotypic alterations are seen in late HIV-1 disease. A study involving participants with advanced HIV-1 disease (<50 CD4 cells/mm³) demonstrated a significant increase in expression of the activation markers CD95, HLA-DR, and CD38 on CD4 T cells compared to uninfected controls and that elevated CD38 but not HLA-DR or CD95 expression was strongly associated with a shorter (<6 month) versus longer (>18 month) survival time ($P = 0.002$). Although the level of naïve cells as measured by dual expression of CD45RA and CD62L was greatly diminished in advanced HIV-1 disease, this was not associated with shorter versus longer survival ($P = 0.338$) (8). Subtyping of CD4 T cells following highly active antiretroviral therapy treatment is relevant for assessing immune reconstitution. The proportion of naïve CD4 T cells is usually determined by dual expression of CD45RA and either CD62L, CD27, or CD28. Although most CD45RA⁺ CD4 T cells are considered naïve, a small percentage (1 to 5%) of CD45RA⁺ cells do not express CD62L, CD27, or CD28 and are not considered naïve (Fig. 2H) (11). Early studies used CD45RA in combination with CD62L to measure naïve T cells; however, due to variable loss of the CD62L antigen on cryopreserved lymphocytes, CD27 and CD28 are now more commonly used. Another marker, CD31, provides additional information about the replicative history of naïve CD4 T cells that may be useful for studies designed to assay the contribution of the thymus to CD4 T-cell reconstitution (14). CD45RA⁺ CD31⁻ naïve cells contain about one-eighth the level of T-cell receptor excision circles (TREC) that CD45RA⁺ CD31⁺ naïve cells contain, suggesting that they are a consequence of homeostasis-driven peripheral expansion. TREC are a molecular measurement of the replicative history of T cells such that populations of cells with high levels of TREC are considered more enriched in recent thymic emigrants than are populations of cells with low TREC levels, which are enriched in peripherally expanded naïve cells.

The phenotypic alterations of CD8 T cells are more profound in early and late HIV-1 disease than observed for CD4 T cells. Alterations include a decrease in naïve CD8 T cells as measured by the dual expression of CD45RA and CD62L and elevations in the memory cell marker CD45RO. The cells expressing markers associated with cytotoxic function (CD57⁺ and CD28⁻) and cell activation (HLA-DR, CD38, and CD95) are also increased. Elevated levels of CD38 expression have been shown to be prognostic for time to AIDS and death in several studies (15, 16). In early HIV-1 disease (median length of infection = 2.8 years) the prognostic significance of CD38 expression was similar to that of HIV-1 plasma viral load, and as the duration of infection increased (median length of infection = 8.7 years), CD38 antigen density was more predictive of AIDS development than CD4 T-cell count or viral load. These prognostic studies on CD38 expression demonstrate that measurement of antigen density can be more relevant than grading cells as positive or negative. In the study of advanced disease described above, elevated expression of CD38 on CD8 T cells was strongly associated ($P = 0.002$) and CD95 was marginally associated ($P = 0.006$) with shorter versus longer survival (8). The study group used for the prognostic studies described above consisted primarily of male Caucasians. Testing these observations on different populations based on age, race, and gender is an area of importance. Other studies have demonstrated that CD38 expression on CD8 cells is predictive of CD4 T-cell loss in a mostly minority, female adolescent population and that CD38 expression predicts virologic failure in HIV-1-infected children receiving antiretroviral therapy (26). The Adult AIDS Clinical Trial Group reported that high pretreatment CD8 T-cell activation levels predicted virologic failure ($P = 0.046$) (19). The methods used to determine CD38 expression on CD8 cells, however, vary across studies. Standardized and more simplified methods of antigen quantitation may help improve and extend this important work so that measurement of CD38 on CD8 cells becomes broadly available to clinical laboratories (13).

Nontraditional Clinical Applications: Paroxysmal Nocturnal Hemoglobinuria Testing, Fetal Red Cell Testing, T-Cell Receptor Vβ Analysis, and Platelet Analysis by Flow Cytometry

JIACHUN X. KUNG AND ERIC D. HSI

19

Flow cytometric immunophenotyping has several well-accepted applications. Determination of lymphocyte subsets in the diagnosis and monitoring of human immunodeficiency virus infection became the first major application that made flow cytometry an economically viable and medically necessary component of most large clinical laboratories. With dependence of modern classification schemes on immunophenotype, it has also become an indispensable part of the routine evaluation of leukemias and lymphomas. Immunophenotyping panels are generally focused upon lineage assignment and documentation of B-cell clonality. Specific phenotypic patterns are also assessed since they can be useful in classification of these disorders.

Flow cytometry is also beginning to be more widely used in other areas of hematologic malignancies, such as a diagnostic adjunct for myelodysplastic syndromes. Multiparameter flow cytometry is also making inroads into the detection of minimal residual disease. These applications can still be considered investigational. In this chapter we focus on four less common clinical applications of flow cytometry: paroxysmal nocturnal hemoglobinuria (PNH), T-cell receptor Vβ (TCR Vβ) analysis, fetal hemoglobin (Hgb F) detection, and platelet surface marker and functional testing.

PNH

PNH is an acquired hemolytic anemia due to a clonal hematopoietic stem cell mutation in the phosphatidylinositol glycan class A gene located on chromosome X. This leads to the inability to synthesize the glycosylphosphatidylinositol (GPI) anchor that binds numerous proteins to the cell membranes (3–5). The critical missing membrane proteins are complement-regulating surface proteins, which include decay-accelerating factor (CD55), homologous restriction factor or C8 binding protein, and the membrane inhibitor of reactive lysis (CD59). These proteins normally interact with complement proteins, particularly C3b and C4b, and dissociate the convertase complexes of the classic and alternative pathways. This interrupts complete activation of complement and thus protects cells from inappropriate complement-mediated lysis. Other cell surface molecules are absent in PNH, and many are listed in Tables 1 and 2 (29).

Three PNH red blood cell (RBC) phenotypes are recognized due to variations in genetic defects that can result in PNH. These are types I, II, and III, which exhibit normal, moderate, and severe complement sensitivities, respectively.

Clinical manifestations of intravascular hemolysis include the breakdown of RBCs with the release of hemoglobin into the urine, which is indicated by distinct dark-colored urine. Classically this occurs in the first morning urine due to concentration of hemoglobin in the urine overnight, which produces the dark color. This feature is a major symptom in PNH patients, with 84% of patients having hemoglobinuria as a chief symptom (28). Lack of GPI-linked proteins on other cell types leads to other manifestations. For example, complement activation plays a role in excessive platelet activation, microparticle formation, and elevated levels in plasma of leukocyte-derived tissue factor, which results in increased risk of thrombosis (23, 33, 42, 76). This is, in fact, a major source of morbidity and mortality in PNH patients (28, 51).

Classical clinical tests for PNH are aimed at demonstrating the presence of RBCs that are exceptionally sensitive to the hemolytic action of complement compared to normal RBCs (25, 26). These are the sucrose hemolysis test, which serves as a screening test, followed by the more specific acidified serum (Ham's) test. With Ham's test, a false-positive test result can be seen in congenital dyserythropoietic anemia, type II (hereditary erythroblastic multinuclearity with positive acidified serum tests). These patients have a negative sucrose hemolysis (sugar water) test. In addition, a false-negative Ham's test can also occur, and the sucrose water test is more sensitive but less specific for PNH. Neither of these assays is sensitive for small PNH populations (as may occur after an active phase of the disease and transfusion in which few PNH RBCs remain) and cannot be used to assess the size of the PNH clone.

Flow cytometry is becoming the preferred method for assessing blood samples for the presence of PNH clones (24). This method offers greater sensitivity and specificity than classical tests in identifying patients with PNH. Furthermore, flow cytometry tests are capable of easily detecting low levels of PNH cells (on the order of 1 to 2% in our experience) in a sample. Analysis of nonerythrocyte populations also allows one to detect PNH cells more easily in patients undergoing hemolysis or in the setting of recent transfusion. PNH granulocytes, in contrast to PNH RBCs, have a normal life span and so the percentage of abnormal granulocytes more accurately reflects the size of the PNH clone (10).

TABLE 1   CD markers for GPI-anchored proteins

Protein[a]	CD marker	Lineage
Endotoxin-binding protein receptor	CD14	Monocytes
Low-affinity IgG Fc receptor	CD16	Neutrophils, T cells
GPI-sialoglycoprotein	CD24	Neutrophils, B cells
GPI-anchored glycoprotein	CD48	Lymphocytes, monocytes
Campath-1 antigen	CD52	Lymphocytes
DAF	CD55	All
LFA-3	CD58	Lymphocytes, erythrocytes
MIRL	CD59	All
Selectin ligand	CD66b	Granulocytes
Ecto-5′-nucleotidase	CD73	Lymphocytes
uPAR	CD87	Monocytes, granulocytes, T cells, NK cells
Thy-1	CD90	Lymphocytes
JMH blood group antigen	CD108	Lymphocytes, erythrocytes
gp 170 kDa	CD109	T cells, platelets
Pre-B, thymocyte growth signal	CD157	Pre-B, pre-T, monocyte, granulocyte

[a]IgG, immunoglobulin G; DAF, decay-accelerating factor; LFA-3, lymphocyte function-associated antigen 3; MIRL, membrane inhibitor of reactive lysis; uPAR, urokinase plasminogen activator receptor; gp, glycoprotein.

Flow cytometry tests are capable of distinguishing types of PNH cells. Type I cells express normal amounts of GPI-linked antigens, type II cells display intermediate expression levels, and type III cells completely lack these antigens. The amounts of these types of cells vary from patient to patient. In a recent analysis, approximately 60% of patients displayed all three types of erythrocytes and 34% of patients showed types I and III, with less than 5% type II (61). Finally, flow cytometry allows quantitation of the PNH clone as a percentage of the total cells in the specimen. Some authors have correlated the amount of the clone with clinical parameters (1, 57). For example, Nishimura and colleagues suggest that decreasing populations of PNH cells are correlated with bone marrow failure (57). Moyo et al. have correlated increasing PNH clone size with risk of thrombosis (51).

There is a lack of consensus on specific methods for analyzing specimens for PNH clones. In general, most authors would state that at least two GPI-linked proteins should be absent on a cell type for one to conclude that a PNH clone is present (29, 61). Ideally, this should be done in a multicolor format to simultaneously assess the same cell (Fig. 1 and 2). One reason for this requirement is to exclude congenital deficiencies of some of these markers, such as CD55 or CD59 (60, 77). The Inab phenotype (congenital lack of the Cromer blood group, located on CD55) has been reported, and these patients lack other evidence of PNH (60). CD59 deficiency has also been reported, although patients appear symptomatic (77).

The PNH assay is unusual since a positive result is *decreased or absence of* reactivity to directly labeled monoclonal antibodies. This can cause some difficulties in cases in which clear separation from type I, II, or III cells is not apparent, making definitive threshold setting difficult. CD59 is preferable for distinguishing between these cell types since it is expressed at a density 10-fold greater than that of CD55 (30).

A kit is commercially available with control beads that assist operators in setting a threshold for lack of expression of CD55 and CD59 (32). These two antigens are analyzed on erythrocytes and neutrophils. A disadvantage of this kit is its reliance on single-color (fluorescein isothiocyanate [FITC]) analysis of the key antigens. Because clinical experience with PNH samples will be limited in most individual laboratories due to the rarity of the disorder, such a "standardized" kit may be useful, although individual laboratories must still validate the assay (32). Using definitions supplied by the manufacturer, the minimum sensitivity for this assay is 3% PNH cells. However, we have found that in

TABLE 2   Parameters used for gating specific cell types and GPI-linked proteins for PNH screening

Lineage	Cell markers useful for gating	CDs for GPI protein
RBCs		
Reticulocytes	Thiazole orange, LS[a]	CD59, CD58, CD55
Erythrocytes	Glycophorin A, LS	CD59, CD58, CD55
Leukocytes		
Neutrophils	CD33, LS	CD66b, CD24, CD16
Monocytes	CD33, LS	CD14, CD48
Granulocytes	CD11b, LS	CD16, CD55, CD59
Lymphocytes		
T	CD3, LS	CD48, CD52
B	CD19	CD24
Progenitor cells	CD34, CD45	CD59
Platelets	CD41, CD42, CD61, LS	CD55

our specimens, the 3% threshold was a bit low, particularly for CD59 on granulocytes when clinical diagnosis of PNH was used as the standard. Dual reagents are available that allow simultaneous assessment of CD55 and CD59 expression on erythrocytes and granulocytes. Analysis for dually negative cells increases sensitivity and specificity in our experience.

In addition to CD55 and CD59, other antigens recommended by many authors include CD66b and CD16 on neutrophils and CD14 on monocytes (1, 24, 1, 27, 32, 61, 62). The latter can be problematic in our experience due to the wide distribution of expression intensity and the difficulty in collecting enough events in specimens with a relatively low monocyte count. These white cell antigens can be paired with CD45 and CD13; this allows for specific gating using CD45, side scatter, and CD13 expression characteristics. CD66b is highly expressed on granulocytes and is suitable for diagnostic purposes.

Detection of a large population of PNH-type cells with these assays in the appropriate clinical setting, such as significant intravascular hemolysis, is diagnostic of PNH. However, interpretation of low levels of these cells in subclinical patients (no evidence of PNH) can be problematic since GPI-deficient clones can be detected in patients with marrow failure syndromes such as aplastic anemia, myelodysplasia, or other clonal bone marrow disorders (34, 45). The significance of such a finding is uncertain; however, it has been reported that patients with bone marrow failure syndrome and minor PNH clones respond to immunotherapy (74). Consequently, it is best to merely report the presence or absence of a PNH clone and its relative abundance. Correlation by the ordering

physician with the clinical findings may help stratify patients into one of three categories: classical PNH, PNH with bone marrow failure syndrome, or subclinical (laboratory PNH) (The International PNH Interest Group, unpublished data). Because of variation in the size of the clone, multiple analyses for a single patient may be needed to confirm the presence of a PNH clone. Due to possible time-dependent loss of antigen expression, a freshly (<24 h) drawn EDTA-anticoagulated specimen is required for appropriate analysis. An example protocol follows.

PNH Staining Protocol (55)

1. Patient sample: EDTA-anticoagulated blood (<24 h old, preferably <12 h).
2. For erythrocytes:
   a. Use 10 μl of 1:10-diluted whole blood in phosphate-buttered saline (PBS).
   b. Incubate for 15 min at room temperature with anti-CD59-FITC and anti-CD59-phycoerythrin (anti-CD59-PE) antibodies (clones MEM54 and MEM140-30; Research Diagnostics, Flanders, N.J.).
   c. Wash once with PBS.
   d. Pellet cells and resuspend with 0.5 ml of PBS for erythrocytes (instead of PBS, incubate for 15 min with 0.5 ml of thiazol orange or Recticount for reticulocytes).
   e. Analyze within 2 h (or place at 4 to 10°C for overnight storage). Dually negative cells should be enumerated.

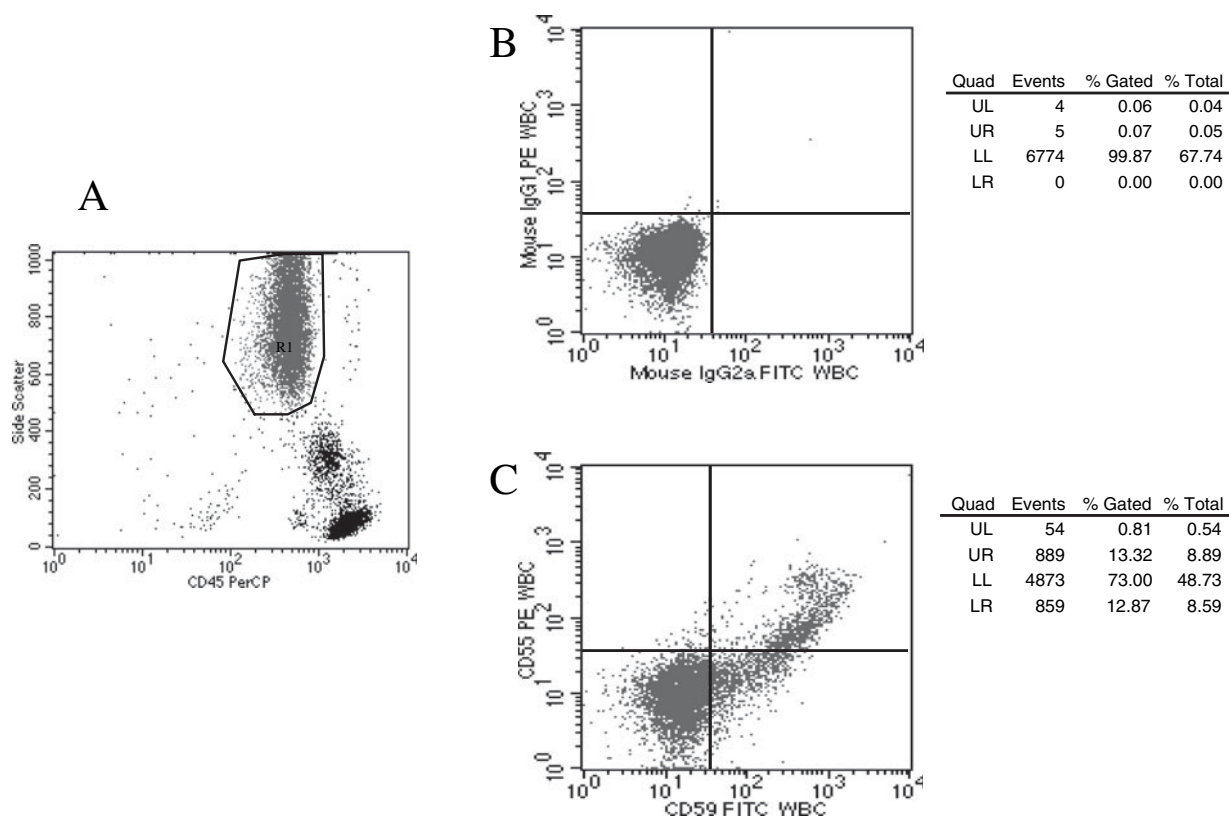

FIGURE 2 PNH analysis of neutrophils. (A) CD45 and light scatter gating of neutrophils; (B) isotype control; (C) two-color CD55 and CD59 staining identifies CD55$^-$ CD59$^-$ neutrophils in PNH patient.

Notes

1. Avoid heparinized plasma since it causes platelet aggregation.

2. Use isotype controls.

3. Perform the test within 24 h after sample collection.

4. Lyse RBCs for leukocyte analysis (otherwise use whole blood for RBCs and platelets).

5. For leukocytes, incubate 50 μl of whole blood with 20 μl of antibodies to CD66b-FITC, CD13-PE, CD45-PerCP, and CD14-allophycocyanin for 15 min (CD66b clone 80H3 from Beckman-Coulter [Hialeah, Fla.] and remaining antibodies from BD Biosciences[San Jose, Calif.]). Lyse erythrocytes and wash with PBS as described above. Analyze granulocyte gate (CD45$^+$ CD13$^+$ CD14$^-$ high side scatter) looking for CD66b-negative cells. CD14 can be used to enumerate monocytes using CD45 side scatter gating but is more difficult in our experience.

6. The lower limit of detection of PNH cells should be determined in each laboratory using normal volunteer samples.

Interferences to stained cells can occur from other cells:

- Erythrocytes: white blood cells and macrothrombocytes
- Neutrophils: eosinophils and immature myeloid progenitors (CD16$^+$ or CD24$^+$)
- Lymphocytes: RBCs, normoblasts, macrothrombocytes, and basophils
- Monocytes: difficult to define by light scattering
- Platelets: require particle-free solutions

Most recently, a fluorescently labeled inactive variant of aerolysin (FLAER) has been shown to be sensitive and specific for assessment of GPI-linked protein deficiency in PNH patients (9). Aerolysin is a toxin produced by *Aeromonas hydrophila* and has the property of binding to GPI anchors; thus, it is useful in identifying PNH cells by lack of binding. Type III PNH cells are completely resistant to lysis by the active toxin (32). It more effectively identifies GPI-deficient nucleated cells than RBCs because of a higher fluorescent signal intensity in the former than in the latter. Flow cytometric assays using FLAER may prove to be a widely used method for identifying PNH cells in the near future. The United Kingdom National Quality Assessment Service has preliminarily tested stabilized PNH samples that may be helpful in assessing performance and developing standardized procedures.

TCR Vβ ANALYSIS BY FLOW CYTOMETRY

T cells recognize antigens via clonally distributed TCR heterodimers, of which the vast majority are composed of α and β chains and a small subset (1 to 5%) carry the alternative γ and δ chains. Demonstration of monoclonal rearrangement of these TCR genes plays a central role in the diagnosis of T-cell malignancy. Classical techniques such as Southern blot hybridization and PCR have enabled monoclonal T-cell proliferations to be detected reliably in clinical samples. (68, 70).

Southern blot analysis is the "gold standard" method for investigation of T-cell clonality, with a sensitivity level in the range of 1 to 5% of clonal cells in the total infiltrate.

Southern blotting using TCR Jβ probes is a reliable and sensitive (fewer false negatives) method but requires a long preparation time and large amounts of high-quality DNA in order to obtain results. PCR-based methods for assessing TCR Vβ or Vγ rearrangement have become popular, and VJγ PCR has become widely used in clinical laboratories. These PCR assays are relatively quick (on the order of days), and assays for TCR-γ rearrangement can be adapted for use in paraffin-embedded tissues. However, the limited repertoire of the Vγ locus, which is attractive from the perspective of consensus primer design, makes false positives possible. The diversity and complexity of the Vβ gene locus require the use of numerous primers in multiplex formats, and false negatives due to lack of consensus primer binding remain a possibility (68, 70). Optimal analysis of PCR products requires capillary gel electrophoresis or heteroduplex analysis (68). Extensive development and validation testing of agreed-upon consensus PCR primers and methods are ongoing for these molecular methods (68).

In recent years, monoclonal antibody reagents specific to various TCR-β family V regions have become available. Since the TCRβ V genes can be divided into functional families, one can use these reagents to assess the TCR repertoire in peripheral blood T cells. Just as immunoglobulin light-chain restriction (kappa and lambda) can be used as a surrogate for B-cell clonality, so too can skewing or restriction of TCR Vβ family expression patterns. In order to facilitate this, commercially available antibodies to 24 specificities covering 19 TCR Vβ families have been combined in a multicolor flow cytometry format to allow assessment of TCR Vβ usage. This format accounts for approximately 70% of T cells in peripheral blood, and normal ranges for each family in healthy volunteers have been determined (67).

The use of Vβ flow cytometry in diagnosing T-cell chronic lymphoproliferative disorders in blood has been assessed (2, 37, 38). Clear overrepresentation of a particular Vβ family can be used as a surrogate for molecular studies for TCR gene rearrangements when one suspects a T-cell lymphoproliferative disorder on clinical and morphological grounds (Fig. 3). Likewise, accounting for only a fraction of T cells using this kit (less than 50%) can also be taken as evidence for a clonal T-cell proliferation. Beck et al. found a 100% sensitivity and 88% specificity for T-cell lymphoproliferative disorders in blood in their study (2). No clear association with a particular disease entity and Vβ family usage has been found. As with all ancillary testing for clonality in lymphoid malignancies, these results should be considered in clinical context. For example, restricted Vβ expression was seen in 2 of 16 control samples (patients presenting with a concern of a lymphoproliferative disorder who ultimately were not found to have a lymphoproliferative disorder) that were also confirmed to be monoclonal by TCR-γ PCR analysis (2). Examples of monoclonal T-cell populations in the elderly or in certain clinical situations such as autoimmune disorders have been documented (20, 59). In addition to assisting in primary diagnosis, TCR Vβ flow cytometry has also been used to monitor therapy in patients with cutaneous T-cell lymphoma. Given its limited sensitivity, it is unlikely that TCR Vβ flow cytometry will have a large role in residual disease detection. The following details a sample protocol.

TCR Vβ Staining Protocol (IOTest Beta Mark Manufacturer's Protocol)

1. Prepare peripheral blood with anticoagulant (EDTA preferred).

2. Incubate blood sample with appropriate antibody for 20 min at room temperature (in the dark, IOTest Beta Mark TCR Vβ Repertoire kit [Beckman-Coulter] and anti-CD3).

3. Lyse erythrocytes.

4. Fix cells and then wash and resuspend them for analysis.

Notes

1. Stain cells with appropriate isotypic conjugated antibodies to serve as controls (for fluorescence limits of background).

2. Lymphocyte gate set with forward scatter (size parameter):

   a. For TCR Vβ usage, one can select for total CD3+ T cells or dual CD3+ CD4+ and CD3+ CD8+ T cells using appropriate gating antibodies.

   b. The manufacturer supplies normal ranges for peripheral blood. A good control is a summation of total T-cell percentage accounted for in the Vβ analysis. A very small number suggests an aberrant population using a Vβ family not detected by the kit reagents. A number greater than 100% suggests a problem with background or analysis thresholds.

Hgb F MEASUREMENT BY FLOW CYTOMETRY

Detection of Hgb F in RBCs has several clinical applications. The most common method is the Kleihauer-Betke test (KBT), which enumerates Hgb F-containing cells based on their relative resistance to acid elution (39). In this test, RBCs are fixed on a slide and exposed to a citric acid sodium phosphate buffer solution that elutes Hgb A but leaves Hgb F in fetal RBCs. Slides are stained with hematoxylin and eosin and a manual count of fetal cells is performed as percentage of RBCs (39). This test has many disadvantages, including its manual nature, subjectivity, limited sensitivity, and high coefficient of variation.

Flow cytometric analysis of Hgb F is superior to the KBT. In this assay, RBCs are permeabilized, stained with fluorescent antibodies to Hgb F, and analyzed by flow cytometry. Determination of Hgb F by flow cytometry has several clinical applications, including the diagnosis and quantitation of fetomaternal hemorrhage (FMH) (11, 14, 44, 56), determining the cellular distribution of Hgb F in adult RBCs (so-called F cells) in various hemoglobinopathies (31), and monitoring therapies aimed at increasing Hgb F, such as in hydroxyurea therapy for sickle cell disease (17, 46, 52, 54).

Much of the effort in developing flow cytometry assays has focused on detecting and quantitating fetal RBCs in maternal blood for the detection and quantitation of FMH (11, 14, 36, 53, 56). Detection of fetal cells can confirm the diagnosis of FMH, and quantitation can guide therapy to prevent maternal alloimmunization to RhD antigen in RhD-negative mothers. These assays show improved sensitivity (as low as 0.02%), precision, and linearity over manual methods (14, 44, 56). Chen and colleagues summarized College of American Pathology survey data showing markedly superior performance of laboratories performing FMH determinations by flow cytometry compared to traditional methods. In a sample made to simulate values close to the 0.6% level, which triggers an additional therapy with Rh immune globulin, approximately 50% of laboratories failed to correctly identify the specimens by traditional methods, while most laboratories correctly identified them by flow cytometry (11). FIGURE 3 Vβ analysis, T large granular lymphocyte leukemia. (A) CD3 gating for analysis. More specific CD4 or CD8 gating may also be done. (B) Dot plot analysis of T-cell gate with Vβ 12 FITC, Vβ 5.2 PE, and Vβ 2 PE/FITC. (C) Bar graph of Vβ expression showing marked overexpression of Vβ 2.

Administration-approved test is now available for this assay. High and low controls are also available for this assay but can also be made using cord blood to spike adult blood samples. This assay specifies procedures for specimen preparation, fixation, staining, data acquisition, and analysis (Fig. 4) (http://www.caltag.com/pdf/L13011.pdf).

Of note, gating strategies have been devised to assist with finding small numbers of fetal RBCs by gating out autofluorescent leukocytes that might contaminate a light scatter RBC gate and are currently recommended by the manufacturer (36, 53, 75). This method suggests that the operator first draw a light scatter gate around erythrocytes and then visualize the gated cells on an FL2-versus-FL1 plot (FITC-conjugated anti-Hgb F). This allows one to exclude autofluorescent cells in FL2 that also show FL1 signal. This procedure results in increased sensitivity. Wide use of flow cytometry for this application may change the opinion of clinicians regarding the use (or lack thereof) of the KBT in managing FMH (15, 16, 66). Familiarity with the variability of F cells, which can at times be strongly positive in some settings, such as thalassemia or other hemoglobinopathy, is needed so that one does not mistake such cells for FMH (36, 35). The following is an example protocol.

Fetal Cell Staining Protocol (65) (Manufacturer Protocol)

1. Prepare EDTA whole blood, less than 30 h old.
2. Use 10 µl of whole blood fixed with 0.5% glutaraldehyde for 10 min; wash 3× in PBS–0.1% bovine serum albumin (BSA).
3. Permeabilize cells with 0.1% Triton X-100 in PBS for 3 to 5 min at room temperature, and wash once in PBS–0.1% BSA.
4. Resuspend in 0.5 ml of PBS–0.1% BSA. Add together 10 µl of cell suspension, 5 µl of anti-Hgb F, and 70 µl of PBS–0.1% BSA. Incubate for 15 min in the dark.
5. Wash with PBS–0.1% BSA, and resuspend in 0.5 ml of PBS–0.1% BSA with 1% formaldehyde.

Notes

1. Patient sample is to be assayed within 20 h.
2. For control cells, a commercially available reagent may be used (Fetatrol) or a control can be made using umbilical cord and adult blood dilutions.
3. The gating strategy to remove autofluorescent cells is important for optimal assay sensitivity.
FIGURE 4 Hgb F testing. (A) Forward and side scatter gating of RBCs. (B) Cells with high FL2 are excluded from acquisition to avoid problems with autofluorescence. (C) Case with no detectable fetal RBCs. (D) Case with 1.6% fetal RBCs.

Practical issues regarding availability (or lack thereof) of this test during off-hours of the laboratory need to be addressed with clinical services, and a KBT may need to be retained in the laboratory as a backup method.

PLATELET ANALYSIS

Structural and functional defects in platelets can lead to a variety of bleeding disorders. Standard clinical tests have been developed to assess platelet function, including bleeding time and platelet aggregometry (41). The traditional bleeding time test is fraught with variability and poor reproducibility, since it is dependent on platelet number and function, fibrinogen concentration, operator technique, patient cooperation, skin temperature, skin quality, incision size, and the site of incision. Platelet aggregometry, performed either by impedance using whole blood or by turbidimetry using platelet-rich plasma, evaluates platelet-platelet binding and agonist-induced platelet activation. Results of these tests are affected by medication, age of sample, processing temperature, stirring rate, and platelet count. Aggregometry may show whether platelet reactivity is affected by a particular clinical condition but is unable to determine the activation status of platelets, to detect distinct subpopulations of platelets, or to measure the extent of activation of individual platelets.

Development of commercially available antibodies to relevant platelet antigens permits the discrimination between activated and resting platelets and permits platelet receptor quantitation (40, 44, 49). A small amount of whole blood (about 10 μl per tube) is needed, and there is minimal sample manipulation prior to analysis. The following paragraphs describe current usage of flow cytometry in diagnosing and monitoring platelet disorders.

Patients with diseases involving genetic abnormalities in platelet surface receptors exhibit aggregation anomalies (44, 58, 64). Glanzmann's thrombasthenia results from mutations in the genes for GPIIb and GPIIIa, thereby preventing the aggregation of platelets in response to fibronectin, fibrinogen, von Willebrand factor (vWF), and vitronectin. The absence of GPIIb and GPIIIa is traditionally confirmed via sodium dodecyl sulfate-polyacrylamide gel electrophoresis of radiolabeled platelet proteins. However, with the availability of antibodies to GPIIb and GPIIIa, flow cytometry offers a more efficient and non-radioactive method for detecting the deficiency concurrently on all desired cellular populations (Fig. 5). With Bernard-Soulier disease, there is defective expression of the GPIb-GPIX-GPV complex (the platelet receptor for vWF) and a lack of response to ristocetin (41). Flow cytometry can be performed to scan for deficiencies in GPIbα, GPIX, and GPV, using the appropriate platelet identifiers (GPIIb and GPIIIa) (see Table 3) (13, 63). Other disorders in this category are the Gray platelet syndrome and May-Hegglin anomaly (MYH9-related disease) (48). Flow cytometry studies have shown that the platelets in gray platelet syndrome have abnormal expression of CD62 (P-selectin) on the surface and in the alpha granule (41).

Platelet dense granule storage pool disease results from a deficiency of dense granules or a defect in granule release via

platelet activation (41). Hereditary and congenital forms such as Hermansky-Pudlak syndrome and δ-storage pool disease and acquired forms such as in myeloproliferative or rheumatologic disorders exist. Clinical diagnosis is supported by monitoring uptake of mepacrine (a fluorescent molecule that is rapidly taken up and localized to dense granules) into dense granules of platelets and its loss with dense granules release upon stimulation (Fig. 6) (22,72). This is more reproducible with flow cytometry than with fluorescence microscopy (6, 49). If the granule release deficiency is a function of a defect in epinephrine or collagen receptor, then confirmation via flow cytometry can be obtained by scanning for either receptor. The following is an example protocol for surface marker expression and analysis of granule release.

Platelet Staining Protocol (from Reference 49; Cleveland Clinic Protocol)

1. Use citrated whole blood or citrated platelet-rich plasma. A simultaneous sample from normal donor should be run with the patient sample as a control.
2. Set up tubes as in Table 4.

    Reagents
    CD41a, CD42b, CD49b, CD36, CD29 (Beckman-Coulter)
    CD61, CD62P, CD42a (BD Biosciences)
    Mepacrine (Q3251; Sigma Chemical, St. Louis, Mo.): 0.1 M solution (10× working stock) in Dulbecco PBS without Ca^{2+} or Mg^{2+}

    Staining medium (9.9 ml of Dulbecco PBS + 100 µl of newborn calf serum [Sigma])
    ADP stock (A2754; Sigma): working solution of 45 mg of ADP in 0.5 ml of distilled H$_2$O (dH$_2$O); store at 2 to 8°C
    Thrombin (T9135; Sigma): one vial diluted with 0.5 ml of dH$_2$O; store at 2 to 8°C
    RGDS (A9041; Sigma): 10 mg diluted with 1 ml of Dulbecco PBS; store at 2 to 8°C

3. Surface staining
  a. Add 100 µl of staining medium to tubes 1 through 7.
  b. Add 5 µl of each appropriate antibody to each tube (Table 4).
  c. Prepare a separate tube containing 50 µl of ADP and 20 µl of RGDS. Label this tube "Platelet activation."
  d. Add 10 µl of whole blood to tubes 1–6 and 450 µl of whole blood to the tube labeled "Platelet activation." Incubate for 15 min at room temperature in the dark.
  e. After 15 min, add 500 µl of cold 1% paraformaldehyde to tubes 1 to 6.
  f. Add 10 µl of "Platelet activation" tube to tube 7 and incubate for 15 min at room temperature in the dark. Add 500 µl of cold 1% paraformaldehyde to tube 7. This serves to determine whether platelets are capable of being activated.
4. Store refrigerated until ready for data acquisition (up to 48 h).

Mepacrine Staining Protocol (from Reference 49; Cleveland Clinic Protocol)

Mepacrine testing should be done with a normal control sample to confirm thrombin activation and mepacrine uptake.

1. In a separate tube, dilute 50 µl of sample blood with 1.95 ml of staining medium.
2. Add 10 µl of mepacrine and 5 µl of appropriate antibody to tubes 8 and 9.
3. Add 250 µl of diluted blood from step 1 to tubes 8 and 9 and incubate for 30 min at 37°C (water bath).
4. Label two blank tubes "8 post incubation" and "9 post incubation." Add 950 µl of Dulbecco PBS to each tube.
5. Remove 50-µl aliquots of incubated blood from tubes 8 and 9 and add to tubes "8 post incubation" and "9 post incubation," respectively. Immediate acquire data. The "8 post incubation" tube will serve as the control for inadvertent activation of platelets and "9 post incubation" will serve as a baseline for mepacrine uptake.
6. Take 500 µl of sample from tube 9 and place in tube 10. Add 20 µl of thrombin to tube 10 and incubate for 15 min at room temperature. Acquire data immediately. This serves to determine mepacrine release.

Interpretive guidelines

Surface Staining

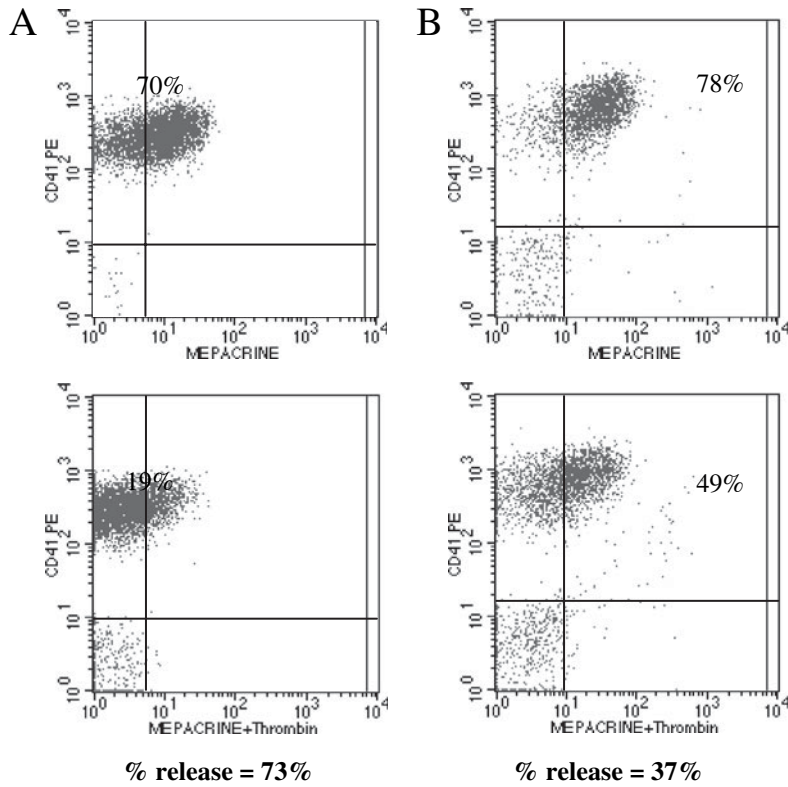
Antibody	Reference range
CD41a (GPIIb/GPIIIa) fibrinogen receptor	95 to 100%
CD61 (GPIIIa) fibrinogen receptor	95 to 100%
CD42b (GPIb) vWF receptor	95 to 100%
CD42a (GPIX)	92 to 100%
CD36 collagen receptor	95 to 100%
CD49b (GPIa) collagen receptor	69 to 100%
CD29 (GPIIa) collagen receptor	95 to 100%


FIGURE 6 Mepacrine release as a measure of granule function. (A) Platelets loaded with mepacrine show normal fluorescence uptake (upper panel) which decreases upon thrombin activation and granule release (lower panel). (B) Abnormal (decreased) mepacrine release compared to normal.

Mepacrine Uptake and Release

Percent release = $[(\text{percent } M_u - \text{percent } M_{thrombin})/\text{percent } M_u] \times 100$, where M_u is mepacrine uptake and $M_{thrombin}$ is percent of mepacrine left in tube 10.

Parameter	Reference range
Mepacrine uptake	54 to 84%
Mepacrine release	58 to 93%
CD62P (P-selectin)	0 to 12%
CD62P + ADP	33 to 86%

Notes (mepacrine portion of panel)

1. No fixing is required, since fixing prevents mepacrine uptake.
2. Mepacrine fluorescence decreases with time. Immediate analysis is required.
3. Dilution of sample blood minimizes platelet aggregation.
4. Platelet-specific antibodies can be used as a gating tool (such as CD61).
5. Carefully monitor the light scattering aspects of the platelets since they can be large or small. Large platelets from

10				Thrombin added for platelet activation and mepacrine increase

[a]A negative control tube is unstained (autofluorescence).

giant platelet syndrome can be mistaken for RBCs or lymphocytes, and thus a platelet identifier is requisite.

6. Specimens should be scheduled with the laboratory so that patient and normal patient control specimens can be drawn immediately prior to processing.

7. Overall interpretation requires knowledge of the clinical setting and recent history of medications that might interfere with platelet function, such as nonsteroidal anti-inflammatory drugs.

Idiopathic thrombocytopenic purpura is primarily a disease of increased peripheral platelet destruction, with most patients carrying antibodies to specific platelet membrane glycoproteins, resulting in splenic sequestration and phagocytosis by mononuclear macrophages (12, 41). Destruction of the circulating platelets, combined with inadequate platelet production by bone marrow megakaryocytes, results in the decreased platelet count. The presence of platelet-associated antibodies (PAIgs) can be ascertained by flow cytometry (18). However, because of issues of sensitivity and specificity of PAIgs, clinical guidelines do not require demonstration of such antibodies (21). Thus, flow cytometry-based assays for PAIg have not become part of routine clinical assays in most laboratories.

Circulating activated platelets have been reported for several diseases, including myeloproliferative disorders, thrombocythemia, hypertension, cardiovascular diseases, diabetes, and polycythemia (38, 40). Flow cytometry using annexin V binding to the exposed aminophospholipids can be employed to monitor the activation process of the platelets during disease progression and treatment, such as for patients undergoing coronary angioplasty and stent implantation (71). Similarly, platelet activation studies have shown that patients with ischemic cerebrovascular disease display excessive platelet and/or endothelial cell activation (47). Furthermore, reticulated platelets (youngest circulating platelets) can be selectively assayed by staining the platelets with thiazole orange (an RNA dye) and gating against platelet-specific markers (e.g., CD42 or CD41) (49). The measurement of reticulated platelets can be used in the assessment of patients with idiopathic thrombocytopenic purpura and assessing bone marrow recovery after chemotherapy or transplantation (7, 19, 74). The latter studies are not routinely performed in our clinical laboratory.

Immunophenotyping of Leukemia and Lymphoma by Flow Cytometry

BRENT LEE WOOD

20

The diagnosis and classification of lymphoma and leukemia have improved greatly over the past two decades, in part due to the widespread application of immunophenotypic studies to hematopoietic neoplasms. As a result, flow cytometric and immunocytochemical studies have become increasingly important in the initial evaluation and subsequent posttherapeutic monitoring of leukemia and lymphoma. The impact of immunophenotypic studies is reflected by their incorporation into current leukemia and lymphoma classifications, beginning with the Revised European-American Lymphoma classification in 1994 (33) and, more recently, in the proposed World Health Organization (WHO) classification (32) (see Tables 1 to 3). An important component of both of these classifications is the stratification of hematopoietic neoplasms by their lineage, i.e., B cell, T cell, or myeloid, and degree of differentiation, features which are in part immunophenotypically defined. Additionally, a number of specific entities are in large part defined by their immunophenotypic profile, e.g., chronic lymphocytic leukemia. Reflecting this importance, guidelines for the use of flow cytometry in the clinical laboratory for the immunophenotyping of leukemic cells have been published (65), and a National Institutes of Health-sponsored conference on the flow cytometric analysis of leukemia and lymphoma was convened in 1995 to attempt standardization of clinical practice (15). Despite these efforts, flow cytometric immunophenotyping of leukemia and lymphoma remains poorly standardized, and significant variation exists between laboratories in terms of methods of specimen preparation, panels of reagents used, methods of data analysis, and reporting of results.

The medical indications for the use of flow cytometric leukemia and lymphoma immunophenotyping in a clinical setting continue to be defined, but three general areas have been identified (21). (i) At a minimum, flow cytometry allows improved reproducibility in the diagnosis and classification of hematopoietic neoplasms, particularly for chronic lymphoproliferative disorders and acute leukemias, and is widely used for this purpose. (ii) Additionally, flow cytometry can evaluate for the presence of biological parameters associated with therapeutic response or outcome, for example, an increased proliferative rate in neoplastic plasma cells (70) or increased CD38 or Zap-70 expression by the neoplastic cells in chronic lymphocytic leukemia (19, 20), immunophenotypic features both associated with a poorer clinical outcome. (iii) Finally, the presence of residual neoplastic cells following therapy can be detected by flow cytometry with a sensitivity down to 0.01% of cells analyzed. Increasing evidence suggests that the persistence of small residual neoplastic populations after therapy is of clinical significance, and the topic continues to be an active area of investigation (17).

INSTRUMENT SETUP AND SPECIMEN PREPARATION

The general principles and procedures for instrument setup and specimen handling are similar to those used for lymphocyte immunophenotyping (64), as discussed in the previous chapter, and are only summarized here, with an emphasis on areas of particular importance to leukemia and lymphoma immunophenotyping.

Biohazard Precautions

Universal biohazard precautions should be used with all specimens, as is standard clinical laboratory practice. This should include the use of laboratory coats and gloves by all laboratory personnel, biological safety cabinets or similar containment devices for specimen manipulation, and avoidance of sharp or potentially sharp materials. Following specimen preparation and prior to analysis, a fixative such as 0.5 to 2% (vol/vol) paraformaldehyde or formaldehyde is commonly added both to stabilize the specimen if analysis is delayed and to inactivate potentially infectious agents. Most current benchtop flow cytometers used in the clinical laboratory are closed systems, unlike cell sorters or older flow cytometers, so aerosolization during analysis is not an important issue. Additional protection during disposal of instrument waste may be provided by the routine addition of bleach at a final concentration of 10% to the instrument's waste receptacle.

Instrument Setup

Optimization and standardization of instrument performance on a daily basis are very important in the immunophenotypic analysis of leukemia and lymphoma (84). Unlike lymphocyte immunophenotyping, where the antigens detected generally result in relatively bright and consistent fluorescence intensities between samples, the intensity of

antigen expression on neoplastic cells is highly variable. Consequently, it is critical that the instrumentation be capable of reliably resolving a wide range of fluorescence intensities in a reproducible manner. On a daily basis, stable optical alignment should be verified using brightly fluorescent microbeads with low and well-defined coefficients of variation (CV), and optimization should be performed if the CV exceed expected values. Fluorescence intensity must also be standardized by adjusting photomultiplier tube (PMT) voltages to provide a consistent level of fluorescence using a stable fluorescence standard, typically a single brightly fluorescent microbead. The PMT voltage should have been initially set so that the autofluorescence of the least autofluorescent population of interest fills the first decade of the logarithmic scale. In actual practice, no significant changes in PMT voltages should be required on a day-to-day basis, and if significant variation is seen, instrument maintenance is required. It is also important to verify the instrument's ability to resolve low-level fluorescence from background noise, a process accomplished by comparing the autofluorescence of unstained lymphocytes to a nonfluorescent bead. On a periodic basis, either weekly or monthly, the linearity of the system should also be verified by using a series of microbeads having defined fluorescence intensities that range from zero to very bright. Linear regression analysis of measured versus actual fluorescence not only confirms the linearity of the system but also provides additional information on the level of instrument noise, the minimum level of fluorescence the instrument is capable of resolving, and the number of decades of fluorescence detected. Such evaluation should be a scheduled part of the routine instrument quality control program.

Multiple fluorochromes, generally three to five, are commonly used simultaneously in the analysis of leukemia and lymphoma. Since most fluorochromes used in flow cytometry have overlapping emission spectra, determination of the fluorescence due to a single fluorochrome requires subtraction of a portion of the signals produced by each of the other fluorochromes from the measured signal, a process performed on the linearized data and termed compensation. The appropriate amount of each signal to subtract, i.e., compensation coefficients, may be represented by an $n \times n$-dimensional matrix where n is the number of fluorochromes. Consequently, as the number of fluorochromes used increases, the number of compensation coefficients that must be determined increases geometrically.

The correct determination of the compensation coefficients is critical for the resolution of weakly fluorescent signals, i.e., low-level antigen expression, and for consistent fluorescence intensities when antibodies are used in multiple combinations (78). To determine the compensation coefficients, a sample is individually labeled with a series of fluorescent molecules or antibodies, one for each fluorochrome to be used, having spectral characteristics identical to those that are to be assayed. The intensity of the fluorescent signal used must be at least as bright as the brightest signal to be measured for each fluorochrome. Antibody capture beads may be used for this purpose but are not entirely equivalent to fresh cells, and settings generated by their use should be confirmed using cells. As each labeled sample is run through the instrument, the compensation coefficients are adjusted to give identical medians between the positive and negative populations for each combination of fluorochromes. The use of mean values, either arithmetic or geometric, while common, is not appropriate since the populations are not normally distributed and often contain outliers that unduly influence the mean. This form of "hardware" compensation can be quite laborious when more than three fluorochromes are used simultaneously, as the number of parameters to evaluate increases dramatically and interactions between the parameters can be surprisingly nonintuitive. In addition, when tandem conjugate dyes, e.g., phycoerythrin (PE)-Texas red, PE-Cy5, etc., are used, the spectral characteristics of the dyes can vary significantly between lots, requiring separate compensation coefficients for each lot of these reagents. For these reasons, "software" compensation methods have been developed which are rapid, offer the ability to save and conveniently apply tube-specific compensation settings, and give superior quality compensation (2). The newer generation of flow cytometers has software compensation incorporated into their systems, although third-party software is also available for offline compensation and analysis. Regardless of the compensation method used, the appropriateness of the compensation settings should be validated daily by the visual inspection of data.

Specimen Handling

Immunophenotyping of leukemia and lymphoma may be performed on any specimen from which a single cell suspension can be generated, including peripheral blood, bone marrow, lymph node, body fluids, tissue, etc. Peripheral blood and bone marrow specimens must be anticoagulated; EDTA, heparin, and acid-citrate-dextrose (ACD) are the anticoagulants most frequently used. Heparin and ACD offer improved stability when the specimen is greater than 12 to 24 h old, as specimens in EDTA will show a progressive loss of myeloid cells. However, ACD should not be used for bone marrow specimens, as it may cause viability problems related to change in pH (86). Specimens should generally be stored at room temperature (16 to 28°C) prior to analysis, although refrigeration will retard degradation when analysis must be delayed.

Specimens containing large numbers of erythrocytes, particularly peripheral blood and bone marrow, require erythrocyte removal to allow efficient analysis of white blood cells. Historically, density gradient centrifugation with Ficoll-Hypaque was used to generate a cell suspension enriched for lymphocytes and/or blasts. While still sometimes used in a research setting, this method results in the selective loss of some cell populations (76) and has largely been replaced by erythrocyte lysis techniques using a variety of commercial and noncommercial preparations (18), of which ammonium chloride is the most common. Current recommended methods involve the addition of antibodies to an aliquot of blood or marrow, followed by erythrocyte lysis, and washing with a buffered salt solution such as phosphate-buffered saline to remove cell debris, the lysing reagent, and unbound antibody. This method allows for rapid specimen preparation and is convenient to use in the clinical laboratory. However, the binding of certain antibodies may be differentially affected by lysing reagents, resulting in either increased or, more commonly, decreased binding depending on the antibodies and lysing reagents involved (57). Addition of a small amount of fixative, i.e., 0.25 to 0.5% formaldehyde, during lysis can minimize these changes and stabilize the specimen. In addition, the degree of erythrocyte lysis may vary between tubes, sometimes dramatically, and serum must be washed away prior to antibody addition for samples in which immunoglobulin light-chain antibodies are to be used. Consequently, a common variation of this method involves performing bulk erythrocyte lysis on a large volume of the specimen followed by washing, aliquoting, addition of antibodies, and washing. This method

eliminates the effect of the lysing reagent on antibody binding, allowing more reproducible binding, and allows consistent specimen processing for all antibodies used, including immunoglobulin light-chain antibodies. This is provided that the lysing reagent does not result in the destruction of antigenic sites, an infrequent problem. However, erythrocyte lysis does result in some destruction of white blood cells, particularly neutrophils, and the activation of some cell populations, such as monocytes, which then may nonspecifically bind antibodies and result in increased background, as well as altering the native expression patterns of some antigens. Additionally, certain tandem fluorochromes, in particular Cy7-containing tandems, may show degradation with this method of sample preparation. All erythrocyte lysis methods also result in some loss of nucleated red cell precursors, distorting the composition of the sample evaluated, particularly for bone marrow. Consequently, an ideal system for erythrocyte removal has not yet been developed.

Tissue specimens are best collected and transported in tissue culture medium (RPMI 1640) at either room temperature or 4°C, if analysis will be delayed. The sample is then disaggregated to form a single cell suspension, either by mechanical dissociation or by enzymatic digestion. Mechanical dissociation is preferred and is accomplished by the use of either a scalpel and forceps, needle and syringe, or wire mesh screen (13) followed by filtration through a fine-gauge wire mesh screen. Antibodies can then be added to the resulting suspension and processed as usual.

Data Acquisition

It is important during acquisition of the sample to collect enough events to allow detection of populations of the desired frequency. For populations that represent a large percentage of the total, relatively few total events need to be acquired, while the converse is true for infrequent populations. Consequently, unless the operator monitors the data in real time and terminates acquisition when a population of interest is well defined, one must decide before acquisition how many events will be collected. One strategy is to collect a specified number of events of some subpopulation of interest, e.g., 10,000 lymphocyte events. This guarantees that a sufficient number of events will be acquired for that subpopulation, but since the frequency of that subpopulation can vary significantly between samples, the total number of events collected and acquisition time can vary tremendously. Also, if an unexpected abnormal population is detected, the number of events may be insufficient for analysis. An alternative method is to acquire a consistent total number of events to achieve a desired degree of sensitivity; e.g., if the ability to detect a population having a frequency of 0.1% is desired and 100 events is determined to be adequate for confident identification, then 100,000 total ungated events would need to be collected. The precision of such a measurement can be estimated from Poisson statistics, given that the $CV = \sqrt{N}/N$ where N is the number of events in the population. This approach allows for consistency in both the number of events collected and acquisition time with little interaction from the operator, but it will collect an unnecessarily large number of events when the population of interest has a high frequency and will result in generally longer acquisition times. A third alternative is to screen the sample with a limited panel of reagents and perform gated acquisition on a subpopulation of interest as a second step, generally on a second separately prepared aliquot. In gated acquisition, only events within the gate of interest are collected and all others are excluded from the listmode file, a strategy primarily used to reduce the size of the resulting listmode file when examining populations of low frequency. However, as a consequence, any events outside of the acquisition gate are not present at analysis and the determination of population frequencies is not possible without reference to the initial screening aliquot. In addition, the expenditure of reagents and preparation time may be significantly increased and the overall work flow becomes recursive, making laboratory operation less efficient.

Instrument carryover of material between samples can become an important consideration when populations of low frequency are evaluated. Many instruments have a manufacturer's specification for carryover of roughly 1%, although most instruments will perform better than this if properly maintained. However, the accumulation of material in instrument tubing does occur to some degree and can manifest as sporadically increased carryover or ultimately as a "plug." This sporadic carryover can result in the appearance of unusual subpopulations of low frequency, depending on the combination of reagents in the preceding sample, and lead to erroneous analysis. To minimize this, a small amount of water may be run through the instrument between each aliquot of sample until the count rate returns to a normal background level.

A final consideration is the rate of sample aspiration. While it is desirable to acquire samples as quickly as is reasonably possible to minimize the use of instrument time, certain instruments are not capable of accurately evaluating specimens at rates over roughly 1,000 events/sec. In addition, at increased sample event rates, the phenomenon of coincidence, i.e., the occurrence of two particles simultaneously in the laser path, becomes increasingly frequent and the use of coincidence correction techniques becomes mandatory.

PATTERNS OF ANTIGEN EXPRESSION

The detection of hematopoietic malignancies by flow cytometry relies on the principle that neoplastic cells express antigens in patterns recognizably different from those of normal hematopoietic cells. Antigen expression in normal cells is tightly regulated, with each antigen following a predictable pattern of expression during cell maturation and activation. In neoplastic cells, this pattern of expression is altered in nonrandom ways that differ from normal, allowing the identification, quantitation, and immunophenotypic characterization of the abnormal population. Patterns of abnormal antigen expression that commonly occur include the following: (i) a gain of antigens not normally expressed by the cell type or lineage (if the abnormally expressed antigen is characteristically expressed by another lineage, this is termed lineage infidelity); (ii) asynchronous antigen expression where antigens normally present on a given cell lineage are expressed at inappropriate times during maturation or activation; (iii) abnormally increased or decreased levels of normal antigens, which in some cases may be entirely absent; and (iv) abnormally homogeneous expression of one or more antigens by a population that normally exhibits more heterogeneous expression. Together, these abnormalities give rise to abnormal maturational patterns or populations that are commonly visualized using two-parameter dot plots. Consequently, the flow cytometric analysis of hematopoietic neoplasms involves a thorough knowledge of the normal patterns of antigen expression on hematopoietic subpopulations, as well as a knowledge of the patterns of expression commonly seen on the ever-expanding variety of hematopoietic neoplasms.

Patterns of Normal Antigen Expression

B-cell maturation occurs largely in the bone marrow through a series of discrete stages characterized by increasing intensity of CD45 expression, gradual acquisition of the mature B-cell antigens CD20, CD21, and CD22 and immunoglobulin light chains, and loss of immature antigens such as CD34, terminal deoxynucleotidyl transferase (TdT), and CD10 (51, 52, 54). Expression of bright HLA-DR and moderate CD19 are present throughout maturation, with some variability in intensity. The least mature stage shows the lowest level of CD45 and expresses both CD34 and nuclear TdT with bright CD10, slightly decreased HLA-DR and CD19, low CD22, and no expression of CD20 or surface or cytoplasmic immunoglobulins. The second stage shows a loss of CD34 and nuclear TdT with a mild reduction in CD10, acquisition of variable CD20 and brighter CD22, an increase in CD45, and slightly increased CD19. Immunoglobulins are acquired at this stage as cytoplasmic immunoglobulin M and are subsequently expressed in combination with kappa or lambda light chains on the surface with maturation. The final stage shows a loss of CD10; further increases in CD20, CD22, and surface immunoglobulins; and the brightest expression of CD45, with a slight decrease in CD19. At all stages, the degree of right-angle light scatter is quite low, although larger forms with a variable degree of increased forward and side scatter are present. Myeloid-associated antigens such as CD13 and CD33 are not usually expressed at any stage of B-cell maturation but may be seen at a very low level in immature stages in some cases.

Mature B cells are present largely in lymph nodes but may be seen in lower numbers in peripheral blood and bone marrow. They are characterized by the expression of bright CD45, the B-cell antigens CD19, CD20, CD21, and CD22, and surface light chains (35). Mature B-cell populations normally consist of a mixture of subsets expressing either surface kappa or lambda light chains with a relatively constant kappa/lambda ratio of 1.4. Within lymph nodes, there is often a discrete subset exhibiting expression of low-level CD10 and brighter CD20 and CD45 corresponding to a subset of germinal center B cells. Populations with this immunophenotype are not normally found in marrow or peripheral blood. Plasma cells represent the terminal stage of B-cell maturation and have a unique immunophenotype characterized by decreased expression of many mature B-cell antigens, including CD45, CD19, and surface light chains, with a complete loss of CD20, and very bright expression of the activation antigen CD38 (31, 92).

T-cell maturation occurs predominantly in the thymus through a series of discrete stages (28). The least mature T cells are characterized by the expression of the pan-T-cell antigens CD2, CD5, and CD7 in combination with expression of CD34 and nuclear TdT. In the subsequent common thymocyte stage of maturation, the cells acquire the coexpression of CD4 and CD8 in conjunction with cytoplasmic CD3 and the common thymocyte antigen CD1a, and they lose expression of CD34 and TdT. Subsequently, the T cells begin to express either CD4 or CD8 in combination with surface CD3 and lose expression of CD1a, the immunophenotype seen in mature T cells. A population of mature T cells normally consists of a mixture of cells expressing either CD4 or CD8 in a relatively constant ratio of between 1:1 and 3:1. The CD4- and CD8-positive subsets also exhibit slight differences in their expression of some pan-T-cell antigens, including generally decreased expression of CD3 and CD5 on the CD8 T cells and more variable expression of CD7 on the CD4 T cells (91). Upon activation, shifts in the

intensity of a variety of these antigens may be seen, in addition to the acquisition of additional antigens, such as HLA-DR, CD25, and CD69. These findings apply largely to T cells expressing the αβ form of the T-cell receptor, which represent the majority of mature lymphocytes. However, a small subset of T cells expressing the γδ T-cell receptor is also often present in increased numbers in reactive states and is characterized by a mature T-cell immunophenotype with expression of brighter CD3, variably decreased CD5, variable low-level CD56, and either no CD4 or CD8 or variable low-level CD8 (36, 62).

NK cells represent a lymphocyte population closely related to T cells, but with a distinct immunophenotype which includes the expression of bright CD7, intermediate CD2, low variable CD8 αα-homodimer, and coexpression of CD56, CD11b, and CD16, without the expression of other mature T-cell antigens, including CD3, CD5, or CD4 (28). NK cells also typically exhibit slightly decreased CD45 and slightly increased right-angle light scatter relative to other lymphocytes.

In contrast to lymphocytes, myeloid cells exhibit a more continuous pattern of antigen expression during maturation (90, 93). Myeloid blasts are readily identifiable by their decreased expression of CD45, mildly increased right-angle side scatter, and expression of intermediate CD34, variable CD13, variable CD33, variable HLA-DR, variable CD38 and CD133, and low CD117. These blasts do not express more mature myeloid antigens such as CD11b, CD14, CD15, or CD16. As the blasts mature to promyelocytes, they exhibit markedly increased right-angle light scatter, gain increased autofluorescent background, begin to express the more mature myeloid antigens CD64 and CD15, and lose expression of HLA-DR, CD34, and CD117. Further maturation toward mature neutrophils results in the increased expression of CD45, CD11b, and CD15, slightly decreased right-angle light scatter and expression of CD64 and CD33, and abrupt acquisition of increasingly bright CD16 at roughly the metamyelocyte stage. CD13 exhibits a variable pattern of expression, with expression at an intermediate level on blasts, increased expression on promyelocytes, and decreased expression through the myelocyte stage, followed by a marked increase with maturation to mature neutrophils. Mature neutrophils are characterized by the expression of bright CD11b, CD13, CD15, and CD16 and low CD33, CD14, and CD10.

Monocytes also mature from the myeloid blasts but retain a lower degree of right-angle light scatter than the neutrophilic lineage (90, 93). Mature monocytes are characterized by the expression of bright CD45, HLA-DR, CD11b, CD14, CD33, CD36, and CD64, with variable CD13 and low-level expression of CD15 and CD16. Immature monocytic forms exhibit patterns of antigen expression intermediate between blasts and mature monocytes, particularly with decreased expression of CD14, CD36, and CD45. CD56 is typically not expressed on immature or mature monocytes but may be seen in some reactive conditions.

Eosinophils have increased right-angle light scatter, with expression of bright CD11b and CD45, low CD33, and low CD15 and no expression of CD16 (90). Basophils are easy to identify by their relatively low right-angle light scatter, slightly decreased level of CD45 relative to lymphocytes, and expression of intermediate CD13 and CD33 without significant HLA-DR, CD15, CD16, or CD117 (95, 99). Most cells have an immunophenotype similar to that of basophils but are characterized by bright CD117 expression and increased right-angle light scatter (23, 24).

Patterns of Abnormal Antigen Expression

Most hematopoietic neoplasms have characteristic immunophenotypic profiles that allow for their detection. In some cases, the immunophenotypic profiles are specific enough to allow definitive classification using flow cytometric data alone (37). However, significant variability in antigen expression exists within each category, and proper diagnosis depends on the recognition of overall immunophenotypic patterns and not on the rigid application of these profiles. As a corollary, caution should be used in making a diagnosis or classification based on the abnormal expression of a single antigen.

Acute Leukemia

Acute leukemia is diagnosed when more than 20% (WHO criteria) (33) or 30% (French-American-British cooperative group [FAB] criteria) (4) of all nucleated cells in either bone marrow or peripheral blood are abnormal blasts. These leukemias are further subdivided based on their lineage of differentiation into acute myeloid leukemia (AML) or acute lymphoblastic leukemia (ALL), and ALL is further subdivided by lineage, with approximately 75 to 80% of ALLs being of B-cell origin and 20 to 25% being of T-cell origin. These subclassifications have therapeutic implications, and flow cytometry plays an important role in their diagnosis and classification.

AML is a clonal proliferation of abnormal myeloid blasts that in many cases retain a limited ability to differentiate along a neutrophilic, monocytic, erythroid, and/or megakaryocytic lineage. AML is more common in adults than children and in many cases is thought to arise from an underlying myelodysplastic syndrome (MDS) (34). The subclassification of AML historically has used primarily morphological criteria in combination with limited cytochemical staining to assign a predominant lineage of differentiation, the FAB classification (4). However, this method has limited clinical significance and influence on therapeutic decision making. More recently, cytogenetic findings have come to play an increasingly important role in AML subclassification and prognostication, and characteristic chromosomal translocations have been associated with differences in prognosis and response to therapeutic regimens (53) (see Table 1). Flow cytometric immunophenotyping is not formally included in current classification systems, but it does show characteristic findings in certain subsets of AML and is commonly used to confirm lineage.

Most AMLs have an immunophenotype similar to that of normal myeloid blasts, with the expression of the early myeloid antigens CD13 and CD33 in combination with HLA-DR, CD34, CD117, and low to intermediate CD45 (11, 55, 56, 75, 83, 94). However, the pattern of antigen expression on abnormal myeloid blasts may be more homogeneous than the usual variable expression of these antigens on normal maturing myeloid blast populations, consistent with their clonal nature. In addition, the intensity of these antigens is often abnormally increased or decreased to absent. The abnormal expression by myeloid blasts of more mature myeloid antigens such as CD11b or CD15 is seen in some cases, and expression of one or more antigens normally expressed on B or T lymphocytes, i.e., CD7, CD2, CD4, CD19, or CD56, occurs relatively frequently.

Certain subtypes of AML have been associated with characteristic immunophenotypic findings. Acute promyelocytic leukemia [AML-M3; t(15;17) AML] characteristically shows an absence of HLA-DR expression, as is seen in normal promyelocytes, with variably increased right-angle light scatter, frequent expression of CD2, and variable to absent

TABLE 1 WHO classification of AML

Classification
AML with cytogenetic abnormalities
t(8;21)(q22;q22) AML1(CBFa)/ETO
t(15;17)(q22;q11-12) PML/RAR-a
inv(16)(p13q22) or t(16;16)(p13;q11) CBFb/MYH11X
11q23 (MLL) abnormalities
AML with multilineage dysplasia (two or more lines)
Prior MDS
No prior MDS
AML and MDS therapy related
Alkylating agent related
Epipodophyllotoxin related
Other
AML, not otherwise categorized
AML with minimal differentiation
AML without maturation
AML with maturation
Acute myelomonocytic leukemia
Acute monocytic leukemia
Acute erythroid leukemia
Acute basophilic leukemia
Acute panmyelosis with myelofibrosis

expression of CD15 and CD34 (40, 67). AML containing t(8;21) is associated with the expression of bright CD34, and low nuclear TdT is associated with coexpression of CD19 and/or CD56 (71). AMLs having monocytic differentiation (AML-M4 and -M5) are often associated with a spectrum of differentiated forms between the low-CD45-positive myeloid blasts and more brightly CD45-positive mature monocytes, with the mature forms often increased in number. Monocytic blasts may also show bright CD33 and expression of one or more monocyte-associated antigens such as CD64, CD36, CD14 (highly specific but not sensitive), and CD4 (highly sensitive but not specific) (42). Acute megakaryocytic leukemia (AML-M7) generally shows the expression of the platelet antigens CD61 and/or CD41, although care must be taken to exclude the possibility of activated platelets adherent to the blasts as a cause for false positivity (5).

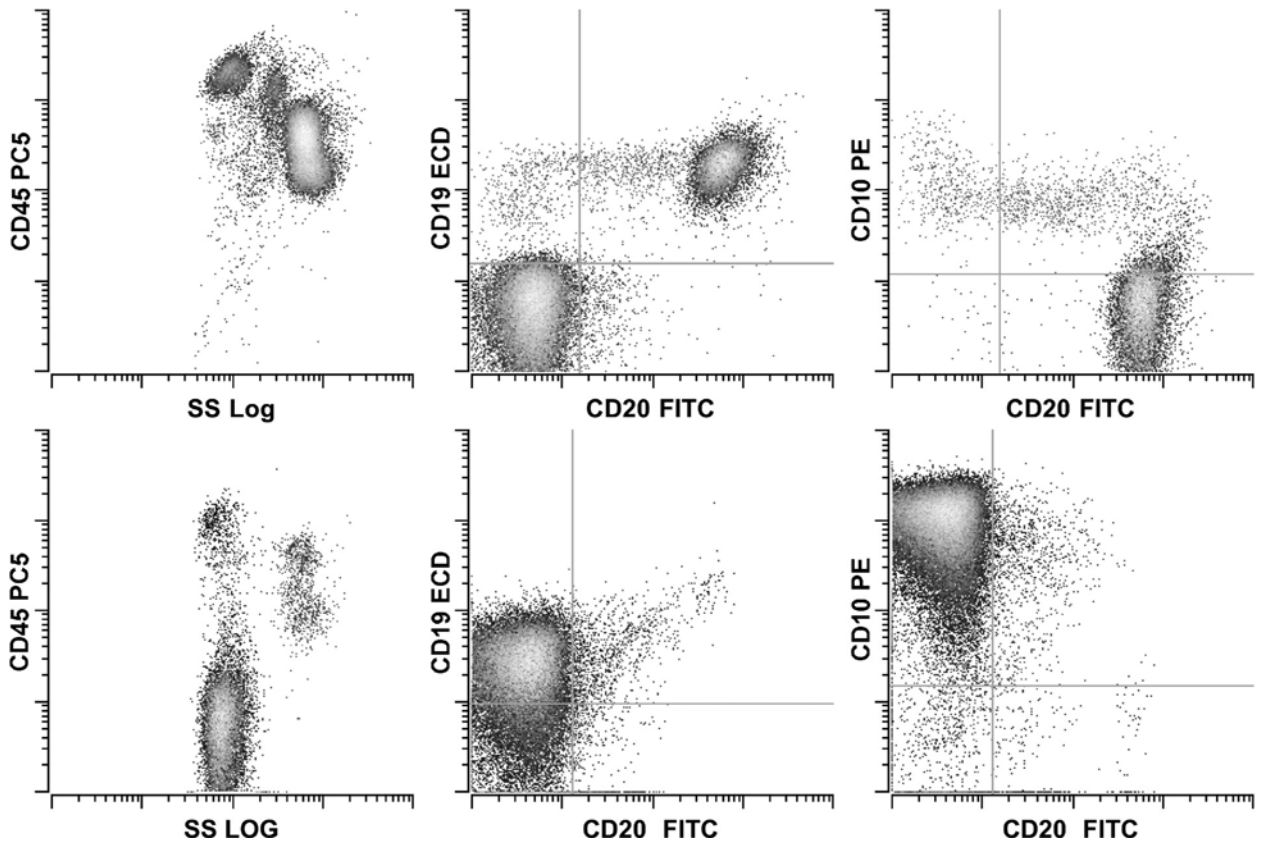
Precursor B-cell lymphoblastic leukemia/lymphoma (ALL of B-cell lineage) is composed of a clonal proliferation of immature B cells having an immunophenotype similar to that of its normal counterpart, i.e., expression of CD19, CD22, CD10, HLA-DR, CD34, and nuclear TdT and decreased CD45 and variable CD20 without surface light chains (10, 25, 97) (see Fig. 1). However, the neoplasm is generally relatively homogeneous in composition and often lacks the presence of discrete maturational stages characteristic of normal B-cell maturation. In addition, the intensity of one or more normal antigens is typically altered, with a common finding being increased CD10 or abnormally decreased or absent CD45, particularly in pediatric patients, for whom the latter abnormality may be correlated with prognosis (10). Often, antigenic combinations not seen during normal B-cell development are present (asynchronous expression). The low or absent expression of both CD9 and CD20 in ALL of B-cell lineage has been associated with the presence of t(12;21), a good prognostic feature (9). The myeloid antigens CD13 and CD33 may be abnormally coexpressed in a significant subset of pediatric (72) and adult (73) cases of ALL, without apparent clinical significance.


FIGURE 1 Normal B-cell maturation (upper row) versus precursor B-cell lymphoblastic leukemia/lymphoma (lower row). The dot plots display white blood cells (left), lymphocytes (center), or B cells (right). Note the small number of B-cell precursors in normal bone marrow relative to the large abnormal B-cell population lacking CD45 expression (bottom left) in the patient with leukemia. The abnormal B cells also show decreased expression of CD19 (bottom center) and increased CD10 without normal maturational acquisition of CD20 (bottom right). FITC, fluorescein isothiocyanate.

Precursor T-cell lymphoblastic leukemia/lymphoma (ALL of T-cell lineage) is composed of a clonal proliferation of immature T cells having an immunophenotype similar to that of a normal thymic counterpart (39). In contrast to that in normal thymus, the neoplastic population appears to be relatively homogeneous, often with an immunophenotype that does not correspond completely to any normal stage of maturation. Most cases express the early T-cell antigens CD2, CD5, and CD7 at some, often abnormal, level. CD4 and CD8 are usually both absent or coexpressed, in the latter case often in combination with CD1a, and surface CD3 is absent or weak, with invariable positivity for cytoplasmic CD3. CD45 is often expressed at a level higher than seen in immature B cells but slightly lower than seen in mature lymphocytes. Nuclear TdT and CD34 may also be present and can help confirm the immature nature of the process, if present. Given that the immunophenotype may be similar to that of normal thymocytes, one must be cautious about making this diagnosis in material from an anterior mediastinal mass, as the lymphocytic component of a thymoma may appear to be somewhat similar.

Mixed-lineage leukemia is an ill-defined concept, but it is minimally characterized by some authors as the expression of at least two myeloid and at least two lymphoid antigens on leukemic blasts. In most cases, examination of the overall surface immunophenotype and/or evaluation for lineage-associated cytoplasmic antigen expression, i.e., myeloperoxidase for myeloid, CD22 or CD79a for B cell, or CD3 for T cell, is able to assign a predominant lineage (16, 30, 59). Consequently, this designation should be used only for cases where the lineage remains uncertain after complete immunophenotyping including cytoplasmic antigen detection. A rare form of acute leukemia containing separate discrete subsets of abnormal myeloid and lymphoid blasts can occur and is better termed acute bilineage leukemia.

The analysis of MDSs by flow cytometry has recently been evaluated, and a number of abnormalities of surface antigen expression on blasts and maturing myeloid cells have been described (22, 46, 98) (see Fig. 2). High-grade myelodysplasia (refractory anemia with excess blasts in the WHO classification) is a precursor to AML and is characterized by the presence of between 5 and 20% blasts with at least two of three marrow cell lineages exhibiting abnormal morphological findings. Consequently, high-grade MDS is usually readily identifiable by the presence of an increased myeloid blast population having an abnormal immunophenotype similar to those seen in AML, but which represents less than 20% of the nucleated cells. Consequently, the overall flow cytometric approach to MDS mirrors that used for AML. In addition, the maturing myeloid forms may show
FIGURE 2   Normal myeloid maturation (upper row) versus MDS (lower row). The dot plots display white blood cells (left), blasts (center), or maturing myeloid cells (right). Note the decrease in side scatter on the maturing myeloid population in myelodysplasia, as indicated by the shift of the maturing myeloid cells to the left so that they overlap the monocytes. The blasts (center) show an increase in HLA-DR expression, and the maturing myeloid cells (right) show an aberrant expression pattern of CD13 and CD16 in myelodysplasia. Note the small number of myeloid cells having normal maturation in the background. SS, side scatter; PB, Pacific Blue.

decreased right-angle light scatter corresponding to morphological hypogranularity, increased numbers of immature forms with increased CD45, asynchronous expression of maturational myeloid antigens CD11b, CD13, CD15, CD33, and CD16, and/or abnormal expression of nonmyeloid antigens such as CD56. The monocytic population may exhibit similar abnormalities, with expression of CD56 being relatively common but not specific. Low-grade myelodysplasia (refractory anemia with or without ringed sideroblasts in the FAB classification) is a more heterogeneous category predominantly characterized by unexplained anemia with minimal morphological abnormalities. While abnormalities similar to those seen in high-grade MDS may be present, blasts are not significantly increased in number and the erythroid lineage is predominantly affected so the myeloid cells may not show demonstrable abnormalities, including myeloid blasts. Rates of proliferation and apoptosis are quite high in low-grade myelodysplasia and decline with progression to higher-grade myelodysplasia (68).

Myeloproliferative disorders have not been well studied by flow cytometry, but abnormalities similar to those seen in MDS can be identified in some cases (45). Myeloid blasts are not generally increased in number but may show immunophenotypic abnormalities, and abnormal CD56 expression on maturing myeloid and monocytic forms is relatively common, particularly in chronic myeloid leukemia (CML) (48). The findings are often subtle, and few data exist to support flow cytometry as a primary method for the diagnosis of these disorders. However, acute leukemia may arise from myeloproliferative disorders as a result of transformation over time, an inevitable occurrence with CML but relatively infrequent otherwise. Blast crisis of CML may be of either lymphoid or myeloid lineage, an important therapeutic distinction, with a higher incidence of cases showing mixed myeloid and lymphoid surface antigen expression (38).

Non-Hodgkin's Lymphoma

Non-Hodgkin's lymphomas are neoplasms composed of clonal proliferations of mature B cells, T cells, or NK cells. Current classification systems stratify lymphomas in part on their morphological and/or immunophenotypic similarities to normal components of the immune system (32, 33) (see Tables 2 and 3). Given the complexity of the immune system, the variety of immunophenotypic alterations that may be seen with activation, and the similarity of neoplastic lymphoid immunophenotypes to normal counterparts, the demonstration of clonality is an important part of the diagnosis of these disorders. However, it is critical to recognize

Burkitt's lymphoma/leukemia

that the members of the immune system normally undergo clonal expansion as part of the immune response, and consequently, clonality does not necessarily equate with malignancy for lymphocytic proliferations (44).

The flow cytometric demonstration of clonality can be achieved most easily for B-cell neoplasms (14, 26). A normal mature B-cell population consists of a mixture of cells expressing immunoglobulins with either surface kappa or lambda light chains in a ratio of roughly 1.4:1. Consequently, the identification of a discrete B-cell population showing expression of either only kappa or lambda light chains is evidence for clonality. A common technique is to calculate the kappa-to-lambda ratio for the total B cells and compare this with numerical cutoffs determined from the examination of a series of normal or reactive lymphoid tissues (27). More sophisticated mathematical procedures have also been used with minimal improvement on this basic idea (3, 74). While these methods successfully identify the presence of B-cell

lymphoma when the clonal population represents the majority of the B cells in the specimen, it has poor sensitivity when the clonal population represents a smaller subset of the B cells, a relatively common occurrence (82). Another method is to overlay single-parameter histograms for kappa and lambda light-chain expression and look for differences in the distribution of intensity that can herald the presence of a clonal subpopulation. While this method is more sensitive, it requires that kappa and lambda be evaluated using the same fluorochrome and hence must be set up in separate tubes, making it difficult to account for nonspecific and/or Fc receptor-mediated immunoglobulin binding. Such undesirable light-chain binding can readily be accounted for by the inclusion of both kappa and lambda in the same tube of reagents. All methods are significantly improved by the incorporation of additional light scatter and immunophenotypic information obtained from multiparametric flow cytometry. At a minimum, this should include the presence of a B-cell-lineage antigen, i.e., CD19 or CD20, in every tube containing light-chain antibodies (49). The analysis of such data is best performed by the visual examination of two-parameter histograms to attempt the detection of discrete abnormal subpopulations rather than relying on numerical cutoffs.

In addition to the determination of clonality, a variety of characteristic abnormal immunophenotypes have been described for B-cell lymphoproliferative disorders that aid in their classification. In B-cell chronic lymphocytic leukemia/small lymphocytic lymphoma (CLL/SLL), the abnormal B cells express the T-cell-lineage-associated antigen CD5 in combination with dim CD20, dim CD22, dim surface light chain, and moderate to bright CD23, with little to no expression of FMC7 (41, 61, 96). The expression of CD38 and/or Zap-70 on the neoplastic B cells has been associated with a poorer prognosis in recent studies (13, 54). Mantle cell lymphoma has a similar immunophenotype but is characterized by coexpression of CD5 with brighter CD20, CD22, and surface light chains than seen in CLL/SLL, with bright expression of FMC7 and a lack of CD23 (96). Hairy cell leukemia has a diagnostic immunophenotype which includes increased forward- and right-angle light scatter and bright expression of CD19, CD20, CD22, and surface light chains, with coexpression of CD103, CD25, and bright CD11c (60, 77). Follicle center cell lymphoma has a somewhat variable immunophenotype but often exhibits mildly decreased expression of CD19, bright CD20, CD38, and variable light chains, with coexpression of the follicle center-associated antigen CD10 detectable in 60% of the cases (1). Marginal-zone and lymphoplasmacytoid lymphomas lack characteristic immunophenotypes at present. Large B-cell lymphomas are a heterogeneous category but generally show increased forward- and right-angle light scatter with light-chain expression of variable intensity, including occasionally a complete loss of surface light chains. Burkitt's lymphoma/leukemia has an immunophenotype similar to that seen in follicle center lymphoma, including the frequent expression of CD10.

The determination of clonality by flow cytometry has recently been described for T-cell or NK-cell neoplasms, utilizing T-cell receptor Vβ subset or killer inhibition receptor subset antibodies, respectively (50, 63). However, their diagnosis most frequently depends on the demonstration of abnormal immunophenotypes, usually the gain or loss in intensity of an antigen normally expressed by that cell type (29, 69). Most peripheral T-cell lymphomas arise from the CD4-positive mature T-cell subset, although CD8-positive

forms are occasionally seen (58). In mycosis fungoides/Sézary syndrome, the abnormal mature T cells characteristically express CD4 with a loss of CD7, a memory T-cell immunophenotype (6, 43). However, considerable variability in the expression of all mature T-cell antigens may be seen, and this disorder cannot be distinguished from other peripheral T-cell lymphomas by immunophenotype alone. Hepatosplenic γδ T-cell lymphoma can be readily identified by an immunophenotype similar to that of its normal counterpart and its expression of the γδ T-cell receptor, in contrast to the expression of the αβ form seen in most other peripheral T-cell lymphomas (81). Large granular lymphocytic leukemia is typically composed of a proliferation of CD8-positive mature T cells (CD3 positive) having variably decreased expression of CD5 with variable expression of cytotoxic antigens, including CD57 and, less consistently, CD16 and/or CD56 (47). The less common NK-cell form of large granular lymphocytic leukemia, now termed aggressive NK-cell leukemia, has a typical NK-cell immunophenotype, commonly with the abnormal expression of CD2, CD7, CD11b, or CD16 and/or CD56, without expression of the T-cell antigens CD3 and CD5. Considerable care must be taken when using immunophenotypic findings to diagnose T- and NK-cell neoplasms, as both populations may possess a variety of small reactive clonal subpopulations with unusual immunophenotypes and a variety of activation states having immunophenotypic alterations which can be mistaken for neoplasia.

Plasma cell neoplasms characteristically express moderate to bright CD38 with decreased to absent CD45, absent CD19, surface or, more commonly, cytoplasmic light-chain restriction, and coexpression of CD56 in 60% of the cases (66, 80). Similar to normal plasma cells, they lack expression of CD20. Abnormalities of DNA ploidy are also common in plasma cell myeloma and may be detected by flow cytometry in combination with immunophenotypic studies to enhance the identification of abnormal plasma cell populations.

REAGENT SELECTION

The construction of panels of reagents for the diagnosis of hematopoietic neoplasms requires the balancing of multiple, sometimes conflicting, objectives (88). Antibodies commonly used for the diagnosis of acute leukemia and non-Hodgkin's lymphoma are listed in Tables 4 and 5. The selection of reagents is largely determined by three basic considerations: the number of simultaneous fluorophores used, the availability of reagents, and the strategy used for population identification. In general, weakly expressed antigens should be coupled with bright fluorophores to maximize their detection, and conversely, brightly expressed antigens should be coupled with weaker fluorophores to maintain the expected range of fluorescence within the dynamic range of the instrument.

The number of simultaneous fluorochromes used is in part determined by the instrument which will be used, with most current instruments allowing up to four simultaneous fluorochromes and more advanced instruments allowing six or more. In general, the greater the number of fluorochromes used, the more specifically one can identify normal and abnormal populations of cells, particularly when they represent small percentages of the total. However, this comes at the cost of increasing technical complexity for both instrument setup and data analysis. The advent of simplified single-laser and multilaser benchtop instruments, the availability of both hardware and software methods to deal with

TABLE 4 Antibodies commonly used in the diagnosis of acute leukemia

Designation	Specificity
CD1	Common thymocyte, early T cells, Langerhans cells
CD2	Pan T cell, NK cells
CD3	Mature pan T cell
CD4	Helper/inducer T cells
CD5	Pan T cell, subset of B cells
CD7	Pan T cell, 25% of AML
CD8	Cytotoxic/suppressor T cell
CD10	Immature B cells, mature granulocytes
CD11b	Maturing myeloid cells
CD13	Myeloid cells
CD14	Maturing monocytes
CD15	Maturing myeloid cells
CD16	Granulocytes, NK cells
CD19	Pan B cell
CD20	Maturing B cells
CD22	Maturing B cells
CD33	Myeloid cells
CD34	Immature hematopoietic cells, stem cell
CD41	Glycoprotein IIb/IIIa, platelets, and megakaryocytes
CD45	Leukocyte common antigen
CD56	NK cells, some stem cell disorders
CD61	Glycoprotein IIb/IIIa, platelets, and megakaryocytes
CD64	Monocytes, activated granulocytes
CD117	Myeloid and erythroid blasts
CD133	Immature hematopoietic cells, stem cell
HLA-DR	Myeloid blasts, B cells, activated T cells

TABLE 5 Antibodies commonly used in the diagnosis of non-Hodgkin's lymphoma

Designation	Specificity
CD1	Common thymocyte, early T cells, Langerhans cells
CD2	Pan T cell, NK cells
CD3	Mature pan T cell
CD4	Helper/inducer T cells
CD5	Pan T cell, subset of B cells
CD7	Pan T cell
CD8	Cytotoxic/suppressor T cell
CD10	Immature and germinal center B cells
CD11c	Hairy cell leukemia, some marginal-zone lymphoma
CD19	Pan B cell
CD20	Maturing B cells
CD22	Maturing B cells
CD23	Activated B cells
CD38	Plasma cells
CD45	Leukocyte common antigen
CD56	NK cells
CD79b	B cells
CD103	Hairy cell leukemia
FMC7	B-cell lymphoma other than CLL/SLL
Kappa light chain	Mature B cells
Lambda light chain	Mature B cells

compensation, and a proliferation of software for off-line data analysis have greatly simplified these tasks. Consequently, it has been recommended that a minimum of three simultaneous fluorochromes, in addition to two light scatter parameters, be used for the diagnosis of hematopoietic neoplasms, with four fluorochromes preferred.

In a three-color analysis, the commonly used fluorochromes are fluorescein isothiocyanate, PE, and either PE-Cy5 or PerCP-Cy5.5. PE-Cy5 produces a brighter signal than PerCP-Cy5.5 but is a tandem conjugate dye and requires more compensation due to variable PE emission/leakage. A large number of antibodies are now available in these fluorochromes from a variety of manufacturers, with the exception of PerCP-Cy5.5, allowing a wide variety of useful antibody combinations. The additional fluorochrome used in a four-color combination depends largely on instrumentation, with PE-Texas red used on single-laser instruments and allophycocyanin (APC) used on dual-laser instruments. PE-Texas red is a tandem dye that is difficult to manufacture reproducibly with low PE leakage and requires significant compensation due to a high degree of spectral overlap with both PE and PE-Cy5 or PerCP-Cy5.5. However, an increasing number of useful antibodies are available in PE-Texas red. The use of APC avoids the compensation and manufacturing difficulties of PE-Texas red, as it is not a tandem conjugate dye but requires a different excitation wavelength, provided by a second laser (633 nm), minimizing spectral overlap with dyes excited by the primary laser (488 nm). However, the secondary laser will partially excite the Cy5 component of PE-Cy5, requiring interlaser compensation, a problem avoided by the use of PerCP-Cy5.5. A variety of antibodies are now available in APC. Current strategies for >4-color analysis include additional dyes such as Pacific blue, Alexa 594, Alexa 700, APC-Cy7, PE-Cy7, and/or PE-Cy5.5 with those already discussed, but these are restricted by limited reagent availability. Few laboratories currently utilize >4-color techniques for routine analysis of hematopoietic neoplasms, but this will change as new multilaser benchtop analyzers are developed and reagents become more available (79).

Three general approaches for the use of antibody panels have been described (88). In the first, a comprehensive panel of antibodies is run, which will answer most relevant questions. This provides extensive information and saves some time, as additional reagents are rarely required, but it may use unnecessary reagents and cannot be used on samples having limited numbers of cells. Another approach is to use a minimal screening panel containing a limited number of reagents, followed by a secondary panel to address specific issues raised in the initial screen. The recursive nature of this approach may be more economical for reagents, but it is lengthier and may be relatively insensitive for the detection of small abnormal populations. A more directed approach may be used where reagents are selected to address specific questions based on clinical and/or morphological information. However, this assumes that the information provided is correct, and unsuspected abnormalities may not be identified. This approach may be the only possible option for a sample with a limited number of cells.

Finally, the strategy used for normal and abnormal population identification is critical for panel construction, and a number are in common use. These strategies are not necessarily mutually exclusive, and often more than one must be used. However, no consensus exists as to optimal combinations of reagents for this purpose. Commonly, one or more fluorescent reagents are included in each tube of a panel to specifically facilitate the identification of a subpopulation of cells that are further characterized by the remaining reagents in that tube. These reagents may identify general subpopulations of cells, e.g., blasts using CD45 in combination with side scatter, or specifically identify a cell lineage, e.g., CD19 for B cells or CD3 for T cells. To allow tracking of the subpopulation between multiple tubes, the reagent(s) used for population identification must be included in every tube used for characterization of that population. This results in some unavoidable redundancy in panel construction. For the further characterization of the identified population, it is important to create combinations of reagents that emphasize normal patterns of maturation for the population, providing

internal controls against which an abnormal population can be assessed. The inclusion of combinations of reagents to detect both aberrant maturational antigen expression, either of degree or of maturational stage, and the expression of non-lineage-associated antigens is desirable. However, it may be difficult to design an optimal panel that will address all these concerns in all situations. It is most important that the operator be familiar with the properties of each antibody combination used, on both normal and abnormal populations.

DATA ANALYSIS

The analysis of flow cytometric data for diagnosis of hematopoietic neoplasms involves identification of normal and abnormal populations within a multiparametric data space typically involving at least six dimensions (7). As multidimensional spaces are difficult to visualize for more than three dimensions, analysis commonly relies largely on the visual inspection of multiple one- and two-dimensional scatterplots or histograms. For a given tube assayed, the number of two-dimensional histograms that should be examined to completely evaluate the data space represents all possible two-parameter combinations, i.e., $\Sigma(n-1)$, where n is the number of parameters evaluated. This results in a rather large number of histograms to evaluate when higher-order multiparametric data are collected. In practice, this process is often simplified by examining only histograms containing combinations of parameters that are felt to be informative, with the associated risk of occasionally overlooking populations that were not anticipated.

Analysis may be restricted to subpopulations of interest by a process termed "gating," whereby the operator encircles a population of interest on a histogram with an electronic line or "gate" and restricts further analysis to that subpopulation of events. Combinations of gates may be created using Boolean logic as a powerful way to more specifically identify subsets of events. Despite the power of these methods, it is advisable to initially examine data ungated before proceeding to more restrictive gating strategies, as populations of interest could be entirely excluded by the premature application of gating. This is particularly important when evaluating for the presence of hematopoietic neoplasms, as the immunophenotype and light scatter properties of the population of potential interest are often unknown. Once a population of interest has been identified, more sophisticated gating is useful to improve the purity of the population being evaluated.

One of the gating strategies inherited from lymphocyte subset analysis is the use of light scatter properties alone to identify populations of interest, i.e., forward- versus right-angle side scatter. While for simple specimens such as lymph node or peripheral blood this might be adequate in some situations, the method is clearly inadequate for more complex specimens such as bone marrow, as significant overlap exists for light scatter properties of normal and abnormal populations (89) (see Fig. 3). Consequently, fluorescent reagents are often included in reagent panels to improve population identification, often creating redundancy between tubes within a panel.

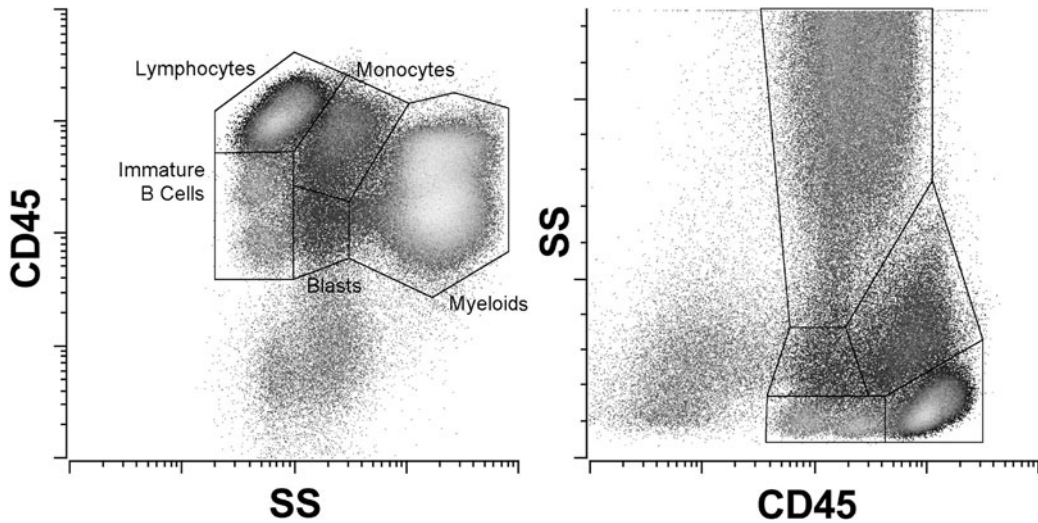
One common method is the use of antibodies to CD45 in combination with right-angle light scatter (see Fig. 4). This method allows the separation of nucleated cell populations into six basic groups: mature lymphocyte, maturing monocyte, maturing myeloid, myeloblast, immature lymphocyte (lymphoblast), and red blood cell (Fig. 4) (8, 87). While this method is very useful for a preliminary identification of populations in complex specimens, particularly for the identification of blasts, often populations identified by this method are not entirely pure and other reagents must be used to confirm their identity. This is particularly true for lymphocyte subpopulations where CD45 versus side scatter does not discriminate between B cells, T cells, or NK cells and often adds little useful information. Consequently, CD45 versus side-scatter population identification is of the greatest utility in the diagnosis of acute leukemia and myelodysplasia and is less useful in the diagnosis of lymphoma. This approach also relies on the assumption that neoplastic populations retain a pattern of light scatter and CD45 expression similar to that of their normal counterparts, an assumption that is not valid in some cases.
FIGURE 3 Forward-scatter (FS) versus side-scatter (SS) display of normal bone marrow using either logarithmic (left) or linear (right) SS as commonly displayed. The axes may be reversed depending upon the operator's preference. The dark line encloses the viable white blood cells. Note the difficulty in resolving the low FS and SS populations, i.e., lymphocytes, lymphoblasts, and myeloblasts, relative to CD45 versus SS gating of the same sample in Fig. 2. The very low scatter events lying outside the dark lines represent unlysed erythrocytes and degenerating cells.


FIGURE 4 CD45 versus side-scatter (SS) gating of normal bone marrow using either logarithmic (left) or linear (right) SS as commonly displayed. Note that the use of logarithmic SS results in tighter clustering of the populations having higher SS, in particular the myeloid cells. The ungated cells with low to negative CD45 represent unlysed erythrocytes.

However, such deviation from these expected patterns may itself be useful to detect the presence of abnormal populations. Particular care must be taken to not overlook the presence of CD45-negative hematopoietic neoplasms such as myeloma, pediatric ALL, or, occasionally, anaplastic large-cell lymphoma using this approach.

Another common method of population identification is the use of lineage-associated antigens to more specifically isolate subpopulations such as B cells with CD19, T cells with CD3, blasts with CD34, etc. (85). In this approach, the three parameters available to uniquely identify populations of interest are the lineage-associated antigen used, forward scatter, and right-angle light scatter. This approach is particularly well suited for the analysis of lymphoma, as it allows more specific dissection of lymphocyte subpopulations (see Fig. 5). However, caution should be used when one relies on the expression of any single antigen for the detection of abnormal populations. In a given case, the neoplastic population may exhibit a complete loss of the antigen used for lineage detection, even for relatively consistently expressed antigens such as CD19 on B cells. This can result in a failure to detect the presence of an abnormal population if care is not taken. Consequently, it is
FIGURE 5 Lineage-specific gating of peripheral blood using CD19 to identify the B-cell population (left). The additional presence of both kappa and lambda light chains in the tube allows the ability to specifically analyze the B-cell population and demonstrate a sizeable clonal B-cell population having lambda light-chain restriction (right). Note the presence of a very small subset of polyclonal B cells having brighter light-chain expression. SS, side scatter; FITC, fluorescein isothiocyanate.

advisable to use at least two lineage-associated antigens within a panel when this approach is used.

Given that neoplastic populations may have an unpredictably wide variety of abnormal immunophenotypes that in some cases deviate markedly from normal, it is prudent to use more than one of the above approaches in some combination when one analyzes multiparametric flow cytometry data. The validity of assumptions inherent in any single method of analysis may be cross-checked using one or more other methods.

DATA REPORTING

The reporting of data resulting from flow cytometric analysis should focus on providing information relevant to those submitting the sample for analysis, generally clinicians or pathologists. Flow cytometric analysis is not a well-standardized procedure, and this is reflected in a variety of reporting methods. Components which should be present in every report include patient demographic information, including relevant clinical information and reason for flow cytometric analysis, sample source, specimen number, dates collected and received, antibodies used, description of data resulting from analysis, and an interpretation of the findings (12). The viability of the specimen should be included in the report if low enough to potentially compromise the analysis. The manner in which analysis results have been historically reported includes a list of antibodies used with the corresponding percentage positive for some population of interest. This format does not generally provide meaningful data for those reading the report, as it is often difficult to determine which distinct populations were identified, whether their immunophenotypes were normal or abnormal, and what the intensity of antigen expression was, and it obscures possible relationships between the parameters. A population-based method of reporting using simple text descriptions is capable of presenting all of the above findings in a manner that is more understandable to those reading the report and is strongly preferred. The inclusion of representative histograms in the report may provide useful information in some cases, but it must be weighed against the labor required. An interpretation of the significance of the findings should be present in all reports and may include a differential diagnosis. It is critical that flow cytometric results be interpreted in light of the patient's clinical setting and in conjunction with other laboratory findings to determine their true clinical significance. It is important to recognize that flow cytometric analysis of hematopoietic neoplasms is not a simple or standardized procedure and requires the involvement and critical judgment of professional laboratory personnel, a fact that should be recognized by appropriate signatures on the final report.

Standardized Flow Cytometry Assays for Enumerating Hematopoietic Stem Cells

D. ROBERT SUTHERLAND, IAN CHIN-YEE,
MICHAEL KEENEY, AND JAN GRATAMA

21

HEMATOPOIETIC STEM/PROGENITOR CELLS EXPRESS THE CD34 ANTIGEN

An important phenotypic characteristic of the stem/progenitor cells in marrow and peripheral blood responsible for multilineage engraftment in the transplant setting was initially established in the late 1980s, when it was demonstrated that the 1 to 3% of marrow leukocytes that expressed the cell surface antigen CD34 (11) contained the majority of CFU activity for myeloid and erythroid lineages and also contained cells exhibiting the phenotypic properties of primitive lymphoid cells. Berenson et al., using a novel CD34 antibody called 12.8 (4) that uniquely cross-reacted with a similar subset of baboon marrow cells, conclusively demonstrated that the CD34 antigen not only was expressed on a variety of lineage-committed progenitors but also was expressed on true hematopoietic stem cells that could reconstitute long-term multilineage hematopoiesis in lethally irradiated animals. Subsequent studies on human subjects have firmly established that CD34+-cell transplants are safe, durable, and generally therapeutically effective.

Confirming earlier data obtained using colony-forming cell assays, CD34+ cells can be found in the peripheral blood of healthy individuals but are extremely rare (range, 0.01 to 0.1%). However, the use of chemotherapy and/or cytokines to "mobilize" CD34+ cells (28) has greatly facilitated the use of peripheral blood stem cells (PBSC) versus marrow for both autotransplantation and, more recently, allotransplantation (reviewed in reference 33). This increased use of PBSC evolved in the absence of any consensus means to monitor the engraftment potential of the stem cell product. Recent studies have indicated that umbilical cord blood (CB) also represents a rich source of CD34+ hematopoietic stem/progenitor cells, and consequently, there has been a proliferation of CB banks worldwide (8). Methods of collection, processing (with or without T-cell depletion), and cryopreservation have similarly proliferated without a rapid, reliable, and standardized method to measure the effects of such manipulations on the engraftment potential of the postthawed CB product.

CLINICAL ISSUES IN ENUMERATING STEM CELLS BY FLOW CYTOMETRY

Currently, the enumeration of CD34+ stem/progenitor cells by flow cytometry represents the most clinically useful surrogate marker of graft adequacy and provides crucial information to the transplant physician. Most transplant centers determine graft adequacy based on the number of CD34+ cells per kilogram of patient body weight. Over the last few years, the "recommended" minimum number of CD34+ cells has fallen from about 10^7/kg to around 2×10^6 to 2.5×10^6/kg, although a full consensus on the latter figure has not yet been reached (35). In addition to determining yield, the number of CD34+ cells mobilized to the peripheral blood is also a predictor of the success of apheresis, and thus an increasing number of centers use peripheral blood CD34+-cell counts to monitor online the yield of CD34+ cells (22). Accurately timing the harvesting of CD34+ cells may be particularly important for patients who have poor bone marrow function or who have received extensive prior therapy. For such poor mobilizers, daily measurements of the CD34+-cell concentration in the circulation to optimize timing of stem cell collections may have merit (29). Early collection of stem cells may be especially useful, for example in heavily pretreated myeloma patients, given the reported increase in malignant-cell contamination of apheresis products noted on later collection days (12).

More recently, there has been a shift in interest from the minimum number of stem cells required to attempts to maximize the CD34+-cell dose, a factor which has been shown by several investigators to correlate inversely with time to engraftment of neutrophils and platelets (37). Furthermore, rapid reengraftment may correlate with not only total CD34+-cell dose but also the presence or absence of certain specific subsets of CD34+ cells (25). The clinical interest in subset analysis of rare populations of CD34+ cells adds to the complexity of this assay and adds demands on the clinical flow cytometry laboratory. Ultimately, the number of viable CD34+ cells (or subsets thereof) actually reinfused to patients is the most clinically important variable determining graft success or failure. A systematic evaluation of viable stem cells from the time of collection to actual reinfusion would be ideal to quality assure these products. We envision this process to involve measurements of peripheral blood CD34+ cells in patients to "time" apheresis, to evaluate the yield of viable cells postcollection, and to evaluate the number of viable CD34+ cells postcryopreservation actually infused.

To be clinically relevant, any flow cytometric assay must meet the following criteria. (i) It must correlate with a clinically meaningful outcome, such as time to multilineage

engraftment. (ii) It must be applicable for the different stem cell products, i.e., peripheral blood, CB, and bone marrow. (iii) It must provide timely results (less than 2 h) and must be reproducible between institutions. (iv) It should be sufficiently flexible to permit more sophisticated qualitative analysis of CD34$^+$ subsets using a multiparametric approach. (v) It should be able to determine the viability of the target (i.e., CD34$^+$) population. (vi) It should be a single-platform assay (see below).

TECHNICAL ISSUES IN THE ENUMERATION OF CD34$^+$ CELLS BY MULTIPARAMETER FLOW CYTOMETRY

CD34 Antigen: Structural Considerations and Choice of Fluorochromes

The CD34 antigen is a heavily glycosylated mucin-like molecule, the structural characteristics of which have important implications for the choice of an appropriate CD34 antibody clone for flow-based enumeration techniques (21, 30). Due to their dependence on terminal sialic acids, which are only found on the most fully glycosylated/processed forms of CD34, class I antibodies generate the most aberrant data in clinical samples, whereas class II and class III reagents detect similar, if not identical, numbers of CD34$^+$ cells in a wide variety of normal and abnormal samples (31). Thus, for accurate enumeration of rare CD34$^+$ cells in hematopoietic samples, it is important to use a CD34 antibody that detects all glycosylation variants of the molecule, i.e., class II or class III antibodies (14, 31, 33).

It is generally advantageous to utilize an antibody conjugated to the brightest fluorochrome excitable, i.e., phycoerythrin (PE), by an argon laser-based flow cytometer. After parallel analysis of a large number of normal blood, cytokine-mobilized peripheral blood, CB, and normal marrow samples, as well as of CD34$^+$ cell lines that fail to express some class I CD34 epitopes, it is our experience that commercially made PE conjugates of the clones QBEnd10, 8G12, Birma K3, and 581 can be utilized with confidence (31). As detailed elsewhere, if fluorescein isothiocyanate (FITC) conjugates of CD34 antibodies have to be used, only class III reagents such as HPCA2 and 581 can be recommended since these reagents detect numbers of CD34$^+$ cells in parallel analyses of clinical samples using the ISHAGE protocol (see below) that are similar, if not identical, to those detected by their PE-conjugated versions (31). Although we have tested a variety of other CD34 antibody conjugates in two-, three-, and four-color combinations, some of these conjugates are not suitable for all applications or instrument platforms (10, 14, 21, 31, 33) and should be rigorously evaluated alongside currently validated reagents before introduction into the clinical laboratory. Overall, it is critical to select an appropriate CD34 antibody clone that retains high specificity and avidity of binding after conjugation to the designated fluorochrome.

CD45 Antigen: Structural Considerations and Choice of Fluorochromes

Several protocols have been developed that use CD45 antibodies to gate total nucleated white blood cells, this number serving as the denominator in the calculation of percent CD34$^+$ cells. For such protocols, it is important that pan-CD45 antibodies that detect not just all isoforms, but all glycoforms, of this mucin-like molecule are used. In this respect, the clones J33, T29/33, and HLE-1 can be used with confidence (14, 31, 33). Note, however, that the PerCP conjugate of HLE-1, while usable on benchtop cytometers equipped with low-powered lasers, can be problematic if used on cell sorters equipped with higher-powered lasers. Of note, a very small fraction of CD34$^+$ cells that do not express CD45 comprises endothelial cells, which have been reported in increased numbers in the blood of patients with solid tumors (23). Although other pan-CD45 antibodies can be used for CD34$^+$ stem cell enumeration, the selected reagent should be carefully evaluated prior to routine use in clinical protocols.

MEASURING CD34$^+$ CELLS BY FLOW CYTOMETRY: TWO-PLATFORM METHODS

While flow cytometric enumeration of CD34$^+$ cells represents the most clinically useful assay of graft assessment, the assays that were initially developed were insufficiently robust, and interinstitutional variability in particular was problematic (6, 18). One source of variability was the method used by many transplant centers to determine the absolute number of CD34$^+$ cells per kilogram of patient body weight. Traditionally, this number was obtained by determining the percent CD34$^+$ cells by flow cytometry and multiplying it by the absolute leukocyte count (LKC) as determined by an automated hematology analyzer (hence the name "two-platform" methodology).

Siena et al. (28) were the first to describe a flow cytometric method to measure percent CD34$^+$ cells in mobilized peripheral blood. This method was initially based on mononuclear cell enrichment by density gradient centrifugation, followed by staining with the class I CD34 antibody MY10 using indirect immunofluorescence. The subsequent development of what was called the Milan protocol (27) was due to the availability around 1990 of class III CD34 antibodies, such as 8G12, that could be conjugated with FITC and, later, with PE without loss of reactivity. The protocol utilized whole-blood staining and lyse-and-wash sample processing, while the gating strategy utilized simple forward-angle (FSC) versus side-angle (SSC) light scatter above an FSC threshold or discriminator to set a denominator. An isotype-matched control was used to set the positive analysis region for CD34$^+$ cells. In the CD34 antibody-stained sample, the number of events that stained brighter than the control and exhibited low to intermediate SSC were counted and used as the numerator in the calculation of percent CD34$^+$ cells. A minimum of 50 CD34$^+$ events were counted in a list mode file of 50,000 events.

Although a number of minor developments were subsequently incorporated to improve the Milan method (18), the inherent difficulties in enumerating bona fide CD34$^+$ cells in increasingly diverse sources of hematopoietic stem cells led to the development of more sophisticated methods utilizing multiparameter gating strategies. The first two-color strategy was developed by Bender et al. (3); in this method, CD45-FITC is used in addition to CD34-PE. CD45 staining was used to establish a more stable denominator by enumerating only nucleated white blood cells in the denominator. CD45$^+$ events were then analyzed in a manner similar to the Milan protocol using an isotype and analysis of CD34 staining versus SSC to enumerate CD34$^+$ cells.

While the above protocols were generally capable of analyzing fresh peripheral blood and apheresis samples, they were inadequate for the accurate enumeration of CD34$^+$ cells in other sources of hematopoietic stem cells, or shipped or otherwise-manipulated samples of less than pristine quality. The approach proposed by Owens and Loken (26) incorporated the

nuclear dye 7-amino-actinomycin D (7-AAD) to exclude dead cells, a CD14 antibody to exclude monocytes, and a CD34 antibody to identify CD34+ cells. A plot of CD14-FITC versus SSC was generated from the live cell gate (7-AAD-negative events) to exclude monocytes. From this histogram, a third plot of CD34-PE versus SSC was generated and compared to an immunoglobulin G (IgG)-PE control versus SSC as in the Milan protocol. Both dim and bright CD34+ events were included in the calculation. CD34+ events were expressed as a percentage of total nucleated cells (live plus dead) based on an FSC-versus-SSC plot.

The Dutch Cooperative Study Group on Immuno-phenotyping of Haematological Malignancies (16) developed a three-color protocol based on LDS-751 and CD14, CD66e, and CD34 antibodies. LDS-751 stains DNA and RNA, and gating on FSC versus LDS-751 allows discrimination between nucleated cells and debris, unlysed erythrocytes, and platelets. Monocytes (CD14+) and granulocytes (CD66e+) were then excluded from further analysis, after which the stem cells were identified as dim or bright CD34+ cells in a CD34-versus-SSC dot plot. Nonspecific staining was analyzed using identical gate settings on a control staining in which the CD34 monoclonal antibody (MAb) was replaced by an isotype control MAb, and any nonspecifically stained events were subtracted from the CD34 result.

CD34+-CELL ENUMERATION USING SEQUENTIAL BOOLEAN GATING

As already indicated, accurate enumeration of rare events such as CD34+ cells in heterogeneous clinical samples by flow cytometry represents a serious challenge for both clinical and research laboratories. Cytometers measure events, whether they are white cells, red cells, platelets, dead cells, or debris. Therefore, to eliminate nonleukocytes and debris from the analysis and generate a much more stable denominator against which to measure CD34+ cells, we used CD45 as a counterstain as described previously (3). However, we also took advantage of the prior observations of Borowitz et al. (5) indicating that leukemic blast cells, which exhibit light scatter properties generally similar to those of lymphocytes, express lower levels of CD45 on their surfaces, thus providing a means of delineating lymphocytes from normal blast cells using this surface marker. Just as lymphocytes, monocytes, and granulocytes form discrete clusters on analysis of CD45 staining versus SSC (5), so do CD34+ cells. Thus, a sensitive and accurate multiparameter flow methodology was devised that utilizes the maximum information available of four parameters: FSC and SSC and CD34 and CD45 staining. These four parameters were combined in a sequential or Boolean gating strategy that was usable on a variety of sources of hematopoietic stem cells (32). Thereafter, this basic protocol was incorporated into a set of clinical guidelines constructed for the International Society of Hematotherapy and Graft Engineering (ISHAGE), nowadays called the International Society for Cellular Therapy, to enumerate CD34+ cells in peripheral blood and apheresis products (31).

The original methodology (32) at the heart of the ISHAGE protocol (31) is very sensitive, being capable of detecting 10 to 20 CD34+ cells per 100,000 CD45+ nucleated white blood cells. The method is highly specific when appropriate pan-CD45 antibodies (that detect all isoforms and glycoforms) and CD34 conjugates (that detect all CD34 glycoforms) are used (see below). It is quick and can be performed on a variety of single- and dual-laser flow cytometers, with only basic software being required for data analysis. The basic ISHAGE protocol can be used to enumerate CD34+ cells in a variety of normal hematopoietic tissues, including marrow and CB as well as abnormal clinical samples from a variety of disease states. CD34+ cells selected from both normal and abnormal marrow, CB, and peripheral blood samples can also be assessed for purity using this flexible method (34).

BASIC ISHAGE PROTOCOL AND GATING STRATEGY

The ISHAGE protocol and critical issues relating to the enumeration of CD34+ cells have been published in detail elsewhere (14, 31, 33). Briefly, as shown in Fig. 1 with a CB sample, the first gate (region 1 [R1]) is established from a plot of CD45 staining versus SSC. As indicated above, this approach allows, during analysis of the list mode data file, the exclusion of red cells, platelets, and other debris commonly found in hematopoietic samples, especially those prepared by lysis–no-wash methods. Sufficient events are acquired in R1 (histogram A) that at least 100 CD34+ cells are displayed in the lymph-blast region, R4 (histogram D). The acquired cells are then sequentially displayed on a plot of CD34 staining versus SSC (histogram B) and R2 is adjusted to include dim and bright CD34+ events with low to intermediate SSC. The events gated by both R1 and R2 are then displayed in turn on a plot of CD45 fluorescence versus SSC (histogram C), and true CD34+ cells form a cluster characterized by low CD45 staining (relative to lymphocytes) and low to intermediate SSC. It is this cluster that determines the size and location of gating R3. Excluded from this gated cluster (R3) are platelet aggregates, nonspecifically stained lymphocytes, monomyeloid cells, and debris. The cells gated within R1, R2, and R3 are then displayed on a light scatter plot to confirm that the selected events fall into a generic lymph-blast region (R4) that is precisely set to include events no smaller than small lymphocytes.

One controversial issue that arose in the early development of the ISHAGE protocols was whether all specifically stained, nonmalignant CD34+ cells express low levels (at least) of CD45 molecules. To address this and other technical issues related to instrument setup and to optimize the gating regions, two additional "housekeeping" plots have been added to the original four-plot strategy. As shown in Fig. 1, R5 on plot A is set precisely to include only lymphocytes (bright CD45, low SS) and these lymphocytes are displayed on plot F (FSC versus SSC). This helps to establish the minimum size range for the lymph-blast region (R4 on histogram F and its duplicate on histogram D), and when appropriately set, nonspecifically stained debris, platelets, and some dead cells, if present and not fully excluded by the previous gates, can generally be excluded. This region also helps to confirm that the forward-angle light scatter (FALS) discriminator and FALS detector volts/gain are adequately set. The discriminator (or FSC threshold) is set to ensure that even the smallest CD45+ lymphocytes scatter above it. FALS volts/gain is adjusted so that the smallest lymphocytes scatter around channel 200 of a 1,024-by-1,024 linear dot plot. After determining the appropriate discriminator setting, R1 is positioned on plot A to include all CD45+ events. The lower extremity of R1 is set low enough to include all dim CD45-positive events (histogram E is used as a guide). Histogram E (CD34-PE versus CD45-FITC staining) helps to establish the lower limit of CD45 expression such that

FIGURE 1   Enumeration of CD34$^+$ cells in a CB sample stained with CD34-PE and CD45-FITC (clones 581 and J33, respectively; Immunotech-Coulter) using the basic ISHAGE protocol (31). Plot A is gated on all events, plot B is gated on R1 events, plot C is gated on R1 and R2 events, and plot D is gated on R1, R2, and R3 events. Plot E is gated on all events, and plot F is gated lymphocytes back-scattered from R5 (plot A) to ensure optimal placement of lymph-blast region R4 as described previously (31). Plots G and H show the same sample stained with isotype control IgG1-PE and CD45-FITC. Only two plots (equivalent to plots C and D) are shown for the control sample. No events satisfying the gating criteria of plots A to D are found in R4 of plot H. Gate statistics are obtained from plot B (CD45$^+$ events).

potential CD34$^+$ cells (that express low levels of CD45) are not excluded. The absolute CD34$^+$-cell count is obtained by multiplying this value by the absolute LKC, obtained from an automated hematology analyzer.

Basic ISHAGE Protocol Calculation

$$\frac{\text{no. of CD34}^+ \text{ events (R4)}}{\text{no. of CD45}^+ \text{ events (R1)}} \times \text{LKC } (\times 10^9/\text{liter}) \times 1,000$$
$$= \text{no. of CD34}^+ \text{ cells} \times 10^6/\text{liter}$$

ISOTYPE CONTROLS

Given the sequential gating strategy at the heart of the ISHAGE method, we reasoned that the use of isotype control antibodies to set the positive analysis region for CD34$^+$ cells would be inappropriate. Thus, the same gating regions that were established for the CD34/CD45-stained sample (Fig. 1, plots A to D) are used to analyze the IgG1/CD45 control sample. In virtually all situations, including samples containing significant numbers of dead cells, few, if any, events are detected. An example of this analysis is shown in Fig. 1. Although only the last two plots (G and H) are shown, the gate statistics indicate that while 66 events were stained by the isotype control in R2 of plot F (not shown), none appear in R4 of plot H. We have, however, seen some isotype controls that stain more events in R2 than the CD34 antibody in specific samples. Even then, due to the sequential gating strategy used in this protocol, it is unusual for any of these events to find their way into R4. Indeed, studies of a large number of normal hematopoietic samples have shown that the sequential gating approach best delineates specific from nonspecific staining and that traditional isotype controls provide no useful information regarding the levels of nonspecific staining in the flow cytometric analysis of rare events, such as CD34$^+$ cells (reviewed in reference 19). Thus, a distinguishing characteristic of the ISHAGE protocol is that the sequential gating strategy used eliminates the need to use an isotype-matched control antibody to set the positive cell analysis region for CD34$^+$ cells (14, 33). In support of this strategy, the European Working Group on Clinical Cell Analysis (EWGCCA) concluded (13) that control staining for nonspecific antibody binding for cell surface marker analysis is redundant because of the Boolean gating strategies used in modern protocols such as ISHAGE, its single-platform variant.

SINGLE-PLATFORM ABSOLUTE CD34$^+$-CELL COUNTING

The use of two-platform methods to obtain the absolute CD34$^+$-cell count is prone to error, particularly if the sample is not in fresh condition, since platelet aggregates, dead cells, and other debris can compromise the accuracy of the absolute LKC and the accuracy of the flow analysis. Furthermore, the variable presence of nucleated red blood cells in CB and other samples leads to an overestimate of the absolute CD34$^+$-cell count. By incorporating a known number of fluorescent counting beads in the flow cytometric analysis, an absolute CD34$^+$-cell count can be generated directly on a flow cytometer, thus eliminating the need for a nucleated-cell count as performed by a hematology analyzer. Assessment of the ratio between the number of beads and CD34$^+$ cells counted allows the direct calculation of the absolute CD34$^+$-cell count. This approach is used by BD

Biosystems (BDB) (San Jose, Calif.) in their TruCOUNT tubes, in the single-platform variant of the ISHAGE protocol (20), and by Beckman-Coulter (Miami, Fla.) in their Stem-Kit assay. Regardless of which of these single-platform assays is used, accurate pipetting of samples (for sample dilution or aliquoting purposes) is required. For the single-platform ISHAGE protocol and Stem-Kit assays, accurate pipetting of the beads is also critical.

ISHAGE Single Platform Including Viability Assessment

The basic ISHAGE method was modified to include a known number of Flow-Count fluorospheres (Beckman-Coulter), and ammonium chloride lysis–no-wash sample processing was adopted. These modifications combine the accuracy and sensitivity provided by the sequential gating strategy of the original ISHAGE protocol with the capability to generate an absolute CD34$^+$-cell count directly from a flow cytometer (20) and form the basis of the Stem-Kit from Beckman-Coulter (see below). As shown in Fig. 2, from list mode data acquired on a BDB FACScan cytometer, from a diluted sample of a 24-h-old apheresis pack, the number of CD34$^+$ cells is determined as described above using gating R1 to R4 (gate 4 in gate statistics) and compared with the total number of singlet beads counted (concentration supplied by manufacturer) in the same list mode file. In the example shown, total beads are gated in R6 of plot E and displayed on plot G (time versus FSC). Using Boolean gating logic, singlet beads are then gated in R7 (G7 in gate statistics). The calculation involved in generating an absolute CD34$^+$-cell count per microliter is as follows: (no. of CD34$^+$ cells × bead concentration × DF)/no. of singlet beads, where the number of CD34$^+$ cells is determined from gate 4 (R1 through R4), the bead concentration is specified per lot, DF is the sample dilution factor, and the singlet bead count is determined from gate 7 (R6 and R7). This value is multiplied by the apheresis pack volume (in liters) to convert this value to an absolute CD34$^+$-cell number × 10^6 per apheresis pack.

As detailed above and elsewhere, for absolute counting of CD34$^+$ cells using bead-based methods, accurate pipetting of sample and beads is critical to the reliability of the assay (14, 20, 33). In our standardized assay, 100 μl of sample and 100 μl of counting beads are used (33).

The addition of the viability dye 7-AAD to the single-platform ISHAGE method permits the determination of the absolute numbers of viable and nonviable CD34$^+$ cells from a sample (20). The ability to perform such sophisticated analysis has clinical utility in the accurate measurement of viable CD34$^+$ cells in packs that may have been manipulated (e.g., purged), potentially damaged by shipping to another site for analysis, or otherwise inappropriately handled prior to analysis. An example of how the 7-AAD is incorporated into the ISHAGE single-platform method is shown in Fig. 2, plot H. In the example shown, dead cells (7-AAD$^+$) are gated in R8 and subtracted, using logical gating, from the other analysis gates. An absolute viable CD34$^+$ cell count of 117/μl is obtained. When the 7-AAD$^+$ cells (dead cells) are not excluded (by removing gate R8) as shown in Fig. 3, and the gating R4 is adjusted on plot F to include all lymphocytes (live plus dead) from R5, a total absolute CD34$^+$-cell count of 162/μl is obtained.

The essential components and fine technical details of the "single-platform ISHAGE with viability protocol" (20) are embodied in the basic protocol constructed for *Current Protocols in Cytometry* (CPC) (14; updated in reference 33).

FIGURE 2 Absolute viable CD34$^+$-cell counting using the single-platform ISHAGE protocol (14, 20, 33) performed on 100 μl of a 24-h-old PBSC sample stained with CD34-FITC and CD45-PE. After 25 min, the sample was lysed with 2 ml of NH$_4$Cl containing 1 μg of 7-AAD. After 10 min at room temperature, 100 μl of Flow-Count beads was added and the sample was analyzed immediately as described previously (14, 20). Dead cells (7-AAD$^+$) gated in R8 and were removed from analysis by logical gating as depicted in plots B, C, D, and F. A total of 456 viable CD34$^+$ cells were counted in gate 4 (not R8 and R1 through R4), 4,082 beads were counted in gate 7 (R6 and R7), and the assayed bead concentration was 1,046/μl. The sample contains 117 viable CD34$^+$ cells/μl.

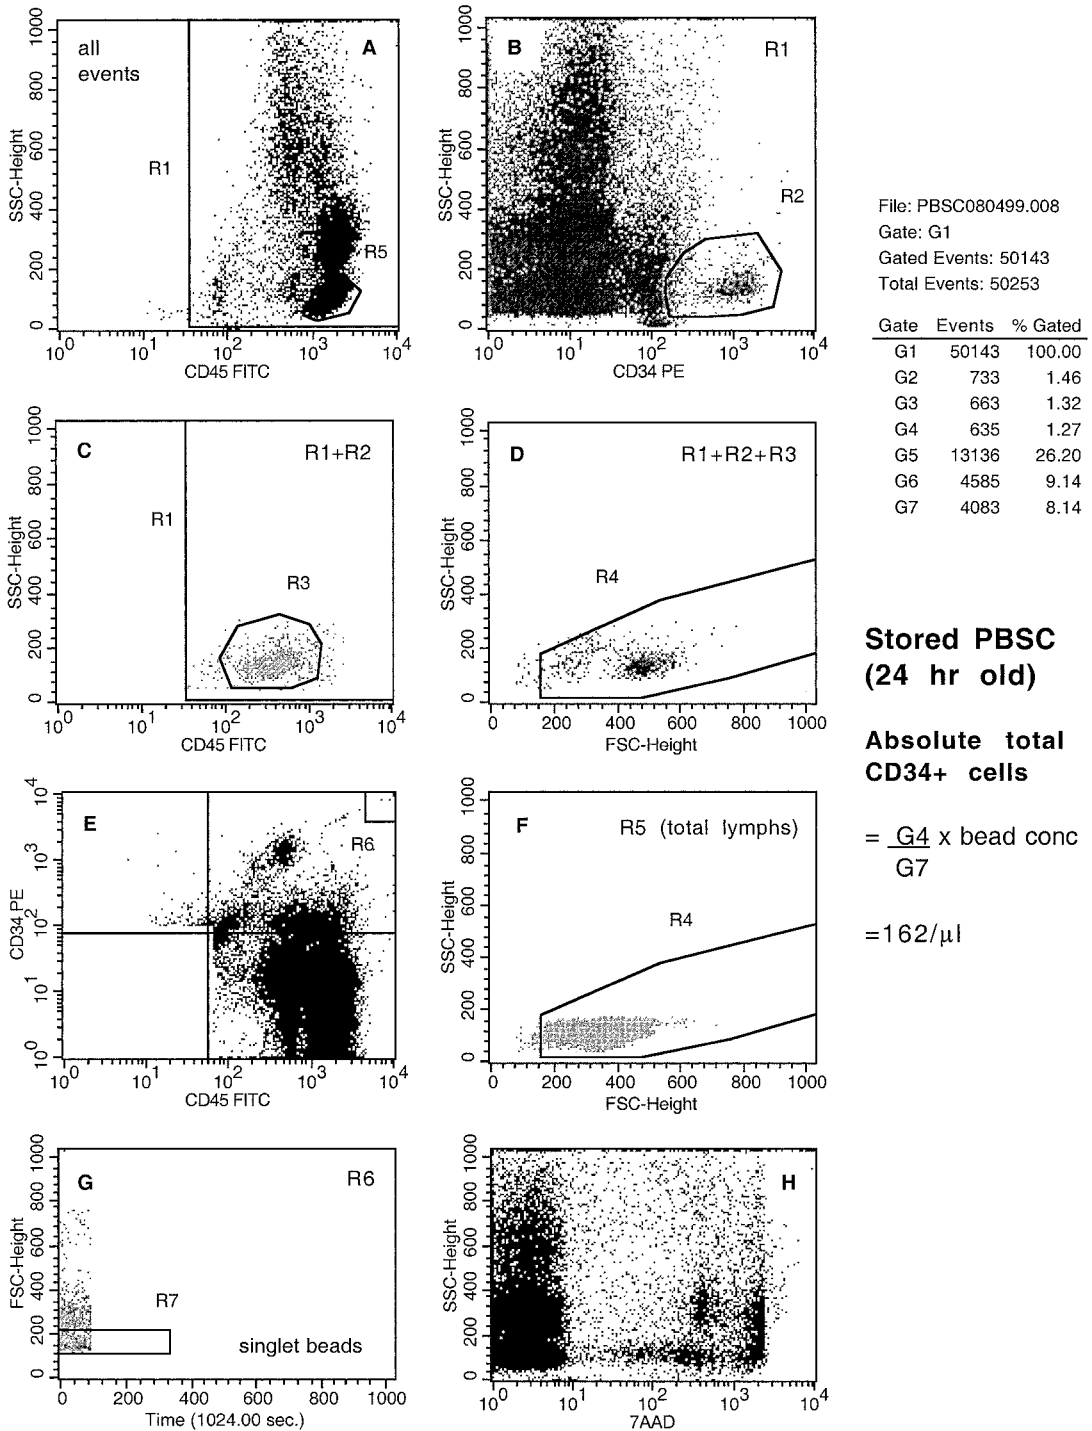
$$= 162/\mu l$$


FIGURE 3 Importance of removing dead cells in accurate enumeration of CD34+ cells by the single-platform ISHAGE protocol. The list mode file from the same 24-h-old sample as shown in Fig. 2 was analyzed without prior removal of nonviable (7-AAD+) cells. Note that most nonviable CD34+ cells and nonviable lymphocytes (plots D and F, respectively) form a second cluster characterized by lower FSC compared to their viable equivalents shown on the corresponding plots of Fig. 2. The sample contains 162 total CD34+ cells/μl.

They are also embodied in the recommendations from the EWGCCA (13), the British Protocol for CD34+-cell enumeration (2), and the German reference protocol (17), among others.

Like earlier versions of the ISHAGE protocols, the single-platform derivatives have been developed to work on both Beckman-Coulter and BDB flow cytometers. However, there are minor technical differences in the way the assay is set up on the different instruments (detailed in references 14 and 33). Briefly, there are two main differences. On single-laser instruments with only three photomultiplier tubes such as the BDB FACScan, the counting beads are visualized using FSC versus time. Since the beads are detected as smaller events than lymphocytes on BDB instruments, the FSC threshold has to be lowered so as not to exclude the beads. As shown in Fig. 2, plot G, the singlet beads appear around channel 160, whereas the viable lymphocytes shown in plot F are found above channel 280. On the Coulter Epics XL and FC500 instruments, the beads appear above channel 800, so there is no need to adjust the FALS discriminator from its normal setting, just below the smallest lymphocytes (14, 20). However, it is our recent experience that certain stabilized samples that are routinely distributed for quality assurance or proficiency testing purposes exhibit reduced FSC properties. For the analysis of such samples, it is advisable to increase the FSC gain of the Coulter instruments to ensure that all CD45+ leukocytes are included in the list mode file. Although the counting beads can be detected on the Coulter Epics XL and FC500 using the same parameters of FSC versus time, the presence of a fourth photomultiplier tube on this single-laser instrument allows the counting beads to be detected in the FL3 channel of the instrument (on an FL3-versus-time plot) while the 7-AAD is detected in the FL4 channel (equivalent to the FL3 channel of the FACScan) (14, 20).

The Stem-Kit Assay

The Stem-Kit from Beckman-Coulter utilizes ISHAGE gating criteria to identify CD34+ cells. The kit also contains a CD45-FITC/CD34 (isoclonic) control to enumerate non-specifically stained events. In this control, unconjugated CD34 antibody is present in large excess to block specific staining of PE-labeled CD34 present at the same concentration as the test. However, given the selectivity of the sequential gating strategy utilized in this protocol, we have not found that the isoclonic control makes a significant contribution to the accuracy and reliability of the assay (20) and, therefore, consider it to be redundant (reviewed in reference 19).

Beckman-Coulter has also developed Stem-Trol control cells, stabilized KG1a cells that have been modified to present the CD34 and CD45 epitopes at densities similar to those found on normal CD34+ hematopoietic cells. The inclusion of Stem-Trol cells is useful in determining and monitoring the accuracy of the pipetting steps of the single-platform method. As this material can be diluted in peripheral blood, it can also be used as a process control, undergoing staining and lysis exactly as performed on the test samples (20). Their staining pattern with respect to CD34 and CD45 reagents can be used as an extra internal control to ensure that the FL1, FL2, and light scatter parameters of the cytometer are adequately set (20).

Beckman-Coulter has developed a software package that automates instrument setup and compensation as well as automated data acquisition and analysis of samples prepared with the Stem-Kit. This software has been developed specifically for use on the Coulter Epics XL and, more recently, FC500 instruments.

ISHAGE Single Platform Using TruCOUNT Tubes

As described by Brocklebank and Sparrow (7), it is also possible to perform the ISHAGE protocol using TruCOUNT absolute counting tubes (BD Biosciences), instead of Flow-Count microspheres. In this setting, due to the small size of the beads, a threshold cannot be set on FSC, necessitating its setting on a fluorescence parameter. An advantage of this approach is that it eliminates the requirement to carefully suspend and pipette the counting beads. However, accurate pipetting is still required if any predilution of the sample is required, as well as for the delivery of the sample into the TruCOUNT tube. An example of the single-platform ISHAGE protocol performed on TruCOUNT tubes is shown in Fig. 4. A threshold was set on FL1 (CD45-FITC). Note that for TruCOUNT tubes, all beads (singlets and doublets, etc.) have to be counted (Fig. 4, plot G, R7), in contrast to the singlet bead count that is collected for Flow-Count beads.

Benefits of Single-Platform CD34+-Cell Enumeration

By including an internal reference bead in the analysis, CD45 positivity is no longer used as a denominator in the calculation of absolute CD34+ cells. Thus, controversial issues such as whether the true denominator is nucleated white blood cells (CD45+ events) or total nucleated cells can be avoided. Instead, the characteristic CD45 expression of CD34+ cells is used solely as part of the sequential gating strategy to accurately identify bona fide CD34+ cells. It must be stressed that focused training is highly recommended for laboratory staff adopting single-platform flow methodologies. As shown in an EWGCCA multicenter trial (1), consistently reproducible results were obtained between multiple centers only after adequate training and monitoring of performance. Notwithstanding the critical requirement for accurate pipetting in single-platform assays, addition of counting beads has the advantage of eliminating the potential introduction of errors in calculating the absolute CD34+-cell count inherent in two-platform methodologies (10, 14, 20). The cytometrist need not be concerned about the presence of nucleated red blood cells, platelet aggregates, and dead cells, which can be counted as leukocytes by some automated hematology analyzers. While the presence of significant numbers of nucleated red cells (that play no role in engraftment) in apheresis samples is quite rare, they are often abundant in CB collections, and single-platform analysis can significantly increase the accuracy of the absolute CD34+-cell number in the latter.

QUALITY ASSURANCE OF CD34+-CELL ENUMERATION

Flow cytometric analysis of CD34+ cells offers a potential means to quality assure all aspects of stem cell processing from mobilization to reinfusion. By analyzing list mode data by a variety of different gating strategies, Chang and Ma demonstrated that gating strategies were a major contributing factor to result variability (9). For an individual sample, the use of different gating strategies could produce as much as a twofold variation in results. In their study, only one gating strategy, the ISHAGE protocol, gave reproducible results from all centers of within ±10% of the median CD34+-cell value on both peripheral blood and PBSC collections.

$$= \frac{G4 \times bead\ count}{G7 \times cell\ volume}$$

$$= \frac{1828 \times 50950}{9099 \times 50}$$

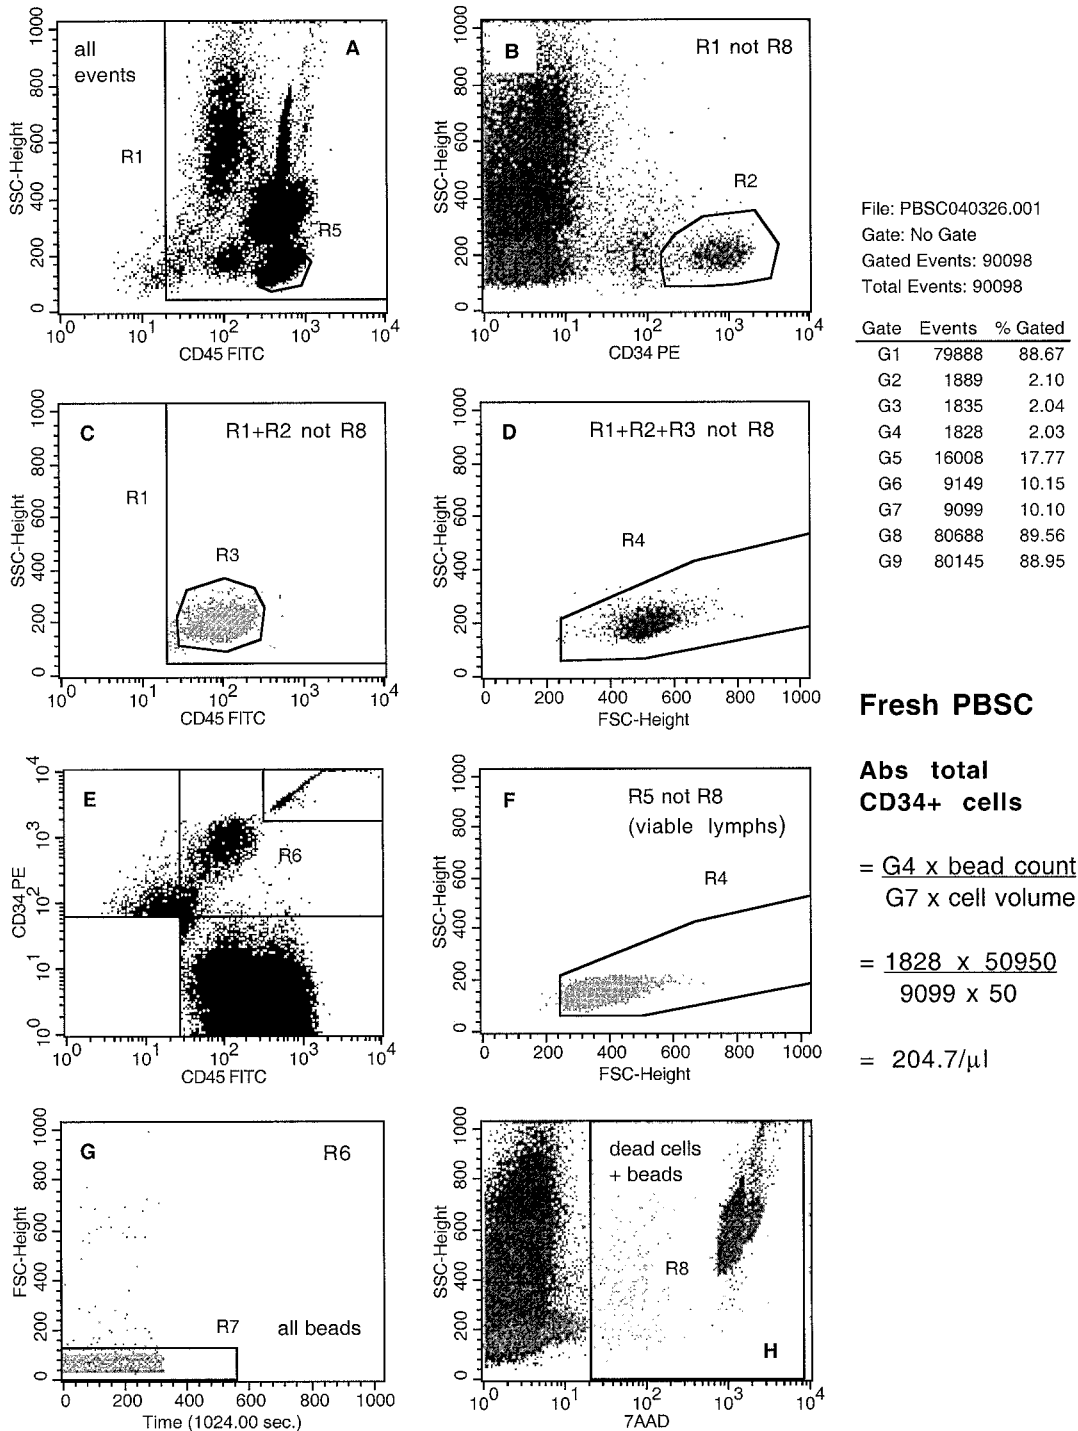
$$= 204.7/\mu l$$


FIGURE 4   Absolute viable CD34$^+$-cell counting with the ISHAGE single-platform protocol using TruCOUNT tubes. Fifty microliters of a fresh peripheral blood sample was stained with CD45-FITC and CD34-PE in a TruCOUNT tube. A threshold was established on FL1 (CD45-FITC) because the size of the TruCOUNT beads precludes the use of an FSC threshold. The total number of beads in the list mode file is obtained from gate 7 (R6 and R7). Gate statistics are obtained from plot A (all events). The sample contains 205 viable CD34$^+$ cells/μl.

Initial experience, however, with interlaboratory studies using various methodologies on shared samples reveals poor reproducibility, with coefficients of variation (CVs) ranging from 3 to 235% (13). As reported by Johnsen et al. (18), the CVs of list mode data on stained and fixed samples sent to 28 laboratories ranged from 10 to 18%. For two fresh samples shipped overnight the CVs were 38 and 34. However, for the 10 most active transplant labs the CVs for the fresh samples were 29 and 16%. A North American multicenter study report (6) showed unacceptable variability among 10 participating laboratories, with improved but still unacceptable variation between 3 Cytometry Associates laboratories using a common protocol. In the first Canadian Laboratory Provincial Testing Program quality assurance send-out for CD34$^+$ stem/progenitor cell enumeration by flow cytometry, 9 of 11 labs had CVs of 14 and 18% for preserved whole-blood samples with CD34$^+$-cell counts of 20 and 40/µl, respectively. All labs used either ISHAGE or ISHAGE-based Stem-Kit methodology (unpublished data). In a study undertaken by the EWGCCA using the single-platform ISHAGE protocol (14, 20), CVs of <10% were obtained by the majority of participating labs on a long-term stabilized blood sample with a target CD34$^+$-cell value of 170/µl (1). In a more recent study involving 36 participants from the Benelux countries, similar CVs were obtained. In contrast, the lowest between-laboratory CVs using dual-platform techniques were 16% (Benelux) and 21% (United Kingdom National Quality Assessment Service) (15). Thus, the experience with CD34$^+$-cell counting confirms that the use of a common standardized protocol and targeted training, where needed, is able to significantly increase reproducibility and reduce variation between laboratories.

IMMUNOPHENOTYPIC CHARACTERIZATION OF CD34$^+$ SUBSETS

While the total number of viable CD34$^+$ cells is the most clinically relevant parameter in determining reengraftment, the ability to reconstitute the human hematopoietic system probably lies within a very primitive subset of this population that does not express lineage-associated antigens (Lin$^-$ phenotype) but expresses the CD90/Thy-1 antigen (24, 34). Rapid multilineage engraftment was observed in the human transplant setting with as few as 8×10^5 highly purified Lin$^-$ CD34$^+$ Thy-1$^+$ PBSC-derived cells (25). Other studies that employed sophisticated animal models of human hematopoiesis have indicated that the AC133/CD133$^+$ subset of CD34$^+$ cells is also enriched in candidate hematopoietic stem cells (38).

Further standardizing an assay to perform subset analysis is even more problematic since most antigens used to identify subsets of CD34$^+$ cells are not expressed on discrete, nonoverlapping populations, but instead are expressed on populations that display a continuum of antigen density from negative to weakly positive. The approach we have developed in concert with the EWGCCA (detailed in references 14 and 33) makes use of the autofluorescence of the gated CD34$^+$ cells to define the lower FL intensity limit of the positive analysis region, following which the experimentally stained sample is to be analyzed (Fig. 5). Though this will not completely account for low-level nonspecific binding of the PE-conjugated antibody to CD34$^+$ cells, it still greatly improves the ability to standardize the analysis of weakly stained subsets of CD34$^+$ cells (14, 33). In the example shown in Fig. 5, a fresh PBSC sample was stained with a combination of CD34-FITC and CD45–PE-Cy5. Bona fide CD34$^+$ cells were

identified and gated per the ISHAGE protocol in R4 of plot D and displayed on a bivariate plot of CD34-FITC versus FL2 (plot E). Since no antibody-PE conjugate is present in this sample, the natural fluorescence, or autofluorescence, in the PE (FL2) channel of the gated CD34$^+$ cells is used to establish the subset positive gating region for the CD90/Thy-1–PE-stained sample shown in plot G. All gating regions remain identical between the two (and any subsequent) tubes. On a technical note, it is crucial to the intra- and interinstitutional reliability of the data generated that the flow cytometer be properly set up and compensated. As shown in plots F and H, respectively, the fluorescence of lymphocytes (gated from the CD45-versus-SSC plot A [not shown]) from the unstained control (plot F) and the CD90/Thy-1–PE-stained sample (plot H) are essentially identical in the FL2 channel (apart from a small number of lymphocytes that have stained specifically with CD90, in keeping with known characteristics of a small subset of T cells). These plots not only demonstrate proper instrument setup and fluorescence compensation but also show that the CD90 antibody used is optimally titrated. Also shown in Fig. 5 are the CD133$^+$ (plot J) and CD33$^+$ (plot K) subsets of CD34$^+$ cells.

DOES ENUMERATING CD34$^+$ SUBSETS HAVE CLINICAL UTILITY?

Whether enumerating specific CD34$^+$ subsets has utility as a predictor of rapid reengraftment remains somewhat controversial. Since several studies have shown that the rate of platelet engraftment is generally rapid in patients given at least 5×10^6 CD34$^+$ cells per kg (37), it is unlikely that monitoring subsets in patients receiving this target dose (or greater) will provide any additional clinical information. At the Toronto Hospital, we monitored CD34$^+$ subsets on those patients in whom the target value of 5×10^6 CD34 cells per kg was unlikely to be met. In this way, we hoped to enumerate specific subsets that correlated best with speed of engraftment. Subsets enumerated included CD90/Thy-1, AC133, CD38^{lo}, CD33^{lo}, and, on selected samples, CD109$^+$ and CD117$^+$. Analysis to date shows, however, that all patients transplanted with CD34$^+$ cells in the range of 2×10^6 to 5×10^6/kg engrafted platelets and neutrophils by days 12 to 14 (unpublished observations). Therefore, it would appear that performing accurate enumeration of CD34$^+$ cells is perhaps more relevant to predicting platelet engraftment than is the qualitative composition of the CD34$^+$ cells, at least for patients receiving at least 2×10^6 to 2.5×10^6 CD34$^+$ cells/kg. In light of this analysis, it may be informative to analyze subsets only in patients whose collections are in the range of 1×10^6 to 3×10^6/kg. Thus, potential clinical applications for CD34$^+$-subset analysis might include evaluating poor mobilizers with inadequate or marginal CD34 collections in addition to measuring qualitative differences in response to different cytokine regimens and quality assuring selected stem cell products during cell processing.

CD34$^+$-CELL SUBSETS IN BACKUP MARROW OF POOR MOBILIZERS

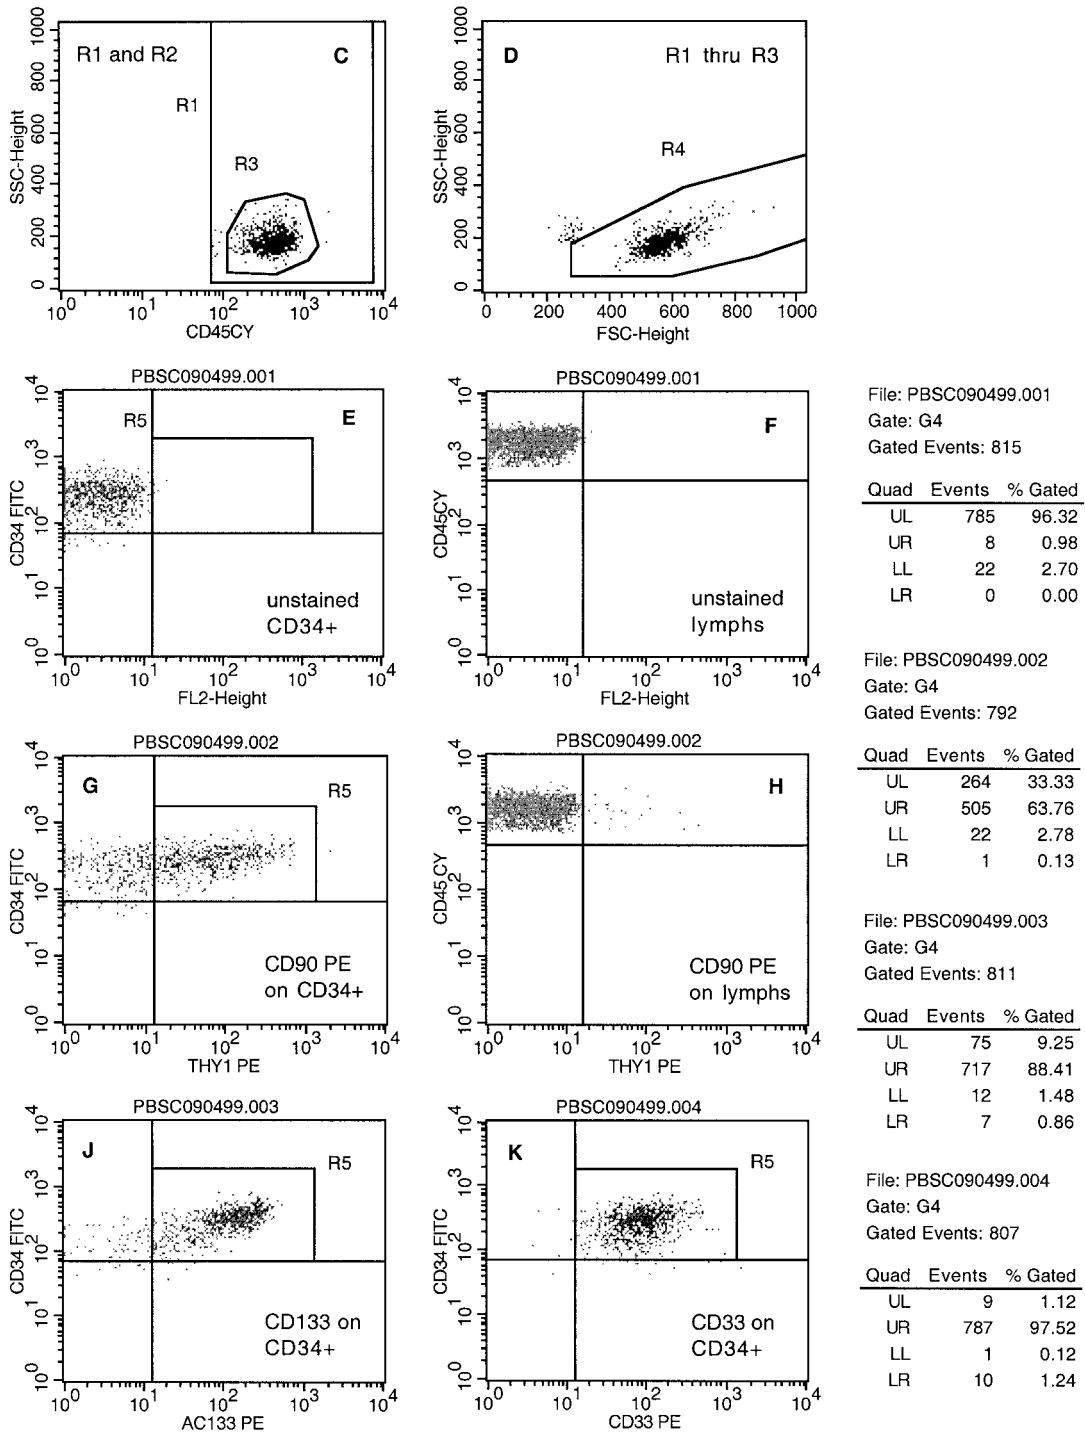
A number of studies have indicated that the use of backup bone marrow cells does not improve engraftment in patients who failed to mobilize sufficient CD34$^+$ PBSC, perhaps suggesting that poor PBSC mobilization is indicative of poor marrow function (36). We analyzed backup marrow from a number of patients who had failed to mobilize an adequate number of CD34$^+$ PBSC. As shown in Fig. 6, using a sample


FIGURE 5   Identifying CD34$^+$-cell subsets using the CPC support protocol (33) and PBSC sample stained with CD34-FITC and CD45–PE-Cy5. CD34$^+$ cells (1.01% of the gated CD45$^+$ events) were identified as described for Fig. 1, plots A to D (plots A and B not shown), and displayed on CD34 versus FL2 to establish positive cell analysis R5 (plot E). Plot F displays gated lymphocytes (from plot B) on a CD45-versus-FL2 plot. Note that the back-scattered lymphocytes have autofluorescence similar to that of gated CD34$^+$ cells (plot E) and cluster parallel with the horizontal axis, indicating optimized FL2/FL3 fluorescence compensation. Plots G and H show the staining of CD34$^+$ cells and lymphocytes, respectively, with CD90/Thy-1–PE. Plots J and K show the staining of the CD34$^+$ cells with CD133-PE and CD33-PE, respectively.

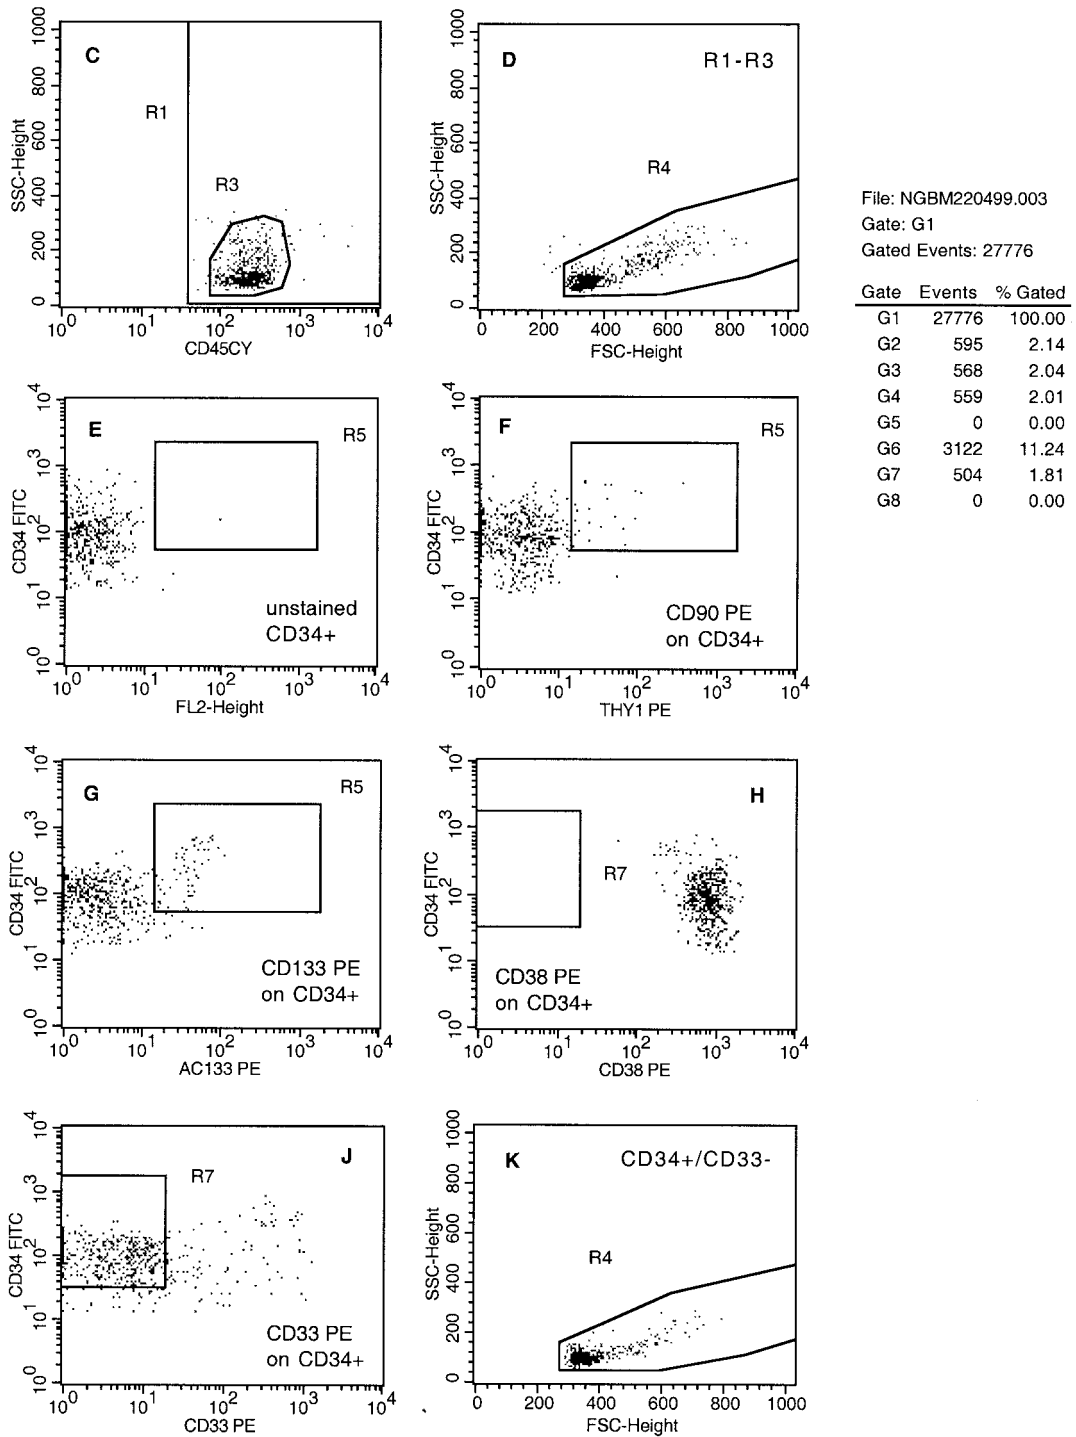

FIGURE 6   Identifying CD34$^+$-cell subsets in the marrow of a poor mobilizer. CD34$^+$ cells (2.00% of the total CD45$^+$ events in G4) are identified in plots A to D (A and B not shown). The majority of CD34$^+$ cells exhibit light scatter characteristics of prelymphoid cells. An unstained control (no PE conjugate) of the gated CD34$^+$ cells from R4 was used to establish gating R5 (plot E). Plots F, G, H, and J show the staining of gated CD34$^+$ cells with CD90/Thy-1, AC133, CD38, and CD33, respectively. The lower right plot shows the light scatter of the CD34$^+$ CD33$^-$ cells.

from a patient with acute myelogenous leukemia, CD34$^+$ cells were gated as described above (plots A to D), and strikingly, as shown in plot D, a majority of the CD34$^+$ cells identified exhibited the characteristics of pre-B cells (i.e., low FSC and SSC signals). When subset analysis was performed using Thy-1, AC133, CD38, and CD33 (plots G, H, J, and K, respectively), there was a demonstrable lack of CD34$^+$ cells exhibiting the composite phenotype of primitive candidate stem cells, with very few CD34$^+$ cells expressing the CD34^{bright} Thy-1$^+$ AC133$^+$ CD38^{dull} phenotype. Additionally, virtually all CD34$^+$ CD33$^{dull/negative}$ cells exhibited the light scatter of lymphoid progenitors. It will be interesting to monitor the engraftment kinetics of such patients should they indeed undergo transplantation with these marrow samples.

SUMMARY

Over the last few years, the number of clinical applications for stem cell transplantation has expanded considerably. At the same time, stem cell collections have been obtained from increasingly diverse sources, including marrow, peripheral blood, and CB, for use in both autologous and allogeneic transplantation. In addition, an increasing array of ex vivo manipulations has been developed to engineer the graft to suit specific clinical requirements. Included in the latter are positive selection techniques to purify CD34$^+$ cells and negative purging techniques to remove residual tumor cells in the autologous setting, or T lymphocytes in the allogeneic setting. Finally, there is widespread interest in the development of clinically useful ex vivo expansion methodologies and gene therapy protocols. As the clinical utility of both unmanipulated and manipulated stem cell products expands, it is critical that robust technologies are developed to accurately monitor the consequences of such procedures on the engraftment potential of the stem cell products. Thus, the graft assessment protocol (i.e., CD34$^+$-cell enumeration by flow cytometry) must be capable of measuring CD34$^+$ cells accurately in a variety of sources of stem cell products without the added expense of redundant isotype controls. It must also be able to distinguish viable CD34$^+$ cells from nonviable CD34$^+$ cells, from nonviable non-CD34$^+$ cells, and from other nonspecifically stained debris. The single-platform variant should be robust enough that viable CD34$^+$ cells can be accurately measured in postcryopreserved samples. Furthermore, the chosen protocol must be flexible enough that, for example, in the allotransplant setting, residual T lymphocytes can be enumerated (33), or in the autologous setting, specific subsets of CD34$^+$ cells can be enumerated (33). In the autologous setting, it may be possible to detect the differential mobilization of specific subsets of CD34$^+$ cells by different growth factor cocktails, or measure the cell cycling status of CD34$^+$ cells and their subsets after mobilization. At present, it is our view that the methodologies based on the original ISHAGE protocol (31) and updated in CPC (14, 33) represent the most accurate and flexible protocols currently available to both clinical and research laboratories for the analysis of the increasingly wide variety of normal and abnormal hematopoietic samples.

Phenotypic Correlates of Genetic Abnormalities in Acute and Chronic Leukemias

ELISABETH PAIETTA

22

The first classification of the acute leukemias in 1976 relied exclusively on the evaluation of cell size, granularity, nuclear shape, cytoplasmic appearance, cytochemical reactions, and dysplastic features of cells surrounding the "leukemic blast." Leukemia diagnostics have come a long way since then. Today, the lineage affiliation of a leukemic cell is accurately defined by multiparameter flow cytometry and prognostically relevant chromosome aberrations are revealed by standard and molecular cytogenetic analyses. In selected cases, researchers have even succeeded in not only elucidating but also reversing the oncogenic mechanism, such as in acute promyelocytic leukemia (APL). APL has become the paradigm for the ultimate goal of leukemia diagnosis: to be able to tell an oncologist what targeted therapy a patient is a candidate for, based on the detection of a specific genotype. APL, furthermore, reflects the major change in criteria that nowadays are or should be used to subclassify leukemias in general. Diagnosis based on similarities in cellular structures has been replaced by outcome-based classifications.

The history of APL (12) goes back to the 1970s, when leukemias with hypergranular morphologies were unified under the French-American-British classification of morphology and cytochemistry (FAB) (69) as FAB M3. In a variant form, M3v, hypergranulated cells were found in bone marrow and circulating leukemic cells had monocytoid features. The description of a balanced translocation between chromosomes 15 and 17 as the hallmark of APL subsequently confirmed the accuracy of the morphologic diagnosis. Only 1 to 2% of non-M3 acute myeloid leukemia (AML) patients express the promyelocytic leukemia protein (PML) retinoic acid receptor α (RARα) gene, the gene fusion product that results at the molecular level from the t(15;17)(q22;q21) translocation. Yet there is a subset of patients in whom, despite the presence of M3 morphology, the t(15;17) translocation cannot be demonstrated (60). While all variant APL translocations involve the *RARα* gene on chromosome 17, its partner gene in the translocation varies.

Previously, the morphologic diagnosis of APL sufficed and could be, but did not have to be, confirmed by karyotyping. With the introduction of effective, APL-specific therapy with all-*trans* retinoic acid (ATRA), however, it became unacceptable to misdiagnose a patient with APL. When it was realized that the differentiation block in APL resulted from transcriptional repression of the retinoic acid signaling pathway due to histone deacetylase activities, it was postulated that histone deacetylase-mediated gene silencing might be a general mechanism of leukemogenesis, at least in AML associated with chromosomal translocations that affect genes encoding transcription factors (57, 61). At the same time, it became clear that in some of the variant APL translocations, ATRA failed to alleviate the transcriptional repression. Thus, it was important to diagnose not just APL but ATRA-responsive APL and this had to happen as quickly as possible after a patient's presentation since ATRA was found to reverse the life-threatening disseminated intravascular coagulation typical of APL (17). Although ideally positioned to confirm the diagnosis of APL, cytogenetic analysis can take 3 to 4 days and may occasionally fail; on the other hand, amplification of aberrant gene sequences by PCR is a method not available to everybody and beset by its own problems.

Because of the unique morphologic appearance of hypergranular leukemic promyelocytes, the heterogeneity invariably introduced in all other FAB classes due to subjective interpretation of cellular features by morphologists largely does not exist in M3 disease. To be able to compare antigen expression patterns in a group of homogenous patients, at least by morphology analysis, was a huge advantage when flow cytometrists started to look for an APL-specific immunophenotype. Indeed, the typical negativity of APL cells for HLA-DR and CD34 was recognized ~20 years ago. Still, it was not until 2004 that an antigen profile was established that reliably served as a surrogate for the t(15;17) or the *PML/RARα* gene and which held up for most of the cytogenetic (molecular) variants (54). Deviations from this profile, such as expression of the neural cell adhesion molecule CD56, proved to offer prognostic information that was not provided by any other diagnostic parameter. If results of flow cytometric tests, which take about 2 h, "are consistent with the diagnosis of APL," subsequent confirmation of this diagnosis by molecular studies is highly recommended; at the very least, flow cytometry results can exclude APL.

But challenges do remain; a priori resistance to ATRA and variable response durations in responsive patients suggest that an even more refined subclassification of APL is needed. Internal tandem duplications (ITD) of the *FLT3* gene that constitutively activate the FLT3 receptor tyrosine kinase (TK) are found in almost 40% of APL cases; they are associated with hyperleukocytosis and possibly with inferior outcome, although definitive studies are pending.

Recently, *FLT3* ITD have been shown to cooperate with the *PML/RARα* gene in the development of APL in a murine model, suggesting that mutant *FLT3* represents the necessary second pathogenetic "hit" in this disease (34). In non-APL AML, *FLT3* gene mutations are the most common genetic aberration. Given their potential prognostic implications, it would be advantageous to be able to predict *FLT3* ITD through other cellular features. Kussick et al. (37) described a small subpopulation of non-APL AMLs (<5% of cases) in which the lack of HLA-DR, CD34, and CD133 (antigenic properties also seen in APL) in association with a normal karyotype predicted *FLT3* ITD. In acute lymphoid leukemia (ALL), activating *FLT3* gene mutations identify a rare patient subset with a unique immunophenotype of immature T lymphoblasts that express the CD117/KIT TK (55). These data suggest that genotypic alterations leading to constitutively activated FLT3 TK may indeed affect the overall phenotype of the leukemic cells.

The basic hypothesis of surrogate marker profiles is that individual genetic lesions result in characteristic distortions of the cellular phenotype with some predictable consistency that can be exploited by sophisticated immunophenotyping.

METHODOLOGIC PREREQUISITES AND KNOWLEDGE

Morphologic Evaluation of Peripheral Blood and Bone Marrow Smears

Access to a microscope and to a hematology laboratory that routinely prepares bone marrow or peripheral blood smears and Wright-Giemsa staining is required. Bone marrow smears must be prepared before the aspirate is mixed with anticoagulant.

Traditionally, morphologic and cytochemical analyses (in particular, those using peroxidase and esterase stains) were the predominant processes utilized in diagnosis. Major drawbacks were the subjectivity and inaccuracy associated with microscopic examination of specimens, a lack of prognostic power of morphology-based classification of leukemia subgroups, and a low level of sensitivity for the detection of blast cells during clinical remission. Today, analysis of antigen expression profiles, cytogenetics, and genetic information has, for the most part, supplanted morphology analysis. Still, examination of both peripheral blood and bone marrow smears is an important first step in the workup for any leukemia patient. Furthermore, the main criterion for the generally accepted definition of remission continues to be the percentage of blast cells present as recognized by morphology. The original FAB classification criteria (5, 69) were recently supplemented with pertinent data on chromosomal and molecular associations in the 2001 World Health Organization (WHO) classification system for hematopoietic tumors (31).

Multiparameter Flow Cytometry and Interpretation of Results

Access to a flow cytometer or to a clinical laboratory or core facility with staff that performs multiparameter flow cytometry with three- or four-fluorochrome combinations is required for the application of flow cytometry to leukemia diagnosis. In addition, a pathologist or cell biologist trained in the interpretation of normal and leukemic hematopoietic antigen expression profiles should be available for the interpretation of flow cytometry data. The choice of anticoagulant in the collection of peripheral blood or bone marrow for flow

cytometry is insignificant. As a side note, controversy exists as to whether the choice of anticoagulants does matter when cells are isolated for the purpose of nucleic acid preparation. (For instance, heparin, the anticoagulant most widely used in clinics, has been condemned by many molecular biologists, although others have found no effect on nucleic acid quality or specific transcript levels.) If samples from one patient are to be used for both flow cytometry and nucleic acid isolation, one should perform appropriate control testing with the anticoagulants used to ensure that they do not impair the aspect of the project that deals with DNA or RNA.

All samples are to be kept sterile. If specimens are to be stored or shipped, they can be kept at 10 to 15°C, without freezing, for 48 to 96 h. Leukemic blasts are considerably hardier than normal cells, and antigen expression does not change during prolonged time periods under appropriate storage conditions. Whole specimens can be stained for flow cytometry; mononuclear cells must be isolated (by density gradient centrifugation) before cells are frozen in a viable state in the presence of dimethyl sulfoxide (10%) and 50 to 90% fetal bovine serum; the serum concentration increases with the granularity of blast cells. Should viability be low after thawing, one must consider the selective retrieval of leukemia subpopulations (47).

Antibodies are grouped in clusters of designation (CD); if at least two antibodies show identical reactivity patterns and are proven to recognize the same antigen, a new cluster is designated. Clusters may be split based on selective reactivities of certain antibodies with a modified version of the antigen. For instance, the CD15 cluster is subdivided since some antibodies recognize the sialylated CD15 antigen (CD15s) while others recognize only the asialo form (CD15). Since the early 1980s, CDs have been established through international meetings, with the last two such meetings held in Harrogate, United Kingdom, in June 2000 (43) and in Adelaide, Australia, in December 2004.

Attention needs to be paid to quality control of flow cytometer performance, the choice of antibodies and of fluorochromes, the design of most informative antibody panels, and the mode of analysis, particularly the fact that data should be reported exclusively for the abnormal cell population (47).

In terms of data reporting, there are two philosophies of flow cytometry that in the minds of many are mutually exclusive. One concept teaches the use of a quantitative approach that reports the percentage of blast cells binding a given antibody; the other relies on quantitative fluorescence and reports fluorescence intensities as a reflection of antigen density on the cell surface. It is imperative that every laboratory establish its own optimal conditions of antibody performance. Despite its importance, quality control of flow cytometer and antibody performance, unfortunately, is not well standardized (47). Choice of antibodies and fluorochromes, staining, and erythrocyte lysing and fixation conditions, as well as flow cytometer settings, will largely affect flow cytometry data. For intracellular antigens, permeabilization and fixation conditions will determine whether an antigen is detected or not. The best example is the failure to detect nuclear expression of terminal transferase (TdT) in leukemic myeloblasts when suboptimal conditions and antibodies are used (50). Experience should guide the decision of when to report the percentage of staining blast cells or the fluorescence intensity. Some antibodies invariably stain all cells from a given lineage but vary markedly in their intensity of staining between normal and malignant cells, suggesting variable antigen densities (e.g., those of CD20 and CD22 on normal versus chronic lymphocytic leukemia [CLL]

B lymphocytes); for other antigens, the fraction of cells binding the antibody will contain the diagnostic information (e.g., the percentage of CD34 + or CD117 + cells in any acute leukemia).

Standard Cytogenetic Analysis and FISH

Access to a cytogenetics laboratory with well-trained cytogeneticists is required for standard cytogenetic analysis and fluorescence in-situ hybridization (FISH). Specimens for cytogenetic analysis are prepared in the same manner as those for flow cytometry, and bone marrow is preferred over peripheral blood. Most cytogenetic laboratories have optimized their processing techniques on specimens drawn in sodium heparin; one truly contraindicated anticoagulant is EDTA (purple-top tubes). At the same time, EDTA should be avoided for the collection of leukemic blasts (especially lymphoblasts), as it can introduce vacuoles into the cytoplasm and confuse the morphology analyses. Samples should be set up within 24 h of collection; if stored, they should be stored at room temperature. AML, ALL, or chronic myelogenous leukemia (CML) tissues should be cultured for 24 h without mitogens before processing. Samples from CLL require stimulation by B-cell mitogens (B-cell CLL) or T-cell mitogens (T-cell CLL) for cell division to occur (22).

To see distinct chromosomes under the microscope, cells must be dividing. This prerequisite is a limiting factor when the abnormal cells have low mitotic indices or very few blast cells are present (in remission) so that normal dividing cells outnumber cells with an abnormal karyotype. FISH is one way to overcome this obstacle. FISH uses fluorochrome-labeled nucleic acid probes and detects abnormalities both in interphase (nondividing) and in metaphase (dividing) cells (25). CLL, multiple myeloma, and plasma cell leukemia are paradigms for diseases in which low mitotic activity prompts the use of interphase FISH. The specific probes used determine which aberrations are detected. In CLL, a series of recurrent genomic aberrations correlates with survival (16); because interphase FISH analysis has a greater chance of detecting these aberrations than standard cytogenetics (given the low mitotic rate of CLL cells), it is the method of choice for determining chromosomal abnormalities in CLL.

FISH has increased sensitivity compared to standard cytogenetic analysis. With optimal strategies, e.g., the use of dual color/dual fusion (D)-FISH, one abnormal cell can be detected in 6,000 normal cells (15). Although such high sensitivity is not important at the time of diagnosis, when the proportion of leukemic cells, by definition, must exceed 20% in the diagnostic tissue, it is essential when FISH is used for the detection of minimal residual disease (MRD); at least three abnormal cells should be seen among a total of 6,000 normal cells prior to concluding the presence of MRD (14). Aside from its higher sensitivity, FISH can detect deletions in chromosomes involved in reciprocal chromosomal translocations (see below).

The consensus is that if cytogenetic abnormalities are absent, at least 20 metaphases must be viewed before the patient is considered to have normal cytogenetics. Given that leukemias with apparently normal karyotypes represent a biologically very heterogenous group, there is major emphasis on categorizing them into subsets with prognostic implications, e.g., based on mutations of the *FLT3* gene, which in non-APL AML occur preferentially in cases with normal cytogenetics (35).

A clone is defined by the presence of two metaphases that share the same chromosome abnormality, unless the change involves loss of a chromosome, in which case three such cells are required (22). In a follow-up specimen, however, one metaphase may be considered a remnant of the original clone. Otherwise, single abnormal metaphases do not count as clonal cytogenetic abnormalities; if they present a specific aberration known to be associated with leukemia, e.g., t(9;22) or t(8;21), FISH or PCR analysis targeted at that aberration is recommended. In most cases, the leukemic cells contain one primary clone with or without additional (secondary) aberrations that result from clonal evolution. Patients with two distinct cytogenetic clones are rare. The International System for Human Cytogenetic Nomenclature in 1995 established a uniform code for designating both constitutional and acquired chromosome abnormalities and for reporting results obtained by FISH. For details on the preparation of metaphase spreads, banding techniques, and quality assurance, etc., the reader is referred to a few excellent publications (15, 22).

At the time of leukemia diagnosis, conventional cytogenetic analysis should be performed, as this method reveals all chromosomal abnormalities that are present. In a large portion of patients, karyotypic aberrations do not lend themselves to either FISH or PCR analysis, because specific probes are not (yet) available. However, if a patient is found to have a genetic lesion that can be monitored by these techniques, they can be very helpful for detecting MRD during clinical remission (71). It is important to remember that if one monitors patients during their clinical course by FISH or PCR targeted at their initial genetic lesions only, clonal evolution or the occurrence of new cytogenetic abnormalities will be missed. An example are CML patients treated with imatinib in whom the development of clonal cytogenetic abnormalities in *BCR/ABL*-negative cells would have been missed had conventional cytogenetic analysis not been performed in some of these cases (9).

Molecular Consequences of Chromosome Translocations and the Creation of Novel Fusion Genes

Chromosome translocations can have two distinct effects at the molecular level: either the inopportune activation of an unaltered gene or the creation and transcription of a novel gene. The first process occurs predominantly in lymphoid malignancies. The translocation places a transcriptionally silent gene under the control of the promoter of a transcriptionally very active gene, e.g., immunoglobulin or T-cell-receptor genes in B or T lymphocytes, respectively. This leads to the inappropriate transcription of a normal gene. Since those deregulated genes encode proteins involved in normal cellular growth and/or differentiation, particularly transcription factors (proteins that bind to specific DNA sequences, thereby stimulating or suppressing the expression of other genes), inappropriate expression results in uncontrolled cellular proliferation.

Alternatively, balanced translocations, interstitial chromosome deletions, or inversions can lead to the creation of novel, leukemogenic fusion genes. At each of the chromosomal breakpoints, a critical gene is disrupted [e.g., the *ABL* gene on chromosome 9 and the *BCR* gene on chromosome 22 in the t(9;22)(q34;q11.2)]; fragments of the two genes are brought together as a result of the translocation. Two hybrid fusion genes are created, one on each of the two chromosomes partnering in the translocation [e.g., *BCR/ABL* on the derivative chromosome 22 and *ABL/BCR* on the derivative chromosome 9, resulting from the (9;22) translocation]. Even if both chimeric genes are transcribed, only one is usually suspected as the transforming gene, based on gene sequences preserved in the fusion product and its in vitro activities. The altered properties of the chimeric proteins

may predict their leukemogenic effects, e.g., the constitutive TK activity of BCR/ABL proteins that are localized exclusively in the cytoplasm, which contrasts with the tightly regulated activity of the normal ABL TK that shuttles between the nucleus and the cytoplasm (36).

Examples for this type of translocation are numerous among the leukemias. The novel fusion proteins are the only true leukemia-specific antigens. Antibodies to a few of these unique proteins exist but have not found widespread use as diagnostic tools; rather, they may be attractive targets for novel therapies. The deregulated BCR/ABL TK, the product of the t(9;22), is the best example for effective therapy through inhibition of the aberrant gene product, for instance, with imatinib (13). Targets for imatinib other than BCR/ABL are therapeutically relevant molecules in myeloid disorders (56).

Since several balanced translocations and the corresponding chimeric gene products have been associated with clinical response in leukemia, modern classification systems have incorporated them as hallmarks of distinct leukemia subtypes (31).

FISH analysis has found large deletions at breakpoints of reciprocal chromosomal translocations. Best characterized, to date, are deletions on either chromosome 9 or 22 of the t(9;22), which, at least in CML, are independent indicators of rapid progression to blast crisis and shorter survival. It is possible that loss of a critical region, involving loss of a tumor suppressor gene, confers a growth or survival advantage or results in an increase in genomic instability. There is strong evidence that similar deletions may exist in other leukemia translocations [e.g., inv(16) and t(8;21)] (30).

PCR Amplification

Balanced translocations, which appear identical by standard cytogenetic analysis, can be genetically very complex. This may be due to chromosome deletions that require FISH for detection (see above) or to differences in the genomic breakpoints that produce structurally and biologically distinct fusion products. Genetic variability may also derive from alternative splicing of fusion transcripts. Specific primer pairs, or combinations thereof, allow for the identification of such genetic variants. For instance, several BCR/ABL oncogenes exist that vary in the amount of BCR gene included; the encoded proteins are associated with distinct clinical and biologic features and may confer distinct prognoses (39, 72). Another example are the more than a dozen different CBFβ/MYH11 fusion messages that are generated by the inversion of chromosome 16 [inv(16)(p13q22)]; in these isoforms, the portion of the MYH11 gene that participates in the creation of the fusion product can vary (11). When combined with the existence of large deletions in the CBFβ gene (30), the complexity of this allegedly simple inversion becomes apparent.

Chromosomal aberrations can be monitored by PCR if the gene sequences affected by the aberrations have been identified, as the sequences are required to serve as templates for primer construction. The PCR technique is an essential tool for (i) subgrouping of patients with apparently identical chromosome abnormalities according to genetic variants and (ii) monitoring of the actual state of remission. In the near future, the definition of "remission" will have to be revisited, particularly for diseases in which the presence of MRD, in the absence of clinical and hematologic symptoms, is confirmed to have treatment implications (45). One caveat to the use of PCR for MRD monitoring relates to the finding of several of these presumably leukemogenic fusion genes in healthy individuals (6).

Cryptic Chromosome Translocations

Rare cryptic translocations derive from submicroscopic insertions of genes, yielding a molecular result identical to that of the common translocations; FISH or PCR can detect them. Whether cryptic translocations, in general, confer the same prognostic significance as visible ones has not yet been established.

The (12;21)(p13;q22) translocation that results in the TEL/AML1, also called ETV6/RUNX1, gene fusion is an exceptional chromosomal aberration in that it is always cryptic. It is the most common genetic rearrangement found in children with precursor B-lineage ALL and associated with excellent prognosis; on the other hand, this fusion transcript is rarely found in adult disease (52).

PRESENTLY ACCEPTED DIAGNOSTIC CLASSIFICATION OF HEMATOLOGIC MALIGNANCIES

The WHO Classification of Hematopoietic Tumors published in 2001 (31) represents the first worldwide comprehensive classification of the hematologic malignancies. The WHO system took the stand of compiling established classification approaches into one; at the same time, new information (e.g., cytogenetics) was incorporated and some subcategories that appeared to be outdated were selectively deleted (e.g., L1 and L2 morphological subgroups in ALL were combined). The committee members decided that sorting neoplasms according to associated prognoses was neither practical nor necessary and could be misleading.

The WHO proposal created novel diagnostic subclasses based on clinically relevant cytogenetic abnormalities and their molecular equivalents, such as t(9;22)(q34;q11.2) (BCR/ABL); t(v;11q23) (rearranged mixed-lineage leukemia [MLL] gene), with "v" standing for one of approximately 50 different translocation partners (genes); t(1;19) (q23;p13.3) (PBX1/E2A); t(12;21)(p13;q22) (TEL/AML1); hyperdiploid, and hypodiploid karyotypes in ALL. AML was subgrouped into (i) AML with recurrent cytogenetic abnormalities, t(8;21)(q22;q22) (AML1/ETO), inv(16) (p13q22) or t(16;16)(p13;q22) (CBFβ/MYH11), t(15;17) (q22;q12) (PML/RARα), and AML with 11q23 abnormalities (rearranged MLL gene); (ii) AML with multilineage dysplasia; (iii) therapy-related AML/myelodysplastic syndrome; and (iv) the largest group of all, AML not otherwise categorized but subdivided into the old FAB morphology categories.

The fifth WHO category for AML comprises "acute leukemia of ambiguous lineage"; to recognize such leukemias, the WHO system advocated the use of scoring systems in the interpretation of immunophenotypic data (31). More than 20 years ago, Bettelheim and Paietta (7, 49) introduced the terms "biphenotypic" and "mixed leukemias" to describe ambiguous cases in which TdT-positive lymphoblasts expressed the myeloid surface antigen CD15 and in which leukemia populations appeared to consist of cells with distinct lineage affiliations, respectively. Even though these terms were understandable back then, in the earliest days of monoclonal antibodies to hematopoietic antigens and in the pre-flow (cytometry) era, their creation was unfortunate. Despite new knowledge and much better technology, these diagnostic terms have persisted as viable parts even of the new WHO classification and are widely abused based primarily on flawed data interpretation. It is now known that in up to 60% of ALL cases, the lymphoblasts express one to two myeloid antigens. The pattern of distribution of myeloid

antigens in ALL varies with the stage of maturation of the lymphoblasts [myeloid antigens CD33 and CD13 in CD10 + early pre-B-ALL and myeloid antigens CD65(s) and CD15(s) in CD10 − undifferentiated pro-B-ALL] (48). Alternatively, TdT and other lymphoid-associated antigens can be expressed by leukemic myeloblasts. The B-lymphoid antigen CD19, for instance, is part of the surrogate marker profile for t(8;21) AML (see below).

Neither the finding of myeloid antigens in ALL nor that of lymphoid antigens in AML per se signifies lineage ambiguity; most notably, it does not affect clinical outcome, unless these antigens form part of a marker profile typical of a prognostic genetic lesion. For instance, expression of CD33 and CD13 in early pre-B-ALL is frequently associated with the presence of *BCR/ABL* transcripts (see below); the *BCR/ABL* transcript, reflecting t(9;22)(q34;q11.2), the Philadelphia chromosome, is found in ~30% of adult ALL cases and is the strongest negative prognostic indicator in this disease (27).

In at least 95% of acute leukemias, a single dominant lineage affiliation can be established through the detection of one of three lineage-*specific* antigens, myeloperoxidase, intracytoplasmic CD22 (cCD22), or intracytoplasmic CD3 (cCD3), for the myeloid, B, or T lineage, respectively. It is essential that myeloperoxidase be tested simultaneously with cCD3 or cCD22 in leukemic blasts that are gated flow cytometrically either through side scatter versus CD45 or through the use of a gating antibody, such as CD34 or CD117. Leukemia populations with truly biphenotypic features are rare and manifest themselves through dual expression of two lineage-*specific* antigens in the same cell, e.g., myeloperoxidase and cCD3, as seen in some cases of CD117+ ALL (55). Unfortunately, these essential antigens are intracellular and thus still present a technical challenge to many flow cytometrists. It is important to remember that CD22 and CD3 can be found on the surfaces of mature B and T lymphocytes, respectively; control staining of the cell surface and gating exclusively on abnormal cells are absolute prerequisites for meaningful results.

To rely solely on standard cytogenetics is problematic when one considers that in national cooperative group adult leukemia trials up to 40% of patients have either normal, invalid, or no cytogenetic results. The WHO proposal failed to appreciate the potential of immune profiles to serve as surrogates for clinically relevant genetic defects in the absence of cytogenetic and/or molecular information.

INTERRELATIONSHIPS OF THE VARIOUS DIAGNOSTIC LABORATORY DISCIPLINES

While the various diagnostic disciplines should work together, compensate for one another's weaknesses, and eventually provide an overall diagnosis, individual diagnostic parameters are often not predictive of one another or even directly comparable. An example is the assumption that a patient who, according to blast immunophenotyping, has differentiated AML must have blasts with FAB M2 morphology. Similarly, blasts appearing to have monocytoid features under the microscope may not necessarily express CD11b and/or CD14, two prototype monocytic antigens. Both immunophenotyping and morphologic evaluation yield significant, but independent, pieces of information. Only in rare circumstances, e.g., in hypergranular APL, will a unique immunophenotype be consistently associated with a particular morphologic appearance.

There are some who believe that gene expression profiling, with its potential to measure the relative abundances of

thousands of transcripts and provide information on the transcriptional activity of leukemic cells on a genomic scale (29), may soon replace other diagnostic disciplines, particularly if combined with protein analyses. Although gene expression arrays benefit from established basic leukemia biology, they can focus on areas in which conventional methods have failed, such as diseases devoid of standard prognostic indicators (e.g., leukemias with normal cytogenetics); the first promising results along these lines have been reported (e.g., references 8 and 70). As part of their prospective ability to elucidate molecular pathways that sustain the growth and survival of the various leukemic cells, gene expression analyses have great potential for discovering novel therapeutic targets; such discoveries may eventually lead to a leukemia classification system based on response to target-specific therapy.

Morphology Versus Immunophenotype
The best example of cooperation between morphologic evaluation and immunophenotyping was the creation of FAB class M0, the subtype with the least morphologic differentiation (69). That M0 leukemias belong to the myeloid lineage is based primarily on the detection of the myeloperoxidase protein through antibody binding; cytochemical staining fails to yield a positive reaction because the myeloperoxidase precursor that is present in these undifferentiated cells lacks enzymatic activity. If myeloperoxidase cannot be detected, affiliation with the myeloid lineage depends on the detection of CD33 and CD13 in the absence of lymphoid-specific antigens (53).

In APL, despite the presence of the same cytogenetic aberration, t(15;17), the hypogranular variant (M3v) demonstrates some immunophenotypic features distinct from those of M3: the stem cell antigen CD34, HLA-DR, and the T-cell antigen CD2 are commonly expressed by M3v leukemic promyelocytes, and antibody to the common leukocyte antigen CD45 binds with fluorescence intensity higher than that seen in M3 cells (54). Grimwade et al. (26) speculated that APL cells that expressed the CD2 antigen were derived from progenitors with T-lineage potential and thus earlier in differentiation than CD2− APL cells. This suggestion was based on their finding that in CD2+ APL cells the *CD2* locus demonstrates chromatin features identical to those of T cells. The expression of CD2 is the strongest indicator for M3v APL (or APL with the S-transcript isoform of *PML/RARα*; see next section). It is important to remember that CD2 is rarely found in AML. The only other AML subtype famous for occasional CD2 expression is inv(16) AML (1). The distinction between CD2+ APL and inv(16) AML is based on the lack of CD11a, CD18, and CD133 in the former (54).

CD2 expression can override all other immunophenotypic "rules" in the characterization of APL. If CD2 expression on leukemic myeloblasts is unequivocally demonstrated, it is recommended that these blast cells be subjected to molecular analysis for *PML/RARα*, irrespective of the cells' morphology or other immunophenotypic features.

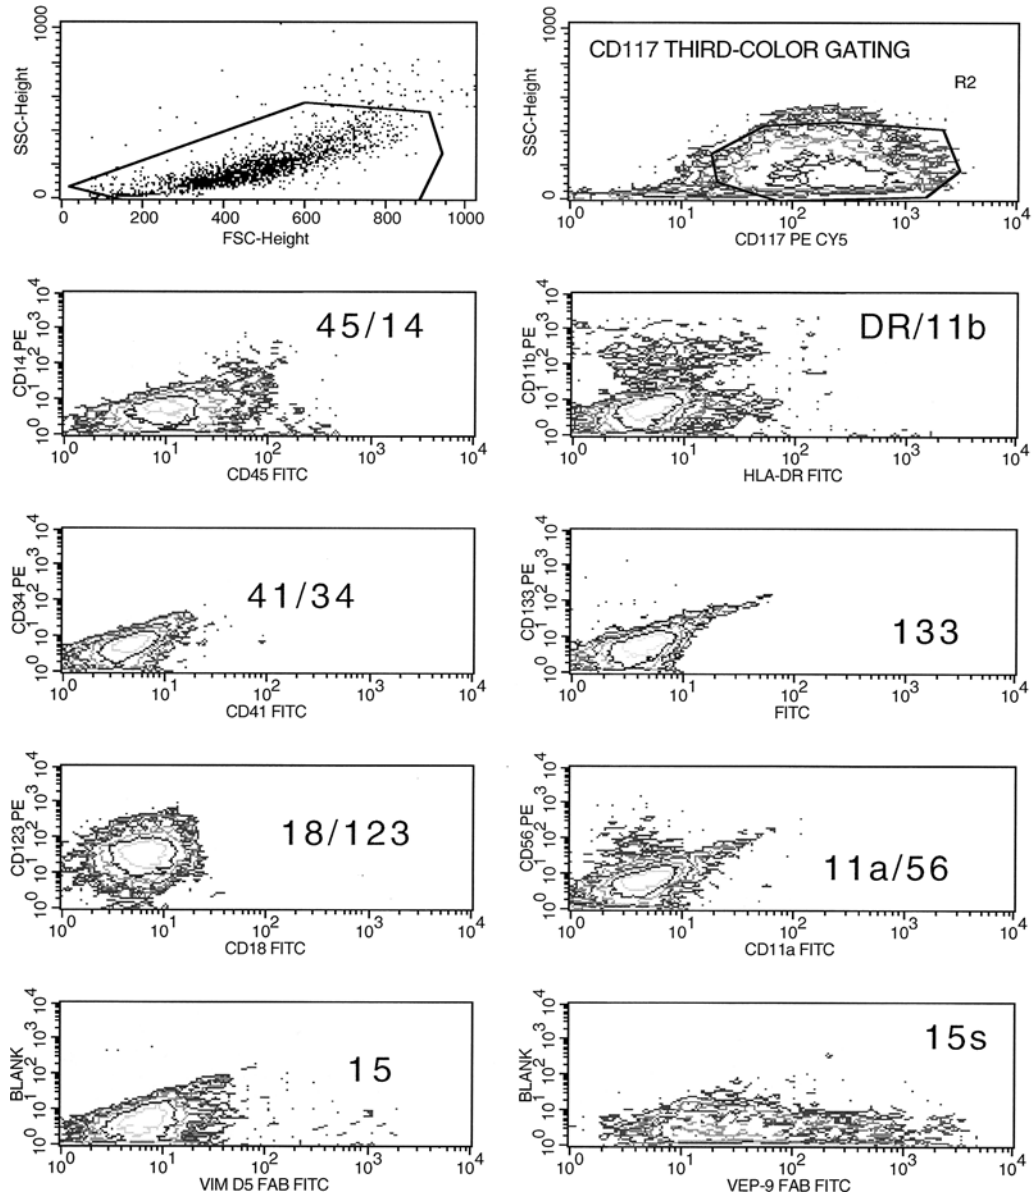
Immunophenotyping Versus Cytogenetic and Molecular Analysis
In APL, differential breakpoints in the *PML* gene lead to either the L (long; bcr1)-, S (short; bcr3)-, or V (variable; bcr2)-transcript isoform of *PML/RARα*. The recently described surrogate marker profile for *PML/RARα* APL, HLA-DR Low CD11a Low CD18 Low (54), is applicable to all three molecular isoforms (Fig. 1). In terms of specific


FIGURE 1 Typical antigen profile of *PML/RARα*-positive APL (for all L- and V-form and many S-form cases and for all M3 and some M3v morphologies). The scattergram in the left upper corner characterizes all cells present by size (forward scatter [FSC]) and granularity (side scatter [SSC]). A gate is set around all cells of interest. In the contour plot to the right, the leukemic promyelocytes are gated on the basis of CD117 expression (R2), whereby cells are stained with CD117 conjugated to phycoerythrin-cyanin 5 (PE CY5); this CD117-PE CY5 antibody is added to every antibody combination so that gating can be limited to leukemic cells. All subsequent contour plots show antigen expression only on gated leukemic promyelocytes. Such or similar gating strategy should always be applied in order to eliminate the inclusion of normal cells in the evaluation of antigen expression patterns. In all contour plots, data along the *x* axes reflect cells stained with antibodies conjugated to fluorescein isothiocyanate (FITC). Along the *y* axes are data for cells stained with antibodies conjugated to phycoerythrin (PE). Any blasts, which bind both FITC- and PE-antibodies in a given combination, appear in the right upper quadrant of the contour plot. For each contour plot, single or double antibodies tested (in addition to CD117) are indicated; CD clusters for all antibodies tested are written into the contour plots. Fluorescence intensity, a measure of antigen density, is usually expressed by the mean fluorescence channel of the cell population stained with the specific antibody of interest (along the *x* or *y* axis) divided by the mean fluorescence channel of the negative isotype control (mean fluorescence intensity or mean fluorescence intensity ratio).

antigenic features, the L- and V-form diseases are indistinguishable but clearly separable from S-isoform APL. Only in S-form disease do leukemic promyelocytes express CD34, CD2, and CD56. CD56, the neural cell adhesion molecule, has been associated with poor clinical outcome in APL (48). Note that, although the presence of CD2 and/or CD56 on a patient's leukemic promyelocytes is highly suggestive of the S isoform because these antigens are never seen in L- or V-isoform disease, there are a large number of S-isoform patients who lack these antigens. CD34 expression may be associated with the molecular isoform or the microgranular morphologic variant (see above). The density of the CD34 antigen is significantly lower on the surfaces of leukemic promyelocytes than on non-APL myeloblasts (46).

While CD56 expression in AML is not uncommon, the expression of the T-cell-affiliated antigen CD2 by leukemic myeloblasts is rarely observed, provided that antigen expression is viewed on gated leukemic cells exclusively. CD2 expression by myeloid leukemic cells, therefore, should raise the immediate suspicion of APL. The only other AML subtype that frequently demonstrates CD2 expression is AML associated with $CBF\beta/MYH11$ [inv(16)(p13q22)] (1). This is an important though not well-appreciated association, given that inv(16) is a subtle cytogenetic abnormality that is easily missed.

The t(9;22)(q34;q11) encodes various isoforms of the BCR/ABL fusion gene that resides in the Philadelphia chromosome, the derivative chromosome 22. All BCR/ABL proteins share similar carboxy-terminal ABL TK domains but differ in the portions of the BCR protein included in the fusion product. In the majority of CML cases and in one-third of BCR/ABL-positive ALL cases, the break within the BCR gene occurs in the major breakpoint cluster region (M-bcr), resulting, when joined with a portion of c-ABL from chromosome 9, in a b2a2 or b3a2 fusion transcript encoding a protein of 210,000 daltons (p210$^{BCR-ABL}$). A break in the minor breakpoint cluster region (m-bcr) forms the e1a2 transcript encoding a 190,000-dalton protein (p190$^{BCR-ABL}$) found mostly in BCR/ABL-positive ALL (39, 72). Lymphoblasts express specific antigenic features dependent upon which BCR/ABL isoform they contain (e.g., the myeloid antigen combination CD33+CD13 and CD25 expression are much more frequent in p210$^{BCR-ABL}$ lymphoblasts) (E. Paietta et al., *Blood* **100**[11]:755a, abstr. no. 2990, 2002). This finding suggests that the two major isoforms affect distinct target cells of transformation.

Cytogenetic Versus Molecular Analysis

Whether or not patients with molecular but not chromosomal evidence of certain genetic lesions are to be considered identical in terms of outcome is still in question. In pediatric and adult T-lineage ALL, overexpression of the transcription factor HOX11 can occur in the absence of the cytogenetic aberration that is linked to the activation of the HOX11 gene, namely, translocations involving 10q24; despite the lack of visible chromosomal rearrangements, the favorable outcome associated with HOX11 overexpression is preserved (18, 19).

The situation is different with t(8;21)(q22;q22), a translocation associated with favorable prognosis in AML; patients who lacked this translocation as determined by standard cytogenetic analysis or FISH but who were found to express its molecular product, the $AML1/ETO$ fusion gene, did substantially more poorly than cytogenetically t(8;21)-positive patients (63).

Gene Profiling Versus All Other Diagnostic Disciplines

Recent results from gene expression profiling suggest that the two morphologic subtypes of APL, M3 and M3v, are clearly separable. Schoch et al. proposed that the difference might lie in the higher frequency of $FLT3$ gene mutations in M3v (64).

In pediatric B-lineage ALL, conventional differentiation stages, such as early pre-B-ALL (CD10$^+$; negative for intracytoplasmic μ chains) versus pre-B-ALL (positive for intracytoplasmic μ chains), do not elicit strong enough gene signatures to stand out in comparison with those of chromosomal translocations (21, 62). Of particular interest are specific gene profiles that correlate with response to therapy and survival outside of standard diagnostic criteria (e.g., references 10, 21, and 68), as they highlight the limitations of present classification systems, particularly in terms of clinical relevance.

SURROGATE MARKER PROFILES FOR GENETIC LESIONS

$PML/RAR\alpha$-Positive APL and Its Variants

APL with M3 (or M3v) morphology is the only AML subtype to date for which morphology and immunophenotype agree. Early definitions were limited in their ability to distinguish APL from other AML subtypes, such as natural killer (NK) cell AML, an important distinction considering that NK AML is unresponsive to ATRA (reviewed in reference 46). The newest definition (54) reliably identifies t(15;17) (q22;q21) APL based predominantly on the following: (i) lack of HLA-DR and CD133, two antigens expressed at differentiation levels more immature than that of promyelocytes during normal myelopoiesis; (ii) absence of several adhesive molecules, such as the leukocyte integrins CD11a (α_L subunit of the leukocyte function-associated antigen 1 [LFA-1]), CD18 (β_2 subunit of LFA-1), and CD11b (α_M subunit of Mac-1 integrin); (iii) low expression of carbohydrate structures which serve as ligands for other adhesion molecules (CD65s and CD15); and (iv) faint expression of CD45, the common leukocyte antigen, and of CD38, a bifunctional ectoenzyme catalyzing both the synthesis and the hydrolysis of cyclic ADP-ribose and involved in cell adhesion to the endothelium. With respect to CD15, it is important to realize that leukemic promyelocytes express CD15 in its sialylated form. Therefore, although CD15s antibodies, such as VEP-9 in Fig. 1, will readily stain APL cells, CD15 antibodies that lack reactivity with the sialylated antigen, such as VIM-D5, will not (46, 54).

In addition to the $PML/RAR\alpha$ fusion gene, which accounts for >98% of APL cases, a common segment of the 5′-truncated $RAR\alpha$ gene has been found to fuse with alternative genes (60). Because such variant translocations are rare, clinical information regarding the responsiveness of associated diseases to ATRA is scarce; recurrent cases of promyelocyte leukemia zinc finger ($PLZF$)/$RAR\alpha$ leukemia, derived from t(11;17)(q23;q21), appear to lack ATRA responsiveness, and nucleophosmin (NPM)/$RAR\alpha$ APL, derived from t(5;17)(q35;q21), is ATRA responsive. Despite their low frequency, the limited immunophenotypic observations available suggest that the main characteristic features of $PML/RAR\alpha$ APL cells hold up for all presently known variant APL translocations that involve rearrangement of the $RAR\alpha$ gene (E. Paietta, unpublished results), i.e., HLA-DR$^{-/Low}$ CD34$^{-/Low}$ CD11a$^-$ CD18$^-$ CD15s$^+$/CD15$^-$. Novel variant $RAR\alpha$ fusion genes keep appearing in the literature, for which ATRA sensitivity in individual cases appears to vary.

Two pieces of evidence should prompt the search for the presence of an alternative *RARα* fusion gene in a patient, (i) the finding of APL-specific immunophenotypic features in a patient negative for *PML/RARα* and (ii) cytogenetic evidence of chromosome 17 abnormalities in such a patient. Occasionally, slight variations from the typical APL profile may be found. Gallagher et al., for instance, found weak expression of CD133 in only the second case of signal transducer and activator of transcription b (*STATb*)/*RARα*-positive leukemia (R. E. Gallagher et al., *Blood* **104**[11]**:**821a, abstr. no. 3005, 2004). If confirmed in further cases, this antigenic peculiarity may serve as a diagnostic tool for this particular APL variant.

The controversy regarding the expression of CD117 by APL cells deserves mentioning. CD117, the stem cell factor receptor KIT, is expressed by normal hematopoietic precursor cells and appears to be lost prior to maturation of normal myeloblasts into promyelocytes (48). The erroneous view that leukemic promyelocytes are equally negative for CD117 could only recently be rectified. The intensity of CD117 staining of leukemic promyelocytes is sometimes very low and can be recognized only by comparison with negative staining of normal cells contaminating the leukemic sample (54). Due to its constant expression by APL cells, CD117 is an excellent tool for the monitoring of residual APL cells posttreatment.

One more word of caution: some flow cytometry books promise a characteristic scattergram for APL, reflecting cells of large size (high forward-angle light scatter [FSC]) with a high degree of granularity (high 90°-angle scatter or side scatter [SSC]). While it is correct that scatter patterns of hypergranular APL cells are different from those of M3v cells, the scatter signal can be quite variable and misleading (54).

AML1/ETO-Positive AML

Translocation (8;21)(q22;q22) is one of the most common recurring cytogenetic abnormalities in AML and is thus considered to represent its own subtype in the WHO classification (31). The two genes involved in this translocation are *AML1* (now called *RUNX1*), a gene encoding a transcription factor on chromosome 21q22.3, and the *Eight-Twenty-One* gene (*ETO,* also called *MTG8*) on chromosome 8q22 (40). This AML subtype is an example of core binding factor (CBF) leukemias; inv(16)(p13q22) AML is another example of a CBF AML.

The immunophenotype of t(8;21) AML allows for a correct prediction of this genetic aberration (20). The distinctive features are expression of CD19, a B-lineage-associated antigen, and of CD56, the neural cell adhesion molecule, by CD34⁺ myeloblasts. The presence of CD56 may explain the increased incidence of granulocytic sarcomas observed in this disease. While the CD19/CD56 marker profile is invariably associated with t(8;21) AML, a substantial portion of t(8;21) patients lack either one or both of these discriminating antigens. In such cases, low expression of the integrin CD11a is a very helpful diagnostic tool. With the exception of t(8;21) AML or t(15;17) APL (and its variants), >90% of AMLs demonstrate strong expression of CD11a. The low expression of CD11a in t(8;21) AML is explained by the inhibition of CD11a promoter activity through the AML1/ETO fusion product (58). Figure 2 compares two cases of differentiated AML (FAB M2), one being *AML1/ETO* negative (Fig. 2A) and the other *AML1/ETO* positive (Fig. 2B). Note that CD7, a T-lineage-affiliated antigen frequently expressed by leukemic myeloblasts, is never expressed in AML1/ETO AML.

In CD13- and/or CD33-negative t(8;21) cases (2, 48), CD19 expression can lead to misdiagnosis as ALL; simultaneous detection of cCD22 and myeloperoxidase in the same cell is an essential tool in the differential diagnosis. Remember that dual absence of myeloperoxidase and cCD22 in such a case is consistent with AML. This marker combination is particularly relevant since CD19⁺ t(8;21) AMLs frequently coexpress PAX5, a B-lineage-associated transcription factor (67). The markers CD34 and CD133 discriminate between CD11aᴸᵒʷ t(8;21) AML and APL.

BCR/ABL-Positive ALL

In 1997, expression of CD25, the α-chain of the interleukin-2 receptor (IL-2R), was reported to predict the presence of *BCR/ABL* fusion transcripts, representative of the (9;22) translocation, in ALL (51). This initial observation, based on data from 144 patients, was subsequently confirmed with 485 adult ALL cases in the Eastern Cooperative Oncology Group Phase III trial, E2993, with a 29% incidence of *BCR/ABL* positivity (Paietta et al., ASH abstract, 2002). Although the final analysis of these data must await closure of the E2993 study, CD25 remained the most predictive marker in the interim analysis, with other antigenic features only aiding in the surrogate marker profile for *BCR/ABL*-positive lymphoblasts: CD25ᴴⁱᵍʰ CD34ᴴⁱᵍʰ CD33+CD13⁺. This profile is significantly different from that of *BCR/ABL*-negative disease ($P < 0.0001$) and is considerably more specific than those previously suggested for *BCR/ABL*-positive ALL, which relied on antigens shared by *BCR/ABL*-positive and *BCR/ABL*-negative lymphoblasts (28). Most strikingly, the higher the fraction of CD25-expressing lymphoblasts, the lower the likelihood of complete remission and the shorter the disease-free survival in *BCR/ABL*-positive ALL.

BCR/ABL-positive lymphoblasts express not only CD25, the α-chain, but also CD132, the γ-chain of the IL-2R, while lacking CD122, the β-chain. Since the presence of all three components of the high-affinity IL-2R is a prerequisite for IL-2-mediated transduction of growth signals, the physiologic role of this partial IL-2R in *BCR/ABL*-positive ALL and reasons for its prognostic implications remain unclear.

CD117/KIT-Positive ALL

CD117 in leukemia immunophenotyping is considered more specific for the myeloid lineage than CD33 or CD13 (48). Early hematopoietic progenitor cells express CD117, the stem cell factor receptor KIT (41). During normal lymphopoiesis, CD117/KIT is expressed by a fraction of CD34⁺ CD3⁻ CD4⁻ CD8⁻ (triple-negative) thymocytes. In normal T-cell progenitors, expression of CD117/KIT coincides with that of CD135, the FLT3 receptor TK that is activated by the FLT3 ligand; FLT3 and CD117/KIT share extensive structural homology (39).

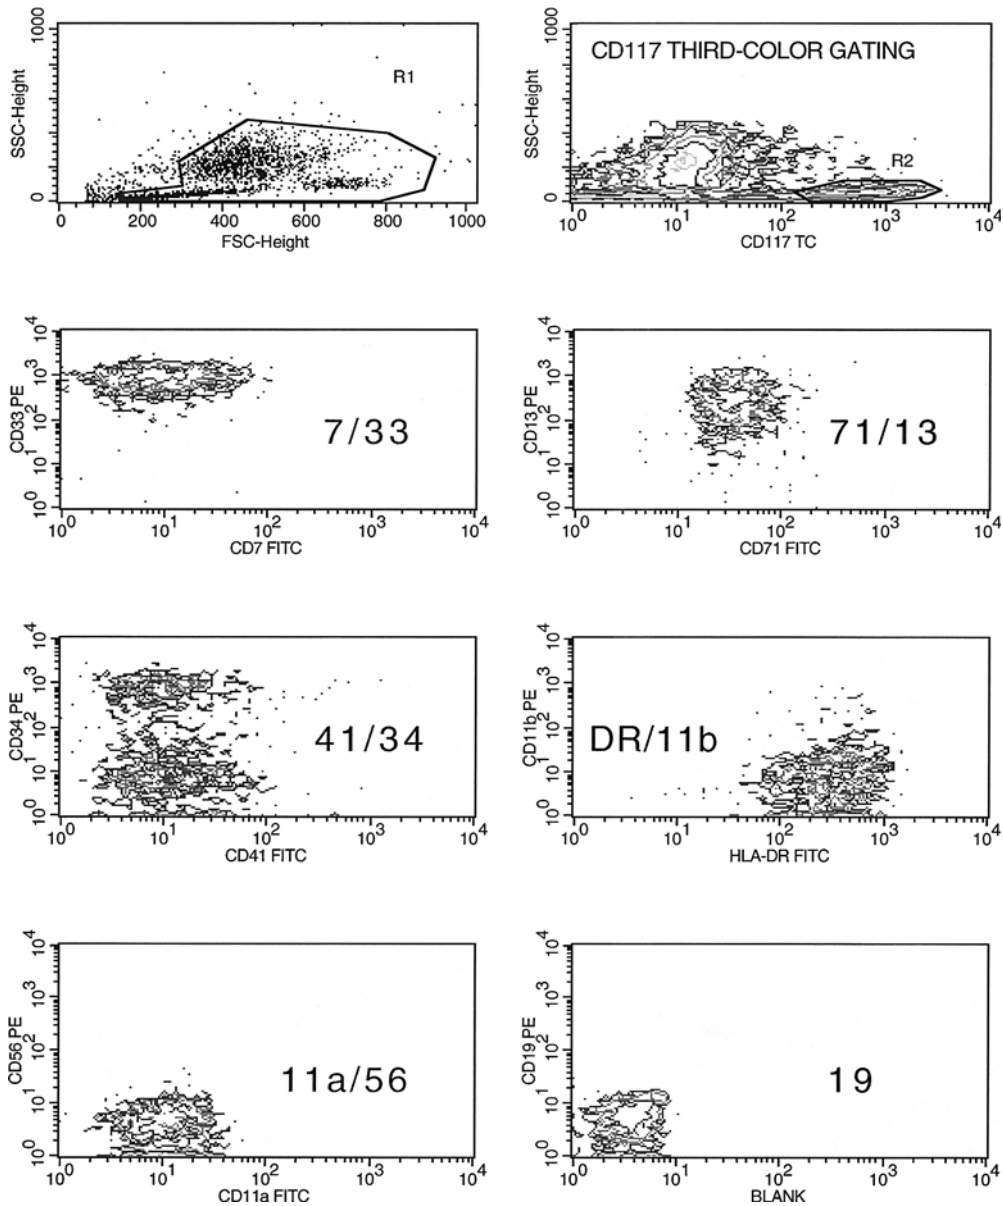
CD117/KIT expression by leukemic lymphoblasts is rare and mostly (albeit not exclusively) associated with the T-cell phenotype. Recently, CD117/KIT-positive T-lineage ALL was characterized as an immunophenotypically distinct subtype, frequently associated with myeloid morphologic features, including the presence of Auer rods (55). CD117⁺ lymphoblasts are surface CD3⁻, CD34⁺, CD62L⁺, CD56⁻, CD2⁺, CD7⁺, CD1a⁻, CD5⁻, CD4/CD8⁻, and TdT positive, expressing one myeloid antigen, CD13. This profile fits the most immature category of T-lineage ALL (4, 18), resembling multipotent thymic precursors. The lack of CD5 expression must be particularly emphasized since it is unique to this subtype of T-lineage ALL.


FIGURE 2 Differential antigen expression profiles of differentiated AMLs dependent upon the presence of the *AML1/ETO* fusion gene. The first panel demonstrates antigen expression in a case of differentiated AML with a normal karyotype (AML-M2), negative for *AML1/ETO*. A small percentage of blast cells was gated by CD117 staining (R2) and analyzed. In comparison, the second panel demonstrates a typical surrogate marker profile for *AML1/ETO*-positive AML. While this case represents a differentiated AML with FAB M2 morphology, many cases with *AML1/ETO* present with a rather undifferentiated phenotype, occasionally CD33 negative. Note the high expression of CD34, which is typical for this AML subtype, the absence of CD11a, the partial expression of CD56, and the weak albeit definite presence of CD19. One more observation of importance is that *AML1/ETO*-positive AML does not involve expression of CD7 on the leukemic myeloblasts. SSC, side scatter; FSC, forward scatter; R1, gating of all white cells excluding debris; R2, gating on CD117⁺ leukemic myeloblasts within R1. TC, third color; PE, phycoerythrin; FITC, fluorescein isothiocyanate; PerCP, peridinin chlorophyll protein. Antibody combinations are written as CDs into the contour plots.

CD117/KIT-positive ALL cases show a high frequency of *FLT3* gene mutations, either ITD or point mutations. *FLT3* is otherwise rarely mutated in leukemic lymphoblasts; only B-lineage ALLs containing *MLL* gene rearrangements have previously been found to demonstrate *FLT3* mutations (3). Thus, CD117/KIT expression in T-lineage ALL might be considered a surrogate marker for *FLT3* gene mutations.

Table 1 gives an overview of currently known surrogate marker profiles for genetic lesions in the acute leukemias.

Antigen-Specific and Gene-Specific Therapy

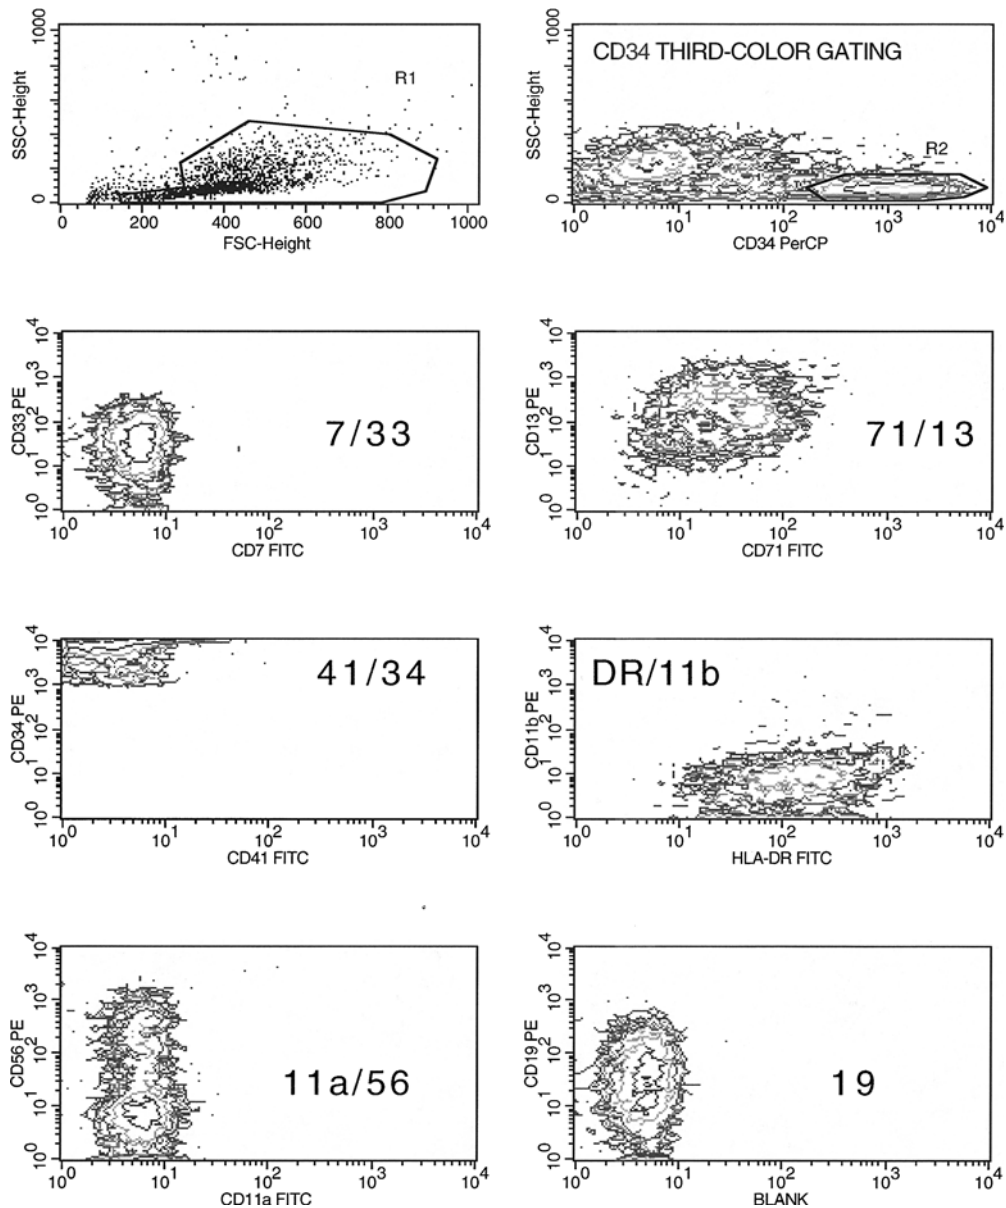
"Treatment by design" is what Larson et al. (38) called the novel approaches to leukemia and lymphoma therapy that take advantage of phenotypic (due to antigens) or genotypic


FIGURE 2 *(continued)*

(due to perturbed signal transduction pathways) features of malignant cells.

Monoclonal antibodies depend on the presence of the specific antigens that they recognize for their activity. In addition, at least for gemtuzumab ozogamicin, the CD33 antibody linked to the cytotoxic drug calicheamicin, antigen-independent endocytosis has been found to provide a nonspecific uptake mechanism, presenting a rationale for the treatment of both CD33$^+$ and CD33$^-$ malignancies (32). Once bound to the cell surface, antibodies per se can induce direct signaling in the malignant cells, which may result, for instance, in apoptosis (programmed cell death) or mediate antibody-directed cellular cytotoxicity (e.g., antibodies to the B-lineage antigen CD20 or to CD52, an antigen expressed by most B and T lymphocytes), or the antibody may be conjugated and function as a vehicle delivering immunotoxins or chemotherapeutic agents (e.g., antibodies to the myeloid

antigen CD33) or radiation (e.g., antibodies to CD20, CD22, or CD33 conjugated with various radioemitters, such as ^{131}I or ^{90}Y) to the target cells. Bispecific antibodies target leukemia-associated antigens and activating antigens simultaneously on cytotoxic effector cells or may otherwise potentiate the signaling events that will eventually lead to inhibition of leukemia cell growth (24, 33, 44, 66). One disadvantage is that antibodies also attach to the corresponding antigen when it is expressed by nonleukemic cells; furthermore, high levels of circulating soluble antigens reduce the bioavailability and thus the efficacy of the administered antibody.

Multidrug resistance (MDR) is the ability of tumor cells to survive exposure to various chemotherapeutic drugs due to the presence of membrane transporter molecules, such as P-glycoprotein (Pgp) or the multidrug-resistance-related proteins (MRPs). Strategies to disable Pgp, at least to date, have yielded conflicting and less than convincing clinical

TABLE 1 Established surrogate marker profiles for genetic lesions in acute leukemia[a]

Phenotype	Diagnosis	Antigenic characteristics
PML/RARα	APL (M3; all L and V form, some S form)	HLA-DR$^-$ CD11a$^-$ CD18$^-$ CD133$^-$ CD45^{Low} CD38^{Low} CD34^{Low} CD15s^{High} CD15^{Low}
	APL (M3v; S form)	As above, except HLA-DR$^{Low-High}$ CD34$^{Low-High}$ CD2^{High} CD56$^{Low-High}$
X/RARα	Variant APLs	As above, with occasional slight variations, such as CD133^{Low} in *STATb/RARα*-positive APLs
AML1/ETO	AML	Myeloid phenotype (often undifferentiated; CD33$^-$); CD34^{High} CD19$^{Low-High}$ CD56$^{Low-High}$
CBFβ/MYH11	AML	Myeloid phenotype; CD2^{High}
BCR/ABL	Adult ALL (p190/p210)	CD25^{High} CD34^{High} CD33+CD13^{High} (usually CD10^{High} cytoplasmic mu$^-$)
Mutant *FLT3*	Adult T-cell ALL	CD117^{High} CD34^{High} CD5$^-$ CD7^{High} CD2^{High} cCD3^{High} CD4/CD8$^-$ CD13^{High}

[a]The description of antigen expression as negative ($-$), low, or high refers both to intensity of fluorescence and percentage of blast cells expressing the antigen. Negative indicates the virtual absence of antibody binding by the leukemic cells beyond the level in the negative isotype control; low can refer either to subset of leukemic cells binding the antibody or to the entire blast cell population binding the antibody with low fluorescence; high indicates expression of the antigen by the majority of blast cells at high density. X/RARα, fusion proteins in which X represents variable partner genes.

results (42); yet, these membrane transporter molecules deserve mentioning in the context of antigen-targeted therapy. Aside from demonstrating the presence of Pgp and other MDR proteins, flow cytometry can confirm the functional integrity of these proteins as drug efflux pumps and thus establish the MDR status of leukemia populations. Furthermore, at least in AML, expression of CD34 correlates positively with Pgp function.

Gene mutations that are associated with cellular transformation present other attractive targets for therapy. I have already mentioned the efficacy of therapeutic doses of ATRA in reversing the perturbed histone acetylation and chromatin remodeling induced by the RARα-fusion proteins expressed uniquely in APL (57, 61). An analogous pathogenetic mechanism has been elucidated for CBF leukemias, such as those associated with *AML1/ETO*, *CBFβ/MYH11*, and *TEL/AML1* fusions. Like RARα, CBF, the heterodimeric transcription factor with components AML1 and CBFβ, is essential for normal hematopoietic development; unlike RARα, CBF does not bind any ligand. But analogous to the action of PML/RARα, the loss of CBF function from the leukemic fusion products leads to active suppression of transcription by maintaining the histones in a deacetylated conformation and making DNA inaccessible to transcription induction. Using histone deacetylase inhibitors may, therefore, be a rather general strategy to overcome leukemic transformation due to disruption of chromatin-remodeling mechanisms (23, 61).

Whether or not *FLT3* gene mutations represent the primary genetic event in cellular transformation is irrelevant for therapy. What is important is that *FLT3* mutations result in the constitutive activation of the FLT3 TK and that inhibitors of this activity have shown clinical efficacy (23, 59). The best evidence that targeted inhibition of aberrant TK signaling can be an effective therapeutic intervention has been obtained in CML and other diseases that respond to treatment with imatinib mesylate, the BCR/ABL TK inhibitor (13, 56). The downstream targets of constitutively activated TK molecules, such as STAT proteins that become activated through constitutive phosphorylation, may also provide rational targets for therapeutic interventions (59, 65).

The principle of targeted therapy, as attractive and promising as it is, requires much more understanding of transforming molecular events and perturbed signaling pathways than the simple administration of indiscriminately cytotoxic chemotherapy. Developing phenotypic profiles as surrogates for underlying genetic aberrations is clinically useful only if

antileukemic therapy is available that targets any component of the disturbed molecular pathways associated with these genetic lesions. *PML/RARα*-positive APL is the paradigm for a leukemia subtype for which a surrogate marker profile is clinically valid given the availability of genotype-specific therapy (ATRA). As the list of known therapeutic targets grows, undoubtedly as the result of gene expression profiling and similar techniques, the role of surrogate antigen profiles will grow, as they can predict the efficacy of targeted approaches in lieu of expensive, time-consuming, and not always accessible gene expression analyses.

Multimeric Major Histocompatibility Complex Reagents for the Detection and Quantitation of Specific T-Cell Populations

JOHN D. ALTMAN

23

T cells play essential effector and regulatory roles in adaptive immune responses. Helper T cells expressing the CD4 coreceptor are required to support effective humoral immune memory—including generation of memory B cells and long-lived, antibody-secreting plasma cells, as well as antibody affinity maturation—and activation of pathways that allow macrophages to kill intracellular bacteria and parasites. Cytotoxic T cells expressing the CD8 coreceptor kill virus-infected cells as well as many tumors. In addition to their roles in pathogen clearance and tumor surveillance, both helper and cytotoxic T cells play roles in immunopathologies such as systemic and organ-specific autoimmunity, contact dermatitis, asthma, and atopy. All T cells express immunoglobulin-like antigen receptors that are the product of somatic gene rearrangements and that recognize peptides bound to major histocompatibility complex (MHC) molecules expressed on the antigen-presenting cell surface. The peptide ligands of MHC molecules are generated by proteolytic processing of proteins that are synthesized endogenously—such as tumor-associated or viral proteins—or outside the presenting cell and brought in through endocytic pathways. The endogenous pathway is largely associated with presentation on class I MHC molecules, which are recognized by CD8$^+$ T cells, while the exogenous pathway is associated with presentation on class II MHC molecules, which are recognized by CD4$^+$ T cells. In humans, the MHC molecules are also commonly referred to as HLA molecules, or human leukocyte antigens.

Efforts to manipulate T-cell responses for a preventative or therapeutic end—such as by inducing new antigen-specific T-cell populations through vaccination, or induction of tolerance in an existing autoreactive population of T cells—are predicated upon the ability to accurately measure quantitative and qualitative aspects of antigen-specific T-cell responses by using in vitro assays. For example, there are now several examples where clinical responses to tumor vaccines are significantly correlated with the magnitude of the induced T-cell response (14, 37), and recent efforts to develop preventative vaccines for human immunodeficiency virus (HIV) (23, 29), malaria (6), and tuberculosis (23, 35) have focused upon the induction of strong, pre-existing T-cell responses.

Through the mid-1990s, nearly all in vitro assays of antigen-specific T cells required moderate to extensive in vitro expansion of low-frequency populations of precursors in order to provide a population of cells large enough to measure in bulk assays such as the chromium release assay for cytotoxic T cells or the tritiated thymidine incorporation assay for T-cell proliferation (once the most common assay for helper T-cell function). For accurate measurements of T-cell immunity as it exists in vivo, the act of in vitro expansion creates at least two significant problems. First, the efficiency of the expansion is highly variable and therefore the results are semiquantitative at best. Second, the stimuli required for in vitro expansion of specific T cells unavoidably alter their phenotype, inducing changes in the patterns of cell surface molecules involved in crucial functions such as cell adhesion and trafficking, as well as potentially altering effector functions such as cytokine secretion profiles.

Starting in the mid-1990s, sensitive new assays have been developed that permit detection of antigen-specific T cells at the single-cell level, largely eliminating the requirement for in vitro expansion (34). These assays fall into two broad classes: functional and antigen binding. Functional assays at the single-cell level require short-term stimulation with antigen, generally for time periods between 4 and 24 h, during which proliferation is minimal, followed by detection of effector molecules—for example, cytokines (50), CD40L (10), or granule-associated transmembrane proteins such as CD107 (7)—using either flow cytometry (31, 54) or ELISpot assays (11, 28). In contrast, antigen-binding methods employ engineered multimers of soluble MHC/peptide complexes labeled with appropriate fluorophores that are used as if they were antibodies in flow cytometry or in situ staining of tissue sections (25). The engineered multimers come in at least three distinct flavors: (i) enzymatically biotinylated MHC/peptide complexes can be mixed with fluorescently labeled streptavidin to create MHC tetramers (3); (ii) the cDNA for an MHC protein can be genetically fused to an immunoglobulin G heavy chain of Fc domain to create MHC dimers (16); and (iii) MHC molecules can be fused to a self-assembling coiled-coil domain to create MHC pentamers.

The MHC tetramer version was the first to be described and has the largest publication record behind it. Identification of antigen-specific T cells by antigen-binding methods requires no assumptions with respect to the potential functions of the target cells. While this is sometimes a drawback, since T-cell effector functions are often the most relevant correlate to a particular disease state or to disease prevention,

the antigen-binding methods can be combined with functional assays and often serve as the best measure of the total T-cell population specific for a defined MHC/peptide epitope. Antigen-binding methods provide two additional unique advantages: (i) they are the most direct method for assessing complex, multiparameter cell phenotypes by flow cytometry and (ii) they are the only practical method for detection of so-called dysfunctional cells, which often arise during chronic exposure to antigens such as tumors or persisting viruses such as HIV and hepatitis C virus. Although tetramers are the focus of this chapter, the other MHC multimers are apparently functionally equivalent. In addition, this chapter will focus on flow cytometry applications of tetramers, their most common use. Tissue staining with MHC tetramers has been demonstrated and promises to be very powerful as more examples appear (14, 17, 24, 33, 38, 39, 49), but it is beyond the scope of this chapter.

TECHNOLOGY AND INSTRUMENTATION FOR HLA TETRAMER ANALYSIS OF ANTIGEN-SPECIFIC T-CELL RESPONSES

Tetramer Reagents—Suppliers

The major commercial supplier of MHC tetramer reagents is the Immunomics division of Beckman Coulter, Inc. (http://www.immunomics.com), which sells them under the iTag trade name. The list of available reagents includes a number of HLA-A and -B class I alleles, several HLA-DR and -DP class II alleles, and a small selection of MHC alleles in other species such as the mouse and the rhesus macaque.

The National Institutes of Health (NIH) has also established a Tetramer Core Facility (http://www.niaid.nih.gov/reposit/tetramer/index.html) that prepares and distributes custom reagents to researchers throughout the world, focusing on reagents not available from Beckman Coulter. (The author of this chapter is the director of the NIH facility, which is located at Emory University in Atlanta, Ga.) The NIH facility currently offers a larger selection of alleles, especially for studies in nonhuman species, including a number of nonclassical MHC proteins such as HLA-E and CD1d. In addition, the NIH facility will prepare custom expression vectors for alleles that are not already available.

Tetramer Reagents—Expression

An extended discussion of the production of tetramer reagents is beyond the scope of this chapter. This section presents some key highlights and points to key references.

Classical class I MHC/peptide complexes are nearly always produced by in vitro folding of antigenic peptides together with denaturant-solubilized subunits expressed in *Escherichia coli* as inclusion bodies (2). In contrast, while *E. coli*-based in vitro folding methods work for some class II alleles, most alleles apparently cannot be produced this way. The reason for the strikingly different success rate for in vitro folding of class I and class II proteins is not well understood, but it may be related to the difference in quaternary structure of the peptide-binding groove, which in class I proteins is formed from a single chain but in class II proteins requires coming together of two separate protein chains. As a consequence, a variety of alternative eukaryotic expression systems for class II proteins have been developed, all providing correctly folded proteins secreted into culture supernatants. Many of these systems fuse complementary leucine

zipper motifs to the carboxy termini of the MHC protein chains in order to promote heterodimerization (22), and some employ covalent attachment of antigenic peptide ligands to the amino terminus of the class II β chain (27). Insect cell systems seem to be the most popular (40) and have been increasingly refined (15), but mammalian-based cell culture systems have also been described (13).

The nonclassical class I proteins are a heterogeneous group, and the expression systems used to produce them defy generalization. In vitro folding methods work well for proteins such as HLA-E, -F, and -G, some of which have known peptide ligands (1), but insect cell systems seem to be more efficient for molecules such as CD1d (32), which binds to glycolipids.

Variant Tetramer Reagents

The CD8 coreceptor is known to bind to a site in the α3 domain of class I MHC molecules, and therefore it is not surprising that the CD8 molecule itself contributes to class I tetramer binding to specific cells (21a). A number of investigators have taken advantage of this observation and have shown that mutant tetramers will bind to "high"- but not "low"-avidity populations of T cells (8, 9, 57); this approach may be particularly valuable for characterization of tumor-specific responses, where high-avidity T cells specific for the relevant tumor antigens may have been deleted during thymic development.

Fluorophores Used for Tetramers

By far the most popular fluorophore labels for MHC tetramers are the algae-derived phycobiliproteins R-phycoerythrin and allophycocyanin. Conjugates of these fluorescent proteins with streptavidin are widely available, and these fluorophores provide some of the best signal-to-noise ratios on most flow cytometers. The R-phycoerythrin label is excited by common argon lasers operating at 488 nm, while the allophycocyanin label requires a red laser operating between 633 and 647 nm. Tetramers labeled with other fluorophores have been described and are in fact required when tetramers are combined with some experimental protocols, such as flow–fluorescent in situ hybridization (Flow-FISH) methods for telomere-length determination (44).

Supporting Antibody Reagents

MHC tetramer stains are nearly always combined with an anti-CD3 antibody as well as either a CD8 antibody (for class I tetramers) or a CD4 antibody (for class II tetramers). These antibodies are widely available from multiple suppliers. There have been reports that some antibody clones specific for these molecules can inhibit tetramer binding (12, 21), probably through steric interference. It is worthwhile to examine several different antibody clones if interference is suspected.

MHC tetramer stains are also combined with a nearly infinite array of antibodies to obtain additional phenotypic information about the target population, such as the expression levels of a diverse array of cell surface markers such as CD62L (the lymph node homing receptor), CD28, CD45RA, CD27, or CCR7, or intracellular markers such as perforin, granzyme B, or Ki67. Tetramers can also be combined with reagents that assess T-cell function, such as cytokines produced after T-cell stimulation (5), though these protocols are often finicky due to down-regulation of surface T-cell receptors induced by stimulation.

Sample Requirements

HLA tetramer staining for flow cytometry can be performed using relevant single-cell suspensions from any source.

Whole blood and Ficoll gradient-purified peripheral blood mononuclear cells (PBMC) are the most common sample types from human subjects, but it is possible to perform tetramer staining on samples from tissue biopsies, including lymph nodes (47), tumors (52), liver (18), lung (51), and even lesions from delayed-type hypersensitivity reactions (14). HLA tetramer staining of in vitro expanded cultures, cell lines, and T-cell clones is also commonly used (40) and can be used to back-calculate precursor frequencies (40) when combined with the CFSE method for tracking cell division (30). (CFSE stands for carboxyfluorescein succinimidyl ester; though this is the common name, it is more appropriately called CFDA-SE, for carboxyfluorescein diacetate, succinimidyl ester.) This chapter focuses on methods employing whole blood and freshly isolated PBMC.

Any assay requiring a blood sample immediately raises questions of which of the three common anticoagulants—heparin, EDTA, or acid citrate dextrose—should be used for blood collection. In general, high-quality tetramer stains may be obtained when any of these anticoagulants are used, especially when the samples are stained less than 24 h after collection. When given a choice, my laboratory has a slight preference for EDTA.

The volume of blood or the number of cells required for the assay is dependent upon the frequency of the target cell population. When the target cell population exceeds 0.1% of the relevant T-cell subset ($CD4^+$ cells when using class II tetramers; $CD8^+$ cells when using class I tetramers), the assay can be performed on as little as 100 µl of whole blood or 10^6 PBMC; for detection of target cell populations in the range of 0.01 to 0.1%, up to 1 ml of blood or 5×10^6 PBMC can be used. In general, background noise limits reliable detection of cell populations below 0.01% of T cells, though extraordinarily skilled investigators working with especially clean samples and reagents can achieve reliable detection down to frequencies of 0.001%.

Additional sample aliquots are often used for negative controls and for setting instrument compensations. Negative control samples—for example, samples stained with an irrelevant control tetramer—should be the same size as the test samples. Sample aliquots for fluorescent compensation settings should be at least 100 µl of blood or 10^6 cells for each antibody used in the experiment. Note that the samples used for compensation settings need not be from the same individual as the test sample, and when sample sizes from an individual are limiting (such as in clinical trial samples), compensation samples should be set up with more easily obtained cells. Very recently, antibody capture beads have been introduced as an alternative for preparation of compensation samples (e.g., BD CompBeads; BD Biosciences, San Jose, Calif.), and cells are no longer required at all.

INSTRUMENT REQUIREMENTS

A flow cytometer with a minimum of three fluorescent channels is required for collection of data from HLA tetramer-stained cells. One channel is required for the tetramer, a second is required for an anti-CD3 antibody, and a third is required for an antibody specific for the coreceptor on the relevant target population—e.g., anti-CD4 when using class II tetramers and anti-CD8 when using class I tetramers. Most three-color instruments, such as the no-longer-available FACScan from BectonDickinson, use a single argon laser with a wavelength of 488 nm.

For the past 8 years, my lab has acquired most of its tetramer data on a four-color FACSCalibur instrument from BDBiosciences. Most often, we use the additional channel to obtain additional phenotypic information about the target population, as noted above. Of course, on a four-color instrument, all of these phenotypic parameters must be analyzed one at a time in separately stained samples. Alternatively, the fourth channel could be used as an exclusion channel, where one or more reagents are used that are known to bind to cells other than the lineage of interest. For example, the iMASC Antibody Gating Kit for class I tetramers, from the Immunomics division of Beckman Coulter, contains antibodies specific for B cells (anti-CD19), granulocytes and monocytes (anti-CD13), and anti-CD4, all labeled with the same fluorophore (PC5). Exclusion gating can often reduce background noise and may permit more reliable analyses of low-frequency populations. Four-color instruments are available with a single argon laser such as the EPICS XL from Coulter, or with two lasers (an argon and a red diode laser) such as the FACSCalibur from BDBiosciences. When using tetramers labeled with the allophycocyanin dye, an instrument equipped with a red laser, operating near 635 nm, is required.

In the past several years, new so-called multicolor flow cytometers such as the LSR-II (BDBiosciences) and the Cyan from DakoCytomation (Fort Collins, Colo.) have been introduced that are capable of measuring up to 17 colors, depending upon the instrument configuration (42). The additional colors can be used for at least two distinct purposes: (i) they enable studies in which multiple cell phenotypes can be measured in the same sample, and (ii) they make it possible to include several distinct tetramers with distinct peptide epitopes (and maybe HLA alleles), each labeled with a separate fluorophore.

In addition to the flow cytometer, a variety of standard laboratory equipment—tabletop centrifuges, pipettes, vortex mixers, microscopes and hemacytometers, etc.—is required.

PROTOCOLS

Background on the General Protocol

The protocols used for standard MHC tetramer staining are identical in all essential details to those used for common antibody staining. As noted in "Sample Requirements," above, whole blood, PBMC, or other single-cell suspensions may be used. The notes in this chapter will focus on whole-blood stains; only simple and standard adaptations are required for other sample types.

Three of the most important parameters in MHC tetramer staining protocols are temperature, staining time, and reagent titer. Whole-blood stains are nearly always performed at room temperature. When PBMC are used, some groups have reported better results when staining at 37°C (55)—especially for class II tetramers (8a)—though excellent results may still be obtained at temperatures down to 4°C. Staining times should be optimized in each system, and they are in the range of 10 to 60 min; this parameter should certainly be standardized.

The optimal titer of a tetramer reagent should be determined in preliminary experiments, starting at a final tetramer concentration of about 25 µg/ml, and performing a two- or threefold dilution series. The optimal titer is often a compromise between the concentration required to achieve saturation and optimal separation from the "bulk" background population, and that required to minimize the frequency of "outlier" populations, which may be characterized

as "noise," rather than background. In practice, the optimal titer often provides "baseline" but less than maximum separation between the positive and negative staining populations. Commercial reagents usually come with suggested titers, but these should be tested in each laboratory.

Appropriate controls for tetramer staining remain a surprisingly vexing issue, especially for work with human samples. T-cell lines or clones of an appropriate specificity often constitute a suitable positive control, but they are not always available, certainly not commercially. Cryopreserved PBMC from an individual previously shown to have cells that stain with a specific tetramer can be used; of course, these are not a renewable resource, though large numbers can be obtained by leukapheresis, though this is also not always convenient or possible. Barring either of these possibilities, the only practical approach requires omission of desired positive controls.

Negative controls are a more simple matter. It is possible to perform the equivalent of an isotype control by staining with an irrelevant tetramer composed of the same MHC allele, loaded with a peptide that the subject does not respond to. This is often less valuable than seems logical, as the control reagent could fail for a variety of reasons. Alternatively, it is possible to stain samples from an individual not previously exposed to the antigen of interest, either matched or mismatched at the HLA allele corresponding to the tetramer. In practice, when performing stains with whole blood samples that contain low to moderate frequencies of relevant antigen-specific cells, the sample itself contains abundant internal negative controls, and it is not necessary to perform additional negative control stains. This approach works quite well when the tetramer stain is very bright (as is often the case), but less well when the intensity of the tetramer-positive population is only moderately greater than the background on genuine nonspecific cells in the same sample. Finally, in some cases the most valuable control for tetramer staining is a sample stained with all of the reagents used in the test sample except for the tetramer itself. This sample, known as a "fluorescence-minus-one" or FMO control, allows for the most precise definition of cells that have fluorescence above background levels (45).

A General Tetramer Staining Protocol

The following steps constitute a general tetramer staining protocol. Individual details, such as the staining volumes, can be varied by knowledgeable investigators.

1. Prepare a 20× stock of a relevant tetramer in ice-cold fluorescence-activated cell sorter (FACS) buffer (2% fetal bovine serum plus 0.1% sodium azide in phosphate-buffered saline). See the notes above on determination of optimal titers.

2. Add 10 μl of the 20× tetramer stock to the bottom of a 12- by -75-mm FACS tube. Add additional antibody reagents as required or desired.

3. Add 200 μl of whole blood and vortex for 5 s.

4. Incubate at room temperature in the dark for 20 to 30 min.

5. Add 2 ml of 1× FACS Lyse solution (Becton Dickinson) and vortex thoroughly. Red blood cell lysis products from other suppliers may be used, but they should be carefully tested.

6. Incubate at room temperature for 10 min in the dark.

7. Pellet the cells by centrifugation for 5 min at $300 \times g$.

8. Carefully decant or aspirate the supernatant.

9. Disrupt the cell pellet by vortexing for 5 min.

10. Wash the cells.

    a. Add 2 ml of ice-cold FACS buffer to the disrupted pellet.

    b. Vortex for 5 s.

    c. Pellet the cells by centrifugation for 5 min at $300 \times g$.

    d. Carefully aspirate or decant the supernatant.

    e. Disrupt the pellet by vortexing for 5 s.

11. Repeat step 10 to further reduce the number of outlier events.

12. Add 300 μl of Ultrapure 2% formaldehyde (diluted from a 10% stock obtained from PolySciences) in phosphate-buffered saline and vortex for 5 s.

13. Acquire the data on a flow cytometer within 24 h. Keep the samples protected from light as much as is practical before and during acquisition.

Compensation Controls

Basic protocols for fluorescence compensation controls have been described (46), and except for a few brief notes, the topic is beyond the scope of this chapter. Briefly, the same antibodies that are used in combination with the tetramers can be used as single stains for compensation controls, especially for lineage-specific markers such as CD3, CD4, or CD8. Usually, the low frequency of antigen-specific populations precludes practical use of the tetramer stain itself as a compensation control. Instead, as a compensation control for the tetramer stain, an antibody specific for a lineage-specific marker such as CD8 should be substituted. As noted in "Sample Requirements," above, the cells used for compensation controls need not come from the same individual as the test samples, and antibody capture beads can be substituted for cells. Capture beads for tetramers are not available, though in some cases the beads could be stained with an unlabeled anti-HLA antibody such as W6/32, followed by secondary staining with a tetramer.

Data Acquisition

The flow cytometer should be set up according to the manufacturer's recommendations and standard protocols, with particular attention paid to the setting of appropriate voltages on the photomultiplier tubes for each fluorescence channel. The appropriate protocol for setting up instrument compensation depends upon the available instrument and software. On analog instruments such as the FACSCalibur, the compensation setting must be adjusted manually before acquisition of data from test samples. In contrast, on new digital instruments such as the LSR-II or the FACSCanto, a data file (containing at least 20,000 relevant events) should be acquired for each of the compensation control samples, and the compensation matrix is then calculated by appropriate instrument software; in this case, uncompensated data are stored, and the compensation matrix can be applied either during or after acquisition.

Following instrument setup, data from the test samples are finally acquired. Since tetramers are usually used to detect low-frequency populations, it is often necessary to acquire a large number of events. For a typical sample, we attempt to acquire 100,000 to 200,000 lymphocyte-gated events, or more if the population frequency is below 0.05% of $CD3^+$ cells. Data are stored in industry-standard flow cytometry standard (FCS) format.

DATA ANALYSIS

The FCS-formatted data files from tetramer staining experiments can be analyzed by any of the common software

packages, including those provided by the instrument manufacturers, or by third parties. We favor the FlowJo software package from TreeStar, Inc., but any package will do.

Standard approaches to gating are used when analyzing tetramer staining data. The steps for one very common approach—illustrated in Color Plate 1—are:

1. Plot FSC (forward scatter) versus SSC (side scatter) and set a gate around the lymphocyte-sized cell population.
2. For lymphocyte-gated cells, plot CD3 versus CD8 and set a gate on the CD3$^+$ CD8$^+$ population.
3. For cells that are both lymphocyte sized and CD3$^+$ CD8$^+$, plot the phenotypic parameter (CD11a in Color Plate 1) versus the tetramer stain (HLA-B7/EBV.RPP in Color Plate 1), and set a gate on the tetramer$^+$ population.

Color Plate 1 illustrates two different displays for the data; in panel A, the "pseudo-color dot plot" format is used, while in panel B, black and white contour plots are used, with the "show-outlier" option turned on for the final plot of CD11a versus tetramer. It is almost always necessary to use a data display that shows tetramer-stained cells as dots, since the frequency of the tetramer-positive population is usually below the 5% level required for the most common settings for contours in most flow cytometry data analysis software packages.

The final gate on the tetramer-positive cells in Color Plate 1 illustrates decisions that are typically made in the analysis of tetramer staining data. The gate is set on a tight cluster of cells that are all CD11a^{hi} and have nearly the same tetramer staining intensity. There are additional outlier events that appear to have tetramer staining intensity slightly above the main clusters of clearly tetramer-negative cells, but since these cells are not tightly clustered and are of lower intensity than the clearly tetramer-positive population, they have been omitted from the analysis.

The frequency of tetramer-positive cells should be reported as a fraction of the major lineage subset used to define them. In the example in Color Plate 1, this would be CD3$^+$ CD8$^+$ lymphocytes. If it is necessary to omit either the CD3 or CD8 stain—for example, to accommodate an additional phenotypic marker—then the frequency should be reported as a fraction of either CD3$^+$ or CD8$^+$ cells.

When tetramer-positive data are phenotyped with two or more markers, the use of overlay plots can be very helpful in displaying the data. An example is shown in Color Plate 2, where the phenotype of the bulk CD8^{hi} population is shown in the orange "zebra-plot" format, while the tetramer-positive population is presented as an overlay of blue dots. The overlay plots allow the simultaneous display of two phenotypic parameters for tetramer-positive cells, but at the cost of losing the display of the intensity of the tetramer stain.

In all of the examples above, the relative frequency of tetramer-positive cells is reported with either CD3$^+$ CD8$^+$ (Color Plate 1) or CD8^{hi} (Color Plate 2) cells in the denominator. In some cases, it may be more desirable to report absolute numbers of tetramer-positive cells per volume of blood, and single-platform methods for doing so have recently been introduced (19).

INTERPRETATION

The interpretation of tetramer staining data is as diverse as the different types of immune responses to which the technique is applied. When tetramers are used to analyze prophylactic vaccine experiments (48) or vaccine clinical trials, the interpretation of both the numbers and phenotypes of the detected antigen-specific cells is relatively

straightforward: at some time between 1 and 2 weeks after vaccination, the frequency of tetramer-positive cells rises from an undetectable level to a peak, at which point the tetramer-positive cells often have a highly activated phenotype that is typical of effector T cells (e.g., CD38$^+$, HLA-DR$^+$, perforin$^+$, granzyme B$^+$, etc.). Over the next several weeks, the frequency of the tetramer-positive cells decreases and they lose their activated phenotype, especially if the antigen in the vaccine is completely cleared. Analysis of prophylactic vaccine responses is by far the simplest scenario.

When MHC tetramers are used to analyze T-cell responses to natural viral infections, at least five complications arise: (i) it is often impossible to establish the time of infection, so the kinetics of the response cannot be determined; (ii) many viruses chronically persist, either at a high level, such as HIV or hepatitis C virus, or in a latent form with periodic (and undetected) reactivation, such as with the herpesviruses cytomegalovirus and Epstein-Barr virus (EBV); (iii) chronic exposure to antigen can lead to deletion of specific T cells, functional inactivation, or T-cell-receptor down-regulation (58); (iv) for all viruses, especially those that do not persist, there is a significant likelihood of repeated exposure; and (v) in all cases, viral variants may arise that have epitopes that are closely related, but not identical, to those used in the tetramer (or those that were in the pathogen present during the primary immune response). These factors are also present for other infectious pathogens, such as *Mycobacterium tuberculosis*. As a consequence of all of these complications, early attempts to correlate disease states with some tetramer measurement—such as an inverse correlation of the frequency of HIV-specific CD8$^+$ T cells with HIV viral load (41) or an association of the failure of HIV-specific cells to clear HIV with a dysfunctional phenotype of tetramer-positive cells (4)—are now regarded with caution (53). Extended discussions of many of these complications are available in several excellent and recent reviews (26, 56).

Interpretation of data using tetramers to analyze tumor- and auto-antigen-specific cells is as complex as for persistent viruses, for many of the same reasons. The most serious complications are the difficulty in accounting for the effects of chronic antigen exposure, which may lead to functional inactivation or purging of the repertoire of high-affinity T cells specific for tumor antigens by induction of peripheral tolerance (36); in addition, the repertoire of tumor-specific cells is in many cases strongly influenced by a process of negative selection during thymic development (20). Only in the most favorable cases has it been possible to correlate data from tetramer staining experiments with clinical responses (14, 37).

Despite the difficulties noted above, antigen-binding methods for the identification of antigen-specific T cells promise to play an ever-expanding role in clinical immunology. Every year, more T-cell epitopes are mapped (43), which increases the range of responses to which the technique might be applied. In addition, immunotherapies that attempt to reactivate or alter the functional activities of antigen-specific cells will continue to rely upon tetramer staining methods to provide the crucial identification of the specific targets of potential therapies.

In Situ Gene Amplification and Hybridization Assays: Disease Monitoring Applications Using Flow Cytometry

BRUCE K. PATTERSON

24

Since the discovery of PCR, the diagnostic field has followed the pathway of taking tissues (plasma, blood, and tissue biopsy samples), preparing nucleic acids (DNA, RNA, or total), and amplifying genes of interest. Lost in the process are the characteristics of the cells from which these genes originated. The loss of this important information has profound implications in the areas of infectious diseases and oncology. The ideal situation in diagnostics would be if one could in a sensitive and specific manner detect certain disease-causing genes, including infectious agents, without destroying the cells. Maintaining the integrity of the cells not only allows one to assess the characteristics of a cell expressing a particular disease-causing gene (e.g., human papillomavirus [HPV] E6 or E7 mRNA expression in a dysplastic or cancerous squamous epithelial cell) but also allows one to enrich for rare cells of interest using antibodies in a multiparameter approach, for example. From a diagnostic perspective, the detection of genes and proteins within a cell would need to be high throughput on a user-friendly platform capable of an expanded menu. All of the aforementioned attributes of an extremely powerful molecular diagnostics platform reside in flow cytometry. In the following sections, I describe multiple approaches of performing molecular biology in a cell. Most importantly, I also describe how to use these assays to gain a better understanding of disease processes and ultimately how these assays can be adopted in clinical laboratories to provide the most comprehensive information on response to a variety of therapies.

MOLECULAR BIOLOGY IN THE CELL: ACCESSING THE TARGET WITHIN

Intracellular detection of nucleic acids, proteins, and phosphoepitopes is performed in research laboratories using a variety of different agents to gain access into the cell while preserving the integrity of the cell. Ideally, these agents should preserve the target of choice, such as DNA, RNA, or proteins, including those subject to phosphorylation. Many of the current fixation and permeabilization reagents fail to preserve all of these macromolecules though they perform well for a particular application. Though consideration of all the best attributes of cell fixation extends beyond the scope of this chapter and they are covered more completely in other reviews (27), a fixative called

PermiFlow approaches the ideal fixative described above. This reagent preserves cell surface and intracellular antigenicity, while maintaining the integrity of DNA and RNA and the phosphorylation state of phosphoepitopes. This fixative is used in many of the applications described herein. In summary, maintenance of the target of interest and protocol simplicity is critical in the clinical application of in situ methodology.

Procedure

Collect a 10-ml venous blood sample aseptically by venipuncture using standard procedures. One hundred microliters of sample per test is required when performing analysis using whole blood. Blood samples should not be refrigerated. For testing using a peripheral blood mononuclear cell (PBMC) preparation derived by differential density centrifugation, 10 ml of whole blood is sufficient for approximately 20 analyses. Centrifuge the 10-ml blood sample at $300 \times g$ for 10 min at room temperature ($25 \pm 5°C$). Discard the plasma layer, which will appear cloudy due to the presence of platelets. Transfer the buffy coat layer (1 to 1.5 ml per 10 ml of whole blood) with a Pasteur pipette to a disposable test tube (10-ml volume). Bring to a volume of 7 ml with room temperature $1\times$ phosphate-buffered saline (PBS). Mix well and transfer to a 15-ml conical centrifuge tube. Underlay 3 to 5 ml of Ficoll-Paque to the cell suspension in the conical centrifuge tube. Do not disturb the interface between the sample and the Ficoll-Paque. Centrifuge at $400 \times g$ for 30 min at room temperature. Mononuclear cells should form a visible, clean interface between the plasma and the Ficoll-Paque. Within 5 min of centrifugation, collect the mononuclear cells from the PBS–Ficoll-Paque interface with a Pasteur pipette and transfer to a 15-ml conical centrifuge tube. Resuspend the mononuclear cells in a 10-ml conical centrifuge at $400 \times g$ for 5 min at room temperature. Aspirate carefully and remove the supernatant. Repeat once. Resuspend the mononuclear cells in 2 ml of $1\times$ PBS and determine the cell number with a hemocytometer or an automated cell counter. Adjust the mononuclear cell density to 5×10^6 cells/ml in $1\times$ PBS. Deliver 10 μl (or typical volume for the reagent in use) of antibody specific for markers expressed on the cell surface to the bottom of each appropriately labeled test tube, except the control tube. Add the appropriate volume of isotype-matched control antibody to the control tube.

Note: Most cell surface-expressed antigens remain immunoreactive after treatment with PermiFlow (Invirion, Inc., Frankfort, Mich.). Therefore, in some instances it may be appropriate to first treat the cells with PermiFlow, wash with wash buffer (1× PBS, pH 7.4), and then incubate simultaneously with antibodies to cell surface and intracellular antigens. Add 100 μl of a single-cell suspension (5 × 10^6 cells/ml in 1× PBS, pH 7.4) to each tube and vortex gently. Incubate for 20 min at room temperature. Collect the cells by centrifugation at 400 × *g* for 5 min at room temperature and aspirate the supernatant. Add 0.5 ml of 1× PermiFlow directly to each tube, vortex, and incubate for 40 min at room temperature. Note: For in situ hybridization or in situ PCR, incubate for 1 to 18 h (see procedures below). Collect the cells by centrifugation at 400 × *g* for 5 min at room temperature and aspirate the supernatant. Resuspend the cell pellet in 1.0 ml of 1× PBS, pH 7.4. Centrifuge at 400 × *g* for 5 min at room temperature and discard the supernatant. Deliver 10 μl (or typical volume for the reagent in use) of antibody specific for intracellular antigens to the bottom of each appropriately labeled test tube, except the control tube. Add the appropriate volume of isotype-matched control antibody to the control tube. Vortex gently and incubate for 40 min at room temperature. Wash the cells with wash buffer and centrifuge. Resuspend the cells in 1.0 ml of 1× PBS, pH 7.4, and analyze by flow cytometry according to the manufacturer's instructions.

Clinical Considerations

Clinical Utility of In Situ Gene Detection: The Virology Model

Viruses can be categorized as RNA or DNA, and since they infect cells, the viral diagnostics area is a true test of molecular diagnostics. To date, the majority of diagnostic tests consist of detection of virus in plasma or lysed cells by solution-based amplification assays such as PCR, transcription-mediated amplification, strand displacement amplification, branched DNA (bDNA), or nucleic acid-based sequence amplification. The power of being able to detect DNA or RNA in cells is illustrated in Fig. 1 using human immunodeficiency virus type 1 (HIV-1) as a diagnostic model system. In HIV-1-infected individuals, T lymphocytes can be free of virus (Fig. 1, far left), be defectively infected (DNA^+, RNA^-) and incapable of producing virus (Fig. 1, second from left), be latently infected (DNA^+, RNA^-), and replication competent (Fig. 1, second from right), or be productively infected (DNA^+, RNA^+), producing viral particles (Fig. 1, far right). Eradication of HIV-1, which was thought to be possible early in the epidemic, would involve clearing the virus and virally infected cells from individuals, thus producing an overall loss of DNA-containing cells (long arrow). Eradication of DNA-containing cells could be monitored using an in situ amplification assay such as real-time PCR in situ, as is discussed below. Presently, however, antiretroviral therapy actually produces a latent-like phenotype in cells;

UNINFECTED	DEFECTIVELY INFECTED	LATENTLY INFECTED	PRODUCTIVELY INFECTED
HIV-1 DNA^-	HIV-1 DNA^+	HIV-1 DNA^+	HIV-1 DNA^+
HIV-1 tat, rev, nef RNA^-	HIV-1 tat, rev, nef RNA^-	HIV-1 tat, rev, nef RNA^{+/-}	HIV-1 tat, rev, nef RNA^+
HIV-1 gag RNA^-	HIV-1 gag RNA^-	HIV-1 gag RNA^-	HIV-1 gag RNA^+

Therapy

Eradication

Choice of test: ------- In cell HIV RNA

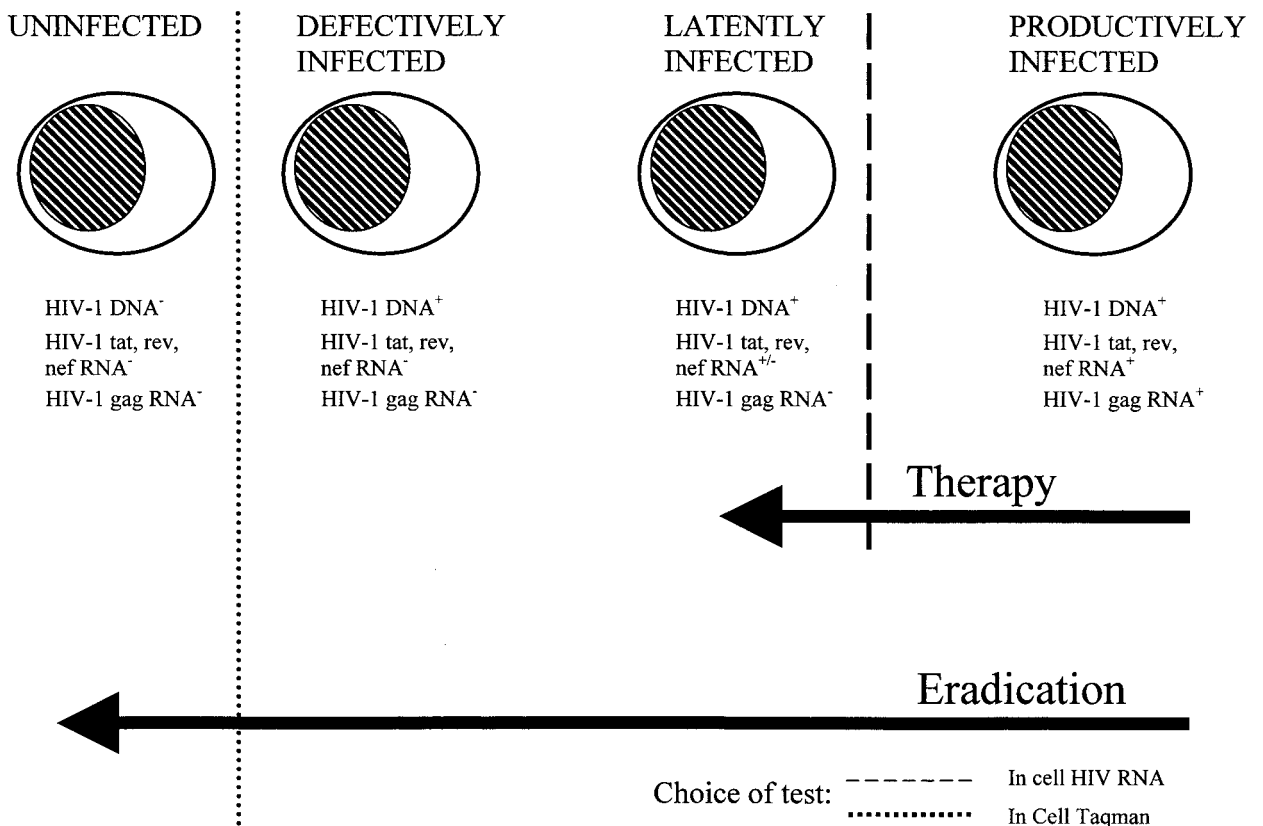

FIGURE 1 Schematic of the HIV-1 life cycle in T lymphocytes and the ideal tests to determine the response to therapy.

that is, cells contain HIV-1 DNA but do not express HIV-1 RNA. The preferred assay in this instance would be one that can monitor production of HIV-1 RNA in cells, given that cells containing HIV-1 DNA will remain relatively stable throughout the course of disease.

AMPLIFICATION TECHNIQUES PRIOR TO IN SITU HYBRIDIZATION

Detection of single-copy DNA and low-abundance mRNA was greatly facilitated in the cell with the advent of in situ PCR soon after the discovery of PCR and the thermal stable polymerase from *Thermus aquaticus* (*Taq* polymerase) (4, 10, 16, 17, 19, 25, 34, 37, 41). The powerful combination of single-copy detection in cells combined with the high-throughput cellular analysis platform of flow cytometry led to the elucidation that HIV-1 infected enough cells to account for the severe immune destruction leading to AIDS (10, 34). This assay was used clinically in several studies monitoring changes in HIV-1 DNA-containing cells during therapy (12, 28, 30, 37). Subsequent work described the combination of cell surface immunophenotyping and in situ PCR by flow cytometry and ultimately real-time PCR (TaqMan) in situ and flow cytometry (30, 31). As opposed to the simpler and quantitative fluorescence in situ hybridization, in situ PCR using flow cytometry still awaits a compelling diagnostic application. Further, HIV/AIDS treatment strategies have yet to reduce the HIV-1 DNA burden in patients, though reducing replication and viral load is now a routine goal of antiretroviral therapy.

Other in situ amplification strategies exist and fall into three categories: target amplification, signal amplification, and signal generation (27, 36). Although these technologies have been generally used for slide-based analyses, adaptation to flow cytometry could also be performed.

3SR In Situ

Self-sustained sequence replication (3SR) is an isothermal amplification strategy that exploits the activities of three enzymes in the reaction mixture. In situ 3SR (IS-3SR) is based on the use of primers with attached RNA polymerase initiation sites and the combination of three different enzymes in the same reaction mixture (DNA polymerase, RNase H, and RNA polymerase), resulting in accumulation of target mRNA through the combination of reverse transcription, DNA synthesis, and in vitro transcription (18). IS-3SR assay shows significantly less amplification efficiency than in situ PCR. So far, IS-3SR has only successfully been applied to cells in suspension and not to tissue sections.

In situ transcription and oligonucleotide-primed in situ labeling (PRINS) are methods used for the detection of mRNA involving the use of an mRNA-complementary primer, reverse transcription, and labeled nucleotides to produce labeled cDNA within a cell (43). However, similarly to the 3SR reaction, potential mispriming or nonspecific incorporation of labeled nucleotides may yield nonspecific results or increased background staining, although probably at a significantly lower level than in techniques applying DNA polymerase enzymes. In situ transcription has so far not found broad acceptance in the field of in situ detection of mRNA.

bDNA In Situ

bDNA technology has been used extensively to measure nucleic acids in serum, plasma, or digested cells and has recently been adapted for the in situ detection of DNA or RNA. The bDNA in situ hybridization method to detect nucleic acids is a signal amplification technology, as mentioned previously, rather than a target amplification like in situ PCR or IS-3SR (35). mRNA and DNA can be detected with similar sets of probes, with the only difference being the requirement for denaturation if the target of interest is double-stranded DNA. Similar to the bDNA assay in nucleic acids extracted from plasma or serum, cells are incubated with a prehybridization solution, hybridized with target probes, and then detected with a series of oligonucleotide probes for signal amplification. In most iterations of this technology, the reagents include a preamplifier, amplifier, and alkaline phosphatase-conjugated probe or probes. This in situ bDNA method is very specific and quantitative at the cellular level, which is an attribute lacking for other target amplification procedures. In situ bDNA, however, is not very sensitive compared with target and probe amplification methods. This lack of sensitivity may be related to the ability of the branched molecule to diffuse in and out of a permeabilized cell.

TaqMan In Situ Assay or FISNA

Unlike some of the target amplification approaches that require too many steps to be clinically useful, TaqMan in situ assay or fluorescence 5′ nuclease assay (or FISNA) requires only a few steps and little "hands-on" time. Because this is by definition a fluorescence-based assay, FISNA has already been adapted for use on a flow cytometer (Fig. 2) (31). One application in particular deserves mention as a potential clinical tool. Like PCR in situ hybridization, FISNA can be used to detect cells containing HIV-1 DNA (2, 23, 26, 40). Though therapies that actually reduce the HIV-1 DNA burden have yet to be developed, this assay is still useful for identifying cellular reservoirs capable of producing viral particles. Further, this technology has been used on tissue sections to identify HIV-1 reservoirs that remain following highly active antiretroviral therapy (Fig. 3) (26).

Procedure

Adherent cells or PBMCs (1×10^6 to 2×10^6 cells/reaction) are washed in PBS twice before fixation in PermiFlow
FIGURE 2   Representative dot plot of simultaneous immunophenotyping for CD4 and real-time PCR in situ (FISNA) detecting cells containing HIV-1 DNA. Biotinylated or 2,4-dinitrophenol (DNP)-conjugated antibodies survive the thermocycling process (30).
FIGURE 3   Representative laser confocal image analysis of real-time PCR in situ (FISNA) detecting cells in the prostate containing HIV-1 DNA following long-term therapy with antiretroviral drugs. These data suggest that reservoirs of HIV-1 DNA-containing cells are not necessarily cleared by long-term therapy (26).

(Invirion, Inc.). Cells are fixed for 1 to 18 h, and HIV-1 *gag* DNA is detected by TaqMan (real-time PCR) in situ or by FISNA. The cells are washed once in $1\times$ PCR buffer without cations (Mg or Mn) and pelleted by centrifugation ($600 \times g$). The PCR is performed in cell suspension ($1\times$ PCR buffer II; 0.35 mM $MgCl_2$; 200 μM each of dATP, dCTP, dGTP, and dTTP; 200 μM each of *gag* primers SK38/SK39 [sequences 5′-ATAATCCACCTATCCCAGTAGGAGAAAT-3′ {SK38} and 5′-TTTGGTCCTTGTCTTATGTCCAGAATGC-3′ {SK39}]; 100 nM *gag* probe FTSK19 [sequence 5′-ATCCTGGATTAAATAAAATAGTAAGAATGTATAGCCCTAC-3′-TAMRA]; and 10 U of AmpliTaq DNA polymerase Gold. Using the GeneAmp PCR System 2400 (PE Applied Biosystems, Foster City, Calif.), reaction tubes are heated to 95°C for 5 min followed by 30 cycles consisting of 94°C for 45 s and 56°C for 2 min, followed by a 15°C soak. The cells are thereafter washed in PBS and analyzed by flow cytometry or laser confocal microscopy. Autofluorescence can be quenched by incubation with trypan blue. The cutoff values are determined based on fluorescence emitted from noninfected cells.

CLINICAL APPLICATION OF ULTRASENSITIVE FLUORESCENCE IN SITU HYBRDIZATION

One of the most important applications of in situ hybridization clinically is for the detection of infectious diseases, in particular those caused by viruses (1, 7, 8, 15, 20–22, 24, 28, 29, 33, 38, 42). Viruses replicate in cells, not in plasma, which the majority of diagnostic tests use as sample. This raises the question of why one of the most powerful cell analysis tools, flow cytometry, is not being used to determine the response of virus replication to antiviral therapy. Unlike PCR in situ hybridization or some of the other in situ amplification techniques previously discussed, fluorescence in situ hybridization offers quantitative information at both the cellular level and the cell population level, making these assays useful for monitoring viral replication clinically (3, 5, 13, 21, 28, 29). For example, one can use fluorescence equivalent bead standards

and the number of fluorochromes per viral copy to calculate the number of copies of HIV-1 expressed in a particular cell (3). Further, the cytometer will determine the number of cells expressing a detectable amount of virus in a heterogeneous cell population such as blood or a liquid-based cervical cytology specimen as described below. As is the case with HIV-1, in situ hybridization combined with immunophenotyping yields additional information on the inhibition of viral replication by drugs or other therapeutics within certain cellular reservoirs (Fig. 4) (1, 13, 21, 28, 29, 33).

HIV

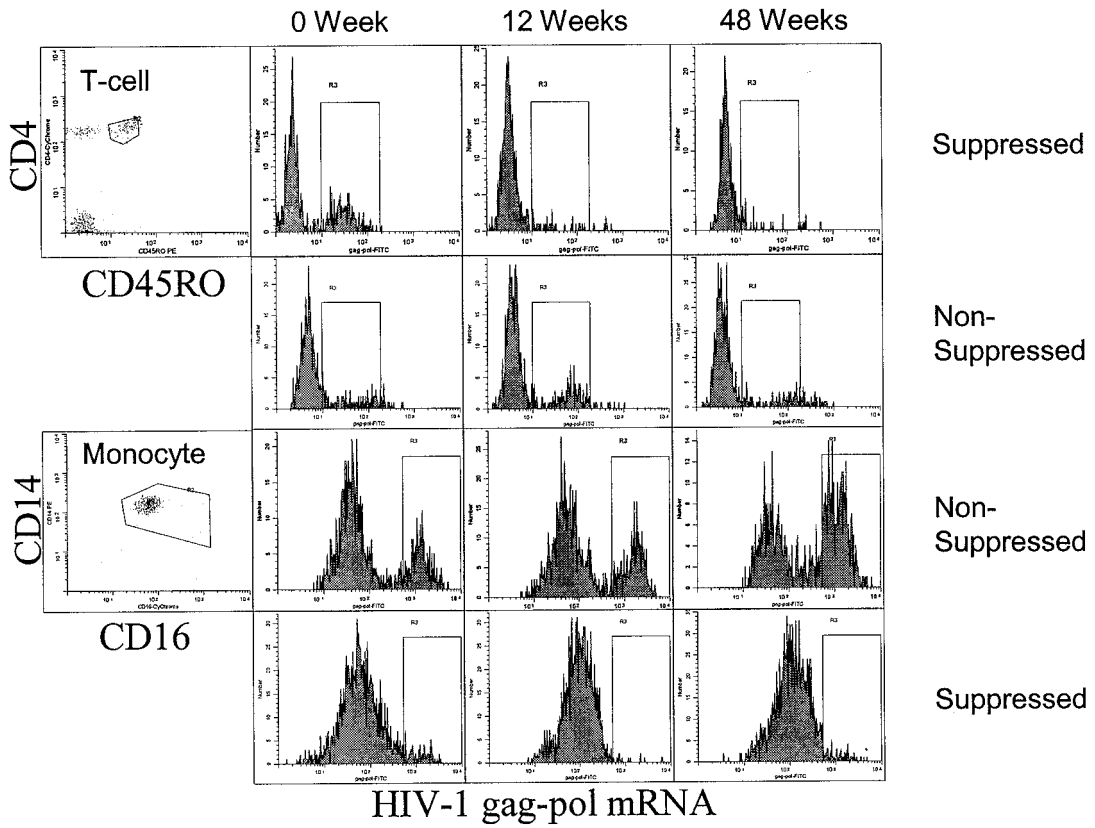
Detection of HIV replication in cells has immediate and important clinical significance. It has been proposed that the diagnostic goal of HIV therapy should be the minimization of viral replication with the hope that HIV evolution is minimized and the prospect of developing drug resistance or immune escape mutations ultimately is minimized (44). Several studies determined that HIV-1 replication can persist in cells in the presence of an undetectable plasma viral load (11, 29, 44). These studies suggested that the diagnostic goal just described can be achieved by combining plasma viral load determinations with a cytometry-based assessment of HIV-1 replication in both T lymphocytes and monocytes/macrophages (29). In fact, Patterson et al. previously showed that HIV-1 replicates in distinct subpopulations of T cells and monocytes/macrophages (Fig. 4) (29). In the T-cell compartment, HIV-1 predominantly replicated in activated, memory T cells with the $CD4^+$ $CD45RO^+$ $HLA\text{-}DR^+$ phenotype. Similarly, HIV-1 predominantly replicates in the $CD14_{lo}$ $CD16_{hi}$ subpopulation of monocytes (Fig. 5). Monitoring these two cellular compartments as well as the plasma provides additional, clinically useful information when the results are reported together (Fig. 5). When persistent viral replication exists in cells despite undetectable plasma viral load, additional agents such as hydroxyurea and the drug Abacavir have been shown to provide additional suppression of HIV-1 replication (14, 32).


FIGURE 4 Monitoring HIV-1 replication in patients on highly active antiretroviral therapy by simultaneous immunophenotyping and ultrasensitive fluorescence in situ hybridization in T lymphocytes (CD4$^+$ CD45RO$^+$) and in monocytes/macrophages (CD14/CD16).
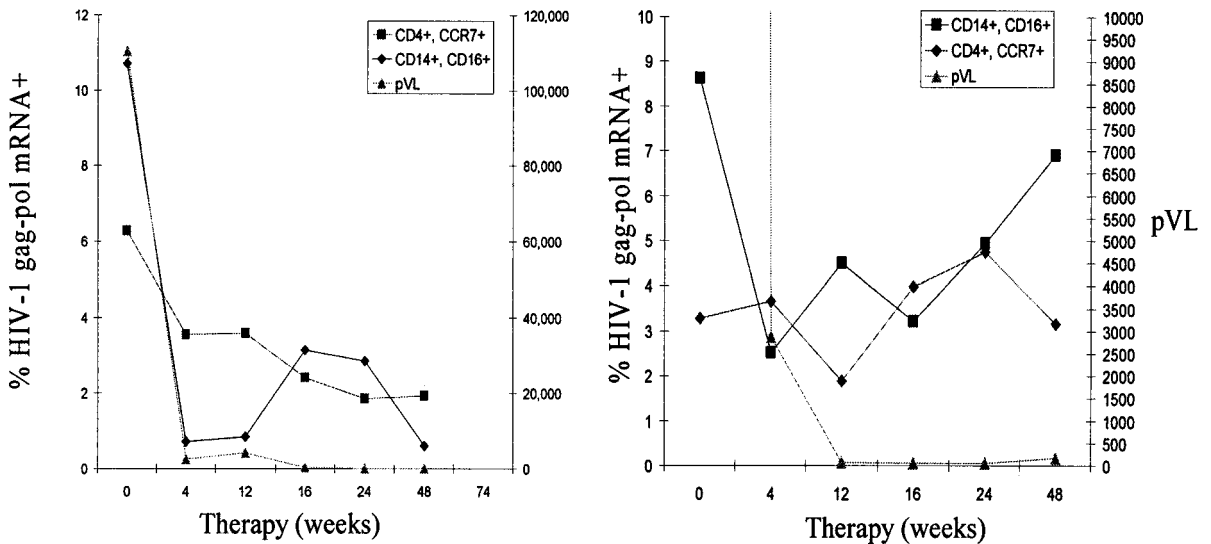

FIGURE 5 Combining plasma viral load (pVL) and simultaneous immunophenotyping and ultrasensitive fluorescence in situ hybridization in T lymphocytes (CD4$^+$ CD45RO$^+$) and in monocytes/macrophages (CD14/CD16) to determine response of multiple tissue compartments to highly active antiretroviral therapy. This extremely powerful test bundle identifies individuals with a maximal response to therapy in all compartments (left) and those individuals with persistent viral replication (in cells) despite undetectable plasma viral load (right). As one might predict for an individual with persistent viral replication, plasma viral load increased during the course of therapy.

The development of HIV-1 entry inhibitors, most notably the CCR5 inhibitors, will present an exciting opportunity for cell-based diagnostics. These compounds target one of the major coreceptors (in addition to CD4) used by HIV-1 to gain entry into susceptible target cells. In preclinical and early clinical studies, these compounds were shown to have little effect on plasma viral load as they prevent entry of HIV-1 into uninfected cells. These compounds will be used as frontline therapy against HIV-1 and as such will need to be assessed for their efficacy. Additional concern exists in the field due to the possibility that using CCR5 inhibitors will select for viral isolates that can use the other major HIV-1 coreceptor, CXCR4, a phenomenon termed "tropism shift" (6). Isolates that use CXCR4 have been shown to be more virulent than isolates that use CCR5 alone (6). Detection of this tropism shift is another application best suited for cell-based diagnostics as demonstrated in Fig. 6.

Procedure

Simultaneous flow cytometric analysis of intracellular HIV-1 RNA and cellular immunophenotyping of PBMCs were done as previously described (1, 13, 21, 28, 29, 33). Duplicate samples containing 5×10^4 to 1×10^6 cells were labeled with optimal concentrations of a T-cell (CD4, CD45RO) cocktail (Invirion, Inc.) or a monocyte/macrophage (CD14/CD16) cocktail (Invirion, Inc.) and incubated for 20 min at room temperature. The cells were washed with PBS, fixed, and permeabilized by the addition of 300 μl of PermiFlow (Invirion, Inc.). The cells were permeabilized for at least 60 min and up to 18 h. The cells were then washed twice in PBS, pH 7.4, and once in 2× SSC (1× SSC is 0.15 m NaCl plus 0.015 m sodium citrate). The cells were then resuspended in 100 μl of hybridization buffer containing a cocktail of 5-carboxyfluorescein-labeled oligonucleotide probes specific for HIV gag-pol mRNA (ViroTect In Cell HIV Detection System; Invirion, Inc.) at 43°C for 30 min. The cells were washed for 5 min at low stringency and then at high stringency for 30 min at 43°C. Multiparameter
FIGURE 6 Simultaneous detection of the HIV-1 coreceptor CCR5 and HIV-1 replication. This combination can be used to monitor response to HIV-1 entry and CCR5 inhibitors. Combining this with CXCR4 in a third color will allow the monitoring of potential tropism shifts.

three-color analysis was then performed on labeled cells in a Coulter XL or BD FACSCalibur flow cytometer.

HPV and Cervical Cancer Screening

Cervical cancer affects approximately 15,000 women per year in the United States and more than 450,000 women worldwide, though the exact number may be greater because of the lack of screening in developing nations. The Papanicolaou (Pap) smear has been the standard of care in the United States for more than 50 years, resulting in a significant decline in deaths due to cervical cancer during this time. More than 99% of cervical squamous cell carcinomas are due to infection by oncogenic genotypes of HPV such as HPV types 16, 18, 31, and 33, among others. HPV detection has been performed by a broad menu of molecular techniques, including hybrid capture (liquid hybridization), genotype-specific PCR, in situ hybridization, and in situ PCR. Most HPV assays, such as type-specific PCR and Hybrid Capture II, detect the presence of HPV L1 DNA from oncogenic types despite the fact that only a minority of women infected with oncogenic types of HPV will progress to cancer. The holy grail of HPV diagnostics is to find the "molecular switch" that defines when transformation of the cell has occurred. Most of the literature suggests that this molecular switch involves the overexpression of the E6 and E7 oncogenes, usually as a result of HPV integration into the chromosomal DNA (39). PCR for E6 and E7 mRNA has been used with some success; however, PCR for E6 and E7 mRNA is difficult to interpret, as some E6 and E7 mRNA is expressed in normal cells. For example, if mRNA from 1 million cells from a liquid-based cervical cytology (Pap) specimen were placed in a PCR for E6 or E7 quantification and the assay determined that 1 million copies of E6 or E7 mRNA were present, the clinician would not know if 1 million cells were making 1 copy per cell or 1,000 cells were producing 1,000 copies per cell. Simultaneous immunophenotyping and ultrasensitive fluorescence in situ hybridization can be used to detect cells in liquid-based cervical cytology specimens to detect the upregulation of E6 and E7 mRNA in cells undergoing transformation (9, 24). Use of this assay on a flow cytometer (Fig. 7) or a capillary-based cytometer (Fig. 8) is a powerful tool to detect cells in which HPV has "switched on" the viral oncogenes E6 and E7.

Procedure

A 1-ml aliquot was removed from a liquid-based cervical cytology specimen (PreservCyt [Cytyc, Boxborough, Mass.] or SurePath [Tripath Imaging, Durham, N.C.]). The cells were pelleted by centrifugation at 400 × g and washed once in PBS, pH 7.4. Cells were resuspended in 100 μl of PBS, pH 7.4, and stained with a 1:10 dilution of phycoerythrin (PE)-conjugated anti-CAM 5.2 and PE-Cy5-conjugated anti-CD16 (BD Pharmingen, San Diego, Calif.). The cells were then incubated at 4°C for 20 min in the dark. Following incubation, the cells were fixed and permeabilized in PermiFlow (Invirion, Inc.) for 1 h at ambient temperature. Following fixation and permeabilization, the cells were washed once in PBS, pH 7.4, pelleted by centrifugation at 400 × g, washed again in 2× SSC, and pelleted by centrifugation. HPV fluorescence in situ hybridization for E6 and E7 mRNA was performed by resuspending the cells in a hybridization mixture consisting of 5× SSC, 30% formamide, and 100 μg of sheared salmon sperm DNA per ml and a cocktail of 5′- and 3′-labeled oligonucleotide probes (HPV OncoTect; Invirion, Inc.). Hybridization was performed at 37°C for 30 min and
FIGURE 7 In situ detection of HPV E6 and E7 mRNA in cervical cytology samples from women with high-grade squamous intraepithelial lesions (HSIL) and women without cytologic abnormalities (WNL). The difference in the percentage of E6 and E7 mRNA-expressing cells is highly statistically significant (24).
FIGURE 8 Ultrasensitive fluorescence in situ hybridization detection of HPV E6 and E7 mRNA expression in liquid-based cervical cytology samples. Hybrid Capture II high-risk HPV-positive samples (top row) and Hybrid Capture II high-risk HPV-negative samples were hybridized and run on a Guava Technologies PCA-96 capillary cytometer.

was followed by a 5-min wash in 2× SSC–0.1% Triton X-100 and a 15-min wash in 0.1% SSC–0.1% Triton X-100. The cells were resuspended in PBS, pH 7.4, with 2% fetal calf serum for flow cytometric analysis.

SUMMARY

Currently, cell-based diagnostics make up a small fraction of the diagnostics market. Cell-based diagnostics that guide therapy to viral infections and cancer much like the her-2/ Herceptin model for breast cancer will continue to grow in popularity. The ability to perform molecular biological and immunological analyses in situ will greatly accelerate this growth. Hybrid instruments that incorporate the attributes of a flow cytometer with the imaging of a confocal microscope are currently available and will begin to find a place in clinical laboratories. At the very least, however, clinical applications of cytometry are beginning to extend beyond leukemia/lymphoma immunophenotyping to other fields, such as virology, where high-throughput analysis of intracellular events is critical for the diagnosis and management of infected individuals.

Introduction

STEVEN D. DOUGLAS

25

A number of advances in basic immunology, molecular biology, and cellular physiology have resulted in major developments in cellular immunologic assays relevant to clinical and diagnostic immunology. The application of these techniques in research and clinical laboratories has led to their high sensitivity and specificity. These techniques afford the clinical immunology laboratorians, the clinical allergists and immunologists, and physicians in allied specialties with assays and techniques which make possible the precise diagnoses of primary and secondary disorders of the immune system. The chapters presented in this section incorporate newer diagnostic assays that have come into use since the previous edition of this manual. Furthermore, new chapters have been added for detection and measurement of T-cell responses to antigens and mitogens and assays for B-cell function and humoral immune responses. Shacklett and Nixon describe methodology for enzyme-linked immunospot assays (ELISPOT) for the detection of antigen-specific CD8 T cells. Several methods for enhancing ELISPOT sensitivity, assay validation, and interpretation are listed in tabular form. The potential clinical utility of this assay in infectious disease, autoimmunity, and cancer immunotherapy is extensive. International efforts are under way to standardize ELISPOT methodology for large-scale human immunodeficiency virus vaccine trials. Other examples include screening for tuberculosis and monitoring of clinical trials for melanoma therapeutics. McCloskey et al. describe four assays for apoptosis. These include the subdiploid method, DNA strand breaks (terminal deoxynucleotidyltransferase-mediated duTP-biotin nick end labeling method), detection with translocated phosphatidylserine (annexin V method), and a more recently developed method involving detection of cells using active caspases. Krogstad has added new details on real-time PCR assays for T-cell receptor excision circles and quantitation of recent thymic migrants. The chapter by Whiteside provides methodology for the assessment of natural killer cell activity in humans, and a figure delineates the conceptual interactions between "activation" and "inhibitory" natural killer cell markers. There is an expanded need for cellular immunologic assays for vaccine assessment in international clinical trials. Standardization of these techniques is essential. Cox et al. provide considerable detail for assay validation, and technical issues related to cell storage and viability, which are relevant and crucial for international vaccine studies. This important chapter provides details for specimen collection, lymphocyte function, CD4 and CD8 T-cell responses, and assays in developing countries. Cryopreservation is also dealt with in detail in the chapter by Weinberg. A new chapter by Currier examines T-cell activation and cell signaling, focusing on early events associated with T-cell activation and clinical application, namely, the identification of genetic signaling defects and signaling defects associated with immunosuppression or malignancy. Procedures are presented for measuring CD69, early cell activation; receptor expression after T-cell activation; and intracellular calcium cell signaling. Nahm and Lorenz provide assays for B cells and antibodies; in particular, these include bactericidal opsonophagocytosis and whole-blood lymphocyte proliferation. The chapter further provides background for the diagnosis of primary and secondary defects in B cells. O'Gorman's chapter provides methodology for the assessment of myeloid and monocytic cell function for the clinical immunology laboratory. Heyworth and Curnutte present approaches for molecular diagnosis of chronic granulomatous disease. There is direct application of these assays in clinical medicine related to primary and secondary immune deficiency, autoimmunity, hematology, rheumatology, transplantation, and a wide array of clinical disorders. These chapters afford a segue toward precise cellular immunologic diagnoses of these important clinical conditions.

Delayed-Type Hypersensitivity Skin Testing

THERON McCORMICK AND WILLIAM T. SHEARER

26

Cell-mediated immunity (CMI) provides the principal immunologic mechanism against a host of intracellular microbiologic agents, including many viruses, fungi, protozoa, and parasites. Screening of this arm of the immune system often begins with delayed-type hypersensitivity (DTH) skin testing. This test is a widely available, cost-effective, and relatively simple tool for assessing the integrity of CMI. Once properly placed, a positive response to DTH skin testing indicates intact CMI, while a negative response may represent either a possible defect in CMI, a lack of previous exposure or an inability to respond. In this chapter, a brief discussion of the molecular mechanism of action and a survey of the different implementation tools, as well as test interpretation, is provided. In addition, the clinical implications of DTH skin testing in disease diagnosis and screening (i.e., tuberculosis) and the monitoring of specific disease progression (i.e., human immunodeficiency virus [HIV]) will be reviewed.

BIOLOGY

The DTH reaction occurs in several steps after the antigen has been introduced intracutaneously. The ensuing inflammatory response is an intact recall response initiated by memory T cells that involves a coordinated process of cytokine and chemokine secretion and cellular infiltration (15). The reaction begins with the uptake and initial processing of the antigen by antigen-presenting cells, such as dendritic cells and/or monocytes (31). During the tuberculin reaction, the antigen is processed in the context of major histocompatibility complex (MHC) class II molecules and presented to naïve $CD4^+$ T cells. In particular, skin-derived dendritic cells are among the first cells to display peptides in the antigen-MHC class II complex (25). Generally, soluble antigens do not enter the MHC class I pathway; therefore, $CD8^+$ T cells have minimal or no contribution to this reaction (27).

Cytokines are derived from this interaction, particularly interleukin-12 (IL-12), IL-18, and gamma interferon (IFN-γ), serving to drive the T helper cells to a Th1 $CD4^+$ profile (47). By 4 to 6 h a lymphocytic and basophilic infiltrate is present in the perivascular area. When the tuberculin reaction is used as a model, 75 to 90% of the mononuclear cells in the perivascular aggregates are $CD4^+$ T lymphocytes and monocytes, with subsequent dermal interstitial infiltration by 12 to 24 h (40). The swelling at the skin testing site can be seen within 24 to 48 h after challenge but becomes most intense between 48 and 72 h (28). IFN-γ, tumor necrosis factor alpha, IL-1, and IL-6 are detected in the dermis within 48 h and are sustained for 7 days after testing (7, 39). Of note, in mice, the cellular response to DTH tends to be predominantly neutrophilic, with reaction elucidation requiring much higher concentrations of antigen than in humans (10). Also, IFN-γ is required for the development of stress-induced DTH in mice (11).

METHODS AND IMPLEMENTATION: MANTOUX METHOD OF SKIN TESTING

DTH skin testing is routinely performed by the Mantoux method. In the Mantoux method, an individual antigen is selected and administered intradermally. Appropriate antigen(s) should be selected on the basis of the likelihood of the individual's exposure. Concentrations and availability of commonly used antigens are shown in Table 1. In general, the lower concentration is preferred for the initial testing in order to avoid a possible severe DTH reaction. Subsequently, the more concentrated form of antigen can be administered if the initial testing is negative.

The ventral surface of the forearm is the preferred site for testing. A 27-gauge needle containing 0.1 ml of antigen should be used for injection into the superficial layers of the dermis (approximately 1 to 2 mm under the epidermis), resulting in a small bleb on the skin 7 to 10 mm in diameter. A distance of at least 3 cm (1.2 in.) between antigens should prevent an incorrect reading in case of large DTH reactions. Syringes without excess airspace at the tip are preferred for accurate delivery of antigens. Two methods of needle insertion can be employed: a bevel-up or a bevel-down method, with the former being more widely used. It is unclear whether DTH testing by these two methods differs in outcome. A study comparing the bevel-up and the bevel-down methods using 0.03 ml of sterile saline per injection showed that the bevel-down method caused less bleeding and discomfort at the site and was more time-efficient in the delivery of multiple injections (24). Trained health professionals should read DTH reactions within 48 to 72 h of testing. The largest diameter of the induration should be recorded. An induration of 5 mm or more in response to a single antigen is considered sufficient evidence for intact CMI. Individuals who do not respond are considered anergic. In our institution, DTH is

TABLE 1 Common antigens for DTH skin testing by the Mantoux method

Antigen	Concn. used for DTH skin testing[a]	Pharmaceutical supplier(s) (examples)
PPD	5 TB/0.1 ml	Aventis-Pasteur, Swiftwater, Pa.
C. albicans	1:10 or 1:100 dil (wt/vol)	Allermed, San Diego, Calif.; Hollister-Stier, Spokane, Wash.
Trichophyton	1:30 or 1:100 dil (wt/vol)	Hollister-Stier, Spokane, Wash.
Tetanus	1:10 dil (wt/vol)	Aventis-Pasteur, Swiftwater, Pa.
Mumps	40 CFU/ml	Aventis-Pasteur, Swiftwater, Pa.

[a]TB, tuberculin units; dil, dilution.

performed with a panel of tetanus (1:10), purified protein derivative (PPD) of *Mycobacterium tuberculosis,* and *Candida albicans* (1:20 and 1:200) antigen as shown in Fig. 1. The rates of positive response with this panel for HIV-positive and HIV-negative individuals are approximately 70 and 80%, respectively. Sensitivity does not increase with the addition of another recall antigen (22). Anergic individuals with strong clinical suspicion of a CMI defect should have peripheral blood obtained for the in vitro lymphoproliferative assay (LPA) to mitogens and antigens. Otherwise, DTH skin testing using tetanus (1:10) and *Candida* (1:20) antigen should be repeated in 3 to 6 months. In cases where antigen avoidance is crucial, such as in immunosuppressed patients in the transplantation setting, trans vivo DTH testing has been proposed for CMI screening (4). This described method involves the injection of human peripheral blood mononuclear cells combined with a set amount of antigen into murine pinnae, with induration measurement within 48 h.

FACTORS THAT MAY AFFECT DTH RESULT

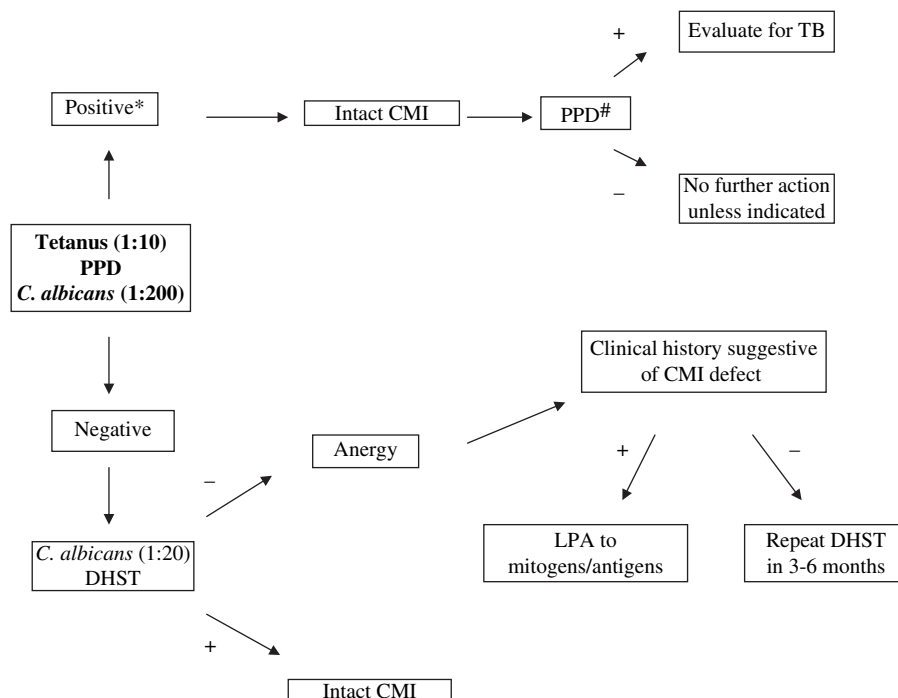
Correct handling and storage of antigens are important in maintaining the efficacy of the reagents and, thus, accurate results. Similar antigens from different sources may produce variable results; therefore, they may not be comparable, especially when serial testing is performed (30). DTH skin testing with two antigens (yeast cell suspension and polysaccharide antigens) from the same strains of *Candida* can produce discordant results in up to 20% of individuals (14). Placement of DTH skin tests and reading of results require trained personnel. Loss of antigens during needle insertion and injection into the deep dermal layers can result in false-negative results. Interpretation of a large wheal reaction as a positive DTH response is not uncommon. Care should be taken in ensuring that only the widest part of the induration is recorded. Positive DTH responses can also develop as a result of repeat testing. This phenomenon is known as the booster effect (32). It should not occur if at least 3 months


FIGURE 1 Suggested procedure for DTH skin testing by the Mantoux method. A positive reaction (*) is signaled by an induration of ≥5 mm in response to a single antigen or an induration of ≥2 mm in response to at least two antigens; a PPD-positive reaction (#) is signaled by an induration of ≥10 mm except in HIV-infected individuals and children at high risk for tuberculosis (induration, ≥5 mm). DHST, DTH skin testing; TB, tuberculosis.

is allowed between tests. The type and dose of antigens may influence such occurrences as well. For instance, DTH testing with *Candida* antigens resulted in a positive response in only 9% of HIV-infected individuals within 1 week of antiretroviral therapy, whereas no response was seen with mumps antigen, *Trichophyton,* or PPD (9).

Awareness of conditions that may affect the DTH response is critical for accurate assessment (Table 2). As an example, acute influenza infection can cause transient impairment of CMI. Reversion of a negative *Candida* DTH skin test was documented for such subjects after 17 days of infection (45). Also, significant alcohol consumption, such as is seen in people with alcoholism, decreases the sensitivity of detection of a DTH response (46). Patients with primary immunodeficiency disorders involving CMI typically show no DTH responses. Some hereditary and metabolic disorders can cause secondary CMI defects and thus are associated with failure to respond to DTH testing (2). Decreased DTH responses are seen in chronic obstructive pulmonary disease patients with poor lung function (12). Prolonged use of systemic corticosteroids has been known to depress CMI and, thus, DTH in patients. However, when one of the more potent inhaled corticosteroids, fluticasone, was used in a double-blind, placebo-controlled study, after 28 days of inhaled therapy, DTH skin responses were not affected (13). There are no current studies reporting a depression of DTH response after a period exceeding 2 months on high-dose inhaled corticosteroids. With regard to childhood immunizations, the measles vaccine can temporarily suppress tuberculin reactivity; thus, a tuberculin skin test should either be placed at the same time as the measles, mumps, and rubella vaccine or postponed for 4 to 6 weeks (1). Also, in the elderly, DTH cutaneous responses to recall bacterial and fungal antigens are reduced in frequency and size (6).

CORRELATION OF DTH SKIN TESTING AND LPA

Another assessment of CMI is performed by using the in vitro LPA. This test entails the proliferation of lymphocytes in response to antigens to which the individual has previously been sensitized. In general, LPA results correspond to those obtained with in vivo DTH skin testing. More specifically, correlation between responses produced by DTH skin testing and LPA depends on the type of antigen, the level of CMI impairment of the subject, and the criteria used in defining a positive response. In HIV-negative individuals, correlation between DTH and LPA responses to frequently exposed recall antigens is excellent (48, 49). However, in a study of an HIV-infected population, the baseline DTH skin testing response to *Candida* antigen was found to be absent while the LPA response to *Candida* antigen was relatively intact (9). After 12 weeks of highly active antiretroviral therapy (HAART), LPA responses to *Candida* normalized to those of control subjects, while only 30% of patients showed a response by DTH skin testing (9). Figure 2 shows the results of a different study revealing concordance between improved DTH (68%) and LPA (57%) responses to tetanus after 48 weeks or more of HAART (48). The differences between the results of these two studies may be due partly to the higher cutpoint (≥10 mm) for defining positive DTH reactions in the former study compared to the latter (≥5 mm). Earlier reports have suggested better correlation between LPA and DTH results when a cutpoint of <5 mm is used (35). Concordance of improvement in DTH and LPA

FIGURE 2 Percentage of patients having a baseline DTH response (induration, >5 mm) and developing an increase in DTH response (at least a 5-mm increase from baseline) to a given antigen after 48 weeks or more of HAART. The total numbers of patients evaluated for tetanus at baseline, week 6, week 18, and any time after baseline were 31, 23, 23, and 31, respectively. Adapted from reference 48.

responses to a specific antigen following treatment was superior for HIV-infected individuals who had CD4$^+$ T-cell counts of 250/μl or more (49). Immune recovery following HAART can be observed better with the LPA response in patients with relatively lower CD4$^+$ T-cell counts than with the DTH response. In the assessment of the CMI response to recombinant gpl60 immunization in asymptomatic HIV-infected patients, the sensitivity of DTH skin testing compared to LPA was 75% (26). Recovery of DTH to a battery of recall antigens correlated well with improved LPA responses to anti-CD2, anti-CD28, and anti-CD3 (33).

CLINICAL IMPLICATIONS OF DTH

DTH skin testing is a practical screening measure for assessing the integrity of CMI. Abnormal DTH responses can signify an associated CMI defect in conditions such as frequent infections, autoimmunity, and malignancy. DTH skin testing is also useful for patients with known immune deficiency. Primary immunodeficient patients who fail to respond to DTH with ubiquitous antigens can experience a predisposition to infections from intracellular pathogens. DTH skin testing is especially helpful in the assessment and management of HIV-infected patients (16). Development of anergy in these individuals predicts disease progression, whereas loss of anergy indicates disease improvement and response to treatment. In addition, DTH skin testing can also aid in the diagnosis of many bacterial and fungal infections such as tuberculosis, leishmaniasis, histoplasmosis, blastomycosis, and aspergillosis. Of these, clinical utility in the diagnosis of tuberculosis is perhaps the most well known. Furthermore, DTH can aid in the assessment of CMI responses to vaccines. For instance, it was used to assess cellular response to HIV type 1 Tat protein immunization in HIV-positive individuals (20).

ASSESSMENT OF CMI

In the healthy HIV-negative population, anergy is typically seen in <5% of individuals; however, prevalence of anergy as high as 15% in such study subjects has been reported (8, 22, 43). In HIV-infected individuals, prevalence of anergy typically ranges between 20 and 50% (8, 29, 34, 36, 41, 42). A noted example of the use of DTH in determining anergy is shown in a large study of 358 HIV-negative and 721 HIV-positive women (29). In Table 3, a comparison of percentages of nonreactivity to Candida, tetanus, or mumps antigens using cutpoints of 1 to 5 mm is shown. The percent nonreactivity was the highest with mumps antigen and the lowest with tetanus antigen, irrespective of HIV status or cutpoints. The difference between nonreactivity in HIV-negative and HIV-positive women was best distinguished by use of the tetanus antigen. Across the board, cutpoints of 1 and 2 mm did not differ in their ability to define anergy. However, raising the cutpoint from 2 to 5 mm did increase the percentage of nonreactivity, regardless of antigens or HIV status. In Table 4, percentages of nonreactivity to different combinations of two antigens and to all three antigens with cutpoints of 1 to 5 mm are shown. Tetanus and mumps antigen testing had the highest reactivity of all the combinations in HIV-negative women. The best identification of anergy in both the HIV-negative and the HIV-positive populations was achieved by using all three antigens and cutpoints of either 1 or 2 mm (Table 4). With this guideline, 90 and 60% of HIV-negative and HIV-positive women, respectively, responded to one or more antigens. Due to the difficulty in measuring the small induration size of 1 mm, 2 mm was recommended as the best cutpoint for establishing anergy.

In HIV-infected individuals, response to DTH skin testing, including the number of positive antigens and the summed response, correlates directly with CD4$^+$ T-cell numbers and clinical stages of HIV disease (3, 17, 35). Klein et al. demonstrated the correlation between DTH responses and numbers of CD4$^-$ T cells in HIV-infected women (29). The inability to respond to a single antigen differed significantly among the subjects in each CD4$^+$ T-cell group, with response seen in patients with CD4 counts higher than 200/μl. In general, women with higher CD4$^+$ T-cell counts were more likely to have a DTH response. Similarly, women in the lower CD4$^+$ T-cell count group (≤200/μl) had significantly lower percentages of DTH reactivity.

DIAGNOSIS OF M. TUBERCULOSIS DISEASE

Prevalence of positive PPD reactions varies among different population groups. The highest prevalence is seen in intravenous drug users, homeless persons, HIV-infected persons, and immigrants from Asia, Africa, and South America (1). In a mixed population of HIV-positive and HIV-negative individuals, a history of a positive PPD reaction predicted subsequent positive testing for 70% of subjects (42).

In general, development of an induration of 10 mm or more in response to PPD is considered a positive reaction, except in HIV-infected individuals and children at high risk for tuberculosis, for whom an induration of 5 mm or more is considered significant. Children with histories of close contact with patients with tuberculosis or immunosuppressive

conditions are considered at high risk for tuberculosis infection (1). Of note, individuals with disseminated tuberculosis may not react to PPD placement. In the United States, where native-born individuals are not routinely immunized with *Mycobacterium bovis* (i.e., Bacille Calmette-Guerin [BCG]), prior immunization with BCG does not alter the criteria for PPD interpretation, since most adult immigrants were immunized as children and are likely no longer sensitized. Nevertheless, persistent positive responses to PPD at 1 to 3 years after BCG immunization have been seen. This may pertain to immigrants from countries where repeated BCG immunization is employed (23).

The revised recommendation by the Centers for Disease Control and Prevention no longer requires DTH for recall antigens (anergy testing) with PPD testing in HIV-infected individuals (5). This recommendation is based partly on the lack of statistical significance in the reduction of tuberculosis in PPD-negative, anergic individuals who were on isoniazid prophylaxis (18). In addition, HIV-positive patients generally have a brisk response to PPD when infected with tuberculosis and may selectively react to PPD without any reaction to recall antigens (19, 34). The lack of antigen standardization and the multiple factors resulting in variations in DTH results have led to difficulties in interpreting anergy testing results (5). However, determination of anergy has important clinical implications in the detection of tuberculosis in the HIV-infected population. Anergic HIV-infected

individuals are at higher risk for active tuberculosis than nonanergic individuals (42). In the large cohort of HIV-infected women discussed above, individuals who reacted to one or more control antigens (*Candida*, tetanus, and mumps) were four to six times more likely to react to PPD (29). When all three antigens and a 2-mm cutpoint were used, anergy was seen in only 9.5% of HIV-negative women but in 40% of HIV-positive women (29). With the same criteria, the rates of positive PPD reaction were 1.4 and 5.8% in anergic and nonanergic HIV-positive women, respectively. However, among HIV-negative women, the rates of positive PPD reaction did not differ according to whether or not the women were anergic. The benefits of anergy testing in this study have been supported by others (21, 33, 37, 44). Therefore, careful consideration of performing anergy testing in conjunction with tuberculin testing in a population at high risk for tuberculosis (HIV-positive patients) should be made. In the HIV-negative population, there is no clear recommendation regarding placement of control antigens with PPD testing. Nevertheless, PPD testing alone appears to be an accurate screening test for tuberculosis (38).

CONCLUSIONS

DTH skin testing provides a practical tool in the assessment of CMI. It can be used to establish defects in CMI, predict progression of and monitor HIV disease, test responses to

vaccines, and diagnose bacterial and fungal infections. For valid interpretation of DTH testing, the skin test placement and accuracy of the skin test reading as well as various health factors need to be taken into consideration. Lastly, DTH correlates well with the more specific in vitro LPA, and it remains the recommended initial screening tool for CMI on the basis of its ease of use and inexpensiveness.

Cryopreservation of Peripheral Blood Mononuclear Cells

ADRIANA WEINBERG

27

The utility of cryopreserved peripheral blood mononuclear cells (PBMC) in clinical and diagnostic immunology is widely recognized. The use of cryopreserved PBMC offers multiple advantages for in vitro studies. The ability to batch specimens permits significant cost reductions through efficient utilization of labor and reagents and permits testing of multiple samples in a single run, thus avoiding interassay variability and providing more meaningful comparisons in longitudinal studies (3, 4).

Immunologic assays on cryopreserved PBMC provide important end points for large clinical trials of highly active antiretroviral therapy (HAART). The incidence of end-organ disease in human immunodeficiency virus (HIV)-infected patients has dramatically fallen since the introduction of HAART. The use of cryopreserved PBMC for the studies of immune reconstitution in these patients permits the selection of samples from well-characterized study subjects (1).

Transportation of frozen PBMC to laboratories for highly specialized tests has certain advantages over shipping of fresh blood (8). Certain populations of blood cells have a limited life span outside the human body, whereas cryopreserved PBMC are stable for prolonged periods when adequately stored or shipped in liquid nitrogen tanks.

Tests developed after the collection of clinical samples can be applied to cryopreserved PBMC. This allows for utilization of archived samples obtained from well-characterized study subjects to answer new scientific questions and avoids costly and unnecessary repetition of clinical studies (2).

Finally, cryopreserved PBMC are used to treat congenital or iatrogenic immune defects. For example, ex vivo generation of anti-cytomegalovirus (anti-CMV) and anti-Epstein-Barr virus cytotoxic T lymphocytes (CTL) can be used to protect stem cell transplant recipients.

The utility of cryopreserved cells depends on the viability and function retention of PBMC after freezing and thawing (7). To achieve optimal results in this respect, technical aspects are critical, but the intrinsic fragility of PBMC subpopulations can also play a role.

TECHNICAL ASPECTS OF PBMC CRYOPRESERVATION

The goal of the cryopreservation is to freeze and thaw the PBMC without compromising cell viability. Cryoprotective agents are essential in order to avoid water crystals and cell burst with freezing. Both glycerol and dimethyl sulfoxide (DMSO) can provide this function, but only DMSO has been extensively studied for cryopreservation of PBMC. Other critical steps of the cryopreservation procedure include inhibition of cell metabolism while in the presence of DMSO, rate-controlled freezing to avoid cell dehydration, rapid thawing, and resuspension in serum-containing medium, which protects the cells against osmotic trauma.

Ficoll-Hypaque-separated PBMC are washed at 4°C, counted, and resuspended at 10^7 PBMC/ml in cold fetal calf serum containing 10% DMSO. The cell suspension is aliquoted into cryovials kept on ice, which are then inserted into a Nalgene Mr. Frosty freezing apparatus or a Cryomed freezing chamber (2). The cells are gradually cooled at a rate of $-1°C$/min during the first 24 h and are then transferred into liquid nitrogen tanks for prolonged storage. For thawing, the cryovials are incubated with agitation in a 37°C water bath until almost all the cryovial content has become fluid. The cell suspension is then transferred to a 15-ml polypropylene conical tube, and warm RPMI containing 10% fetal calf or human AB serum is slowly added, at a rate of approximately 1 ml/min for the first 5 min, and then another 5 to 10 ml of medium is rapidly added. Benzonase (Novagen) or other DNases can be added to the thawing medium to avoid excessive clumping. While the use of these products may improve PBMC recovery, it does not affect viability or function. Thawed cells are washed two or three times by centrifugation, counted, and assessed for viability before being used in immunologic assays.

FUNCTIONAL ASSAYS USING CRYOPRESERVED PBMC

Lymphoproliferative Assays

Lymphoproliferative responses measure mainly CD4-dependent immune responses. Severely impaired CD4 responses confer broad immunodeficiency. More subtle CD4 deficits impair defenses against certain pathogens, such as viruses, mycobacteria, yeasts, and certain protozoa, that are highly dependent on cell-mediated immunity.

Several studies compared responder cell frequency and lymphocyte proliferation assays (LPAs), traditionally used to assess CD4 responses, with cryopreserved versus fresh PBMC collected from immunocompromised patients or healthy
FIGURE 1   CMV-specific responder cell frequency (RCF) in cryopreserved versus fresh PBMC from HIV-infected patients (gray triangles) and uninfected controls (solid squares). The diagonal represents the slope of equivalence between fresh- and frozen-cell assays.

hosts. These investigations showed that antigen- and mitogen-induced proliferation of fresh and frozen cells was highly correlated, despite the loss of responders or decrease in stimulation indices in cryopreserved cells compared with fresh cells (Fig. 1). In Fig. 1, which shows a plot correlating CMV-specific responders in fresh and frozen PBMC, the majority of the data points fall below the line of equivalency, illustrating the loss of responders in cryopreserved preparations.

The viability of cryopreserved PBMC significantly affects the results of proliferative assays. The studies of normal hosts and HIV-infected patients illustrated in Fig. 2 show that a viability of $\geq 70\%$ of cryopreserved PBMC is necessary to reproduce the LPA results obtained with fresh cells. In contrast, LPA responses of PBMC with a viability of $<70\%$ increase or decrease with the viability of the cell preparation, introducing a variable that is extraneous to the status of the cell donor. In addition, cell recovery of cryopreserved PBMC and CD4 cell numbers of the donor do not affect the result of lymphoproliferative responses in cryopreserved PBMC in comparison with fresh cells.

Cytotoxic Assays

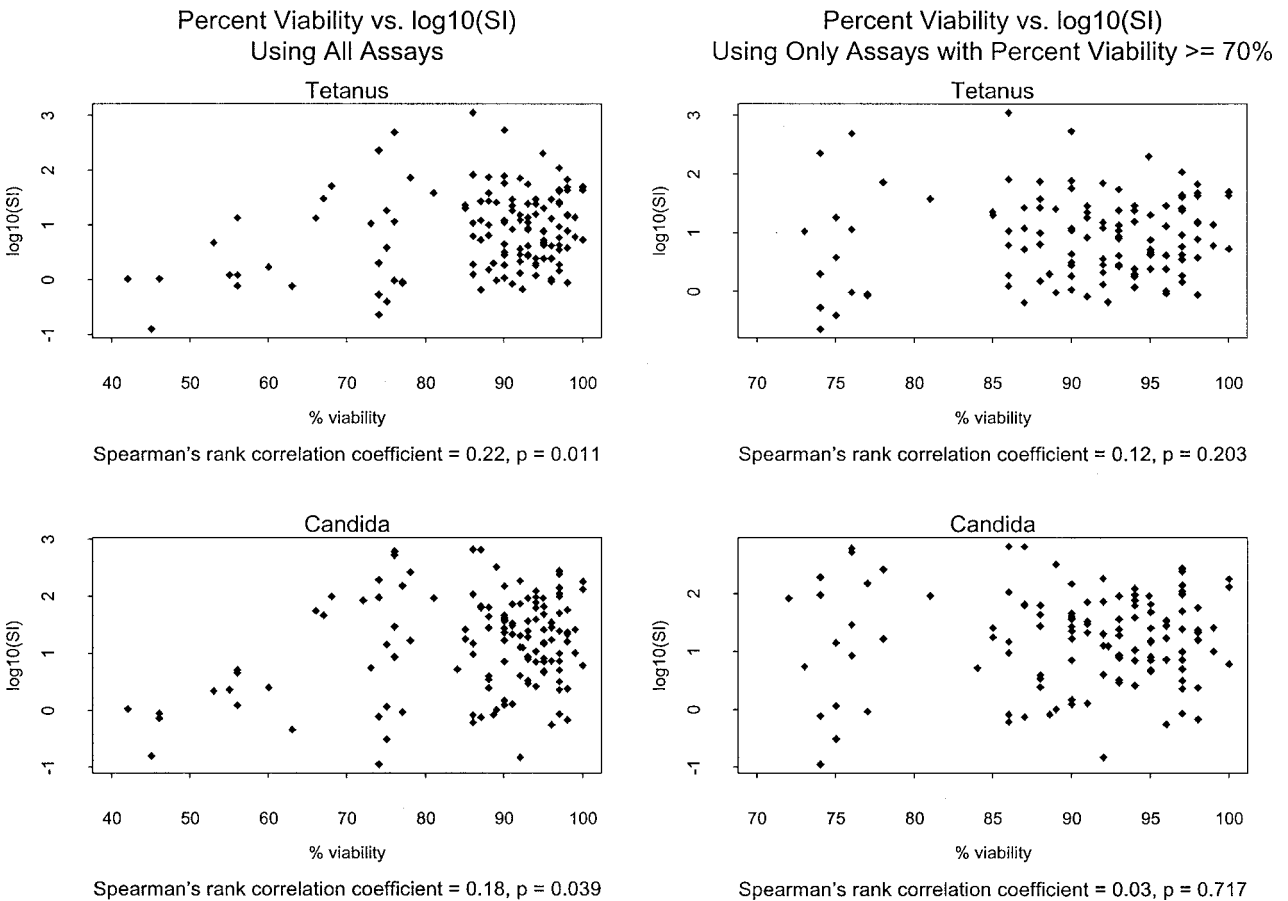
Defenses against viral infections and malignancies rely predominantly on cyotoxic immune responses. Several studies of bone marrow transplant patients have shown that protective


FIGURE 2   Effect of viability on cryopreserved PBMC LPA results. Data were derived from samples from HIV-infected patients. The column on the left shows that when all samples were analyzed, the LPA results significantly increased with greater viability. A breakpoint in the distribution pattern can be observed at a viability of 70%. The column on the right shows that when only samples with a viability of $\geq 70\%$ were analyzed, the LPA results were independent of the PBMC viability. SI, stimulation index.

immunity against CMV coincides with the return of specific CTL. Exogenous generation and transfusion of specific CTL can protect immunocompromised hosts against several viral infections and malignancies.

CTL activity of cryopreserved PBMC is comparable to that in fresh-cell assays. The use of cryopreserved PBMC allows for better scheduling of these complex assays which involve effector and target preparation.

Natural killer (NK) cell activity, in contrast to CTL, is more labile to freezing and thawing. Several investigators, but not all, have found significant losses of NK cell-mediated lysis following cryopreservation. Because of these conflicting data, the use of cryopreserved PBMC for NK cell assays is not recommended, unless carefully controlled experiments validate this procedure in the individual laboratory.

Cytokine-Based Assays

Cell-mediated responses are modulated by cytokines released by mononuclear phagocytes, NK cells, and T lymphocytes. These cytokines, which regulate many cell surface recognition molecules and affect the recruitment of inflammatory cells into an area of infection, are likely to play a pivotal role in the expression of cell-mediated immunity. PBMC produce a range of cytokines in tissue culture following mitogen and antigen stimulation, which have been used to characterize their functional status.

Inducible-cytokine assays measure the amount of cytokine released by stimulated PBMC in the culture supernatant. Studies of HIV-infected patients and uninfected controls show that gamma interferon (IFN-γ) production is essentially the same in fresh and cryopreserved PBMC (Fig. 3). There are conflicting data on interleukin 2 (IL-2) levels in frozen versus fresh cell cultures, and more studies are necessary to clarify this subject (6). However, the rank order correlation between either IFN-γ or IL-2 released by cryopreserved cells compared with fresh cells is highly significant, indicating that inducible-cytokine assays of cryopreserved cells are suitable for comparative analyses of the immune response, such as longitudinal observations.
Single-cell intracellular cytokine assays use flow cytometry to enumerate antigen- or mitogen-stimulated PBMC that synthesize cytokines. The single-cell intracellular cytokine assays provide a sensitive and specific indication of the cell mediated response. Furthermore, the single-cell assay can analyze the phenotype of the cytokine-producing cells, thus further characterizing the immune response. To date, the findings with frozen PBMC in these assays are similar to those for the inducible-cytokine assays; i.e., there is a strong correlation between the results with fresh and cryopreserved PBMC. However, additional studies are needed in order to fully evaluate the utility of frozen cells for these assays.

The enzyme-linked immunospot assay (ELISPOT) is yet another format for measuring cytokine-producing cells. This assay detects captured cytokines diffusing from single antigen- or mitogen-stimulated cells. The assay is extremely sensitive and versatile. It can be performed with fractionated PBMC, such as purified CD8 or CD4 cells. ELISPOT has traditionally measured IFN-γ-producing responder cells but can be adapted to detect other cytokines. The IFN-γ ELISPOT is commonly performed on cryopreserved PBMC because the results are comparable to those obtained with fresh cells and there are considerable cost savings when assays are done in batches.

SURFACE MARKERS ON CRYOPRESERVED PBMC

Immune Phenotyping by Flow Cytometry

Enumeration of PBMC subsets by flow cytometry provides important information on the immune capacity of the host. As such, flow cytometry-based immune phenotyping is a standard procedure in the evaluation of immunodeficiency disorders. The distribution of major surface markers, such as CD3, CD4, CD8, CD19, and CD14, is essentially unchanged by cryopreservation (4, 5). The percentages of T-cell subsets in fresh and cryopreserved PBMC typically show statistically significant correlations, despite the fact that fresh-cell assays are typically performed with whole blood, whereas frozen-cell assays use PBMC separated by Ficoll-Hypaque. The percentage of cells bearing certain immune phenotypic markers (CD4, CD8, etc.) was stable over many decades of frozen PBMC storage in the multicenter AIDS cohort study (MACS) cohort (3). As with the LPA, cell recovery does not influence the distribution of T-cell phenotypes in cryopreserved PBMC. Furthermore, results of phenotyping of cryopreserved PBMC are stable across a wide range of baseline CD4 cell numbers, demonstrating the robustness of this complex procedure.

Cell membrane markers used for advanced immunophenotyping, such as CD21, CD22, CD28, CD38, HLA DR, CD95 (Fig. 4A), and CD45RA and RO, are well preserved during the freezing and thawing processes. In contrast, CD62L, which is commonly used for the identification of naïve T-cell populations, is present in significantly smaller amounts on the surface of cryopreserved PBMC than on fresh PBMC (Fig. 4B). Hence, it is desirable to avoid the use of anti-CD62L monoclonal antibodies for advanced immunophenotyping of cryopreserved PBMC.

T-Cell Receptor Vβ Repertoire

Definition of the T-cell receptor repertoire has become increasingly prevalent in studies of the maturation and senescence of the immune system. These assays can provide valuable information about immune deficiency stages and immune restoration. Flow cytometry- and PCR-based methods are

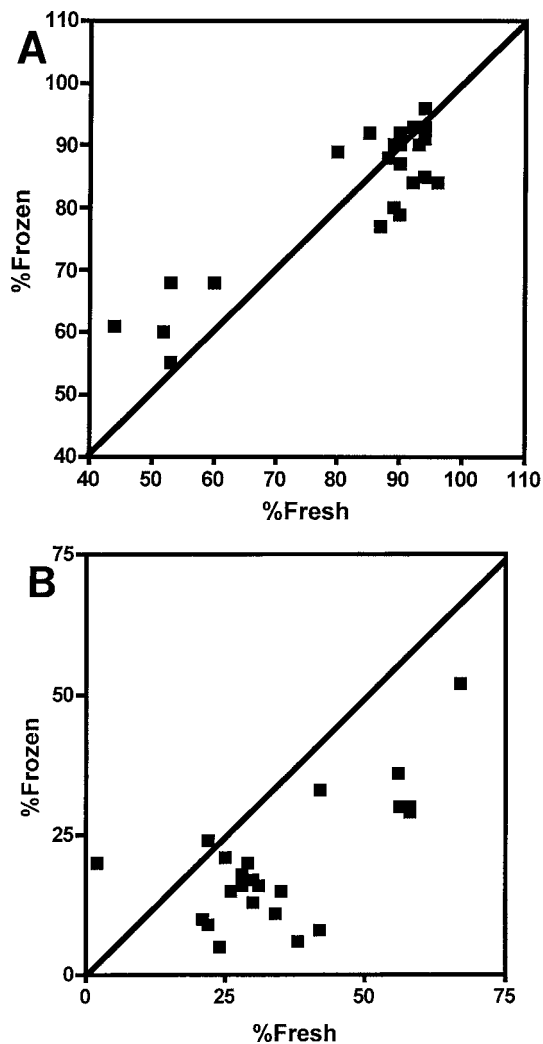
FIGURE 3 CMV-specific IFN-γ in cryopreserved versus fresh PBMC from HIV-infected patients (gray triangles) and uninfected controls (solid squares). The diagonal represents the slope of equivalence between the fresh- and frozen-cell assays.


FIGURE 4 Effect of cryopreservation on flow cytometric immune phenotyping. Data were derived from HIV-infected subjects. Cell membrane markers CD95 (A) and CD62L (B) were used. The diagonal represents the slope of equivalence between the fresh- and frozen-cell assays, which give identical results.

used for T-cell receptor characterization. The two techniques seem to yield similar results when performed with fresh and cryopreserved PBMC.

Anne Sevin (deceased) performed the statistical analysis of the data presented in Fig. 2 and prepared the illustration.

Methods for Detection of Antigen-Specific T Cells by Enzyme-Linked Immunospot Assay (ELISPOT)

BARBARA L. SHACKLETT AND DOUGLAS F. NIXON

28

CD3$^+$ CD8$^+$ T-cell receptor (TCR) $\alpha\beta$ thymus-derived T cells form the major effector cell component of the immune response against a viral infection. Naïve CD8$^+$ T cells encounter antigen, expand, and divide, and effector cells mediate a range of antiviral functions. After the acute viral infection is contained, the number of active effector cells declines but antigen-specific memory CD8$^+$ T cells persist, ready to expand rapidly upon reexposure to antigen. Most CD8$^+$ antigen-specific T cells recognize viral antigen as a peptide presented by a major histocompatibility complex (MHC) class I molecule. The TCR of the antigen-specific CD8$^+$ cell interacts with the MHC class I viral peptide complex on the surface of the antigen-presenting cell.

Antigen-specific CD8$^+$ T cells can be detected by identification of a specific TCR which will interact with a unique MHC class I peptide complex or functionally through effector activities after stimulation with specific antigen. The traditional method for the detection of antigen-specific CD8$^+$ T cells has been the ^{51}Cr release assay. This assay detects the ability of an effector cell population to lyse a target cell population labeled with the gamma emitter ^{51}Cr. Over the past few years, other assays have been developed to study the antigen-specific CD8$^+$ T-cell response. These are generally easier to use and have become standard in the field. The assay most widely utilized is the enzyme-linked immunospot assay (ELISPOT). This assay detects the secretion of cytokine after specific stimulation, usually with a specific peptide or recombinant vaccinia virus with a foreign gene insert. The sensitivity of the assay has been estimated as 50 or fewer antigen-specific T cells per 10^6 lymphocytes, at least 1 log$_{10}$ more sensitive than traditional limiting dilution analysis or bulk ^{51}Cr release assay (20).

The ELISPOT was first described in 1983 as an alternative to plaque-forming assays for the detection of antibody-secreting cells (9). In the initial report, spleen cells from immunized mice were incubated in antigen-coated, 96-well polystyrene plates. After removal of the cells, bound antibodies were detected by an immunoenzyme procedure. In areas of the plate where antibody production had occurred, the substrate was deposited in circular zones (spots), which could then be enumerated with the naked eye (9). It was not long before the ELISPOT was modified for the detection of cytokine-secreting T cells, by use of nitrocellulose membranes and cytokine-specific monoclonal antibodies (MAbs) (8). A survey of the recent literature reveals that ELISPOT is now widely used to detect T-cell responses to autoantigens, tumor antigens, and antigens from a variety of infectious agents. ELISPOT has also become the method of choice for rapid mapping of T-cell epitopes (1, 3).

ELISPOT PROTOCOL

The protocol given below is for the detection and enumeration of gamma interferon (IFN-γ)-secreting T cells from human immunodeficiency virus type 1 (HIV-1)-infected subjects after specific stimulation of peripheral blood mononuclear cells (PBMC) with recombinant vaccinia viruses (rVVs) expressing HIV-1 gene products (16). This assay may be adapted for use with synthetic peptides, including overlapping peptide pools, as described elsewhere (1, 3).

Day 1: Coating of ELISPOT Plates

1. Mix 25 μl of anti-IFN-γ MAb clone 1-DIK (1 mg/ml; Mabtech no. 3420-3) with 5 ml of sodium bicarbonate buffer (pH 9.6) (2.93 g of NaHCO$_3$, 1.59 g of Na$_2$CO$_3$, and 0.2% NaN$_3$ in a volume of 1 liter of H$_2$O, sterile filtered). (Note that some laboratories use standard phosphate-buffered saline [PBS] as a coating buffer.)

2. Add 50 μl of the above primary antibody solution to each well of a sterile MultiScreen 96-well filtration plate (Millipore no. MAHA S4510), ensuring that the bottom of each well is entirely covered; refrigerate at 4°C overnight. ELISPOT plates with hydrophobic polyvinylidene fluoride membranes may also be used; consult manufacturers' recommendations for use of these plates.

Note: coated plates must be left in the refrigerator for a minimum of 5 h or can remain at 4°C for up to 5 days before proceeding to the next step.

Day 2: Addition of Cells and Stimulating Antigen

3. Invert the plate to discard unbound primary antibody and pat down firmly onto paper towels to remove excess liquid from wells. Using a multichannel pipettor, add 200 μl of PBS (Cellgro) to each well. Avoid touching the bottom of wells with pipette tips. Invert the plate to discard liquid, and again pat down firmly onto paper towels. Repeat the above washing step with PBS three more times. (Note: plates may also be washed with a hand-held squirt bottle.)

4. Mix 5 ml of heat-inactivated pooled human serum (Biowhittaker) with 45 ml of RPMI 1640 (Cellgro), and subject to sterile filtration. Add 50 μl of the above blocking

solution to each well and incubate the plate at 37°C under 5% CO_2 for 1 h.

5. While the plate is incubating in blocking solution, prepare cells for addition to the plate. Either fresh or frozen PBMC can be used. Usually 1×10^5 to 2×10^5 cells are required per well, and each condition is assayed in triplicate (for example, an assay in which responses to the HIV antigens Env, Gag, Pol, and Nef are being measured will require 4×3 wells in addition to triplicate background and one positive control well [4 additional wells]; if the optimal 2×10^5 cells are added per well, 3.2×10^6 cells are required). Frozen cells can be thawed, or fresh PBMC can be isolated from whole blood; the cells are washed three times in RPMI 1640 supplemented with 15% fetal calf serum and resuspended in 5% pooled human serum solution (same as blocking solution in step 4) at a concentration of 1×10^5 to 2×10^5 cells per 100 μl.

6. After the 1-h incubation in step 4, add 100 μl of cell suspension to each well. It is not necessary to remove the blocking solution.

7. If using rVV to stimulate cells, add to appropriate wells at a multiplicity of infection of 2. Note: for consistency it is recommended that all rVVs be diluted to the same concentration; a versatile concentration is 2×10^8 rVVs/ml. If using peptide to stimulate cells, add peptide so that the final concentration of the peptide in each well (150 μl total volume) is 10 μg/ml. For a positive control, add phytohemagglutinin (PHA) to the well so that the final concentration of PHA is 10 μg/ml. Incubate the plate at 37°C under 5% CO_2 for 1 h. (If not using vaccinia viruses, incubate overnight at 37°C under 5% CO_2 and then proceed to step 9.)

8. If using vaccinia viruses, add 30 μl of filtered fetal calf serum (Gemini Bioproducts) to each well. Return the plate to the incubator at 37°C under 5% CO_2 and incubate overnight (14 to 20 h).

Day 3: Assay Development

9. Aspirate the contents of each well, being careful not to touch the membrane at the bottom of the well. Add 200 μl of 0.05% Tween solution to each well (250 μl of Tween 20, 500 ml of PBS). Invert the plate to discard washing solution and pat firmly on paper towels to remove excess liquid from wells. Repeat the washing step three more times.

10. Mix 5 μl of biotin-conjugated anti-IFN-γ MAb clone 7-B6-1 (1 mg/ml; Mabtech no. 3420-6) with 5 ml of PBS (Cellgro). Add 50 μl of the above secondary antibody solution to each well and incubate the plate at 37°C under 5% CO_2 for 2 h.

11. Twenty minutes before the end of the 2-h incubation, prepare the avidin-peroxidase complex solution (Vectastain ABC kit, Vector Laboratories Elite PK-6100 Standard). Add 1 drop each of solutions A and B to 5 ml of 0.1% Tween solution (the washing solution used in step 12). This complex must be prepared at least 20 min prior to use.

12. Invert the plate to discard unbound secondary antibody and pat firmly on paper towels to remove excess

liquid from wells. Add 200 μl of 0.1% Tween solution to each well (500 μl of Tween 20, 500 ml of PBS). Discard the wash solution as described above and repeat the washing step three more times.

13. Add 50 μl of this ABC solution (prepared in step 11) to each well and incubate the plate at room temperature on a flat surface for 1 h.

14. Wash the wells four times as in step 12.

15. Add 50 μl of stable diaminobenzidine (DAB) (ResGen/Invitrogen no. 750118) to each well. Incubate at room temperature for 5 min on a flat surface.

16. Invert the plate to discard DAB into sink. Rinse the wells thoroughly with tap water three times. Remove the plastic underdrain, wipe the back of the plate gently with absorbent paper towels, and allow the plate to air dry. Count spots under an inverted microscope or with the aid of an automated reader (AID, Autoimmun Diagnostika, distributed by Cell Technology, Inc., Columbia, Md.).

17. Analyze ELISPOT data by subtracting the average number of spot-forming cells (SFC) in triplicate background wells (stimulated by media alone) from the average number of SFC in test wells. Convert the result to SFC per 10^6 cells by multiplying by 5 (in the case of 2×10^5 cells/well) or 10 (in the case of 1×10^5 cells/well).

METHODS OF ENHANCING ELISPOT SENSITIVITY

In an effort to increase the sensitivity of ELISPOT, several groups have developed modifications of the standard protocol involving the addition of exogenous cytokines, costimulatory antibodies, or antigen-presenting cells. A partial listing of these methods is given in Table 1; for additional details, the references should be consulted.

QUALITY CONTROL AND ASSAY VALIDATION

The ELISPOT is relatively new, and considerable methodological variation exists among laboratories. However, in recent years, there has been an effort to standardize procedures in view of initiating large-scale clinical trials (4, 12, 13, 18, 20).

As a positive control for cytokine release, many laboratories rely on polyclonal stimuli (PHA or staphylococcal enterotoxin B). However, these reagents may give rise to a nearly confluent lawn of spots. Recently, Currier et al. introduced a control peptide pool consisting of 23 peptides derived from influenza virus, cytomegalovirus, and Epstein-Barr virus, corresponding to known CD8 epitopes restricted by a variety of MHC class I alleles (7). This pool, known as CEF (cytomegalovirus–Epstein-Barr virus–flu), is recognized by approximately 85% of the general population and is available through the National Institutes of Health AIDS Research and Reference Reagent Program (http://www.aidsreagent.org).

The quality of ELISPOT results may be affected by cell viability, cell concentration, addition of antigen-presenting cells,

TABLE 1 Methods of enhancing ELISPOT sensitivity

Method	Comments	Reference(s)
Costimulatory antibodies	May increase background	Ott et al. (19)
Monocyte-derived dendritic cells	Mature dendritic cells are more efficient than immature dendritic cells	Larsson et al. (17)
B cells	May increase background	Altfeld et al. (2)
IL-7, IL-15	May increase background	Calarota et al. (5), Chitnis et al. (6), Jennes et al. (14)

TABLE 2 Parameters influencing ELISPOT variability

Parameter	Comments	Reference(s)
Background	Assays with background of >120 SFC/10^6 cells considered invalid	Mwau et al. (18)
Cell no. (PBMC)	Optimal no. is 2×10^5/well	Russell et al. (20)
Cryopreservation	Average recovery, 60%; viability, 90%.	Russell et al. (20)
	Positive responses remain detectable.	Russell et al. (20)
	Magnitude of responses is diminished.	Mwau et al. (18)
	Controlled stepwise freezing is optimal.	Mwau et al. (18)
Detection threshold	50 SFC/10^6 PBMC (0.005%)	Russell et al. (20)
ELISPOT reader	Automated readers superior to manual counting	Herr et al. (11), Janetzki et al. (13)
Incubation time	16–20 h	Russell et al. (20)
Peptide preparations	Dimethyl sulfoxide, <1%.	Mwau et al. (18), Russell et al. (20)
	Optimal length: 15-mers.	Russell et al. (20)
	Effect of concn: 2 μg/ml adequate; 5–10 μg/ml maximal; 20 μg/ml inhibitory.	Russell et al. (20)
	Peptides should be filtered.	Karlsson et al. (15)
Vaccinia viruses	Titer on susceptible cell line. Routinely verify expression of foreign protein by Western blotting.	Larsson et al. (16)

source of stimulating antigen, length of stimulating peptides, dimethyl sulfoxide content of peptide preparations, infectivity of vaccinia virus stocks, operator variability, reader variability, and numerous other factors. These issues are addressed in detail by several recent reports, as shown in Table 2.

INTERPRETING ELISPOT DATA: ESTABLISHING BACKGROUND LEVELS AND IDENTIFYING POSITIVE RESPONSES

Statistical methods for evaluating ELISPOT results and determining the appropriate positive cutoff have varied considerably between laboratories. Although many research laboratories continue to rely on empirical approaches, several recent reviews have addressed the need to standardize ELISPOT data analysis for phase I and II clinical trials. A summary of statistical methods reported in the recent literature is given in Table 3.

RESEARCH AND CLINICAL APPLICATIONS OF THE ELISPOT

Since the first reports describing the T-cell ELISPOT nearly 20 years ago, ELISPOT has been used to detect T-cell responses to autoantigens, tumor antigens, and antigens from a variety of infectious agents including bacteria, viruses, and protozoa. An expanding variety of individual antibodies, matched reagent sets, detection reagents, and complete kits are now manufactured commercially, and new ELISPOT products are continuing to be introduced at a rapid rate. As of this writing, reagent sets and/or kits are commercially available to assess the following molecules: interleukin 1β (IL-1β), IL-2, IL-4, IL-5, IL-8, IL-10, IL-12, IL-13, IL-16, IFN-γ, granulocyte-macrophage colony-stimulating factor, tumor necrosis factor alpha, transforming growth factor β, RANTES/CCL5, MIG/CXCL9, granzyme B, perforin, and sFAS ligand. However, the majority of these assays are currently limited to research settings.

Nevertheless, as ELISPOT technology becomes more accessible, sponsors of phase I and II clinical trials are expected to become increasingly reliant on this sensitive, rapid method to assess T-cell responses. ELISPOT is now widely utilized in research on infectious diseases, autoimmunity, and cancer immunotherapy. As novel vaccines and immunotherapies move into the development pipeline, ELISPOTs will require standardization and validation appropriate to large-scale clinical trials. International efforts

TABLE 3 Methods of analyzing ELISPOT data

Data analysis method	Reference
Empirical approaches	
Positive response: >3× mean of negative control wells and >50 SFC/10^6 PBMC	Addo et al. (1)
Positive response: >2× mean of background wells and >20 SFC/10^6 PBMC	Currier et al. (7)
Positive response: >5 more SFC/well than in negative controls and >2× mean of negative control wells	Ewer et al. (10)
Positive response: >2× average of background wells and >50 SFC/10^6 PBMC	Mwau et al. (18)
Statistical approaches	
Unpaired t test to determine whether SFC are significantly greater in test wells than controls	Herr et al. (11)
Exact binomial test to determine whether SFC are significantly greater in test wells than controls	Russell et al. (20)
Comparison of several statistical methods; a permutation-based criterion using a resampling adjustment for multiple comparisons is recommended	Hudgens et al. (12)

are already under way to standardize ELISPOT methodology for large-scale HIV vaccine trials (12, 18, 20). Other areas currently under development include an ELISPOT-based screen for tuberculosis (10) and ELISPOTs to monitor clinical trials for melanoma therapeutics (4). Standardization and validation of any bioassay is a lengthy process and will require many multicenter studies. As ELISPOT readers continue to improve and statistical methods achieve broader acceptance, the trend towards increasing standardization is likely to accelerate rapidly within the next few years.

Evaluation of the T-Cell Receptor Repertoire

SAVITA PAHWA

29

During the process of differentiation in the thymus, T cells undergo rearrangement of their T-cell receptor (TCR) genes and mature into single positive cells of either the CD4$^+$ or the CD8$^+$ phenotype. Approximately 95% of the peripheral blood T cells bear the αβ TCR, while the remaining bear the γδ TCR. The TCR structure, repertoire generation, and interaction with antigen have been extensively studied (2, 9–11, 16, 41). The αβ TCR is a heterodimer composed of two polypeptide chains, α and β (Fig. 1). In humans, the genes of the α chain are located on chromosome 14 and those of the β chain are on chromosome 7. The function of the TCR is to confer antigen recognition capacity to T cells; CD4 and CD8 T cells recognize antigens that are presented as processed peptides in association with major histocompatibility complex class II and class I molecules, respectively (11). The entire 685-kb β-chain gene locus has been sequenced (42). Twenty-six TCR Vβ families have been described on the basis of sequence homology (2), and some Vβ families are further divided into subfamilies, e.g., Vβ 5, which is divided into 5.1 and 5.2 (also referred to as 5S1 or 5S2, respectively, where "S" stands for "segment"). The simplified structure of the β chain consists of V-D-J-C segments that correspond to variable, diversity, joining, and constant regions, respectively. In the α chain, the D segment is absent. For the β chain, 47 Vβ, 2 Dβ, and 13 Jβ segments have been identified, and for the α chain, 42 Vα and 61 Jα segments are known. The V-D-J recombination events in the β chain and the V-J recombination events of the α chain together form the basis of genetic diversity of the TCR, generating a repertoire size of 10^{15} different TCR αβ dimers (24).

For study of the TCR repertoire, analysis of the Vβ chain affords the most practical approach. The variable regions of α and β chains contain relatively stable and hypervariable regions. The hypervariable regions of α and β chains together form three complimentarity-determining regions, referred to as CDR1, CDR2, and CDR3, of which CDR3 is the most hypervariable. The fine antigen specificity of the TCR is dependent primarily on the CDR3 region of the β chain, which lies close to the antigenic peptide (8). The CDR3 region of the β chain is formed by the D segment and parts of the V and J segments (see Fig. 2). It is sandwiched between the conserved amino acid motifs -Y-(L/F)-C-A-S- of the V segment at the 5' end and -F-G-X-G- of the J segment at the 3' end (37). The V-D and D-J junctions, designated N, contain one to six nucleotides (9), resulting in CDR3 segments of various lengths ranging between 5 and 15 amino acid residues.

TCR Vβ REPERTOIRE IN HEALTH AND DISEASE

A complete TCR repertoire is developed by 24 weeks of gestation, and the CDR3 segments in both CD4 and CD8 T-cell subsets are fully mature at the time of birth (37, 43). Perturbations in the TCR repertoire may occur due to the loss, underexpression, or expansion of one or more T-cell clones, in particular Vβ families. Alterations in the peripheral T-cell repertoire have been previously reported for healthy individuals (21, 35, 40, 47) and individuals in diseased states (6, 12, 27, 39, 48, 49, 52). The perturbations seen in healthy subjects are few and relatively stable and may arise due to chronic stimulation with antigens of known or unknown origin (47), following vaccination (23) and with aging (44). Tumor-infiltrating lymphocytes have been shown to have a distinctive TCR Vβ repertoire profile (45). In pathologic conditions, the perturbations may be extensive, e.g., in human immunodeficiency virus (HIV) infection (7, 17), involving both CD4 and CD8 T cells. Clonal expansions, particularly involving CD8 T cells, have been described for the acute and chronic phases of HIV infection in adults and children (17, 27, 49). Clones responsive to antigens of interest (25) can be tracked, and somatic mutations have been observed in sequenced PCR products of appropriate Vβ families (3). Following therapy, a perturbed Vβ profile can normalize, as in hairy cell leukemia (28).

METHODS FOR ANALYZING THE TCR Vβ REPERTOIRE

General Considerations

The TCR Vβ repertoire can be analyzed by different methods, including PCR (18, 30), heteroduplex PCR analysis (50, 51, 53), and flow cytometry (26). Anchor PCR analysis (30) amplifies the entire gene segment of the known and unknown families of the TCR repertoire but fails to resolve fine specificity of the CDR3 segment or the Vβ gene usage. In the heteroduplex assay, the amplified cDNA forms a duplex, and the output may compromise the fine specificity of each Vβ family in comparison to that determined by the CDR3 length analysis. TCR repertoire analysis by flow cytometry utilizes monoclonal antibodies (MAbs) against the TCR β chains and has the advantage of coupling the identification of TCR Vβ families with phenotypic characterization of T cells. However, the
FIGURE 1 Organization of the αβ TCR showing the constant, transmembrane, and variable regions of the α and β chains.

method is limited by the availability of MAbs and its inability to determine diversity and restrictions in TCR gene usage, as is feasible by PCR analysis.

For analysis of TCR CDR3 lengths by PCR, the number of PCRs or probes needed to detect all Vβ genes can be cumbersome, especially when multiple samples need to be analyzed. Several groups have applied the multiplex PCR method for the analysis of TCR genes (1, 15, 18, 33, 39). In this chapter, we will update methods (4) for assessment of the TCR Vβ repertoire in peripheral blood by CDR3 length spectratyping by multiplex PCR and with MAbs by flow cytometry. Other methods, viz., Southern blotting, semi-quantitative PCR, anchor PCR, and heteroduplex analysis, are briefly discussed below (for a summary, see Table 4).

TCR Vβ CDR3 Length Analysis by PCR

Principle
The CDR3 segments within each Vβ family vary from 5 to 15 amino acids in length, and this variation can be examined by resolving the PCR products on the basis of their size. Of the

26 Vβ families, Vβ 10 and Vβ 19 are pseudogenes (42, 54) and are excluded from analysis. The PCR is performed with Vβ-specific forward primers and a ^{32}P-labeled or fluorescently labeled Cβ-R reverse primer. In the multiplex PCR, for each reaction, two or more Vβ primers are used in combination on the basis of their product sizes. Figure 2 shows examples of the β-chain regions selected for use in the design of primers for the CDR3 length analysis. CDR3 length analysis of the TCR Vβ repertoire can be performed with peripheral blood T cells as well as T cells isolated from other sites. It is advisable to examine purified populations of CD4 and CD8 T-cell subsets because the perturbations can be strikingly different in the two subsets. Analyses can also be performed with purified T-cell subpopulations within the CD4 and CD8 T-cell subsets, e.g., naive and memory T-cell subsets.

Steps for Performing TCR Vβ CDR3 Length Analysis
The major steps in the CDR3 length analysis for the TCR Vβ repertoire include isolation of T-cell populations of interest, RNA extraction, cDNA synthesis, and the multiplex PCR.

Sample Collection, Storage, and Processing to Isolate T-Cell Subsets from Peripheral Venous Blood
Whole blood is collected by venipuncture into a tube containing an anticoagulant such as heparin, acid-citrate-dextrose, or EDTA. A blood volume of 5 to 8 ml is required, based upon the age of the subject and CD4 and CD8 T-cell counts; usually less blood is required from younger children and infants because of higher lymphocyte counts. The blood can be processed up to 24 h after the draw if left at room temperature. Anticoagulated blood samples can be shipped at room temperature for overnight delivery to the laboratory performing this assay. Peripheral blood mononuclear cells (PBMCs) are isolated from the blood by standard methods. T-cell subsets of interest are purified either by fluorescence activated cell sorting or by immunomagnetic separation. T-cell subsets may be immunomagnetically separated from PBMCs by using commercially available magnetizable polystyrene bead reagents (e.g., from Miltenyi Biotec, Dynal Corp. or StemCell Technologies) coated with specific MAbs as described elsewhere (31). The aim should be to obtain highly purified subpopulations (>98% purity); purity of the isolated cells should be checked by flow cytometry. We have used 40 μl of Dynal beads for positive selection of an estimated 10^6 CD4 or CD8 T cells in PBMC samples. For the PCR assay, a concentration of 10^6 cells of each T-cell subset is optimal. Cryopreserved PBMCs may be used if cells are recovered with ≥95% viability.
FIGURE 2 Schematic representation of the β-chain transcript of the TCR. For CDR3 length analysis PCR, a nested reverse Cβ-R primer is used in combination with multiplexed forward Vβ primers. The locations of one set of Vβ primers (set A), primer Cβ-R for PCR and reverse primer Cβ-14 for reverse transcription, are indicated (single-headed arrows). -Y-(L/F)-C-A-S- and -F-G-X-G-T-, the amino acid residues that flank the CDR3 region of the β chain of the TCR. The V, CDR3, J, and C regions are also indicated (double-headed arrows).

Vortex mixer

UV range spectrophotometer

2-ml screw-cap microtubes with conical bottom (Sarstedt, Newton, N.C.)

TRI reagent (Sigma, St. Louis, Mo.)

Chloroform, molecular biology grade (Sigma)

Isopropanol, molecular biology grade (Sigma)

Glycogen (Glycoblue; Ambion, Austin, Tex.)

Ethanol, molecular biology grade (Sigma)

Molecular-biology-grade water (Ambion)

75% ethanol (75 ml of ethanol plus 25 ml of molecular-biology-grade water)

Procedure. Lyse the cells by addition of TRI reagent (200 µl for ≤10⁶ cells) while the cells are attached to beads and vortex at full speed for 20 s. The lysate can be stored at −80°C or processed immediately for RNA extraction. Thaw the cell lysate if frozen previously, and bring it to room temperature and vortex. To the cell lysate in TRI reagent, add chloroform (0.2 ml of chloroform/ml of TRI reagent). After the cell lysate is mixed vigorously with chloroform for 20 s, allow the mixture to stand for 10 min at room temperature and centrifuge at high speed (12,000 × g) for 15 min. The mixture separates into three phases. Transfer the top aqueous phase into a separate Eppendorf tube without disturbing the interphase. The interphase can be discarded or used to isolate DNA and protein for other use. Add glycogen at a concentration of 75 µg/ml of the aqueous phase and mix by gentle vortexing to enhance the precipitation of RNA. Glycogen is particularly useful when dealing with low (<10⁶) cell numbers. Add an equal volume of chilled isopropanol to the aqueous phase, and leave the tube at −20°C overnight for precipitating RNA. On the next day, centrifuge at high speed (12,000 × g or 14,000 rpm) for 15 min to pellet the RNA precipitate, and discard the supernatant. In the same manner, wash the RNA twice with 500 µl of 75% ethanol. Dissolve the RNA pellet in molecular-biology-grade water (Ambion), using ~10 µl/≤4 × 10⁶ starting cells. Determine the optical density of the RNA solution in a spectrophotometer at wavelengths of 260 and 280 nm (at 260 nm, 1 optical density unit = 37 µg of RNA per ml). The ratio A_{260}/A_{280} should be ≥1.7. The dissolved RNA can be stored at −80°C until used. Repeated freezing and thawing of RNA should not be done.

Newer commercial kits (e.g., RNeasy, Qiagen) have greatly simplified the process for RNA extraction and do not require phenol-chloroform extraction.

Reverse Transcription for cDNA Synthesis

The reverse transcriptase (RT) enzyme uses RNA-dependent DNA polymerase activity to synthesize cDNA from an RNA template. The cDNA may be synthesized with oligo(dT) or TCR-specific C-region (Cβ-14) primers. The following protocol uses a constant-region primer (Cβ-14) that specifically reverse transcribes the TCR transcripts from total cellular RNA. Typically, murine leukemia virus (MuLV) RT is used in a 60-µl cDNA synthesis reaction volume for 0.5 µg of RNA. For smaller amounts of RNA (<0.5 µg), the MuLV RT reaction volume is scaled down to 30 µl or the Omniscript RT kit (Quiagen, Valencia, Calif.) may be used

instead, as described below. Up to 100 RNA samples can be processed at a time by one individual.

Reagents for MuLV RT.
Test RNA

MuLV RT enzyme (Gibco BRL, Rockville, Md.)

5× buffer (supplied with the enzyme)

0.1 M dithiothreitol (DTT) solution, supplied with the enzyme

DEPC (diethyl pyrocarbonate)-treated molecular-biology-grade water (Ambion)

Cβ-14 primer for reverse transcription

RNasin (PE Biosystems, Foster City, Calif.)

Deoxynucleoside triphosphates (dNTPs) (Gene Amp dNTP set containing dATP, dCTP, dGTP, and dTTP [PE Biosystems])

Reagents for Omniscript RT.
Omniscript RT kit (Quiagen), which contains the reagents 10× buffer, dNTP mix, water, and Omniscript RT

Additional reagents needed: RNasin and primer Cβ-14, as desribed above

Procedure for reverse transcription using MuLV RT.
1. Prepare a 10 mM dNTP mix with equal volumes (10 mM each) of dATP, dGTP, dCTP, and dTTP (Gene Amp dNTPs). The dNTP mix is prepared in bulk and stored at −20°C in aliquots.
2. In a 200-µl PCR amplification tube, add test RNA in a 10-µl volume.
3. Heat the RNA to 65°C for 10 min and then place it immediately on ice to avoid secondary structure formation.
4. During these 10 min, prepare the following 50-µl mix for each RNA sample in an Eppendorf tube and place on ice:

5× first-strand buffer	12.0 µl
10 mM dNTP mixture	6.0 µl
0.1 M DTT	12.0 µl
Primer Cβ-14 (5 pmol/µl)	2.0 µl
RNasin (20 U/µl)	3.0 µl
MuLV RT (200 U/µl)	1.0 µl
DEPC-treated water	14.0 µl

5. Add the mixture described above to the tube containing RNA on ice to give a total volume of 60 µl.
6. Place the tube in a thermocycler; reverse transcription for cDNA synthesis is performed at 42°C for 1 h followed by 95°C for 5 min followed by 4°C for 5 min.
7. The synthesized cDNA can be stored at −20°C for several months before PCR amplification. Do not repeatedly freeze and thaw the cDNA.

Procedure for reverse transcription using the Omniscript RT kit. This method is useful for RNA quantities of <0.5 µg. Follow the steps described above as for the MuLV RT procedure but use 4 µl of Cβ-14 and mix the other reagents in the volumes specified by the manufacturer to give a final reaction volume of 40 µl instead of 60 µl. The temperature conditions for cDNA synthesis are the same as those for MuLV RT.

Multiplex PCR for CDR3 Length Analysis

The multiplex PCR may be performed with fluorescently or radioactively labeled primers. In the radioactive method, the PCR products are resolved on a sequencing polyacrylamide gel

and the spectratype is analyzed with a phosphorimager. In the PCR with fluorescent primers, the products are resolved on an automated DNA sequencer that directly computes the size and area of the peaks representing the CDR3 segments. The two labeling methods give comparable results (33), but the fluorescent approach is preferred because it is less labor-intensive. Variations in the fluorescent PCR have been developed to further reduce the complexity. Both approaches are described here. The basic steps are the same for the two methods and include labeling of the Cβ primer (with P32 or fluorescent dyes), preparation of the multiplex Vβ primer sets, preparation of the master mix, and PCR of the cDNA. A simplified flow sheet for these protocols is shown in Fig. 3.

Radioactive Multiplex PCR Steps

Steps in the radioactive PCR consist of labeling of the Cβ-R primer, performing of the PCR, and resolution of the PCR products on a sequencing gel.

Equipment and reagents.

Aluminum-backed sequencing gel equipment with each well having at least a 10-μl loading capacity and wedged by spacers (0.2 to 0.4 mm)

Push-column beta-shield device (Stratagene, La Jolla, Calif.) with push columns (Stratagene), for purification of labeled probe

Thermocycler

Gel dryer

0.2-ml PCR tubes

Water baths (37 and 65°C)

T4 polynucleotide kinase (T4PNK) (Gibco)

5× kinase forward reaction buffer (supplied with the enzyme)

Molecular-biology-grade water (Ambion)

[γ-^{32}P]ATP (10 mCi/ml; NEN, Boston, Mass.)

1× STE buffer (100 mM NaCl, 20 mM Tris [pH 7.5], 10 mM EDTA)

AmpliTaq Gold polymerase enzyme, stored at −20°C (PE Biosystems)

AmpliTaq Gold buffer (supplied with the enzyme)

25 mM MgCl$_2$ (supplied with the enzyme)

TCR Vβ primers and unlabeled Cβ-R primers (Table 1) obtained in lyophilized form from either a commercial source or a core facility

^{32}P-labeled Cβ-R primer (described below)

4× gel loading dye (0.05 g of NaOH, 9.5 ml of formamide, 5 mg of bromophenol blue, and 5 mg of xylene cyanol, 10-ml final volume with molecular-biology-grade water and stored at 4°C)

Hyperfilm-MP (Amersham, Piscataway, N.J.)

Labeling of primer Cβ-R. Primer Cβ-R is labeled in a forward reaction using [γ-^{32}P]ATP and T4PNK. The steps are outlined below.

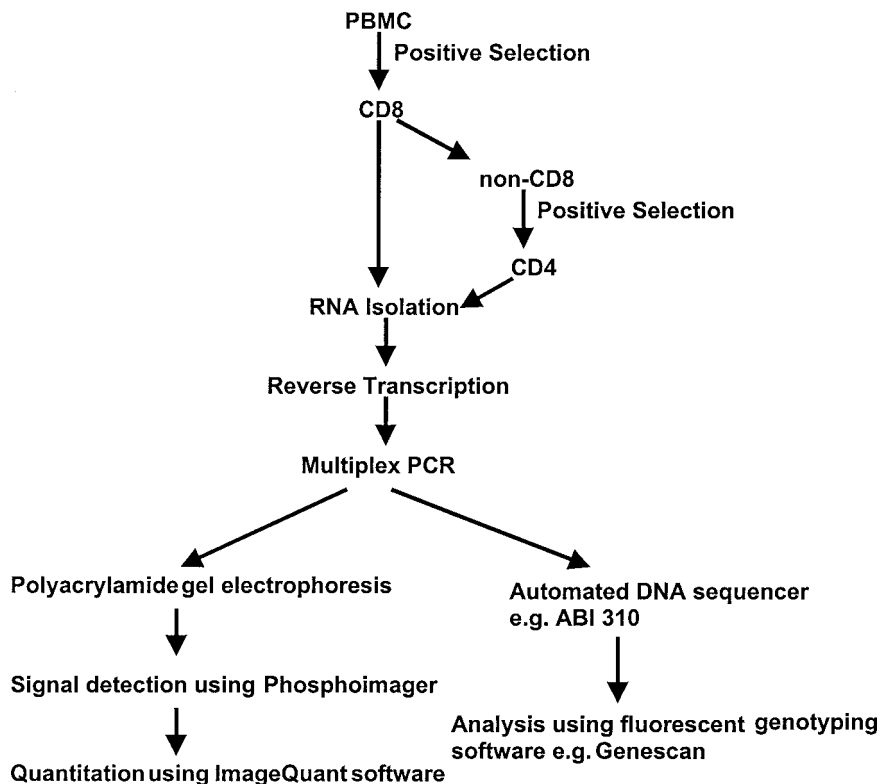
1. Prepare stock solutions of the unlabeled Cβ primer by reconstitution in molecular-biology-grade water to a concentration of 100 pmol/μl and store at −20°C until use.


FIGURE 3 Flow chart indicating various steps for the CDR3 length analysis of CD4 and CD8 T cells by the radioactive and fluorescent multiplex PCR methods.

2. Mix the following reagents in an Eppendorf tube and spin for a few seconds:

Cβ-R (100 pmol /μl) . . . . 1.0 μl
5× T4 kinase buffer . . . . 4.0 μl
[γ-^{32}P]ATP (10 mCi/ml) . . . . 4.0 μl
Water . . . . 10.0 μl
T4PNK . . . . 1.0 μl
Total volume . . . . 20.0 μl

3. Incubate the above mixture at 37°C (in a water bath) for 10 min and then incubate for another 10 min at 65°C (in a water bath). Stop the reaction with 50 μl of 1× STE buffer, and purify the labeled primer by passing it through a push column according to the manufacturer's instructions. This step yields ~0.7 pmol of labeled Cβ-R per μl.

Preparation of Vβ primer and Cβ-R primer working sets. A list of the primers used for the PCR is given in Table 1. In the multiplex PCR, one to three primers are mixed in sets A to L, as follows: A (Vβ 1, Vβ 18, Vβ 23), B (Vβ 2, Vβ 4, Vβ 8), C (Vβ 3c, Vβ 13.1), D (Vβ 5.2, Vβ 5.1), E (Vβ 6, Vβ 20), F (Vβ 7, Vβ 22), G (Vβ 9, Vβ 16), H (Vβ 11, Vβ 12), I (Vβ 15, Vβ 13.2), J (Vβ 14, Vβ 17), K (Vβ 24), and L (Vβ 21). The final concentration of each primer is 2.5 pmol/μl. Stock solutions of the lyophilized primers (Vβ and Cβ-R) are prepared by reconstituting each primer in water to a concentration of 100 pmol/μl and are stored as 100-μl aliquots at −20°C until use. To prepare working solutions for the three-primer mixes (sets A and B), prepare 7.5 pmol of each primer per μl by adding 46.25 μl of molecular-biology-grade water to 3.75 μl of the stock solution. For the remaining Vβ primers

and Cβ primer, prepare 5 pmol of each primer per μl by adding 47.5 μl of molecular-biology-grade water to 2.5 μl of the stock solution of the Vβ primer. For multiplexing primer sets (A to J), the working solutions of relevant primers are mixed in equal volumes. For K (Vβ 24) and L (Vβ 21), the 5-pmol/μl solution is used. The prepared multiplex sets may be stored at −20°C in 100-μl aliquots. Prepare the Cβ-R working set from 100-pmol/μl stock solution at 5 pmol/μl by adding 47.5 μl of molecular-biology-grade water to 2.5 μl of the stock solution of the Cβ primer, and store it at −20°C in 100-μl aliquots.

Preparation of the master mixture. To avoid handling of small volumes, prepare sufficient master mixture for 14 tubes before use. The master mixture is prepared for a 12.5-μl PCR mixture. In a 2-ml Eppendorf tube, mix the following reagents:

AmpliTaq Gold buffer . . . . 17.5 μl
MgCl$_2$ (25 mM) . . . . 14.0 μl
dNTPs (10 mM mixture) . . . . 14.0 μl
Cβ-R (0.7 pmol/μl, labeled) . . . . 8.4 μl
Cβ-R (5 pmol/μl, unlabeled) . . . . 5.6 μl
Water . . . . 93.63 μl
cDNA . . . . 14.0 μl
AmpliTaq Gold polymerase . . . . 1.0 μl
Total volume . . . . 168.13 μl

Mix well by gentle vortexing, and place the mixture on ice.

Add 11.5 μl of the master mixture to each of the tubes A through L containing 1 μl of Vβ mix. This gives a final PCR volume of 12.5 μl.

[a] The CDR3 region encompasses residues 95 to 106. Location indicates the nucleotide distance of the 5' end of the primer from codon 95.

PCR amplification.

1. Place the tubes containing the Vβ primer sets and the master mixture in the thermocycler.

2. Heat at 95°C for 12 min for activation of AmpliTaq Gold.

3. Set for 35 cycles for the PCR as specified: 94°C for 30 s for denaturation, 55°C for 30 s for annealing, and 72°C for 1 min for extension.

4. Follow by heating at 72°C for 10 min for final extension.

5. Maintain at 4°C until the next step.

Polyacrylamide gel electrophoresis: running the gel.

1. Mix 6 μl of the PCR product from each tube with 2 μl of gel loading dye and run the mixture in 12 separate lanes corresponding to sets A to L on a 6% acrylamide gel using 1× TBE (Tris-borate-EDTA) buffer. The procedure for running gels described in *Current Protocols in Immunology* (36) can be followed. Continue the run until the second dye (xylene cyanol) front reaches approximately 1 in. from the end.

2. Dry the gel in the gel dryer at 80°C for 45 min to 1 h. Check with a Geiger counter to ensure the presence of signals. Place the gel and film in a cassette at −70°C overnight. Develop the film the next day or after a longer time if the signal intensity is weak. Carefully mark and cut the area of interest and reexpose the gel to the phosphorimager for quantitation.

3. In the phosphorimager, using ImageQuant software or software with similar capabilities, analyze the intensity of signals generated by bands in each Vβ family by marking them with a rectangle that includes all the bands in that family (Fig. 4). If the PCR products lie close to each other, e.g., Vβ 11 and Vβ 12, be careful not to include bands from the adjacent family. The readout is a spectratype showing the CDR3 bands as peaks in each Vβ family.

Fluorescent Multiplex PCR Steps

Equipment and reagents.

Automated DNA sequencer such as the ABI 310 genetic analyzer or other equipment with similar capabilities

AmpliTaq Gold polymerase

AmpliTaq Gold buffer (10×)

10 mM dNTP mixture (see above)

25 mM MgCl₂

cDNA

DEPC-treated or molecular-biology-grade water

Vβ upstream primer sets (prepared as explained for radioactive PCR)

Fluorescently tagged Cβ-R primer (5.0 pmol/μl) (PE Biosystems), tagged to 6-carboxyfluorescein (6-FAM) (blue), tetrachloro 6-carboxyfluorescein (TET) (green), and hexachloro 6-carboxyfluorescein (HEX) (yellow) dyes and stored in dark tubes to protect the contents from light

POP4 polymer (performance-optimized polymer 4) and 10× buffer (PE Biosystems)

Deionized molecular-biology-grade formamide (Sigma)

Make 1-ml aliquots and store at −20°C. Standard molecular size markers (35 to 350 bp) coupled to a red fluorescent dye (6-carboxytetramethyl-rhodamine [TAMRA]; Genescan 350 Tamra; PE Biosystems) are also used. It is important to avoid working in excessive light and to not expose any of the fluorescent products to bright light for long periods.

Preparation of master mixture. Prepare sufficient quantity for 14 tubes. In a 2-ml Eppendorf tube, mix the following reagents:

AmpliTaq Gold buffer	17.5 μl
2.5 mM dNTP mix	14.0 μl
25 mM MgCl₂	14.0 μl
cDNA	14.0 μl
AmpliTaq Gold polymerase	1.0 μl
DEPC-treated water	93.7 μl
Total volume	154.2 μl
FIGURE 4 CDR3 length analysis of the Vβ chain of TCR showing radiolabeled PCR products resolved by polyacrylamide gel electrophoresis. The figure shows an example of dominance of Vβ 7 from CD8 T cells of a healthy subject. The Vβ7 family (rectangle) is shown as an example of the step for further analysis with ImageQuant software.

Preparation of Vβ primer and Cβ-R primer working sets.

1. Label a set of 12 PCR tubes A through L. Add 1 μl of each Vβ primer mix to the tubes.

2. Vortex the master mixture gently, and aliquot 51.4 μl of the master mixture into each of three Eppendorf tubes labeled "blue," "green," and "yellow" and kept on ice.

3. Add 7 μl each of primer Cβ-R (5.0 pmol/μl) labeled with the blue, green, or yellow dye to the three tubes above corresponding to each dye color. Gently vortex the mixture after adding the fluorescent primers.

4. Add 11.5 μl of the master mixture plus fluorescently labeled Cβ-R from the blue, green, and yellow tubes to tubes A to L containing Vβ primers as follows: blue to tubes A, D, G, and J; green to tubes B, E, H, and K; and yellow to tubes C, F, I, and L. Spin the tubes briefly, or flick firmly if strips are used.

PCR amplification.

1. Perform the PCR under the conditions described above for the radioactive method. Maintain the tubes at 4°C and keep them protected from light until the next step.

2. Prepare a set of four sterile Eppendorf tubes labeled 1 to 4 and add 7 μl of water to each tube. Mix 1 μl of PCR product from the 12 tubes labeled A to L with the tubes labeled 1 to 4 as follows: tube A, B, and C products, tube 1; tube D, E, and F products, tube 2; tube G, H, and I products, tube 3; and tube J, K, and L products, tube 4. This step achieves 1:10 dilution of each PCR product.

3. Prepare another set of four tubes labeled 1 to 4, each containing 0.5 μl of Genescan 350 Tamra standard and 12 μl of deionized formamide. Add 1 μl of the diluted PCR product from tubes 1 to 4 to the corresponding tubes 1 to 4. Denature the contents of the tubes at 95°C for 5 min, and immediately place the tubes on an ice-water bath for at least 5 min.

Running the sample on a genetic analyzer. Training (provided by the manufacturer) is required to operate the ABI 310 genetic analyzer equipment. Prepare the instrument by using a capillary (47 cm by 50 μm; marked green). Filter "c" is used for the 6-FAM, TET, HEX, and TAMRA combination. Launch the ABI 310 collection software, and prepare the sample sheet by entering the appropriate information. In the injection list, set the instrument for a 24-min run and a 5-s injection time for each sample. Load and run the samples. The raw data are collected by the ABI Prism 310 collection software and simultaneously analyzed by the Genescan software. After the run is complete, open the run folder through the Genescan software, define new standards, and analyze the data in the "analysis control" window. Raw data are then visualized in the "results control" window.

Variation of the Fluorescent Multiplex PCR Using Labeled Vβ Primers

Recently, a variation of the fluorescent multiplex method for TCR Vβ CDR3 length spectratyping has been described (14, 39), in which the Vβ primers instead of Cβ-R are labeled with fluorescent probes. This method simplifies the earlier method by reducing the number of PCR tubes from 12 to 7, reduces assay time, and improves the resolution. The Vβ primers are divided into three groups and labeled with the fluorescent dyes 6-FAM, TET, and HEX, as shown in Table 2. The fluorescently tagged Vβ primers are then mixed in seven sets, in tubes A to G as follows: A (Vβ 1, 2, 5.1, 5.2), B (Vβ 6, 7, 8, 9, 16), C (Vβ 12, 13.1, 13.2), D (Vβ 11, 20, 15), E (Vβ 3, 21, 17, 24), F (Vβ 14, 18, 23), and G (Vβ 4, 22). Each multiplex PCR mixture contains 1 μl of cDNA, 1 μl of each TCR Vβ primer, 2 μM Cβ-R, 1 mM (each) dNTPs, 2 mM $MgCl_2$, and 1 U of AmpliTaq Gold DNA polymerase in a final reaction volume of 12.5 μl. For the Vβ 2, 7,

TABLE 2 Primers used for TCR Vβ analysis with fluorescently labeled Vβ primers[a]

Dye	TCR Vβ family	Sequence	Amplicon size (bp)	Tube

[a] In this method, the Vβ primers were labeled with appropriate fluorescent tags as described in the text. For multiplexing primers, see materials and methods.

13.1, and 17 primers, it was determined that the labeled primers had to be mixed with unlabeled primers at a ratio of 3:1 in order to prevent disproportionately high signal intensity. The PCR conditions are 94°C for 12 min for enzyme activation followed by 35 cycles of 94°C for 20 s, 58°C for 20 s, and 72°C for 30 s and finally 1 cycle of 72°C for 10 min. The PCRs can be carried out on a PTC-225 Peltier thermal cycler (M J Research, San Franciso, Calif.).

Quality Control

Controls for radioactive as well as fluorescent PCRs can be established by storing adequate amounts of cDNA that can be repeatedly used. For quality assurance purposes, sufficient master mixture should be made for a given batch of samples and should be tested with the control cDNA.

Cautionary Notes

- RNA needs to be handled with care to prevent degradation. RT is sensitive to mechanical damage; therefore, vortexing should be avoided. The enzyme is temperature sensitive, so it should not be taken from the freezer until it is ready to use and should be kept on ice when not at -20°C. Do not leave on ice for >5 min.
- For longer storage of RNA, Superasin (Ambion) at 1 U/μl may be used to dissolve the RNA. If the cells for RNA extraction need to be stored for more than a year, then the use of "RNA later" from Ambion may be considered. The reagent is reported to be capable of extracting intact RNA even if the cells are left at 25°C for a week or -80°C for archival storage.
- The dNTPs should not be exposed to bright light or room temperature, as these result in hydrolysis of the dNTPs. Avoid repeated freezing and thawing of dNTPs, since it has been shown that after three to five freeze-thaw cycles the PCR can fail (22).
- The fluorescent Cβ primers or PCR products should not be exposed to bright light for longer periods, as that leads to quenching.
- Inadequate cell numbers may result in erroneous data (38). In our hands, the lowest cell number (purified CD4 or CD8 T cells) which can give reliable results is 0.5×10^6.
- If a large number of assays need to be performed, it is advisable to make the master mixture (containing PCR buffer, MgCl$_2$, dNTP mix, water, and Vβ primer) in bulk and freeze it at -20°C until it is used. It is convenient to use 50% of the recommended water in this mixture and use the remaining 50% for making the cDNA mixture to prevent handling of small volumes while preparing the cDNA mixture. For fluorescent PCRs, the fluorescent Cβ primers may also be added to the mixture as appropriate. The cDNA, the remaining 50% of the water, the Cβ primer (for radioactive assay), and the *Taq* polymerase must be mixed fresh on the day the PCR is performed. The PCR products should not be discarded until the data have been examined. In the fluorescent PCR, if the signal intensities are below detection limits, then the same PCR products can be rediluted to achieve a 1:4 dilution instead of a 1:10 dilution. The diluted sample should then be mixed with the deionized formamide and size standards as described above and the sample should be run with an injection time of 10 s instead of 5 s.
- In circumstances in which high background levels are encountered, use of a runoff PCR can be considered (7).

Data Interpretation and Analysis

Examples of the TCR repertoire spectratype obtained on a sequencing gel or the fluorescent equipment are shown in Fig. 4 and 5, respectively. Bands in the sequencing gel are converted into peaks by the ImageQuant software and give information similar to that of the fluorescent PCR but without the CDR3 sizes that are computed by the automated DNA sequencer. Each band or peak represents one or a set of T-cell clones bearing the same CDR3 length. In most instances, each peak represents a mixture of clones with different amino acid compositions. Within a TCR Vβ family, the difference between each successive band or peak is three nucleotides, i.e., one amino acid (40). Analysis of the TCR Vβ repertoire has not been standardized for the clinical laboratory. An unperturbed polyclonal repertoire for any Vβ family is represented by a set of peaks or bands distributed in a Gaussian pattern, with the highest-intensity CDR3 segment lying in the center. A "normal" profile of an unperturbed repertoire for CD4 and CD8 T cells can be generated with umbilical cord blood T cells (Fig. 5A) (17) and can be used as the standard against which the test sample is evaluated. Deviation from this Gaussian pattern is termed perturbation, skewing, or restrictions and results from either overrepresentation, underrepresentation, or absence of one or more CDR3 segments (38).

Counting the number of "peaks" that represent CDR3 lengths in each family is a simple approach for examination of each Vβ family. The peaks are distinct and are easy to identify (Fig. 5). Each CDR3 segment is represented by a particular size, which varies only slightly between individuals. Thus, all the "peaks" in the Vβ 1 family lie in the 186- to 210-bp range. In order to count the peaks in the fluorescent PCR readout, it is important to adjust the signal intensity (y-axis scale) to that of the highest peak in that Vβ family. For example, in Fig. 5A, the families Vβ 1, 2, 3, 5.2, 5.1, 6, 7, 9, 12, 13.2, 17, 24, and 21 are appropriately scaled, while for the remaining, i.e., Vβ 18, 23, 4, 8, 13.1, 20, 22, 16, 11, 15, and 14, the intensity needs to be adjusted to 1,000 or less. In a normal representation, each Vβ family exhibits a Gaussian pattern with ~6 to 12 peaks, with the exception of Vβ 23, which shows ~4 to 6 peaks.

A normal control range may be established by studying a group of cord blood samples or samples from age-matched healthy controls. A reduction in the number of peaks compared to that of the control range thus represents restrictions in the repertoire. One cannot rely solely on counting peaks, as peak numbers may remain in the normal range despite loss of the Gaussian pattern (e.g., Vβ 9 in Fig. 5B) or may remain in the normal range in the presence of dominance of particular segments (e.g., Vβ 2 in Fig. 5B). A more objective approach is to estimate the degree of perturbation in relation to a standard control by statistical methods (7, 17, 38). A control profile can be obtained by calculating the average distribution of samples obtained from normal cord blood. Areas occupied by each set of CDR3 segments within each TCR Vβ family are used for computing the distribution. For example, each Vβ profile may be measured as a frequency histogram (17), which is then translated into a relative frequency probability distribution, where the total area is 1. Differences in the distribution profiles between the test and control samples are used to estimate the degree of perturbation. Thus, for the test sample, perturbation in each TCR Vβ family and an estimate of average perturbation in the total repertoire can be determined.

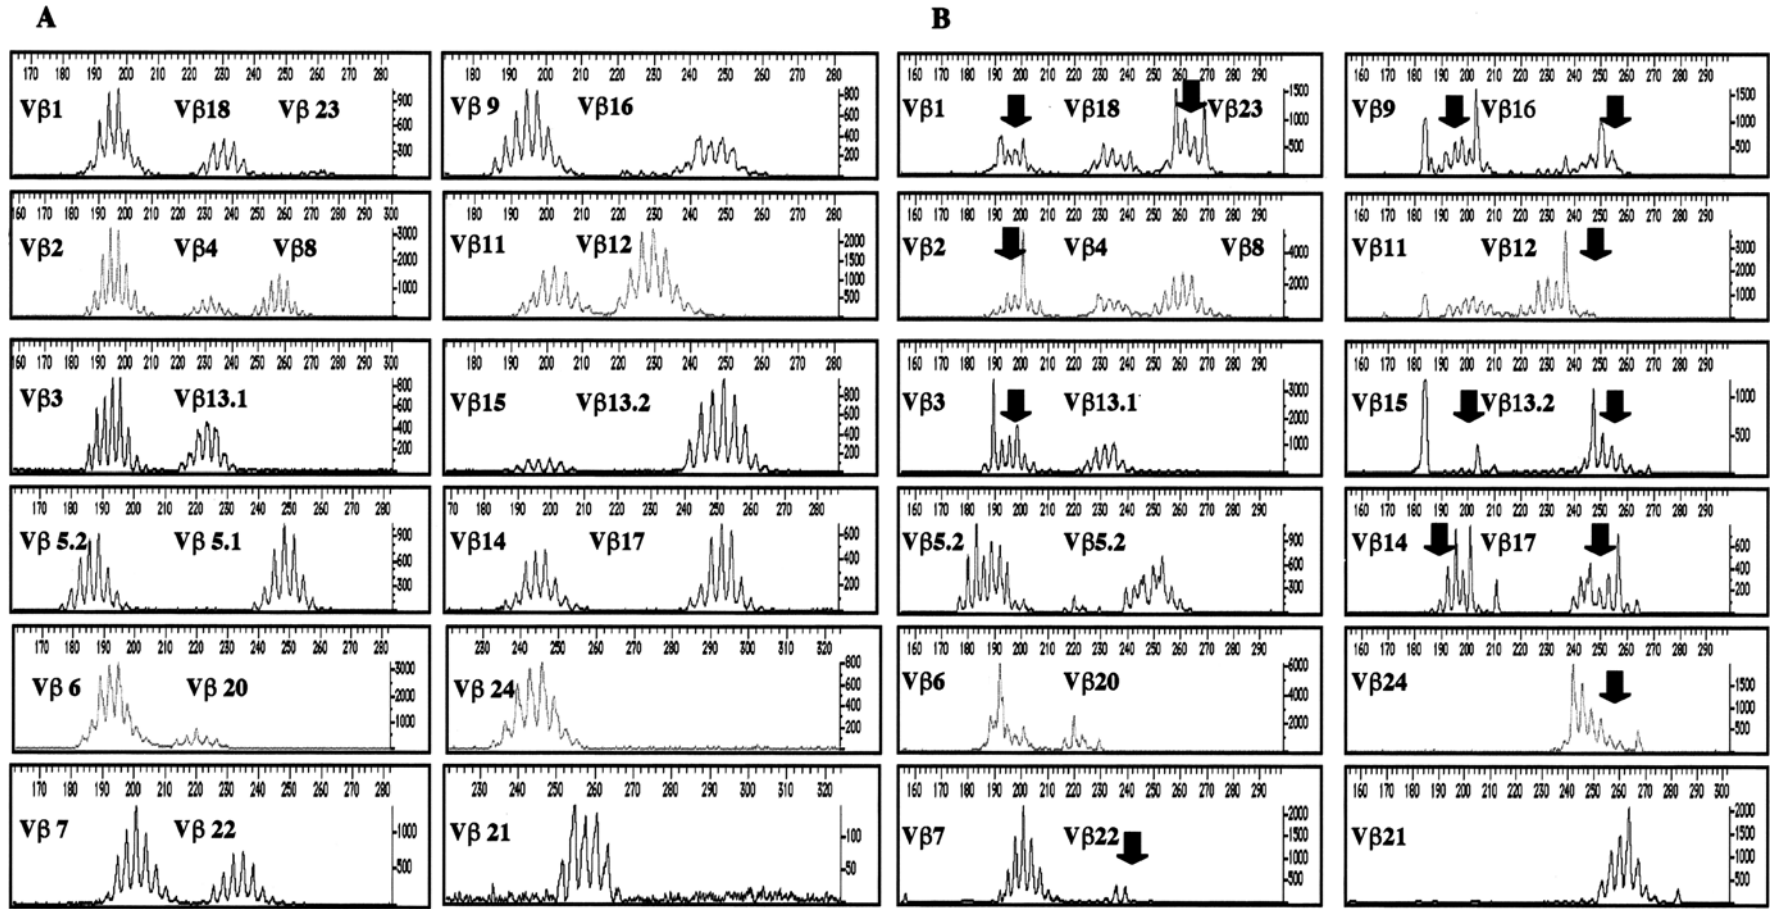
All Vβ families in a T-cell population are not equally expressed. The usage of Vβ families also varies between individuals and with the state of T-cell activation (32). In the


FIGURE 5 CDR3 spectratype generated after the fluorescent PCR products were resolved on an automated DNA sequencer (ABI 310). The *x* axis for each set represents the size of the PCR product, and the *y* axis represents the signal intensity. (A) TCR repertoire of cord blood CD4 T cells showing normal Gaussian patterns for all Vβ families. (B) TCR repertoire of peripheral blood CD8 T cells from an HIV-infected child, showing perturbation (arrows).

peripheral blood, Vβ 15, 16, and 23 are used less frequently, while Vβ 1, 2, 3, 4, 5, 7, and 8 are reported to be present at a higher frequency. Precaution should be taken while interpreting the data under specific experimental settings, as the Vβ primers differ in their ability to proportionally amplify their targets (19). If one band or peak is strongly expressed (Vβ 9 in Fig. 4 and Vβ 2 in Fig. 5B), the likelihood of clonal expansions or dominance should be considered. Arbitrary criteria have been established (18) for suspected clonal dominance on the basis of the expression of a single dominant peak with a signal intensity of ≥50% of the total intensity of the other CDR3 segments in that particular Vβ family. Determination of clonality requires further testing to identify the sequence of the dominant clones.

Note that some perturbations may be present in healthy subjects. Large restrictions in the repertoire, the absence of one or more Vβ families, or frequent changes with the appearance and disappearance of perturbations in one or more Vβ families are indicative of ongoing immune responses or changes in the peripheral T-cell compartments.

Assessment of Clonality

A PCR product of a Vβ family that exhibits dominance, as discussed above, may be directly sequenced by using the Vβ-specific primer and the Cβ primer. The presence of a single sequence is suggestive of clonal expansion (18, 40). This sequence helps identify the preferred usage of the Jβ segment and the sequence of the CDR3 regions. However, more than one expanding clone may utilize the same CDR3 segments, or, alternatively, more than one CDR3 segment in one Vβ family may exhibit dominance (Vβ 7 in Fig. 4 and Vβ 14 in Fig. 5B) within that Vβ family. In such cases, the direct sequencing approach is not useful, and to confirm clonality the frequency with which a particular clone is present must be determined. For this task, the PCR product should be cloned in an appropriate vector and sequenced to determine the frequency with which different clones are expressed (17). The sequencing is performed by standard protocols (20). Once the clonotype is defined by sequencing, clonotypic primers can be designed to monitor the persistence or loss of a particular clone over time.

Analysis of the TCR Vβ Repertoire by Flow Cytometry

Flow cytometry allows a quantitative estimate of the expression of the TCR Vβ families at the protein level with MAbs. Fluorescently tagged MAbs that specifically recognize the idiotypic determinants on the variable regions of each Vβ family are used for the analysis (13). As it is a flow cytometry-based assay, it is amenable to multiparameter analyses (34, 46) using other reagents in combination, as needed. Thus, Vβ family usage in CD4 or CD8 T-cell subsets can be studied without sample manipulation. This assay is less labor-intensive and can be performed by a trained flow cytometry operator without special training. The drawbacks of the flow cytometric approach are that it does not provide information about the TCR Vβ repertoire diversity and perturbations that are more precisely defined by CDR3 length analysis.

Equipment and Reagents

Flow cytometer with the ability to analyze four colors

Sterile polystyrene round tubes (12 by 75 mm) (Falcon, BD BioSciences, San Diego, Calif.)

Hanks balanced salt solution (HBSS) without Ca or Mg and phenol red (Biowhitaker, Walkersviller, Md.)

Fluorescent conjugated MAbs for TCR Vβ families, T-cell subsets, and isotype controls (stored at 4°C protected from light)

Coulter lysing buffer (Coulter Corp., Miami, Fla.)

Coulter fixative (Coulter)

CD4-phycoerythrin-cytochrome 5 (CD4-PC5) and CD8-allophycocyanin (CD8-APC) (Immunotech) MAbs

Isotype controls for these reagents include immunoglobulin G2a (IgG2a)-fluorescein isothiocyanate (FITC) and IgG1-phycoerythrin (PE) (BD Biosciences).

Staining Protocol

Each laboratory needs to standardize its staining combination and choice of MAbs. Depending on the number of parameters being studied and the capacity of the cytometer, it is advisable to include anti-CD3 MAb in the panel. A possible format is to perform four-color analysis with two TCR Vβ antibodies as well as antibodies for CD4 and CD8 in each tube. The fluorochrome label could be FITC and PE for TCR Vβ antibodies, PC5 for CD4, and APC for CD8. The panel of TCR Vβ antibodies from Immunotech is shown in Table 3.

1. For each sample, label twelve polystyrene tubes (12 by 75 mm) A to K for the panel of antibodies shown in Table 3 and one isotype control.

2. To each tube, add 100 μl of heparinized whole blood.

3. Add 10 μl of IgG2a-FITC and IgG1-PE isotype MAbs to the isotype tube and 10 μl of each TCR-specific reagent (A to K, Table 3) to the appropriate labeled tube.

4. Add 5 μl each of CD4 and CD8 MAbs to all the tubes.

5. Vortex the tubes gently, and incubate them for 10 min in the dark at room temperature.

6. Add 3 ml of HBSS, vortex the tubes gently, and centrifuge the tubes at 300 × g for 5 min.

7. Aspirate the supernatant and add 1 ml of Coulter lysing buffer (for experimentation, dilute 1:25 with HBSS freshly before use) to each tube.

TABLE 3 Panel of Vβ-specific MAbs

Reagent	Specificity	Fluorochrome	Clone
A	Vβ 3	FITC	CH92
	Vβ 7	PE	ZOE
B	Vβ 9	PE	FIN9
	Vβ 16	FITC	TAMAYA1.2
C	Vβ 20	FITC	ELL1.4
	Vβ 5.1	PE	IMMU157
D	Vβ 13.1	PE	IMMU222
	Vβ 13.6	FITC	JU74.3
E	Vβ 5.2	PE	36213
	Vβ 2	FITC	MPB2D5
F	Vβ 23	PE	AF23
	Vβ 21.3	FITC	IG125
G	Vβ 11	PE	C21
	Vβ 14	FITC	CAS1.1.3
H	Vβ 22	PE	IMMU546
	Vβ17	FITC	E17.5F3
I	Vβ 8.1 and 8.2	PE	56C5
	Vβ 18	FITC	BA62
J	Vβ 1	PE	BLB37.2
	Vβ 21.3	FITC	1G125
K	Vβ 12	FITC	VER2.32.1
	Vβ 5.3	PE	3D11

TABLE 4 Methods for assessing the TCR repertoire

Method	Purpose	Reference(s)
Southern blotting	TCR gene rearrangement at different stages of T-cell development	19
Semiquantitative PCR	Quantitative estimation of TCR Vβ usage	3
Anchor PCR	Amplification of known as well as unknown TCR transcripts	19
Heteroduplex analysis	Assessment of clonality	31, 35
CDR3 length analysis	Global assessment (qualitative) of TCR Vβ gene usage and diversity at CDR3 length level	
Flow cytometry	Quantitative estimation of TCR Vβ usage; allows simultaneous phenotypic and functional characterization	9

8. Vortex the tubes gently, and incubate them for 2 min at room temperature.

9. Add 250 μl of Coulter fixative and vortex the tubes again.

10. Add 2 ml of HBSS, gently vortex the tubes, and centrifuge the tubes at $300 \times g$ for 5 min at room temperature.

11. Aspirate the supernatant and resuspend it in 3 ml of HBSS wash buffer.

12. Centrifuge the tubes again at $300 \times g$ for 5 min at room temperature.

13. Aspirate the supernatant, gently tap out the pellet, and resuspend the pellet in 250 μl of 1% paraformaldehyde.

14. Store the mixture at 4°C and protect it from light until it is analyzed.

15. Analysis should be performed after 2 h or anytime thereafter within 7 days of sample processing.

Sample Analysis

The instrument should be set up for compensation. The percentages of each Vβ family can be calculated by gating on lymphocyte subsets. The accuracy of the cell count depends on the number of events counted and the frequency of the subset analyzed. Since the Vβ families may constitute as little as 0.5% of the T cells, counting of at least 10^4 events is recommended (13). A standard range for the expression of the TCR repertoire can be established by using cord blood or age-matched controls, depending on the experimental settings. The 5th and 95th percentiles can be used to calculate the normal range. Increased Vβ expression suggests that a particular Vβ family is expanded but does not necessarily imply clonal expansion. Clonality can be confirmed only by CDR3 length analysis, followed by sequencing of the PCR products.

Other Methods for Evaluation of TCR Vβ Repertoire

Southern blotting can be used for assessment of TCR Vβ and Jβ segments (Table 4). The extracted DNA is treated with a set of restriction enzymes. The products of digestion are separated by agarose gel electrophoresis, blotted onto a nylon membrane, and probed with a set of labeled Jβ probes (29). The method yields information about TCR gene rearrangement at various stages of T-cell development. This method is particularly useful in examining maturation arrest and lineage commitment in lymphoid malignancies.

Vβ gene usage can also be determined by using the semiquantitative PCR technique (5). In this method, the RNA is reverse transcribed with random hexanucleotides. The cDNA is coamplified with 5'-labeled Vβ and 3'-labeled Cβ specific primers and primers for TCR Cα as an internal control. The ratio of Vβ to Cα is used to normalize the data and estimate the Vβ usage. This method gives a quantitative estimate of the Vβ usage.

Anchor PCR (29, 30) generates information about all the known and unknown Vβ families since it does not use the specific Vβ primers. In this method, cDNA is synthesized from total RNA and its 5' end is tagged with a poly(G) tail. A PCR is then performed using an upstream poly(C) primer and a downstream TCR C-region-specific primer. The products are then cloned in appropriate vectors and sequenced to characterize the CDR3 region.

Heteroduplex analysis is a sensitive and useful way to assess clonality (5, 16, 47). Here, the amplified PCR products are denatured and randomly reannealed in the presence of carrier DNA of the specific Vβ family. The reannealed products are electrophoresed on a polyacrylamide gel and stained with ethidium bromide. Smearing of the products on the gel suggests a polyclonal repertoire, while single and distinct bands reflect oligoclonality. Sequencing of the PCR product is required for confirmation of clonal expansions.

Molecular Diagnosis of Chronic Granulomatous Disease

PAUL G. HEYWORTH AND JOHN T. CURNUTTE

30

BACKGROUND

Chronic granulomatous disease (CGD) is an uncommon primary immunodeficiency caused by defects in the genes encoding any one of four protein components of the phagocyte NADPH oxidase. This complex enzyme system, also known as the respiratory burst oxidase, is composed of gp91-*phox* and p22-*phox*, which are integral membrane proteins and together form flavocytochrome b_{558}, the redox center of the enzyme; the soluble proteins, p40-*phox*, p47-*phox,* and p67-*phox*; and the small GTP-binding protein, Rac. In normal activated phagocytes, the enzyme assembles at the plasma and phagosomal membranes and catalyzes the one-electron reduction of oxygen to form superoxide. Although superoxide itself has little microbicidal activity, its toxic derivatives (e.g., hydrogen peroxide, hypohalous acids, and hydroxyl radical) are potent microbicides and are important for killing many invading microorganisms. CGD is characterized by an absence or severely diminished levels of superoxide generation, and affected individuals suffer from severe, recurrent, sometimes fatal bacterial and fungal infections.

The minimum incidence of CGD in the United States was estimated at between 1 per 200,000 and 1 per 250,000 live births (based on a national registry of patients [21]), and most patients (~75%) are diagnosed before the age of 5 years. Mutations in *CYBB* (chromosome Xp21.1), the gene encoding gp91-*phox*, account for approximately 70% of all cases of CGD. This form of the disease is inherited in an X-linked recessive manner, and, as predicted by the genetics, the vast majority of patients are male. The three other CGD subtypes have an autosomal recessive mode of inheritance, with cases equally distributed between males and females. The most common of these is caused by defects in the p47-*phox* gene, *NCF-1* (on chromosome 7q11.23), which accounts for about 20% of cases. Defects in the p67-*phox* gene, *NCF-2* (on chromosome 1q25), and in the p22-*phox* gene, *CYBA* (on chromosome 16q24), each account for approximately 5% of cases. These subtypes of CGD are referred to as X91, A47, A67, and A22 CGD, with addition of the superscripts [+], [−], or [0] to indicate a normal level, a reduced level, or an absence of the affected oxidase component, respectively.

This chapter focuses on defining the CGD subtype and identifying the specific genetic defect. (The initial diagnosis of CGD is discussed in another chapter.) Before genetic analysis of CGD patients is performed, it is advisable to identify the affected protein component to pinpoint the defective gene. In most cases of CGD (~90%), the affected protein component is undetectable. Consequently, immunoblot analysis of neutrophil extracts with antibodies specific for each of the components provides a relatively straightforward way of narrowing down the identity of the defective gene. Spectroscopic analysis of neutrophil extracts for flavocytochrome b_{558} can also be used to distinguish between defects arising in membrane-bound and cytosolic proteins. An absence of p47-*phox* or of p67-*phox* determined by immunoblotting can confidently be interpreted as identifying the defective gene as *NCF-1* or *NCF-2*, respectively. However, for diagnostic purposes, note that the subunits of flavocytochrome b_{558} are interdependent for full maturation and expression, with the result that the absence of one subunit (gp91-*phox* or p22-*phox*) leads to the secondary absence or greatly diminished levels of the other.

It is also important to note that approximately 5% of X-linked CGD cases (and one case each of A22 and A67 CGD) evaluated to date are caused by missense mutations (or short in-frame deletions) that lead to the expression of normal amounts of apparently inactive protein. An additional 10% of X91 CGD patients have low but detectable levels of flavocytochrome b_{558} (as determined by either immunoblotting or spectroscopy [see below]), which can be either nonfunctional or, in a few cases, very weakly active. Therefore, immunoblotting by itself does not always provide a definitive answer. In the absence of both flavocytochrome subunits, a distinction between different CGD subtypes usually can be made by looking for a mosaic pattern of NADPH oxidase activity (e.g., by the nitroblue tetrazolium slide test or flow cytometry using dihydrorhodamine or dichlorofluorescein) in female relatives of the patient. Such a pattern of mosaicism is indicative of a carrier of X-linked disease. However, failure to identify the mother as an X-linked carrier does not rule out an X-linked origin, since more than 10% of defects in *CYBB* appear to arise from new mutations in germ line cells. Carriers of autosomal recessive CGD are more difficult to detect since their phagocytes stain normally in the nitroblue tetrazolium slide test and usually show rates of superoxide generation which are within the normal range. Carriers of A22 and A67 CGD are most easily identified unambiguously once the mutation has been identified in the proband. Detection of carriers of A47 CGD with a high degree of confidence is problematic because genomes of all normal individuals include at least one, and in most cases

two, highly homologous p47-*phox* pseudogenes that bear the ΔGT mutation prevalent in this form of the disease.

For recent, comprehensive reviews of CGD and NADPH oxidase, see references 6, 9, 14, 17, 19, 20, and 21.

IDENTIFICATION OF THE AFFECTED NADPH OXIDASE SUBUNIT

Concept

Since the affected oxidase subunit is absent in most cases of CGD (exceptions are noted above), the subtype often can be identified by using two complementary approaches: reduced-minus-oxidized difference spectroscopy and immunoblot analysis of neutrophil extracts. The use of spectroscopy relies on the fact that gp91-*phox* and p22-*phox* together form flavocytochrome b_{558}, a heme-containing protein that has a characteristic absorbance spectrum. In most (but not all) cases of CGD in which either the gp91-*phox* or the p22-*phox* gene is affected, flavocytochrome b_{558} is absent. Immunoblot analysis can also be used to determine (or confirm) an absence of these two components and to establish the presence or absence of p47-*phox* and p67-*phox*. Antibodies to one or more of the four *phox* proteins, p47-*phox*, p67-*phox*, p22-*phox*, and gp91-*phox*, are commercially available from BD Biosciences, Santa Cruz Biotechnology, and Upstate Biotechnology. Antibodies to all the *phox* proteins may also be available from individual investigators. As with all antibodies used for diagnostic purposes, each should be validated with samples from unaffected individuals and patients of known CGD subtype, under the specific set of conditions to be used.

Sample Requirements

Spectroscopic and immunoblot analyses require neutrophils purified from a minimum of 30 and 10 ml of blood, respectively. Blood should be collected into and immediately mixed with sodium heparin or specially formulated acid-citrate-dextrose (0.14 M citric acid, 0.20 M sodium citrate, 0.22 M glucose; mix 1 part acid-citrate-dextrose with 5 parts blood) as an anticoagulant and stored at 4°C. A sample from a normal control individual (not a family member) should be collected at the same time. Neutrophils should be purified within 24 h of drawing blood.

Flavocytochrome b_{558} Detection

Reduced-Minus-Oxidized Difference
Spectroscopy (2, 5)

Sample
The sample consists of a pellet(s) of 10^7 neutrophils.

Reagents

100 mM KH_2PO_4 (pH 7.25) (phosphate buffer)
2% (vol/vol) Triton X-100 in phosphate buffer
Sodium dithionite crystals (store desiccated)

Equipment
Sensitive UV-visible recording spectrophotometer and semimicro (1-ml) cuvettes are needed.

Method

1. Resuspend the neutrophil pellet in 400 µl of Triton X-100 in phosphate buffer, and thoroughly disperse by repeated aspiration using a 200-µl micropipettor tip.

2. Incubate on ice for 5 min.
3. Centrifuge at 27,000 × g for 20 min at 4°C.
4. Carefully transfer 350 µl of the supernatant to a semi-micro cuvette, add 400 µl of phosphate buffer, and mix by inversion.
5. Record the oxidized (untreated) spectrum of the sample between 600 and 400 nm, using phosphate buffer as a reference.
6. Reduce the sample with a few crystals (~200 µg) of sodium dithionite, and mix by inversion.
7. Record the reduced spectrum as described above.
8. Subtract the oxidized spectrum from the reduced spectrum, and plot the result.
9. Calculate the flavocytochrome b_{558} content from the height of the peak at 427 nm according to the formula $(A_{427} - A_{413})/106,000 =$ molar concentration of flavocytochrome b_{558} heme. To convert this concentration to picomoles of heme per milliliter, multiply by 10^9; multiply by 0.75 to account for the actual volume in the cuvette; and finally multiply by 400/350, since only 350 µl of the original 400-µl extract was used. This calculation gives the amount of flavocytochrome b_{558} heme (in picomoles) in the original pellet of 10^7 neutrophils.

Controls
Compare the patient spectrum with that of a normal control sample collected at the same time.

Pitfalls
Contamination of the sample with traces of hemoglobin will cause the appearance of absorption bands that closely resemble flavocytochrome b_{558}, even if no flavocytochrome b_{558} is present. Therefore, great care should be taken during the hemolysis steps of neutrophil purification to ensure that all erythrocytes are removed.

As discussed at the beginning of this chapter, some missense mutations in *CYBB* (and one known mutation in *CYBA*) can lead to the expression of normal levels of nonfunctional protein. In these rare cases, the presence of flavocytochrome b_{558} is not informative in deciding which gene is affected.

Interpretation
Normal values for flavocytochrome b_{558} are 74 ± 13 pmol of heme/10^7 cells. Female carriers of X-linked CGD generally have approximately half of this value (Fig. 1), but there is some variability, depending on the degree of skewing of X-chromosome inactivation. In most cases, patients deficient in either gp91-*phox* or p22-*phox* have undetectable levels of flavocytochrome b_{558} and the absence of the absorbance bands at 558, 530 and 427 nm is clear (Fig. 1).

Immunoblotting of Neutrophil Extracts

Sodium Dodecyl Sulfate-Polyacrylamide Gel
Electrophoresis (SDS-PAGE) and Immunoblotting
(1, 3, 12)

Sample
The sample consists of purified neutrophils from the patient and a normal control, suspended in cold phosphate-buffered saline (PBS) at 10^7 cells/ml.

Reagents

PBS (pH 7.4)

Stock solution of the protease inhibitor diisopropylfluorophosphate (DFP)
FIGURE 1 Reduced-minus-oxidized difference spectra of Triton X-100 extracts of neutrophils from a patient with X-linked CGD, his mother (carrier), and a normal control. The absorbance bands at 427, 530 and 559 nm, characteristic of flavocytochrome b_{558}, are indicated (arrows). The broad absorbance band around 470 nm is due to myeloperoxidase. The spectra have been manually offset for clarity.

SDS-PAGE sample buffer

10% polyacrylamide gels and electrophoresis buffer

Polyvinylidene difluoride or nitrocellulose membrane

Primary antibodies against gp91-*phox*, p22-*phox*, p47-*phox*, and p67-*phox*; secondary antibodies conjugated to an appropriate detection agent

Equipment

An electrophoresis unit, blotting apparatus, and power supply are required.

Method

1. Treat purified neutrophils with DFP at a final concentration of 5 mM for 10 min at 4°C, wash once in PBS, and resuspend in PBS in a screw-cap tube at 10^7 cells/ml. Prepare patient and normal control samples at the same time.

2. Pellet cells in 1-ml aliquots by centrifugation for either a single ~8-s pulse in a microcentrifuge set at full speed, or 6 min at 250 × g and 4°C.

3. Remove as much of the PBS as possible without disturbing the cell pellet, and immediately add 1 ml of SDS-PAGE sample buffer to the pellet. Mix rapidly by repeated aspiration with a 1-ml micropipette tip. (The sample will be slightly stringy.)

4. Place the tube in a boiling-water bath for 5 min.

5. If samples are not to be immediately subjected to SDS-PAGE, store them at −80°C until use.

6. Run 40 to 60 μl of each sample on a 10% acrylamide gel, and transfer to a polyvinylidene difluoride or nitrocellulose membrane, using standard electrophoresis and transfer protocols.

7. Detect proteins by using primary antibodies to each oxidase component and appropriate secondary antibodies. Dilutions will have to be determined empirically, depending on the antibody titer and the detection method used.

Controls

Prepare and process a neutrophil extract from a normal individual, preferably from blood shipped with the test sample.

Pitfalls

p67-*phox* is particularly susceptible to proteolysis; therefore, neutrophils should be prepared from freshly drawn blood samples and DFP or a commercially available protease inhibitor cocktail should be used.

Although the protein core of gp91-*phox* has a predicted molecular mass of 65 kDa, it is heavily glycosylated and migrates on SDS-PAGE as a very broad and rather diffuse band (or series of bands) between ~70 and 120 kDa.

Interpretation

As discussed above, the absence of either flavocytochrome b_{558} subunit, gp91-*phox* or p22-*phox*, leads to the secondary absence of the other subunit. An absence of these subunits therefore implies X91⁰ or A22⁰ CGD. Consideration of the sex of the patient, family history, and/or carrier status of the mother may provide further information about the mode of inheritance and therefore the CGD subtype. An absence of p47-*phox* or p67-*phox* identifies the subtype as A47⁰ or A67⁰ CGD, respectively.

IDENTIFICATION OF SPECIFIC GENE DEFECTS

Concept

The molecular defects that cause the X91, A22, and A67 forms of CGD are highly heterogeneous in nature, with many of them being family specific. In contrast, in A47⁰ CGD, a single defect has been found on ~94% of alleles examined. In addition to confirming the CGD subtype, the identification of specific mutations can provide important information for detecting or confirming carriers among patients' family members and for prenatal diagnosis in affected families.

Detection of Mutations in the gp91-*phox* Gene (*CYBB*)

Once genomic DNA has been isolated, single-strand conformational polymorphism (SSCP) analysis can be used initially to examine the 13 exons of the gene, in order to identify the region likely to contain a mutation. Once identified, the exon can be analyzed by direct sequencing. About 160 bp of the 5' regulatory region of the gene is amplified together with exon 1. Exon 9 is amplified and analyzed in two fragments.

Preparation of DNA

Isolate genomic DNA from 3 to 5 ml of whole blood anticoagulated with EDTA, using any one of several commercially available kits. The Puregene DNA isolation kit (Gentra Systems, Inc., Minneapolis, Minn.) gives good results. Alternatively, an automated DNA extractor can be used.

SSCP Analysis

Sample

The sample consists of genomic DNA isolated from whole blood (see "Preparation of DNA" above).

Reagents

SSCP dye: 2 ml of 0.5 M EDTA (pH 8.0), 250 μl of 20% SDS, 10 mg of xylene cyanol, 10 mg of bromophenol blue. Add formamide to give a final volume of 50 ml. Store at −20°C.

Master mix (volumes given are for each reaction tube; multiply by the number of reactions to be run): 5 μl of 10× Perkin-Elmer PCR buffer II (Perkin-Elmer Applied Biosystems, Foster City, Calif.), 5 μl of 25 mM MgCl₂, 2.5 μl of a mix of four deoxynucleoside triphosphates (dNTPs) each at 2.5 mM, 0.5 μl of AmpliTaq, 11 μl of sterile ultrapure H₂O.

Oligonucleotide primers at 180 ng/ml (sequences are given in the SSCP column in Table 1)

Tris-borate-EDTA (TBE) buffer

20% TBE gels, 15-well (no. EC-63155; Novex, San Diego, Calif.) or similar

SYBR Green II gel stain (Molecular Probes, Eugene, Oreg.); for each gel, dilute 5 μl of SYBR Green II in 50 ml of 1× TBE.

Equipment

A Novex ThermoFlow or similar unit is required.

Method

1. Dilute patient and control DNA samples to a concentration of 500 ng/25 μl; 8 μg (in 400 μl) will be enough for 14 PCRs.

2. Place 14 PCR tubes on ice for each DNA sample to be analyzed (one tube per exon except for exon 9, which is amplified in two reactions).

3. Aliquot 0.5 μl of each primer into the bottom of the appropriate PCR tube (two primers per tube).

4. Aliquot 2.5 μl of 1 M KCl into the exon 6 and exon 13 PCR tubes.

5. Pipette 24 μl of master mix into each PCR tube.

6. Pipette 500 ng (in 25 μl) of each DNA sample into the bottom of each PCR tube, pipetting up and down gently three times.

7. Amplify by PCR under these conditions: an initial denaturation for 5 min at 94°C, followed by 30 cycles of 30 s at 94°C, 30 s at 58°C, and 30 s at 72°C, followed by a 7-min extension at 72°C; hold at 4°C.

8. For SSCP analysis with the ThermoFlow unit, set the refrigerated circulator to 12°C; this will yield a buffer temperature of 14 to 15°C. Fill the core of the ThermoFlow with 1× TBE buffer. Set the power supply to 2 h 20 min, 300 V, 30 mA, and 10 W. Circulate until the buffer is at the desired temperature.

9. Aliquot 10 μl of SSCP dye into each one of 14 fresh PCR tubes, and add 2 μl from the completed amplification reactions. Heat the tubes to 94°C for 4 min in a thermocycler, and rapidly cool them in a bath of ice slush for at least 3 min.

10. Remove any bubbles from the wells, and load the samples.

11. When the run is complete, stain the gel with SYBR Green II.

Pitfalls

Not all mutations lead to observable shifts on the gel. SSCP analysis identified the affected exon in about 90% of gp91-*phox*-deficient CGD patients evaluated by us and others (7, 14). If mutations are undetectable by SSCP analysis, a complete set of PCR-amplified fragments can be sequenced (see the following procedure).

Interpretation

Figure 2 shows a stained gel from SSCP analysis of exons 1 through 7 of CYBB and shows a shift in exon 1. For ease of comparison, patient and control samples for each exon were run side by side. Exon 1 of the patient's *CYBB* gene was subsequently found to contain an insertion of four nucleotides (see the following procedure). An absence of PCR product for one or more exons may indicate a large deletion in the patient's gene.

Amplification and Sequencing of Specific *CYBB* Exons from Genomic DNA (14, 18)

Sample

The sample consists of genomic DNA isolated from whole blood (see "Preparation of DNA" above). PCR amplicons from SSCP analysis (see the previous procedure) can be sequenced directly, but they do not always provide sufficient unambiguous sequence for the detection of a mutation localized to the 5' or 3' end of the fragment.

Reagents

The procedure requires amplification buffer (e.g., 10× Perkin-Elmer PCR buffer) containing 0.125 mM each dNTP, 90 ng of each specific primer, 2.5 U of AmpliTaq polymerase, and 500 ng of genomic DNA, in a total volume of 50 μl. The primers used are indicated in Table 1 (Amplification).

Equipment

A thermocycler and automatic sequencer are required (alternatively, manual sequencing can be used).

Method

1. Amplify the exons under these conditions: initial denaturation for 3 min at 94°C, followed by 30 cycles of 30 s at 94°C, 30 s at 58°C, and 30 s at 72°C, followed by a 7-min extension at 72°C.

2. Purify the amplified fragments by using a QIAquick PCR purification kit (Qiagen, Valencia, Calif.) or the equivalent, as specified by the manufacturer.

3. Sequence the fragments in both directions with the ABI Prism BigDye Terminator cycle-sequencing ready reaction kit (Perkin-Elmer). Set up sequencing reaction mixtures as follows: 2 μl of ready reaction premix, 3 μl of 5× sequencing buffer, 10 ng of sequencing primer (Table 1), and 2 μl of PCR product in a 20-μl total reaction volume. Purify the sequencing reaction products in 96-well MicroAmp trays by precipitation with 80 μl of 75% isopropanol before analysis.

Controls

Samples of DNA from unaffected individuals should always be run in parallel.

Pitfalls

As with other genes, not all mutations are exonic or at intron-exon borders; some may be found in regulatory regions of the gene or within introns. Analysis of mRNA may be informative when intronic mutations cause splicing errors.

CYBB contains a number of polymorphisms that should not be confused with disease-causing mutations. Some known polymorphisms in *CYBB* are tabulated in reference 7, but others may exist.

Sequencing of exon 6 can be problematic. If a clean sequence is not obtained, use a nested PCR protocol and primers 6LA2 and 6RA3 for the second reaction.

Detection of large deletions in female carriers can be problematic due to the presence of the normal allele.

[a] The initial number indicates the exon for which the primer is used; negative numbers represent primers in the 5′ untranslated region used for amplification and sequencing of this region together with exon 1.

[b] Lowercase letters are used for intronic primers, and uppercase letters are used for primers within exon 9.
FIGURE 2 SSCP analysis of exons 1 through 7 of the *CYBB* gene. After electrophoresis of amplified and denatured DNA, the gel was stained with SYBR Green II. In each bracketed pair of lanes, the patient sample is on the left and the normal control is on the right. In the analysis shown, exon 1 of the patient contained an aberrant band (arrow); for all the other exons, the control and patient single-strand bands were the same. A four-nucleotide insertion was subsequently identified in exon 1 of this patient's *CYBB* gene. Nondenatured, double-stranded DNA appears at the bottom of the gel.

Interpretation

The *CYBB* sequence from the patient should be compared with the *CYBB* sequence from an unaffected individual and with the published sequence (GenBank accession no. NM-000397).

Detection of Mutations in the p22-*phox* Gene (CYBA)

For identifying mutations in *CYBA*, the gene can be amplified by PCR using paired synthetic oligonucleotide primers specific for each of the six exons of the gene (Table 2).

Amplification and Sequencing of *CYBA* from Genomic DNA (4, 15)

Sample

The sample consists of genomic DNA isolated from whole blood (as described above in "Preparation of DNA" in the *CYBB* section).

Reagents

The procedure requires amplification buffer [33.5 mM Tris-HCl (pH 8.8), 8.3 mM $(NH_4)_2SO_4$, 3.35 mM $MgCl_2$, 85 μg of bovine serum albumin per ml, 5% dimethyl sulfoxide], containing 0.125 mM each dNTP, 90 ng of each specific primer, 2.5 U of AmpliTaq polymerase, and 500 ng of genomic DNA, in a total volume of 50 μl. The primers used are indicated in Table 2 (Amplification).

Equipment

A thermocycler and automatic sequencer are required (alternatively, manual sequencing can be used).

Method

1. Amplify the exons under these conditions: for exons 1, 2, 3, and 5, do an initial denaturation for 3 min at 94°C, followed by 30 cycles of 5 s at 94°C and 1 min at 70°C, followed by a 7-min extension at 72°C. For exons 4 and 6, do an initial denaturation for 3 min at 94°C, followed by 30 cycles of 30 s at 94°C, 15 s at 63°C, and 30 s at 72°C, followed by a 7-min extension at 72°C.

2. Purify and sequence amplified DNA fragments as described above for *CYBB*, using the primers indicated in Table 2 (Sequencing).

Controls

Samples of DNA from unaffected individuals should always be run in parallel.

Pitfalls

CYBA contains a number of polymorphisms that should not be confused with disease-causing mutations. Known polymorphisms are documented in reference 4.

As with other genes, not all mutations are exonic or at intron-exon borders; some may be found in regulatory regions of the gene or within introns. Analysis of mRNA may be informative when intronic mutations cause splicing errors.

Detection of large deletions can be problematic in heterozygotes.

Interpretation

The *CYBA* sequence from the patient should be compared with the *CYBA* sequence from an unaffected individual and with the published sequence (GenBank accession no. M21186 and J03774).

Detection of Mutations in the p47-*phox* Gene (*NCF-1*)

More than 90% of all A47 CGD patients analyzed to date are homozygous for the deletion of GT from the normal GTGT at the beginning of exon 2 (ΔGT/ΔGT genotype). Therefore, once an absence of p47-*phox* protein has been established for a patient, the initial molecular analysis can focus on the amplification and sequencing of exon 2, using primers 2LB2 and 2RB2 (Table 3), to determine if the patient has this prevalent genotype.

Amplification and Sequencing of *NCF-1* Exon 2 for the Common GT Deletion (8, 11, 16)

Sample

The sample consists of genomic DNA isolated from whole blood (as described above in "Preparation of DNA" in the *CYBB* section).

Reagents

The reagents are the same as for the amplification and sequencing of *CYBB* (see above).

Equipment

A thermocycler and automated sequencer are required (alternatively, manual sequencing can be used).

Method

1. For amplification of the exon, perform an initial denaturation for 3 min at 94°C, followed by 30 cycles of 30 s at 94°C, 30 s at 62°C, and 30 s at 72°C, followed by a 7-min extension at 72°C.

2. Purify and sequence amplified DNA fragments as described above for *CYBB*, using the primers in Table 3.

Controls

A sample of DNA from an unaffected individual should always be amplified and sequenced in parallel. A negative control sample (containing no DNA or DNA from a patient known to be homozygous for ΔGT) can be useful, in the event that the normal (GTGT) sequence is seen in a p47-*phox*-deficient patient (see "Pitfalls"). This control will exclude the possibility of normal-DNA contamination of buffers, primers, etc.

Pitfalls

The appearance of ΔGT- and GTGT-containing sequence (see "Interpretation") in a patient who is known to be deficient in p47-*phox* (<10% of A47 CGD patients) indicates the presence of a mutation other than ΔGT on one allele or both alleles of *NCF-1*. Allele-specific PCR strategies that amplify only GTGT-containing sequence have been developed. These prevent coamplification of pseudogene DNA and facilitate identification of the rare, non-ΔGT mutations.

[a] The initial number indicates the exon for which the primer is used; primers designated 5' are in the 5' untranslated region and used for amplification and sequencing of this region together with exon 1.
[b] Exons 9 and 10 and exons 13 and 14 are amplified in single reactions and then sequenced separately (introns 9 and 13 are very short).

A detailed description of these protocols is beyond the scope of this chapter, but they are fully documented in references 8 and 11.

The identification of carriers (GTGT/ΔGT) among family members of ΔGT/ΔGT A47 CGD patients remains highly problematic, since the genomes of all normal individuals include at least one, and in most cases two, highly homologous p47-*phox* pseudogenes that bear the common ΔGT mutation.

Interpretation

In normal controls, a double sequence is seen after the initial GT at the start of exon 2, due to coamplification of the normal functional gene and p47-*phox* pseudogenes. A47 CGD patients who are homozygous for the common mutation (ΔGT/ΔGT) will show only ΔGT sequence at this position. The GenBank Accession numbers for p47-*phox* cDNA are M25665 and M26193.

Detection of Mutations in the p67-*phox* Gene (NCF-2)

For identifying mutations in *NCF-2*, the gene can be amplified by PCR using paired synthetic oligonucleotide primers specific for each of the 16 exons of the gene (Table 4).

Amplification and Sequencing of *NCF-2* from Genomic DNA (10, 13)

Sample

The sample consists of genomic DNA isolated from whole blood (as described above in "Preparation of DNA" in the *CYBB* section).

Reagents

The reagents are the same as for the amplification and sequencing of *CYBB* (see above). The primers used are indicated in Table 4 (Amplification).

Equipment

A thermocycler and automated sequencer are required (alternatively, manual sequencing can be used).

Method

1. Amplify the exons under these conditions: initial denaturation for 3 min at 94°C, followed by 30 cycles of 30 s at 94°C, 30 s at 58°C, and 30 s at 72°C, followed by a 7-min extension at 72°C.

2. Purify and sequence amplified DNA fragments as described above for *CYBB*, using the sequencing primers in Table 4.

Controls

Samples of DNA from unaffected individuals should always be run in parallel.

Pitfalls

NCF-2 contains a number of polymorphisms that should not be confused with disease-causing mutations. Known polymorphisms are tabulated in reference 4, but others may exist.

As with other genes, not all mutations are exonic or at intron-exon borders; some may be found in regulatory regions of the gene or within introns. Analysis of mRNA may be informative when intronic mutations cause splicing errors.

Interpretation

The *NCF-2* sequence from the patient should be compared with the *NCF-2* sequence from an unaffected individual and with the published sequence (GenBank accession no. M32011).

Clinical Evaluation of Myeloid and Monocytic Cell Functions

MAURICE R. G. O'GORMAN

31

Granulocytes (predominantly polymorphonuclear leukocytes) and monocytes collectively form the major components of the innate or nonadaptive immune system and are the main cells involved in inflammatory processes. Monocytes are also intimately involved in the adaptive immune response, but these functions will not be discussed in detail in this chapter. Their functions are both diverse and complex, and although they share many functions, these subsets represent very distinct cell lineages. Granulocytes (of which neutrophils or polymorphonuclear leukocytes represent >90%) are far more abundant than monocytes (approximately 60 to 70% of circulating leukocytes, compared with 1 to 6% for monocytes), and they have a much shorter half-life (approximately 1 to 3 days) than monocytes (weeks to months). Both cell types are derived from precursors in the bone marrow. In a 24-h period, the bone marrow of an average individual produces over 100 billion granulocytes. Most common clinical problems are manifested when the circulating granulocytes fall below critical levels (neutropenia). There are, however, specific clinical manifestations in which granulocytes or monocytes are present in normal numbers but are deficient in one or more of their functions.

With the implicit understanding that monocytes and granulocytes represent distinct cell lineages, this chapter will review laboratory procedures which can be utilized to assess their functions and phenotypes. Clinical assays used for the assessment of cell surface marker expression (defining specific cell lineages and functions), cellular activation, binding, directed migration (chemotaxis), endocytosis and/or phagocytosis, and finally killing (collectively referred to as phagocytic cell function) will be reviewed. Although there is a complete armamentarium of laboratory procedures which have been utilized to investigate phagocytic cell functions, few are practical enough to be implemented in a routine clinical use laboratory setting. In this chapter, assays which have proven to be adaptable for routine clinical use or have potential for increased utility in a clinical context will be reviewed. It is no coincidence that the majority of the procedures described are performed on a flow cytometer. The multiparametric nature of this technology for assessing single cells, the availability of flow cytometers in most clinical laboratories, and the increased commercial availability of probes, dyes, monoclonal antibody reagents, and kits developed to assess specific physiologic processes make flow cytometry the ideal clinical tool for the assessment of phagocytic cell functions.

Eosinophils and basophils complete the peripheral myeloid cell subsets. Eosinophil function will not be addressed here, and basophil function will be briefly described in the context of allergy in the last section of this chapter.

CLINICAL INDICATIONS FOR THE ASSESSMENT OF PHAGOCYTIC CELL FUNCTIONS

The principal clinical manifestation of neutropenia or abnormal phagocyte function is repeated bacterial infections. If a patient has a history of repeated bacterial infections, is not neutropenic, and has no abnormalities in either immunoglobulin (antibody) or complement, then abnormalities in phagocytic cell function should be assessed. Disorders involving abnomalities in phagocytic cell function, although rare, lead to profound morbidity. The laboratory can provide specific information leading to a diagnosis and, in most cases, effective therapeutic options. For young infants, the development of whole-blood assays which require very small blood samples has simplified the assessment of phagocytic cell functions. The clinical entities necessitating an evaluation of granulocyte and monocyte function are quite varied. For example, pediatric patients with repeat infections, slow wound healing, and delayed umbilical cord separation may be evaluated in the laboratory for abnormalities in microbial killing (for a diagnosis of chronic granulomatous disease [CGD]) or abnormalities in adhesion molecule expression (for a diagnosis of leukocyte adhesion deficiency type 1 [LAD-1]). With the current options of bone marrow transplantation, gene therapy, and immunotherapy protocols, laboratories are playing increasingly important roles in monitoring and assessing patients' responses to therapy. The laboratory can provide information on engraftment of functional cells following bone marrow transplantations, the frequency of circulating transfected cells in the peripheral blood of patients enrolled in gene therapy protocols, and the efficacy of immune modulatory therapy.

Monocytes play a key role in the innate immune response but are also centrally involved in the initiation and regulation of adaptive humoral and cell-mediated immune responses. Monocytes process and present antigens during the initiation of specific immune responses and are intimately involved in the induction, activation, and differentiation of B cells to immunoglobulin-secreting cells and of T cells to cytotoxic T cells. They act both directly via cell-cell contact and

indirectly via the secretion of cytokines and chemokines. Although these functions are clearly central for the elaboration of a normal immune response, the assessment of the latter is currently relegated to specialized research laboratories and will not be discussed further in this chapter.

MONOCYTE AND GRANULOCYTE ISOLATION

Monocytes

It is well recognized that any physical manipulation of the monocyte subset alters its normal resting state. Physical isolation procedures may also lead to the selective loss of specific monocyte subsets. As they circulate in the peripheral blood, monocytes can be induced by a variety of stimuli to adhere to the vascular endothelium and migrate into various tissues, where they differentiate into specialized cells, collectively referred to as macrophages, for example, Kupfer cells in the liver, microglial cells in the central nervous system, and synovial cells in the joint capsule. With the appropriate stimuli, monocytes can also be induced to differentiate into dendritic cells. Although many studies have utilized isolated and purified monocytes and granulocytes in order to investigate their functions (for procedures on the isolation of monocytes and macrophages, refer to the appropriate chapters in previous volumes of this text [4, 7]), it is more desirable to assess their functions directly in whole blood if and when possible. Nonphysical or so-called analytical isolation

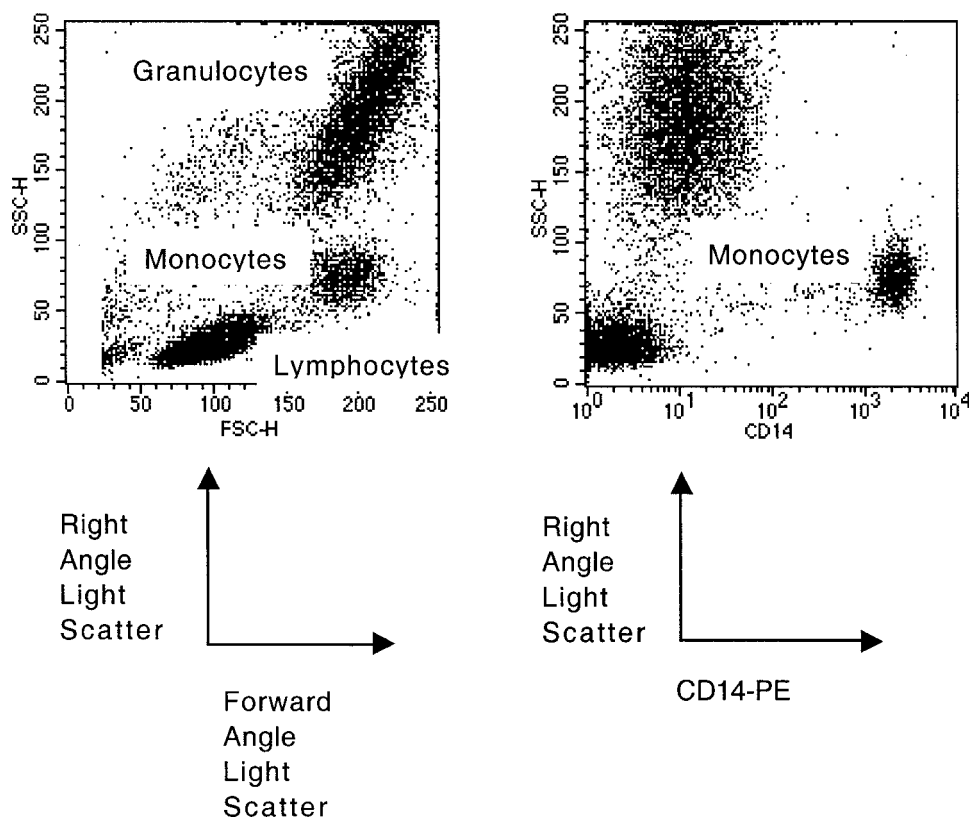
of monocytes can be performed based on the innate physical properties of these cells, as detected in a flow cytometer (Fig. 1). It is more effective, however, to identify monocytes by a combination of cell surface markers and light scatter properties, for example, CD14 and right-angle light scatter (Fig. 1). Defining lineage-specific surface markers for monocytes remains an area of significant debate, as evidenced by a conference convened in the fall of 1999 entitled "Definition of Human Blood Monocytes" (21). Although there was no clear consensus regarding the best marker to encompass all monocyte subpopulations, the summary was stated as "...the enumeration of the total monocytes with CD14 and CD16 antibodies is state of the art at this point in time." With the combination of CD14 and CD16 antibodies, specific monocyte subsets have been identified. For example, CD14$^+$ CD16$^-$ cells have been reported to function as dendritic cell precursors (19), and CD14$^+$ CD16$^+$ cells are elevated in patients with sepsis, psoriasis, or atopic dermatitis; in neonates; and in human immunodeficiency virus-infected patients with neurological involvement (18). The major population of blood monocytes is strongly positive for CD14 (CD14^{++}) and negative for CD16$^-$. More recently, a combination of monoclonal antibodies which included CD163 with either CD14 or CD64 conjugated to the same fluorochrome was reported to increase the detection of all monocytes by flow cytometry (20). This combination has not been widely adopted, and the increased cost of adding an additional marker must be considered in the context of the gains in clinical significance achieved.


FIGURE 1   Two-dimensional dot plots illustrating the separation of monocytes and granulocytes (and lymphocytes) by their inherent light-scattering properties (forward-angle light scatter versus right-angle light scatter) (left) or the combination of a light-scattering property (right-angle light scatter) and a specific lineage-defining surface antigen (CD14-PE) (right).

PMN (Neutrophils)

Polymorphonuclear leukocytes (PMN) generate very distinct light scatter properties and can easily be identified on a correlated histogram of right-angle light scatter versus forward- or near-forward-angle light scatter (Fig. 2). Like monocytes, PMN express specific patterns of surface markers; for example, CD33 is useful for differentiating PMN from monocytes because each cell type expresses characteristic levels of expression (Fig. 2). HLA-DR is also helpful for differentiating granulocytes from monocytes, since PMN are HLA-DR negative while monocytes are positive for this marker. Other markers which are useful for assessing lineage restriction as well as the activation status of these phagocytic cells are the immunoglobulin G (IgG) Fc receptor molecules, CD16, CD32, and CD64 (for more information on Fc receptors, see references 5 and 13). Resting PMN express CD16 and CD32. PMN express CD64 during development and after specific stimulation, but CD64 is absent from the cell surface by the time mature PMN are released into the circulation. Circulating monocytes express CD32 and CD64, but upon differentiation into macrophages, monocytes express CD16. In summary, monocytes can be most accurately and completely assessed by surface labeling with a combination of CD14 and CD163, while PMN are easily identified on the basis of characteristic light scatter properties and also by their characteristic cell surface levels of CD33.

ASSESSMENT OF PHAGOCYTIC CELL FUNCTION

Once monocytes or PMN have been "analytically isolated" or "gated" on the flow cytometer, various functional parameters can be assessed. In vivo, in response to appropriate stimuli, phagocytes quickly adhere to and migrate out of the vasculature. Early changes following cellular activation include an increase in the expression of adhesion markers and immunoglobulin Fc receptors. Surface marker upregulation is quickly followed by the rolling, adhesion, and directed migration of cells out of the vasculature, through the endothelium, and towards the inflammatory focus (chemotaxis). Once the cells arrive at their target foci, they adhere to (via adhesion molecules and Fc receptors), engulf (via phagocytosis), and through various oxidative and nonoxidative mechanisms, kill and degrade invading microorganisms. The next sections will review clinical assays for the assessment of each of these functions.

Upregulation of Adhesion Molecules

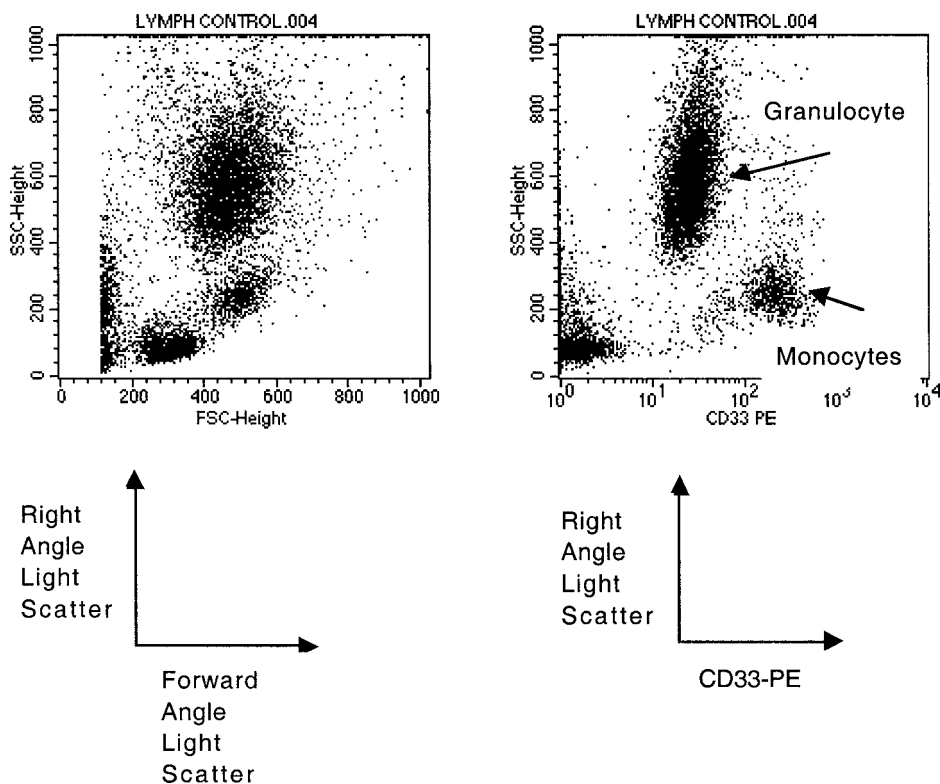
In vivo, inflammatory mediators at or near the site of inflammation, such as complement fragments, endogenous lipid mediators, and chemokines such as interleukin-8 (IL-8) and monocyte chemoattractant protein 1, cause granulocytes and monocytes to leave the circulation. Before they extravasate from the blood vessels, however, they undergo a series of well-regulated adhesion steps. First, the cells slow down and roll


FIGURE 2   Two-dimensional dot plots illustrating the inherent light-scattering properties of monocytes and granulocytes (left) as in Fig. 1. (Right) For the same tube, the same populations were visualized on the basis of right-angle light scatter (y axis) versus the level of cell surface CD33-PE expression (x axis). Note the high level of expression of CD33 on monocytes, the less densely expressed levels of CD33 on granulocytes, and the negative expression on lymphocytes.

along the endothelium, primarily via low-avidity interactions between the sialylated Lewis X antigen (CD15s) on the phagocytes and the CD62 selectin family molecules on the endothelium, before they eventually stop if activated appropriately. Stopping and extravasation involve high-avidity interactions between the β1 and β2 integrin families of adhesion molecules on the phagocytic cell surface and the appropriate counterreceptors (e.g., ICAM-1 and CD54) on the endothelium. In vitro, the β2 leukocyte integrins CD11a, CD11b, and CD11c (α chains) and CD18 (the common β chain) can be induced to increase on the cell surface within minutes after stimulation with phorbol esters. Patients with abnormalities in the expression of the β2 leukocyte integrins (resulting from mutations within the gene coding for CD18) suffer from a disease referred to as LAD-1. Clinically, these patients are characterized as having delayed umbilical cord separation, nonpurulent bacterial and fungal infections (despite persistent leukocytosis), and periodontitis or gingivitis. Patients with abnormalities in the expression of sialyl-Lewis X (CD15s) have a similar clinical presentation, and this disorder is referred to as LAD-2 (9). In the next section, a clinical laboratory procedure for the measurement of the β2 leukocyte integrins on resting and in vitro-activated PMN developed as a clinical laboratory screening test for the diagnosis of LAD-1 is described.

Measurement of β2 Leukocyte Adhesion Molecule Upregulation in Whole Blood as a Screening Test for the Diagnosis of LAD-1

CD11a (LFA-1) is expressed on all leukocytes, and CD11b and CD11c are expressed on monocytes, granulocytes, and NK cells. There are commercially available monoclonal antibodies to each of these cell surface markers which represent the α-chain components of the β2 leukocyte integrin subfamily. In addition, there are monoclonal antibodies available to the common β chain, CD18. None of the α chains are expressed on the cell surface without CD18. Our laboratory has developed an abbreviated and simplified procedure to measure the expression of the β2 leukocyte integrins on granulocytes (or other cell subsets) in whole blood (17) as a screening test for the diagnosis of LAD-1.

It is important that the expression of β2 leukocyte integrins on the PMN of LAD-1 patients is significantly reduced on both resting and in vitro-activated cells. Of the β2 leukocyte integrins, CD11b is the most densely expressed and also displays the largest increase upon stimulation, which makes this marker the most sensitive marker for the assessment of LAD-1 (Fig. 3). The other β2 leukocyte integrins, i.e., CD11a, CD11c, and CD18, have characteristic patterns of expression on lymphocytes, granulocytes, and monocytes and can also be assessed by utilizing the same protocol (17). These procedures can be performed on very young infants and require a minimal amount of blood, which may also be advantageous for monitoring gene therapy and bone marrow transplant patients.

Briefly, 900 μl of phosphate-buffered saline (PBS) and 100 μl of EDTA-anticoagulated whole blood are added to each of three tubes, labeled "1," "2," and "3," and mixed well. Next, 15 μl of phorbol myristate acetate (PMA) (final concentration, 100 μg/ml) is added to tube 3. All tubes are incubated at 37°C in a shaking water bath for 15 min. After this time, the tubes are centrifuged at 300 × g for 5 min, the supernatants are removed, the cells are resuspended, and 20 μl of an IgG2a-phycoerythrin (PE) (Becton Dickinson) isotype control is added to tube 1, while 20 μl of the monoclonal antibody CD11b-PE (Leu-15; Becton Dickinson) is added to tubes 2 and 3. The tubes are allowed to incubate at room temperature for an additional 15 min and then 2 ml of lysing solution is added to each tube (FACSlyse; Becton Dickinson), vortexed, and allowed to stand for 10 min. After this time period, samples are centrifuged at 300 × g for 5 min and washed two times with PBS containing 1% fetal bovine serum and 0.25% sodium azide. After the last wash, cells are resuspended in 1% paraformaldehyde. Alignment and other quality control parameters for setting up the flow cytometer are performed per daily routine (see chapter 18). On a dot plot displaying forward-angle light scatter versus right-angle light scatter, an electronic gate is drawn around the granulocyte subpopulation, and PE fluorescence (CD11b-PE) is evaluated. On a FACScan or FACScalibur instrument (Becton Dickinson), this is the FL2 parameter. Tube 1 (isotype control) serves as the control for background fluorescence (i.e., nonspecific as well as Fc receptor binding) and is used to optimize the FL2 parameter by setting the voltages on the photomultiplier tube (FL2) such that the entire peak of FL2 fluorescence is contained within the first decade (Fig. 3, top histogram at right). Note that the level of fluorescence emitted by the granulocyte population labeled with the isotype control is significantly higher than the level of fluorescence emitted by the lymphocyte population incubated with the same isotype control reagents. Once the flow cytometer is optimized, 10,000 events are collected as list mode data. The second tube (i.e., unstimulated cells labeled with CD11b) is then analyzed. This represents the baseline level of CD11b expressed on granulocytes. Note that normal resting granulocytes express significant levels of CD11b (Fig. 3, middle histogram at right). Tube 3 (i.e., PMA-stimulated CD11b-PE-stained cells) is run last, and for healthy persons, the level of CD11b should be significantly higher than that observed on resting PMN (Fig. 3, bottom histogram at right). The level of expression of CD11b is recorded as the mean fluorescent channel (MFC), which is proportional to the actual number of CD11b molecules expressed on the cell surface. Cell surface molecule upregulation can then be assessed either relative to the isotype control (MFC of CD11b on monocytes in tube 2 [baseline] or tube 3 [activated]/MFC of tube 1 [isotype control]) or relative to the level of CD11b expressed on resting (unstimulated) cells (MFC of CD11b on monocytes in tube 3 [activated]/MFC of CD11b on monocytes in tube 2 [baseline]).

This procedure can be used to measure the baseline and activation levels of other inducible adhesion markers expressed on granulocytes or monocytes (e.g., CD18, CD11a, and CD11c). In addition to PMA, other stimuli can be used, for example, opsonized zymosan (0.4 mg/ml) as well as f-Met-Leu-Phe (10^{-5} M) for particulate- versus receptor-mediated activation, respectively. In our laboratory, by using a 4-decade log scale from channel 1 to channel 10,000, we have observed the following ranges (MFCs for the 10th and 90th percentiles) of CD11b expression for a population of healthy adults. For the IgG2a isotype control, the range is 2 to 10; for resting CD11b-PE, the range is 28 to 153; and for in vitro PMA-activated PMN, the range is 263 to 1,135. Note that cells can express CD11b at levels higher than these ranges and that this is normal and not consistent with a diagnosis of LAD-1, but rather is indicative of normal in vivo activation. Only a profound decrease in the expression of CD11b (and all other β2 integrins) on both resting and in vitro activated PMN is consistent with a diagnosis of LAD-1. Laboratories should establish their own normal ranges.

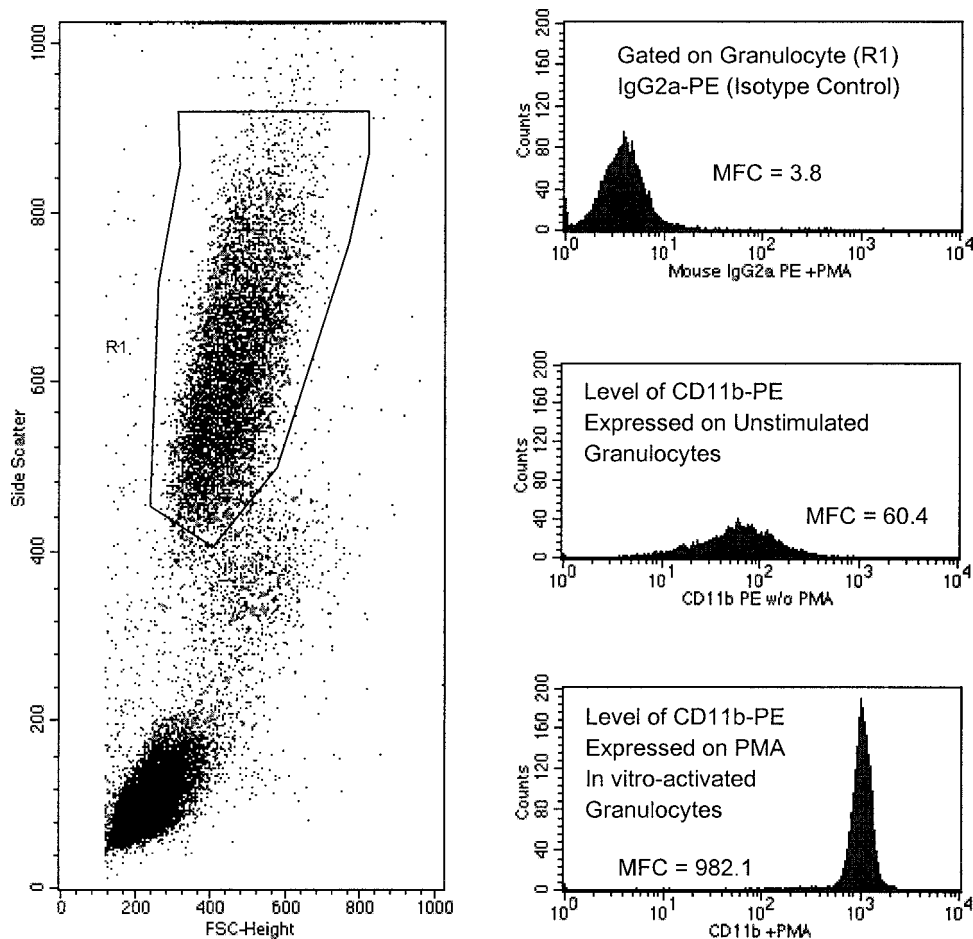
Immunoglobulin Fc Receptor Upregulation
Of the three Fcγ receptors, CD16, CD32, and CD64, CD64 has the most potential for routine clinical use. Resting


FIGURE 3 Summary of the results of a flow cytometric screening assay for the dignosis of LAD-1. The large dot plot represents the light-scattering characteristics of lysed whole blood and is used to electronically gate the granulocyte population (R1). The events in this gate are then evaluated for the surface expression of CD11b. The top histogram on the right shows the expression level of the isotype control antibody (negative control), which is used as a positive versus negative discriminatory set (so that the granulocyte population is contained within the first decade on a 4-decade log scale). The middle histogram on the right illustrates the level of expression of CD11b-PE on resting unstimulated granulocytes. The bottom histogram on the right indicates the level of expression of CD11b-PE on granulocytes which have been stimulated in vitro with a phorbol ester (PMA; for details, see the text). Results are expressed in MFC. Note the level of expression of CD11b on resting PMN (MFC = 60.4) relative to that of the isotype control (MFC = 3.8) and to the level achieved after in vitro stimulation (MFC = 982.1). These results would be consistent with normal expression and not with a diagnosis of LAD-1 (15).

granulocytes and monocytes obtained from healthy individuals express very low levels of CD64 on the cell surface, but the number of CD64 molecules is rapidly upregulated during infections and in patients with active systemic vasculitis. In vitro, CD64 is rapidly upregulated on granulocytes and monocytes in response to gamma interferon, granulocyte colony-stimulating factor (but not granulocyte-macrophage colony-stimulating factor), and IL-12. Cross-linking of CD64 triggers an oxidative burst as well as antibody-dependent cytotoxicity, so it is assumed that upregulation in vivo is physiologically significant (5). The assay for upregulation of CD64 originally reported and developed by Bruce Davis and colleagues (1, 4, 5) is slowly gaining attention in the clinical community, as evidenced by an increase in the number of reports of its applications in the literature. It has been reported that 95% of granulocytes obtained from individuals with a bacterial

infection (with a documented positive culture) expressed cell surface CD64 above the normal range (6). The measurement of CD64 upregulation on monocytes or granulocytes provides a unique laboratory measurement in circumstances where confirmation of an acute inflammatory process may influence patient management. Additionally, monitoring of monocyte and/or granulocyte CD64 levels in patients receiving gamma interferon has been used to ascertain compliance and to modify the dose scheduling (11, 12). CD64 expression is elevated in rheumatoid arthritis patients, and changes in the level of expression have been used to assess responses to therapy in this patient population (3). The level of CD64 expressed on granulocytes in vivo has also been reported to be useful for distinguishing between acute inflammatory autoimmune disease and systemic infections (2). A kit-based assay for the assessment of CD64 expression on granulocytes has been

codeveloped by Trillium Diagnostics and Verity Software House, is manufactured by R&D Systems (Minneapolis, Minn.), and is currently being reviewed by the Food and Drug Administration for clearance as an in vitro diagnostic test (B. Davis, personal communication).

Chemotaxis

Chemotaxis assays are complex, time-consuming, and very rarely performed in clinical laboratories. The assays that are performed have not changed in several years, and the reader is referred to another reference (4) for a review of these procedures. A kit-based assay for the assessment of chemotaxis activity by flow cytometry is available from Orpegen Inc. (Heidelberg, Germany).

PHAGOCYTOSIS

Phagocytosis is a complex physiological process involving the engulfment and internalization of material bearing appropriate surface molecules. The measurement of phagocytosis is confounded by the difficulty of differentiating bound from internalized material, regardless of whether this process is evaluated by microscopy or flow cytometry (10). The procedure below assesses phagocytosis by flow cytometry and differentiates between surface-bound and internalized particles.

Whole-Blood Flow Cytometric Assessment of Phagocytosis

The method described below is commercially available as a kit (Orpegen) and includes an optional procedure to exclude from analysis cells with bound bacteria that have not been internalized (i.e., phagocytosed) (14). Fresh heparinized whole blood is recommended, as citrate and EDTA reduce phagocytosis. Briefly, whole blood is cooled in an ice water bath for 15 min and 100 μl is added to the bottom of each of two 5-ml polystyrene tubes. A cooled (15 min in an ice bath) Escherichia coli preparation (fluorescein isothiocyanate [FITC]-labeled E. coli preopsonized with immunoglobulin and complement from pooled sera) is mixed well, 20 μl is added to the whole blood and vortexed, and one tube is incubated at 37°C in a shaking (2 Hz) water bath for 10 min while the other tube remains on ice as the negative control (no phagocytosis occurs at 0°C). At the end of the incubation period, the samples are removed and immediately placed in ice in order to stop phagocytosis. Ice-cold quenching solution (100 μl) is added to each sample and vortexed. This step significantly reduces the fluorescence emitted by any bacteria adhering to the cell surface but not yet internalized. Samples are then washed two times with 3 ml of cold (4°C) wash solution, and after the last wash, the supernatants are discarded, the pellet is resuspended, and 2 ml of prewarmed (room temperature) 1× lysing solution is added. Samples are then incubated at room temperature for 20 min. This step lyses the red blood cells and fixes the remaining leukocytes. After the lysis step, samples are washed once more, and 100 μl of DNA staining solution is added. The samples are vortexed, incubated for 10 min at 0°C, and then analyzed on a flow cytometer (or under a fluorescence microscope) within 30 min. (In the instructions in the package insert, a FacScan [Becton Dickinson] flow cytometer is referred to.) During acquisition, red fluorescence (FL2) in a histogram of FL2 versus cell count is displayed, and a "live" acquisition gate is set on the events which display a level of fluorescence equivalent to the DNA content of human DNA diploid cells. This procedure excludes from analysis

debris, bacterial aggregates, and unlysed red blood cells which may have the same scatter parameters as leukocytes. At least 15,000 leukocytes (events) are acquired. Forward-angle light scatter versus right-angle light scatter is displayed for analysis, and a gate is drawn around the monocyte or granulocyte population (this can be facilitated by a three-color staining procedure with a PE-labeled CD14 or CD33 monoclonal antibody for monocytes and granulocytes, respectively) (Fig. 1 and 2). An evaluation of the percentage of cells having phagocytosed the E. coli is performed with the FL1 parameter (FITC). The percentage of FITC-positive cells is then determined, as well as the mean fluorescence intensity (a correlate of the number of bacteria per cell). Each laboratory should determine its own normal ranges. It must be noted that the bacteria provided are already opsonized; however, an additional effect is achieved by the plasma products present in whole blood. This should be acknowledged when working with cells which are not present in whole blood (i.e., purified granulocyte and purified monocyte populations will not show the same level of phagocytic activity). Additionally, the assay was established to provide a ratio of bacteria to cells of 25:1, with a white blood cell count of 8,000/μl, or 40:1, with a white blood cell count of 5,000/μl. Counts above or below these values, e.g., in pediatric samples, require a correction for the amount of bacteria being added. Color compensation for spectral overlap may be adjusted by using the following two controls: one tube contains FITC-labeled phagocytosed bacteria only, i.e., no DNA stain, and one tube contains the DNA stain only, i.e., no FITC-labeled bacteria (an optional third tube would contain the PE-labeled antibody only). The flow cytometer must be calibrated and checked each time the assay is performed by placing a stably fluorescent bead into the same channel before each run and checking that position after each run.

KILLING

Following adherence and phagocytosis, digested microorganisms are killed by a variety of oxidative and nonoxidative mechanisms. Microbicidal killing assays represent the "gold standard" for the assessment of phagocytic killing function, but these assays are very complex and time-consuming (take days) and are performed only in very specialized laboratories (4). The generation of reactive oxygen intermediates (ROI) which occurs in response to a variety of stimuli, including phagocytosis, represents one of the most significant mechanisms of intracellular killing. The NADPH oxidase system is responsible for the generation of ROI, and patients with mutations in the genes coding for this enzyme suffer from very severe and potentially fatal infections as well as other complications as a result of the formation of large granulomas. This disorder, CGD, can be screened for in vitro. The procedure described below is a whole-blood flow cytometry assay which detects the elaboration of ROI following in vitro activation of the NADPH oxidase system. In the presence of peroxidases and hydrogen peroxide, appropriately stimulated PMN (or monocytes/macrophages) oxidize the preloaded nonfluorescent dye dihydrorhodamine-123 (DHR-123) to rhodamine-123, which makes it brightly fluorescent and amenable to measurement on a flow cytometer. The granulocytes of patients with either the autosomal or the X-linked form of CGD as well as granulocytes (expressing the mutated X chromosome) obtained from females who carry the X-linked form of CGD fail to generate hydrogen peroxide when stimulated and can be easily and reliably

identified in this assay by their inability to generate a positive fluorescent signal.

Whole-Blood Flow Cytometry for the Measurement of ROI

The whole-blood flow cytometry procedure for the measurement of ROI was developed for use as a clinical whole-blood assay, requires minimal blood, is relatively easy to perform, and has been widely adopted as a diagnostic screening test for CGD (16). Briefly, 100 μl of whole blood is added to each of three 5-ml polystyrene tubes and diluted with 900 ml of Ca^{2+}- and Mg^{2+}-free PBS. Optimally titrated DHR-123 is added (25 μl) to two of the tubes, one tube is stimulated, and one tube is left unstimulated (negative background control). All of the tubes are then incubated at 37°C in a shaking water bath for 15 min. Note that the DHR-123 is diluted from a stock in dimethylformamide to 5 mg/ml and stored frozen at −70°C (stable for up to 1 year), and all subsequent dilutions are done in PBS (working concentration, 45 μg/ml; final concentration, 1.125 μg/ml). Next, 10 μl of PMA (final concentration, 100 μg/ml; Sigma, St. Louis, Mo.) is added to one of the tubes containing DHR-123, and again all tubes are incubated for 15 min in a 37°C water bath. Note that PMA is initially diluted in dimethyl sulfoxide for a stock concentration of 1 mg/ml and then diluted in PBS to a working concentration of 10 μg/ml. After the last incubation, the samples are centrifuged at 400 × g for 5 min, the supernatants are discarded, the cells are resuspended, and an ammonium chloride-based lysing solution is added in order to lyse the red blood cells. Samples are mixed vigorously and left for 10 min at room temperature in the dark. After this incubation, the samples are washed two times with PBS and resuspended in 1 ml of 1% paraformaldehyde. Samples are run on a flow cytometer, and 10 to 15,000 events are acquired. For analysis, a histogram of forward-angle light scatter versus right-angle light scatter is displayed, and a gate is drawn around the monocytes or granulocytes (Fig. 4). On most analytical flow cytometers, the fluorescence can be measured in either the FL1 or FL2 photomultiplier tube. Analysis is expressed as the MFC, which is a correlate of the amount of DHR-123 that is oxidized and therefore an indirect measure of the level of ROI generated. The amount of fluorescence emitted by granulocytes is expressed as the normal oxidative index (NOI), which is calculated by dividing the MFC of the stimulated cells (plus DHR-123 and PMA) by that of the unstimulated cells (DHR-123 only). In our laboratory, the level of response obtained in whole blood from healthy individuals (NOI) is always >30. Conversely, patients with a diagnosis of CGD have an NOI which is <10. X-linked carriers of CGD will have two populations of granulocytes, one normal, i.e., with an NOI of >30, and one abnormal, with an NOI similar to that observed for a patient with CGD. Whole blood anticoagulated with either heparin or EDTA can be used, but note that if samples are to be kept for longer periods (up to 48 h), heparin is recommended.

Intracellular Staining

There have been significant improvements recently in the ability to detect intracellular antigens by flow cytometry. Although the current clinical applications for detecting intracellular antigens are limited, it is conceivable that in the future there will be an increased demand for this type of analysis. For example, it may be desirable to measure the ability of phagocytes to elaborate specific cytokines or cytokine inhibitors in response to provocative stimuli.

Currently, it is possible to identify rare patients with myeloperoxidase deficiency by measuring the intracellular levels of myeloperoxidase. It is important that patients with a complete myeloperoxidase deficiency can have a false-positive test for the diagnosis of CGD (15). It is recommended that patients with a positive screening test for CGD by either the DHR-123 assay or the dichlorodihydrofluorescein diacetate (DCFH-DR) assay who clinically do not appear to have a diagnosis of CGD be screened for the presence of myeloperoxidase by the use of intracellular staining protocols. For details of intracellular staining protocols, see the chapter on immunophenotyping.

Basophil Activation as a Measure of IgE-Dependent Allergen-Specific Responses in Allergic Patients

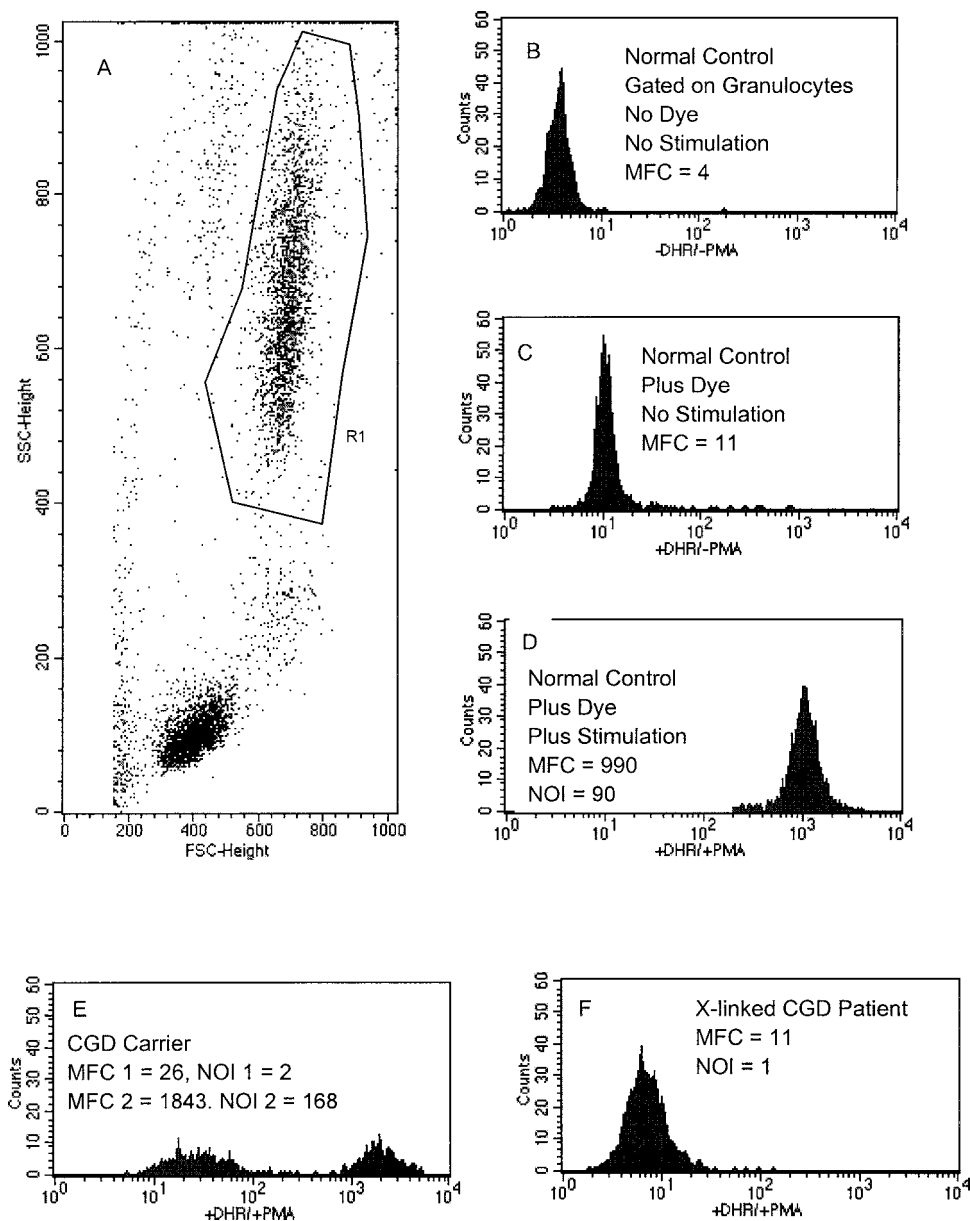
Flow cytometry allows for a relatively simple alternative to the time-consuming two-step process of measuring basophil degranulation in vitro (incubation and then measurement of specific mediators). The ability to measure basophil activation in response to an in vitro challenge with allergens has the potential to become a routine assay in the clinical laboratory. We have utilized a Basotest kit manufactured and distributed by Orpegen. (As a known positive control for tree pollen allergy myself, I can attest to the fact that the assay did in fact correctly identify sensitization to a seven-tree pollen combination and not to a mite preparation.) A recent review covers this area relatively comprehensively, discussing technical issues (CD63 versus CD203c, allergen concentrations, native versus recombinant allergens, etc.) as well as various laboratories' experiences with this relatively new flow cytometry procedure (8). A summary of the applications and test sensitivities and specificities of flow cytometric methods for detecting basophils is presented in Table 1 (8). Although this methodology is early in its development and will require more validation through clinical trials, it is an exciting avenue with potential applications not only in diagnosis but also in the monitoring of immunotherapy. Briefly, the principle of the assay is as follows. The assay is performed with sodium heparin-anticoagulated whole blood. If the patient is known to have high IgE levels, the blood should be washed once prior to the initiation of the assay. The whole blood is usually incubated at 37°C for 20 min with an appropriate stimulation buffer (IL-3) that increases the sensitization of the basophils without inducing degranulation. An appropriate concentration of the potential allergen(s) and positive (e.g., f-MetLeuPhe) and negative (pyrogen-free dilution buffer) controls are then incubated with the whole blood at 37°C for approximately 20 min. After this incubation, the samples are put on ice and labeled with a combination of antibodies against IgE (to allow for gating on basophils) and the appropriate activation marker (CD63 or CD203c) on ice and in the dark. After the labeling procedure, the red cells are lysed, the sample is washed at least one time, and the cells are fixed. Whole blood can be held for up to 24 h, and prepared samples should be analyzed within 2 h of red cell lysis. Analysis is accomplished by setting a gate around the low-right-angle light scatter, high anti-IgE-positive cells and measuring the expression of the basophil activation marker. The background or negative control sample is used to set the discrimination marker. The normal range for the positive controls should be established in each laboratory and then used to validate whether the test is performing properly or not prior to the analysis of patient samples. This test has the potential to become a valuable addition to allergy and/or immunology laboratories, but more clinical trial experience and better allergen preparations must be available before this assay becomes widely applicable.


FIGURE 4   Summary of the flow cytometry procedure used to screen patients suspected of having CGD. The results illustrated are for a healthy control (D), an X-linked CGD carrier (E), and a CGD patient (F). The large two-dimensional dot plot on the left (A) illustrates the innate light scatter properties of lysed whole blood, with an electronic gate (R1) drawn around the granulocyte cluster. The histogram on the top right (B) represents the innate fluorescence emitted by granulocytes which have not been incubated with the oxidation-sensitive dye DHR-123; this tube is used to establish the baseline fluorescence settings for the flow cytometer. Histogram C represents gated granulocytes which have been incubated with the dye (DHR-123) but which have not been stimulated (baseline oxidative state). Histogram D represents granulocytes which have been incubated with the dye and which have been stimulated in vitro with PMA (see the text for details). Note that the NOI, which is the geometric MFC of the granulocyte population in histogram D (MFC = 990) divided by the MFC of the granulocytes in histogram C (MFC = 11), is 90, which is consistent with normal expression (i.e., an NOI of >30). Note that in histogram E, there are two populations of cells expressing different levels of fluorescence, one with an NOI of 2 (abnormal) and the other with an NOI of 168. This result is consistent with an X-linked CGD carrier status. The last histogram (F) illustrates an example of the results obtained for a patient with a diagnosis of CGD (note that the NOI [2] is significantly less than 30).

TABLE 1 Sensitivity and specificity of flow cytometric analysis of in vitro allergen-activated basophils[a]

Allergen	Gold standard or reference test[b]	n	Sensitivity (%)	Specificity (%)	Reference value
Cypress pollen	Hx + SPT + NC	34	91	100	71
Lolium perenne	Hx + SPT+IgE	51	93.3	98.4	86
House dust mite	Hx + SPT+IgE	53	93.3	98.4	86
Apple-mediated oral allergy syndrome	Hx	26	100[c]	100[c]	73
Pollen-associated food	Hx	29	≥85	≥80	72
Hevea latex	Hx + SPT+IgE	29	93.1	91.7	49
	Hx + SPT	43	93.0	100	70
Muscle relaxants	Hx	21	64	100	74
β-Lactam antibiotics	Hx + SPT	58	50	93.3	50
Metamizol	Hx ± SPT	26	42.3	100	89
Serum of patients with chronic urticaria[d]	Hx + ASST	20	70	65	53

Flow Cytometric Detection and Quantification of Apoptotic Cells

THOMAS W. McCLOSKEY, BARBARA N. PHENIX, AND SAVITA PAHWA

32

Interest in apoptosis has increased dramatically during the past 10 years, despite the fact that it was first observed over a century ago (31) and was conceptualized during ancient Greek times (13). Once the widespread biological significance of this process became apparent, investigators began to study cell death as it related to both hyperplastic and hypoplastic disease. Dysregulation of the apoptotic pathway can result in diseases of aberrant cell numbers, including cancer and AIDS. As pathways which regulate apoptosis continue to be discovered, the ability to modulate it becomes very real; such an achievement could have tremendous medical implications.

In 1971, Kerr (26) described a process of cell death called shrinkage necrosis, the initial events of which were cytoplasmic condensation and compaction of nuclear chromatin followed by nuclear fragmentation. The next year, a landmark paper by Kerr et al. (27) named this cell death cascade apoptosis. These investigators noted that apoptotic bodies and mitotic figures coexisted in tumors, and they had the foresight to speculate that hyperplasia might result from decreased cell death rather than increased cell division. Programmed cell death is a normal, physiological event which occurs without inflammation, so nontargeted bystander cells are not harmed. It is the body's mechanism for eliminating cells which are no longer needed or potentially injurious. Often referred to as cell suicide, an initiating trigger is required, after which the entire series of events leading to its own demise are carried out by the cell itself. Apoptosis is a critical component of normal embryonic development (5) which plays a prominent role in the formation of the nervous (52) and immune (61) systems. After maturation, it also plays a role in maintaining homeostasis, as it occurs naturally at the end of the life span of differentiated cells. Recent evidence has brought to light the function of death inducers, such as Fas ligand (which binds to the receptor Fas [CD95]), in protecting immune privileged sites (4).

However, alterations in cell survival contribute to several human diseases (57), including those of either cell accumulation or cell depletion. As a result of the intensive investigation in this field in recent years, numerous mammalian and viral regulatory proteins which interact with apoptotic pathways have been identified (15, 29, 35, 38), leading to potential therapeutic implications for cancer (40). Since the deletion of self-reactive leukocytes is beneficial for the host, dysregulated cell death is reported to be involved in autoimmune disease (49). Increased peripheral lymphocyte apoptosis has emerged as an important pathogenic factor during human immunodeficiency virus (HIV) infection (19, 46); in fact, our understanding of the immune system's interaction with both viral (51) and bacterial (60) pathogens may unveil cell death as a critical variable determining an effective host response.

The intensive research conducted thus far has led to an enhanced understanding of the cellular processes involved in apoptosis (Fig. 1) and the diseases in which dysregulated cell death plays a role (reviewed in reference 14). The interaction of death receptors with their respective ligands is an important area of investigation which has discovered multiple death-inducing molecules. Much progress has been made in clarifying intracellular signal transduction pathways following triggering at the cell surface (reviewed in reference 2). Physiological cell death is a highly regulated process which may be determined by the balance of pro- and antiapoptotic molecules within the cell (reviewed in reference 23), leading to cells that are either prone to die or protected from death. In addition, chemical or radiation exposure which disrupts the DNA may initiate deletion of a particular cell or, alternatively, may activate DNA repair mechanisms. Recently, the important role of mitochondria (reviewed in reference 22) as central players in several major pathways of apoptosis has been elucidated.

The characteristic series of events typical of apoptosis are generally cell membrane blebbing, chromatin condensation, and fragmentation of DNA. Such distinguishing features are visible microscopically, particularly in DNA-stained samples observed under a fluorescence microscope. Thus, visual determination and quantification of apoptosis in a sample should accompany flow cytometric measurement. Many of these features can be utilized to resolve apoptotic cells cytometrically. After the diffusion of fragmented chromatin, DNA content measurements can distinguish apoptotic from live cells by detection of a subdiploid population. Strand breaks within the DNA molecule can be fluorescently tagged via an enzymatic reaction by the terminal deoxynucleotidyl transferase-mediated dUTP nick end labeling (TUNEL) method. The exposure of phosphatidylserine is an apoptotic event which can be revealed by the specific binding of annexin. Activation of the caspase cascade can be detected by using fluorescence-based techniques. Each of these features of apoptotic cells has been taken advantage of to allow the resolution of dying cells within a heterogeneous sample.
FIGURE 1 Major mechanisms for regulation of cell death. Cell death pathways may involve (i) the interaction between a cell surface receptor capable of signaling for apoptosis and its ligand; (ii) DNA damage, after which chromosome repair or cell deletion mechanisms may commence; (iii) alterations in the mitochondria, which are major cellular organelles involved in the decision for replication or elimination; and (iv) an imbalance in apoptotic regulatory molecules, such as those in the Bcl-2 family.

METHODS FOR DETECTION OF APOPTOSIS

As interest in apoptosis has increased due to its pivotal role in many fields of cell biology, the requirement for clinical assessment has also risen. For example, it may be important to know the percentage of cells which are dying for a disease characterized by increased lymphocyte apoptosis, such as HIV infection (8, 36). In addition, confirmation of the primary immunodeficiency Canale-Smith syndrome (autoimmune lymphoproliferative syndrome) (12, 16, 50) requires a demonstration of reduced apoptosis in response to Fas stimulation. A determination of the in vitro sensitivity of cancer cells to apoptosis may be helpful for selection of the most appropriate chemotherapeutic regimen for treatment (6).

The study of apoptosis is being increasingly applied to many different cell types (e.g., hepatocytes, neurons, cardiac myocytes, etc.). The methods described here are approaches to investigate apoptosis in lymphocytes. For investigations of lymphocyte apoptosis in the peripheral circulation, blood should be collected by venipuncture into sterile Vacutainer tubes containing anticoagulant. Blood samples should be processed as soon as possible and no later than 6 h after blood draw and should be maintained at room temperature until the time of processing. Peripheral blood mononuclear cells are isolated by standard techniques (as discussed elsewhere in this manual) and then processed for the evaluation of lymphocyte apoptosis per the objectives of the study (see "Important Considerations" in this chapter). The methods discussed here refer to the analysis of apoptotic cells in the sample of interest by utilizing flow cytometry, which has emerged as a technology well suited to quantifying dying cells (11, 43). Many of the events of cell death can be detected by using fluorescent dyes or fluorochrome-conjugated reagents and can be measured by flow cytometry.

Detection of Cells with Reduced DNA Content (Subdiploid Method)

One of the hallmarks of the process of apoptosis is the activation of endonucleases. Fragmented chromatin results in cells with a diminished total DNA content, a characteristic which can be utilized to tag these cells within a mixed population (Fig. 2). By utilizing nucleic acid-specific dyes such as propidium iodide, apoptotic cells can be distinguished from live cells within the same sample (42). This assay is applicable to both human cell lines (24) and primary isolates (36).

Reagents

Ethanol (100%; Pharmco Products, Brookfield, Conn. [www.pharmco-prod.com/products.html])

Propidium iodide (50-μg/ml stock; Molecular Probes, Eugene, Oreg. [www.probes.com])

RNase (1-mg/ml stock; Sigma, St. Louis, Mo. [www.sigma.com])

Procedure

1. Centrifuge samples and aspirate supernatant.

2. Resuspend pellet in 0.5 ml of Hanks balanced salt solution (HBSS), vortex, add 1.5 ml of ethanol, and vortex.

3. Incubate for 1 h at 4°C.

4. Centrifuge samples and aspirate supernatant. (Note that higher centrifuge speeds may be required after ethanol fixation.)

5. Add the following to the pellet: 250 μl of Hanks balanced salt solution, 250 μl of RNase, and 500 μl of propidium iodide.

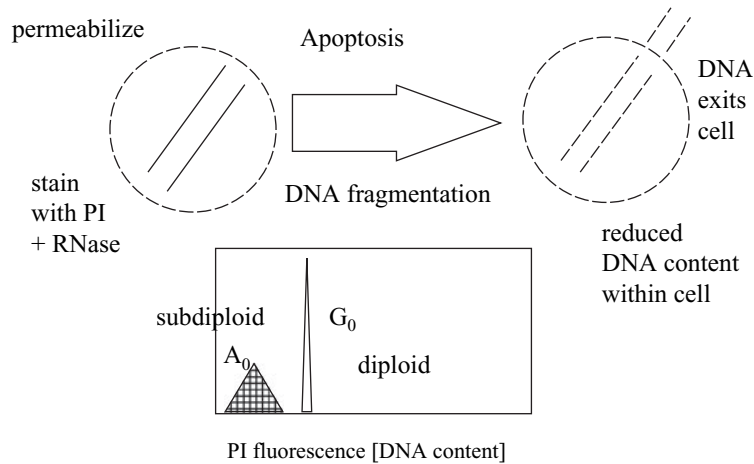
6. Incubate the mixture for 15 min at room temperature and then maintain the mixture at 4°C in the dark until flow cytometric analysis (Fig. 3). The time after fixation for optimal analysis should be determined for each system, as


FIGURE 2 Rationale for subdiploid apoptosis assay. A hallmark of apoptosis is the activation of endonuclease, resulting in the fragmentation of cellular DNA. Samples are fixed and permeabilized with ethanol, which allows DNA fragments to escape past the plasma membrane. Staining with propidium iodide (PI) and measuring the DNA content flow cytometrically reveal a population with reduced DNA content representing apoptotic cells. (Inset) Apoptotic cells are a distinct population with reduced fluorescence (shaded population).

additional fragmented DNA will continue to diffuse out of cells (for approximately 24 to 48 h).

Assay Interpretation and Pitfalls

Apoptotic cells are visible as a distinct peak with a reduced fluorescence intensity compared to that of the live cells located in the G_0 peak. The conventional flow cytometric thought process of locating the diploid peak and then measuring those cells with greater fluorescence (cycling cells) must be dismissed. Instead, the goal here is to locate those cells with reduced fluorescence and to distinguish them from other "events" which may also have reduced fluorescence. Tight coefficients of variation for the G_0 peak are essential for this assay. The machine alignment should be checked and set carefully. Samples should be run at low differential pressures to maximize the resolution of apoptotic and intact cells. Nucleic acid dyes with differing binding properties work equally well in this assay (39, 56).

Careful gating and analysis are essential in order to achieve accurate measurements when using the subdiploid assay. Samples are initially gated on light scatter and then on a doublet discrimination histogram of peak versus integral (height versus area on some instruments) fluorescence to exclude clumps. The discriminator (threshold) setting on the machine should be adjusted for propidium iodide fluorescence equal to 25% of the G_0 peak (e.g., if the G_0 peak is set at channel 400, the cytometer should be triggered on red fluorescence corresponding to channel 100). The rationale governing this setting is that apoptotic cells (A_0) will possess slightly less DNA than intact cells. Although this conservative analysis scheme may miss some late-stage apoptotic cells, it will exclude from the measurement many potentially confounding events, such as apoptotic bodies, mitochondria, and nuclear and cellular fragments, all of which would erroneously elevate the observed percentage of apoptosis. Thus, incorrect levels of apoptosis may be enumerated by the inclusion of noncellular events in the apoptotic region of the histogram and their counting as apoptotic cells. These data are always collected on a linear fluorescence scale.

The subdiploid assay is highly recommended as an initial assay for a simple evaluation of apoptosis. The major advantages of this method include its ease, similarity to familiar assays of the cell cycle, and low cost, and in addition, following flow cytometric analysis, samples can be spun down onto slides and examined by fluorescence microscopy (note that improved cellular morphology for microscopic examination may be obtained by splitting samples and making slides prior to fixation and staining). Apoptotic cells are readily detectable due to membrane blebbing or condensed and fragmented chromatin. These visual results can be compared
FIGURE 3 Representative histogram of subdiploid method for assay of apoptosis. Peripheral blood mononuclear cells (PBMC) from an HIV-infected child were cultured for 3 days and then processed by the subdiploid assay. Cells with reduced DNA content compared to G_0 cells are clearly visible.

to those obtained with the cytometer for accuracy of gating and analysis regions. The drawbacks of this method are its incompatibility with monoclonal antibody labeling, as those subsets undergoing apoptosis in a mixed population cannot be determined, and that caution must be exercised to exclude noncellular events which have subdiploid levels of fluorescence from the final analysis.

Assay Variations

Instead of allowing fragmented chromatin to diffuse from permeabilized cells, a citrate-based buffer can be utilized to extract it (as described in reference 20). Another variation on this assay utilizes hypotonic lysis to isolate free nuclei (42), after which a similar analysis is performed. This procedure may be useful in circumstances where cell adherence is a problem, as free nuclei can be released. However, the ability to differentiate apoptotic nuclei from debris by measuring light scatter is compromised compared to that of the whole-cell assay.

Detection of Cells with DNA Strand Breaks (TUNEL Method)

The TUNEL method (Fig. 4) is based on the enzyme-mediated insertion of nucleotides into DNA strand breaks which are present in apoptotic cells (21). The use of fluorochrome-conjugated nucleotides offers a single-step procedure (30). The TUNEL method is recommended for its outstanding sensitivity and specificity, as it has demonstrated excellent agreement with fluorescence microscopy for both cell lines ($r = 0.98$; $P = 0.0001$) and isolated lymphocytes ($r = 0.75$; $P = 0.0001$) (34). TUNEL assays have been facilitated by the introduction of kits by various manufacturers.

Reagents

Apo-Direct TUNEL kit (Phoenix Flow Systems, San Diego, Calif. [www.phnxflow.com])

Permeafix fixation and permeabilization reagent (Ortho Diagnostic Systems, Raritan, N.J. [www.ortho.com])

Procedure

1. Cells are incubated for 40 min at room temperature with Permeafix.

2. Samples are centrifuged, the supernatant is removed, and cells are resuspended in 1 ml of wash buffer.

3. Samples are centrifuged, the supernatant is removed, and cells are resuspended in 50 µl of TUNEL labeling solution containing the following (in each tube): 10 µl of TdT reaction buffer, 0.75 µl of TdT enzyme, 8 µl of fluorescein-dUTP, and 32 µl of distilled H_2O (note that a useful negative control is obtained following incubation in labeling solution in which the enzyme has been omitted).

4. Incubate samples with TUNEL labeling solution for 60 min at 37°C.

5. Add 1 ml of rinse buffer to each tube.

6. Centrifuge, aspirate the supernatant, and resuspend the cells in rinse buffer.

7. Analyze by flow cytometry (Fig. 5).

Assay Interpretation and Pitfalls

Apoptotic cells labeled by TUNEL are visible as a distinct population with increased fluorescence intensity compared to the live cells present in the tube. This assay depends on an enzyme-mediated insertion of labeled nucleotides; appropriate enzyme function should be verified. This may be accomplished by the use of negative and positive control cells (prefixed cells, either nonapoptotic or partially apoptotic), which are provided with the kit and should be prepared for each experiment. These cells demonstrate both the absence of nonspecific labeling in live cells and the presence of specific labeling in known apoptotic cells. Quantification of the percentage of TUNEL-positive cells among the positive control cells can be useful for daily quality control of the assay. This method is also reliant on adequate permeabilization of the sample. Thus, when problems are encountered during use of the TUNEL procedure, the permeabilization step should be checked. An appropriate and useful control sample is prepared by omitting the enzyme but subjecting
FIGURE 4 Rationale for TUNEL apoptosis assay. Endonuclease activation during apoptosis results in DNA strand breaks. Samples are fixed and permeabilized. The enzyme terminal deoxynucleotidyl transferase inserts fluorescently labeled nucleotides, allowing the resolution of apoptotic from live cells. (Inset) Apoptotic cells exhibit an increased fluorescence intensity compared to live cells (shaded population). FITC, fluorescein isothiocyanate.
FIGURE 5 Representative histogram of TUNEL assay. PBMC from an HIV-infected child were cultured for 3 days, prepared by the TUNEL method, and analyzed flow cytometrically. Apoptotic cells exhibit a bright fluorescence intensity.

the sample to all other steps of the procedure. A biological variable affecting this assay is the number of DNA strand breaks that the apoptotic cells possess, which will determine the ability to resolve them from live cells. It is possible, therefore, that early apoptotic cells with minimal chromatin damage will not incorporate enough fluorescence to allow detection.

Assay Variations

Alternative reagents available for the fixation and permeabilization step include (i) paraformaldehyde-FACS Perm (Becton Dickinson, San Jose, Calif. [www.bdfacs.com]), (ii) Cytofix/Cytoperm (Pharmingen, San Diego, Calif. [www.pharmingen.com]), (iii) Fix and Perm (Caltag, Burlingame, Calif. [www.caltag.com]), (iv) Intraprep (Coulter, Miami, Fla. [www.coulter.com]), (v) paraformaldehyde-ethanol, and (vi) paraformaldehyde-saponin. (Note that single-step fixation and permeabilization reagents may enhance cell recovery.) This assay is compatible with monoclonal antibody labeling of surface antigens (Fig. 6). Cells are labeled prior to fixation and then processed as described above.

Detection of Cells with Translocated Phosphatidylserine (Annexin V Method)

The annexin V assay (Fig. 7) for the detection of apoptosis is based on the exposure of phosphatidylserine on the outer plasma membrane (33, 59). This phospholipid is normally sequestered in the inner cell membrane exclusively, and its translocation acts as an important signal for the clearance of deceased cells (32). Fluorochrome-conjugated annexin is capable of binding phosphatidylserine, thus allowing the detection of apoptotic cells.

Reagents

Annexin binding buffer (Pharmingen [www.pharmingen.com])

Fluorescein-conjugated annexin V (Pharmingen [www.pharmingen.com])

Paraformaldehyde (Electron Microscopy Sciences, Fort Washington, Pa. [www.emsdiasum.com/ems])
FIGURE 6 Determination of DNA strand breaks within a specific subpopulation. PBMC from an HIV-infected child were cultured for 3 days. The sample was then labeled with an anti-CD4–phycoerythrin (PE) monoclonal antibody, fixed and permeabilized in Ortho Permeafix, and then subjected to the TUNEL procedure. This experimental design allows the quantification of apoptotic CD4 cells.

Procedure

1. Suspend cells in 1 ml of binding buffer.
2. Centrifuge the sample, aspirate the supernatant, and resuspend the cells in 100 μl of binding buffer.
3. Add 5 μl of annexin, vortex, and incubate for 10 min at room temperature.
4. Add 1 ml of binding buffer, centrifuge, remove the supernatant, and resuspend the cells in binding buffer.
5. The sample may be analyzed on a flow cytometer immediately or fixed in 1% paraformaldehyde (Fig. 8).

Assay Interpretation and Pitfalls

Apoptotic cells revealed by the annexin assay will exhibit an increased fluorescence intensity compared to that of the live cells in the same sample. This assay depends on the presence of two distinct populations in the test sample, since otherwise it is difficult to determine the background fluorescence. A drawback of this method is the lack of a control molecule to determine nonspecific binding of annexin, and thus a continuous distribution of annexin fluorescence is problematic.

Any sample manipulation which results in damage to the cell membrane may allow annexin binding to live cells. The inclusion of propidium iodide in this assay is often used to detect such cells, but cells in the late stages of apoptosis will also admit propidium iodide through their membranes and should rightfully be included in a count of total apoptosis. Thus, careful sample preparation is a prerequisite for accurate quantification of apoptosis by the annexin method. Simultaneous assessments of annexin binding and propidium iodide exclusion may be used to determine early from late apoptosis, if that is the intent of the investigator.

The binding of annexin to phosphatidylserine is a calcium-dependent process, thus requiring calcium-enriched buffers. This assay has the unique attribute of detecting apoptotic cells without the requirement of fixation. The potential exists for phosphatidylserine-expressing cells to be sorted, placed back in culture, and subsequently reassayed.
FIGURE 7 Rationale for annexin V apoptosis assay. In live cells, a state of membrane asymmetry exists in which phosphatidylserine (PS) is sequestered in the inner portion of the plasma membrane. During apoptosis, phosphatidylserine translocates to the outer cell membrane. Fluorochrome-conjugated annexin V binds specifically, thus tagging apoptotic cells. (Inset) Annexin-positive cells exhibit enhanced fluorescence compared to live cells (shaded population).

Assay Variations

This procedure is compatible with monoclonal antibody labeling (Fig. 9). Fluorochrome-conjugated antibodies can be added simultaneously at the annexin binding step. For samples in which contaminating erythrocytes may present a problem, the lysis of red cells with commercial reagents and/or the use of a fixative which eliminates red cells may be incorporated (as described in reference 34).

Detection of Cells Containing Active Caspases

The execution of apoptosis consistently involves the activation of a family of cysteine aspartyl proteases, termed caspases.

Caspases cleave their target proteins at specific aspartate residues and are important mediators of the apoptosis cascade (1, 41). Caspases exist as inactive zymogens and are processed in cells undergoing apoptosis by self-proteolysis and/or cleavage by other proteases (9, 58). Several methods currently exist for the detection of active caspases. Antibodies to active caspases (anti-active caspase-3; Beckman Coulter) bind to a conformational epitope that is exposed by activation-induced cleavage of procaspase 3 (7). Cell-permeative fluorogenic caspase substrates (28, 47) such as those from Phiphilux, Oncoimmunin, College Park, Md.,
FIGURE 8 Representative histogram for detection of apoptosis by annexin method. PBMC from an HIV-infected child were cultured for 3 days, prepared by the annexin method, and analyzed by flow cytometry. Phosphatidylserine-expressing cells are distinguishable from live cells as a separate peak.
FIGURE 9 Determination of phosphatidylserine exposure within a specific subpopulation. PBMC from a healthy adult were cultured for 3 days. The sample was labeled with anti-CD8–phycoerythrin-cyanine 5 (PE-CY5) and annexin fluorescein, washed, and fixed. Subsequent analysis allows the quantification of apoptosis within the CD8 subset.

and fluorescent inhibitors of caspases (10, 54) such as those from Molecular Probes both allow for the identification of intracellular caspase activity (Fig. 10).

Reagents

Vybrant FAM caspase-3 and -7 assay kit (Molecular Probes [www.probes.com])

Procedure

1. Resuspend 10^6 cells in 1 ml of culture medium.
2. Add 10 µl of 30× fluorescent inhibitor of caspases (FLICA) working solution directly to 300 µl of cell suspension. Mix.
3. Incubate for 60 min at 37°C and 5% CO_2, with protection from light. Mix during incubation to prevent settling.
4. Add 2 ml of 1× wash buffer.
5. Pellet cells by centrifugation. Discard the supernatant and resuspend cells in 1 ml of wash buffer.
6. Pellet cells by centrifugation. Discard the supernatant and resuspend cells in 400 µl of wash buffer.
7. Analyze on a flow cytometer with a 488-nm excitation wavelength and green emission immediately or fix in 1% paraformaldehyde for later analysis.

Assay Interpretation and Pitfalls

Apoptotic cells containing active caspase-3 or -7 will exhibit an increased fluorescence intensity compared to that of the live cells in the same sample. This assay depends on the presence of two distinct populations in the test sample; otherwise; it is difficult to determine the background fluorescence. A potential drawback of this method is that interactions with other cellular sites may contribute to the signal intensity of nonapoptotic cells (48).

Hoechst 33342 and propidium iodide are also included in the Vybrant FAM caspase-3 and -7 assay kit, allowing for additional evaluations of membrane permeability and the cell cycle. However, samples may not be fixed if these additional reagents are to be used. The potential exists for active caspase-expressing cells to be sorted, placed back in culture, and subsequently reassayed.

Assay Variations

The Vybrant FAM caspase-3 and -7 assay procedure is compatible with monoclonal antibody labeling. Fluorochrome-conjugated antibodies may be added after the washing step (step 6). Resuspend the cell pellet in an appropriate volume of phosphate-buffered saline and follow regular surface labeling protocols. This kit may also be used in conjunction with other apoptosis detection reagents, such as red-excited annexin V-allophycocyanin.

USE OF JURKAT CELLS AS CONTROLS FOR APOPTOSIS ASSAYS

Negative and positive controls are necessary to characterize the assay system as well as to verify its consistency. Negative controls may consist of primary isolates (e.g., peripheral blood lymphocytes) from healthy individuals or cell lines in growth phase. These should be cells that exhibit no signs of deterioration, which additionally should be checked for viability by a trypan blue assay. Positive control cells may be produced within the laboratory. The acute T-cell leukemia cell line Jurkat is readily induced to undergo apoptotic cell death. Jurkat T lymphocytes (clone E6-1; ATCC TIB-152) may be obtained from the American Type Culture Collection (Manassas, Va. [www.atcc.org]).

Reagents

RPMI 1640 culture medium (Whittaker Bioproducts, Walkersville, Md. [www.biowhittaker.com])

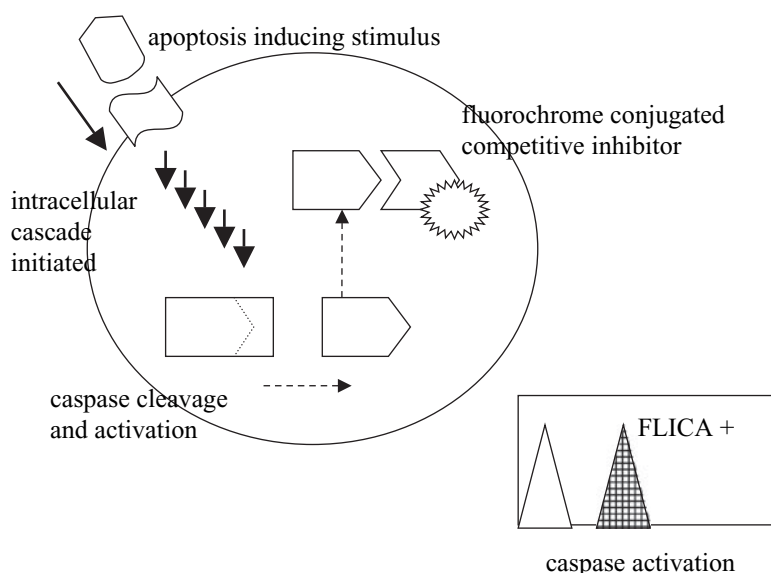
Fetal calf serum (Hyclone Laboratories, Logan, Utah [www.hyclone.com])


FIGURE 10 Rationale for caspase apoptosis assay. A cell encounters an apoptosis-inducing stimulus, which initiates a cascade of intracellular events. Among these events in caspase-dependent apoptosis are the cleavage and activation of caspase enzymes. The fluorescent inhibitor of caspases (FLICA) is able to compete with the natural ligand and bind to activated caspase. (Inset) Cells can be analyzed by flow cytometry, and apoptotic cells will be detectable via their increased fluorescence.

L-Glutamine (Whittaker Bioproducts [www.biowhittaker.com])

Penicillin-streptomycin (Whittaker Bioproducts [www.biowhittaker.com])

CD95 antibody (clone CH-11 [immunoglobulin M]; Upstate Biotechnology, Lake Placid, N.Y. [www.upstatebiotech.com])

Procedure

1. Maintain Jurkat cells in RPMI 1640 medium with 10% fetal calf serum, 2 mM L-glutamine, 100 U of penicillin G/ml, and 100 μg of streptomycin/ml. Set up 12- by 75-mm tubes with 10^6 cells/ml.

2. Add anti-CD95 (100 ng/ml) antibody to tubes and incubate for 2 to 4 h at 37°C. (Time course data are available in reference 34.)

3. Harvest cells and apply apoptosis assay for quantification of cell death.

IMPORTANT CONSIDERATIONS

Initial ventures for the detection, quantification, and characterization of apoptotic cells should address the following issues. In what cell type is apoptosis occurring? Which method is most applicable? What are the kinetics of the death process, i.e., is a period of cell culture required before apoptosis can be detected? What are appropriate negative and positive controls? How can the presence of apoptosis be verified in the test sample?

Regarding cell type, there is a major difference between performing apoptosis assays with cell lines and performing them with primary isolates. Cell lines consist of one cell type and are homogeneous in nature. In contrast, a sample isolated from a subject may have contaminating cell types along with the cells of interest. This issue ties in with method selection. For a mixed sample, a method must be chosen which has the potential to simultaneously utilize another parameter to mark the cells of interest. For example, for the measurement of T-lymphocyte apoptosis in a human peripheral blood sample, the TUNEL method combined with labeling for anti-CD3 would be an appropriate choice. It is also critical to ensure that the cell isolation method does not differentially select for live or apoptotic cells. For example, adherent cells undergoing apoptosis may disengage themselves and could be lost during a wash procedure, or a centrifugation step may fragment dying cells without affecting healthy cells. These events would result in erroneous measurement of the percentage of apoptotic cells.

Careful consideration should be given to the kinetics of cell death. Each flow cytometric assay takes a snapshot in time, i.e., it measures the percentage of apoptotic cells (by the characteristic being used to detect them) in the total number of cells that the instrument senses. Thus, the assay does not provide information on the cumulative amount of cell death which has occurred, but rather that in process at the time of assay. For an in vitro model system, such as a cell line induced to undergo apoptosis, a time course study can be performed over several hours to determine the peak response. For primary cells, the detection of maximal levels of cell death may require ex vivo culturing for one to several days (36, 45). Cell counts provide useful information during culture periods because they yield an estimate of the total number of cells lost. Furthermore, the question of timing becomes even more important if the experimental design is attempting to estimate in vivo levels of deceased cells. Can apoptosis be detected immediately in freshly isolated cells? The assay chosen for this application is critical, as in vivo clearance of apoptotic cells is very efficient, making their detection difficult. Can samples be obtained in one laboratory and then shipped to another for apoptosis assessment? Results obtained through testing by the AIDS Clinical Trials Group suggest that shipping influences apoptosis.

The choice of controls is critical, both for assurance that the assay is performing as expected and for the detection of biological variability. As outlined earlier, Jurkat cells serve as a readily prepared positive control for apoptosis. However, depending on the experimental design, an investigator may wish to include both negative and positive control samples for the cell type of interest. Therefore, one requires a known live sample of the cell type under study as well as an induced apoptotic sample. Any discussion of controls naturally leads to the important issue of verification of results. Since cellular, and especially nuclear, morphology is the defining characteristic of apoptotic cell death, microscopy remains the method of choice for verifying apoptosis results. Fluorescence microscopy following staining of the sample with a DNA dye such as propidium iodide will allow the direct quantification of apoptotic cells within the sample. In addition, it may reveal artifacts which might account for unexpected flow cytometric results. It is important to bear in mind that flow cytometers do not quantify apoptosis; they measure fluorescence, and it is left to the operator to interpret the data.

ALTERNATIVE METHODOLOGY

Four flow cytometric assays for apoptosis have been presented. These methods performed well in a multiassay comparison study (34). In contrast, since apoptotic cells are generally able to maintain membrane integrity, trypan blue dye exclusion is not recommended as a means of apoptosis quantification. Many other methods have been reported, including the detection of changes in the mitochondrial membrane potential (62), the use of Hoechst in combination with propidium iodide or 7-amino actinomycin D (53, 55), the use of flow cytometric light-scatter parameters (44), and the use of the Apo 2.7 monoclonal antibody (63). Depending on the experimental design, these alternative methods may prove useful. For example, changes in the mitochondrial membrane potential are thought to be among the earliest events in apoptosis. However, time-dependent assays using live cells are inherently more difficult to perform.

Besides allowing for the detection of apoptosis itself, many reagents are available for the flow cytometric investigation of the molecules involved in cell death, including both cell membrane-associated and cytoplasmic molecules. For example, monoclonal antibodies against members of the Fas and Bcl-2 families of proteins are readily attainable. Cytokines, which are often important accessories in apoptosis initiation, are evaluable by the use of fluorochrome-conjugated immunoglobulins. The increasing availability of these reagents continues to open new avenues for apoptosis research by flow cytometry. In addition to advances in reagent technology, the laser scanning cytometer (3) represents novel instrumentation suitable for the quantification and investigation of apoptosis. The expression of genes involved in apoptosis may be evaluated at the DNA and mRNA levels by using appropriate assays described elsewhere in this book.

PRECAUTIONS IN DATA INTERPRETATION

Systems have been reported in which apoptosis occurs in an atypical fashion. For example, model systems of cell death have been described in which cells do not exhibit decreased DNA content (17), do not label with the TUNEL reaction (37), and do not express phosphatidylserine (18). These reports emphasize the importance of verifying data obtained with any single method. Microscopic evaluation, a positive control of death induction in the test system, and the use of more than one method may be required to validate apoptosis data.

CONCLUSIONS

The appreciation of the fact that a complete understanding of the cell cycle includes knowledge of physiological cell death has generated tremendous research interest in the process of apoptosis and has led to the development of many assays for examining apoptosis. The consideration of potential variables and artifacts, microscopic examinations of samples, and the choice of method stand as critical components in the successful investigation of apoptosis.

Our increased understanding of the role of apoptosis in cell biology has elevated it to a place of important stature in both science and medicine. Its significance is underscored by its tremendous evolutionary conservation, as baculoviral inhibitors of apoptosis are capable of interaction with mammalian caspases (25). Furthermore, as evidenced by the deletion of autoreactive clones in the human thymus, apoptosis is essential for life. Dysregulated cell death, however, such as the rising apoptosis associated with AIDS progression, is clearly associated with pathogenesis. The potential to treat human disease via manipulation of apoptotic pathways holds great promise, and as the elucidation of both protective and inductive cell death signaling mechanisms continues, such possibilities approach realization.

Quantification of Recent Thymic Emigrants: T-Cell-Receptor Excision Circles

PAUL KROGSTAD

33

The thymus is the site of differentiation of bone marrow-derived precursors into mature CD4$^+$ and CD8$^+$ T cells. In the absence of thymic development, as in complete DiGeorge syndrome, there is an absence of mature blood T cells, resulting in profound immunodeficiency. The peripheral T-cell populations are established by birth, and postnatal thymectomy does not cause overt immunodeficiency. Since thymic weight begins to decrease after puberty, it was long assumed that the thymus is active early in life, declining substantially in early adulthood. However, recent anatomic and functional studies have demonstrated that the differentiation of new T cells within the thymus (thymopoiesis) continues well into adulthood (6, 10, 13), exhibiting a gradual age-related decline. Moreover, postnatal thymectomy has been associated with lower levels of T cells (7).

Several clinical developments have come together to heighten interest in identifying parameters of thymopoiesis. Among these are the elucidation of the nature of several primary immunodeficiencies, the use of more potent chemotherapeutic regimens for the treatment of cancer, and the demonstration that multidrug regimens for human immunodeficiency virus (HIV) infection produce improvement of immune function in many individuals (10, 16, 17). The changes in T-cell populations seen during highly active antiretroviral therapy (HAART) for HIV infection are particularly provocative. Significant increases in the number of circulating CD4$^+$ T cells are seen in 50% or more of children and adults treated with HAART (10, 15). However, a significant number of patients with an excellent virological response to HAART (that is, complete suppression of detectable viremia) show no discernible increase in CD4$^+$ T-cell numbers, while others demonstrate immunologic improvements (an increase in CD4$^+$ T-cell populations) that are discordant with the virological response (the presence of ongoing viremia) (3, 15).

METHODS FOR QUANTIFICATION OF THYMOPOIESIS

In chickens, blood lymphocytes may be identified as recent thymic emigrants (RTEs) by the use of antibodies that react with the cell surface marker chT1 (14). No similar phenotypic marker of mammalian RTEs has been identified, but the differential and mutually exclusive expression of two isoforms of CD45 (CD45RO and CD45RA) has been used to distinguish naïve T cells from those which have undergone proliferation in response to antigenic stimulation. In particular, naïve CD4 and CD8 T cells exhibit cell surface expression of CD45RA, CD27, CD62L, and other markers, while CD45RO expression is seen on memory T cells (4). This simple model has been complicated by the observation that CD45RO cells can revert to the expression of CD45RA (1, 8, 10). As an additional confounding factor, CD45RA T cells are long-lived (21). Consequently, the simple enumeration of CD45RA$^+$ T cells does not provide a clear measure of thymopoiesis.

Methods have recently been developed to quantify RTEs based on the use of quantitative PCR detection of DNA molecules generated during rearrangement of the gene loci encoding the α and β chains of the T-cell receptor (TCR) during T cell differentiation. This process involves the excision of DNA fragments that persist in cells as circular extrachromosomal molecules, termed TCR rearrangement excision circles (TRECs) or TCR deletion circles (5, 24). The initial step in productive recombination at the TCR α chain locus (TCRA) involves deletion of the TCR δ gene locus (TCRD) embedded within it. End-to-end ligation of recombination signal sequences produces a TREC with a unique nucleotide sequence termed the signal joint (Fig. 1). Subsequently, an additional recombination event brings the variable (V) and joining (J) segments of the TCRA into contiguity, producing a coding-joint TREC. Although stable, these TRECs are not replicated (and therefore are not truly episomes) and are diluted by cellular division (5).

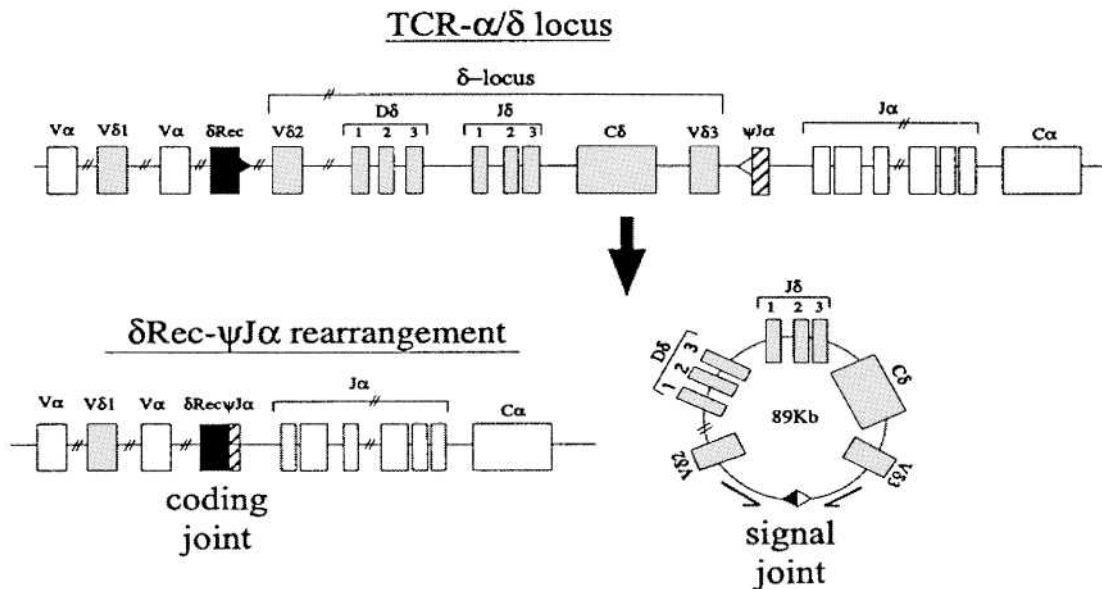
The observation that the excision events involved in the production of functional α chains are identical in 70% of αβ T cells (22) led to the development of straightforward PCR-based strategies to quantify these αTRECs. Douek et al. (5) initially described a quantitative-competitive PCR assay employing internal standards bearing an internal deletion in the signal joint and coding joint sequences. This method was successfully used to characterize the age-dependent decrease in thymopoiesis, to investigate the role of the thymus in the expansion of the peripheral blood T-lymphocyte pool in HIV infection during HAART (5), and to evaluate the success of transplantation of thymus tissue in complete DiGeorge syndrome (17). Since then, a similar approach with real-time PCR methods has been used to quantify TRECs, and they have been shown to serve as an independent predictor of the progression of disease following transfusion-related HIV infection (2, 9, 18, 24). Moreover, TRECs have been shown to be


FIGURE 1 Production of αTREC. The TCRD locus is shown embedded within TCRA. Recombination releases an 89-kbp signal-joint TREC containing a distinctive sequence that may be detected by oligonucleotide primers spaced approximately 180 bp from either side of the joint. A second recombination event brings the Vα and Jα sequences into contiguity, releasing a second TREC containing the coding joint (not shown). (Modified from reference 24 with permission of the publishers.)

diminished or absent following thymectomy performed during pediatric cardiothoracic surgery or during adulthood to ameliorate the manifestations of myasthenia gravis (7, 20).

PCR quantification of TRECs derived from TCR β chain locus rearrangement has also been described and has been used to provide additional evidence that the differentiation of T cells with a diverse TCR repertoire continues until late adulthood (19). Moreover, rearrangement of the TCRB locus occurs during the early, double-positive phase of T-cell maturation, in which thymocytes express both CD4 and CD8. Proliferation occurs during subsequent steps of maturation, leading to intrathymic dilution of TCRB-derived TRECs. In addition, the methods employed to detect these βTRECs are more complex. For these and other reasons, αTRECs are seen as the optimal target for quantitation (11).

METHODS FOR QUANTITATION OF αTRECs

Separation of CD4+ and CD8+ T Cells (Optional)

The quantitation of TRECs may be performed with unsorted cells or with subpopulations of cells purified by fluorescent cell sorting, magnetic bead separation (5), panning, or other techniques. In view of its high yield and relative simplicity, magnetic cell sorting with CD4 and CD8 microbeads and positive selection columns is often used.

Magnetic Cell Sorting Method

1. Rapidly thaw cryopreserved peripheral blood mononuclear cells in a 37°C water bath and immediately dilute the cells in 8 to 10 ml of complete medium (RPMI medium with 20% fetal bovine serum).

2. Pellet the cells by low-speed centrifugation, resuspend them in 100 μl of ice-cold medium, and transfer the suspension to a 1.5-ml microcentrifuge tube.

3. Label the cells by the addition of 2 μl of CD4 MultiSort microbeads (Miltenyi Biotec) and incubate the mixture at 4°C for 12 min. Stop the labeling reaction after 12 min by the addition of 500 μl of complete medium.

4. Pass labeled cells through a MACS MS+ separation column (Miltenyi Biotec). Rinse the column twice with 500 μl of complete medium. After collecting the eluate, remove the column from the magnet and place it in a 1.5-ml conical tube. Flushing the column with 1 ml of complete medium yields the CD4+ cells.

5. To obtain CD8+ cells, collect the eluate while the column is on the magnet by incubating the column with 20 μl of MACS MultiSort release reagent for 10 min at 4°C. To stop the action of the release reagent, add approximately 5 ml of complete medium. Centrifuge the solution at 300 × g for 10 min, resuspend the cell pellet in 68 μl of medium, and add 30 μl of MultiSort Stop reagent. Then, add 2 μl of CD8+ microbeads and incubate the mixture for 12 min. CD8+ cells are obtained by passing the mixture through the MACS MS+ separation column as described above.

6. The purity of the cells obtained in this fashion is examined by flow cytometry using conventional methods. We routinely obtain a purity of >80% CD4+ or CD8+ T cells from aliquots of cryopreserved peripheral blood mononuclear cells.

Preparation of Cell Lysate for PCR

Suitable approaches to the preparation of cellular lysates include the disruption of cells with a lysis buffer containing 7 M urea followed by phenol and ethanol extraction (23), the use of commercial nucleic acid preparation reagents such as Trizol (Gibco BRL) or TriReagent (Molecular Research Center, Cincinnati, Ohio) (5), and the preparation of a crude DNA lysate as described below.

1. Purified CD4+ or CD8+ cells are washed with phosphate-buffered saline and pelleted by low-speed centrifugation,

and the cells are resuspended in PCR-grade proteinase K (100 μg/ml; 100 μl per 100,000 cells) (Boehringer Mannheim) in 0.5 mM EDTA.

2. Incubate the cells at 56°C for a minimum of 1 h, and then inactivate the protease by incubating the cells at 95°C in a dry bath incubator for 15 min.

3. Centrifuge the cells briefly at full speed (10,000 to 16,000 × g for 3 to 5 min) in a microcentrifuge to pellet cell debris and transfer the supernatant to a new tube.

PCR Quantitation by Radioisotope Method

A. PCR setup. Assemble reaction mixtures containing the following reagents:
1. 5 μl of DNA lysate
2. 4 pmol each of the SJ1 and SJ2 primers (Table 1)
3. 0.5 U of Platinum *Taq* polymerase (Gibco)
4. 2 to 5 μCi of [α-^{32}P]dCTP (3,000 Ci/mmol)
5. 2.5 μl of 10× PCR buffer (200 mM Tris-HCl [pH 8.4], 500 mM KCl)
6. 1.8 mM MgCl$_2$
7. 200 μM dideoxynucleotide triphosphates (including dCTP)
8. Deionized water to bring the final volume to 25 μl

B. In a DNA thermal cycler, denature the samples at 95°C for 5 min and perform 24 to 35 cycles of amplification as follows:
1. Denaturation at 94°C for 30 s
2. Annealing at 60°C for 30 s
3. Extension at 72°C for 35 s

C. The total cellular DNA from the lysate must be quantitated by a second method. If nucleic acids have been purified by using agents that remove cellular proteins, a spectrophotometric estimation of the amount of chromosomal DNA may be satisfactory. Alternatively, PCR detection of a cellular gene such as β-globin may be employed, as previously described (23).

D. Electrophoresis. PCR products are prepared for electrophoresis by the addition of 5 μl of 6× loading buffer (0.2% xylene cyanol, 0.2% bromophenol blue, 50% sucrose [wt/vol], 100 mM EDTA [pH 7.4]). Equal amounts of each reaction mixture (5 to 15 μl) are separated through a nondenaturing 6% polyacrylamide gel. The radiolabeled PCR products are detected and quantified by use of a phosphorimager with appropriate imaging software (e.g., ImageQuant [Amersham Pharmacia Biotechnology]).

E. Calculation of TRECs. For quantification of the number of TRECs in test samples, a standard curve is constructed by amplifying in parallel a set of reaction mixtures containing 0, 10^1, 10^2, 10^3, and 10^4 copies of a cloned signal joint sequence (see below). A linear relationship generally

may be found between the $\log_{10}$-transformed signal intensity and 10^1 to 10^4 TRECs with 22 to 25 cycles of amplification. Interpolation along this standard curve is used to determine the number of TRECs in test samples. Prior to beginning the analysis of samples, the number of cycles of amplification needed to produce a linear standard curve must be determined for a given thermocycler.

Real-Time PCR Quantitation

As noted above, Douek et al. initially described a quantitative-competitive PCR approach to quantify αTRECs. Subsequently, Sempowski et al. (20) and others (24) described real-time molecular beacon-based PCR methods to quantify signal joint and cellular DNA sequences. The molecular beacon approach obviates the gel electrophoresis and phosphorimager detection steps described above. We present below a slight modification of the protocol presented by Sempowski et al. that we have used to quantify αTRECs (7) by using a spectrofluorometric thermocycler (ABI PRISM 7700; Applied Biosystems, Foster City, Calif.) (18).

A. PCR setup. Assemble reaction mixtures containing the following reagents:
1. 5 μl of DNA lysate
2. Platinum *Taq* buffer (200 mM Tris-HCl [pH 8.4], 500 mM KCl) (2.5 μl)
3. 50 mM MgCl$_2$ (1.75 μl)
4. 10 mM dioxynucleoside triphosphates (0.5 μl)
5. 12.5 μM 5′ forward primer (1 μl) (Table 1)
6. 12.5 μM 3′ reverse primer (1 μl) (Table 1)
7. 5 μM TREC probe (1 μl) (Table 1)
8. 25 μM Rox internal reporter dye (5-carboxy-x-rhodamine, succinimidyl ester) (0.5 μl)
9. Platinum *Taq* (Gibco Life Sciences) (5 U/μl; 0.125 μl)
10. Deionized water to bring the final volume to 25 μl

B. In an ABI PRISM 7700 thermal cycler, denature samples at 95°C for 5 min and perform 40 cycles of amplification as follows:
1. Denaturation at 95°C for 30 s
2. Annealing at 60°C for 60 s
3. The instrument should be set to record the fluorescence emission during the annealing phase of each cycle. The cycle threshold is set to the level at which all positive control reactions demonstrate exponential DNA amplification.

C. The total cellular DNA from the lysate must be quantitated by a second method. If nucleic acids have been purified by using agents that remove cellular proteins, a spectrophotometric estimation of the amount of chromosomal DNA is satisfactory. Alternatively, PCR detection of a cellular gene may be employed. Following the protocol for TREC amplification, we

TABLE 1 PCR primer and probe sequences

Primer or probe	Sequence (5′ → 3′)
Radiolabeled PCR	
SJ1	AAA GAG GGC AGC CCT CTC CAA GGC AAA
SJ2	AGG CTG ATC TTG TCT GAC ATT TGC TCC G
Real-time PCR	
Forward primer	CACATCCCTTTCAACCATGCT
Reverse primer	GCCAGCTGCAGGGTTTAGG
Probe	FAM-ACACCTCTGGTTTTTGTAAAGGTGCCCACT-TAMRA[a]

[a]FAM, 6-carboxyfluorescein; TAMRA, 6-carboxytetramethylrhodamine.

amplify sequences found in the CCR5 chemokine receptor gene by using the following primer-probe combination supplied by D. Douek (18): forward primer, 5′-TACCTGCTCAACCTGGCCAT-3′; reverse primer, 5′-TTCCAAAGTCCCACTGGGC-3′; 5 μM probe (1 μl), 5′-FAM-TTTCCTTCTTACTGTCCCCTTCT GGGCTC-TAMRA-3′. A standard curve is established by using fivefold dilutions of human peripheral blood lymphocyte DNA to generate samples containing 750 ng to 1.2 μg/5 μl. These standards and test samples are analyzed in duplicate, and the mean DNA quantity is used for data analysis.

D. Calculation of TRECs. All samples are analyzed in triplicate. TREC values for the unknown samples are determined by interpolation along a standard curve produced by linear regression to correlate the cycle threshold values and TREC copy numbers (see below). The mean of the triplicate TREC values is used for data analysis; the coefficient of variation is generally <20%. TREC data are reported as number of TREC per million cells, using an estimate of 8 μg of DNA per 1 million peripheral blood mononuclear cells.

Negative and Positive Controls

αTRECs are not present in CEM, HUT78, MT2, and other T-cell lines (reference 24 and our unpublished data). DNAs prepared from these cell lines in parallel with test samples are used as a negative control for TREC PCR. Buffer blanks are used as additional negative controls.

For the production of a cloned standard for TREC quantitation, the primers SJ1 and SJ2 are used to amplify TREC sequences from 0.1 to 0.5 μg of peripheral blood mononuclear cell DNA (40 cycles of amplification under the conditions described above). The 395-bp product of this amplification is extracted from an ethidium bromide-stained 1.2% agarose gel and ligated into a TA cloning vector (Invitrogen Corp., Carlsbad, Calif.) according to the manufacturer's specifications. The product should be sequenced to determine that it contains the features of a signal joint and a sequence matching the primers SJ1 and SJ2 (5, 22, 24). Once the sequence has been confirmed, the plasmid is digested with EcoRI to release the fragment, which is purified by gel electrophoresis and diluted in tRNA (prepared at 10 μg/ml in TE buffer [10 mM Tris-HCl, pH 8.0, 1 mM EDTA]) or salmon sperm DNA (20 μg/ml) to produce a set of standards at known concentrations. For the radioisotope-labeled PCR approach, we use standards for the range of 10^1 to 10^4 TREC copies/5 μl. For the real-time PCR method, we use 10-fold dilutions covering the range of 10^1 to 10^6 TREC copies/5 μl.

Technical Pitfalls

As with any PCR-based assay, extreme caution must be applied to minimize the possibility of contamination of reagents, micropipettes, and other equipment with DNA carried over from a prior amplification or DNA from the standards. The accurate quantitation of TREC molecules necessitates that the cloned standard be prepared by using plasmid DNA that has been fastidiously prepared and carefully quantified by spectrophotometry. In particular, the optical density at 260 nm of the plasmid standard stock should be measured at several dilutions prior to the preparation of standards. The input DNA in cell lysates should be quantified, especially if cells cannot accurately be counted prior to preparation of the lysate. The concentration of cellular DNA

can be determined by PCR quantitation of β-globin or CCR5 gene sequences, as described above.

Interpretation

The methods described above yield reproducible data over a broad dynamic range. High TREC concentrations have been associated with changes in T-cell populations after the transplantation of thymic tissue in patients with DiGeorge syndrome and, in some cases, after HAART for HIV infection (5, 17, 24). Moreover, recent data suggest that TREC values may prove to be a useful predictor of disease progression for HIV infection (9). Nonetheless, TREC data must be interpreted with caution. Physiological changes and pathophysiological processes that alter T-cell proliferation and survival are likely to affect this parameter of thymic output (11, 12).

Measurement of NK-Cell Activity in Humans

THERESA L. WHITESIDE

34

Natural killer (NK) cells comprise a morphologically distinct subset of lymphocytes which have the capability to spontaneously kill virally infected or transformed targets but spare most normal cells (7). Recent studies have indicated that NK cells are capable of mediating the killing of susceptible targets by several distinct mechanisms, of secreting a broad spectrum of cytokines, and of extravasating as well as entering tissue sites, including premalignant and malignant tissues (8). In contrast to other immune effector cells, e.g., T lymphocytes, NK cells mediate cytotoxicity under conditions that do not require prior immunization or antigen sensitization (7). The process of target recognition by NK cells seems to involve unique sets of receptors present on the NK-cell surface, including "killing inhibitory receptors" (KIRs), which interact with major histocompatibility complex (MHC) ligands, and NK-cell-activating receptors (NKARs) interacting with non-MHC ligands on target cells (Fig. 1).

The NK cell recognizes a "self" peptide complexed with MHC class I molecules on the surface of a target cell and turns off its lytic machinery. In other words, the NK cell is poised not to kill "self"; the NK cell is only able to kill its target when an inhibitory signal is absent, especially when its activating receptors are signaling (Fig. 1). Ligands for activating C-type lectin-like receptors (e.g., NKG2D and CD94/NKG2) or natural cytotoxicity receptors (e.g., NK p30, NK p44, and NK p46) are expressed by target cells that are susceptible to NK cell lysis (2, 6). For example, many tumor cell targets susceptible to NK-cell-mediated cytotoxicity express NK-cell-activating ligands such as the MHC class I chain-related molecules MICA and MICB or UL-16 binding proteins, which bind to NKG2D receptors on NK cells (6). Tumors that down-regulate MICA and MICB expression tend to be resistant to NK-cell-mediated lysis. This highly sophisticated receptor-driven recognition system ensures that normal cells are spared and only targets that are altered are eliminated. The alterations that may be recognized by NK cells and result in lysis typically involve a down-regulation or loss of MHC class I molecules, which often occurs in tumor cells or virally infected targets. Also, genetic changes that are likely to lead to the expression of new antigens on the cell surface or to a reduction or absence of self epitopes on target cells are recognized by NK cells. Therefore, the killing of susceptible targets by NK cells is a highly regulated process involving negative signaling by KIRs, which recognize specific self peptides in the context of MHC class I molecules, as well as positive signaling by NKARs upon interaction with their ligands (Fig. 1). In short, NK cells discriminate between normal and abnormal targets by balancing positive and negative signals through their activating and inhibitory receptors. It is important, however, that cytokine-activated NK cells (e.g., lymphokine-activated killer [LAK] cells) lose this selectivity in killing, and by bypassing negative signals, proceed to kill a broad array of target cells. Also, NK cells express a variety of the tumor necrosis factor family ligands and up-regulate these molecules upon activation, so in addition to perforin- and granzyme-mediated lysis, they are capable of inducing apoptosis in targets endowed with corresponding death receptors, such as FasR, TRAILR, and TNFR1 (5).

The role of NK cells in innate immunity has been well recognized. Recent data suggest that in addition to their lytic functions, NK cells are involved in a variety of biologically important pathways, which include facilitating hematopoiesis, modulating neuroimmunologic processes, mediating immunoregulation, influencing fetal development, and engaging in interactions with a variety of tissue cells at the site of tumor growth or tissue injury (7, 8). The biologic importance of NK cells provides a strong rationale for measuring their numbers and function during health and disease. In most cases, NK activity is determined in the peripheral blood and only rarely in the target tissue, largely because it is difficult to isolate NK cells from diseased tissues in humans. In rare instances when this was done, information about tissue-infiltrating NK cells indicated that substantial phenotypic and functional differences may exist between circulating and tissue-infiltrating human NK cells (8). For example, NK cells residing in the liver are activated and have the phenotype of LAK cells, while NK cells isolated from tumors are functionally impaired (8). NK cells present in the peripheral circulation of healthy donors are in the resting stage, although during disease NK activity is frequently altered, and the extent of this alteration may be of clinical and scientific importance.

CONCEPT

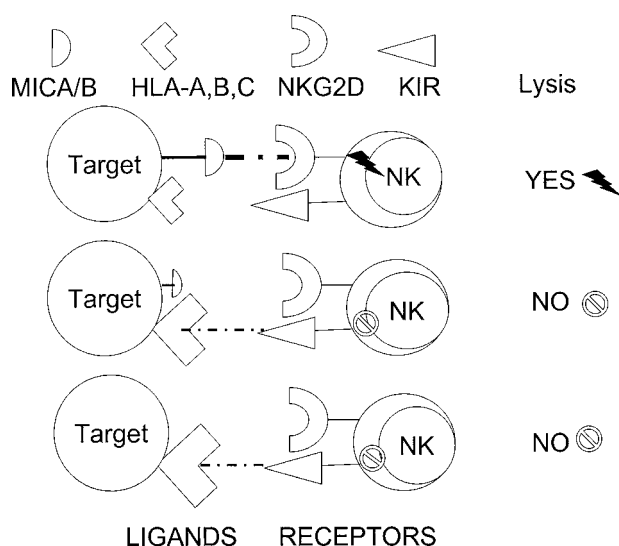
Although many modifications of assays measuring NK activity have been developed recently, the 4-h ^{51}Cr-release assay using K562 leukemia cells as targets still remains a prototype NK-cell assay. Many of the newer cytotoxicity assays are


FIGURE 1 Interactions between NK cells and targets that are NK-cell sensitive or resistant. Targets expressing NK-cell-activating ligands, such as MICA and MICB, in conjunction with a down-regulated expression of HLA-A, -B, and -C molecules are sensitive to killing by NK cells expressing inhibitory receptors (KIRs) and activating receptors (NKARs), such as NKG2D. However, targets that have lost the expression of MICA and MICB and express normal levels of HLA-A, -B, and -C are resistant to lysis by NK cells. Positive and negative signals resulting in target cell lysis and the absence of lysis, respectively, are indicated.

based on flow cytometry and are nonradioactive. Therefore, they may be preferable to ^{51}Cr-release assays. However, these newer procedures have not been validated by comparisons with the ^{51}Cr-release assay and are not uniformly accepted. For these reasons, the ^{51}Cr-release assay is described here in detail, with a focus on its reliability, reproducibility, and result interpretation. The assay involves the coincubation of effector cells with ^{51}Cr-labeled target cells in triplicate wells of a 96-well microtiter plate at various effector-to-target (E:T) ratios, followed by the determination of levels of radioactivity released from lysed target cells into the supernatants. It is essential to emphasize that this assay measures just one of many NK-cell functions and that it may not be the best or even the most biologically relevant assay available today. Nevertheless, until the flow-based multiparameter assays are validated, the ^{51}Cr-release procedure remains the "gold standard." It has been the most widely used assay, and much experience has accumulated to define its attributes and limitations. In combination with flow cytometry for the enumeration of cells expressing the NK-cell phenotype, the assay can provide a quantitative estimate of NK-cell function during human health and disease.

PROCEDURES

Sample Requirements

About 10 ml of heparinized venous blood (one full green-top Vacutainer tube) or suspensions of NK cells isolated from body fluids or tissues are needed for NK-cell enumeration and assay. This translates into 10×10^6 peripheral blood mononuclear cells (PBMC), which are recovered by Ficoll-Hypaque centrifugation performed under standard conditions. More

venous blood should be obtained from individuals who are leukopenic. Blood should be drawn in the morning to avoid diurnal variation and should be processed as soon after phlebotomy as possible. Blood samples that are shipped to a reference laboratory require special handling: an overnight carrier must be used and specimens traveling in ambient (25°C) temperature must reach their destinations within 24 h of collection.

The NK-cell assay must be performed with fresh, not cryopreserved, cells. The cryopreservation of effector cells, even when performed under optimized conditions and using a rate-control freezing device, significantly and unpredictably decreases NK activity. We have compared the NK activities of fresh and cryopreserved PBMC from the same individuals and have encountered differences as large as 100%, although PBMC from certain individuals can be cryopreserved without such losses in cytolytic function. Since one cannot a priori decide or predict the degree of such loss, either freshly separated PBMC or NK cells freshly separated from body fluids or tissues are used as effector cells in this assay.

Materials and Reagents

Effector cells: PBMC or NK cells separated from heparinized body fluids

RPMI medium supplemented with 5% (vol/vol) fetal bovine serum, referred to as RPMI-5

Trypan blue solution for viable cell counts

5 mCi of Na^{51}CrO$_4$/ml (specific activity, 250 to 900 mCi/ml)

Suspension of ^{51}Cr-labeled K562 cells in RPMI-5 medium containing 5×10^4 cells/ml

5% (vol/vol) solution of Triton X-100 in phosphate-buffered saline

10-ml round-bottomed polypropylene snap-cap tubes

96-well round-bottomed sterile microtiter plates (e.g., Costar)

15-ml conical polypropylene tube

1-ml tuberculin syringe with 25-gauge needle

Equipment and Instrumentation

Eight-channel micropipettor capable of delivering 100-μl aliquots

Disposable micropipette tips

Sorvall RT-6000 centrifuge with H-1000B rotor (or equivalent) and microplate carriers

Gamma scintillation counter and counting tubes

An area designated for radioisotope use and disposal of ^{51}Cr

Procedure

1. For each effector cell suspension to be tested, determine the number of viable cells by trypan blue exclusion. Transfer each cell suspension to a separate 10-ml round-bottomed polypropylene snap-cap tube, and by using RPMI-5 medium warmed to room temperature, adjust the suspension to have a cell concentration appropriate for achieving the desired starting E:T ratio. The E:T ratio will vary depending on the potency of the effector cells. If resting NK cells (e.g., in PBMC) are tested, then a starting E:T ratio of 50:1 is recommended. In this case, the suspension of PBMC should be adjusted to 2.5×10^6 cells/ml. For LAK cells, the starting E:T ratio may be 6:1, and the starting cell suspension should be adjusted to 3.125×10^5 cells/ml.

2. Gently vortex the first starting suspension of effector cells. Deliver 200 μl of the suspension into each of triplicate wells in row B (B1, B2, and B3) of a microtiter plate. Follow the same procedure with all other starting suspensions, placing cells in triplicate wells in rows C to H. Up to seven different effector cell suspensions can be tested in one microtiter plate. Be careful to label each row carefully to identify the starting cell suspension. Row A is used for preparing control wells.

3. To each of the wells in columns 4 to 12 of rows B to H, add 100 μl of RPMI-10 medium, using an eight-channel micropipettor with seven tips attached.

4. Using the eight-channel micropipettor with seven tips attached, remove 100-μl aliquots from well 1 in rows B to H and transfer them to well 4 in rows B to H. Mix thoroughly by pipetting up and down with the micropipettor, remove 100-μl aliquots, and transfer them to well 7 in rows B to H. Mix thoroughly, remove 100-μl aliquots, and transfer them to well 10 in rows B to H. Mix thoroughly, remove 100-μl aliquots from well 10, and discard. Repeat this serial twofold dilution process for well 5 in rows B to H, with transfers of 100-μl aliquots to wells 8 and 11. Then, starting with well 6 in rows B to H, transfer 100-μl aliquots to wells 9 and 12. Note that it is not necessary to change pipette tips while performing these twofold dilutions of effector cells. This format allows for the testing of four different E:T ratios, with each tested in triplicate, as follows: 50:1 in wells 1 to 3, 25:1 in wells 4 to 6, 12.5:1 in wells 7 to 9, and 6.25:1 in wells 10 to 12.

5. Using the micropipettor with eight fresh tips attached, add 100 μl of target cell suspension to each well in rows A to H. Target cells are labeled with ^{51}Cr prior to the NK-cell assay (see below).

6. Add 100 μl of RPMI-5 medium to wells 1 to 6 in row A (spontaneous release controls) and then add 100 μl of Triton X solution to wells 7 through 12 in row A (maximal release controls).

7. Cover the microplate with a lid and centrifuge it for 3 min at $200 \times g$ (1,000 rpm in an H-1000B rotor with a microplate carrier) at room temperature without using a brake. Transfer the microplate to a humidified 37°C CO$_2$ incubator (5% CO$_2$ in air) and incubate it for 4 h.

8. After the incubation, remove 50 or 100 μl of the supernatant (without disturbing the cell pellet!) from each well by using the eight-channel micropipettor. Transfer the supernatants to prelabeled counting tubes. A cell harvesting system (e.g., Skatron) can be used and is recommended.

9. Measure the radioactivity in each harvested supernatant (from all control and experimental wells) by using a gamma counter.

10. Calculate the percent specific lysis (activity of NK or LAK cells) according to the following formula:

$$\% \text{ specific lysis} = 100 \times \frac{(\text{mean experimental cpm} - \text{mean spontaneous-release cpm})}{(\text{mean maximal-release cpm} - \text{mean spontaneous-release cpm})}$$

Labeling of Target Cells with ^{51}Cr

Cultured tumor cells such as K562 cells or a leukemia cell line should be in the logarithmic phase of growth. The cell viability is always checked by trypan blue exclusion prior to labeling and should be ≥75%.

1. On the day of the assay, determine the number of viable tumor cells and transfer 2×10^6 to 10×10^6 viable cells to a 15-ml conical polypropylene tube. Centrifuge the cells for 5 min at $200 \times g$ (1,000 rpm in a Sorvall RT 6000 centrifuge with an H-1000B rotor) at room temperature. Decant the supernatant.

2. By using a 1-ml tuberculin syringe with a 25-gauge needle, transfer an aliquot of 5-mCi/ml Na$_2^{51}$CrO$_4$ containing 100 μCi of ^{51}Cr to the cell pellet. For best results, a ^{51}Cr solution that is no more than 1 to 2 weeks past its maximum activity date should be used.

3. Mix the cells gently and incubate them for 1 h at 37°C in a 5% CO$_2$ incubator. Rotate the tube gently every 15 min to mix the cells.

4. Wash the cells at least twice, each time adding 10 ml of RPMI-5 medium, centrifuging the mixture for 5 min at $200 \times g$, and then decanting the supernatant into a radioactive liquid waste container. Finally, suspend the cells in 10 ml of RPMI-5 medium.

5. Determine the number of viable cells by using trypan blue exclusion, adjust the concentration of cells to 5×10^4/ml, and then check the radioactivity of the labeled cells by placing 0.1 ml of the final cell suspension into a vial or tube and counting for 1 min with a gamma scintillation counter. Labeling is satisfactory when the cell suspension incorporates 0.2 to 1.5 cpm per cell.

Controls

The NK-cell assay includes several different types of controls, as follows:

Assay controls: maximal-^{51}Cr-release controls and spontaneous-^{51}Cr-release controls (see above).

Intra-assay controls: fresh PBMC from a healthy donor are tested in row B as well as row H.

Interassay controls: cryopreserved, thawed, and pretested PBMC from three different selected healthy donors, who are known to have low, medium, and high levels of NK activity and whose PBMC cryopreserve well, are tested every time the assay is performed. These three cell samples are monitored for NK activity over weeks or months, providing a measure of the assay's reproducibility.

Biologic variability controls: fresh PBMC from the same healthy donors are obtained repeatedly at various time intervals and used to chart the biologic variability in NK-cell activity over time.

Quality Control and Quality Assurance

Criteria for an acceptable NK-cell assay are defined on the basis of intra-assay and interassay variability, which must be established for every laboratory. For an NK-cell assay to be accepted or rejected, a quality control program has to be in effect. This program should involve the following components:

The definition of intra-assay as well as interassay variability, based on the continually monitored performance of fresh as well as cryopreserved control cells, as described above.

Continued maintenance and frequent (every 6 months) analysis of the control cell performance to confirm that the assay is in control.

Strict adherence to the standard operating procedure (SOP) and written documentation of changes that may be introduced.

The formulation and availability of written criteria for assay acceptance or rejection.

The establishment of a proficiency program, with an exchange of samples between several laboratories.

Quality assurance for the NK-cell assay is particularly important. Handling of samples and the quality of effector cells are likely to have a major impact on the results. Therefore, it is essential to document in writing any departure from the SOP for sample collection or delivery to the testing laboratory as well as from the SOP for assay performance. Quality assurance is also concerned with the quality of target cells and their ability to spontaneously release the radioactive label. Cultured K562 cells must be in the logarithmic phase of growth to perform optimally as target cells. Radioactivity counts depend on the gamma counter's performance, and thus routine maintenance checks and control radioactive counts need to be regularly performed and documented in writing.

Pitfalls and Troubleshooting

NK-cell assays are not easy to perform reliably, and they require considerable effort to implement and interpret. The most difficult single problem with cytotoxicity assays employing tumor cell targets is the unacceptably high level of spontaneous release of ^{51}Cr (i.e., >5%). While careful culturing and frequent splitting of nonadherent K562 target cells to maintain them in the logarithmic phase of growth tend to control the problem, it is likely that it will appear periodically. We tend to resort to a newly thawed batch of cryopreserved target cells to correct this problem. A new batch of target cells is put in culture at about 2- to 3-month intervals. It is also important to perform mycoplasma assays on K562 target cells with regularity to avoid artifacts due to mycoplasma infections. The second perennial problem is a lack of assay reliability from day to day, which originates from unpredictable losses in NK activity. Such losses may be due to specimen handling, including the time elapsed between the cell harvest and testing, or to biologic variability, which cannot be controlled. For a number of healthy donors tested for NK activity repeatedly over a period of several months in our laboratory, significant biologic variability was observed. For this reason, designations of low, normal, or high NK activity for an individual should be based on three, not one, assays performed over time. In clinical trials, patients generally serve as their own baseline controls, and drug-related changes from the baseline are computed. Samples for NK activity assays are drawn in the morning to avoid diurnal variations. Samples arriving at the laboratory after an overnight shipment need to be processed and tested immediately. Shipments should be carried out in ambient temperatures, and green-top tubes, not separated mononuclear cells in medium, should be shipped. There is generally a loss of NK activity in specimens shipped or stored overnight, which varies from 10 to 25%. It is best to avoid shipping and to perform NK-cell assays on freshly harvested morning specimens, adhering as strictly as possible to the SOP. The third common problem concerns the interpretation of results. NK-cell assays performed at a single E:T ratio are not meaningful. At least four E:T ratios should be included in the assay to allow for the construction of a lytic curve defining a relationship between the percent specific lysis and the E:T ratio. For acceptable NK-cell assays, this curve is linear.

Interpretation

While the results of NK-cell assays are expressed as percentages of specific lysis at various E:T ratios, it is more convenient to present these results in lytic units (LU). This type of data transformation is especially useful when comparisons between the levels of lysis mediated by different effector cells tested at multiple E:T ratios are performed. Instead of comparing lytic curves, which is inconvenient, it is possible to transform the specific lysis data into a single number which accurately reflects the ability of a batch of effector cells to kill 20% of a predetermined number of target cells (4). A computer program for the calculation of LU is available from the reference laboratories engaged in NK-cell measurements, or LU can be calculated manually as described by Bryant et al. (1). Briefly, an LU is defined as the number of effector cells required to lyse a specific percentage, usually 20%, of a predetermined standard number (T_{STD}) of target cells (e.g., the T_{STD} could be 5×10^3). Assume that 20% lysis of 5×10^3 target cells occurs at the 12:1 E:T ratio. Multiplying this E:T ratio by the number of targets in the assay (5,000) shows that 6.0×10^4 effectors are required to lyse 20% of the targets. Thus, one LU consists of 6.0×10^4 effector cells. However, to allow a measure of lytic activity that increases with the level of cytotoxicity, the results are generally reported as the number of LU contained in a specified number of effector cells (E_{STD}); commonly, E_{STD} is chosen to equal 10^7 effector cells. These calculations can be expressed by the following formula:

$$\text{number of LU}/10^7 \text{ effector cells} = \frac{E_{STD}}{\left(E{:}T_{20}\right)\left(T_{STD}\right)}$$
$$= \frac{10^7}{\left(E{:}T_{20}\right)\left(5 \times 10^3\right)}$$

where $E{:}T_{20}$ is the E:T ratio at which 20% of the target cells are killed.

The results of NK-cell assays performed with PBMC cannot be adequately interpreted unless a simultaneous estimation of the absolute number of NK cells present in the peripheral circulation is made and the results are expressed on a per-NK-cell basis. This is because the NK-cell assay does not discriminate between a high level of lytic activity mediated by a few NK cells and one mediated by many NK cells that are present in a particular batch of PBMC tested for NK activity. By the same token, the enumeration of NK cells in the circulation is not indicative of NK activity. Few NK cells can be highly effective at mediating lysis, and many NK cells may have only weak activity. Thus, assays of NK activity should be accompanied by NK-cell enumeration. A simultaneous measure by flow cytometry of the percentage of CD56$^+$ CD16$^+$ NK cells in the PBMC followed by a calculation of their absolute number (for which the white blood cell and differential lymphocyte counts must be available) is necessary to be able to express the units of NK activity per NK cell. Alternatively, fluorospheres (Flow-count fluorospheres; Beckman Coulter, Miami, Fla.) can be used to determine by flow cytometry the absolute number of CD56$^+$ CD16$^+$ NK cells among the PBMC present in the assay. Results presented in LU per NK cell are more meaningful than those expressed either as the percent specific lysis or LU alone, because they account for the actual number of NK cells responsible for the measured activity. In my laboratory, NK activity and NK-cell enumeration are offered as a panel, and both are routinely performed on all specimens. Of course, when the assay is performed with purified NK cells, this calculation is unnecessary.

NK cells can be subdivided into two functionally distinct populations on the basis of CD56 and CD16 expression on the cell surface (3). Approximately 90% of NK cells are CD56^{dim} CD16^{bright}, express abundant KIRs, and are highly cytotoxic. The remaining 10% are CD56^{bright} CD16$^{dim/neg}$. These NK cells

have the ability to produce high levels of immunoregulatory cytokines, such as tumor necrosis factor alpha, but express few KIRs and are poorly cytotoxic. This phenotypic and functional heterogeneity of NK cells probably reflects their various maturation stages, and it considerably complicates the analysis of the NK-cell repertoire during disease, where one or another NK-cell subset may be preferentially expanded. The clinical significance of the two NK-cell subsets may be that CD56[dim] cells represent cytotoxic effector cells, while CD56[bright] NK cells play an immunoregulatory role due to their ability to produce cytokines (3).

NK activity may vary substantially among healthy individuals, and therefore it is necessary to establish a normal range of NK activity by testing PBMC from many different donors who are presumably representatives of the general population in a particular geographic area. For example, in my laboratory, a mid-80% range for normal NK activity is 53 to 301 $LU_{20}/10^7$ cells based on 140 individual determinations. While establishing a normal range for NK activity, it is important to consider both the age and sex of the blood donors. Generally, NK activity in males is significantly higher than that in females (i.e., males [$n = 49$] have a median activity of 201 $LU_{20}/10^7$ cells, while females [$n = 103$] have a median activity of 115 $LU_{20}/10^7$ cells), as determined in my laboratory. There is some statistical evidence that NK activity increases with age, but in my laboratory, this trend is not significant. In an individual, the level of NK activity tends to be stable over time, provided that this individual remains healthy and is not experiencing severe or prolonged stress or taking medications known to alter NK activity.

CONCLUSIONS

Measurements of NK activity are difficult to perform in a clinical laboratory setting. They require considerable expertise, constant vigilance, and extensive quality control and quality assurance. Consequently, the assay is relatively costly. While the use of transformed data simplifies interpretation, it also creates concerns about data manipulation. The format of data presentation may vary from one institution to another, and minor variations in the SOP might account for the lack of interlaboratory agreement. There is no NK-cell proficiency program in effect, and each laboratory is responsible for defining its own criteria for assay acceptance or rejection.

A variety of nonradioactive assays have been developed to measure NK activity, as alluded to earlier. These assays measure either secretory-type killing, and thus may be equivalent to the ^{51}Cr-release assay, or nonsecretory killing (apoptosis), which can also be mediated by NK cells (9). The results of the latter tend not to correlate with those of ^{51}Cr-release assays. On the other hand, when ^{51}Cr-release assays have been used for serial monitoring, relatively poor correlations between NK activity and clinical responses have been observed in many cases. This is not surprising in view of the current knowledge about NK cells. These effector cells can perform multiple functions, utilize more than one mechanism of killing to eliminate susceptible targets, and secrete multiple cytokines upon activation. Therefore, the biologic relevance of any one in vitro assay for NK activity is not clear at present, and future measurements of NK activity are likely to include assays for measuring a broader range of NK-cell functions.

Cellular Immune Assays for Evaluation
of Vaccine Efficacy

JOSEPHINE H. COX, MARK deSOUZA, SILVIA RATTO-KIM, GUIDO FERRARI,
KENT J. WEINHOLD, AND DEBORAH L. BIRX

35

It is estimated that routine immunization with currently licensed vaccines against polio, diphtheria, whooping cough, tetanus, and measles could prevent 3 million annual deaths worldwide. Tuberculosis (TB), malaria, and human immunodeficiency virus (HIV), for which no effective vaccines are available, are responsible for 7 million deaths per year worldwide. Most of these deaths occur in developing countries, where the economic impact of endemic diseases is immense and the need for vaccines is most pressing. Vaccines for approximately 100 different bacterial and viral organisms are currently under development, with current progress ranging from basic research and development through phase I to III clinical trials (23, 49).

Vaccine development now increasingly draws on the expanded understanding of the immune mechanisms involved in preventing or controlling viral, bacterial, and parasitic infections (13). In the 20th century, successful vaccines were produced against many acute viral and bacterial infections. The challenge facing current vaccinologists is how to develop vaccines to control chronic persisting or recurrent diseases like TB and HIV, hepatitis C virus, and human papillomavirus infections (3). A greater understanding of the immune response, particularly of cell-mediated immune responses in malaria, TB, HIV, and cancer patients, will lead to improved vaccine design (2, 5, 26, 36, 37, 52). Currently, in vitro analyses of cellular immune responses are being used for assessments of the efficacy of therapeutic and prophylactic vaccines, for clinical diagnosis, and for studies of immune regulation (21, 34, 41, 53, 56, 57).

Concurrent with progress in vaccine design, there is a need for sophisticated cellular immunologic testing at specialized centralized laboratories, at clinical sites involved in vaccine trials, or on-site in developing countries. There has been a dramatic increase in the number of countries and institutions involved in vaccine trials in the past 5 years (34, 37, 54). Both privately and publicly funded organizations have focused some of their primary efforts toward a worldwide approach for testing vaccines.

With the increase in institutions involved in vaccine testing, there is a need for collaborative efforts that focus on the reproducibility of measuring immune responses across organizations. Previously, cellular assessments of immunity were performed with nonstandardized reagents and with protocols that were different from laboratory to laboratory. As a consequence, performance characteristics differed from laboratory to laboratory, making it almost impossible to compare the immunogenicity of one vaccine to that of another. In a study of 11 laboratories that used standard operating procedures and common reagents, there was a larger-than-expected discordance in the outcome of an enzyme-linked immunospot (ELISPOT) assay (11). The publicly funded Partnership for AIDS Vaccine Evaluation (PAVE [www.hiv-pave.org]) and the privately funded Enterprise organization (www.glf.org) are organizations leading the effort toward the standardization of cell processing, sample storage, and immunogenicity assessments at the preclinical and clinical stages of vaccine development (27). The requirements for standardizing cellular immunology assays, cell processing, and cell freezing are seen as necessities by various regulatory agencies because they will allow quicker interagency and interlaboratory comparisons for making the best informed decisions on which candidate vaccines will be worth sponsoring for advanced development. Table 1 lists organizations involved in validating immunogenicity assays for human vaccine trials. The transfer of technically demanding assays to developing countries is necessary, or alternatively, samples need to be processed, stored, and then shipped to central laboratories for testing. This chapter was compiled by authors who have been involved in HIV vaccine testing for 15 years and have been collaborating with or have worked in laboratories in both developed and developing countries.

PROCESSING AND COLLECTION OF PBMC FROM WHOLE BLOOD

The assessment of T-cell function may be affected by procedures, beginning with the blood draw and through cell separation, cryopreservation, storage, and thawing prior to the assays. Additionally, the time from blood collection to actual processing for lymphocyte separation is critical. Different procedures for collection and separation of peripheral blood mononuclear cells (PBMC) are shown in Table 2, along with their potential advantages and disadvantages.

When conducting cellular immunology assays, the integrity of the PBMC, especially the cellular membranes, is critical for success. A correct cellular separation process yields a pure, highly viable population of mononuclear cells consisting of lymphocytes and monocytes, with minimal red blood cell and platelet contamination, that retains optimum functional capacity. The standard method for the separation

TABLE 1 Organizations involved in validating immunogenicity assays for human vaccine trials

Organization	Website	Role
British Association of Research Quality Assurance	www.barqa.com	Assists in the understanding, interpretation, and implementation of national and international regulations covering good laboratory practice (GLP), good clinical practice (GCP) and good manufacturing practice (GMP).

Clinical and Laboratory Standards Institute (formerly NCCLS)	www.clsi.org	Nonpartisan body that facilitates the development and availability of useful, accurate medical services, including criteria for validating immunogenicity assays.
National Association of Testing Authorities, Australia	www.nata.asn.au	Australia's GLP compliance monitoring authority; a private, nonprofit company owned and governed by its members and by representatives from industry, government, and professional bodies.

of PBMC is the use of Ficoll-Hypaque gradients, as originally described by Boyum (6). A high degree of technical expertise is required to execute the procedure. Two new types of collection vessels that are available commercially have greatly simplified PBMC separation and are applicable for vaccine studies because of their ease of use and potential for automation (10).

Protocol 1. Separation of PBMC by Using CPTs

Vacutainer cell preparation tubes (CPTs; Becton Dickinson [http://www.bd.com/vacutainer/products/molecular/citrate/procedures.asp]) provide a convenient, single-tube system for the collection and separation of mononuclear cells from whole blood. Blood is drawn into the CPT and can be immediately centrifuged, allowing the gel to form a stable barrier between the anticoagulated blood and Ficoll. The

separated blood can then be transported at ambient temperature to the processing and/or storage laboratory. This step reduces the risk of sample contamination and eliminates the need for additional tubes and processing reagents. In many instances, in particular when biosafety level 2 safety cabinets are not available on-site, the CPT method is useful because the centrifugation step can be done on-site and the remaining processing steps can be performed after shipment to a central laboratory within the shortest time possible, optimally within 8 h. The central laboratory can complete cell processing in a biosafety level 2 cabinet and set up functional assays or cryopreserve the samples as needed. The simplicity of the CPT separation method gives it superior technical reliability in our hands over the Ficoll-Hypaque method and is the method of choice for our phase III vaccine trial in Thailand, despite the increased cost associated with the

TABLE 2 Stages and variables in the separation and cryopreservation of PBMC from whole blood

Procedure or technology	Equipment or reagent	Advantage(s)	Disadvantage(s)
PBMC collection	Heparin	Greater cellular stability than EDTA	Impacts DNA isolation; plasma from whole blood cannot be used for PCR-based assays
	EDTA		Time-dependent negative impact on T-cell responses
	Sodium citrate	Greater cellular stability than EDTA	
PBMC separation	Standard Ficoll		Technically challenging, time-consuming
	CPTs	Rapid, technically easy, with less interperson variability; blood is drawn into the same tube that is used for separation	Subject to temperature fluctuations manifested by gel deterioration and contamination in PBMC fraction
	Accuspin or Leucosep tubes	Rapid, technically easy, with less interperson variability	
PBMC cryopreservation	Nalgene "Mr. Frosty" freezer	Cheap, technically easy	Lack of ability to monitor temperature
	Controlled-rate freezer	Accurate temperature control; the temperature is monitored and recorded	Expensive, requires a supply of LN
Counting	Hemacytometer	Cheap	Subjective counting procedure
	Automated counter	Accurate	Some automated counters do not have the capacity to count viable cells; expensive

method. The CPT method reduces interperson variability related to removing the PBMC layer from Ficoll and thus allows for uniformly higher cell yields.

Note that CPTs are sensitive to excessive temperature fluctuations, resulting in deterioration of the gel, which impacts successful cellular separation. This is a particularly serious problem in tropical countries, where ambient storage temperatures may be >25°C. Following PBMC separation, one may macroscopically observe the presence of gel spheres in the cellular layer which are very difficult to distinguish from the actual PBMC. This has been observed after storage at temperatures of >25°C. Where possible, the tubes should be stored at temperatures no higher than 25°C. Once the tubes are filled with blood, the temperatures should be kept between 18 and 25°C. Blood-filled CPTs should under no circumstances be stored on ice or next to an ice pack. It is recommended that they be separated from any ice packs by bubble wrap or another type of insulation within a cooler so that temperature fluctuations are kept to a minimum.

Materials and Reagents

Vacutainer CPTs (Becton Dickinson)

Sterile phosphate-buffered saline (PBS) without Ca^{2+} and Mg^{2+}, supplemented with antibiotics (penicillin and streptomycin)

Sterile RPMI medium containing 2% fetal bovine serum (FBS) and supplemented with antibiotics

Method

Specimens should be centrifuged as soon as possible after collection. The manufacturer recommends that the initial centrifugation step (see below) to separate the lymphocytes should occur within 2 h. The plasma and leukocytes, which are then separated from the red blood cells by the gel barrier, can be mixed by inversion, and processing should be completed within 8 h of the first centrifugation. The specimens should be put into a cooler box and transported at room temperature (18 to 25°C) to the processing laboratory.

1. Spin tubes at room temperature (18 to 25°C) in a horizontal rotor (with a swinging-bucket head) for a minimum of 20 min and a maximum of 30 min at a relative centrifugal force (RCF or g) of 1,500 with the brake off. To calculate the revolutions per minute (rpm), use the following calculation, where r is the radial distance from the centrifuge's center post to the tube bottom (in centimeters):

$$\text{rpm speed setting} = \sqrt{\frac{RCF \times 100,000}{1.12 \times r}}$$

2. Remove the tubes from the centrifuge and pipette the entire contents of each tube above the gel into a 50-ml tube. This tube will now contain both PBMC and undiluted plasma. An additional centrifugation step will allow the removal of undiluted plasma, if desired. Wash each CPT with 5 ml of PBS–1% penicillin–streptomycin (Pen/Strep). This wash step will remove cells from the top of the gel plug. Combine these cells with the cells removed from the tube. This wash increases the yield of cells as much as 30 to 40%.

3. Spin down this tube at 1,600 rpm for 15 to 20 min at room temperature with the brake on.

4. Resuspend the PBMC pellet in RPMI with 2% FBS, and wash it one more time to remove contaminating platelets. PBMC are counted and cryopreserved or used, as required.

Protocol 2. Separation of PBMC by Using Accuspin or Leucosep Tubes

More recently, Leucosep and Accuspin tubes have become available. Further information on Leucosep tubes is available at www.gbo.com, and information on Accuspin tubes is available at www.sigmaaldrich.com; the working principles of these tubes are the same. The tubes are separated into two chambers by a porous barrier made of highly transparent polypropylene. This biologically inert barrier allows the elimination of the laborious overlaying of the sample material over Ficoll. The barrier allows the separation of the sample material added to the top from the separation medium (Ficoll added to the bottom). The tubes are available in two sizes (15 and 50 ml) and may be purchased with or without Ficoll. There is an advantage of buying the tubes without Ficoll in that they can be stored at room temperature rather than refrigerated. This may be an important problem if cold space is limiting or the cold chain is difficult; also, the expiration date of the Ficoll will not affect the tube expiration. The following procedure describes the separation method for Leucosep tubes that are not prefilled with Ficoll-Hypaque. The Accuspin procedure is virtually identical.

Note that whole blood can be diluted 1:2 with a balanced salt solution. While this dilution step is not necessary, it can improve the separation of PBMC and enhance the PBMC yield. The procedure is performed by using aseptic technique.

Materials and Reagents

Accuspin or Leucosep tubes

Ficoll-Hypaque

Sterile PBS without Ca^{2+} and Mg^{2+}, supplemented with antibiotics (Pen/Strep)

Sterile RPMI medium containing 2% FBS and supplemented with antibiotics

Method

1. Warm the separation medium (Ficoll-Hypaque) to room temperature and keep it protected from light.

2. Fill the Leucosep tubes with separation medium, using 3 ml for 14-ml tubes and 15 ml for 40-ml tubes.

3. Close the tubes and centrifuge them at 1,000 $\times$ g (see protocol 1 for g-to-rpm conversion) for 30 s at room temperature.

4. Pour whole blood or diluted blood into the tubes, using 3 to 6 ml for 14-ml tubes and 15 to 30 ml for 50-ml tubes.

5. Centrifuge the tubes for 10 min at 1,000 $\times$ g or for 15 min at 800 $\times$ g in a swinging-bucket rotor with the centrifuge brake off.

6. After centrifugation, the sequence of layers from top to bottom should be as follows:
   1. Plasma and platelets
   2. Enriched PBMC fraction
   3. Separation medium
   4. Porous barrier
   5. Separation medium
   6. Pellet (erythrocytes and granulocytes)

7. Plasma can be collected to within 5 to 10 mm of the enriched PBMC fraction and further processed or stored for additional assays.

8. Harvest the enriched PBMC, wash them with 10 ml of PBS containing 1% Pen/Strep, and centrifuge them at 250 $\times$ g for 10 min.

9. Resuspend the PBMC pellet in RPMI with 2% FBS and wash it one more time to remove contaminating platelets. PBMC are counted and cryopreserved or used, as required.

EFFECT OF CELL SEPARATION AND ANTICOAGULANT ON LYMPHOCYTE SUBTYPES

We conducted experiments to determine the effect of the time from blood draw to processing on cell subsets within the white blood cell component and on PBMC purity (defined as lymphocytes plus monocytes/lymphocytes plus monocytes plus neutrophils plus eosinophils plus basophils). Whole blood was collected into two sodium citrate-containing CPTs from each of 20 subjects who gave informed consent (9 females and 11 males) and was processed within 2 and 30 h of collection according to the standard operating procedure described above (protocol 1). Following processing, a complete blood differential was obtained by using automated technology. As shown in Fig. 1, the lymphocyte population was diminished, while the neutrophil and monocyte populations were increased, as the time to processing of whole blood increased. The PBMC purity decreased, from 92% within 2 h of collection to 80% 30 h after collection. Cell viability measurements by trypan blue exclusion were identical for the two time points.

In a separate experiment, we assessed the effect of the time from collection to processing on the proportions of lymphocyte subsets (total T cells, CD4 and CD8 T cells, B cells, and NK cells). Subsets were assessed by two-color flow cytometry. Whole blood was collected into sodium citrate-containing CPTs from 19 HIV-seronegative Thai subjects who gave informed consent (10 females and 9 males). Two tubes were collected per subject. The first tube was processed as described previously within 2 h of collection, and the second tube was processed 24 to 26 h after collection. Flow cytometry was conducted on the enriched PBMC fraction. Delayed processing had little impact on the percentages of the various lymphocyte subsets, although with the exception

of B and NK cells, there was a general decrease with the longer time from collection to processing (Fig. 2).

We compared the viability and percentages of lymphocytes and neutrophils after processing of paired samples (from 20 subjects) of whole blood collected into citrate-containing CPTs and acid citrate dextrose tubes and transferred to Leucosep tubes. PBMC separation with both tube types was conducted by using the manufacturers' protocols. Figure 3 shows that the data were comparable for the three parameters measured, although the overall percentage of lymphocytes was marginally higher with Leucosep tubes than with CPT separation for 19 of 20 subjects tested.

LYMPHOCYTE FUNCTION ASSAYS FOR VACCINE TRIALS

Flow cytometric analyses of lymphocyte subpopulations, as well as cell viability tests, are not necessarily indicative of cell function. Therefore, in addition to monitoring PBMC viability and recovery, it is also important to examine T-cell function. The last 10 years have seen a change in how lymphocyte function can be measured. Sophisticated assays are now available to dissect the fine specificities and functions of lymphocytes. Such assays include lymphocyte proliferation assays (LPAs), cytotoxic T-cell (CTL) assays, ELISPOT assays, tetramer assays, intracellular cytokine secretion (ICS) assays, and polychromatic flow cytometry assays (19, 22, 30, 32, 48).

CTL assays and LPAs do not directly measure the frequency of precursor cells in the peripheral circulation. Cells in culture may expand at different rates, some may undergo antigen-induced apoptosis, and others may not expand under these conditions. The classic CTL assays and LPAs allowed the measurement of two important functions, namely, the ability to lyse relevant target cells and the ability to proliferate in response to antigen, respectively. With a limiting dilution format, they also allowed an estimate of the precursor-T-cell frequency. The advantages of the ELISPOT, ICS, and tetramer assays are that they are quantitative and directly measure the frequency of T cells circulating in the
FIGURE 1 Effect of time to processing of whole blood on white blood cell subsets. Whole blood was collected from 20 subjects into CPTs (two per subject) and stored at 22 to 25°C for 2 and 30 h prior to processing. Hatched bars, 2 h; white bars, 30 h.
FIGURE 2 Effect of time to processing of whole blood on lymphocyte subsets. Whole blood was collected from 19 subjects into CPTs (two per subject) and stored at 22 to 25°C prior to PBMC separation and measurements of lymphocyte subsets by flow cytometry. Hatched bars, 2 h; white bars, 30 h.
FIGURE 3 Comparison of viability (V), percent lymphocytes (%Ly), and percent neutrophils (%Ne) of PBMC following separation of paired samples from 20 subjects by using CPTs and Leucosep (L) tubes. Hatched bars, CPTs; white bars, Leucosep tubes.

blood without any further in vitro manipulation. It should be pointed out that none of these assays are able in their present forms to measure simultaneously all possible effector mechanisms of CD8[+] or CD4[+] T-cell populations. Each assay has its limitations, but it is not really known for any given disease which is likely to be the main effector mechanism that correlates with protection or vaccine efficacy (30, 45). Hence, it is important to evaluate as many cell functions as possible and to stay up-to-date with the rapidly expanding field of cellular immunology assays.

There is no doubt that ELISPOT and, most recently, ICS assays are becoming the cellular assessment tools of choice. This is because cryopreserved PBMC can be used, allowing batch testing of samples and thereby decreasing interassay variation and increasing the possibility of automation of the procedures (10). A description of each of these assays is outside the scope of this chapter, but these methods are presented elsewhere in this manual (chapters 27 and 28).

Because HIV vaccine candidates entering human phase I trials are increasingly being conducted multinationally, there is a need for the standardization of these assays. ELISPOT and ICS assays will aid in the determination of the best candidate vaccine to move forward into phase II or III testing. This selection should be based on comparative immunogenicity analyses of the potential vaccines tested. The wide use of standardized reagents, assay kits, and protocols for ELISPOT and ICS assays will allow intergroup assay comparisons among laboratories and among the different vaccines tested.

Effect of Time to Cell Separation and Anticoagulant on Lymphocyte Function

CD8[+] T-Cell Functions

Whole-blood samples left too long in the presence of anticoagulants or at nonphysiologic temperatures adversely affect the PBMC separation process and may also cause changes which can subsequently affect PBMC function (4, 11, 60). Several laboratories within the PAVE network have now described that there is a dramatic effect on the number of gamma interferon (IFN-γ)-secreting cells if PBMC are not processed in a timely fashion (within 8 h). A peptide pool consisting of 23 cytomegalovirus, Epstein-Barr virus, and influenza virus (CEF) epitopes was used to directly quantify the integrity of PBMC and the number of IFN-γ-secreting cells when PBMC were separated from whole blood at different times after collection (12). For an evaluation of the effect of the time to cell separation on cell functions, whole blood from 12 individuals was collected in tubes containing sodium heparin anticoagulant, and processing of the blood was either performed immediately or after overnight storage of the blood at approximately 25°C. The ELISPOT assay was then performed immediately after PBMC separation. Eight of the freshly isolated PBMC samples secreted IFN-γ in response to the CEF epitope pool. When whole blood was stored overnight prior to the separation of PBMC, six of the eight PBMC samples had a marked reduction in the number of IFN-γ-secreting spot-forming cells (SFC). Three samples exhibited a more than fivefold reduction, and three had a one- to twofold reduction in the number of IFN-γ-secreting SFC (Fig. 4). One of the responders changed to a nonresponder, with a 25-fold decrease in response, from 123 to 5 CEF epitope-specific SFC/10[6] cells. The responder with the highest CEF epitope response was the least susceptible to the effects of a delay in processing. For this patient, there were 2,789 and 3,056 CEF epitope-specific SFC per 10[6] PBMC for blood processed immediately and overnight after cryopreservation, respectively (data not shown). The data suggest that low to moderate responders are the most susceptible to delays in processing and that delays may substantially affect the interpretation of vaccine
FIGURE 4   Time to processing affects production of IFN-γ. The processing of seven blood samples and ELISPOT assay setup were either performed immediately (solid bars) or after overnight storage of blood at room temperature in a safety cabinet (stippled bars). PBMC were stimulated with a pool of CEF peptides. The average number of background SFC attributable to PBMC only was subtracted.

immunogenicity. The optimal time frame for the collection of blood samples and the processing, separation, and cryopreservation of PBMC is <8 h or the same day as blood collection.

The effect of three different anticoagulants on T-cell function was measured by an ELISPOT assay. All 10 samples were processed within 6 h of collection, and the secretion of IFN-γ in response to the CEF epitope pool was examined. Figure 5 shows that equivalent CEF responses were obtained regardless of the anticoagulant used. A Kruskall-Wallis test revealed that there were no significant differences among the CEF-induced responses ($P = 0.58$).

CD4+ T-Cell Functions

The standard LPA measures antigen-induced cell division. Cells (usually PBMC) are incubated in the presence of various concentrations of an antigen (specific) or mitogen (nonspecific) stimulus of interest. After a period of 2 to 7 days, tritiated thymidine is added to the cultures for 6 to 24 h. The amount of tritiated thymidine incorporated into the cells is measured by liquid scintillation counting and reflects the proliferation of cells in response to the mitogen or antigen. LPAs are straightforward and robust. Lymphoproliferative responses of different samples can be compared by using a stimulation index (SI). The SI is the ratio of the scintillation counts obtained in the presence of antigen to the counts obtained in the presence of culture medium alone. Comparable lymphoproliferative responses of fresh PBMC separated with CPTs or Ficoll-Hypaque have been documented (61). In our own studies in Thailand, six HIV-1-seronegative subjects had comparable lymphoproliferative responses to a mitogen and an antigen. The median SIs of PBMC separated with Ficoll and CPTs in response to phytohemagglutinin were 34 (4 to 65) and 52 (8 to 211), respectively (ranges are given in parentheses). The median SIs in response to tetanus toxin were identical (4), with ranges of 1 to 55 and 2 to 89 for Ficoll and CPTs, respectively. Heparin

and citrate anticoagulants do not appear to adversely affect lymphoproliferative responses (61).

Summary of Critical Issues for Processing and Collection of PBMC

To optimize and standardize blood collection and processing procedures that will yield functionally intact T cells, follow these guidelines:

- Limit the time between blood draw and processing to <8 h.
- Avoid extremes of temperature during cell shipment and processing.
- Minimize red blood cell and platelet contamination by the use of good technique and multiple washing steps.
- Use the correct centrifugation speed for PBMC separation.
- Heparin and sodium citrate anticoagulants appear to be interchangeable for use in immunology assays. However, for some molecular assays (e.g., assays of HIV viral load), a sodium citrate anticoagulant is recommended.
- Batch test and perform quality assurance and quality control for all antigens and mitogens in each assay prior to use on precious samples.
- All batches of media, ELISPOT plates, serum, and wash buffers as well as antibodies and detection reagents should be tested prior to conducting assays.

EFFECT OF CRYOPRESERVATION ON IMMUNE FUNCTION ASSAYS

For successful cellular immunology studies, the viability, recovery, and function of PBMC need to be optimal. There are clear advantages to being able to batch assays from multiple time points from a clinical trial, but this requires the cryopreservation of PBMC in a manner that maintains their functional capabilities. One study analyzed the integrity of ~600 cryopreserved samples collected and processed within 5 to 24 h of collection from four different sites in the Multicenter AIDS Cohort Study (28). Approximately one-third of the samples were from HIV-1-seronegative individuals, and two-thirds were from HIV-1-seropositive individuals. The median number of viable cells recovered was about 50% of the total number stored, and the median viability was at least 90%. Cells were stored for up to 12 years, and during this time period the percent cell viability stayed remarkably stable, with few differences between the sites (Fig. 6). The viability of the cells was >85% in 519 of 596 specimens tested. Other studies have documented similar findings (42, 59). On the other hand, the viable-cell recovery rate over time has been shown to be quite variable. In a study by Kleeberger et al. (28), the median number of total cells recovered per vial was 7.75×10^6 (range, 1×10^6 to 25×10^6) for an input cell number of 10×10^6 cells (Fig. 7). For one of our Thai studies, PBMC from HIV-1-seronegative patients enrolled in a vaccine trial were processed and cryopreserved at two geographically separate sites (Bangkok and Chiang Mai). The samples from Chiang Mai were shipped to a central immunology laboratory in Bangkok in aliquots of 5 million cells/vial. PBMC from both sites were thawed and tested in an LPA at the AFRIMS Department of Retrovirology cellular immunology laboratory. The mean cell recovery of PBMC per vial for samples from Bangkok was 5.08 million cells (range, 1.33 to 8.67 million) and that for samples from Chiang Mai was 3.25 million cells (range, 1.67 to 6.33 million). Seventy-eight samples from each site were tested.

FIGURE 5 The effect of three different anticoagulants on T-cell function was measured by an ELISPOT assay. White box, heparin; shaded box, EDTA; stippled box, acid citrate dextrose. Ten samples were processed within 6 h of collection, and the secretion of IFN-γ in response to the CEF epitope pool was examined. The data are shown with a box plot of IFN-γ-secreting SFC/million PBMC. The box plot shows the distribution of values; from the top to bottom, lines are drawn parallel to the *x* axis, indicating the 95th, 75th, 50th (median), 25th, and 5th percentiles. A Kruskall-Wallis test revealed that there were no significant differences between the CEF-induced responses in PBMC collected in heparin, EDTA, and acid citrate dextrose.

FIGURE 6 Percent viability of stored PBMC over time, indicated by center. PBMC were thawed, and their viability was assessed by a trypan blue exclusion technique. (Reproduced with permission from reference 28.)

The reasons for the variability in cell recovery rates can come from several sources, including (i) errors in counting, (ii) different methods of freezing, (iii) different methods of thawing cells, (iv) the number of centrifugation and washing steps between thawing counting, (v) the length and type of storage conditions, (vi) the origin of the PBMC, and (vii) storage and shipping conditions. Since the goal of cryopreservation is to allow batch testing of samples to be performed, it is critical to limit the variability in the above parameters and thus to optimize cell function, viability, and recovery.

Effect of Different Shipping Methods on Immune Function Assays

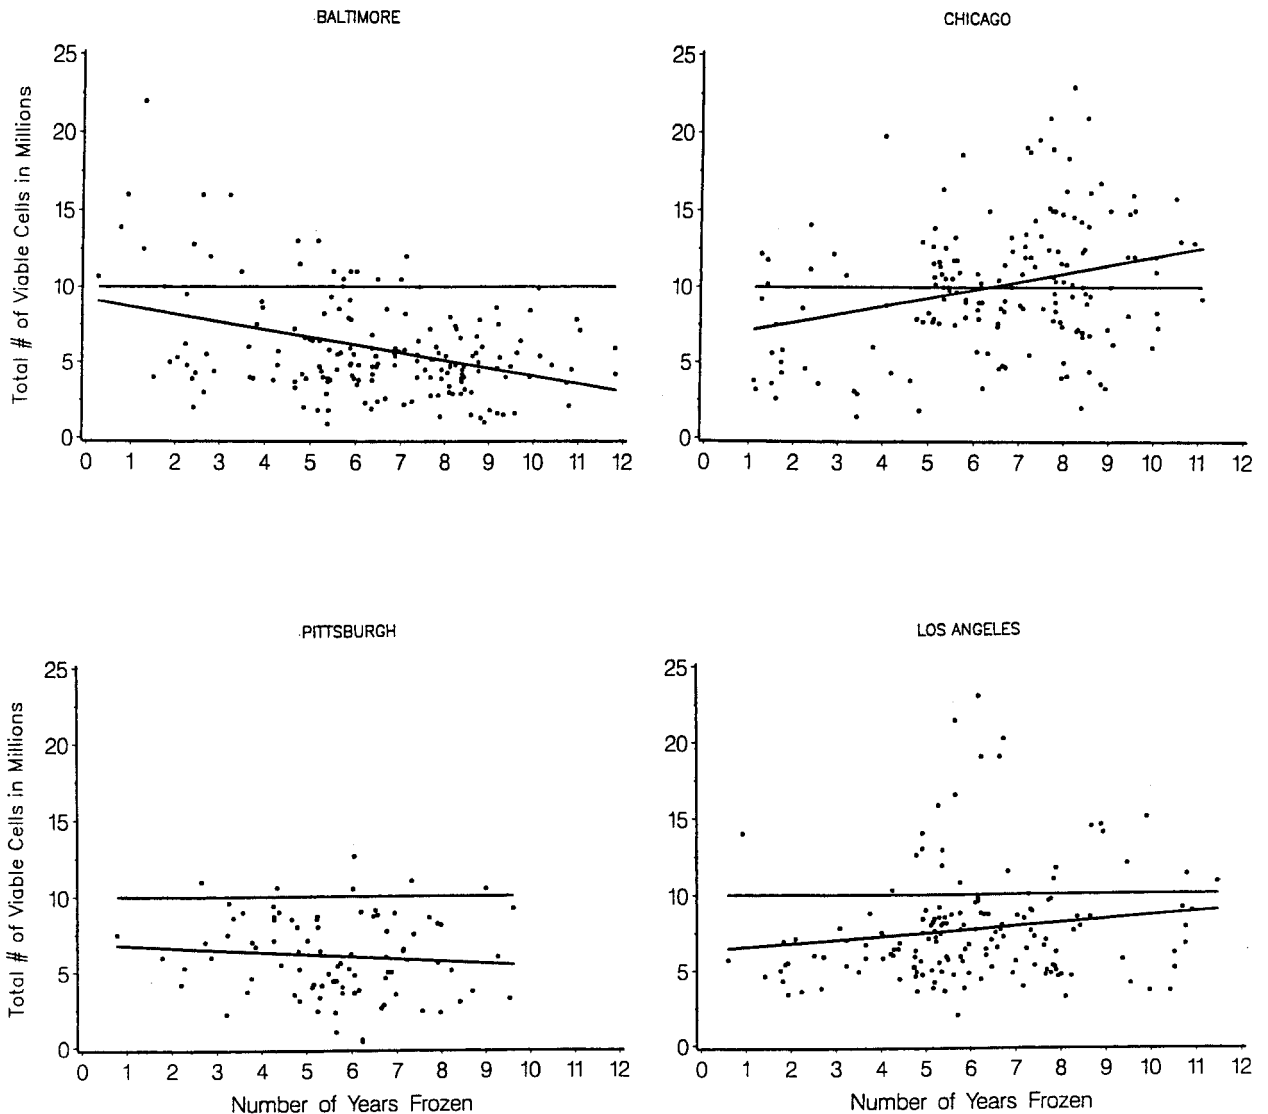
After optimizing the cell processing, separation, and cryopreservation techniques, it is essential that cells are shipped correctly so that a deterioration of function does not occur during shipment. In some instances, it is necessary to ship specimens to a central laboratory, mainly if the equipment and reagents for processing are not readily available on-site. Currently, two methods of shipment are widely used: samples are placed on dry ice or in specially constructed liquid nitrogen (LN) cryoshippers such as MVE vapor shippers (www.chartbiomed.com). The LN in the MVE shipper is absorbed into a specially designed foam liner. LN is released slowly to ensure that vapor-phase LN is present inside the shipping container. Samples can be kept at a consistent temperature of $\leq -140°C$ for periods of 10 to 18 days, depending on the size of the shipper. Ongoing work is being done to evaluate the function of PBMC that are cryopreserved and shipped on dry ice ($-70°C$) and stored for long periods in LN, thus avoiding too many shifts in temperature. Moving PBMC up and down a temperature gradient may be detrimental to cell viability, recovery, and function. Relocating PBMC from LN ($-180°C$) to dry ice ($-70°C$) and back to LN may impair


FIGURE 7　Viable cell recovery over time, indicated by center. Reference lines at 10^7 cells mark the original numbers of PBMC stored per vial. (Reproduced with permission from reference 28.)

PBMC function (J. H. Cox, L. Galley, et al., unpublished data). For the long-term storage of cells, the use of vapor-phase LN is the optimal method.

Summary of Critical Issues for Cryopreservation and Shipping of PBMC

To optimize and standardize cryopreservation and shipping that will yield functionally intact T cells, follow these guidelines:

• Use a slow freezing procedure to bring the temperature of the cells down to $\sim -140°C$.
• Nalgene "Mr. Frosty" or controlled-rate freezers provide optimal and comparable results.
• Store and ship cells in vapor-phase LN at $-140°C$ or lower.
• Avoid fluctuations in the temperature.
• Long-term storage should be done in vapor-phase LN or at temperatures below $-140°C$.

USE OF CRYOPRESERVED PBMC FOR CELLULAR IMMUNE ASSAYS

Provided that the viability, recovery, and functional integrity of PBMC are optimal, a comprehensive series of cellular immunoassays can be performed. The sections below describe our experience with individual assays and provide information regarding which assays can be performed with fresh and frozen PBMC. The results are collated from data collected over a 10-year period in our laboratories in both the United States and Thailand.

CD4 T-Cell Assay by LPA

For LPAs, well-cryopreserved PBMC can be used (43, 50, 55). In one of our studies, 141 HIV-1-infected individuals 18 to 60 years of age with CD4 counts of >400 cells/mm³ were enrolled in a double-blind placebo-controlled safety and efficacy therapeutic vaccine trial for HIV infection. Heparinized whole blood was collected prior to vaccination, and after Ficoll separation, PBMC were used for LPAs.

Proliferation assays were performed with fresh PBMC from patients whose clinical visits were at local cell-processing sites. PBMC collected at remote sites were cryopreserved and shipped to our laboratory, where they were assayed at a later date. The proliferative responses of PBMC from HIV-infected individuals to a range of concentrations of HIV-1 Env gp160, HIV-1 Gag p24, tetanus toxoid, diphtheria toxoid, *Candida albicans,* and mitogens were assessed. A positive response was defined as an SI of ≥5 for any antigen at any concentration. Although there were occasional statistically significant differences in comparative analyses (data not shown), results for fresh PBMC were similar to those for cryopreserved PBMC (Table 3). The percentages of responders to mitogens, recall antigens, and HIV antigens were consistent for comparisons of fresh and cryopreserved PBMC. In general, values obtained with frozen samples were lower than those obtained with fresh samples, but the percentages of antigen and mitogen responders were comparable.

In a very careful study by Schiller et al., the extent of T-cell proliferation in response to HIV-1 Gag antigen in fresh and cryopreserved PBMC from HIV-1-seropositive and -seronegative patients was examined (55). The inter-assay variation was very low, and regression analyses showed a strong positive correlation between the SIs obtained in assays in which two aliquots of cryopreserved PBMC each from six different HIV-1-infected subjects were tested. Generally, the SIs for fresh samples were higher than those for cryopreserved samples, and when a cutoff of 5 was used, 11 of 24 assays performed with fresh PBMC had an SI above the cutoff and 13 of 24 assays performed with cryopreserved PBMC had an SI above the cutoff. Similar results have been obtained in other laboratories (51, 61).

CD8 T-Cell Assays

$CD8^+$ T lymphocytes are able to mediate a variety of effector mechanisms and may provide the basis for protective immunity against a diverse array of infectious pathogens and tumors. For this reason, current vaccine strategies have been directed towards eliciting strong $CD8^+$ T-cell responses. The chromium release assay has been the assay of choice for many years for the evaluation of $CD8^+$ T-cell cytotoxicity. This technically demanding assay needs to be performed on fresh cells if the samples are from individuals receiving an HIV vaccine. It has been demonstrated by many laboratories, including ours, that the sensitivity and reproducibility of the assay are lost once the PBMC are frozen (9). Because of the complexity and difficulties associated with performing CTL assays, most institutions involved in vaccine trials no longer perform this assay, although the Walter Reed group and the U.S. HIV Vaccine Trials Network have deployed this assay at international sites with

optimal results (7, 24, 44, 58). In our experiences, the most difficult component of the chromium release assay is the importation and disposal of radioactive chromium. For a discussion of the use of CTL assays in vaccine trial settings, the previous edition of this manual and additional references should be consulted (8, 9, 35).

The ELISPOT assay can be used with fresh and cryopreserved specimens, and under ideal conditions, fresh and cryopreserved PBMC have been shown to have similar functional activities (12, 29, 39, 53, 57). ELISPOT and ICS assays are being standardized and compared across laboratories, and their performance characteristics are being established. As these assays become available and standardized, their usefulness for the detection of human immune responses in the field will become clearer (11). Since these assays all measure different aspects of the $CD8^+$ T-cell response, the correlations between vaccine efficacy, cytolytic effector function, the release of IFN-γ, and tetramer binding will need to be defined (15, 30, 33, 40, 45, 53, 62). A thorough review of methods for detecting CD8 T-lymphocyte function by ELISPOT, tetramer, and ICS assays is provided elsewhere in this volume (chapter 28). It should also be noted that major histocompatibility class II tetramers have now been developed and that they, along with intracellular cytokine assays, allow the ability to more directly measure $CD4^+$ T-cell responses in vitro.

EVALUATION OF CELLULAR IMMUNE RESPONSES IN DEVELOPING COUNTRIES

The advantages of conducting vaccine studies in the country of interest are numerous, with the most important being that the relevant population for vaccine or therapeutic intervention is being evaluated on-site. The influences of host genes, health and nutrition status, and disease burden of patients are taken into consideration by conducting studies in-country. The additional advantages of performing testing on-site are: (i) it avoids the problem of having to use cryopreserved samples if fresh samples provide better reproducibility and sensitivity, (ii) it avoids problems associated with shipping valuable samples, (iii) it facilitates the transfer of technologies and a build-up of human capacity and the physical infrastructure, (iv) it allows investigators from developing countries to test samples from their own country, (v) laboratories involved in such studies can train and employ staff from within their country, providing economic benefits and other incentives, and (vi) national health authorities can gain valuable experience by testing investigative phase I vaccine trials prior to commitments to larger intervention studies. Sophisticated cellular immunology studies can be done in developing countries, as exemplified

TABLE 3 Lymphoproliferative responses in fresh and cryopreserved PBMC from HIV-1-infected individuals

Antigen or mitogen	Concn range (μg/ml)	% responders (SI of >5)	
		Fresh PBMC ($n = 76$)	Cryopreserved PBMC ($n = 65$)
gp160 Env	0.4–6.2	34	32
p24 Gag	12.5–25	52	32
Phytohemagglutinin	0.5–2	100	100
Pokeweed mitogen	0.6–2.5	97	100
Concanavalin A	5–20	100	100
Tetanus toxoid	1.6–6.5[a]	75	73
Diphtheria toxoid	5.8–23[a]	70	56

[a] Concentration is given in limits of flocculation (L.f.).

by several recent vaccine trials conducted by us and other groups (16, 34, 44, 54).

T-cell responses elicited by vaccines may differ in geographically and genetically diverse populations as a result of variations in the distribution of T-cell subtypes and phenotypes, HLA types, disease burdens, antivaccine vector responses, and other iatrogenic factors. Listed below are some of the issues that may influence the elicitation of T-cell responses in diverse populations.

- Viral or parasite variation: vaccines may need to be tailored to circulating strains or variants present in the population (17, 47). Reagents for testing the immunogenicity of vaccines need to match the vaccine strains.
- Regional and tribal HLA types may influence responses to vaccines (25, 46).
- Vaccine-induced T-cell responses may be influenced by other host factors, such as the microbe burden, nutritional status, and host immunogenetic influences (1, 18, 38).

Other Considerations for Conducting Vaccine Trials in Developing Countries

Field studies and vaccine efficacy trials present a huge undertaking, both for sponsoring international agencies and for the developing countries involved. A thorough review of these issues is beyond the scope of this article, but the reader can refer to some excellent review articles (2, 14, 20, 31). In addition, it cannot be emphasized enough that consideration and respect are of paramount importance between the sponsoring country and the country in which the studies are being conducted. Possible issues to take into consideration may include the following:

- Confidentiality and ethical issues may arise.
- The blood volume that participants are willing to provide is often less than that expected for U.S. trials.
- Compliance issues are likely to be a problem when people have poor transportation options or come from remote areas.
- The ability to accurately convey the study rationale in a different language.
- Difficulties may exist in transporting samples from field sites to the central laboratory.
- Seasonal droughts and monsoons may significantly affect compliance.
- The use of isotopes for immunology assays poses problems for availability and disposal.

Obtaining Equipment and Supplies

The enormous cost of purchasing and shipping equipment to developing countries necessitates that careful consideration is given to setting up a new laboratory to ensure that compatible and reliable equipment is purchased. One of the greatest problems with conducting immunologic assays in developing countries is that the special equipment and reagents required for these tests are not routinely carried by the manufacturer's local agent. Local agents tend to carry supplies that are necessary for clinical assays, such as routine hematology. Hence, there is a need for careful planning for the acquisition of equipment and reagents. Since the first edition of this chapter was written, this issue has dramatically improved as more and more vaccine trials are being conducted overseas. Many biotechnology companies have deployed not only sales representatives but also technical representatives at overseas sites.

With respect to equipment, one must first consider the voltage employed by the country in which the equipment is to be used. Our experience in Thailand underscores the need to stress the voltage requirement (often more than once!) with equipment companies when ordering from the United States. While transformers may be an alternative for many pieces of small laboratory equipment such as microscopes, they generally lead to a poor performance of larger equipment such as centrifuges. The second major consideration is the continuity of the power supply, and a backup fuel generator is often essential for critical equipment. Protection against electrical power surges with uninterrupted power source regulators is a critical component for all pieces of equipment used in the field. The number of overseas representatives of laboratory equipment companies has increased over the last few years, but the cost of purchasing the equipment in-country is often higher due to customs duties. Many international groups have opted to purchase equipment at their headquarters and then ship it to the overseas laboratories. Although this is cheaper in the short term, it often voids the warranty for service in-country. Receiving equipment internationally can take up to 1 year from the date of purchasing. One should estimate at least a 1-year lag time before functional capabilities are in place. The ease of maintaining equipment is also an important consideration. While many scintillation counters are becoming more automated, this feature is useless in the field if there is no one in the country to service the equipment. Service engineers from Europe or the United States are likely to be required, with increased cost and time considerations. This is particularly pertinent to large equipment such as scintillation counters, where shipment of the equipment to the manufacturer for repair is not an option because it is too costly. In the event of scintillation counter failure, one has the advantage with the LPA of being able to freeze the plate due to the long half-life of tritiated thymidine. However, for CTL assays using ^{51}Cr, the short half-life of the isotope (<1 month) may preclude this step.

Equipment such as refrigerators with glass doors is particularly convenient for laboratory personnel, but in tropical countries, where the laboratory temperature tends to be marginally higher than those in the United States and Europe, this type of door puts extra work on the compressor, leading to a more rapid deterioration of the equipment. Similarly, if there is an electricity failure, which may result in laboratory temperatures of up to 35°C, the rate of heat loss from a glass-door-refrigerator is more rapid than that from a refrigerator with an insulated metal door, often reaching room temperature within 30 min. Low-temperature freezers (−70°C or less) generate a great deal of heat, thereby putting extra work on the compressors, and hence it is a good idea to consider a designated air-conditioned room for freezers. Provided that LN is readily available within the country, LN freezers are often a better means for storing PBMC than electric freezers, as maintenance is minimal. Given the high cost and unreliability of the supply of LN from commercial vendors in many developing countries, laboratories may wish to invest in their own LN plant. The storage capacity can be in excess of 100 liters, with the start-up time to full LN production being only 10 min. There are several commercial options for this process, including Stirling Cryogenics (www.stirling.nl). The plant requires a separate housing structure of approximately 3 by 3 m and can be installed with on-site operator training in 7 days.

In many developing countries, particularly those that rely heavily on imported materials, one must consider the time that equipment and reagents may be held in customs and excise prior to their release, as it may exceed 1 month.

Many of the problems with ordering equipment also pertain to the ordering of reagents. The ordering of reagents also has the additional constraint of expiration dates. Many reagents may have a long expiration date, but others, such as CD-Chex, a CD4$^+$ T-cell flow cytometry control reagent, do not. Hence, one may have to establish a link with a laboratory in the United States or Europe for shipments of these reagents. Additionally, the required storage temperature of the reagents must be considered. Appropriate shipping documents must be sent at the time of shipment to the laboratory to ensure that the customs department is notified about proper storage of the supplies in the event of a delay in processing.

The quality of water in the country in which the assays are to be conducted must be taken into consideration as well. While one may have the necessary filtration system, quality assurance of the water may be problematic if there is not a laboratory capable of conducting coliform counts and silicon testing of the water supply. Filters used in deionizing systems in developing countries typically need to be replaced sooner than those in the United States. Another point of concern is the adequate drainage of buildings in developing countries, so that high-volume sink drainage goes to a septic tank or sewer and not directly into the water table. While it is more costly to order premade media because of the requirement of greater refrigeration capabilities, this is the best choice for quality control and quality assurance issues.

Many cellular immunology assays require the use of radioactive materials. One must be cognizant of the procedures for handling radioactive materials in each developing country because the regulations concerning shipping, use, and disposal of these reagents may differ from those in developed countries.

In our experience, the best way to establish cellular immunology assay capability in the field is to have laboratory personnel from the sponsoring country conduct site visits to the country where laboratory infrastructures are being built. Visits need to be made to clinical and university laboratories to ascertain what equipment and reagents are in use, are serviceable, and are readily available on-site (with particular attention to the time intervals between ordering and receipt). The need to learn about rules and regulations concerning the use of radioactive isotopes is critical. In addition, sponsoring countries should allow personnel from the developing countries to train in their laboratory facilities, especially if they will be involved in the execution of cellular immunology assays. A period of no less than 3 months is recommended. A major dilemma faced by investigators from one country operating in another is at what point national laboratory guidelines from the vaccine trial support country should be implemented. These questions can only be answered by dialogues with those who will conduct the assays and representatives from the necessary local regulatory agencies.

Summary of Equipment and Supply Requirement Issues

- Customs duty and tax fees in addition to shipping fees for equipment and supplies are likely to be imposed.
- Permits are required for shipping infectious materials internationally (International Air Transportation Association [www.IATA.org]).
- Refrigerators, freezers, and incubators may have problems with maintaining temperatures where the ambient temperature often exceeds 25°C.

- Problems are likely to be encountered with equipment service contracts and general equipment maintenance.
- For local purchases, a petty cash account in-country should be established.
- Special requirements for the power and voltage supply to laboratory equipment must be considered.
- Backup power and voltage regulators are usually necessary.
- Water quality and water sanitation and drainage issues are important.
- Laboratory safety (chemical, biological, and radiological) standards need to be set to the same level as those in developed countries.

T-Lymphocyte Activation and Cell Signaling

JEFFREY R. CURRIER

36

The early consequences of T-cell activation are a succession of intracellular biochemical events resulting in a tyrosine kinase cascade, phosphorylation of linker proteins, assembly of the signalosome, cytoskeletal reorganization, formation of the immunological synapse, activation of transcription factors, and rapid expression of new cell surface molecules. Measurement of these events can be used to assess a number of clinically relevant parameters, such as the current state of immune competence, the presence and number of activated T cells, and the capacity for antigen-specific and antigen-nonspecific responsiveness. T-cell activation is a prerequisite for all subsequent functional activities of T cells (e.g., cytokine production and proliferation and target cell cytolysis) and hence can be indirectly assessed by many methods covered elsewhere in this manual (see other chapters in section E). This chapter focuses upon methods that measure early events associated directly with T-cell activation. Historically, the presence in tissue or body fluids of T cells with various activated phenotypes has been used as a clinical correlate of progression of many autoimmune and infectious diseases. Activation of T cells directly ex vivo in an antigen-independent or antigen-dependent manner also has important clinical applications. Typically, antigen-independent activation of T cells ex vivo is performed to assess the current state of immunocompetence as a result of either immunosuppressive therapy, possession of a genetically linked immunodeficiency, or the presence of an infectious agent. Antigen-dependent (or antigen-specific) activation of T cells can be used to demonstrate either that a patient's T cells and antigen-presenting cells (APCs) are capable of acting in concert to initiate an immune response or that prior sensitization to a specific antigen has occurred. The initiation of T-cell activation is brought about by a remarkably complex cell-cell interaction between a T cell and an APC. Central to this interaction is the T-cell receptor (TCR), which binds to major histocompatibility complex (MHC) molecules and short peptide antigens on the surface of the APC. The interaction of a large number of accessory, adhesion, and costimulatory molecules contributes to T-cell activation by formation of the "immunological synapse" which increases the avidity of the TCR-MHC interaction and initiates independent signal transduction events (15, 20, 27). A review of the signaling events associated with T-cell activation is presented here. To present a sufficiently broad overview, the details of each aspect of T-cell signaling are necessarily limited; however, for

greater detail the reader is referred to comprehensive reviews cited throughout the text.

TCR STRUCTURE AND RECOGNITION

The TCR is a multisubunit complex composed of six different polypeptide chains: α, β, γ, δ, ε, and ζ. The TCR α and β chains form a disulfide-linked heterodimer and confer the specificity of ligand binding. By virtue of genetic rearrangement, germ line-encoded $V\alpha$, $J\alpha$, and $C\alpha$ and $V\beta$, $D\beta$, $J\beta$, and $C\beta$ segments recombine to form millions of TCR $\alpha\beta$ variants, each with different molecular specificities (16). Crystal structure analysis has confirmed that the molecular specificity of the TCR is conferred by the solvent-exposed membrane-distal variable regions of the α and β chains (19). The ligand for this receptor is a complex of short peptide antigens (generated by intracellular processing of self-proteins or foreign pathogens), bound noncovalently to class I or class II MHC molecules on the surface of an APC (43). The noncovalently associated subunits of the TCR complex are the monomorphic γ, δ, ε, and ζ chains (formally designated CD3). The TCR ζ chain exists predominantly as a $\zeta\zeta$ homodimer, but in some cases ζ and its splice variant η exist in the TCR complex as a $\zeta\eta$ heterodimer. An important characteristic of the TCR complex is that it links the exquisite specificity of the polymorphic TCR $\alpha\beta$ heterodimer with transmembrane signal transduction mediated by the cytoplasmic domains of the invariant CD3 subunits and the TCR γ, δ, ε, and ζ chains (2, 5, 31).

TYROSINE KINASE CASCADE AND PHOSPHORYLATION OF LINKER PROTEINS

Ligation of the TCR complex to its cognate peptide-MHC counterpart or with particular anti-CD3 monoclonal antibodies (MAbs) initiates the process of T-cell activation and delivers the primary signal for the activation of resting T cells. The earliest biochemical events elicited by T-cell activation are the phosphorylation of proteins in the TCR-CD3 complex and the activation and interaction of Syk and Src family protein tyrosine kinases (PTKs) (8, 44). Within seconds of TCR stimulation the cytoplasmic tails of the TCR and CD3 γ, δ, ε, and ζ chains are phosphorylated on specific immunoreceptor tyrosine-based activation motifs (ITAMs) by the CD4 or CD8 coreceptor-associated Src family kinase

Lck. A highly ordered sequential phosphorylation of six tyrosines of the TCR ζ ITAMs is dependent upon the strength of TCR occupancy. Recruitment of a Syk family kinase (most notably ZAP-70 and Syk itself) to this complex by the interaction of its Src homology 2 domain with the phosphorylated TCR ζ and CD3 chains results in its transphosphorylation by Lck (24). The multiple-tyrosine-phosphorylated ZAP-70/Syk family has a crucial role in TCR activation. Self-phosphorylated ZAP-70 serves as a scaffold for recruiting positive and negative regulators of TCR signaling such as α-tubulin, Sam-68, Vav-1, VHR, Shc, Grb-2, LAT, and SLP-76 (23, 24). The last two adapter proteins play a pivotal role in TCR signaling, as they serve as nucleation points for higher-order macromolecular structures referred to as the signalosome (9, 28). Once phosphorylated by Syk kinases, LAT and SLP-76 participate in coupling the TCR to Ca^{2+} mobilization, Ras-signaling pathways, and NFAT-dependent interleukin-2 (IL-2) production. Importantly, LAT is palmitoylated, which targets it (and the molecules it recruits) to glycolipid-enriched microdomains known as lipid rafts. Recruitment of the tyrosine-phosphorylated TCR to lipid rafts is a critical step in T-cell activation and presumably concentrates the downstream signaling machinery in close proximity, facilitating enzymatic activity and molecular scaffold formation (18, 28). Redistribution of the TCR to lipid rafts also sequesters negative regulatory phosphatases away from the TCR (22). The selective disruption of lipid rafts results in attenuation of activation and signal transduction in T cells, further underscoring their importance.

SECONDARY MESSENGER MOBILIZATION

The net result of this tyrosine phosphorylation cascade is the activation of the key enzyme phospholipase C-γ1 (PLC-γ1) and the formation of complexes containing the Src homology 3-binding adapter proteins LAT, Grb2, Sos, SLP-76, and Vav complex (24). Once recruited to the lipid rafts of the plasma membrane, PLC-γ1 cleaves membrane phospholipids and releases the intracellular second messengers inositol 1,4,5-triphosphate (IP_3) and diacylglycerol (DAG)(4, 26). IP_3 has the critical role of regulating the transient mobilization of intracellular calcium ($[Ca^{2+}]_i$) stores from the endoplasmic reticulum. This early $[Ca^{2+}]_i$ flux is short-lived (on the order of several minutes only) and requires an additional transmembrane Ca^{2+} flux from outside the cell to inside to maintain the persistence required for IL-2 gene transcription (37). This effect can be directly mimicked in vitro by the calcium ionophore ionomycin. DAG activates the proto-oncogene Ras via its direct interaction with one of the protein kinase C (PKC) family kinases. In concert with several adapter proteins (such as Shc, Grb-2, Sos, SLP-76, and Vav) which are activated or recruited by the Syk kinases and LAT, the activation of Ras by PKC then results in downstream activation of the serine-threonine kinase pathway (39). This key enzyme cascade in turn directly regulates key nuclear events involved in gene transcription and T-cell growth. The stimulation of T cells in vitro with phorbol esters (e.g., phorbol myristate acetate [PMA]) induces the rapid activation of both PKC and Ras. The transmission of signals from Ras and PKC to the nucleus involves the regulation of the ubiquitous mitogen-activated protein (MAP) kinase pathway (9, 24, 39). The concerted activity of both PMA and ionomycin can therefore imitate many of the early molecular consequences of TCR-dependent T-cell activation.

A second important pathway involving inositol lipid metabolism occurs immediately after TCR engagement. The enzyme phosphatidylinositol-3-hydroxyl kinase (PI3K) is weakly activated when the TCR alone is stimulated, but optimal activation occurs only when TCR and the costimulatory molecule CD28 are both triggered. CD28 regulation of PI3K depends upon its recruitment to the plasma membrane via interaction with the tyrosine-phosphorylated cytoplasmic domain of CD28. All of the downstream targets of phosphoinositides generated by PI3K are not yet well defined; however, they include members of the Tec/Itk PTK family (29). The pleckstrin homology domains of the Tec/Itk family and several important serine-threonine kinases can bind the products of PI3K. The binding of the products of PI3K to pleckstrin homology domains couples cell surface receptors to a diverse array of signal transduction pathways (41).

As a consequence of the early signal transduction events discussed above, many biochemical and physiological changes occur in activated T cells. Most of the biochemical events that occur in T cells immediately following activation are shared with many other cell types in response to external stimuli. These events include the activation of kinases and initiation of signaling cascades (as discussed above), changes in cytoplasmic pH, ion flux, and changes in cyclic nucleotide levels. An increase in cellular pH has been observed in T-cell lines following mitogenic activation and is presumably mediated by the plasma membrane Na^+/H^+ antiporter in response to inositol phosphate hydrolysis. Transient fluxes in cyclic nucleotides (cyclic AMP and cyclic GMP) have also been observed in mitogen-activated T cells. The specific role, if any, of cyclic nucleotides in T-cell activation is not yet defined; however, their role in regulating a variety of cellular functions in many cell types is well documented.

T cells, like many cell types, have an electrochemical gradient across their plasma membrane. The transient hyperpolarization and depolarization of this gradient have been observed immediately following T-cell activation and include the transport of Na^+, K^+, Cl^-, and Ca^{2+} ions. The measurement of $[Ca^{2+}]_i$ flux is significant for assessing T-cell activation because of its central role in the initiation of IL-2 gene transcription, an event specific to activated T cells. As discussed earlier, the intracellular second messenger IP_3 accounts for the transient increase in $[Ca^{2+}]_i$ (first minutes of T-cell activation), but sustained increases in $[Ca^{2+}]_i$ (typically several hours after initial T-cell activation) require a transmembrane flux from outside the cell. This is provided by a non-voltage-gated Ca^{2+} transmembrane channel that opens when intracellular stores are depleted and closes when they are replenished. The functional consequences of increased $[Ca^{2+}]_i$ flux include polarization of the cytoskeleton and cooperation with Ras and MAP kinase pathways for the activation of IL-2 gene transcription. The calcium phosphatase calcineurin is an essential link in the synergized activities of $[Ca^{2+}]_i$ flux and the MAP kinase pathways. Critically, calcineurin is the target of the immunosuppressive drugs cyclosporine and FK506. These drugs form a complex with cytosolic calcineurin and inhibit calcium-mediated signal pathways in T cells.

The ability to conveniently measure $[Ca^{2+}]_i$ flux in ex vivo mitogen-activated T cells allows for rapid assessment of the overall state of a patient's T-cell competence. For the activation of naive T cells to occur there is a formal requirement for a second, or costimulatory, signal in addition to the TCR-derived signal. In most instances this signal is delivered via the CD28 molecule on the surface of the T cell upon interaction with either of its ligands, the B7-1 and B7-2 molecules, on the surface of professional APCs (1). The biochemical mechanism by which CD28 transduces its signal

remains ill defined, but its cytoplasmic tail alone is sufficient to mediate the signals required for costimulating IL-2 gene transcription. Memory T cells, or T cells that have been previously activated in vivo, have a less stringent requirement for functional activation but in general still require a second signal. This signal may be delivered either via a soluble factor such as a cytokine or by a cell surface molecule on the APC. The absence of a costimulatory signal in conjunction with a TCR-derived signal leads to a nonfunctional, or anergic, state in the target T cell. The function of costimulation in the priming phase of an immune response is presumably to ensure that antigenic peptides that are recognized are nonself peptides presented only by professional APCs (3).

Activation of T cells may also be accomplished independently of the TCR and CD28. Cross-linking the CD2 surface molecules of T cells with specific antibody pairs can initiate a signaling cascade and induce cytokine production, cytolytic activity, and proliferation. CD2 is a cell surface glycoprotein expressed on all mature peripheral T cells in humans (46). The natural ligand for CD2 is CD58 (LFA-3), which is expressed on many cell types, including APCs. The interaction of CD2 and CD58 regulates the response of T cells to antigen and augments cytokine production and proliferation. In common with the TCR activation pathway, CD2 cross-linking activation requires the presence of a functional CD3ζ chain. CD2 has a unique mechanism of engagement of intracellular machinery based on proline-rich motifs which bypasses members of the ZAP-70/Syk family, which are not phosphorylated by this mode of activation (40). CD2 can substitute for CD28 as a costimulatory molecule for inducing many functions of T cells, including cytokine synthesis, cell proliferation, and target cell recognition.

CYTOSKELETAL REORGANIZATION AND CONSEQUENCES OF EARLY SIGNAL TRANSDUCTION EVENTS

Subsequent to and in some cases concomitant with the immediate biochemical consequences of T-cell activation, many specialized cellular responses occur. The reorientation and redistribution of the cytoskeleton constitute an important consequence of T-cell activation, since they are closely linked to functional outcome. As discussed earlier, the phosphorylation of TCR ITAMs following TCR engagement serves as a focal point for cytoskeletal reorientation and formation of the microtubule-organizing center (13, 17, 33). This new layer of complexity in TCR signaling has been termed the immunological synapse or supramolecular activation complex (14, 25, 33, 42). During an antigen-dependent response a rapid accumulation of actin cytoskeletal proteins occurs at the interface of the APC–T-cell interaction. The potential functional consequence of microtubule-organizing center reorientation is to properly orient and localize T-cell responses. In the case of helper T cells, newly synthesized cytokines would be delivered toward the relevant APC, and in the case of cytotoxic T cells this would result in the focused secretion of prepackaged cytolytic granule constituents towards the target cell. Activation of the cytolytic mechanism is also dependent upon $[Ca^{2+}]_i$ flux, and as with cytokine gene transcription it can be mimicked by the synergized activity of PMA and ionomycin.

Gene activation and transcription are a common response to receptor-mediated signal transduction in many cell types. Following T-cell activation a specific set of responsive genes becomes transcriptionally active. This subset includes both newly synthesized genes and genes that are already expressed but are now up-regulated and expressed at higher concentrations. The immediate-early response genes represent the first wave of T-cell activation-induced genes, and their activation may be detected within minutes of receiving an appropriate stimulus. The immediate-early response genes do not rely upon protein synthesis for expression; however, many later response genes do rely upon protein synthesis for their activation. In fact, many of the early response genes are transcription factors for late response genes which mediate complex cellular functions such as the progression to the cell cycle (e.g., T-cell proliferation) and acquisition of differentiated functions (e.g., memory cells with polarized cytokine production profiles). As far as the practical measurement of early T-cell activation is concerned, the most important response genes are cell surface receptors. Receptors of various functions appear on the surface of activated T cells at different times and in different concentrations. The kinetics of expression may vary from within minutes to hours and even days after activation, indicating that different mechanisms of transcriptional regulation are operative. The kinds of T-cell surface receptors up-regulated upon activation include adhesion molecules, accessory molecules for modifying immune responses, cytokine receptors, nutrient receptors, and many molecules with still-undefined functions. In addition, new antigenic epitopes may be revealed on existing cell surface molecules, indicating that translational and posttranslational regulation of protein expression is also modified upon T-cell activation.

MEASUREMENT OF T-CELL ACTIVATION IN CLINICAL APPLICATIONS

The development, activation, and normal function of T cells are all dependent on the ability to signal properly through TCR, to transmit such signals, and to respond appropriately to these signals. The importance of each of these outcomes, particularly with respect to its clinical relevance and practicality of measurement, will now be discussed. Genetic defects affecting expression of important surface receptors or any of the signaling pathways may be manifested as one of the many different forms of inherited immunodeficiency (11, 38). Signaling defects in T cells may also be associated with malignancy; however, these are often manifestations of the negative effects of tumors on the host immune system (45). Immunodeficiency may also be acquired transiently as the result of an immunosuppressive therapy (e.g., cyclosporine) or as the long-term consequence of infectious disease (e.g., AIDS resulting from human immunodeficiency virus type 1 [HIV-1] infection). Assessment of inherited immunodeficiency can be performed by in vitro antigen-independent T-cell activation using surface receptor-specific MAbs or pharmacological agents which mimic T-cell activation (e.g., PMA and ionomycin) and by measuring calcium flux and/or surface receptor up-regulation. A lack of calcium flux would indicate a defect in early signal transduction, while normal calcium flux and decreased up-regulation of surface receptor expression would indicate a downstream defect in receptor signaling.

Defects affecting the termination of T-cell activation and growth may result in systemic autoimmune disease. Measurement of the activation status of T cells isolated directly from peripheral blood can give an indication of the presence of systemic autoimmune disease. The chronic expression of early or late activation markers can be conveniently measured with minimal handling required. Localized autoimmune diseases may be assessed with either peripheral T cells or cells biopsied from the site of inflammation.

The subsequent antigen-dependent activation of these cells in vitro and measurement of functional outcomes such as intracellular calcium flux and surface receptor up-regulation can then be used to monitor sensitization to a specific antigen.

PROCEDURES

Method 1. Measurement of Receptor Function in Early Cell Activation: CD69 Activation Assay

The CD2 receptor plays an important role in TCR activation by binding to the ligand CD58 (LFA-3) and optimizing the complex interaction between the TCR complex and the MHC-peptide complex on the APC (12, 46). In addition, cross-linking this receptor independent of the TCR complex interaction can induce intracellular calcium release and up-regulate the early activation marker molecule, CD69. The CD69 molecule is a 34-kDa dimeric glycoprotein expressed early after activation and is present on B and T cells as well as a variety of hematopoietic cells (48). For this reason genetic defects or infectious diseases that may affect early cell signaling events can be measured. For example, early-stage HIV-1-positive individuals showed impaired CD69 induction after stimulation with anti-CD2/2R (35). Anti-CD2/2R is a mixture of two MAbs that recognize different epitopes on the CD2 molecule and therefore produces cross-linking of the receptor (30, 32). Figure 1 shows a three-color staining analysis of CD69 expression in CD3$^+$ CD4$^+$ lymphocytes in unlysed whole-blood preparations from an HIV-1-seronegative individual, an HIV-infected individual with a CD69 response in the normal range, and an HIV-infected individual with a low CD69 response to stimulation with anti-CD2/2R MAbs. This figure demonstrates the use of
FIGURE 1   Three-color analysis of CD69 expression in CD3$^+$ CD4$^+$ lymphocytes in unlysed whole-blood preparations from an HIV-1-seronegative individual (top panels), an HIV-infected individual with a CD69 response in the normal range (middle panels), and an HIV-infected individual with a low CD69 response to stimulation with anti-CD2/2R MAbs (bottom panels). T cells were gated as 90° light scatter, and CD3 staining was carried out (left panels). CD69 expression was measured in CD3$^+$ CD4$^+$ lymphocytes cultured for 4 h in medium alone, with a stimulatory anti-CD2/2R MAb combination, or with PMA (right panels). PMA will spontaneously activate all cells within this time period and is considered the positive control.

CD69 percentage to measure the reduced signaling that occurs through the CD2 receptor in some patients with early-stage HIV-1 infection.

Sample Requirements

Ten milliliters of whole blood was collected from patients in heparin-treated Vacutainer tubes and processed within 2 to 4 h. Cell viability must be greater than 95% or additional reagents are required to identify the nonapoptotic or membrane-damaged cells.

Materials and Reagents

CD2/2R MAb mixture (Becton Dickinson Corp.): Dilute to a final concentration of 5 μg/ml per 10^6 cells.

Isotype controls, CD4-fluorescein isothiocyanate (CD4-FITC), CD8-FITC, CD69-phycoerythrin (CD69-PE), and CD3-PerCP (Becton Dickinson Corp.): Dilute to a final concentration of 5 μg/ml per 10^6 cells.

PMA (Sigma Chemical Co.): Dilute stock with dimethyl sulfoxide (DMSO) and use at a final concentration of 100 ng/ml.

Wash buffer: Dilute 0.1% bovine serum albumin and 0.1% sodium azide in phosphate-buffered saline (PBS) (without Ca^{2+} or Mg^{2+} ions).

Coulter-Immunolyse (Beckman-Coulter Corp.): Make a 1:20 dilution of Coulter-Immunolyse with cold PBS (without Ca^{2+} or Mg^{2+} ions).

1% Formaldehyde: Add 2.5 ml of 20% buffered formaldehyde (Tousimis Research Corporation) to 47.5 ml of PBS.

Vacutainer tubes (Becton Dickinson Corp.) or equivalent blood collection system

Equipment and Instrumentation

Flow cytometer: Elite-ESP (Beckman-Coulter) equipped with a 488-nm argon laser and five photomultiplier tubes (PMT1, PMT2, PMT3, PMT4, and PMT5) in addition to a solid-state light scatter detector (FALS). The 488-nm monochromatic light excites all conjugates in the assay: FITC, PE, and PerCP. All data are stored in list-mode file format (FCS), and complete analysis is performed using Flow-JO software (Tree Star, Inc.).

Standard water bath capable of reaching and maintaining 37°C

Procedure

1. Collect 10 ml of whole blood in heparin-treated Vacutainer tubes and process within 2 to 3 h.
2. Mix 100 μl of whole blood with anti-CD2/2R MAb (5 μg/ml) in a 12- by 75-mm test tube.
3. Cap all tubes and incubate for 4 h in a 37°C water bath.
4. Add 2 ml of cold wash buffer and centrifuge at $400 \times g$ for 5 min.
5. Resuspend cell pellet in 240 μl of wash buffer and 20 μl of each clone tested to a total volume of 300 μl per tube. Stain cells with the following combinations: immunoglobulin G (IgG)-FITC, IgG-PE, and IgG-PerCP; CD4-FITC, CD69-PE, and CD3-PerCP; and CD8-FITC, CD69-PE, and CD3-PerCP.
6. Incubate at 4°C for 30 min.
7. Add 2 ml of cold wash buffer and centrifuge at $400 \times g$ for 5 min.

8. Remove all supernatant from cell pellet and vortex in remaining buffer. Add 1 ml of cold Coulter-Immunolyse to each tube for 2 min and vortex. Red blood cells (RBCs) should be completely lysed if a clear solution is observed.
9. Add 250 μl of Coulter-Immunolyse fixative and vortex.
10. Add 2 ml of wash buffer and centrifuge for 5 min at $400 \times g$. Repeat wash twice using 2 ml of wash buffer.
11. Remove supernatant and resuspend cell pellet in 200 μl of PBS and 200 μl of 1% formaldehyde. Incubate at 4°C for at least 2 h.
12. Place each sample on a flow cytometer and collect 5,000 gated events within the CD3+ gate and store as a list-mode file (FCS).
13. Using Flow-JO analysis software, gate on the CD3+ T cells and measure the percentage of cells which are CD4+ (or CD8+) and CD69+.

Controls and Calculations
Positive control: PMA-activated cells

1. Mix 100 μl of whole blood with 100 μl of PMA to a final concentration of 100 ng/ml in a 12- by 75-mm test tube.
2. Cap all tubes and incubate for 4 h in a 37°C water bath.
3. Add 2 ml of cold wash buffer and centrifuge at $400 \times g$ for 5 min.
4. Resuspend cell pellet in 240 μl of wash buffer and 20 μl of each clone tested to a total volume of 300 μl per tube. Stain cells with the following combinations: IgG-FITC, IgG-PE, and IgG-PerCP; CD4-FITC, CD69-PE, and CD3-PerCP; and CD8-FITC, CD69-PE, and CD3-PerCP.

Isotype control: These clones (IgG1-FITC, IgG1-PE, and IgG1-PerCP) provide the general location of cursors to define the negative and positive regions of test clones.

Standardization, Quality Control, and Quality Assurance

Determining a kinetic curve will require an evaluation of time with the various stimulants used. In general, a 4- to 6-h analysis is needed to determine the linearity of the surface expression of CD69 (Fig. 2). In this example the kinetics of CD69 expression on CD4+ T cells are illustrated. Whole blood from an HIV-1-seronegative subject (Fig. 2A) and an HIV-1-infected patient (Fig. 2B) was cultured without further stimulus or stimulated with soluble anti-CD2 MAb, bead-bound anti-CD3 MAb, or PMA. Flow cytometric measurements were performed on cells stained with anti-CD3, anti-CD4, and anti-CD69 MAbs. The percentage of cells positive for CD69 was calculated for cells in the CD3+ CD4+ gate. Results are shown from a representative HIV-1-seronegative individual and an HIV-infected patient with a depressed CD69 response.

Interpretation

Individuals whose percentages of T cells (CD4 or CD8) are below 2 standard deviations of those of healthy uninfected individuals are considered nonresponders. Each stimulant used to activate lymphocytes and measure the level of CD69 expression should be evaluated by a kinetic curve over 4 to 6 h as described in the standardization section.

Method 2. Measurement of Receptor Expression after T-Cell Activation: Quantitative Fluorescent Receptor Expression Assay

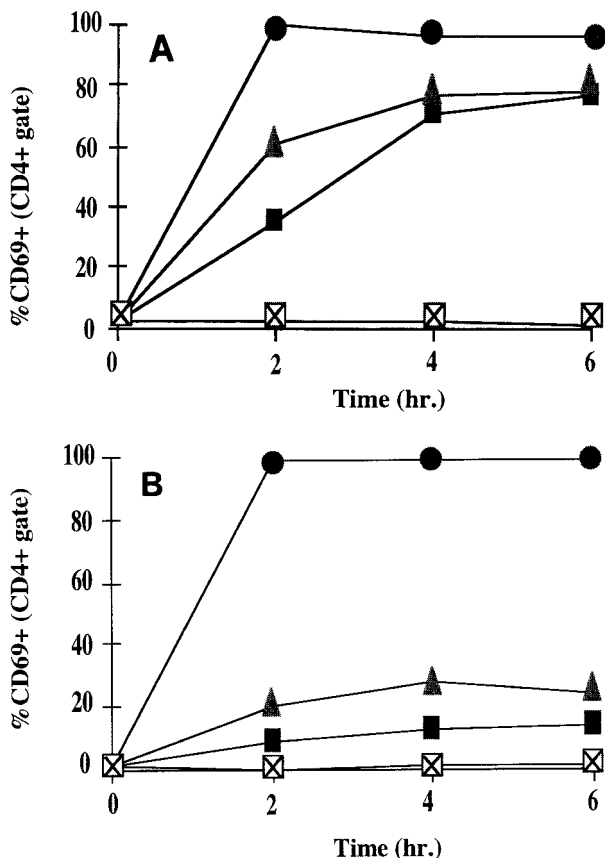
In addition to the percentages of cells which can change in response to infectious diseases or vaccine stimuli, the expression


FIGURE 2 Kinetics of CD69 expression on CD4[+] T cells. Whole blood from an HIV-1-seronegative individual (A) and an HIV-infected patient (B) was cultured without further stimulus (⊠) or stimulated with soluble anti-CD2 MAb (■), bead-bound anti-CD3 MAb (▲), or PMA (●). At the indicated times, flow cytometric measurements were performed on cells stained with anti-CD3, anti-CD4, and anti-CD69 MAbs. The percentage of cells positive for CD69 was calculated for cells in the CD3[+] CD4[+] gate. Five uninfected controls and five HIV-infected patients were studied. Results shown are from a representative HIV-1-seronegative individual and an HIV-infected patient with a depressed CD69 response.

of receptors, which are generally tightly controlled by the release of cytokines and other proteins, can be up-regulated or down-regulated in response to these protein signals. Viruses have evolved mechanisms to evade the immune response by interfering with intracellular trafficking and cell surface expression of important immune receptors such as MHC class I or II molecules, cytokines, and chemokines. For example, the Nef protein produced by HIV can down-regulate the expression of HLA class I and CD4 molecules on the cell surface (7, 10). During an ongoing immune response, lymphocytes can express many activation markers at various expression levels. In general, this group includes CD95 (FAS), CD38, CD26, CD25, and many of the chemokine receptors (CXCR4, CCR3, and CCR5). In this example, the up-regulation of the activation receptor CD38 on the surface of the CD8[+] T cells is correlated with a poor prognosis and a more rapid progression in HIV disease (21, 36). The measurement of this expression can be performed by comparing

changes (median intensity) of the CD8[+] CD38[+] T cells of infected individuals (Fig. 3A and B) to a standard curve (Fig. 3C) as described below. Additionally, highly active antiretroviral therapy down-regulates the level of CD38 expression (47). Thus, a change in receptor expression might indicate changes in disease progression or an effective method to monitor the treatment course.

Sample Requirements

Collect 10 ml of whole blood in heparin-treated Vacutainer tubes and process within 6 to 8 h. Cell viability must be greater than 95% or additional reagents are required to identify the nonapoptotic or membrane-damaged cells.

Materials and Reagents

Wash buffer: Dilute 0.1% bovine serum albumin and 0.1% sodium azide in PBS.

Coulter-Immunolyse (Beckman-Coulter Corp.): Make a 1:20 dilution of Coulter-Immunolyse with cold PBS (without Ca^{2+} or Mg^{2+} ions).

Isotype controls, CD4-FITC, CD8-FITC, and CD3-PerCP (Becton Dickinson Corp.): Dilute to a final concentration of 5 μg/ml per 10^6 cells.

CD38-PE (1:1; Becton Dickinson Corp.): Dilute to a final concentration of 5 μg/ml per 10^6 cells. This reagent is designed to produce a protein/fluorescence ratio of 1.0. This means that one antibody molecule is conjugated with only one fluorochrome, making this reagent ideal for quantitative fluorescence analysis.

Equipment and Instrumentation

Flow cytometer: Elite-ESP (Beckman-Coulter) equipped with a 488-nm argon laser and five photomultiplier tubes (PMT1, PMT2, PMT3, PMT4, and PMT5) in addition to a solid-state light scatter detector (FALS). The 488-nm monochromatic light excites all conjugates in the assay: FITC, PE, and PerCP. All data are stored in list-mode file format (FCS), and complete analysis is performed using Flow-JO software (Tree Star, Inc.).

Procedure

1. Collect 10 ml of whole blood in heparin-treated Vacutainer tubes.

2. Mix 100 μl of whole blood with the indicated clone combinations (5 μg/ml) in a 12- by 75-mm test tube to a total volume of 300 μl with PBS as follows: tube 1, IgG1-FITC, IgG1-PE, and IgG1-PerCP (isotype control); tube 2, CD8-FITC, CD38-PE, and CD3-PerCP.

3. Incubate tubes at 4°C for 30 min.

4. Add 2 ml of cold wash buffer and centrifuge at 400 × g for 5 min. Repeat wash one additional time.

5. Remove all supernatant from cell pellet and vortex in remaining buffer. Add 1 ml of cold Coulter-Immunolyse to each tube for 2 min and vortex. RBCs should be completely lysed as determined by observing a clear solution.

6. Add 250 μl of Coulter-Immunolyse fixative and vortex.

7. Add 2 ml of wash buffer and centrifuge for 5 min at 400 × g. Repeat wash twice using 2 ml of wash buffer.

8. Remove supernatant and resuspend cell pellet in 200 μl of PBS and 200 μl of 1% formaldehyde. Incubate at 4°C overnight.

CD3+ and L90

A

CD3+ T Cell Gate

CD8+ CD38+

B

Median = 22

Standard Curve (CD38-PE)

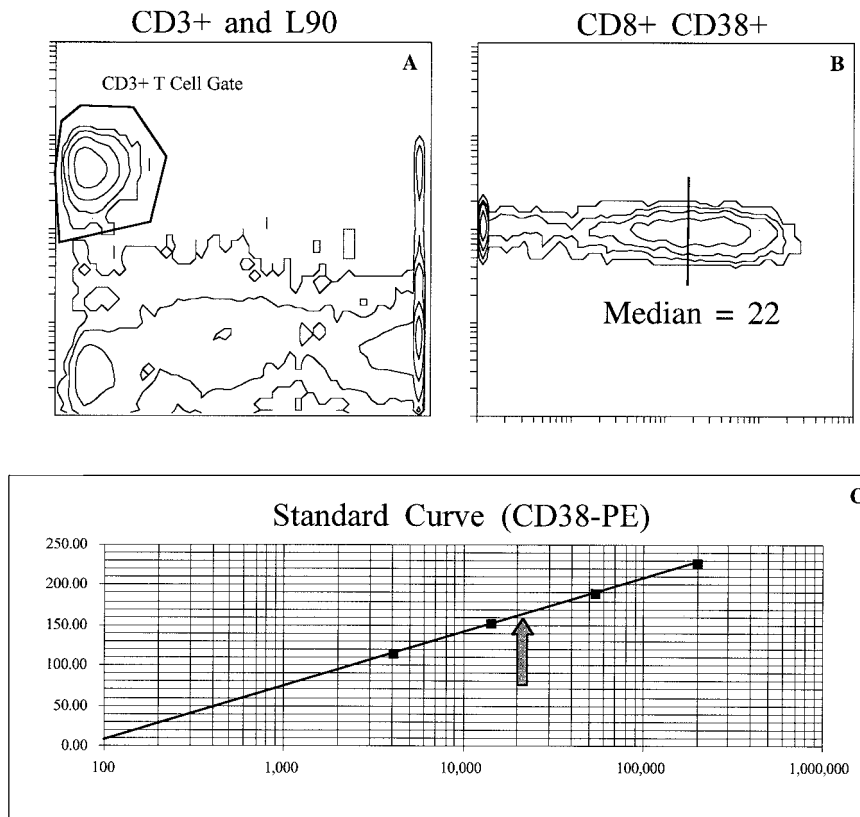
C


FIGURE 3 Representative histograms show the measurement of the CD38 intensity from CD3+ CD8+ T cells. (A) T-cell gate population (CD3+ cells) on a side scatter-versus-CD3 histogram; (B) CD38 median measured on a CD38-versus-CD8 histogram; (C) calibration curve of antibody binding capacity values versus histogram channel number (scale, 0 to 255). Median channel number (relative linear channel) is converted to a 256-standard channel number and then read from the calibration curve (C) to determine the antibody binding capacity. In this example, a median channel measurement of 22 was determined to represent an antibody binding capacity of 21,272.

9. Using Flow-JO analysis software, gate on the CD3+ T cells and measure the median value of cells which are CD8+ and CD38+. Each median value is compared to the standard curve (as described below) to calculate the receptor expression.

Controls and Calculations

Isotype control: These clones (IgG1-FITC, IgG1-PE, and IgG1-PerCP) provide the general location of cursors to define the negative and positive regions of test clones.

Positive control: The Daudi cell culture lines are cancer cells expressing high levels of CD38. These cells are available commercially (PanBIO INDX, Inc.) as a fixed stable product, which when stained with anti-CD38 provides a reproducible positive control.

Standardization, Quality Control, and Quality Assurance

QSC standard curve: Quantum Simply Cellular (QSC) beads have a standardized amount of goat anti-mouse clone on the surface to capture reacting mouse clone added to these beads. Figure 3C shows the typical standard curve produced by the procedure listed below.

Shown is a plot of the median values versus each bead intensity as assigned by the product insert.

1. Mix 280 μl of QSC beads with 20 μl of anti-CD38 MAb (final concentration, 5 μg/ml) in a 12- by 75-mm test tube.
2. Incubate for 30 min at 4°C.
3. Add 2 ml of PBS and centrifuge at 400 × g for 5 min.
4. Resuspend in 150 μl of PBS and 150 μl of 1% formaldehyde.
5. Acquire at least 2,000 total counts of data on the flow cytometer and run the analysis in the Flow-JO software. Plot the median values versus each bead intensity as assigned by the product insert.

Interpretation

The sensitivity of the quantitative fluorescence is based on the use of the standard curve as described in the standardization section. Tolerance ranges for each receptor can be defined by the measurements based on healthy, uninfected individuals. Median channel values obtained from the flow cytometer can be translated into receptor expression using the standard curve and compared to the normal range. Values outside of 2 standard deviations from the median (median values obtained, usually ca. 10 to 20 measurements) are considered significant.

Method 3. Measurement of T-Cell Activation Function: Intracellular Calcium Cell Signaling Assay

As discussed in detail in the introduction, the measurement of ligand binding to specific cell surface receptors is a complex but highly organized event. One of the best-studied examples is TCR complex binding to a specific peptide-MHC complex on the APCs. After these cell surface events occur, PTKs sequentially activate PLC-γ1. This active enzyme forces the hydrolysis of phosphotidylinositol 4,5-bisphosphate, causing an increase in IP_3. Within seconds following stimulation of the TCR or other surface receptors a substantial increase in IP_3 is observed. This molecule acts as a secondary messenger to increase the intracellular calcium levels as well as PKC from the stores associated with the endoplasmic reticulum. Increases in calcium cause activation of genes whose products are involved in the transcription of DNA sequences such as the IL-2 gene. In this method the calcium measured results from the increase that occurs after cell surface events have occurred and in general

indicates a cell committed to the lymphocyte activation process. The outcome of the committed cell process may be the secretion of cytokines such as IL-2, chemokines, or hormones involved in cell growth.

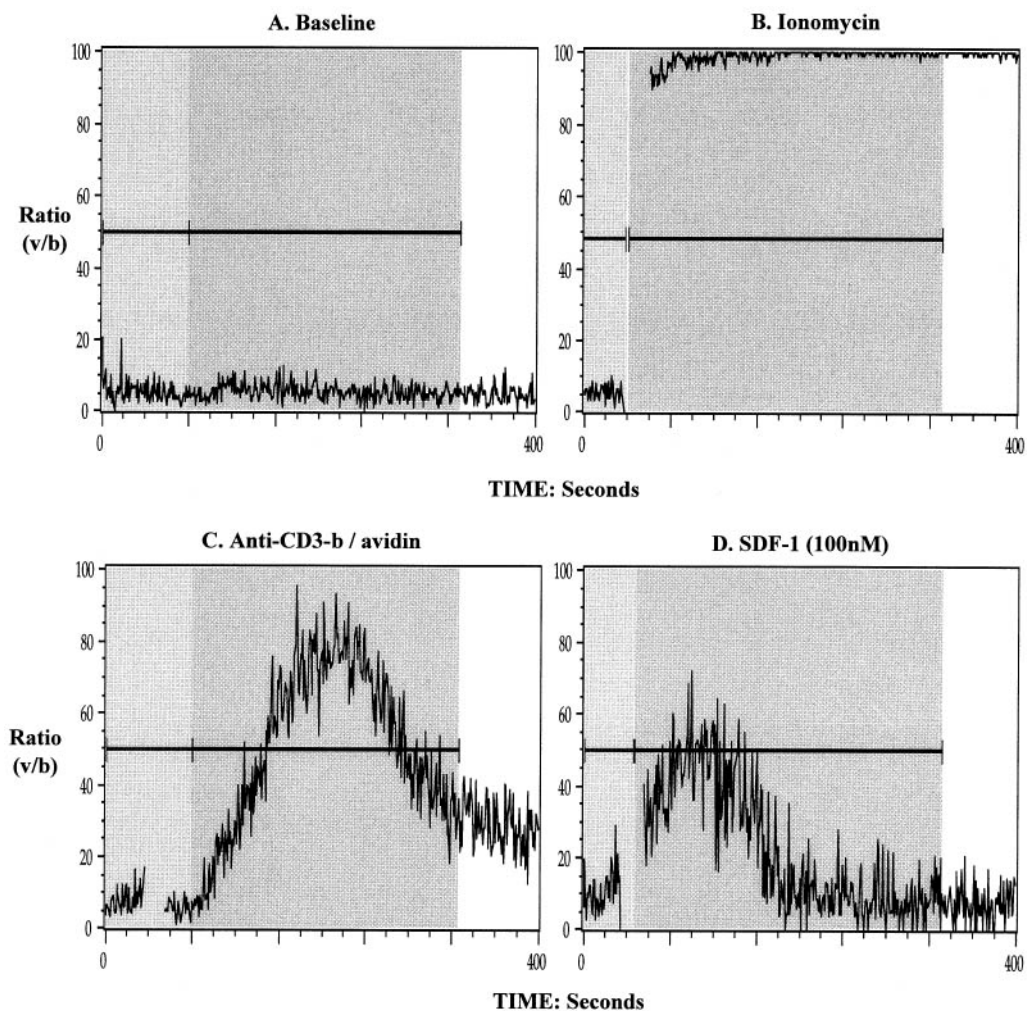
In this example (Fig. 4), the binding of chemokines to specific cell surface receptors, such as the interaction of SDF-1 with CXCR4, increases intracellular calcium levels. The consequence of this increase can influence the release of soluble cytokines, which can increase the surface expression of chemokine receptors. Increases in chemokine synthesis and secretion can have dramatic effects on lymphocyte trafficking and the immune response (6, 34). The well-known fluorescent dye INDO-1 can be transported through the cell membrane and once in the cytoplasm is converted by cell esterases into the active form, INDO-1-a. This active form interacts with free calcium, causing a change in the fluorescent properties of this dye. In resting cells, where very little free calcium is measurable (<200 nM), the dye exhibits high blue light emission and low UV light emission, making the violet/blue


FIGURE 4 Representative calcium assay graphics showing the measurement of the v/b ratio versus time. The first cursor indicates the resting phase, and the second cursor represents the responding phase. (A) Baseline curve with no stimulation added; (B) INDO-1-labeled cells stimulated with ionomycin (2 μg); (C) INDO-1-labeled cells stimulated with avidin after pretreatment of cells with anti-CD3 (see control section for details); (D) INDO-1-labeled cells stimulated with SDF-1 (100 nM) after 7 days of cell activation.

(v/b) ratio low. However, upon cell activation and release of free calcium (<200 nM) the v/b ratio is increased, indicating calcium binding to INDO-1 dye and changing the spectral characteristics (e.g., low blue light emission and high UV light emission).

Sample Requirements

Collect whole blood (40 ml) in heparin-treated Vacutainer tubes and process within 2 to 4 h. Cell viability must be greater than 95% or additional reagents are required to identify the nonapoptotic or membrane-damaged cells.

Materials and Reagents

Prepare Pluronic/INDO working solution.

1. Reconstitute a 50-μg ampoule of INDO-1 AM (Molecular Probes) with 50 μl of DMSO. Mix well by pipetting and incubate for 2 min at room temperature (RT). INDO-1 is both hygroscopic and light sensitive, so this reagent must be made fresh for each use.

2. Add 25 μl of the 20% Pluronic F-127 stock. Mix well by pipetting and incubate for 2 min at RT. (Note: Heat under hot tap water to resolve into a clear liquid before use.)

3. Add 62.5 μl of the fetal calf serum stock. Mix well by pipetting and incubate for 2 min at RT.

4. Keep at RT and protect from light; reagent will remain stable for 24 h.

INDO medium (Hanks balanced salt solution [HBSS] with Ca^{2+} and Mg^{2+} ions and 1% fetal calf serum): add 0.5 ml of fetal calf serum into a final volume of 50 ml of HBSS (with Ca^{2+} and Mg^{2+} ions). If HBSS does not contain Ca^{2+} and Mg^{2+} ions, add 0.07 g of $CaCl_2$ and 0.07 g of $MgSO_4 \cdot 8H_2O$ in 500 ml of HBSS. Stored at 4°C, the reagent is stable for 1 month.

Pluronic F-127 solution: Prepare a 20% (wt/vol) stock solution in DMSO (Sigma Chemical Co.). Store at 4°C and protect from light. Dissolve reagent gels at RT by placing under hot tap water until all dissolved. Reagent will remain stable for 6 months at 4°C.

Stocks of MIP-1β, eotaxin, and SDF-1β (R&D Systems Inc.) are frozen at concentrations of 50 μg/ml (2,700 nM) in 50-μl volumes in 0.1% fetal calf serum (heat inactivated) in sterile PBS. Dilute stocks with INDO medium to make a working concentration of 22.2 μg/ml (1,200 nM) by adding 62.5 μl of INDO medium into 50 μl of stock ligand (R&D Systems Inc.).

Streptavidin (Southern Biotechnology Corp.): Add 20 μl of a stock concentration of 1,000 μg/ml or 40 μg per

cell activation. Note: This control may not work in some cell lines.

Ionomycin (working concentration = 1 mg/ml [molecular weight, 747.1]; Sigma Chemical Co.): Use 2 μl (3 μM) per cell activation.

CD3-biotin (Becton Dickinson Corp.): Dilute to a final concentration of 5 μg/ml per 10^6 cells.

Phytohemagglutinin: Dilute to a final concentration of 100 μg/ml in sterile culture medium (Gibco BRL).

Ficoll-Hypaque (Sigma Chemical Co.): Sterile lymphocyte density medium; use undiluted.

IL-2 (R&D Systems Inc.): Dilute to 20 U/ml in sterile culture medium.

Culture medium: Mix the reagents shown in Table 1 in a sterile container. Store at 4°C for 1 month.

Equipment and Instrumentation

Flow cytometer: Elite-ESP (Beckman-Coulter Corp.) equipped with a 488-nm argon laser, a 325-nm HeCad laser, gated AMP, and five photomultiplier tubes (PMT1, PMT2, PMT3, PMT4, and PMT5) in addition to a solid-state light scatter detector (FALS). The 488-nm monochromatic argon laser excites all conjugated MAbs in the assay: FITC, PE, and PerCP. The 325-nm HeCad laser excites the active form of the INDO-1 dye. All data are stored in listmode file format (FCS), and complete analysis is performed using Flow-JO software (Tree Star, Inc.).

Procedure

1. Collect 40 ml of whole blood in heparin-treated Vacutainer tubes and process within 4 to 6 h.

2. Centrifuge Vacutainers at $600 \times g$ for 20 min and remove leukocytes located on top of the RBC fraction (i.e., the buffy coat layer). Dilute this fraction 1:2 with sterile PBS and overlay onto 5 ml of Ficoll-Hypaque. Centrifuge at $600 \times g$ for 30 min at RT. Remove lymphocyte layer (middle layer), dilute 1:2 with sterile PBS, and centrifuge at $400 \times g$ for 5 min.

3. Resuspend cells in culture medium containing phytohemagglutinin (50 μg/ml) and IL-2 (20 U/ml); culture cells for 3 days at 37°C in 5% CO_2. After 3 days in culture, replace medium with culture medium containing IL-2 (20 U/ml) and culture for an additional 4 days.

4. Add 10×10^6 cells to a 15-ml conical tube, wash twice in INDO medium, and resuspend cells in 1 ml of INDO medium. Note: Use at least 0.25×10^6 to 1.0×10^6 cells per reaction; ideally 500,000 cells should be used.

TABLE 1 Culture medium reagents (Gibco BRL) required for the protocol

Reagent (concn)	Vol (ml)	Concn (%)	Final concn
Fetal calf serum (sterile filtered)	100	10	10% (vol/vol)
Penicillin (10,000 U/ml) + streptomycin (10,000 μg/ml)	10	1	100 U/ml 100 μg/ml
Gentamicin (40 mg/ml)	2.5	1	100 μg/ml
Glutamine (200 mM)	10	1	2 mM
RPMI 1640	877.5	NA[a]	NA
Total	1,000		

[a]NA, not applicable.

5. Add 7 μl of Pluronic/INDO working solution to 1 ml of cells. Note: Since time to activation is critical (complete activation within 2 h from the addition of the dye), samples should be staggered by 40 min. Keep samples on ice until the INDO dye is added.

6. Incubate at 31°C for 40 min. Note: Time and incubation periods are important in that the cell esterases must convert the entire enzyme into the active form. For this reason, time studies are necessary to determine this critical step. Generally, for most cells 40 min will be long enough; however, cells like monocytes will process the stain faster because of the increase in active esterases with these cells.

7. Wash twice ($400 \times g$ for 5 min) in INDO medium.

8. Add enough medium to adjust the cell concentration to 10^6/ml (example: if cells are at a concentration of 10×10^6/ml, add 9 ml of INDO medium). Remove 500 μl per reaction (500,000 cells). Cells are now ready for analysis. Hold on ice no longer than 2 h before activation.

9. Incubate 500 μl of INDO-loaded cells (0.5×10^6) at 37°C for 5 min.

10. Run on flow cytometer for at least 30 s for background analysis (unstimulated fraction) before pausing to add stimulant.

11. After 30 s add stimulant to achieve the final concentrations shown in Tables 2 and 3 for each activation.

12. From saved listmode files, complete analysis using the Flow-JO software program. Report percentage of cells responding over baseline of the unstimulated cell fraction.

Controls and Calculations

CD3 staining for biological positive control: This control determines the intact nature of the cell signaling proteins and thus after cross-linking with avidin acts as a positive control.

1. Resuspend 0.5×10^6 cells in 500 μl of INDO medium and label this tube as the CD3 control.

2. Add 40 μl of anti-CD3-biotin clone (final concentration, 5 μg/ml).

3. Place on ice in the dark for 20 min.

4. Add 2 ml of INDO medium and centrifuge at $400 \times g$ for 5 min.

5. Wash once with 2 ml of INDO medium and centrifuge at $400 \times g$ for 5 min.

6. Resuspend in 500 μl of INDO medium before analysis.

Alignment of the HeCad Laser

Using the standard blue beads (324/421; Molecular Probes), dilute 1/1,000 with PBS (or until the rate of 300/s can be established), and run using the calcium protocol and filters as described by the protocol, except the 325LP should be substituted for the 381BP filter. With this filter in place light should be collected in both the violet and blue photomultiplier tube

parameters (simulating positive signal detection). When the 381BP filter is in place only blue light will be observed (simulating baseline signal detection). Hence, this controls for both alignment and the ability of the instrument to measure UV light (Color Plate 3).

Unstimulated or baseline negative control: INDO-loaded cells run for the first 30 s before any stimulant is added provide a negative control as well as an internal control.

Calculations

INDO-1 AM: Molecular mass is 1,009.9 g/mol. One vial contains 0.05 mg. The total diluent volume in Pluronic/INDO working solution is 0.1375 ml; use 7.0 μl of working solution in 1 ml of cell suspension.

The molarity (in millimoles per liter) of INDO-1 AM in the Pluronic/INDO working solution is calculated as follows: 0.05 mg/(1,009.9 g/mol $\times$ 0.1375 ml $\times 10^{-3}$ liter/ml) = 0.05/0.13886 = 0.36.

The final concentration (molarity) (in millimoles per liter) of INDO-1 AM in the cell loading mixture is calculated as follows: (0.007 ml $\times$ 0.36 mM)/1 ml = 0.00255, or 2.55 μM. Thus, the final concentration of INDO-1 AM in the cell loading mixture is 2.55 μM.

The concentration of Pluronic F-127 in stock solution is 20% (0.025 ml of Pluronic F-127 stock solution in Pluronic/INDO working solution). The total diluent volume in Pluronic/INDO working solution is 0.1375 ml. Use 7.0 μl of working solution in 1 ml of cell suspension. The concentration (Z) of Pluronic F-127 in the Pluronic/INDO working solution is calculated as follows: (0.025 ml $\times$ 20%)/0.1375 ml = 3.636%.

The final concentration (Z) of Pluronic F-127 in the cell loading mixture is calculated as follows: (0.007 ml $\times$ 3.636%)/1 ml = 0.025%.

The final concentration of MIP-1β = 128 nM.

The final concentration of SDF-1β = 125 nM.

Standardization, Quality Control, and Quality Assurance

To standardize the mean calcium peak response, by using the formula below, the mean peak response can be translated into calcium concentration (nanomolar). It is important to note that the dissociation constant (K_d) varies dramatically as a function of temperature, pH, and ionic strength. Hence, it is critical to keep these parameters consistent from test to

TABLE 2 Experimental nanomolar equivalents for final concentrations of stimulants

Final concn (μg/ml)	Equivalent concn (nM)	
	SDF-1	MIP-1β
1	125	128
0.5	62.5	64
0.1	12.5	12.8

TABLE 3 Chemokine test layout

Stimulant	Vol required (μl)	Final concn	Expected result
INDO medium	NA[a]	NA	Negative control
Streptavidin	20	40 μg/ml	Positive control
SDF-1	100	100 nM	Test
MIP-1β	100	100 nM	Test
Eotaxin	100	100 nM	Test
Ionomycin	2	2 μg/ml	Positive control

[a]NA, not applicable.

test and experiment to experiment to use this calculation. In this equation the K_d is the effective dissociation constant (250 nM at 37°C, pH 7.05), and R, R_{min}, and R_{max} are the fluorescence intensity ratio (v/b) values at test, zero, and saturating levels of calcium, respectively. S_{f2}/S_{b2} is the ratio of blue or green fluorescence intensity of the calcium-free and bound dyes. Since this term is a constant that depends primarily on the filters used for the INDO-1 analysis, it can be considered equivalent to 1 when using the same instrument for the calcium determination. The R_{min} can be determined by using certified blank beads (Flow Cytometry Standards Corp.) and calculating the intensity ratio (v/b). Finally, the R_{max} can be determined by the addition of the calcium ionosphere ionomycin to INDO-1-loaded cells as follows: $[Ca^{2+}] = K_d \times (R - R_{min})/(R_{max} - R) \times S_{f2}/S_{b2}$.

Interpretation

The resting cell concentration of free calcium is approximately 200 nM, with less than 5% of total cells above baseline. Percentages greater than 5% or calcium concentrations two times more than the baseline are considered to indicate responding cells. These values can be compared to those from a normal group to determine significance ($n = 20$) with each stimulant used.

Quality Control and Quality Assurance

Tube-to-tube reproducibility: With addition of anti-CD3 to each test sample the total number of CD3$^+$ T cells can be determined. The acceptable tolerance is 5% between tubes within the same run. In the calcium assay, reproducibility can be determined by using the baseline fluorescence intensity ratio (v/b). The tolerance on these values should be within 5% of each run.

Lot-to-lot reproducibility of MAb: MAbs can be tested against a normal cell line, which is fixed to maintain stability (CD Chex cell control; Streck Laboratories). In general, the percentage or the intensity of fluorescence can be monitored from lot to lot with a tolerance ±10% from defined ranges provided in the product insert.

Microscopic examination: After staining samples or loading cells with INDO-1 dye, a sample can be observed under a fluorescence microscope for correct fluorescence. As an example, cells stained with CD38-PE should appear yellow, while cells stained with CD4-FITC should appear green. In the calcium assay, cells stained with INDO-1 in the active form should appear blue under a mercury arc lamp with a UV filter setup.

College of American Pathologists surveys: Cell proficiency surveys can test both accuracy and reproducibility of immunophenotyping. However, there is currently no proficiency program available for the calcium assay.

Pitfalls and Troubleshooting

The more common problems found in the above-mentioned assays and the corrective actions are listed in Table 4.

TABLE 4 Problems and corrective actions

Problem	Corrective action
High angle interference in the forward scatter vs. L90 light scatter pattern	Suspect RBC contamination from unlysed cells. Check expiration date on lysis reagent and correct dilution. Run autofluorescent control to check lysis reagent before adding to test samples.
Limited cell recovery after separation on Ficoll-Hypaque	Suspect failure to use this density medium at RT. Warm Ficoll-Hypaque to RT before adding cells and centrifuge at RT.
Loss of CD4 on the surface of T cells after exposure to PMA	Suspect kinetic issue or concentration of PMA. A loss of CD4 will occur after PMA treatment due to the activation of PKC. This is generally observed with longer incubation times and higher concentrations of phytohemagglutinin. If longer time is needed, adding monensin (2 µM) to the culture will inhibit this process.
Loss of cells or inconsistent CD3$^+$ T cells from tube to tube	Suspect cells may be lost due to low centrifuge speed. Increase speed for all cell washes to $400 \times g$ and centrifuge for at least 5 min at 4°C.
Decreased number or loss of INDO-1-positive cells	Suspect incubation time or temperature. Most cells will be completely loaded with the active form of INDO-1 at 40 min. Check using a fluorescence microscope equipped with UV filters. Active dye will fluoresce blue after exposure to UV irradiation.
No violet or blue light emission but cells are INDO-1 positive	Suspect UV laser alignment. Repeat HeCad laser alignment procedure as outlined in the control section.
High INDO-1 background fluorescence	Suspect tubing is contaminated with previously run stimulant. Replace tubing and wash between runs with DMSO-distilled H$_2$O and INDO medium. Additionally, run all ionomycin controls at the end of all test samples.
Ionomycin control is negative	Suspect cells are not loaded correctly or INDO-1 dye reagent has expired. Load cells with INDO-1 within a 2-h window of analysis and prepare INDO-1 dye from frozen stock on the day of analysis.

REMARKS AND CONCLUSIONS

The combined use of flow cytometry and evolving technologies, such as gene microarray systems and proteomics, will tremendously increase our understanding in the field of T-lymphocyte activation and signaling.

Functional Assays for B Cells and Antibodies

MOON H. NAHM AND ROBIN G. LORENZ

37

The primary cells of the adaptive immune system are T cells, B cells, and natural killer cells. These lymphocytes assist the host in eliminating both intracellular pathogens (T cells) and extracellular pathogens (B cells and antibodies) through B-cell–T-cell interactions, as well as interactions with cells and molecules of the innate immune system. B cells recognize foreign antigen by the B-cell receptor (BCR), a membrane-bound immunoglobulin generated through a complex genetic recombination process (3). The BCR recognizes conformational protein antigens, as well as nonprotein antigens. Two types of B cells have been described based on expression of cell surface molecules and function. B1 (CD5[+]) B cells are thought to be a more "natural" type of B cell which responds to T-cell-independent forms of antigen (i.e., bacterial polysaccharides) (22, 25). B2 B cells respond to T-cell-dependent antigens, such as the more classical protein antigens tetanus and diphtheria toxoids. Both classes of B cells respond to BCR binding of foreign antigen by proliferation, differentiation into antibody-secreting plasma cells, and formation of memory B cells.

The function of the humoral immune response differs depending on the class of antibody produced and the differentiation state of the B cell. Naive B cells express CD19, CD20, and surface immunoglobulin M (IgM) and IgD (Table 1). After BCR stimulation, B cells become memory cells or plasma cells. These cells express unique antigens. In addition, immunoglobulin class switching occurs and IgG, IgA, or IgE is produced. Each of these immunoglobulin classes has distinct functions. IgM can bind pathogens and activate complement. IgG can directly neutralize bacterial toxins, block adhesion of pathogens, and also activate complement. IgA can also neutralize toxins and block adhesion of pathogens, but it functions primarily at mucosal sites, while IgE plays a role in the immune response to parasites. After BCR stimulation, the immunoglobulin produced by B cells also increases its affinity for antigen, therefore improving the functionality of the humoral response.

Primary defects in the humoral components of the immune response are usually recognized by such clues as frequent development of infections early in life and difficulty in clearance of infections. The type of infection will often clue the clinician in to a possible B-cell or antibody defect (Table 2). In addition, frequent or incompletely cleared infections are also often a clue (Table 2). Primary immunodeficiencies are covered in greater detail in chapter 101.

A more immediate concern to most physicians is the increasing incidence of secondary immune deficiencies due to infections such as human immunodeficiency virus (covered in chapter 95), cancer (multiple myeloma), chronic renal failure, autoimmune processes, or posttransplantation immunosuppression.

In some patients, the absence of B-cell function is clear because B cells are undetectable. In many cases, patients may have B cells but their function is abnormal because the B cells are either tolerized or anergic. There is also a need to measure functionality of antibodies since not all antibodies are protective. A very young child may produce ineffective antibodies. Elderly persons may produce ineffective pneumococcal antibodies, and human immunodeficiency virus patients may make ineffective antibodies. The ineffective antibodies may express inappropriate isotypes or V regions, resulting in low-avidity antibodies or the inability to activate complement.

APPROACHES FOR ASSESSING B-CELL FUNCTION

A complete blood count (CBC) is often the first test performed in the evaluation of the humoral immune response. However, the CBC is clearly not a good screening test, as often the total lymphocyte count in humoral immunodeficiencies is normal or only slightly decreased. Therefore, the next step in the evaluation of a possible humoral immunodeficiency is the measurement of serum antibody concentrations.

In Vivo B-Cell Function

Immunoglobulins

The most direct measure of in vivo B-cell function is immunoglobulin secretion by plasma cells. Serum immunoglobulins are most commonly measured by automated nephelometry (described in detail in chapter 8). The immunoglobulins routinely measured in serum are IgG, IgA, and IgM. The normal ranges for serum immunoglobulins vary depending on both the age and gender of the individual (8). A significant seasonal variation in serum IgA levels has also been described (40). In addition to the measurement of total serum immunoglobulin concentrations, levels of subclasses of IgG and IgA can also be determined by automated nephelometry. Patients have been reported to have deficiencies of one or

TABLE 1 B-cell markers used in flow cytometry

Marker	B-cell population
CD19	Early B cells to B-cell blasts
CD20	Pre-B cells to B-cell blasts
CD23	Activated B cells
CD27	Memory B cells
CD5	B1 B cells
Surface IgM	Immature, mature, and memory B cells
Surface IgD	Mature and memory B cells
Surface IgG, IgA, and IgE	Isotype-switched memory B cells
CD138 (syndecan 1)	Plasma cells

more subclasses of IgG even when they have normal levels of total serum IgG. However, the true biological significance of IgG subclass deficiencies remains controversial (7, 21). The rate of bacterial infections is increased in some individuals with low serum IgG2 concentrations but not in others, e.g., Wiskott-Aldrich syndrome patients (27). Therefore, it is more clinically significant to measure functional levels of serum antibody to typical vaccine components, such as tetanus, diphtheria, pneumococcus or *Haemophilus influenzae* type b (for protein antigens refer to chapter 52, and for polysaccharides refer to chapter 51).

The presence of antibodies against vaccine components, detected by random sampling, is indicative of an intact humoral immune system in children who have received their vaccines. If titers of immunoglobulins against common vaccine antigens are low, then specific antigen challenge should be performed. Serum samples are obtained before and 2 to 3 weeks after vaccination. The paired sera are then tested simultaneously, and a patient is considered to have mounted an adequate response if a fourfold or greater rise in specific titer is seen. This type of challenge can be performed either with polysaccharide vaccines (pneumococcal or meningococcal vaccines) or with neo-protein antigens such as bacteriophage φX174 or keyhole limpet hemocyanin (4, 13, 29).

In addition to the measurement of serum immunoglobulins against vaccine antigens, the levels of B1 B-cell production of anti-A or anti-B isohemagglutinin IgM antibodies can also be investigated. The presence of these T-cell-independent antibodies against blood group antigens depends on both the age of the patient and the patient's blood group (i.e., no

antibodies are seen in the serum of blood type AB individuals). As IgM is produced by the newborn, this type of testing can be performed earlier than testing for vaccine-induced immunoglobulins. A normal titer is at least 1:8 (11).

Peripheral Blood B Cells
The actual number of B cells in the peripheral blood cannot be determined by the CBC. B cells can, however, be identified through the use of flow cytometry (see chapter 18, this volume). In this technique, cells are characterized by their expression of cell surface markers and the percentage and absolute number of B cells expressing certain immunophenotypes are compared to age-matched reference values (36). The most classic B-cell surface markers are CD19 and CD20 (Table 1). CD19 is a critical signal transduction molecule that regulates B-lymphocyte development, differentiation, and activation. Its expression is seen on B cells from the earliest recognizable B-lineage (early immunoglobulin gene rearrangements) to B-cell blasts. However, the expression is lost upon plasma cell maturation. CD20 is expressed on B cells from the pre-B stage to the B-cell lymphoblast stage but is not found on early B-cell progenitors or plasma cells. In general, CD19+ CD20+ cells constitute between 5 and 10% of the total peripheral blood lymphocyte pool. Upon antigen activation, a number of cell surface markers are detected on B cells (Table 1). The presence or absence of these markers can be useful in the evaluation of B-cell deficiencies in patients. One recent example is the absence of CD27+ IgD− IgM− mature class-switched memory B cells in X-linked hyper-IgM syndrome and a subpopulation of patients with common variable immunodeficiency (1, 30, 39). It has also recently been reported that flow cytometry can be used to identify antigen-specific B cells, using the fact that the BCR can be "stained" by its specific antigen (37).

In Vitro B-Cell Function
Flow cytometric analysis of B-cell populations is only useful to identify defects in the actual numbers of B cells. In order to identify functional abnormalities, additional studies must be undertaken. The classic evaluation of B-cell function is through isolating peripheral blood lymphocytes from the patient and culturing them with agents known to activate normal B cells. This assay is known as the lymphocyte proliferation assay (LPA) (14, 35). In the LPA, either whole blood or purified peripheral blood mononuclear cells (PBMC) are cultured with a variety of stimulants to determine the B-cell response. The cells are cultured with the stimulants for 3 to 7 days, and the effects of this activation can be measured by cellular proliferation and antibody secretion. The agents that specifically activate B cells are listed in Table 3. B cells can also be exposed to protein antigens such as tetanus toxoid, and then specific antibody (and isotype) secretion into the media can be characterized. As the amount of antibody secreted is small, these levels cannot be detected by nephelometry, and enzyme-linked immunosorbent assay (ELISA) or ELISPOT must be used instead (see chapter 28, this volume). As LPAs are not available in most clinical immunology laboratories, this testing must often be performed on patient samples that are shipped to a specialized testing facility. This sample transport introduces a significant concern regarding sample integrity, as the testing requires live, functional B cells for accuracy. Many laboratories performing LPAs consequently require a normal sample to be shipped with the patient sample, to control for transport issues.

TABLE 2 Associations with humoral or B-lymphocyte deficiencies

Infectious agents
  Streptococcus pneumoniae
  Streptococcus pyogenes
  Haemophilus influenzae
  Ureaplasma urealyticum
  Giardia lambia

Clinical conditions
  Recurrent otitis
  Recurrent pharyngitis
  Recurrent sinusitis
  Recurrent bronchitis
  Recurrent conjunctivitis

TABLE 3 In vitro activators for B-cell proliferation and immunoglobulin production

Activator[a]	Target	Dose range	Source[c]	Reference
SAC	BCR	0.004%	Calbiochem	9
Anti-IgM	BCR	10 µg/ml	BioRad	10
PWM	—[b]	1–10 µg/ml	Sigma	16
Tetanus toxoid	BCR	1–20 µg/ml	Wyeth	16

[a] SAC, *Staphylococcus aureus* Cowan I; PWM, pokeweed mitogen.
[b] PWM requires T cells to be present for its mitogenic effect on B cells; therefore, it is not a specific assay of B-cell function.
[c] Multiple sources exist for some products.

Cellular Proliferation

The ability of B cells to proliferate in response to stimulation in the LPA is usually presented as the stimulation index (SI). Currently the proliferative response is measured by the incorporation of tritiated thymidine ([³H]thymidine) into DNA of replicating cells. Therefore, the SI is expressed as the counts per minute of the stimulated wells divided by the counts per minute of the control wells (wells with patient B cells but no stimulus). A second method of reporting is the net counts per minute, which are the counts per minute of the stimulated wells minus the counts per minute of the control wells. An alternative method for the measurement of proliferation in the LPA is the analysis of the cell cycle by flow cytometry (2). In this readout of proliferation, stimulated and control cells are permeabilized and stained with propidium iodide, and the cells in the S phase of the cell cycle are counted. Normal ranges for proliferation in the LPA have been difficult to establish due to a high degree of variability in this assay secondary to different culture conditions in each laboratory. Therefore, the LPA is best utilized as a qualitative indicator of lymphocyte function, rather than a quantitative assay.

Secretion of Soluble Mediators

In addition to proliferation, stimulation of B cells in the LPA induces B cells to produce and secrete immunoglobulins. Measurement of mitogen- or antigen-induced immunoglobulin secretion will assess whether the immunoglobulin class or isotype of interest is produced in the amounts expected by age or disease state. The total culture levels of immunoglobulins are assayed by ELISA (see chapter 28, this volume). The amount of immunoglobulins produced can also be assayed at the single-cell level by ELISPOT. This assay is most useful to determine antigen-specific B-cell frequency, which is not determined by proliferation or total immunoglobulin assays.

APPROACHES FOR ASSESSING ANTIBODY FUNCTION

Antibodies provide protection to the host in various ways. Antibodies can neutralize toxins (e.g., tetanus toxin), neutralize viruses, prevent the adhesion of bacteria to the host cells, kill bacteria in the presence of complement, and opsonize bacteria for phagocytes (19). Consequently, a variety of assays can be used to measure antibody function. While antibody function assays can be performed with experimental animals, in vivo assays are impractical and thus in vitro assays are widely used. As examples of in vitro antibody function assays, we describe in vitro bactericidal assays and in vitro opsonization assays in detail below.

Bactericidal Assays

In bactericidal assays, antiserum is mixed with bacteria and complement. The antibodies bind to the bacteria and activate complement. The activation of the complement damages the bacterial surface and results in their death. The number of surviving bacteria can be determined by plating a sample of reaction mixture on an agar plate. Then, by testing the bactericidal properties of the serum samples at multiple dilutions, one can determine the dilution that kills half of the bacteria.

Generally, the complement-mediated bactericidal mechanism does not kill gram-positive bacteria, although there are exceptional cases (15). This mechanism is primarily relevant in the study of antibodies to gram-negative bacteria, which have thin walls. This assay method has been extensively used in developing meningococcal vaccines (38). Studies with meningococcal antibodies have shown that the animal source of the complement can influence the results. For example, generally rabbit serum produces higher bactericidal titers than human serum. In case of antibodies to group B meningococcus, human complement may detect antibodies to subcapsular antigens, but rabbit complement may detect antibodies to the capsule itself (38).

A major technical problem associated with the use of the bactericidal assay is determining the number of surviving bacteria. The classical approach is to plate the sample on an agar plate and count the bacterial colonies. This method is too tedious to use with a large number of samples. Although an effort has been made to automate the counting of bacterial colonies, other investigators have explored the use of dyes that either develop a color or become fluorescent in proportion to the number of live bacteria (20, 26, 31).

Opsonophagocytosis Assays

Opsonophagocytosis is the primary protective mechanism of antibodies against gram-positive bacteria. Various methods have been developed to measure the opsonizing capacity of antibodies in vitro. The classical approach is to perform an opsonophagocytic killing assay (18). In this assay, the bacteria are opsonized (coated) with antibodies and complement. Then the bacteria are exposed to phagocytes for phagocytosis and killing. The number of surviving bacteria is then determined. To rapidly determine the phagocytosis of bacteria, a new approach has recently been developed. In this approach, target bacteria are made fluorescent and the uptake of bacteria by phagocytes is measured with a flow cytometer (17, 24). Fluorescent bacteria can be prepared by

chemically tagging a fluorochrome or by inserting a gene for a fluorescent protein.

Opsonophagocytosis assays have been extensively studied for use during the development of pneumococcal vaccines. Since pneumococcal vaccines induce antibodies against 7 to 23 different serotypes, there is a need to develop functional assays that can simultaneously study antibodies to multiple serotypes. The multiplex assays would reduce not only the amount of work but also the need for expensive reagents and precious serum samples. One approach is to use target bacteria labeled with different fluorochromes that flow cytometers can differentiate (23). A flow cytometer-based assay can then be used to identify the uptake of different target bacteria.

Another approach, the antibiotic resistance strategy, uses target bacterial species with different antibiotic resistances (6, 18, 28). For instance, one bacterial species can be susceptible to penicillin but resistant to streptomycin. The other can be susceptible to streptomycin but resistant to penicillin. If these two bacterial species are mixed and tested together, the number of surviving bacteria of each species can be determined by using agar plates containing different antibiotics. This strategy is simpler to use and has been used successfully for up to seven different target bacteria (6). With automation of colony counting, the antibiotic sensitivity strategy may be simpler to adopt.

The increased use of functional assays has shown the importance of standardization. In the past, the Centers for Disease Control and Prevention has coordinated a collaborative study to demonstrate that functional assays can be standardized if various aspects of the assays (e.g., protocol and reagents) can be carefully controlled (33). For opsonization assays, phagocytes can vary. For instance, peripheral blood granulocytes can differ depending on the donor's genetic traits (e.g., Fc receptor allele) or health status. Thus, the use of a cell line such as HL-60 has been promoted. A recent study showed that even the source of the cell line must be standardized because samples of a cell line from different sources appear to have different biological properties (12).

METHODOLOGIES

In Vitro Whole-Blood LPA

Materials and Reagents

  RPMI 1640 (1×) liquid with L-glutamine, containing 10% human AB serum (heat inactivated for 1 h at 56°C)

  Penicillin and streptomycin (P/S) (100×; 5,000 U of penicillin per ml and 5,000 μg of streptomycin per ml) liquid

  Pokeweed mitogen (Sigma Chemical Co., St. Louis, Mo.) dissolved in phosphate-buffered saline (PBS) and kept frozen at –20°C at a concentration of 1 mg/ml. Keep frozen in small aliquots and use a fresh aliquot for each assay.

  Tritiated thymidine ([³H]thymidine) sterile, aqueous solution

  96-well round-bottomed tissue culture plates with lids (sterile)

  Scintillation fluid

  Pipette tips (sterile)

  Ficoll-Hypaque (density, 1.077 g/liter)

  PBS

  15-ml conical centrifuge tubes

  Serological pipettes (sterile)

  Class II laminar-flow biosafety hood

  CO_2 incubator with >95% humidity

  Cell harvester

  Pipetters and pipette aid

Procedure

1. Obtain a fresh heparinized venous blood sample. The sample should be held at room temperature (RT) prior to analysis and should be analyzed within 24 h of draw. A normal healthy control should be drawn at the same time as the patient sample and treated in a similar manner.

2. Dilute fresh heparinized blood 1:2 with sterile PBS and place in a 15-ml sterile conical centrifuge tube.

3. Underlay the Ficoll-Hypaque solution, using 3 ml of Ficoll-Hypaque per 10 ml of blood-PBS mixture.

4. Centrifuge for 20 min at $400 \times g$ in a refrigerated centrifuge at 18 to 20°C, with no brake.

5. Harvest the PBMC from the interface using a sterile pipette and wash three times in PBS ($200 \times g$, 10 min, 18 to 20°C).

6. Resuspend PBMC in RPMI 1640–10% AB serum, with P/S and glutamine at 10^6 live cells/ml. Use PBMC within 1 h. Viability can be ascertained by trypan blue exclusion.

7. In a sterile hood, add 100 μl of each antigen/mitogen concentration being tested to each well. This needs to be done in triplicate.

8. Add 100 μl of the diluted PBMC to each well.

9. Put on the sterile lid and place the plate in a CO_2 incubator at 37°C with 5% CO_2. To measure cell proliferation, incubate for 3 days for mitogens and 6 to 7 days for recall antigens.

10. To determine cell proliferation by [³H]thymidine incorporation, on the morning of day 3, each well is pulsed with 0.5 μCi of [³H]thymidine in 20 μl of RPMI 1640 (no serum). After 6 h the cells are harvested on fiberglass filters using a cell harvester. The filters are placed into scintillation fluid and counted on a beta scintillation counter. Triplicates are averaged and the SI is reported.

11. To assay for total antibody production, the assays are incubated for 7 days at 37°C with 5% CO_2. Remove the culture supernatant and use for ELISA determination (see chapter 28, this volume).

H. influenzae Type b

This procedure was adapted from the protocol of S. Romero-Steiner et al. used by the Centers for Disease Control and Prevention (32, 34).

Materials and Reagents

  Microtiter plate (round bottom)

  Cryovial

  Chocolate II agar plates (catalog no. 21169-21267; Becton Dickinson)

  Fildes enrichment (catalog no. 220810; BBL, Sparks, Md.) (see note 1 of assay notes at end of the procedure)

  Brain heart infusion (BHI) broth

  BHI broth with 2% Fildes enrichment (5)

Hanks' buffer with Ca^{2+} and Mg^{2+} (Life Technologies)

Dilution buffer: Hanks' buffer with Ca and Mg and 2% Fildes enrichment

Bacteria: *H. influenzae* type b strain Eagan or GB3292

Newborn rabbit serum for complement (Pel-Freez, Brown Deer, Wis.)

CBER standard serum (lot 1983). A serum standard from the Food and Drug Administration with 70 μg of antibody per ml is available.

Gamma globulin (Bayer, Elkhart, Ind.) for quality control purposes

Procedure for Preparing Bacteria

1. Inoculate *Haemophilus* bacteria onto a chocolate II agar plate and incubate the plate overnight (16 h) at 37°C in a 5% CO_2 atmosphere.

2. Transfer about 10 isolated bacterial colonies to 20 ml of BHI broth with 2% Fildes enrichment in a 50-ml glass vial and incubate at 37°C and 5% CO_2 until the optical density at 600 nm becomes 0.4 to 0.5 (note 2).

3. Add 3 ml of sterile glycerol to the bacterial culture (20 ml). Mix well. Dispense 0.5 ml into each cryovial.

4. Quickly freeze all cryovials (except one) at –70°C. Once frozen, store the vials at −70°C until use. The nonfrozen vial will be used in step 5.

5. Determine the bacterial recovery from frozen vials. (It should be greater than 80%.)
   a. Thaw a vial of frozen bacteria (step 4).
   b. Dilute both the unfrozen and thawed bacteria (step 4) 10^{-6}-, 10^{-7}-, and 10^{-8}-fold in dilution buffer.
   c. Plate 100 μl from each dilution onto a chocolate II agar plate.
   d. Incubate the plates overnight at 37°C in a candle jar.
   e. Count the colonies.
   f. Determine the ratio of the number of thawed bacteria to the number of unfrozen bacteria. The ratio should be >0.8.

6. Determine the dilution necessary to get about 1,000 CFU per 20 μl.
   a. Prepare six tubes with 0.9 ml of dilution buffer.
   b. Rapidly thaw an aliquot of bacteria.
   c. Add 100 μl of thawed bacteria to 1 ml of dilution buffer. Perform 10-fold serial dilutions by transferring 100 μl.
   d. Plate 10 μl in triplicate onto a chocolate II agar plate.
   e. Incubate the plates overnight at 37°C in a candle jar.
   f. Count the colonies and determine the average.
   g. Determine the dilution factor required to yield 1,000 CFU/20 μl.

Assay Procedure (note 4)

1. Perform twofold serial dilutions (8 or 10 dilutions) of antisera with dilution buffer.

2. Add 10 μl of diluted antiserum to duplicate wells of a microtiter plate.

3. Thaw an aliquot of bacteria.

4. Dilute the thawed bacteria in dilution buffer to prepare 1,000 CFU/20 μl.

5. Add 20 μl of the diluted bacterial suspension.

6. Incubate at 37°C for 15 min in a 5% CO_2 incubator.

7. Add 25 μl of baby rabbit complement (note 3).

8. Add 25 μl of dilution buffer.

9. Incubate the plates at 37°C for 60 min in a 5% CO_2 incubator.

10. Plate 5 μl of the reaction mixture onto a chocolate II agar plate.

11. Incubate the plates at 37°C in 5% CO_2 for 16 h.

12. Count the surviving bacteria.

13. Determine the serum dilution that kills ≥50% of the bacteria.

Assay Notes

Note 1: Fildes enrichment is a peptic digest of sheep blood. It is rich in hemin and NAD. Although 5% supplement is usually used (5), we found that 2% supplement is sufficient for bactericidal assays.

Note 2: Bacteria will be in the exponential phase of growth. It takes about 2 to 3 h. The broth acquires an amber color.

Note 3: Complement lots should be qualified prior to use in the assay. Both active and heat-inactivated baby rabbit complement is used to show that no bacterial killing is found during a 1-h incubation period.

Note 4: Serum growth controls (all reagents except complement source) should be included when the serum source is unknown or it is suspected to contain antibiotics or any other inhibitory substances.

Double Serotype Opsonophagocytic Killing Assay

The procedure for the double serotype opsonophagocytic killing assay was adapted from that described by Kim et al. (18).

Materials and Reagents

Tissue culture flask, vent cap (T-75 cm²) (no. 430641; Corning)

Tissue culture flask, vent cap (T-150 cm²) (no. 430825; Corning)

Microtiter plate (round bottom) (no. 3799; Costar)

Square petri dish (100 by 15 cm) (no. 08-757-10K; Fisher)

N,N-Dimethylformamide (DMF) (no. D131-1; Fisher)

2,3,5,-Triphenyltetrazolium chloride (TTC) (no. T-8877; Sigma)

Streptomycin sulfate (no. S-6501; Sigma)

Optochin (ethylhydrocupreine hydrochloride) (no. E-9876; Sigma)

Todd-Hewitt broth (no. 249240; Difco)

Yeast extract (no. 212750; Difco)

Bacto Agar (no. 214010; Difco)

10× Hanks' balanced salt solution (HBSS) (without Ca, Mg, or phenol red) (no. 14185-052; Gibco BRL)

10× HBSS (with Ca and Mg, without phenol red) (no. 14065-056; Gibco BRL)

RPMI 1640 (no. MT 10-040-CMRF; CellGro)

P/S (100×) (no. 15140-148; Gibco [Invitrogen])

GlutaMax-1 (100×) (no. 35050-061; Gibco [Invitrogen])

Fetal bovine serum (FBS; Fetalclone 1) (no. SH30080.03; HyClone)

Baby rabbit complement (no. 31038-100; Pel-Freez)

HL-60 cell line (CCL-240; American Type Culture Collection)

Target bacteria: These are shown in Table 4 (*target pneumococci are available from the NIH Respiratory Pathogen Reference Laboratory at* the University of Alabama at Birmingham, Birmingham, Ala.).

World Health Organization pneumococcal assay validation sera: These are available from D. Goldblatt in London, England.

−70°C ethanol: Keep a beaker with 400 ml of ethanol at −70°C for freezing bacteria.

Streptomycin stock solution: Prepare a 100-mg/ml stock solution in water. Make 1-ml aliquots and store at −20°C.

Optochin stock solution: Prepare a 5-mg/ml stock solution in water. Make 1-ml aliquots and store at −20°C.

Glycerol stock: Mix 20 ml of water and 100 g of glycerol. Autoclave and store at RT.

1% Sterile gelatin stock solution: Add 1 g of gelatin to 100 ml of water. Autoclave and store at RT.

Overlay agar: Add 15 g of Todd-Hewitt broth, 2.5 g of yeast extract, and 3.75 g of Bacto Agar to 500 ml of water. Autoclave and store at RT.

Todd-Hewitt–yeast broth (THY broth): Add 30 g of Todd-Hewitt broth and 5 g of yeast extract to 1 liter of water. Autoclave and store at 4°C.

Todd-Hewitt–yeast extract agar plate (THYA plate): Add 15 g of Todd-Hewitt broth, 2.5 g of yeast extract, and 7.5 g of Bacto Agar to 500 ml of water. Autoclave and let it cool down (to about 56°C). Pour 12 ml into a square petri dish and allow the plates to cool to RT. Store at 4°C in a humidified chamber for up to 1 month.

TTC stock solution for overlay agar: Dissolve 1 g of TTC in 100 ml of water, filter sterilize (0.22 μm pore size), and store at 4°C protected from light (up to 2 months). Warm the TTC stock solution to RT to dissolve any precipitate before use.

Procedures

Procedure for Routine HL-60 Cell Propagation

1. Add 100 ml of the tissue culture medium (RPMI 1640 with 1% L-glutamine plus 10% FBS + 1× P/S) with HL-60 cells ($\sim 10^5$ cells/ml) to a T-75 cm² flask.

TABLE 4 Pneumococcal strains used as targets for the opsonization assay

Serotype	Name
4	OREP4
6A	OREP6A
6B	STREP6B
9V	STREP9V
14	OREP14
18C	OREP18C
19A	STREP19A
19F	OREP19F
23F	STREP23F

2. Place the flasks in an incubator (37°C, 5% CO_2, see note 6); they can lie flat or upright.

3. When the cells become confluent, split the culture 10× (e.g., 10 ml of cells/90 ml of fresh medium).

4. The feeding cycle is ~ 2 to 3 days.

Procedure for HL-60 Cell Differentiation

1. Centrifuge the HL-60 cells at 1,200 rpm (Sorvall, RT-7 with RTH-250 rotor) for 5 to 10 min at RT. Remove **ALL** of the supernatant (to completely remove any antibiotics).

2. Gently resuspend the cell pellet in the differentiating medium (RPMI 1640 with 1% L-glutamine + 10% FBS + DMF [0.8%, vol/vol]) and adjust the concentration to $\sim 4 \times 10^5$ cells/ml.

3. Add 100 ml of the cell suspension to a T-150 cm² flask.

4. Incubate the flask in an incubator (37°C, 5% CO_2; see note 6) for 5 to 6 days; it can lie flat or upright. Do not feed the culture during this period.

5. Two flasks will usually yield enough differentiated cells to prepare four to six microtiter assay plates at ~ 150:1 (HL-60 cells to bacteria).

Procedure for Preparing Target Bacteria

1. Inoculate bacteria onto a blood agar plate and incubate overnight at 37°C in a candle jar (note 1). Pneumococci yield alpha-hemolytic colonies that can be identified by a green halo surrounding the colony.

2. Transfer ~ 10 isolated colonies to each of 10 tubes containing 10 ml of THY broth. Incubate for 3 to 6 h in a 37°C water bath until the top 150 μl of the culture broth has an optical density at 600 nm of 0.2 to 0.4.

3. Harvest the top 2 ml of the broth from each of the 10 tubes and pool (the pool will be 20 ml).

4. Add 7.6 ml of the 80% sterile glycerol and 20 ml of THY broth to the 20-ml bacterial pool. Dispense 0.5-ml aliquots into cryovials.

5. Do **NOT** freeze one vial, which will be used in step 6. Quickly freeze all the remaining cryovials in 95% ethanol kept at −70°C, and store the vials frozen at −70°C until used. The frozen vials can be stored up to ~ 18 months.

6. Determine whether the viability of frozen bacteria is greater than 80% using the unfrozen aliquot from step 5.

7. Determine the dilution necessary to get about 100 CFU/5 μl on THYA plates (note 2).

Procedure for the Double Serotype Opsonization Assay

1. Incubate the serum samples to be tested at 56°C for 30 min to inactivate the endogenous complement.

2. Dry the THYA plates by removing the lids and placing the plates in a laminar-flow hood for 30 to 60 min (see note 4). After plates are dry, replace lid to prevent overdrying, and keep at RT until needed.

3. Prepare opsonization buffer B by mixing 35 ml of sterile water, 5 ml of 10× Hanks' buffer (with Ca^{2+} and Mg^{2+}), 5 ml of 1% gelatin, and 5 ml of FBS. Prepare 1× HBSS (without Ca^{2+}, Mg^{2+}, or phenol red) and 1× HBSS (with Ca^{2+} and Mg^{2+}, without phenol red).

4. Locate (but do not remove) the frozen bacteria and complement in the −70°C freezer.

5. Prepare the microtiter assay plates (see note 7 for an example of assay setup).

    a. Add 20 µl of opsonization buffer B to rows A through G, columns 1 through 12. Also, add 20 µl of opsonization buffer B to row H, columns 1 and 2, but **NOT** to row H, columns 3 through 12.

    b. Add 30 µl of heat-inactivated serum samples (in duplicate) to row H, columns 3 through 12, according to the template. Perform threefold serial dilutions by transferring 10 µl from row H to G, mixing, and transferring 10 µl from row G to F, etc. Serum samples added to row H are undiluted. Serum samples yielding a high titer may have to be retested at a higher starting dilution.

6. Rapidly thaw an aliquot of each of the two frozen bacterial strains and dilute them according to the dilution factors calculated earlier in opsonization buffer B. Add 10 µl of the bacterial mixture to each well, including all control wells.

7. Incubate the microtiter plates at RT for 30 min without shaking.

8. During this time, take the complement out of the freezer to thaw. Also, melt the overlay agar in a microwave and place in 56°C water bath until needed (note 5).

9. Also, during this incubation, prepare the differentiated HL-60 cells.

    a. Transfer the DMF-differentiated HL-60 cells from the culture flasks to 50-ml centrifuge tubes.

    b. Centrifuge the HL-60 cells at 1,200 rpm (e.g., Sorvall, RT-7 with RTH-250 rotor) for 5 min at RT.

    c. Remove the supernatant and wash the cells with 1× HBSS (without Ca^{2+} or Mg^{2+}) by centrifugation as described above.

    d. Remove the supernatant and wash the cells with 1× HBSS (with Ca^{2+} and Mg^{2+}) by centrifugation as described above.

    e. Remove the supernatant, and suspend the cells at 10^7 cells/ml in opsonization buffer B. Keep the cells at RT until needed.

10. Following the 30-min incubation (step 7 above), add 10 µl of complement to the appropriate wells (add 10 µl of opsonization buffer B to the appropriate control wells).

11. Add 40 µl of HL-60 cells to the appropriate wells (add 40 µl of opsonization buffer B to the appropriate control wells).

12. Incubate the microtiter plates on a shaker (400 rpm) for 60 min at 37°C.

13. After the incubation period, place the microtiter plates on ice (to stop the phagocytic process).

14. Plate 5 µl of reaction mixture from each well onto two THYA plates (one plate will receive overlay containing optochin and the second plate will receive overlay containing streptomycin). Using a multichannel pipette, remove 5 µl from each well in an eight-well column, and apply as eight 5-µl spots to THYA plates on the left side, center, and right side of the plate (for a total of three microtiter plate columns, or 24 individual wells). Tilt the plates to the right to shape the spot into a small strip of fluid (~1.5 to 2 cm long).

15. Leave the plates at RT for 10 to 20 min to let the excess fluid seep into the agar.

FIGURE 1 Setup template for assay with multiple plates. (A) First plate arrangement. (B) Additional plate arrangement.

16. Divide equally the overlay agar (56°C) into two containers. Add TTC to a final concentration of 25 µg/ml to each container of overlay agar (note 3).

17. To one container of overlay agar, add optochin to a final concentration of 1.5 µg/ml. Add 12 ml of this overlay per plate to one replicate of the THYA plates spotted in step 14 above.

18. To the other container of overlay agar, add streptomycin to a final concentration of 150 µg/ml. Add 12 ml of this overlay per plate to the second replicate of the THYA plates spotted in step 14 above.

19. After the overlay has solidified (~30 min), place the plates, right side up, in a candle jar and incubate them for 16 to 18 h at 37°C. Colonies that grow on the THYA plates with the optochin overlay are bacteria of the optochin-resistant serotype, and those that grow on the THYA plates containing streptomycin are bacteria of the streptomycin-resistant serotype.

20. Count colonies and calculate the opsonization titer. The opsonization titer is the final dilution of serum that gives half the number of colonies as the complement/HL-60 control wells. If an undiluted serum sample killed 50% of the available bacteria but the next dilution (1/3) killed 0% of the available bacteria, then the opsonization titer is 4 [e.g., $1/(20/80) = 4$, where 20 is the volume of serum in microliters and 80 is the total volume of the reaction in microliters].

Assay Notes

Note 1: To maintain the integrity of the pneumococcal bacterial stock cultures, remove the stock vial(s) containing bacteria from the freezer, quickly remove a fleck of ice from the stock vial, and immediately streak onto a blood agar plate. Replace the stock vial into the freezer promptly.

Note 2: Baby rabbit complement and/or HL-60 cells can influence the number of viable bacterial cells. Their effect must be determined ahead of time and should be considered in calculating the final dilution of bacteria used in the opsonophagocytic killing assay.

Note 3: TTC turns red upon heating and should **NOT** be added before autoclaving or before reheating in a microwave oven. Add TTC to the agar after it cools to ~56°C.

Note 4: Drying the THYA plates for the correct amount of time is very important. Usually 30 to 60 min is sufficient, although drying times vary depending on the humidity in the air. Underdrying the plates results in an excess number of colonies around the perimeter of the spot. This can affect the counting of the colonies. Overdrying the plates can cause the spots to run together when the plates are tilted.

Note 5: Use a microwave oven to reheat the agar slowly to avoid boiling and accidental burns.

Note 6: It is important to maintain the CO_2 concentration at ~5%, as HL-60 cells are sensitive to subtle pH changes that can occur when the percent CO_2 changes. It is recommended that the percent CO_2 be checked regularly with an outside reference (such as a FYRITE gas analyzer produced by Bacharach, Pittsburgh, Pa.).

Note 7: A setup template for a typical assay involving multiple plates is shown in Fig. 1. Note that control wells are found only on the first plate.

Introduction

JOHN J. HOOKS

38

Fifty years ago, Issacs and Lindenman first described the interferons as soluble molecules secreted by cells. When cells or a whole organism, such as an embryonating hen egg, were treated with interferon, virus replication was depressed. The field of cytokine biology and the related molecules, including chemokines and adhesion molecules, has come a long way from these early beginnings.

Today it is almost impossible to discuss normal homeostasis, development, or pathologic processes without including a description of cytokines, chemokines, and adhesion molecules. These multifunctional proteins exert biological properties which suggest a key role in hematopoiesis, immunity, infectious disease, tumorigenesis, homeostasis, tissue repair, and cellular development and growth. Because of their major participatory role in nearly all pathophysiologic processes and their therapeutic potential, there is a need to identify and measure cytokines, chemokines, and adhesion molecules. In the clinical laboratory, cytokine assessment has been used to monitor disease progression and activity. In addition, the increasing use of cytokines and cytokine antagonists as therapeutic modalities requires the measurement of cytokine levels to determine the pharmacokinetics of the administered molecule. In the research laboratory, the measurement of cytokine gene expression is currently being explored with the hope that this approach will offer clues to better define the mechanisms of cytokine action in disease processes.

This section encompasses reviews on cytokines and chemokines. The intent of this section is to provide the reader with an up-to-date description of appropriate ways to detect gene and/or protein expression of these molecules. We begin with an introductory chapter by Daniel Remick. In the 6th edition of this Manual, Remick provided a detailed overview of the varied forms of analysis of cytokines, focusing on protein analysis and bioassays of cytokines and cytokine receptors. In this 7th edition, Remick has focused on the newer multiplex technologies that are rapidly becoming available for laboratory analysis. Two of the newer technologies, flow cytometry and molecular analysis, have been assigned separate chapters. Ghanekar, Maecker, and Maino identify the utility of flow cytometric analysis of cytokines and cytokine receptors in chapter 40. They identify some of the recent advances with multiwell plate loaders for flow cytometers. Chapter 41, by Kruse and Rieckmann, provides insight into approaches to monitor molecular analysis of cytokines and cytokine receptors. They focus on improvements of the recently developed real-time quantitative PCR. These methods provide high sensitivity and allow quantification of minute amounts of mRNA in small samples due to the exponential amplification of the target sequence and the generation of fluorescent molecules that are detected during the amplification reaction. Chapter 42, by Medoff and Luster, is devoted to an in-depth analysis of chemokines and chemokine receptors. This is clearly a rapidly developing area of study: analysis of chemokines continues to provide insight into the pathophysiology of several inflammatory diseases. The final chapter, by Andrew Pachner, contains new material not covered in previous editions and reflects the growing importance of cytokine therapy. Pachner identifies the various ways to monitor the development of antibody to cytokine therapy, with an emphasis on IFN-β therapy for multiple sclerosis.

In addition to the chapters included in this section, chapters incorporating discussions on cytokines, chemokines, or adhesion molecules can be found throughout this Manual. For example, section E incorporates several chapters that review various aspects of interactions among these molecules and selected cells of the immune system. O'Gorman addresses phagocytic cell function (chapter 31), McCloskey et al. focus on apoptosis (chapter 32), and Whiteside talks about NK cell assays (chapter 34). Likewise, in section Q, Reinsmoen and Zeevi (chapter 138) identify cytokines in their evaluation of cellular immune responses in transplantation. Also within that section, novel molecular approaches to detect cytokine and chemokine gene expression are extensively reviewed by Hartono et al. (chapter 139). They demonstrate a correlation of molecular detection of cytokines with rejection in solid organ transplantation.

This wide distribution and interest in cytokines, chemokines, and adhesion molecules reinforces the concept that these molecules are an integral part of a variety of immune cell functions. The immunology laboratory, with effective quality control and quality assurance programs, is in a unique position to provide the medical community with accurate identification and quantitation of these important bioregulatory molecules.

Multiplex Cytokine Assays

DANIEL G. REMICK

39

Cytokines are low-molecular-weight proteins representing important components of the inflammatory and immune responses (36). In response to external stimuli, they are rapidly induced and secreted into the extracellular milieu. In some situations, cytokines are constitutively present. Cytokines exert numerous biological activities which are critical for host defense, physiologic responses to stress, and immune surveillance. The world of cytokine biology has exploded in the past decades. It can be said without hyperbole that cytokines are critical from birth (gestation) (4) to death (apoptosis) (20).

Given the wide range of activities induced by cytokines, there is great interest in accurate measurement of these critical mediators. It is important to know if the cytokines are present during a particular disease process since they may potentially serve as a target for therapy (35). Conversely, there may be value in documenting that cytokines are depressed during a disease state such that the appropriate therapy is administration of exogenous cytokines such as granulocyte colony-stimulating factor. Clear evidence of the interest in measuring cytokines is demonstrated by the numerous companies which prepare and market kits for quantifying levels of cytokines.

Since there are numerous cytokines, a final biological outcome may not be dependent upon a single cytokine. Indeed, it has been reported that the ratio of cytokines to cytokine inhibitors provides the best documentation for progression of disease (1, 2). The best insights into the disease state will probably be achieved when multiple parameters are analyzed and assessed. As in making a clinical diagnosis, as much information as possible is needed in order to arrive at the correct determination for the precise disease process.

As a result of these issues, multiplex cytokine assays are beginning to be developed which will allow measurement of several cytokines simultaneously. While some of these assays were described over 5 years ago, they are beginning to mushroom into the commercial sector. As will be discussed further below, flow cytometric array assays are now marketed by more than 10 separate vendors. The technology has developed to the point that papers are now being written which directly compare the different kits from different vendors (17).

While this book chapter will examine measurement of cytokines, it should be borne in mind that this technology is not limited to measuring only these inflammatory mediators. Indeed, virtually any molecule that exhibits a specific interaction with another molecule may be measured by either a traditional enzyme-linked immunosorbent assay (ELISA) or a multiplex assay. Whether the interaction is a ligand-receptor interaction, a nucleic acid-protein interaction (3), or the traditional antibody-antigen interaction, the multiplex technology may be adapted to allow measurement (50). The principal consideration is the specificity of the interaction, such that the results are specific for measuring the analyte in question.

This chapter will explore both traditional ELISAs and the newer multiplexed assays. For each of the methods, I will examine the technology, instrumentation, and data analysis. Pitfalls that may arise with the assay will be explored to provide a better understanding of the limitations of the technique in question.

TRADITIONAL ELISA

I will begin with an explanation of the traditional ELISA. This is done because most of the newer assays are still based on the same antibody-antigen interaction that is most easily understood through examination of a single ELISA for a single cytokine. Virtually all ELISAs are based on the concept that a specific antibody will recognize a specific antigen. This concept dates back to the pioneering work of Yalow and Berson, who discovered that an antibody could recognize insulin (49). This single finding revolutionized the process for the detection and quantification of specific analytes.

Most commercially available ELISAs are based on a sandwich, or two-antibody, technique. A simpler method is the direct ELISA. For this assay, the antigen is bound directly to the surface of the microtiter well in the plate (Fig. 1). An antibody which specifically detects the cytokine in question is applied to the plate. For purposes of illustration, I use the cytokine interleukin 6 (IL-6) in the schematic figures. There are multiple methods for detecting the antibody bound to the antigen. The antibody may be directly conjugated to an enzyme such as horseradish peroxidase. An enzymatic reaction will occur within the well of the microtiter plate. Alternatively, the antibody may be detected by a second antibody. For example, the first antibody may be a mouse monoclonal antibody which recognizes human IL-6. The second antibody may then be a goat anti-mouse antibody which has been labeled with horseradish peroxidase. An alternative method for detecting the primary antibody is
FIGURE 1 Direct ELISA. In the direct ELISA, the analyte is first bound to the bottom of the microtiter well. In this example, the analyte is IL-6. Unbound IL-6 is washed away, and excess protein binding sites are blocked in order to reduce background. In the next step, biotin-labeled antibody (biotin-Ab) directed against IL-6 is added; the small circle represents the biotin moiety directly attached to the antibody. After washing, streptavidin (SA) conjugated to horseradish peroxidase (HRP) is added and a final wash is performed. Following addition of a colorimetric substrate, the color develops. The intensity of the color development is directly proportional to the amount of IL-6 in the first step.

to attach a biotin moiety to the antibody. Streptavidin conjugated to horseradish peroxidase is applied next. For all of these assays, the enzyme conjugated to the detection moiety develops color. The process follows a fairly simple equation in which more antigen present results in more antibody binding which results in greater concentrations of the enzyme which results in stronger color development.

For the sandwich ELISA, there is a slight modification. First, an antibody is bound to the surface of the microtiter well (Fig. 2). This antibody has specificity for the cytokine which will be detected, in this case IL-6. The sample is then applied to the well, and the IL-6 binds to the antibody. During washing, all the proteins which are not IL-6 should be washed away. The only entity remaining in the well should be the IL-6 bound to the antibody. Subsequent development steps are similar to those for the direct ELISA described above.

There are several critical elements in developing a sensitive and specific ELISA. The same critical elements apply to multiplexing assays, but again these elements are more easily understood when a single cytokine is considered. First and foremost, the primary factor driving the sensitivity and specificity is the quality of the antibodies (26, 47). There is simply no substitute for having high-quality antibodies for the assay. As a specific example, antibodies are available which detect the precursor form of IL-1β but not the mature, processed form (7, 8). This may result in gross underestimation of the total amount of IL-1β present in cell lysates, because the antibodies selected for detection may not be optimal. In many situations, the antibodies have already been matched for the development of a sandwich ELISA. With a few simple techniques, it is possible to buy these antibodies and establish ELISAs for the detection of cytokines in one's own laboratory (25). In this regard, the commercial vendors are excellent sources of good-quality reagents.

Another important aspect is the selection of the proper blocking reagent. After the antigen or the antibody has been applied to the plate, it is important that nonspecific binding sites on the plate are blocked. In my experience, it is not possible to predict the optimal blocking reagent and testing needs to be done in order to determine which reagent will work the best. The "matrix" of the sample may also affect the best blocking reagent. For example, in tissue culture supernatants, the protein content is extremely low compared to that in organ homogenates or plasma. A blocking reagent such as bovine serum albumin which works quite

well for tissue culture supernatants may be suboptimal for measuring cytokines in human plasma. Testing different blocking reagents, which are available from the commercial vendors, will generally produce a low background.

Different enzymes may be conjugated to the detection moiety, whether it is an antibody or streptavidin. Horseradish peroxidase is the most commonly used enzyme, but alkaline phosphatase may also be used.

A number of substrates may be used in the assay; the substrate will depend upon the enzyme used for detection. The color development reagents are available from a number of commercial vendors, and they may be purchased already prepared. It is also possible to buy the individual reagents necessary for the substrate preparation and assemble one's own color detection components. This results in significant cost savings compared to purchasing already prepared material and in my hands results in similar sensitivity and specificity (25). Several authors have reported that the use of chemiluminescent reagents results in greater sensitivity (18, 27, 31, 39). I have found that careful attention to the details of the assay will allow the development of an ELISA using the colorimetric reagents that has better sensitivity than the chemiluminescent assays and also results in significant cost savings (41).

Once the assay has been completed, it is necessary to calculate the results. Typically, the readout from an ELISA reader is the absorbance measured at a specific wavelength. If a fluorescent or chemiluminescent detection reagent has been used, then relative light units are the output. Regardless of the output, the actual concentrations of the cytokine in the sample are determined by comparison to a standard curve. There are several commercial software programs available which will perform these calculations. These programs may come bundled with the plate reader, or one may purchase separate, stand-alone software. Examples of data analysis are presented later in this chapter.

This has been a brief overview of the traditional ELISA, an assay run literally in hundreds of labs thousands of times every week. This assay is robust and relatively straightforward and has exquisite sensitivity and specificity. Given the tremendous utility of measuring a single cytokine, a natural extension is to measure multiple cytokines.

SEQUENTIAL ELISA

One easy method for measuring multiple cytokines in a single sample is to perform a sequential ELISA. In most biological
FIGURE 2   Indirect or sandwich ELISA. This ELISA shares many features with the assay described in the legend to Fig. 1. The major difference is in the first step, in which an antibody (Ab) directed against the analyte is bound to the bottom of the microtiter well. This antibody is termed the capture or coating antibody. Following addition of the analyte, the biotin-labeled detection antibody (biotin-Ab) is applied, followed by horseradish peroxidase (HRP)-conjugated streptavidin (SA-HRP). Color development proceeds, and the intensity of the color is directly related to the amount of the analyte. This is termed a sandwich ELISA because the analyte is sandwiched between two antibodies.

samples, multiple cytokines are present simultaneously. The antibody directed against the cytokine which is present on the plate should react only with its specific cytokine. When the sample containing multiple cytokines is added to the microtiter well, only the cytokine recognized by the antibody will remain bound on the plate (Fig. 3). Therefore, when the sample is removed, all of the other cytokines will be taken away and will be available for detection by another ELISA. Thus, it is possible to measure the cytokines in sequence by stretching the sample to detect multiple cytokines. In fact, a basic description of this technique has been published previously (28). I also found in my laboratory that it is possible to do sequential ELISAs and detect several cytokines simultaneously (my unpublished data).

The sequential ELISA still has several pitfalls. First, the sample volume necessary is still greater than that used in most multiplex assays. Second, the amount of time required to measure each one of the cytokines is not reduced in the sequential ELISA, so there is no cost savings with regards to time. Third, if there is potential cross-reactivity of the antibodies, then measurement of the first cytokine will result in an overestimate of the amount of that cytokine present and measurement of the next cytokine in the sequence will result in an underestimate of the amount of that cytokine present. Despite these caveats, the sequential ELISA is a method that is available to anyone who is presently running ELISAs.

PLATE-BASED MICRO-ELISAS

None of the previously described techniques using traditional ELISA plates measure multiple cytokines at once. The breakthrough in technology comes about when several cytokines may be detected simultaneously from a small sample volume. The first report demonstrating the feasibility of this approach was published in 1999 (22). This publication documented the ability to detect up to eight different analytes simultaneously in a single well. The analytes that the researchers detected were immunoglobulins derived from different species, such as rabbit, guinea pig, and human. The detection was achieved by placing very small amounts of these immunoglobulins in the bottom of a 96-well glass-bottom plate. The amount of immunoglobulin that was placed on the bottom of a well was approximately 200 pl.

This is in contrast to a typical ELISA, in which the bottom of the entire well is coated with a single antibody directed against a single cytokine, with a volume of approximately 100 μl. Therefore, the amount of antibody used for detection is 500,000 times smaller in the microarray assay than in the traditional ELISA. I will discuss in greater detail below how the use of a smaller volume of antibody does not result in lower signal intensity.

An individual spot of the immunoglobulin was designated as an element, and six-by-six arrays of these elements were printed onto the bottom of each well. Four identical arrays could be printed, resulting in the deposition of up to 144 elements. Precise control of the locations of the individual elements is necessary so that the locations can be appropriately mapped to the later images.

Each one of the immunoglobulins affixed to the glass bottoms of the wells was then detected with the appropriate biotinylated secondary antibody. For this assay, alkaline phosphatase was used as the detection enzyme. This enzyme results in color development in the region of the spot. A charge-coupled device (CCD) camera was used to record the image. Typically, special modifications to the CCD camera are made, including the addition of specialized hardware and cooling to improve the optical image. Additionally, a black Teflon mask is usually applied around the individual wells to prevent scatter of the light from one well to the next.

Once the image has been captured, the intensity of the individual spot is mapped back to its precise location. Since each element detects a single cytokine, the intensity of an element is directly proportional to the concentration of the cytokine. Similar to the method in traditional ELISA, a standard curve is prepared with a separate set of wells. The intensity of the color, or the number of relative light units if fluorescence or chemiluminescence has been utilized, is compared back to the standard curve to determine the concentration of the analyte in question.

Although the technique described in this initial publication was used only to measure immunoglobulins, which are present in high concentrations and relatively easy to detect, the innovation was the simultaneous measurement of multiple discrete molecules within the same well (22). This served as a launching point for the development of other assays.

Shortly after this report was published, another study used a 96-well plate to detect three separate molecules
FIGURE 3 Sequential ELISA. A sample containing a mixture of cytokines is applied to an IL-6 ELISA. IL-6 binds to the anti-IL-6 antibody attached to the bottom of the well. When the sample is removed, cytokines which are not IL-6, such as tumor necrosis factor (TNF), may be used in a subsequent ELISA. Ab, antibody; B, biotin moiety; biotin-Ab, biotin-labeled antibody; HRP, horseradish peroxidase; SA-HRP, horseradish peroxidase-conjugated streptavidin.

simultaneously (48). In this study, prostate-specific antigen, prostate-specific antigen bound to α_1-antitrypsin, and IL-6 were measured at the same time. The report carefully compared the results of the protein microarray with the results obtained from a traditional ELISA. The results were surprisingly consistent, especially when one considers that the researchers included serum samples from patients. However, the sensitivity of the individual determinations was not exceptional.

Another report published in the same year from a commercial vendor showed that this technology could be used to detect multiple human cytokines (23). In this study, the sensitivity was very close to that observed in a traditional ELISA. This initial study had three-by-three arrays of the monoclonal antibodies detecting seven different cytokines. More recent iterations of this technology have detected far more cytokines.

As one can imagine, when one is working with extremely small sample volumes the printing of the arrays is a critical issue. The deposition of the small sample volumes must be uniform, and the alignment must be extremely precise (10). There are several manufacturers of spotters. In many situations, spotters that have been used for the preparation of DNA microarrays may be successfully used for protein applications. These are typically contact type printers, where a quill tip is dipped into the protein solution and the solution is dotted onto the substrate. While these work quite well for nucleic acid microarrays, better results are typically obtained with noncontact printers. In one extremely novel and low-cost approach, a standard ink jet printer was used for depositing the antibodies (38).

The substrate onto which the antibodies are spotted is also important. Nucleic acids spot quite well onto glass slides, but antibodies are not optimally placed onto glass. The surface of the glass slide may be derivatized in order to improve binding of the antibodies (10). Alternatively, the antibodies may be spotted onto other substrates such as nitrocellulose which have a high protein binding capacity. Other membranes

are also suitable. For 96-well plates, traditional ELISA plates may be used since these have already been developed and tested for binding of antibodies. A potential disadvantage is that it may be difficult to spot onto the bottom of the 96-well plate.

Since only a small amount of antibody is spotted and the spot is extremely small, the immediate concern is that the signal intensity would be extremely small. In fact, the signal intensity may be greater with the smaller amounts of antibody. In a traditional ELISA, the antibodies spread across the bottom of the entire plate. Once the analyte binds to the antibody, the signals also spread across the entire plate. In contrast, with the microarrays, the antibodies are usually at higher concentrations. This is shown schematically in Fig. 4. In this figure, each of the black dots represents an antibody to IL-6 which has been coupled with IL-6 and subsequently detected. If the same amount of one analyte (IL-6) is bound to the same number of antibodies but the antibodies are now more closely spaced, the resulting signal intensity will be higher.
FIGURE 4 Increase in signal intensity with smaller spot size. On the left, each black dot represents the analyte bound to an antibody, which spreads across the entire well. On the right, the same number of antibodies are bound to the analyte, but they now occupy a smaller space, with a resulting increase in signal intensity.

Special Equipment Required

Spotting device. Accurately placing each of the individual spots into the well of the microtiter plate requires a high-quality spotting device. This device must be one capable of accurately and reproducibly placing the capture antibody in a precise location. Additionally, because of the depth of the microtiter plate, the robotic arm doing the plating must have pipette tips able to clear the tops of the wells. This problem does not occur with the glass slide-based arrays, as will be discussed below. As previously described, noncontact printers provide the most uniform arrays when working with proteins. This is a rapidly changing market, and the investigator should carefully research the spotters available on the market before purchase. Alternatively, plates may be purchased from a commercial vendor with the antibodies to the individual cytokines already placed in the bottoms of the wells. Presently there is only one commercial vendor selling the arrays in a microtiter plate format (Pierce; http://www.piercenet.com). The plates may be purchased off the shelf, or custom arrays may be ordered. The product is sold under the name Searchlight. Another vendor for plate-based microarrays is Meso Scale Discovery (42).

Detection equipment. Microarray assays are run using a colorimetric reagent, and a CCD camera is used to record the image. This is a high-quality camera which is specially modified in order to reduce background and provide a greater range of sensitivity and specificity.

MEMBRANE-BOUND-ANTIBODY ARRAYS

A series of recent papers have been published which describe technology capable of detecting multiple cytokines in a relatively simple format (9, 11, 12, 19). The authors have manually arrayed antibodies to several cytokines on a membrane. Simplicity of design represents an attractive feature of this methodology. In the initial study, several important steps were evaluated to arrive at the optimal conditions for the assay. Some of the parameters that were studied include the concentrations of antibodies and the best membranes for use.

For this type of assay, there are multiple antibodies directed against specific cytokines bound to a membrane. Each antibody is spotted onto the membrane in a different location, and the location is determined by the map. Diluted samples are placed onto the membrane, which is then incubated for 1 h. Following washing, a cocktail of detection antibodies is placed onto the membrane. After washing again, the detection reagent is added and the spots representing the individual cytokines are detected by chemiluminescence. X-ray film, or a phosphorimager, may be used to determine the intensity of the individual spots.

Advantages to this technology are that it is easily performed in virtually any laboratory. The incubation may be done in a simple six-well tissue culture dish, and the cytokines are arrayed on a membrane about the size of a postage stamp.

A significant disadvantage to this technology is a lack of quantification. In most other multiplexed assays, standard curves are generated and the concentration of an individual cytokine is determined from the standard curve. Without a standard curve, it is difficult to perform the precise quantification necessary for many scientific investigations of cytokine biology. Additionally, published results from our laboratory have shown that the sensitivity of the membranes is at least 2 logs lower than that of the traditional ELISA for several cytokines (5).

Special Equipment Required

X-ray film processor or phosphorimager. X-ray film may be used to capture the relative intensities of the individual spots, or this step may be done more quantitatively using the phosphorimager. Most institutions have an X-ray film processor available from molecular biology experiments in which Northern blots were developed, so it may not be accurate to consider this as special equipment.

GLASS SLIDES WITH MICROARRAYS

Glass slides have been extensively used for gene chip analysis. For traditional gene chips, portions of nucleic acid are spotted onto the slide. Each bit of nucleic acid coats a specific gene, as reviewed in reference 29. A similar format is used for the protein microarrays; however, instead of placing nucleic acid sequences onto slides and performing DNA hybridization, a compound is placed onto the slide which will interact with a specific protein. Typically, this means that an antibody directed against cytokines is placed on the individual slide, and that is the method that I will describe here.

The antibodies used for the protein microarrays are usually those which have already been demonstrated to be effectively employed in an ELISA format. These antibodies typically have been screened to determine that they have appropriate sensitivity. Additionally, when the antibodies are purchased from commercial vendors, they have frequently been tested against multiple different cytokines to ensure appropriate specificity. A careful examination of the antibody description supplied by the company will allow one to determine if cross-reactivity may represent a potential problem.

For protein microarrays, the capture antibody is placed onto the slide. The surface of the glass slide may be altered to enhance the binding of the antibody. Alternatively, a matrix may be applied to the surface of the cell to enhance the antibody binding. A number of different coatings are available for this purpose, although one of the simpler solutions is to affix nitrocellulose membranes to the surface of the slide. Nitrocellulose has a high protein binding affinity and will avidly capture the antibody (45). However, appropriate blocking reagents must be used in order to prevent a high background resulting from nonspecific binding of other proteins. Several different blocking reagents are available, but there is frequently a trade-off with these reagents. The trade-off arises because though one blocking reagent may be optimal for one antibody pair, a different blocking reagent is optimal for another antibody pair. In other words, the best blocking reagent for detecting tumor necrosis factor may be bovine serum albumin and the best blocking reagent for the antibodies detecting IL-6 may be casein. As in the traditional ELISA, a significant amount of trial and error is necessary in order to arrive at the appropriate combination of reagents.

Once the slide has been blocked, the detection antibodies are added. Because the assay is in a multiplex format, all of the detecting antibodies are added all at once in a cytokine antibody detection cocktail. Usually these antibodies have a biotin moiety attached to them in order to improve the sensitivity of the signal. Each of the individual antibodies needs to be appropriately titered in order to achieve a strong signal with low background. It is also important to keep the antibodies at the correct concentrations in order to prevent cross-reactivity. If an antibody is present in too high a concentration, it is possible that there will be a loss of specificity.

Virtually all of the slide microarray formats detect the antibodies through the use of fluorescent tags. These fluorescent reagents are directly attached to steptavidin, which binds to the biotin attached to the detection antibody. The slide is then read in a glass slide reader by using the same equipment used for the gene chip array work. Similar software is also employed in order to properly align the individual spots and quantitate the intensity of the signal. An example of a spotted microarray is shown in Fig. 5, which was directly obtained from the image obtained from the glass slide reader.

The fluorescent tags most commonly used to determine the intensity of the spots are the cyanine (Cy) dyes. These dyes are extremely stable and emit with a bright intensity. Two principal dyes are used, Cy3, which has an emission maximum at 563 nm, and Cy5, which has an emission maximum at 662 nm. These dyes may be used together since the spectra essentially do not overlap.

When the cytokines are detected in the multiplex format, antibody specificity becomes an even more critical issue. Even slight cross-reactivity between individual antibodies may result in false-positive signals. Rigorous testing must be performed in order to document that the antibodies detect only that against which they are directed. This testing may be accomplished in the multiplex format by running the entire assay and detecting the presence of a cocktail of cytokines. In this cocktail of cytokines, one of the cytokines will be left out. In the multiplex assay which detects 18 different cytokines, 19 different cocktails will need to be prepared. One of these will have all of the cytokines present, and the fluorescence intensity for each individual cytokine will be determined. The remaining 18 cocktails will each have one of the cytokines intentionally left out. When these cocktails are run on the microarray, the intensity should be virtually nonexistent for the cytokines which are missing. Fig. 6 represents an example of this type of study for examining cross-reactivity. In this example, the cocktail was prepared with 17 different cytokines, although the microarray was designed to detect 18 cytokines. The missing cytokine for this assay was IL-12. As can be observed, no signal was detected from any of the spots that were arrayed with the antibodies detecting IL-12. This demonstrates that this assay has the appropriate level of specificity. Similar results were obtained in the other studies in which the individual cytokines were deleted.

After the intensity of the individual spots has been quantified, data analysis becomes the next important critical issue. In order to efficiently manage the information, the
FIGURE 5 Example of a microarray. Panel A shows six individual nitrocellulose pads arranged on a glass slide. Each pad has been spotted in an 8-by-12 format. The black area between the pads is the place where a silicon gasket was adhered to the surface to allow each of the wells to function individually, similar to the way in which an individual well in a 96-well plate is independent from its neighbors. The antibodies have been spotted in an identical manner onto each of the nitrocellulose pads. Panel B is an enlarged picture of one of the individual pads and highlights the detail of the spots. The antibodies have been spotted in quadruplicate on the pad in a vertical fashion. Each individual spot has a diameter of 150 μl, and the distance between the spot is 300 μm. The total volume delivered to each spot was 350 to 367 pl. In the far-right column of spots, those in the top eight positions are extremely bright and the lower four have virtually no signal. This line of eight plus four spots may be used for alignment of the protein chip. The intensity of the individual spots may be quantified and used to determine the cytokine concentration in the sample. This image shows excellent reproducibility of the quadruple spots.

Missing IL-12
FIGURE 6 Specificity of the microarray. For this microarray, 18 different cytokines were tested. A cocktail containing recombinant cytokines was prepared, but IL-12 was not added to the cocktail. There is a strong signal from all the other cytokines, but no fluorescence was observed on the array for IL-12. This demonstrates the specificity for the array.

software needs to generate a mathematical model of the standard curve. The concentrations of the cytokines in the unknown samples are then calculated by referring back to the model of the standard curve.

There are multiple mathematical models that may be used to generate the appropriate fit for the standard curve. The same set of data may be analyzed by different iterations of the standard curve. For example, the data may be analyzed by plotting the number of relative light units (i.e., fluorescence intensity) versus the concentration of the cytokine. A simple linear expression may then be used to draw a straight line through the points. Alternatively, the data may be graphed on a log-log scale, and again, a straight line may be fitted to the points. I have had the most success using the concentration of the cytokine on a log scale and the fluorescence intensity on a linear scale. Examination of the graph usually shows an S-shaped or sigmoidal-type curve. Software is available which automates and reduces the time necessary for data analysis.

Examples of a standard curve prepared from the multiplex assay for the cytokine IL-8 are shown in Fig. 7. The exact same standard curve was subjected to different mathematical models to determine the one which would yield the optimum performance. As can be observed, plotting the information on a log-linear scale and using polynomial regression result in the highest correlation between the standard curve and the actual data.

Another level of data analysis is needed when substantial amounts of information are collected: analysis of the biological significance of the findings. In contrast to gene chip data, where only the relative abundances of different genes are determined, the actual levels of the cytokines have been measured. The levels may be important because previous publications have indicated that elevated levels of some cytokines are associated with worse prognosis. For example,

levels of IL-6 in plasma predict outcome in mouse models of infection (37, 46).

A modification of the slide-based microarray method has been developed which allows amplification of the signal (40). The same sandwich type ELISA is used, but the detection antibody contains a small fragment of a DNA primer. A circular piece of DNA hybridizes to the primer conjugated to the antibody, and the circular piece of DNA is used for the amplification step. Amplification occurs when DNA polymerase is incubated with the sample in the presence of labeled nucleotides. As the DNA polymerase works on the circular piece of nucleic acid, an elongated string of labeled nucleic acid is generated. With this method, researchers were able to measure up to 75 cytokines. However, because of antibody cross-reactivity, it was necessary to separate the samples into two separate reaction mixtures. This helps to illustrate the point, raised previously, that the major limitation for many of these methods is specificity of the antibodies.

There is another variation that is used with the glass slides, a method that compares normal to abnormal samples but does not quantify the amount of protein present. For this type of assay, samples are obtained from healthy sources and also from those in altered states. Altered-state sources may be patients who have disease or may be tissue or stimulated cells. All of the proteins from one sample are labeled with one color; for example, the normal samples may be labeled in green. All of the diseased or altered-state samples are labeled with a second color, such as red. The proteins from the normal and the diseased or altered-state samples are then mixed together. In this situation, there is a mixture of red and green molecules in the same tube.

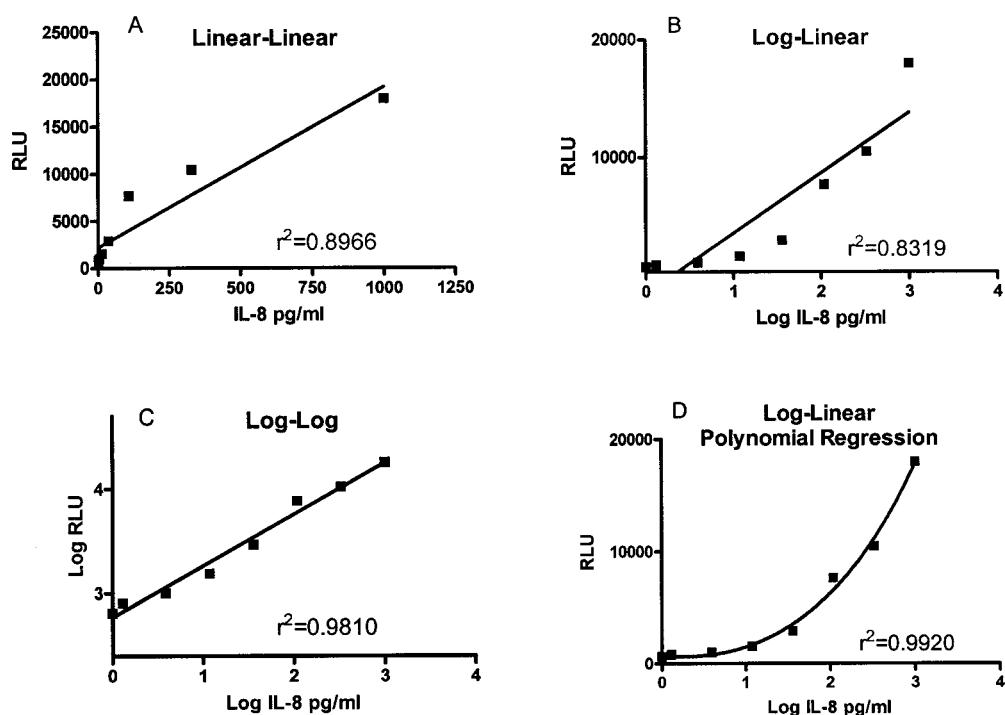
As a specific example, one could take tissue culture supernatants from endotoxin-stimulated macrophages to represent the altered state and label these in red. Among these proteins would be IL-6. Tissue culture supernatant from unstimulated


FIGURE 7 Mathematical modeling of the standard curve. Data from a microarray standard curve were used to generate a mathematical model for calculations for unknown samples. In panel A, the number of relative light units (RLU) and the concentration of the cytokine (IL-8) were plotted on a linear-linear scale. The correlation coefficient (r^2) was not very precise. In panel B, the concentration of the IL-8 was plotted on a log scale and the number of RLU was plotted on a linear scale. This resulted in even worse correlation. In panel C, both the number of RLU and the IL-8 concentration were plotted on a log scale and a very good linear regression could be fitted. However, the optimal modeling of the curve was obtained when the number of RLU was plotted on a linear scale, the IL-8 concentration was plotted on a log scale, and a fourth-order polynomial regression line was used. The results for all four panels were obtained using the same data from the IL-8 standard curve, but similar results are observed with most other cytokines.

cells would represent the control state and in this situation would be labeled in green. Both of these protein samples would compete for binding to the antibodies which had been placed on the slide. In this specific example, there would be a large amount of IL-6 labeled in red because the stimulated cells would secrete a large amount of IL-6. Normal, unstimulated cells would have very low concentrations of IL-6, and there would be virtually no IL-6 labeled in green. When the samples were placed on the slide, the IL-6-specific antibodies would be occupied mostly by red IL-6. Looking at the ratio between the red and green proteins would reveal the relative up or down regulation in the disease or altered state. For this example, the results would predict that lipopolysaccharide up regulates IL-6. This approach has been used successfully in several experiments and has been used specifically to demonstrate that certain proteins become up regulated following radiation treatment (43).

Special Equipment Required

Spotter. A high-quality spotter is required in order to prepare the microarrays. It is possible to obtain acceptable results using the same type of equipment used to prepare slides for gene chip studies. However, for spotting of proteins, noncontact printing generally results in better-quality arrays. Commercial companies presently produce prespotted slides with the capture antibodies already spotted onto the slides. Two such companies are Proteoplex (http://www.proteoplex.com) and Schleicher and Scheull (Fast slides). Custom arrays may also be prepared by commercial vendors.

Detection equipment. The glass slide may be read in a glass slide reader, or there are commercial services that will read the slides.

CAPILLARY ELECTROPHORESIS

A recent paper has described a novel method for rapidly detecting cytokines. In a special apparatus, antibodies directed to specific analytes were placed in the injection ports, where they were permanently bound (32). The samples containing the cytokines were then added, and all the bound proteins were labeled with Alexa Fluor 633. Electrophoresis was performed by lowering the pH, which dissociated the labeled cytokine from the antibody. The retention time determined the cytokine, and the intensity of the label correlated with the concentration. The entire process was very rapid and could be completed in just a few minutes. Additionally, the sample volume required for the assay was only a few microliters. By using this technology, six cytokines could be quantitated in less than 2 min. However,

the chemistry of coupling the antibodies and performing the electrophoresis and detection presently is beyond the capabilities of most laboratories.

BEAD ARRAY ASSAYS

Bead array assays are rapidly becoming the rage in cytokine measurement. The first papers hinting at the capabilities of using a flow cytometer to measure cytokines were published more than 10 years ago (6, 21). There are several commercial vendors marketing the bead array assays. The assays may generally be divided into two groups, those that utilize the Luminex platform and the assays designed by BD Biosciences. The differences between these two types of assays will be described in greater detail below. The bead array assays may be used to measure proteins such as cytokines and immunoglobulins. Additionally, they have been used extensively for the development of assays for examining polymorphisms in genetic material (13, 14). HLA typing has been revolutionized by the adaptation of this technology (30).

Bead array assays for the measurement of cytokines are all based on the standard antibody cytokine interactions already described. They are represented schematically in Fig. 8. The first and most important step in the bead array assay is finding a specific antibody that may be conjugated to the bead. The quality of the antibody drives the sensitivity and specificity of the assay, as with virtually all immunoassays. The steps are similar to the basic steps shown in Fig. 2 for a sandwich ELISA. As the first step, the capture antibody is conjugated to the bead. This bead mixture is then incubated with the samples containing the cytokines. After the cytokines are bound to the capture antibody, a biotinylated detection antibody is added, followed by streptavidin which is coupled to a fluorescent probe. The entire mixture is then run on a flow cytometer. Although this is a simple description of the overall assay, several features allow the assay to be performed rapidly and in a multiplexed manner.

The beads are an important part of the overall assay since they are the component that allows the samples to be run in a multiplexed manner (15). There are two variations on the way the individual beads are detected. In the first version, which is used by BD Biosciences, a single fluorescent molecule is incorporated into the beads (24). The beads are distinguished by the various amounts of the fluorescent probe inside the beads. Careful manufacturing allows the individual groups of beads to be distinguished from one another. For this example, the antibodies to IL-6 would be conjugated to

bead set 1 and the antibodies to tumor necrosis factor would be conjugated to bead set 2. When these beads are mixed together, the fluorescence intensity of the fluorochrome inside each bead indicates whether one is analyzing tumor necrosis factor or IL-6. Up to six different sets of beads may be distinguished with this method.

The other method for discriminating among the individual bead sets involves mixing two different fluorescent dyes in various mixtures. The individual groups of beads are then differentiated based on two-color analysis. The groups of beads may be clumped according to the relative intensities of the two separate fluorochromes. Similar to the method for the assay previously described, one group of beads is conjugated to antibodies to tumor necrosis factor and a separate group of beads is conjugated to antibodies to IL-6. Up to 100 different discrete sets of beads may be differentiated on the basis of the various concentrations of the two fluorescent dyes. This is the technology used with the Luminex platform. There are several commercial vendors who manufacture the beads conjugated to the antibodies, but all of them use the Luminex equipment. An example of an assay run using the Luminex platform is shown in Fig. 9.

We have described how the individual beads are grouped, but how does the quantification of the cytokines occur? Quantification takes place through the measurement of the intensity of the fluorescent tag attached to streptavidin. As in the traditional ELISA, the intensity of the signal is directly related to how much detection antibody has attached to the cytokine. A standard curve with several concentrations of cytokines is prepared and run in the assay. Fig. 10 shows an example of the standard curve with mouse IL-1β. The steps that are involved with the precise measurement of the cytokine include, first, the detection of the groups of the beads. The intensity of the streptavidin fluorescent tag for each group of beads is then assayed and compared to the standard curve in order to determine the concentrations of the cytokines within the sample. In Fig. 9, there are 22 individual groups of beads which may be assayed, which indicates that there are 22 individual groups or individual cytokines that may be measured in this multiplexed assay.

There are several advantages to the bead array assays. First, it is possible to perform the assays without washing the beads, limiting many of the time-consuming and tedious steps in a traditional ELISA (15, 44). It is possible to do these assays without washing because the fluorescence intensity of only the molecules bound to the beads is measured, not the intensity of everything in the solution. In
FIGURE 8 Schematic representation of the principle of a flow cytometric bead-based assay. The capture antibody specific for the analyte, in this example IL-6, is attached to a bead. The IL-6 binds to this antibody, which is then followed by a detection antibody which is biotinylated. Streptavidin conjugated to phycoerythrin is then added, and the entire complex is analyzed with the flow cytometer.
FIGURE 9 Example of the readout from a bead-based flow cytometry assay. In this example, the individual beads have different concentrations of two fluorescent dyes. The groups of beads are detected on the basis of the fluorescence intensities. The individual dots represent individual beads, and the darker-colored dots are doublets. The clear areas around collections of beads indicate those areas used for analysis. In this example, 22 individual cytokines have been detected. The intensity of the fluorescence of each individual bead is captured in a third fluorescent channel and compared to the standard curve in order to determine the concentration of the cytokine.

a traditional ELISA, the fluorescence intensity or color is measured in the well. Unless unbound antibodies are washed away, the background will be extremely high. In the bead array assay, the flow cytometer will analyze the group of beads to determine the specific fluorescence intensity and not the overall fluorescence intensity.

A second significant advantage is that up to 100 discrete groups of beads may be analyzed; thus, up to 100 different cytokines may be measured in a multiplexed assay. The major limitation is obtaining antibody with sufficient specificity in order to prevent cross-reactivity.

Many of the steps for the bead array assays may be automated, which is a third distinct advantage of this methodology. Automated sampling of each of the discrete wells used for an individual sample may be done, allowing walk-away ease of use.

Finally, the volume of sample required to measure multiple cytokines is extremely small. This is an advantage of any of the multiplexed assays, which generally require smaller sample volumes than the traditional ELISA. Even use of the sequential ELISA requires a larger sample volume than that typically used in a bead array assay.

At the present time, the range of bead array assays available for the Luminex platform is much greater than that of any other presently available array assay. In fact, there are at least 75 different identified cytokines that may be measured by using this platform. The cytokines include those of

human, rat, and mouse. Additionally, this technology may be used for allergy testing, tissue typing, detection of cardiac markers and cancer markers, and diagnosis of infectious diseases. The bead array assays have been successfully used to measure cytokines in human plasma (33), though
FIGURE 10 Example of a standard curve generated from the bead-based flow cytometry assay. In this example, a standard curve using recombinant mouse IL-1β is displayed. MFI, mean fluorescence intensity.

appropriate caution must be observed with plasma or serum samples (34).

Special Equipment Required

Preparation of Beads

While it is possible to conjugate the antibodies to the purchased beads, in reality this is technically difficult to do. Presently, most investigators will find it necessary to rely upon commercial sources for the conjugated beads. Fortunately, there are several vendors in the marketplace at the present time. This is encouraging news for investigators, since it is not likely that all of the vendors would terminate manufacturing of beads at the same time. Inevitably as the market matures, there will be fewer vendors, but the strong should survive such that those companies with excellent technical assistance, range of reagents, and ease of use will continue to sell products. The fact that several companies are marketing their products for the bead array assays also indicates that business analysts have determined that there is a robust market available for their wares. Again, this increases enthusiasm among investigators since the technology is more likely to persist. Additionally, the technology has been used to detect more than just cytokines. As a result, the flow cytometry apparatus is more widely available since it can be used for multiple applications.

By working with the vendors, it is possible to have custom-prepared sets of beads. The companies are pleased to conjugate specific antibodies to the beads and then multiplex the reagents into kits for the customer. Provided that there is an appropriate antibody available, there is really no limitation on what is available.

Flow Cytometry

For some of the commercial kits, it is not necessary to have a special, dedicated instrument. Any standard flow cytometer may be used for measuring cytokines provided that the appropriate software has been employed. Since many institutions already have flow cytometers which have been used for routine cell work, there is no real additional expense for running the assays. If the investigator desires to purchase a Luminex instrument, this will be a substantial additional cost.

COST COMPARISON

A true comparison of different multiplexed formats requires a delineation of the costs involved. I performed such analysis using a bead array assay based on the Luminex platform in contrast with a conventional ELISA which would be performed in the sequential format. For the ELISA, the cost remains essentially the same for each cytokine that is measured. However, in the bead array the cost decreases with the number of cytokines that are measured. This savings comes about as the cost of the kits decreases as the number of cytokines multiplexed increases. The cost analysis is carefully delineated in Table 1. The analysis was carefully constructed to include the time of a skilled technician as well as the cost of reagents. When the ELISA is performed, the major component of the cost is the salary of the person who actually performs the assay. The cost analysis was based on a single technician being able to process five plates of samples per day. Five plates of samples would amount to measuring approximately 200 samples for a single cytokine per day. When calculating the cost for the beads, I based the cost on the use of only a single well of the 96-well plate for each sample. Many investigators would use two individual wells to

TABLE 1 Cost analysis for cytokine measurements[a]

Parameter	Assay	
	ELISA	Beads array
No. of cytokines	1	17
Vol (μl)	50	50
Cost per sample (dollars)	1.95	59
Cost per cytokine (dollars)	1.95	1.87–3.31
Lower limit of detection	1–10	1–10
Range (logs)	3	3
Expandability	Not expandable	Expandable

[a] The cost of measuring cytokines by traditional ELISA, used in the sequential format, is directly compared to the cost of doing a bead array assay. Included in these costs are the necessary reagents, including buffers, antibodies, and kits purchased from the manufacturer. Also included is the time of a technician, assuming that the technician could test up to five full plates (about 200 samples) per day. The cost of this time is also included in cost analysis for the bead assays.

measure a sample, and the cost would proportionally increase. As can be observed in Table 1, the total cost for measuring a single cytokine by ELISA is about $2, whereas the same sample run in a multiplexed assay would cost about $59.

However, the cost decreases as the number of cytokines which are measured increases. This is delineated in Table 2, demonstrating that there is a sliding scale for the cost of measuring cytokines in a single sample. When approximately 17 cytokines are measured, it is less expensive to use the bead array assay than to perform multiple ELISAs. Again, it must be borne in mind that the cost of doing the ELISA principally involves the time of a technician and that has been included in the cost calculation.

There is one significant cost which has not been included in these analyses, that of the capital equipment necessary to perform some of these assays. Specifically, I did not include the cost of a plate reader, a flow cytometer, or a Luminex platform. Typically, these large pieces of equipment are purchased through capital funds and may be considered a fixed cost for the assays. In other words, if one cytokine is measured there is still the cost of buying a flow cytometer and this cost is the same if one runs 100,000 cytokines.

Issues concerning the sample volumes necessary to run the individual assays also become important. These are especially critical when dealing with rodents such as mice from which only a small volume of plasma may be obtained. Since only a single sample is required to run the multiplexed assay, the bead array assays or the spotted arrays consume significantly less sample volume than even a sequential ELISA. The amounts of sample necessary to run several different cytokines are listed in Table 3.

TABLE 2 Sliding-scale cost of measuring cytokines[a]

No. of cytokines	Cost (dollars) for:	
	ELISA	Bead array assay
4	7.80	13.25
6	11.70	19.28
14	27.30	27.95
17	33.15	31.79

[a] As the number of cytokines measured in a multiplexed assay increases, the cost decreases. The cost per cytokine per assay remains relatively fixed in the ELISA format, but as more antibodies are multiplexed to different sets of beads, the bead array assay decreases in cost. At about 17 cytokines, the bead array assay becomes more cost-effective than the ELISA.

TABLE 3 Sample volumes required for performing assays[a]

No. of cytokines	Vol (μl) needed for:	
	ELISA	Bead array
1	50	25
6	75	25
20	145	25

[a] As the number of cytokines measured increases, the sample volume necessary for the ELISA increases while that for the bead array assays remains static. The calculation of the sample volumes for the ELISA assumes that the assay is being performed in sequential manner.

While this cost analysis was performed for measuring cytokines in a bead array assay, similar comments may be made regarding an alternative multiplexed format such as the spotted arrays on glass slides or spotted arrays in a 96-well plate. Additionally, analysis of issues such as the purchase of capital equipment and the amount of a technician's time necessary to perform the assays would probably give similar results. Specifically, as more cytokines are measured, the cost per cytokine would go down for the multiplexed assay and would remain the same, of course, for the sequential ELISA. Additionally, the sample volume would remain static for a spotted microarray.

CONCLUSIONS

Multiplex assays for measuring cytokines are rapidly becoming standard across the world. A clear indicator of the enthusiasm for these assays may be found in the large number of companies which are presently producing and manufacturing multiplex cytokine kits. There are several platforms that are available for measuring the cytokines, and the market is not yet sufficiently mature to conclusively address which of these offers the best speed, sensitivity, and specificity and the lowest cost. At the risk of attempting to predict the future, it is probably safe to say only that multiplex assays are here to stay.

Monitoring of Immune Response Using Cytokine Flow Cytometry

SMITA A. GHANEKAR, HOLDEN T. MAECKER, AND VERNON C. MAINO

40

The emergence of highly sensitive quantitative antigen-specific-T-cell assays during the last 10 years has dramatically enhanced our understanding of the immune response at the single-cell level. The most widely used of these assays include the enzyme-linked immunospot (ELISPOT) assay, assays using major histocompatibility complex (MHC) oligomers, and cytokine flow cytometry (CFC) or intracellular cytokine staining (ICS) assays. Each of these methods has distinct advantages and limitations. MHC oligomers (e.g., tetramers) can be used to rapidly assess frequencies of T cells specific for defined peptide antigens by using flow cytometry (1, 4). However, this method is limited to analysis of single-peptide specificities and is restricted to single MHC alleles, making this approach impractical to evaluate responses to multiple antigenic peptides or proteins in heterogeneous populations. An alternative assay for detecting antigen-specific T cells based on cytokine expression is the ELISPOT assay (2). ELISPOT is a useful non-flow cytometric method for rapidly screening large numbers of samples for the presence of antigen-specific-cytokine-producing cells. However, because the ELISPOT assay cannot simultaneously determine the phenotype of the antigen-reactive populations, this approach has limited value in defining the heterogeneity of the immune response.

Because flow cytometry assays offer multiparametric assessments of minimally manipulated cells without a need for presorting or preenrichment, CFC has become an integral tool for assessment of immune function. CFC assays can be used to evaluate responses to complex antigens as well as peptides or peptide mixes (6, 9). Low levels of background staining achieved by use of an optimized procedure and high-quality reagents for fixation, permeabilization, and intracellular staining facilitate confident quantitation of low-frequency events in response to any protein (for CD4+ T cells) or peptides (CD4+ and CD8+ T cells). The CFC assay can also be applied to a variety of other cell types, including NK cells, monocytes, and dendritic cells, to unfold functional events associated with innate immunity. Because of its more quantitative and informative output, increasing numbers of researchers involved in vaccine clinical trials for diseases such as cancer and AIDS in addition to bacterial and parasitic infections are using CFC for detection of antigen-specific T cells in peripheral blood mononuclear cells (PBMC) as well as whole blood (3, 4, 10, 12, 15, 17, 18). In this chapter, we describe the optimized methods for CFC that offer increased throughput and robustness compared to the method described previously (8).

CONCEPT

The basic principle of the CFC assay is that whole blood or PBMC are activated with a specific antigen in the presence of a secretion inhibitor such as brefeldin A (BFA) or monensin for a short duration (6 h). The activated cells are then fixed and permeabilized to enable fluorophore-conjugated anti-cytokine antibodies to enter the cell and bind to the intracellular cytokines. Staining with a subset-specific cellular marker(s) can be performed at the same time as intracellular staining for markers such as CD3, CD4, and CD8 or before fixation of the cells when antibodies directed against fixation-sensitive epitopes are used. After acquisition of cells with the use of a flow cytometer, the cells of interest are gated and cytokine-positive cells are reported as a percent positive response after subtraction of the background value (percent positive in the absence of a stimulus or the presence of an irrelevant stimulus).

In order to bring together the high-content benefit of flow cytometry and the high-throughput aspect of ELISPOT, the CFC assay has recently been optimized for a multiwell format (19) from an originally devised tube format (8, 20, 21). The samples in the plates can then be acquired using a multiwell-plate loader connected to the flow cytometer. Dynamic gating strategies that account for sample-to-sample staining variability can simplify data analysis and improve the reproducibility of the results. In addition, use of lyophilized reagents (both activation agents and staining antibody cocktails) in the multiwell plates can simplify the assay further by preventing errors in assay setup and lot-to-lot variations in reagents, which are a concern for large trials. The procedural details to be discussed in this chapter include recommendations for sample type and handling, choice of antigen(s) and plates, and the gating strategy for this improved CFC format using cytomegalovirus (CMV) pp65 peptide mix as a model antigen.

PROCEDURE

Instructions for Processing Reagents

SEB

Add 2 ml of sterile phosphate-buffered saline (PBS) directly to a 1-mg vial of staphylococcal enterotoxin B (SEB; positive activation control; Sigma). Cap the vial and shake to

dissolve all the powder. Store this stock solution at 4°C. On the day of use, prepare working stock by diluting 1:10 in sterile PBS.

Peptides

Dissolve single peptides in dimethyl sulfoxide at a concentration of 2 mg/ml. Freeze aliquots of 5 μl each at −80°C. On the day of use, prepare working stock by diluting 1:10 in sterile PBS to achieve a final concentration of 2 μg/ml.

Peptide Mixes

CMV pp65 and human immunodeficiency virus (HIV) Gag-p55 peptide mixes (15 amino acid residues in length, overlapping by 11 amino acid residues each) have been described previously (9). These peptide mixes are also available commercially (BD Biosciences, San Jose, Calif.). Store small aliquots of these peptide mixes at −80°C and dilute in sterile PBS on the day of use to achieve a final concentration of approximately 2 μg/ml/peptide.

BFA

Dissolve BFA (Sigma) powder at 5 mg/ml in dimethyl sulfoxide and store frozen as 20-μl aliquots. Just before use, dilute 1:10 in PBS and use at a 10-μg/ml final concentration.
BD FACS Lysing Solution and BD FACS Permeabilizing Solution 2
Dilute BD FACS lysing solution and BD FACS permeabilizing solution 2 (each 10×) in deionized water to make a 1× working solution. Store at room temperature.

Paraformaldehyde

Dilute a 10% solution of paraformaldehyde 1:10 in 1 × PBS. Store at 4°C.

Wash Buffer

The wash buffer consists of 0.5% bovine serum albumin and 0.1% NaN₃ in PBS. Store at 4°C.

Complete RPMI 1640 Medium

Supplement sterile RPMI 1640 medium with 10% sterile heat-inactivated fetal bovine serum and 1% sterile antibiotic-antimycotic (cRPMI). Store at 4°C.

CFC PROTOCOL FOR DETECTION OF ANTIGEN-SPECIFIC T CELLS BY USING PBMC IN A 96-WELL-PLATE FORMAT

The 96-well-plate format protocol is recommended for antigenic stimulation of freshly isolated as well as cryopreserved PBMC. The flow chart for plate-based CFC is depicted in Fig. 1, and a representative analysis of one of the PBMC samples (from a CMV-seropositive donor) stimulated with the pp65 peptide mix is shown in Fig. 2A.

PBMC Preparation

Fresh PBMC

1. Blood should be collected in tubes with sodium heparin and used within 8 h after being drawn for better quality of cells. PBMC can be harvested from blood by using Ficoll-Hypaque solution according to the manufacturer's instructions. Alternatively, PBMC can be harvested by centrifugation of blood that is collected in cell preparation tubes (Vacutainer CPT, BD Vacutainer).

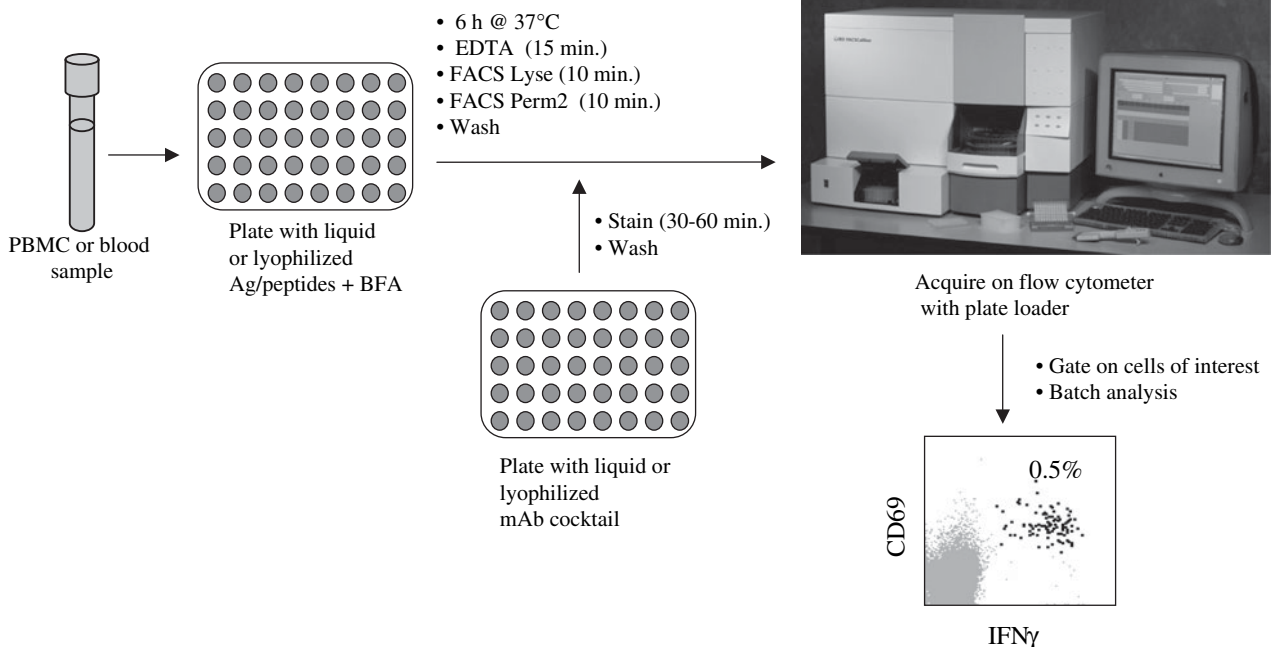
2. Prepare a working concentration of 5×10^6 PBMC/ml in room-temperature cRPMI. Check for clumps and remove


FIGURE 1 Flow chart of plate-based CFC assay. PBMC or whole blood is added to appropriate plate(s) as described in the text. After 6 h of incubation at 37°C, the cells are processed as described in the protocol. After staining with mAb cocktails for CFC, the cells are acquired on a flow cytometer using a plate loader and the data are batch analyzed. Ag, antigen; FACS Lyse, BD FACS, lysing solution; FACS Perm 2, BD FACS permeabilizing solution 2.

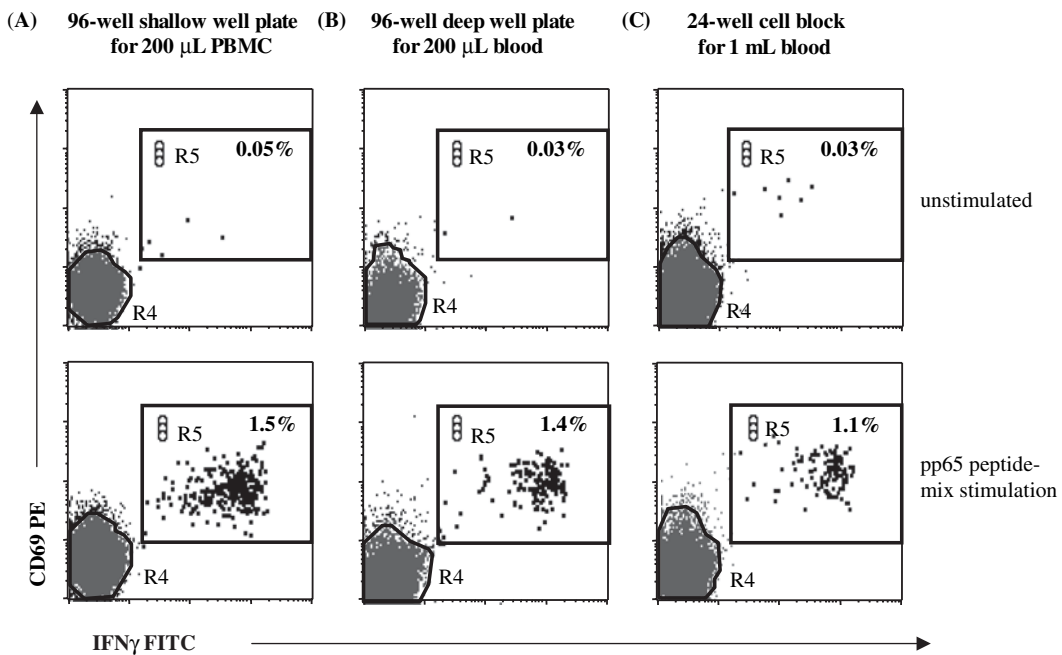
(A) 96-well shallow well plate for 200 μL PBMC **(B)** 96-well deep well plate for 200 μL blood **(C)** 24-well cell block for 1 mL blood


FIGURE 2 Representative four-color flow cytometric analysis of plate-based CFC. PBMC 10^6 (A), 200 μl of whole blood (B), or 1 ml of whole blood (C) from a CMV-seropositive donor was stimulated (or not) with the pp65 peptide mix in a 96-well shallow-well plate, a 96-well deep-well plate, or a 24-well deep-well block, respectively. Samples were processed as described in the "Procedure." The plots were gated on CD3$^+$ CD8$^+$ lymphocytes. Responses and staining intensities of IFNγ$^+$ CD69$^+$ cells were comparable in all three assays. R4, snap-to region to identify double-negative population; R5, manually drawn region around cytokine$^+$ CD69$^+$ cells.

them with a pipette tip or a cell strainer. Proceed with PBMC activation (see below).

Cryopreserved PBMC

1. Cryopreserved PBMC should be thawed at 37°C and diluted and washed using warm medium (22 to 37°C cRPMI).

2. Resuspend cells at a final working concentration of 5×10^6 PBMC/ml in cRPMI. Make sure to remove any clumps if present.

3. Plate 200 μl/well in a polypropylene V-bottom or polystyrene U-bottom 96-well plate (Falcon; BD Discovery Labware). This will result in a concentration of 10^6 cells per well (we have tested 5×10^5 to 2×10^6 cells per well with equivalent results). Prepare additional wells for manual compensation, if desired.

4. Incubate the covered plate at 37°C for 12 to 18 h.

PBMC Activation

1. Prepare working stock solutions of activating reagents.

2. Label three tubes "NS" (for nonstimulated control), "SEB," and "Peptide." Prepare stimulation reagents in bulk by combining costimulatory monoclonal antibodies (mAbs) CD28 and CD49d (recommended when a whole antigen instead of peptides is used), a stimulus (add nothing to the nonstimulated control), BFA, and PBS in the appropriately labeled tubes. Add appropriate amounts of PBS to bring the volume to 20 μl per well for each condition on the plate; use at least one extra well to account for fluid loss. An example is given in the matrix shown in Table 1.

3. Add 200 μl of fresh PBMC to the wells containing appropriate stimuli, or add appropriate stimuli to PBMC that have rested overnight. Mix well by pipetting.

4. Incubate the covered plate for 6 h at 37°C. Following incubation, cells may be held in the sealed plate at 4 or 18°C for up to 18 h.

5. Add 20 μl of 20mM EDTA to each well and incubate for 15 min at room temperature. Mix the cell suspension well with a pipette.

6. Centrifuge the plate at $250 \times g$ for 5 min; aspirate the supernatant with a manifold (7-mm-diameter multiwell-plate aspirator manifold; V&P Scientific Inc., San Diego, Calif.). Keep the plate flat while aspirating to avoid loosening the pellet. Insert the manifold fully into the plate and hold until no more liquid is aspirated; approximately 30 μl will remain in the wells. Resuspend cells in 100 μl of 1× BD FACS lysing solution. Incubate at room temperature for 10 min. For batch processing of longitudinal study samples, cells may be frozen at this point. Place the sealed plate, containing cells in FACS lysing solution, in a −80°C freezer. When ready to stain, thaw the plate at 37°C and continue as described below.

TABLE 1 Example of stimulus preparation per well

Condition	Amt (μl) of:			Total volume (μl)
	Stimulus	BFA	PBS	
No stimulus	0	4	16	20
SEB stimulation	4	4	12	20
Peptide stimulation	5	4	11	20

Permeabilization and Staining of Activated Cells

1. Add 100 μl of wash buffer to each well and centrifuge at $500 \times g$ for 5 min. The cell density decreases after treatment with BD FACS lysing solution, requiring a higher centrifugation speed to pellet the cells.

2. Aspirate the supernatant and resuspend cells in 200 μl of $1 \times$ BD FACS permeabilizing solution 2. Incubate at room temperature for 10 min.

3. Centrifuge at $500 \times g$ for 5 min. Aspirate the supernatant.

4. Resuspend the cell pellet in 200 μl of wash buffer and centrifuge at $500 \times g$ for 5 min. Aspirate the supernatant and repeat this wash step one additional time to ensure complete removal of the permeabilizing solution. This helps to avoid background staining of the negative population.

5. Add staining mAbs to each well (e.g., BD FastImmune gamma interferon [IFN-γ]–CD69–CD4–CD3 cocktail or FastImmune IFN-γ–CD69–CD8–CD3 cocktail; BD Biosciences) and mix by pipetting. Add single-color mAbs to compensation control wells, if used.

6. Incubate the plate at room temperature for 30 to 60 min in the dark.

7. Add 175 μl of cold wash buffer and centrifuge at $500 \times g$ for 5 min, aspirate the supernatant, and use a pipette to resuspend the cells.

8. Repeat step 7 two times with 200 μl of wash buffer. Because of the small well volume, these extra washes are recommended to reduce the background staining.

9. Resuspend the pellet with 200 μl of cold 1% paraformaldehyde.

10. Keep the plate at 4°C in the dark until acquisition using a plate loader on a flow cytometer, which should be performed within 24 h.

CFC PROTOCOL FOR DETECTION OF ANTIGEN-SPECIFIC T CELLS USING HEPARINIZED BLOOD IN A DEEP-WELL-PLATE FORMAT

The deep-well-plate format protocol is recommended for antigenic stimulation of whole blood. Deep-well plates are used because processing of whole blood after activation requires a higher volume of lysis reagent than that of PBMC for complete lysis of red blood cells. For blood volumes of up to 200 μl, use a 96-well deep-well plate (BD Discovery Labware), and for activation of up to 1 ml of blood, use 24-well deep-well blocks (Qiagen, Hilden, Germany). Blood should be drawn into tubes containing heparin as an anticoagulant and used within 8 h after being drawn. Representative analysis of a blood sample (from a CMV-seropositive donor) stimulated with the CMV pp65 peptide mix is shown in Fig. 2B.

Whole-Blood Activation

Preparation of stimuli and activation of blood are the same as described above for the PBMC assay (PBMC activation steps 1 through 5) except that heparinized whole blood is added to the wells of a deep-well plate containing appropriate stimuli. After treatment of samples with 200 μl of EDTA per well, resuspend cells in 1.5 ml of $1\times$ BD FACS lysing solution. Incubate at room temperature for 10 min. For batch processing of longitudinal study samples at a later time, pellet the cells by centrifugation, remove the supernatant, resuspend cells in the remaining volume of the liquid, and place the

sealed plate in a -80°C freezer. When ready to stain, thaw the plate at 37°C and continue as described below.

Permeabilization and Staining of Activated Blood

1. Add 1.5 ml of wash buffer to each well and centrifuge at $500 \times g$ for 5 min. The cell density decreases after treatment with BD FACS lysing solution, requiring a higher centrifugation speed to pellet the cells.

2. Aspirate the supernatant using a 35-mm-diameter multiwell-plate aspirator manifold (V&P Scientific Inc.) and resuspend the cells in 1 ml of $1 \times$ BD FACS permeabilizing solution 2. Incubate at room temperature for 10 min.

3. Centrifuge at $500 \times g$ for 5 min. Aspirate the supernatant.

4. Resuspend the cell pellet in 1.5 ml of wash buffer and centrifuge at $500 \times g$ for 5 min. Aspirate the supernatant using a manifold and repeat this wash step one additional time to ensure complete removal of permeabilizing solution, thus avoiding background staining of the negative population.

5. Add staining mAbs to each well (e.g., BD FastImmune IFN-γ–CD69–CD4–CD3 cocktail or BD FastImmune IFN-γ–CD69–CD8–CD3 cocktail; BD Biosciences) and mix by pipetting. Add single-color mAbs to compensation control wells, if used.

6. Incubate the plate at room temperature for 30 to 60 min in the dark.

7. Add 1.5 ml of wash buffer and centrifuge at $500 \times g$ for 5 min; aspirate the supernatant and pipette the pellet to resuspend cells.

8. Repeat step 7 one time with 1.5 ml of wash buffer.

9. Resuspend the pellet with 200 μl of cold 1% paraformaldehyde. Keep the plate at 4°C in the dark until acquisition using a plate loader on a flow cytometer, which should be performed within 24 h. The cells can be transferred from a deep-well plate into a shallow-well plate before acquisition if the plate loader does not accept deep-well plates.

Acquisition and Gating

1. Set up the flow cytometer photomultiplier tube and compensation values either automatically by using calibration beads and appropriate calibration software or manually by using cells treated the same way as the samples and either unstained or stained individually with each of the fluorochromes (e.g., CD8-fluorescein isothiocyanate [FITC], CD8-phycoerythrin [PE], CD8-peridinin chlorophyll protein-Cy 5.5 [PerCP-Cy5.5], and CD8-allophycocyanin [CD8-APC]). Unstained cells can be used to adjust the photomultiplier tube settings of the flow cytometer, followed by compensation using single-stained controls.

2. Acquire at least 20,000 relevant (CD4$^+$ or CD8$^+$) events, preferably 40,000 in order to obtain high power and confidence levels for comparisons of small antigen-specific responses to unstimulated controls.

3. Display of the data, gating strategy for reporting the percent response, and data interpretation have been described in detail earlier (8). The cells are first gated by drawing a region around lymphocytes, followed by another region around CD3$^+$ CD4$^+$ or CD3$^+$ CD8$^+$ cells. Then a logical gate containing lymphocytes and CD4 or CD8 cells is applied to cytokine-versus-CD69 plots (e.g., IFN-γ–FITC versus CD69-PE). Even though this is a short-term assay, expression levels of CD3, CD4, and CD8 are down-regulated on activated cells. Thus, it is important to include those down-regulated cells when drawing a region around these populations.

4. A response region is then drawn around the IFN-γ^+ CD69$^+$ population (Fig. 3, R5) from a positive control sample, and this region is copied to the plots for other samples. The percentage of gated cells within this region is obtained from region statistics for each of the plots and reported after subtracting the response of an unstimulated control.

Dynamic Gating and Analysis of CFC Data

Gating of flow cytometry data for analysis is a frequent source of assay variation, especially in rare-event assays such as CFC where antigen-specific responses may be as low as 0.1%. Relatively minor differences resulting from subjective gating can quantitatively affect CFC results, since cytokine-positive cells are not distributed symmetrically within the CD3$^+$, CD4$^+$, or CD8$^+$ cell populations. By using a software package that contains a cluster-finding algorithm (e.g., Snap-To gating), much of the subjectivity in gating can be avoided. Such an algorithm allows gating to be both dynamic and unbiased in that it can automatically track populations that might be displaced from one sample to another without requiring user input. It can also provide consistency in results, as size and movement of the gated regions can be set and tethered regions can be created to identify rare populations by their relative positions with respect to more dense populations. We have designed templates for CFC analysis that utilize Snap-To and tethered regions to identify the required cell populations and report a percentage of cytokine$^+$ CD69$^+$ cells (Fig. 3).

Batch processing of the data using such an analysis template and automatic export of statistical results to a spreadsheet can both save time and prevent errors. In our laboratory, results obtained with expert manual gating were highly correlated with those obtained using a dynamic gating template for analysis of samples stimulated with the CMV pp65 peptide mix, the HIV p55 peptide mix, or SEB (19).

Performance of Lyophilized Antigens and Lyophilized Antibodies in CFC Assays

In situations where large numbers of samples need to be evaluated, e.g., in vaccine immune response-monitoring studies, it is desirable to minimize time and errors that may occur in assay setup and processing. One way to achieve this is to use preconfigured plates with lyophilized reagents (antigens as well as antibody cocktails). This method will also avoid lot-to-lot variations in the reagents in addition to issues with cold storage, as lyophilized reagents provide prolonged stability at room temperature.

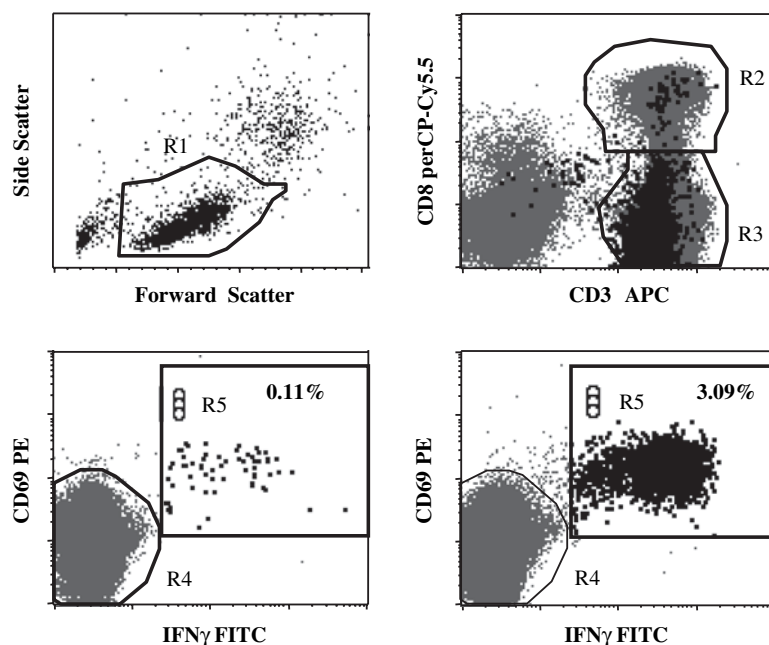
We have optimized the process of using lyophilized antigens and lyophilized antibody cocktails for CFC assays of both PBMC and whole blood. The comparison of lyophilized reagents to liquid reagents in a CFC assay using pp65 peptide mix-activated blood resulted in highly significant correlation in the frequency of the response and staining intensity (Fig. 4). Using lyophilized reagents for activation as well as for staining, researchers in our laboratory have obtained


FIGURE 3 Example of CFC data analysis using dynamic gating. Analysis templates are typically defined using a positive control sample (e.g., SEB-activated PBMC or blood). R1 (lymphocytes based on forward- and right-angle light scatter), R2 (CD3$^+$ CD8$^+$ cells), and R3 (CD3$^+$ CD8$^-$, i.e., CD3$^+$ CD4$^+$ cells) are all Snap-To regions. The sizes and the movement of R2 and R3 are maximized to automatically include activated cells that have down-regulated CD3 and CD8 (bold dots) and to track the "roaming" populations that may be a result of variations in reagents, donors, and instrument settings. In the lower left plot that is gated on CD3$^+$ CD8$^+$ cells (R1 and R2), R4 is another Snap-To region (double-negative population) that is tethered to manually drawn region R5 that identifies cytokine-positive events (rare-event response region). The plot on the lower right is gated on CD3$^+$ CD8$^-$ cells (R1 and R3), and regions R4 and R5 are selected, copied, and pasted onto this plot. The percentage of gated events in R5 is reported.

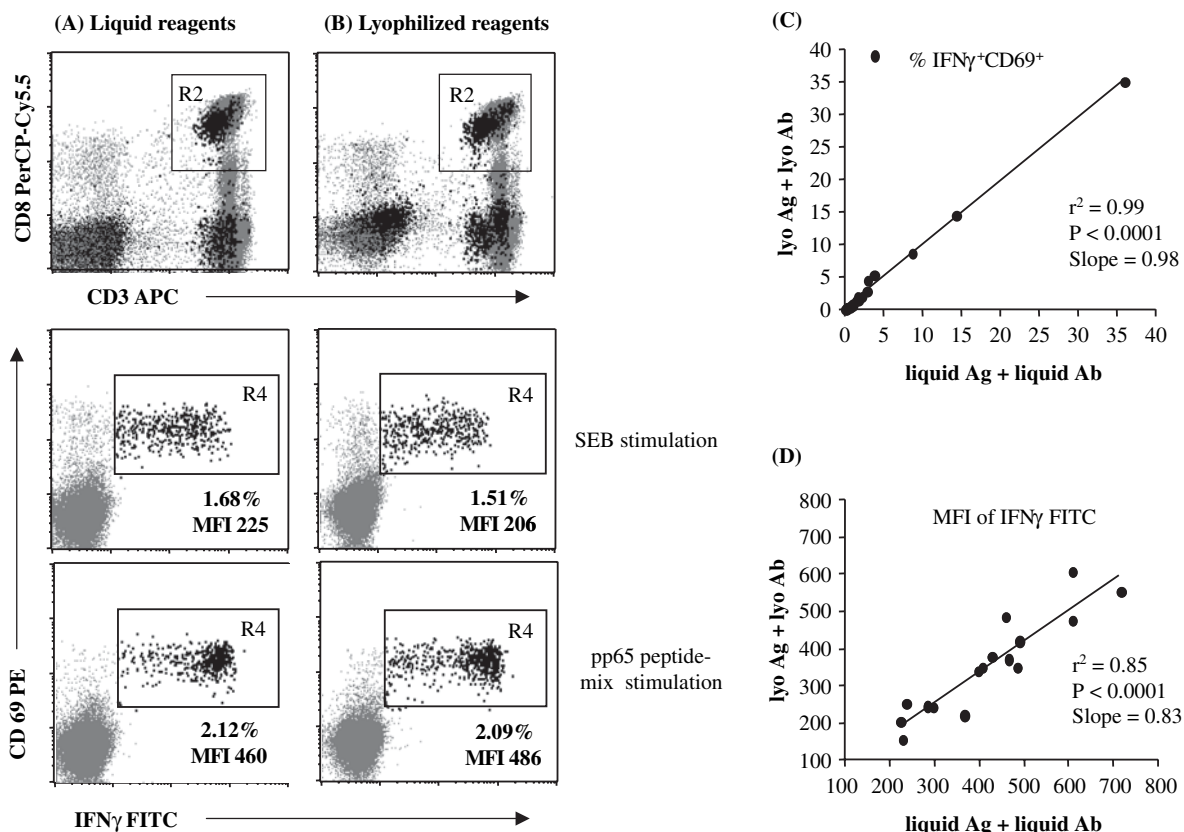
(A) Liquid reagents   **(B) Lyophilized reagents**


FIGURE 4 Performance of lyophilized reagents in CFC. Whole blood from a CMV-seropositive donor was activated with either liquid (column A) or lyophilized (column B) SEB or the pp65 peptide mix. The cells were processed as per the procedure described in the text. Cells were stained with either liquid (column A) or lyophilized (column B) cocktail containing IFN-γ–FITC, CD69–PE, CD8–PerCP-Cy5.5, and CD3–APC. Comparable frequencies (percent positive) and staining intensities (mean fluorescence intensity [MFI]) of CD3, CD8, IFN-γ, and CD69 were observed with both sets of reagents. Significant correlation between liquid and lyophilized reagents was observed in terms of percent positive (C) and staining intensities (D) of responding cells (CD4+ and CD8+ gated; $n = 8$). R2, region to identify CD8+ T cells; R4, region to identify cytokine+ CD69+ cells; lyo, lyophilized; Ag, antigen; Ab, antibody.

CD4 and CD8 T-cell response ranges of normal healthy donors to antigens such as SEB, CMV lysate, the CMV pp65 peptide mix, and a variety of cancer antigens (M. Inokuma and H. T. Maeker, unpublished results). Use of (i) lyophilized reagents for the CFC assay, (ii) a dynamic gating template for automated data analysis, and (iii) batch export of statistics saved a considerable amount of time, making it possible to acquire CFC data from a large number of donors in a relatively short time.

CONTROLS

Detailed description of the appropriate positive and negative controls for CFC assays has been published previously (8). In this chapter, we describe the use of two additional controls that utilize lyophilized cells to ensure the quality of the assay. One type of control is cells lyophilized after activation, lysis, and permeabilization that may be reconstituted, washed, and stained (Fig. 5B). Another type is cells lyophilized after going through the entire process, including staining, that may be reconstituted, washed, and analyzed on the cytometer by the user (Fig. 5C). The former serves as a staining control and the latter can be used as a positive

control to check the instrument setup. These lyophilized cell controls perform as well as nonlyophilized cells in the CFC assay (Fig. 5).

STANDARDIZATION OF CFC ASSAY

Complexity of the assay, in addition to biological variation of activated samples, tends to increase the variability in functional assays. We have observed intra-assay variability within 10% and interassay variability within 25% when the assays were performed as described previously, using tubes and liquid reagents for activation and staining and manual gating of the flow data (14). In order to be able to compare data from multisite clinical trials, it is important that the assay design is well controlled with regard to reagents, gating, and use of proper controls to reduce inadvertent errors. When 11 different laboratories used the procedures described here with lyophilized antigen and antibody reagents in plates, the interassay variation in antigen-specific responses of CD4 and CD8 T cells averaged 14% (11). This variation was significantly lower than that in another study performed by six different laboratories using liquid reagents and manual gating; the coefficient of variation was

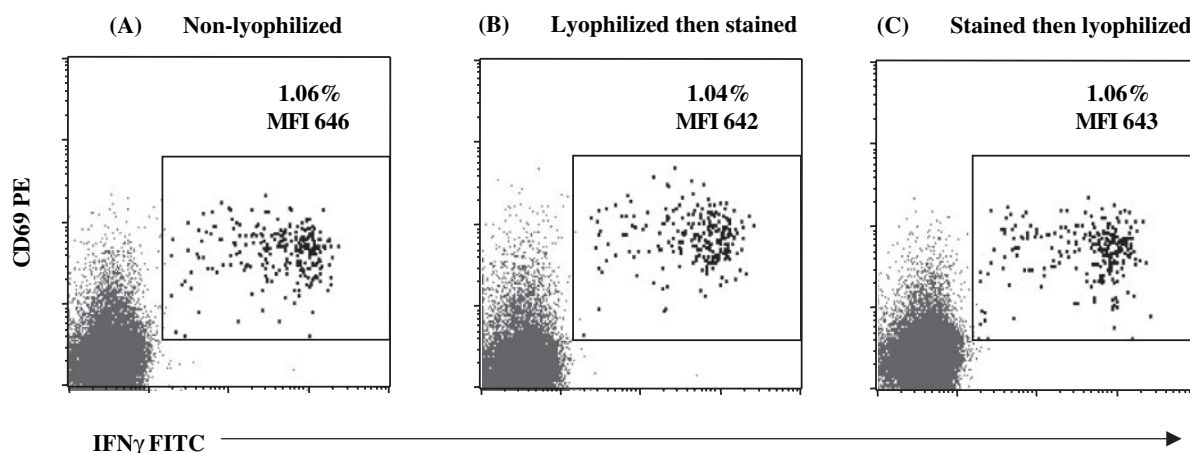
(A) Non-lyophilized   **(B) Lyophilized then stained**   **(C) Stained then lyophilized**


FIGURE 5   Use of lyophilized cells as process controls. CMV pp65 peptide mix-activated whole blood was lysed or fixed and permeabilized according to the protocol, and three aliquots were processed as described below. (A) Nonlyophilized. The first aliquot was stained with IFN-γ–FITC–CD69–PE–CD8–peridinin chlorophyll protein–Cy5.5–CD3–allophycocyanin, washed twice, and analyzed immediately. (B) Lyophilized then stained. The second aliquot was lyophilized, reconstituted in wash buffer, washed once, and then stained as described above. (C) Stained then lyophilized. The third aliquot was stained as described for panel, A, lyophilized, reconstituted in wash buffer, washed once, and then analyzed. Equivalent frequencies and staining intensities of responding cells were obtained for all three sets of cells.

40% but was reduced to 33% when data were analyzed using a template designed with dynamic gates (M. Suni and H. T. Maecker, unpublished data).

TROUBLESHOOTING TIPS AND NOTES
A guide to troubleshooting for CFC assays has been published (8) that addresses problems such as poor cell recovery, low or no levels of cytokine-positive cells, poor staining intensity, and high background levels, etc. When the assay is performed in plates, some additional measures need to be taken.

1. Use of appropriate-length multiwell aspirators is required for consistent assay performance in terms of cell yields and quality of staining.
2. Because the plates cannot be vortexed, it is important to mix the cell suspension several times with a multichannel pipette while avoiding cross-contamination of wells.
3. In order to avoid sample-to-sample carryover that may occur during acquisition using a plate loader, it is recommended that strong positive control stimuli (e.g., SEB or phorbel myristate acetate plus ionomycin) be placed in the wells towards the end of the plate.
4. For CFC assays using whole blood from HIV-positive donors, there may be a need to use more than 200 μl of blood per well because of lower CD4$^+$-T-cell counts. In such a situation, 24-well deep-well plates should be used for activation of up to 1 ml of whole blood per well. The size of wells in these plates allows for use of 8 ml of FACS lysing solution and higher wash volumes than the 96-well plate formats for subsequent washes.

REMARKS AND CONCLUSION
We have described how plate-based CFC assays for both whole blood and PBMC can increase the throughput that is a necessity for immune-response monitoring in clinical trials. As shown in Fig. 2, CFC assays performed using (i) PBMC in shallow-well plates (ii) whole blood in 96-well deep-well plates, or (iii) whole blood in 24-well deep-well blocks in parallel resulted in comparable frequencies of IFNγ$^+$ CD69$^+$ cells and IFN-γ staining intensities. Plate-based CFC allows for activation, processing, and staining in a single plate, reducing the labor required and the cell loss that results from sample transfers (19). In addition, batch analysis using dynamic gating improves reproducibility of the results and lowers subjectivity in gating, facilitating standardization and robust assay performance. CFC assays can be used efficiently to detect more than one cytokine (e.g., IFN-γ, interleukin-2, and tumor necrosis factor alpha) per stimulus by using six-color or eight-color analysis (16). All these characteristics of plate-based CFC provide the benefits of high-content information and higher efficiency of detection than that of ELISPOT assays, with comparable throughput (5, 7, 13). In fact, current National Institutes of Health clinical trials for HIV vaccines will be using this CFC assay format as part of their routine immune-response monitoring. Increasing usage of plate-based CFC in multisite clinical trials will undoubtedly accelerate the search for a surrogate biomarker(s) of vaccine efficacy.

Molecular Analysis of Cytokines and Cytokine Receptors

NIELS KRUSE AND PETER RIECKMANN

41

REAL-TIME QUANTITATIVE PCR

Background

During the last decades, analysis of cytokines and cytokine receptor research have gathered much interest. Numerous methods have been developed for the detection and quantification of cytokines and cytokine receptors, which may be detected at either the protein or the mRNA level (see Table 1). For quantification at the protein level, enzyme-linked immunosorbent assays, biological assays, and extracellular as well as intracellular cytokine staining (31) have been widely used. Problems with protein quantification derive from the low concentrations of cytokines and cytokine receptors present in the blood or other body fluids and the minor amounts secreted into cell culture supernatants, especially if cells are not stimulated. Furthermore, detectability of cytokine proteins in plasma may be hampered by specific and nonspecific cytokine inhibitors (5). Higher sensitivity is obtained when the expression of mRNAs coding for cytokines and cytokine receptors is utilized. Quantification of cytokine mRNA expression is possible by using Northern blotting (4), RNase protection assays (24), in situ hybridization (30), and quantitative PCR. Although Northern blotting and RNase protection assays have been shown to give excellent quantitative results, these techniques are very labor-intensive and require large amounts of starting material (1). Furthermore, the sensitivity of these assays is rather low as indicated by a detection limit of 10^5 mRNA copies (12). In situ hybridization allows not only for more-sensitive quantification of mRNA (12) but also, in combination with immunocytochemistry, for identification of the expressing cell type (13). The most sensitive assay for quantification of mRNA molecules available today is reverse transcription of mRNA into cDNA in combination with PCR (RT-PCR) (8). With this technique, even single molecules of specific mRNAs were reported to be detectable due to the exponential amplification of target molecules (23), and reproducible quantitative results can be obtained with copy numbers as low as 50 molecules (14, 15, 29).

In this chapter, we will focus on improvements of the recently developed real-time quantitative PCR (7, 9) that has been used in our laboratory for a couple of years in comparison to other available techniques (14, 15). The methods described allow quantification of minute amounts of mRNA in small samples due to the exponential amplification of the target sequence and the generation of fluorescent molecules that are detected during the amplification reaction.

Analysis of Cytokine and Cytokine Receptor Expression in Cell Culture and Tissue

Gene expression can be analyzed in tissues or cell culture systems. The real-time RT-PCR has been evaluated for the quantification of mRNA expression in cell culture systems (e.g., peripheral blood mononuclear cells, dendritic cells, and cerebral endothelial cell cultures of different species), tissues (those of the central and peripheral nervous systems), and whole blood (fresh and stored frozen). Depending on the starting material, the procedure of RNA purification has to be optimized and may vary considerably. As RNA molecules are subject to degradation by ubiquitous RNases, special emphasis has to be placed on preserving the integrity of the molecules during isolation and storage. We recommend immediately dissolving the tissue and cell culture material in a buffer containing guanidine thiocyanate and β-mercaptoethanol to denature proteins and inactivate RNases. If possible, samples should be snap-frozen in liquid nitrogen and stored at −80°C until use. For quantification of RNA or DNA in blood samples, devices for transportation to specialized laboratories have been developed that preserve the integrity of the nucleic acids (e.g., PAXgene blood RNA or DNA system from QIAGEN) even if stored at room temperature.

Concept

Principle of PCR

PCR is suitable to specifically amplify target sequences by a millionfold. A typical amplification reaction mixture includes a sample of RNA, cDNA, or DNA (the template), two sequence-specific oligonucleotide primers, deoxynucleoside triphosphates, reaction buffer, magnesium, and a thermostable DNA polymerase. PCRs are performed in thermal cyclers, which take the reaction mixture through a series of different temperatures. Incubation of the reaction mixture at 95°C leads to denaturation and unfolding of the target sequence. Lowering the temperature to 40 to 60°C allows the oligonucleotide primers to specifically anneal to the template and prime the amplification reaction. At temperatures between 60 and 72°C, thermostable DNA polymerases elongate the primers and amplify the target sequence. Under

optimal conditions, each cycle theoretically doubles the number of template molecules. A recent development in PCR technology was the invention of real-time PCR based on the 5′ nuclease assay (10). PCR are performed in real-time thermocyclers from various companies (e.g., Applied Biosystems, Stratagene, Roche, BioRad, MJ Research, Incyte, Smartcycler, and Corbett). These machines can be classified into flexible and high-throughput systems. The flexible systems allow the user to run up to 96 temperature profiles per run, and most high-throughput thermocyclers allow only one temperature profile per run. Furthermore, the instruments differ considerably in ramping and therefore in the time required for analysis.

The compositions of the real-time PCR assay mixtures differ from the mixture described above in that a third oligonucleotide (an internal probe) is added to the reaction mixture and anneals to the template between the oligonucleotide primers. The probe is labeled with a reporter dye at the 5′ end and a quencher dye at the 3′ end. Furthermore, the 3′ end is phosphorylated to prevent elongation by the DNA polymerase. When the probe is intact, the proximity of the reporter dye to the quencher dye results in suppression of the reporter dye fluorescence, primarily by Föster-type fluorescent resonance energy transfer (FRET) (6, 18). During PCR amplification, the DNA polymerase displaces the probe from the template and cleaves it by its 5′→3′ nuclease activity. Both dyes now become separated, FRET does not work anymore, and the reporter dye fluorescence can now be detected. A schematic representation of the reaction is shown in Fig. 1. The amount of reporter fluorescence generated is directly proportional to the number of template molecules as one probe molecule is cleaved for each double strand synthesized. Fig. 2 illustrates the increase in reporter fluorescence during the amplification reaction.

During PCR with the ABI PRISM 7700 sequence detection system, all PCR assay mixtures are sequentially excited every 7 s by an argon laser. The light is directed through fiber-optic cables to the tubes. The fluorescence emission is collected from each well and transferred through a system of lenses, filters, and a dichroic mirror to a spectrograph. Here the light is separated across a charge-coupled device camera. A computer collects the fluorescent signals from the camera and applies analysis algorithms. In addition to the described double-dye oligonucleotide probes for sequence-specific detection, several other formats have been developed. These include molecular beacons, scorpions, hybridization, and Elipse probes. (An overview is given at http://www.eurogen-tec.com/code/en/page_07.asp?Page = 409.)

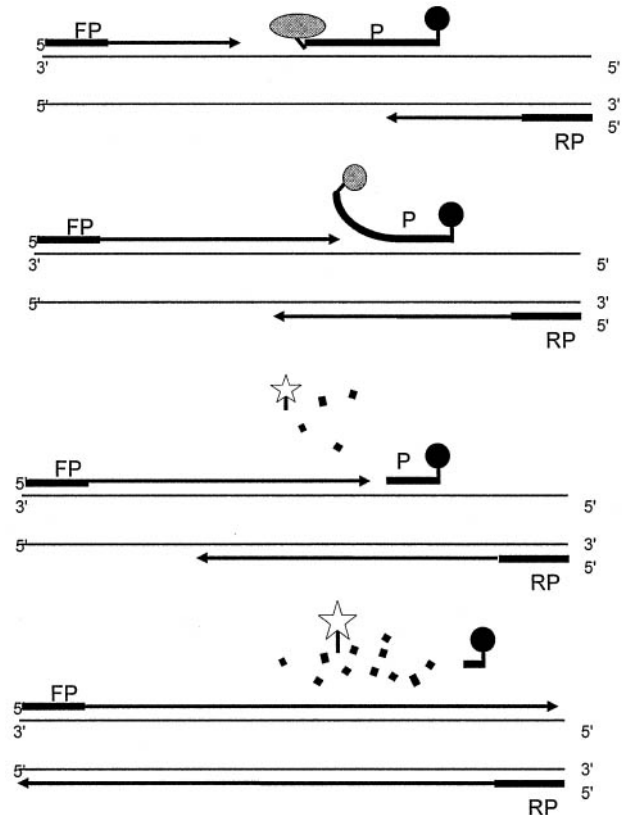
Sequence-unspecific detection is obtained by using SYBR Green I. This initially nonfluorescent dye intercalates into DNA double strands and fluoresces upon light activation. A potential drawback of this detection method is that


FIGURE 1 Schematic representation of the quantification reaction. Fluorescence signals are generated during the PCR as, upon elongation of one primer, the internal probe is first displaced from the template strand and then cleaved by the *Taq* DNA polymerase. Separation of reporter and quencher dye leads to detectable amounts of reporter fluorescence. F, sense primer; R, antisense primer; P, probe.
FIGURE 2 Increase in reporter dye fluorescence during amplification reactions. Fluorescence intensities are measured in cycles 5 (dashed line) and 40 (solid line) in the range of 500 to 660 nm. While the TAMRA signal at 580 nm is hardly changed, the FAM signal at 535 nm strongly increases due to separation of reporter and quencher dyes by probe cleavage.

FIGURE 3 Multicomponent view. The changes in FAM, (squares), ROX (triangles), and TAMRA (circles) fluorescence intensities during PCR are shown. ROX serves as a passive reference dye and remains unchanged during PCR. The fluorescence of FAM, as the reporter dye, increases during PCR due to separation from the quencher upon probe cleavage. The TAMRA fluorescence decreases during PCR due to reduced energy transfer from the reporter dye after probe cleavage.

unspecifically amplified sequences as well as primer dimers contribute to the signal. For this reason, a melting curve analysis has to be performed after the PCR is run in order to quantify the amount of specific product.

Predeveloped Assays

Predeveloped assays are available from several vendors. With these assays, the labor-intensive establishment and optimization of quantitative real-time PCR assays is no longer neccessary. The assays are developed in such a way that the sequence of interest and a housekeeping gene from the sample are amplified in separate wells. The results are then subjected to a mathematical calculation in order to determine the concentration difference in a pathological or stimulated sample in relation to a standard sample (see below). Most of the assays developed thus far show comparable amplification efficiencies. Therefore, many targets can be amplified and quantified from a single sample in parallel.

Kinetic Control of Amplification Reaction

Real-time PCR enables control of reaction kinetics. An example is given in Fig. 3. The multicomponent view illustrates the change in fluorescence energies of the different dyes contained in the reaction mix. 6-Carboxy-X-rhodamine (ROX) serves as a passive reference dye to control for pipetting errors. It should give a straight line at the same level for all assays within one experiment. 6-Carboxyfluorescein (FAM) and 6-carboxytetramethylrhodamine (TAMRA) are the reporter and quencher dyes, respectively, covalently attached to the probe molecules. During the first cycles, only a few probe molecules are cleaved and the ratio of the dye intensities does not change significantly. During cycles 3 to 15, the sequence detection system software calculates the mean and standard deviation of the FAM fluorescence. Addition of 10 standard deviations to the mean is defined as the threshold level. Fluorescence intensity has to exceed this threshold value to be regarded as significant. As during the exponential phase of the amplification reaction, as the cleaved probe molecules accumulate, FAM fluorescence increases and

TAMRA fluorescence decreases due to reduced FRET. Increase in FAM fluorescence should be as high as possible to allow sensitive detection of template molecules.

Procedure

Preparation of RNA (Total RNA or mRNA)

RNA can be used either as total RNA or as mRNA. Preparation of total RNA has the advantage that, in case of RNase contamination of mRNA, due to the high concentration of rRNA and tRNA the target RNA sequence is relatively protected against degradation. During preparation, it is essential to immediately inactivate RNases contained in the tissue or cells. RNases are usually inactivated by guanidine thiocyanate in combination with β-mercaptoethanol. Guanidine thiocyanate is a strong denaturing agent. It efficiently lyses cells or tissues and denatures proteins. β-Mercaptoethanol acts by reducing disulfide bridges. For purification of RNA, several methods have been developed. Most of them are based on separation of RNA from contaminating DNA and proteins by phenol-chloroform extraction. After mixing and centrifugation, DNA is concentrated in the phenol phase, proteins are concentrated in the interphase, and RNAs are concentrated in the upper aqueous phase. RNAs are further purified from the aqueous phase by alcohol precipitation and several washing steps. Besides the procedure described, numerous kits are commercially available for RNA preparation from different tissues and cell populations. These kits often contain resin-based separation materials and are nontoxic, and the procedures are fast and less laborious. Up to 96 samples can be processed in parallel.

Preparation of Standards

Decisions should be made about what kind of standard should be used for quantification of cytokine mRNAs. Standards may be either cRNA reverse transcribed in vitro (25) or cDNAs cloned into a plasmid vector (cDNA standards) (14, 15). Using cRNA as a standard allows absolute quantification of mRNA expression if known amounts of

cRNA are prepared and reverse transcribed in parallel with sample mRNAs and used to generate standard curves. This procedure controls for RNA recovery and efficiency of reverse transcription in different samples. However, one has to keep in mind that if multiple mRNAs are to be quantified, cRNAs for each target sequence have to be processed, which may impact the comparability between individual cytokine quantifications. With the use of cDNA standards, one does not control for RNA recovery and efficiency of reverse transcription. Therefore, only relative quantification is possible. We routinely use cDNA standards as we usually quantify multiple mRNAs in our samples. If the standards are handled appropriately and reverse transcription has initially been optimized, the results from different experiments are comparable and highly reproducible.

For preparation of standards, cDNAs encompassing the entire coding sequence should be cloned into a plasmid vector. This method has the advantage that, during establishment of new quantitative assays, one often has to try several oligonucleotide combinations in order to find a combination sensitive and specific for target cDNA and not prone to interfere with genomic DNA. Sequence identity has to be confirmed by sequencing because even single base pair exchanges may critically impact the optimal hybridization conditions for the internal probe that determines quantification efficacy. Furthermore, in several instances nucleotide sequences derived from databases may harbor single nucleotide exchanges due to naturally occurring polymorphisms within the population. An alternative method for relative quantification is used in predeveloped assays from several companies. These rely on the comparative cycle threshold (C_T) or $\Delta\Delta C_T$ method (22). One or multiple genes of interest (target) and an appropriate endogenous control from a sample are amplified in two separate assays. For both sequences, the C_T is determined. ΔC_T is calculated as follows: $C_{T endogenous\ control} - C_{T gene\ of\ interest}$. A calibrator sample is treated similarly. The expression of the gene of interest in a sample is then normalized to its expression in the calibrator sample by calculating $\Delta\Delta C_T$ as follows: $\Delta\Delta C_T = \Delta C_{T sample} - \Delta C_{T calibrator}$. The amount of target normalized to the endogenous control and relative to the calibrator sample is $2^{\Delta\Delta CT}$.

Synthesis of cDNA [Oligo(dT), Random Hexanucleotide, and Sequence-Specific Oligonucleotide Priming]

Different methods have been applied for the synthesis of cDNAs from purified total RNA or mRNA. Reverse transcription may be primed by oligo(dT) oligonucleotides (14, 15), random hexanucleotides (20), or sequence-specific oligonucleotides (32). While reverse transcription with sequence-specific oligonucleotides should lead to reverse transcription of only the respective mRNA, both oligo(dT) and random hexanucleotides prime reverse transcription of a mixture of mRNAs. Oligo(dT) restricts reverse transcription to poly(A)$^+$ mRNAs, whereas random hexanucleotides prime reverse transcription of all RNAs, including rRNA and tRNA, both of which allow cDNA preparation for multiple-target amplification.

Choice of Oligonucleotides for Amplification and Quantification

To prevent amplification of genomic DNA, oligonucleotide primers should anneal to different exons separated by long introns. Higher specificity may be obtained if at least one oligonucleotide anneals to the mRNA template at an exon-exon boundary (Fig. 4). Several software packages are available to analyze physicochemical characteristics of oligonucleotide sequences such as melting temperature (T_m), G+C content, secondary structure, and primer dimer formation, etc. We routinely use PrimerExpress software (PerkinElmer). This software automatically chooses combinations of oligonucleotide primers and a corresponding internal probe according to predefined parameters. The T_m of the oligonucleotide primers should be 58 to 60°C. The G+C content should be 30 to 80%. The higher the G+C content, the shorter the oligonucleotide will be for a given T_m. For quantitative assays, the T_m of the probe sequence should be approximately 10°C above the primer T_m. Extensive secondary-structure formation and primer dimer formation should be avoided. The probe sequence must not start with a G since guanidine serves as a quencher for reporter dyes. Runs of five or more identical nucleotides are to be avoided. If possible, the probe sequence with a low G/C ratio should be used. The last five nucleotides at the 3′end of the oligonucleotide primer should not include more than two G's plus C's to improve priming specificity. Alternatively, Web-based programs are available from several companies. During recent years, several databases of validated oligonucleotides for quantitative PCR have appeared on the Web (http://appliedbiosystems.com/catalog/myab/StoreCatalog/products/CategoryDetails.jsp?hierarchyID=101&category3rd=111951&trail=0; https://www1.qiagen.com/Products/PCR/QuantiTect/Search/Default.aspx; https://catalog.invitrogen.com/index.cfm?fuseaction=viewCatalog.viewProductDetails&sku=108M01& productDescription=953; http://medgen.ugent.be/rtprimerdb).

Specificity for mRNA templates may be validated by using genomic DNA as a template. No fluorescence signal should be generated in this amplification reaction. To exclude significant depletion of oligonucleotides by contaminating genomic DNA, defined amounts of cDNA and cDNA with a contaminating amount of genomic DNA (e.g., 50 ng, corresponding to roughly 8,500 copies of genomic DNA) should be amplified in separate reactions. C_Ts for both reactions should be the same. This guarantees that contaminating genomic DNA has no influence on the results of mRNA quantification. An example is shown in Fig. 5.

Amplicons should be as short as possible. Real-time PCR works best with amplicon sizes of 50 to 150 bp. Figure 6 illustrates the effect of amplicon size on amplification efficiency. Figure 6A shows the amplification plots of interleukin-2 (IL-2) cDNA standards amplified with oligonucleotide primers IL2S and IL2AS (Fig. 4), and Fig. 6B shows the amplification plots of the same template with primers IL2S2 and IL2AS2 (Fig. 4). Both quantifications were performed with the same internal IL-2 probe (Fig. 4). The amplification plots differ in that amplification with primers IL2S2 and IL2AS2 gives a much steeper amplification plot than that with primers IL2S and IL2AS. This demonstrates that during PCR with primers IL2S2 and IL2AS2 the number of cleaved probe molecules per cycle is much larger than it is during PCR with primers IL2S and IL2AS, and therefore the efficiency of amplification is higher. Amplification efficiency can be calculated from the slope of the standard curve according to the following equation:

$$\% \text{ Efficiency} = [10^{(-1/\text{slope})} - 1] \times 100$$

In Fig. 7, the standard curves for the experiment from Fig. 6 are shown. As easily seen for defined amounts of target molecules, the threshold for detection of fluorescence is reached much earlier with primers IL2S2 and IL2AS2 than with the original primers. The slopes of the curves were –3,622

FIGURE 4 Nucleotide sequence of human IL-2 cDNA (HSIL2R). Sequence characteristics must be taken into account when oligonucleotide probes are chosen for quantification. Here, the cDNA sequence for human IL-2 is shown with exon boundaries double underlined and oligonucleotide binding sites underlined. The names of the oligonucleotides are indicated at the starting nucleotides. Note that the IL-2 probe spans an exon boundary.
FIGURE 5 Specificity of oligonucleotide primers for cDNA. Means of results in three amplification plots for no-template controls (solid squares), cDNA (open squares), genomic DNA (solid triangles), and coamplified cDNA and genomic DNA (open triangles) are shown. The amplification of NTC and genomic DNA does not generate a fluorescence signal. The amplification of cDNA and cDNA plus genomic DNA results in identical amplification plots. Delta Rn, normalized reporter fluorescence (see text).

(Fig. 7A) and –3,559 (Fig. 7B), which indicates 89 and 91% amplification efficiency, respectively. Short amplicons have the advantage that the rate of incorporation of wrong nucleotides is reduced. Furthermore, with a short distance between primer and probe, one ensures that the first polymerase molecule attached to the primer cleaves the probe, as roughly 60 nucleotides are incorporated into the growing strand before the polymerase molecule detaches from the template.

Optimization of Reaction Conditions (MgCl$_2$ and Oligonucleotide Concentration)

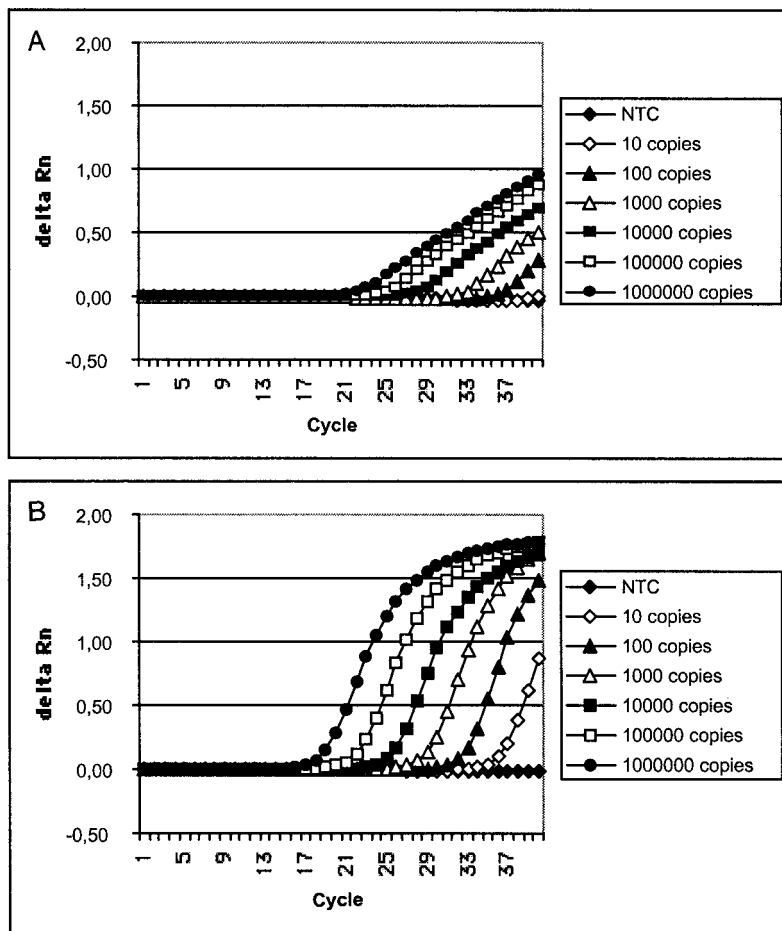
The performance of amplification reactions is affected to a large extent by the concentrations of magnesium ions and oligonucleotide primers. Usually, specificity of primer annealing increases with decreasing magnesium ion concentration. With real-time PCR, specificity in terms of amplification of only the correct sequence is not the major goal, since hybridization and cleavage of the internal probe guarantee specificity of target quantification. In contrast, one should try to make the reaction as sensitive as possible, i.e., to get the lowest C_T for a given template concentration. To achieve this, the first step in optimization of the reaction conditions is to test several magnesium ion concentrations in increments of 0.5 or 1.0 mM in the range of 2 to 9 mM. The concentration giving the lowest C_T is used for the next step, optimization of oligonucleotide primer concentration.


FIGURE 6 Amplification of IL-2 plasmid standards with two different oligonucleotide combinations. IL-2 plasmid standard molecules (10 to 10^6) were amplified with oligonucleotides IL2S and IL2AS (A) or IL2S2 and IL2AS2 (B) within one experiment. The oligonucleotide binding sites are shown in Fig. 4. With both primer combinations, the same probe (IL-2 probe) was used. Note that usage of oligonucleotides IL2S2 and IL2AS2 results in steeper amplification plots and higher fluorescence intensities. NTC, no-template controls; delta Rn, normalized reporter fluorescence.

Forward and reverse primers are titrated in a checkerboard dilution in the range of 100 to 300 (or 900) nM final concentrations. Again, one is interested in the concentration giving the lowest C_T for a given template concentration. For these experiments, the probe concentration can be kept at 100 nM. A further point of interest is the slope of the amplification plots. This should be as steep as possible because the more labeled probes that are cleaved within one cycle, the higher the efficiency of the amplification reaction (Fig. 6).

Evaluation of Experimental Results

After data analysis is performed, plotting the input number of standard molecules against the C_T determined to detect the respective fluorescence signal generates a plot. This provides the standard curve for the experiment. For unknown samples, the C_T for each sample is detected and transmitted to the computer. The sequence detection software now takes each C_T from the unknown samples to calculate the amount of starting copy number in the assay by comparing individual C_T to those of the standard curve (Fig. 7).

Controls

As data from the real-time PCR are continuously recorded, a retrospective quantitative analysis of the amplification process may be performed. Data analysis starts with a view at the amplification plots of the PCR. The increase in fluorescence intensity for all reactions is displayed on the monitor. This enables the researcher to judge if all reactions were performed with equal efficiencies. Variations in efficiency can easily be detected by changes in amplification profiles. Comparison of C_Ts for defined standard concentrations allows for comparison of different experiments. If quantitative experiments are properly standardized, C_Ts for the standard concentrations yield comparable results within a range of ≤8%. All quantitative determinations should be performed at least in triplicate. The sequence detection software allows assignment of replicates within the experiments. After data analysis, the experimental report constitutes a table with the number of molecules determined in each assay as well as the mean and standard deviations of results for the triplicates.
FIGURE 7 IL-2 standard curves generated with two different oligonucleotide combinations. IL-2 plasmid standard molecules (10 to 10^6) were amplified with oligonucleotides IL2S and IL2AS (A) or IL2S2 and IL2AS2 (B) within one experiment. The oligonucleotide binding sites are shown in Fig. 4. With both primer combinations, the same probe (IL-2 probe) was used. Note that usage of oligonucleotides IL2S2 and IL2AS2 results in earlier detection of significant fluorescence, i.e., higher sensitivity. Coeff., coefficient.

Standardization, Pitfalls, and Troubleshooting

In order to achieve a high reproducibility of quantitative analysis, all experimental procedures should be highly standardized as much as possible. Within one study, all reagents required should be purchased from the same vendor, if possible from the same lot. If different lots have to be used, the comparability of results should be verified. In the case of quantitative PCR assays, we sometimes found significantly variable amplification efficiencies with different oligonucleotide batches. The plasmid standards should be stored as aliquots of defined concentrations. Dilution series of standards should be prepared freshly. Freezing of plasmid standard dilution series is not recommended since repetitive freezing and thawing may lead to degradation of DNA molecules.

Application

Real-time PCR is a valuable tool for research and clinical applications. Minor variations in cytokine expression under physiological conditions are often not detectable with enzyme-linked immunosorbent assay techniques. The high sensitivity of the exponential amplification of target molecules (mRNA or DNA) and the high reproducibility of the real-time PCR makes this technique an ideal tool to analyze even minor changes in mRNA concentrations in clinical samples. Serial analysis of cytokine mRNA expression in whole-blood samples has been performed with excellent reproducibility (15).

Differential quantitative expression of cytokine mRNAs in cultures of human purified peripheral blood mononuclear cells and endothelial cells stimulated with various agents has been analyzed in our laboratory. These studies demonstrated that significant changes in mRNA expression can be detected as early as 4 h after initiation of the cultures. The amount of mRNA correlates with the secretion of protein into the culture supernatant (16). Therefore, physiological changes in cytokine mRNA expression can be detected much earlier than changes in protein expression.

ALLELIC DISCRIMINATION PCR

Background

Genetic disorders and drug responses may be critically determined by small variations within functional relevant parts of the genome (11, 19). About 0.1% of the nucleotides are changed between the two chromosomes of a diploid cell (3, 17). These changes are known as single nucleotide polymorphisms (SNPs). Methods used for the analysis of SNPs include, among others, restriction fragment length polymorphism (28), single-strand confirmation polymorphism (31), and sequencing (2). All these techniques are time-consuming and require multiple post-PCR steps that limit the number of samples that can be analyzed per day. For large-scale SNP analysis, routine applications, and pharmacological research, methods are warranted that are reliable, easy to perform, and suitable for automation. The 5′ nuclease assay offers the possibility of analyzing hundreds of samples per day without the need for any post-PCR processing. A major advantage of allelic discrimination PCR is that the amplification of the target sequences may be performed in any thermocycler. The ABI PRISM 7700 sequence detection system is required only for establishing the optimal reaction conditions and measuring the amount of fluorescence generated during amplification in a plate read mode.

Concept

Principle of Allelic Discrimination Using Oligonucleotides Labeled with Fluorescent Dyes

Real-time PCR also allows for allelic discrimination of SNPs in genomic DNA samples (21, 26, 27). Internal probes labeled with different reporter dyes for each allele are used within one reaction (e.g., probe 1 labeled with FAM for the wild-type allele and probe 2 labeled with TET (6-carboxy-2′,4,7,7′-tetrachlorofluuprecein) for the mutant allele). Depending on the haplotype, either probe 1 or probe 2 is cleaved if homozygous DNA is present. If heterozygous DNA is present, both probes are cleaved. If the wrong probe is hybridized to the template, the mismatch within the probe sequence introduces so much instability that upon initial strand displacement by the DNA polymerase the incorrect probe floats away before cleavage while the correct probe sticks to the template and gets cleaved. The sequence detection system software automatically makes allele calls by calculating the ratio of fluorescence intensities for probe 1 and probe 2 for each DNA sample. DNA homozygous for allele 1 should give a high FAM/TET ratio, and DNA homozygous for allele 2 should give a low FAM/TET ratio. Heterozygous DNA should give a FAM/TET ratio of approximately 1.

Procedure

Preparation of DNA

Numerous kits are commercially available for preparation of genomic DNA from different sources. Most easily, DNA can be prepared from blood cells. One milliliter of whole blood is sufficient to yield good-quality genomic DNA for several hundred allelic discrimination reactions.

Preparation of Standards

DNA fragments comprising the polymorphic position of interest and the primer binding sites should be cloned into a plasmid vector. The sequence identity should be confirmed by sequence analysis.

Choice of Oligonucleotides for Amplification and Detection

The physicochemical characteristics of the oligonucleotides should be as described above for quantitative assays with the only exception that the T_m of the internal probes should be approximately 7°C above the primer T_m. For successful allelic discrimination, it is extremely important that T_ms for both probes be as similar as possible to achieve comparable annealing efficiencies and differentiate as little as one base pair exchange.

Optimization of Reaction Conditions (MgCl$_2^-$ and Oligonucleotide Concentrations and Annealing Temperature)

The aim of optimizing the reaction conditions for allelic discrimination PCR is to increase cleavage of the correct internal probe and concurrently decrease cleavage of the false internal probe. Allelic discrimination PCR usually works with 5 mM Mg^{2+}. Oligonucleotide primer concentrations are titrated in a checkerboard test at concentrations of 50, 300, and 900 nM with 100 nM final concentrations of both internal probes. The concentrations giving the lowest C_T and the highest delta Rn values should be used for further experiments. (Delta Rn is the ratio of the fluorescence emission intensity of the reporter dye to the fluorescence emission intensity of the passive reference dye minus baseline.) Next, the internal probe concentration is titrated at concentrations of 50, 100, and 200 nM with the fixed primer concentration determined before. This test serves to find the conditions for best discrimination between the two alleles, i.e., the highest ratios between the fluorescence signals generated by cleavage of the matching and the mismatching probes. Improvement of discrimination can be obtained by changing the annealing temperature in 1°C increments. An example of increase in fluorescence intensities obtained in an allelic discrimination experiment is given in Fig. 8.

Evaluation of Experimental Results

Figure 9 presents the results from an allelic discrimination experiment. In this experiment, the internal probe specific for the wild-type allele at position −308 of the human tumor necrosis factor alpha (TNF-α) promoter (TNFα−308G) was labeled with TET as the reporter dye. The internal probe for the mutant allele (TNFα−308A) was labeled with FAM as the reporter dye. It is expected that in the presence of homozygous wild-type DNA the TET-labeled probe is preferentially cleaved, giving rise to significant TET fluorescence and, if any, very little FAM fluorescence. In the presence of homozygous mutant DNA, significant FAM fluorescence with little TET fluorescence should be generated. Heterozygous DNA, due to cleavage of both probes, should give increases in both fluorescence signals. Based on the data from the standards run within the experiment, the sequence detection software generates a plot of FAM versus TET fluorescence for the standards and the unknown DNA samples. As clearly visible from Fig. 9, three populations are distinguished according to the amount of FAM and TET fluorescence generated during amplification. Samples giving a high TET/FAM ratio are identified as homozygous GG, and those giving a high FAM/TET ratio are identified as homozygous AA. Heterozygous DNAs give intermediate ratios.

Remarks and Conclusions

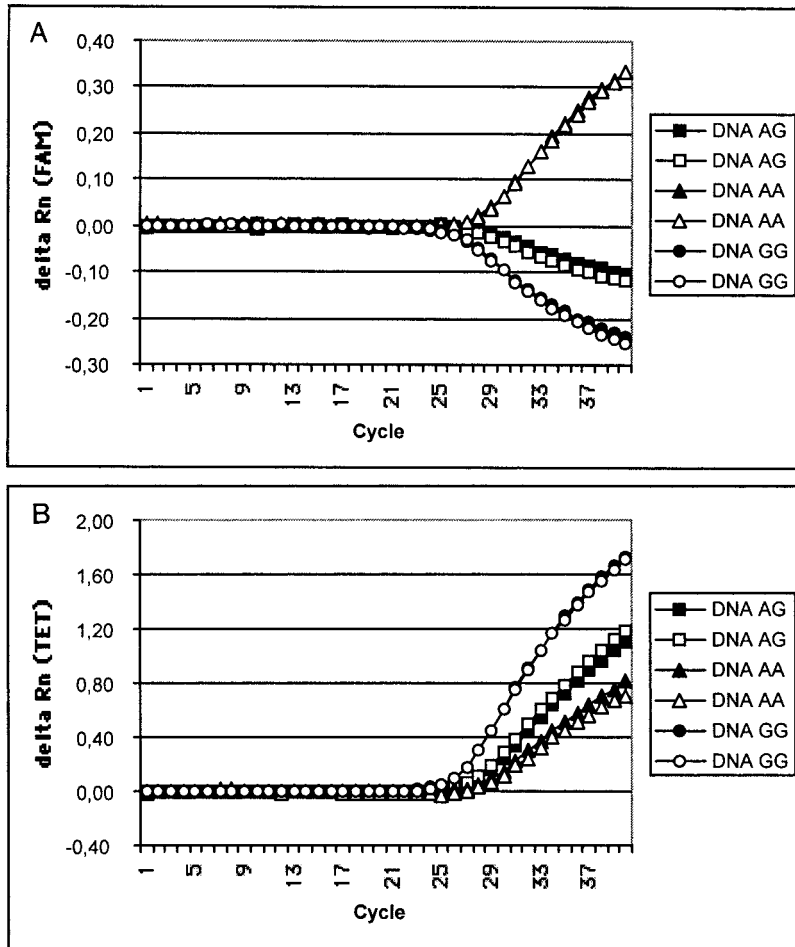
Real-time PCR can be regarded as a state-of-the-art technique to investigate the expression of cytokine and cytokine receptor mRNA in different tissues or experimental or clinical settings. Several advantages of the system described in


FIGURE 8 Increase in FAM (A) and TET (B) fluorescence during PCR amplification of different TNF-α haplotypes. Three different haplotypes of the human TNF-α promotor (DNA AG, DNA AA, and DNA GG) were amplified in the presence of two different internal probes. One is labeled with TET and specific for the wild type (TNFα-308G), the other is labeled with FAM and specific for the mutant promotor (TNFα-308A). If homozygous DNA TNFα-308A is present, the FAM fluorescence gives the higher intensity. If homozygous DNA TNFα-308G is present, the FAM fluorescence gives the lower intensity. The opposite holds true for the TET fluorescence. Heterozygous DNA in both cases gives intermediate intensities. Delta Rn, normalized reporter fluorescence (see text).
FIGURE 9 Identification of TNF-α haplotypes by allelic discrimination PCR. After PCR, the FAM and TET fluorescence intensities were determined for each sample. Plotting FAM fluorescence against TET fluorescence revealed different populations representing three haplotypes. High TET and low FAM intensities identify wild-type alleles; high FAM and low TET intensities identify mutant alleles. Heterozygous DNA gives intermediate results. NTC, no-template controls.

this chapter include its broad applicability, high sensitivity, wide dynamic range, and ease of adaptation to almost every field of interest (e.g., analysis of mRNA expression in research and clinical settings, detection of bacterial or viral infection, detection of contamination in dairy products, and determination of point mutations in genomewide screenings, etc.), as well as the potential for online control of reaction kinetics to verify the likelihood of results. A major advantage of the real-time PCR is its application as a high-throughput analytical system in routine diagnostics and research, as, in contrast to other conventional PCR-based techniques, no post-PCR processing of the reaction products is required.

Chemokine and Chemokine Receptor Analysis

BENJAMIN D. MEDOFF AND ANDREW D. LUSTER

42

BACKGROUND

Overview

The active movement of leukocytes towards a site of antigen challenge, infection, or tissue damage represents a central aspect of the establishment of both the inflammatory and the immune responses (78, 106). The movement of cells towards a chemical gradient of a particular stimulus or chemotactic factor is called chemotaxis. Chemotactic factors which induce the directional movement of leukocytes include the chemokines, a superfamily of proteins 8 to 10 kDa in size, which signal chemotaxis through seven-transmembrane G protein-coupled cell surface receptors (GPCRs) (6, 40, 66, 78, 106, 108). In this chapter, the methodological approaches to studying the role of chemokines and chemokine receptors in the physiology of immune and inflammatory responses will be described. Although assays of chemokines or chemokine receptors have yet to be used for widespread clinical applications, this chapter will discuss the role of these proteins in the pathophysiology of several inflammatory diseases and suggest potential clinical uses for these proteins.

Chemokines and Chemokine Receptors: Basic Principles

Chemokines

Approximately 50 chemokines which share 20 to 70% homology in amino acid sequence have now been identified (6, 40, 66, 78, 106, 108) (Table 1). Chemokines share the common function of attracting leukocytes to sites of an inflammatory or immune response. Chemokine families are defined on the basis of the spacing of the first two cysteine amino acids in the mature protein. Based on this criteria, four families of chemokines exist. In α, or CXC, chemokines, the cysteine residues are separated by a single amino acid. A further subdivision of CXC chemokines relates to the presence or absence of the sequence glutamic acid-lysine-arginine (ELR) near the N terminus of the protein. In general, ELR CXC chemokines chemoattract neutrophils whereas non-ELR CXC chemokines attract lymphocytes. In β, or CC, chemokines, the cysteine residues are adjacent to each other. There are two chemokines that do not fit into these two categories: the so-called C chemokine, lymphotactin, which has only one proximal cysteine residue, and the

CXXXC chemokine, fractalkine, which has three intervening amino acids between the two proximal cysteine residues. Fractalkine is also unique in that it is expressed as a cell surface glycoprotein with the chemokine domain sitting on top of a mucin-like stalk and has both transmembrane and cytoplasmic domains.

It has recently been proposed that the chemokines be given numerical names, like the interleukins and the chemokine receptors (144). In the proposed nomenclature, CC chemokines are named CCLn, for CC chemokine ligand, where n is the number that corresponds to the gene symbol number given to each chemokine as it was mapped and designated SCYn for small secreted cytokine. Likewise, the CXC chemokines are named CXCLn, for CXC chemokine ligands.

Chemokine Receptors

All chemokines signal via seven transmembrane-spanning GPCRs (114, 137), which are named by a numbering system based on the type of chemokines to which they bind (Table 1). GPCRs are a highly versatile group of proteins which have evolved to sense subtle changes in concentration gradients and are involved in signal transduction for vision, olfaction, hormone reception, and neurotransmission in addition to directional cell movement (33, 87, 134). The GPCRs as signal transducers of chemotaxis appear to be highly conserved in evolution, being present on amoebae and slime molds, and are involved in the signaling of chemotaxis in these simple eukaryotes.

GPCRs consist of an extracellular N terminus, an intracellular C terminus, and seven transmembrane-spanning regions (114, 137). Chemokine binding to the extracellular portion of the receptor results in intracytoplasmic signaling, which is mediated in part through heterotrimeric G proteins of the Gαi subclass. Chemokines may present to chemokine receptors in both the liquid and solid phases (109). Chemokine receptor binding occurs with both the chemokine in solution and the chemokine bound to the matrix and cell surface glycosaminoglycans (5, 124, 125). The binding of chemokine to receptor results in a complex signaling cascade, which may result in directed cell movement, cell activation, differentiation, and/or cell proliferation (6, 78, 106). Activation of chemokine receptors is usually accompanied by a transient rise in the level of intracellular calcium. The G protein is itself coupled to a number

of downstream intracytoplasmic signal transduction pathways, including those involving protein kinase C (PKC), tyrosine kinases, and phosphatidylinositol 3-kinase (PI 3-kinase) (34, 125) (Fig. 1). The direct link between these signal transduction pathways and the activation of the cytoskeletal machinery involved in cell motility is not known. However, Rho proteins, which are known to be involved in actin-dependent processes, are thought to be involved in linking chemokine receptor activation to activation of the cytoskeletal machinery (27, 70, 115).

Role of Chemokines and Chemokine Receptors in Disease

Overview

The attraction of leukocytes to sites of inflammation and infection is an essential component of the host response to disease. Chemokines and chemokine receptors have been shown to be an integral part of this process and have been implicated in the pathophysiology of many infectious diseases and inflammatory disorders (78). Although chemokines are

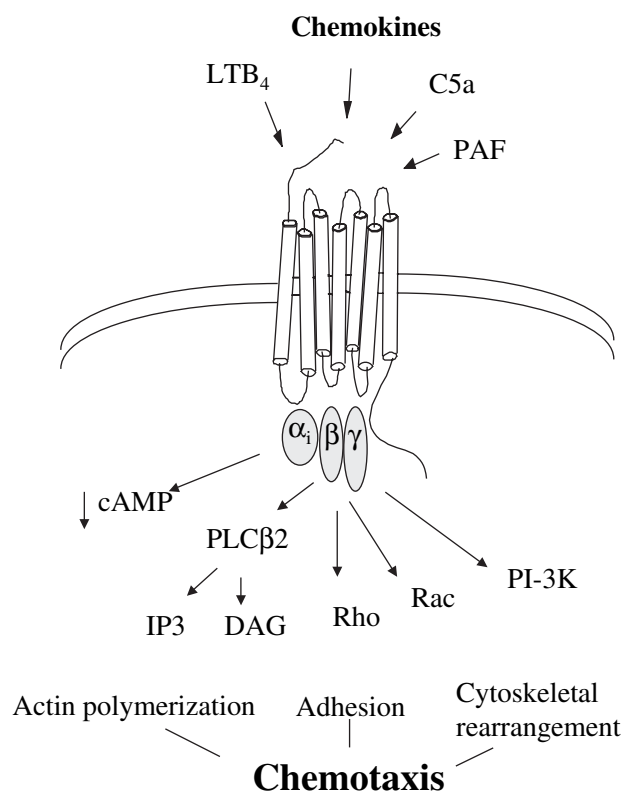

FIGURE 1 Chemokine receptor signal transduction. Chemokine receptors are a subfamily of seven-transmembrane-spanning GPCRs. They are coupled to heterotrimeric G proteins of the Gi subclass, which are distinguished by their pertussis toxin sensitivity. Chemokine receptor activation leads to the stimulation of multiple signal transduction pathways, including the activation of PI 3-kinase (PI-3K) and phospholipase C, leading to the generation of inositol triphosphates, intracellular calcium release, and PKC activation. Chemokine signaling also induces the upregulation of integrin affinity and the activation of Rho, leading to cytoskeletal reorganization. Agonist-stimulated receptors also activate G protein receptor kinases, which leads to receptor phosphorylation, arrestin binding, G protein uncoupling (desensitization), and clathrin-mediated receptor endocytosis (internalization). clearly important for the ability of the host to control infections, they can also be detrimental in certain inflammatory conditions, such as asthma and atherosclerosis, in which inflammatory cells are recruited into sites in the body and cause the development of an inflammatory infiltrate and damage to the site (32). The chemokine-chemokine receptor axis likely participates in the pathophysiology of these diseases by leading to the pathologic accumulation and activation of leukocytes in affected tissues. In such disorders, it has been suggested that the chemokine-chemokine receptor axis could be used both as a diagnostic tool and as a therapeutic target for controlling the inflammation. The following section will highlight the role of chemokines and their receptors in four different inflammatory conditions, namely, atherosclerosis, arthritis, asthma, and transplantation. The potential clinical applications of assays for chemokine and chemokine receptor expression will be discussed.

Atherosclerosis

Atherosclerosis is the underlying process in coronary artery disease and peripheral vascular disease, two of the most common causes of morbidity and mortality in the United States. It is believed that atherosclerotic lesions develop in response to repeated insults to the arterial wall. Inflammation is a critical component in this process (72), and prominent leukocyte recruitment occurs in almost every stage of lesion development from the appearance of the fatty streak lesion to the formation of complex plaques (118). Immunohistochemical analysis of atherosclerotic lesions reveals that approximately 80% of leukocytes in the atheroma are monocytes/macrophages while T lymphocytes (predominantly memory cells) make up 5 to 20% of the inflammatory infiltrate (40). The recruited monocytes and T lymphocytes are thought to play a key role in the pathogenesis of atherosclerotic plaque, and thus the molecular signals that attract these cells into the lesions are likely important for lesion formation (40, 82). The expression of multiple chemokines has been shown to be upregulated in human atherosclerotic lesions (Table 2).

In addition, studies with mouse models of atherosclerosis have shown that deletion of the chemokine CCL2/monocyte chemoattractant protein 1 (MCP-1) or the chemokine receptors CCR2 and CXCR2 leads to significant reductions in macrophage recruitment into vessel walls and decreased formation of atherosclerotic lesions. These data strongly support a role for chemokines in the development of atherosclerosis.

Based on these data, one could potentially utilize the expression levels of these chemokines as a noninvasive marker of atherosclerosis or as a tool to assess disease through molecular imaging techniques (55, 140). Several studies now exist demonstrating a correlation between atherosclerosis and levels of MCP-1 in serum (26, 38, 94); however, the use of this information for testing in humans has not been widely adopted.

RA

Rheumatoid arthritis (RA) is a chronic inflammatory disease of the joints that can lead to long-term joint destruction with severe disability in affected patients. The underlying pathology is notable for prominent leukocyte infiltration of the synovial tissue of the joints. The majority of cells recruited into the synovium are neutrophils and mononuclear leukocytes that presumably help propagate the inflammation and joint destruction. Chemokine expression studies

have shown markedly increased levels of certain chemokines in synovial tissue from patients with RA compared to those in tissue from normal joints. Both CC (i.e., CCL3/macrophage inflammatory protein 1α[MIP-1α], CCL5/RANTES, and CCL2/MCP-1) and CXC (i.e., CXCL10/gamma interferon-inducible protein 10 [IP-10], CXCL8/interleukin-8 [IL-8], and CXCL5/epithelial neutrophil-activating peptide 78 [ENA-78]) chemokines are expressed in fibroblasts and macrophages in the synovia of RA patients (54, 60-62, 104). Consistent with this chemokine expression, synovial fluid T cells recovered from patients with active RA express high levels of the chemokine receptors CCR5 and CXCR3 (73). In addition, patients who are homozygous for a null mutation in the CCR5 gene have fewer swollen joints and less morning stiffness than RA patients with the normal alleles (39). Finally, studies with animal models of arthritis have demonstrated that inhibition of CCR2, CCR1, CCR5, CXCR2, CXCL8, and CXCL5 attenuates joint swelling and leukocyte infiltration (4). These data clearly show that chemokines are important mediators of the joint inflammation seen in this disease (Table 3) (122).

Measurement of chemokine expression in serum could be used as a surrogate to quantify the degree of inflammation in the joints. In one study, higher levels of CCL3/MIP-1α, CXCL8/IL-8, and CXCL5/ENA-78 in sera were found in patients with active RA than in those with inactive disease (61, 62, 65). Presently, there are only limited studies looking at the role of measurements of chemokine and chemokine receptor function or levels in RA. However, the therapeutic role of chemokine inhibition is being explored with at least one chemokine antagonist in clinical trials for RA.

Asthma

Asthma is one of the most common chronic diseases in the world, with an incidence in excess of 5% of the population. It is characterized by chronic inflammation of the airways that in most cases is allergic in nature. Experimental studies with animal models and humans suggest that inhalation of an allergen initiates a cascade of events that lead to the recruitment of eosinophils, neutrophils, lymphocytes, and mast cells into the airways (21). Chemokines have been implicated as important mediators of this cellular recruitment (Table 4) and are likely crucial for the development of allergic inflammation in the airways (77, 79). Data from bronchoalveolar lavage and lung biopsy studies have demonstrated the upregulation of the chemokines CCL11/eotaxin-1, CCL24/eotaxin-2, CCL7/MCP-3, CCL13/MCP-4, CCL5/RANTES, CCL17/thymus and activation-regulated chemokine (TARC), CCL22/macrophage-derived chemokine (MDC), and CXCL10/IP-10 in patients, during asthma attacks or after allergen challenge (78). Some of these chemokines recruit eosinophils and others affect T-cell trafficking. Animal models of asthma suggest that no single chemokine controls all aspects of cell trafficking into the airway; rather, multiple chemokines likely work in a sequential and redundant manner to orchestrate the inflammation (80).

As in the other diseases profiled in this chapter, measurements of chemokine and chemokine receptor levels are not widely used in asthma; however, there are several scenarios in which such measurements may be useful. For instance, currently clinicians monitor the effectiveness of therapy in people with asthma based on symptom reporting and crude measures of lung function. Acute exacerbations of asthma are life-threatening complications of this disorder that can often occur rapidly. In addition, it is hypothesized that long-term low-grade inflammation that can be missed with routine monitoring may lead to scarring of the airways and permanent changes in lung function. Unfortunately, the available technology does not allow us to easily measure the degree of airway inflammation and thus predict a patient's risk of exacerbation or airway scarring or remodeling. Chemokine expression in the lung or blood could be used as a reliable noninvasive marker of inflammation in the airways and thus would be of great value in the management of asthma. The technology to measure chemokine levels in exhaled breath condensates is available and has been used in limited studies for measurements in children with asthma (71). In addition, expectorated sputum or serum has been used in assays to measure chemokine levels and predict exacerbation in patients (67, 123). Finally, allergic asthma can often be confused with related disorders such as emphysema, bronchiolitis, and eosinophilic bronchitis. These disorders have different forms of airway inflammation and thus may have different profiles of expressed chemokines. Therefore, it may be possible to use the chemokine or chemokine receptor profiles of samples from the lung or serum to accurately diagnose a

patient with airway inflammation. The use of measurements of markers of inflammation such as chemokines may have a large impact on the diagnosis and management of asthmatics.

Organ Transplantation

Organ transplantation is often the only effective treatment for the large number of patients with end-stage kidney, liver, heart, or lung disease. Although a transplant is often life-saving therapy, it ushers in a new set of problems and diseases for the organ recipient. These include increased risk of infection (including opportunistic infections), organ ischemia-reperfusion injury, acute rejection, and chronic organ dysfunction from chronic rejection. These processes involve recruitment of leukocytes into the transplanted organs, with neutrophil recruitment dominating in infections and ischemia-reperfusion injury and lymphocyte and monocyte recruitment involved in rejection. Chemokine expression has been clearly shown to be important in all of these processes (Table 5) and represents a potential therapeutic target to prevent these complications of transplantation (31).

Chemokine expression in infections of organs has been well documented and depends on the nature of the microbe infecting the host (78, 128). Organ ischemia-reperfusion injury, acute rejection, and chronic rejection lead to increased expression of multiple chemokines that are surprisingly similar in all organs after transplantation (31). However, organ-specific differences do exist, so one cannot fully generalize the response to all transplanted organs (1). In the limited studies looking at chemokine expression following human organ transplantation, the expression of CXCL8/IL-8 has been associated with ischemia-reperfusion injury (28) and CCL5/RANTES, CCL2/MCP-1, CCL3/MIP-1α, CCL4/MIP-1β, CXCL9/monokine induced by gamma interferon (MIG), CXCL10/IP-10, and CXCL11/interferon-inducible T-cell alpha chemoattractant (I-TAC) have been associated with acute rejection (8-11, 28, 29, 143). In chronic rejection of lungs, CXCL8/IL-8, CCL5/RANTES, CXCL9/MIG, CXCL10/IP-10, CXCL11/I-TAC, and CCL2/MCP-1 are upregulated and may be predictive of the development of this complication (10, 100).

Frequent episodes of acute rejection and untreated low-grade rejection are thought to lead to chronic organ dysfunction, which is the major limiting factor in long-term graft survival. Thus, the ability to better detect these processes could have a major impact on the management of posttransplant patients. The expression of specific chemokines during episodes of acute rejection or low-grade chronic rejection may be a biomarker of inflammation and may allow better detection of these processes. Monitoring for occult infections with chemokine expression would also be of use for the transplant population. Although no large studies have utilized measurements of chemokines for monitoring of transplant patients, the ability to measure chemokine levels in serum, urine, or sputum makes this a potential future indication for the technology.

Methodological Approaches

Overview

Since inflammatory and immune cell localization appears to be central to the pathogenesis of a wide variety of diseases, numerous avenues for studying the role of chemokines and chemokine receptors have emerged. These techniques follow a logical progression from the characterization of the inflammatory or immune cell infiltrate through the measurement of chemokine and chemokine receptor distribution in diseased tissues, the establishment of in vitro models of chemotaxis, and in vivo dissection of the role of chemokines in animal models of the disease process. This series of approaches has enabled the definition of the role of chemokine-chemokine receptor-driven immune and inflammatory cell localization in a variety of diseases.

Analysis of the Cellular Infiltrate and Chemokine-Chemokine Receptor Milieu

The first step towards understanding whether localization of immune or inflammatory cells influences a disease process is to define the cellular composition of the infiltrate seen in sites in the body which are affected by the disease. This may be best done by one of two methods, immunohistochemistry of tissue sections or staining of cellular preparations obtained from disaggregated pathological specimens. There are a large number of monoclonal antibodies which enable the definition of subpopulations of immune and inflammatory cells and the characterization and quantitation of chemokine and chemokine receptor expression (95, 132).

Monoclonal antibodies that are reactive to specific antigens expressed on T cells, B cells, monocytes/macrophages, dendritic cells, neutrophils, eosinophils, and basophils-mast cells can be utilized to detect these cells or specific subsets of these cells in frozen sections by using immunohistochemical techniques. The immunoperoxidase technique, utilizing the avidin-biotin complex, has excellent sensitivity, and stained slides can be mounted and stored permanently. In addition, sections can be counterstained with hematoxylin and eosin, for example, to provide additional morphologic information. Serial sectioning allows the assessment of three-dimensional relationships between subsets of immune and inflammatory cells within tissue specimens. Appropriate isotype controls should be run with experimental immunostaining to establish levels of background nonspecific staining.

Fluorescent conjugated monoclonal antibodies targeting specific cell surface molecules can be similarly used to establish the cellular makeup of a tissue infiltrate (95). Tissue samples can be physically disaggregated and then passed through a sterile sieve. Mononuclear cell preparations can then be stained with monoclonal antibodies, and the immunophenotypes of cell populations can be determined by fluorescence-activated cell sorter-based flow cytometry. Up to 12 different fluorochromes can be used, depending on the number of available lasers, to define cell subpopulations. Again, appropriate isotype antibody controls should be used to establish background and nonspecific staining.

A third aspect of analysis of a cellular infiltrate is the determination of levels of chemokine or chemokine receptor expression. A combination of methods can be used, including RNA in situ hybridization, immunohistochemistry, quantitative reverse transcriptase PCR, enzyme-linked immunosorbent assay (ELISA) or protein multiplexing technology, and flow cytometry (16, 121). Monoclonal antibodies directed against a number of chemokines suitable for use in staining of tissue sections, ELISA, or protein multiplexing have been defined. These antibodies can be used as a basis for measuring chemokine protein concentrations from tissue lysates and fluid collections. A number of different chemokines can now be detected by sandwich ELISAs. Some of these ELISAs are now commercially available as kits. Initially, microtiter plates are coated with the capture antibody and nonspecific protein binding is adsorbed with goat serum or bovine serum albumin. Chemokine-containing samples are then added to the wells of the plate, and this step is followed by exposure to a second enzyme-conjugated antibody. Similarly, these chemokine-specific monoclonal antibodies are also available conjugated to a fluorochrome or to fluorescent bead arrays, which allows them to be used to assess intracellular chemokine levels in permeablized cells or to assess the levels of multiple chemokines simultaneously in various biologic samples, both by utilizing flow cytometry technology. Monoclonal antibodies specific for individual chemokine receptors are also commercially available and are used to determine the expression of chemokine receptors on individual cells in situ or those isolated from inflammatory tissue or fluid via immunohistochemistry or flow cytometry.

Analysis of Chemotactic Responses: In Vitro Assays

Having defined the chemokine and chemokine receptor expression in the diseased tissue, one can examine the chemotactic responses of the specific leukocyte subpopulations to chemokines. A variety of transmigration assays exist which exploit the ability of migratory cells to polarize and migrate in response to a chemotactic gradient. The in vivo correlate of in vitro transmigration is thought to be the migration of cells towards sites of tissue injury, pathogen invasion, and/or immune challenge. Cells to be used in the transmigration assays can be derived from a number of sources, including the diseased tissue itself or purified subpopulations of inflammatory and immune cells isolated from the peripheral blood.

Boyden Chamber

The Boyden chamber designed in 1962 represents the original system by which the chemotactic responses of cells can be quantitated (19). The assembly consists of two chambers, an upper and a lower one, separated by a polycarbonate filter of standard pore size. The chemokine, dissolved in medium containing a low percentage of serum or 0.5% bovine serum albumin, is loaded into the lower chamber. A fixed number of indicator cells in suspension in an identical medium are loaded into the upper chamber. The unit is then sealed and incubated at 37°C for 2 to 3 h. Transmigration is then assessed in two ways. The polycarbonate membrane is carefully

removed from the assembly, and the cells which are adhered to the underside of the filter are quantitated following staining with Giemsa. Alternatively, the cells which have transmigrated into the lower chamber are counted using a hemocytometer and the proportion of migrating cells is determined. Ultimately, a so-called checkerboard analysis of chemotaxis can be performed in which every chemokine concentration in the lower chamber is considered in relation to every tested concentration of the chemokine in the upper chamber. Chemotaxis is defined as cell movement towards increasing chemokine concentration. Chemokinesis refers to random or nondirectional cell movement in response to a stimulus. In the checkerboard analysis, chemotaxis is measured when there is a greater concentration of chemokine in the lower chamber than in the upper one and chemokinesis is measured when the concentrations of chemokines are equivalent on both sides of the membrane (Fig. 2). Modifications of the standard Boyden chamber have been made, including one using an image analyzer to quantitate the number of cells which migrate in response to a chemokinetic agent (36, 101).

Transwell Assays

More recently, transmigration assays have been performed in a transwell system (15). In this assembly, each lower

Migration
towards chemokine
(Chemotaxis)

Random movement in response to the chemokine in the absence of a gradient
(Chemokinesis)
FIGURE 2 Transmigration assay system. Positive, negative, and absent gradients of a chemokine are established in order to assess chemotaxis (movement towards a chemokine) and chemokinesis (random movement of cells in response to a chemokine in the absence of a gradient). Cells are plated into the upper chamber of the transwell system or Boyden chamber, and the proportion of migrating cells is determined by accurate counting of cells which migrate to the lower chamber. The upper and lower chambers are separated by a polycarbonate membrane of standard pore size (between 3 and 8 μm), dependent on the migrating cell type.

chamber is associated with an independently removable upper chamber containing the polycarbonate membrane of fixed pore size. A checkerboard analysis of chemotaxis can be similarly performed with the transwell system. The Boyden chamber appears to be markedly better for analyzing granulocyte movement with a polycarbonate membrane of 3-μm pore size, whereas transwells containing membranes with a 5- or 8-μm pore size have proven to be useful for quantitating mononuclear cell migration. Several modifications of transmigration assays have been designed. These include the assessment of transmigration through a layer of cells grown on the transwell membrane. Transmigration of lymphocytes, eosinophils, or monocytes through an endothelial cell layer has been assessed by this means (14). Transmigration systems allow the further phenotypic characterization of responding cell subpopulations from a complex mixture of input cells. By using flow cytometry, cells which transmigrate can be phenotypically compared with those that do not (56, 119). Automated quantitation of transmigration has been achieved by loading cells to be tested with a vital fluorescent dye, such as CMFDA (5-chloromethylfluorescein diacetate) or acridine orange, and then using a fluorescent plate reader to quantitate the number of cells in the lower chamber (25, 88). A further modification of the fluorescent plate reader technique includes the ability to read the kinetic changes associated with transmigration into the lower chamber over time.

Direct Visualization

Measurement of transmigration with a Boyden chamber or transwell assay can be confirmed using time lapse video microscopy (Fig. 3) (97). The active movement of cells is viewed with a video camera as the cells respond to gradients of a chemokinetic agent. A continuous gradient of chemokine or a point source of chemokine can be used to manipulate the directional movement of cells. Cell movement can also be tracked using digital video, and images can be analyzed for cell polarization and speed of movement towards a chemokine source by using leukocytes or organisms such as *Dictyostelium* spp. (59, 92, 116, 131).

Adhesion Assays

The migratory response of immune cells in vivo involves a rapid adhesive event in which the circulating cell is stimulated to firmly adhere to the endothelial surface over which it flows and rolls and is necessary for a cell to undergo diapedesis into an immune organ or an inflammatory site (66, 78, 106). This event is triggered by chemokines and involves the upregulation of integrin affinity on leukocytes. This aspect of cell migration can be studied in vitro using a static adhesion assay or dynamically using a flow chamber to visualize the adhesion of leukocytes to endothelial cell monolayers. In the latter systems, endothelial cell layers are established on coverslips, fluorescently labeled leukocytes are passed over these monolayers at controlled flow rates, and the number of cells rolling or sticking to the endothelial layer is determined using image analysis and digitized time lapse video microscopy. In vivo flow systems have been designed which use intravital microscopy to visualize and quantitate the adhesion and transmigration of fluorescently labeled leukocytes in the vasculature of living animals (14).

Analysis of Chemotactic Responses: In Vivo Assays and Imaging

Several systems have been developed to assess leukocyte infiltration into specific anatomical sites in vivo. Chemokines can be injected intradermally, subcutaneously,
FIGURE 3 Digitized time lapse photography of cells moving in the presence of a gradient of a chemokine. Positive and negative gradients of a chemokine can be established in methylcellulose as previously described (52). Cells are plated into methylcellulose, and a gradient is established by inoculating the methylcellulose at a fixed point with the chemokine. Cells are then visualized migrating in response to the gradient by using time lapse video microscopy.

or intraperitoneally, and the leukocyte infiltration thus caused can be quantified. Recruitment of endogenous leukocytes or adoptively transferred leukocytes can be assessed in this manner. Leukocytes can be labeled ex vivo with radiolabels, such as indium-111 (48, 49), or with fluorescent dyes such as green fluorescent protein (GFP) or CMFDA (141). In addition, monoclonal antibodies exist that can recognize adoptively transferred antigen-specific T cells or allelic markers. A transgenic mouse has been engineered in which the vast majority of T cells express a T-cell receptor (TCR) which binds ovalbumin (OVA). This specific TCR chain can itself be detected using a monoclonal antibody (23, 117). T cells reactive to a specific antigen can be quantitated and the localization of adoptively transferred OVA-specific T cells in specific anatomic sites can be detected by immunostaining for OVA-specific TCRs.

New technology known as molecular imaging allows scientists to assay several different aspects of chemokine biology in intact organisms. It is now possible to evaluate, with imaging, the distribution of injected chemokines as well as track the movement of cells in response to chemokines or inflammation (136). This is a rapidly developing field that utilizes techniques of molecular and cell biology, advanced

imaging technology, and highly specific probes that serve as sources for the imaging signal. Specifically, whole-body imaging of animals or humans after injection of radiolabeled chemokines or bioluminescent cells allows localization of the labeled material to specific organs and areas of the body. Whole-body imaging of radioactive material or light generated deep within the body is now feasible in laboratory animals and potentially in humans, representing an exciting new tool for studying chemokine biology.

Analysis of Signal Transduction Associated with Active Cell Movement

The signal transduction events activated by ligand binding controlling leukocyte migration are not entirely defined and involve many different signaling pathways. A dramatic polarization of the cell occurs in response to a chemotactic gradient, which is the result of asymmetric signal transduction and the establishment of intracellular molecular gradients. While all of the molecular details remain to be elucidated, certain signaling molecules appear to play important roles in chemokine-induced cell movement. Chemokine receptors are coupled to the Gi subfamily of G proteins and pertussis toxin, which ADP-ribosylates and

irreversibly inactivates the Gα subunits of the αi class, inhibiting the majority of chemokine-induced effects on leukocytes, including chemotaxis, calcium flux, and integrin activation (7). Other signaling events activated by the majority of chemokine receptors include the activation of phospholipase C, leading to generation of inositol triphosphates, intracellular calcium release, and PKC activation. Inhibition of chemokine-induced chemotaxis by wortmannin implicates PI 3-kinase in chemokine receptor signal transduction. Mouse strains engineered with a null mutation in the p110 subunit of PI 3-kinase γ have defects in chemokine-induced neutrophil and macrophage migration, confirming the importance of this enzyme in directed leukocyte movement (52). Phorbol myristate acetate activation of integrins implicates PKC as a potential mediator by which chemokines activate integrins. Chemokine signaling also leads to guanine nucleotide exchange on Rho, indicating the activation of Rho (70). Rac and Rho are small GTP binding proteins that are involved in controlling cell locomotion through regulation of actin cytoskeletal rearrangement leading to membrane ruffling and pseudopod formation.

The first and most immediate indication of a signal being transduced in relation to chemokine-induced signaling is a measurable rise in intracellular calcium concentration. The calcium flux is transient and may be detected using several methods (20, 24, 43, 129, 130). Cells are examined by using cuvette-based techniques, which assess calcium flux in populations of cells, and flow cytometry-based systems, which assess individual cell calcium flux responses to chemokines. The emission ratio dyes such as indo-1 and fura-2 are commonly used for flow cytometry-based and cuvette-based methods, respectively. Cells to be tested, including monocytes and lymphocytes, are loaded with ionic calcium binding dyes. Cells are then exposed to sequential pulses of a chemokine, and the change in intracytoplasmic fluorescence is monitored. Control substances include ionomycin, which selectively causes a large calcium flux since it serves as a calcium ion channel in the membrane. EDTA can be used to deplete all calcium from the medium and hence eradicate any cell-related calcium flux. Modifications have been made in order to determine the calcium flux in single cells. Adherent cells on a single slide can be visualized and loading of calcium dyes and intracytoplasmic changes in calcium concentrations can be monitored directly under a fluorescent microscope with an associated image analyzer.

Activation of additional signal transduction pathways can be meaured in cells in response to activation by chemokines (53). Adenylate cyclase assays, phosphoinositide turnover, protein kinase activation, and assays of protein tyrosine kinase activity have all been utilized to measure chemokine receptor activation.

Although the precise mechanistic link between chemokine receptor activation and the activation of the cytoskeletal machinery which induces cellular migration remains unknown, the polymerization of filamentous F-actin has been used as a measure of chemokine-induced functional signaling (126, 138). Intracellular F-actin polymerization can be quantitated using fluorescein isothiocyanate-labeled phalloidin and flow cytometry (103). This technique has been especially useful for assaying small numbers of responding cells. Polymerized F-actin can also be visualized in cells by using confocal microscopy in conjunction with a fluorescently labelled monoclonal antibody directed against F-actin. Studies have revealed that signal transduction occurring after exposure to a chemokinetic gradient results in the polarization of the cell's cytoskeletal elements and the polymerization of activated actin at the leading edge of a cell's newly formed pseudopodia. The Arp2/3 complex has recently been shown to colocalize with and nucleate sites of actin polymerization. A recently engineered GFP-Arp2/3 fusion protein has been used to visualize sites of actin polymerization in the advancing pseudopods of migrating cells by using phase-contrast fluorescent time lapse photography (135). A time lapse fluorescent microscope with a digital spot camera can be used to visualize the polarization of actin polymerization and pseudopod formation in cells transduced with the GFP-Arp2/3 construct and exposed to gradients of chemokines.

Animal Models To Assess the Role of Chemokines and Chemokine Receptors in Development and Disease

The above-mentioned techniques provide data which suggest how chemokines and their receptors may play a role in immune and inflammatory cell function in health and disease. Genetically modified mice in which the gene for a specific chemokine or chemokine receptor has been deleted or is overexpressed in a tissue-specific manner have been used to study both physiological and pathological processes. The effect of neutralization of a specific chemokine or chemokine receptor by specific antibodies on disease processes has also been utilized. These animal models currently provide the cornerstone for determining functional roles of chemokines and chemokine receptors in vivo (17, 74, 81, 89, 110, 111).

The role of chemokines and their receptors in vivo is complex. In an attempt to correlate in vitro determinations of chemokine activities and chemokine receptor expression with in vivo physiology and pathology, gene-targeted mice which fail to express a chemokine or chemokine receptor have been created by selective homologous recombination (110, 111). The phenotype of the so-called knockout is then compared to that of wild-type mice under physiological and pathological conditions. The generation of knockout mice involves the introduction of a mutant gene into embryonic stem cells in vitro and the selection for homologous recombination at the desired locus, which results in the deletion of a specific gene. Animals are then produced which are homozygous for the deleted gene. Embryonic, fetal, and neonatal development is then examined in these mice with a targeted disruption of both wild-type alleles in order to determine whether the gene deletion has effects on embryogenesis, hematopoiesis, or immunologic abnormalities, such as thymic development. In the adult mouse inflammatory and immune responses can be examined. Knockout mice corresponding to more than 10 of the chemokines and all of the chemokine receptors have been developed (96). So far, only the deletion of the stromal cell-derived factor 1 (SDF-1) and CXCR4 genes has been shown to be embryonically lethal and is associated with severe neurological, cardiological, and hematological abnormalities (81, 89). In contrast, fetal development is not affected in other chemokine-chemokine receptor knockouts, such as those not expressing eotaxin, MCP-1, and CCR2 (17, 74, 111). However, resting levels of eosinophils in the murine jejunum are reduced in the eotaxin knockout mouse, which indicates a physiological role for this chemokine in the homeostatic trafficking of eosinophils (84, 111).

Many important roles for chemokines and their receptors have been elucidated in experiments using knockouts and inhibitory antibodies. Different aspects of the host response to infectious pathogens have been shown to be dependent on neutrophil-active chemokines and their receptors, such

as MIP-2 and CXCR2 (22), monocyte-active chemokines and their receptors, such as MCP-1 and CCR2 (68, 128), T-cell-active chemokines and their receptors, such as IP-10 (58), and NK cell-active chemokines, such as MIP-1α (113). Likewise, individual chemokine receptor knockouts have revealed an important role for this family of molecules in inflammatory and autoimmune diseases and allograft transplantation. For example, attenuated immunopathology has been noted in MCP-1 knockout and CCR2 knockout mice in models of atherosclerosis (18, 44) and glomerulonephritis (13, 127). Decreased inflammatory responses and increased allograft survival have been noted in CCR1 (17) and CXCR3 (47) knockouts. These in vivo experiments have revealed the significant role of individual chemokines and chemokine receptors in the immune and inflammatory responses that could not be appreciated by in vitro assays that implicated apparent functional redundancy.

CONCLUSIONS

The Boyden chamber stood as the singular system for quantitating leukocyte migration in response to chemokinetic agents for more than 20 years. However, in the past 5 years, and since the discovery of the chemokine-chemokine receptor superfamilies, there has been a considerable expansion in the number of methodological approaches available to scientists for quantitation of cell migration. These techniques vary widely, from phase-contrast fluorescent digital video microscopy to examine individual cell movement in response to chemokines to the use of knockout mice to delineate the effects of specific chemokines and chemokine receptors in vivo. These diverse methodological approaches have revealed an intricate world of immune and inflammatory cell localization, which appears to be critical to the pathophysiology of a wide variety of disease processes ranging from allergic lung inflammation to atherosclerosis to the way in which the immune system handles infectious agents such as *Toxoplasma gondii*.

During the next 10 years, we should expect to see a further expansion in the methodological approaches to studying the roles of chemokines and chemokine receptors, and this expansion should itself lead to a greater understanding of human diseases and the development of novel therapeutic approaches in order to combat them.

Laboratory Monitoring of Cytokine Therapy

ANDREW R. PACHNER

43

Cytokines, anticytokine antibodies, and cytokine receptors, available as recombinant proteins, are becoming increasingly utilized by physicians to treat a variety of diseases, particularly autoimmune diseases. These medications, cytokine-based therapies (CBTs), a subclass of a group of therapeutic agents called "biologics," have a significant role in therapy. However, there are also major problems with their use, including high cost, immunogenicity, adverse effects, and unknown mechanisms of action. Because of this, laboratory monitoring for drug efficacy as well as for antidrug antibodies and side effects has increasingly become a focus of investigation. Laboratory monitoring for all of the cytokine therapies currently available (see Table 1) is beyond the scope of this chapter. Also not covered in this review is pretherapy genetic testing, which has been studied as a means of increasing the likelihood of positive therapeutic response or decreasing the likelihood of adverse events (18). I instead focus on general strategies, as well as on monitoring for two cytokine therapies, beta interferon (IFN-β) and infliximab.

The goal of laboratory monitoring for cytokine therapies is to maximize the efficacy and minimize adverse effects of these agents. The optimal monitoring strategy will depend on the characteristics of the specifics of the therapy, but general strategies can be identified. In IFN-β therapy for multiple sclerosis (MS), many of these general strategies have been utilized with significant benefit to MS patients. In other CBTs, monitoring has not been as extensively utilized.

GENERAL STRATEGIES OF LABORATORY MONITORING OF CBTs

Mechanisms of Action of CBTs

Cytokines bind to specific receptors on the surface of their target cells, triggering signal transduction with subsequent upregulation of specific genes (Fig. 1). These agents tend to have a relatively narrow spectrum of action and are thus considered "smart bombs," able to effectively suppress the "bad guys" and not affect the "good guys." Because efficacy is dependent upon activation of specific receptors, an understanding of the receptors is essential, i.e., their patterns of expression, ligand binding characteristics, signal transduction molecules, pattern of induced gene activation, etc. These details are imperfectly understood for most CBTs.

Because of the lack of knowledge about it, the mechanism of action in human disease is speculative. A good example is IFN-β therapy of MS. Interferons are a heterogeneous class of molecules which share the ability to protect cells from viral lysis. IFN-α and -β are classed as type 1 interferons, while IFN-γ is considered a type 2 interferon. The type 1 interferons bind to the IFN-α/β receptor, also called IFNAR, while IFN-γ binds to its own receptor. Binding of IFN-β to the IFNAR results in signal transduction, activation of kinases, and activation of transcription factors, with subsequent increases in the levels of the mRNAs and proteins. The MxA gene is an example of such a gene (see below). IFN-β was initially tested in MS in pursuit of the hypothesis that the disease was virally linked and that an antiviral therapy such as IFN-β would ameliorate the natural history of the disease (21). The viral hypothesis has not been completely invalidated, but most researchers now believe that IFN-β induces a change in the immune/inflammatory system in such a way that "harmful" inflammation is decreased. A large body of literature exists on possible mechanisms of IFN-β in MS (6, 11, 12, 45), but speculation is rampant and hard data are sparse. Whatever proves to be the operative mechanism of action, at this point, IFN-β is used as a therapy in MS without a firm understanding of how it works.

Similar considerations apply to tumor necrosis factor (TNF) blockers, used extensively in rheumatoid arthritis (RA) and inflammatory bowel disease. A variety of cell types secrete TNF-α as a 17-kDa soluble protein which then aggregates, forming trimers. The trimers bind to two receptors: p55 TNF receptor 1 and the p75 TNF receptor. TNF-α also induces other cytokines, such as interleukin 1 (IL-1) and IL-6. Another action of TNF-α is to increase leukocyte migration by inducing expression of adhesion molecules by both leukocytes and endothelial cells. Infliximab (Remicade; Centocor) is an intravenously administered chimeric monoclonal immunoglobulin G1 (IgG1) specific to TNF. It is composed of human constant and murine variable regions.

The multitude of TNF blockers currently available have as their putative mechanism of action blockade of TNF binding to the TNF receptor. Infliximab binds specifically and with high affinity to human TNF-α, but its precise mechanism of action in RA or Crohn's disease is not known. Mere neutralization of TNF is not the main therapeutic effect, at least in Crohn's disease, since other TNF-α blockers

TABLE 1 Partial list of cytokines available for therapy in the autumn of 2004

Cytokine or cytokine receptor	Disease(s)	Company(ies)	Year of launch (United States)
IFN-α (Infergen, Intron, PegIntron, Alferon, Pegasys, Roferon)	Hepatitis C, melanoma, leukemia, lymphoma, condyloma acuminatum, Kaposi's sarcoma	Numerous	
IFN-β (Betaseron, Avonex, Rebif)	MS	Berlex, Biogen, Serono	1993
IL-2 (aldesleukin [Proleukin])	Melanoma, renal cell cancer	Chiron	1998
IFN-γ-1b (Actimmune)	Chronic granulomatous disease/osteopetrosis	InterMune	2000
GM-CSF[a] (sargramostim [Leukine])	Reconstitution after chemotherapy	Immunex	1995
TNFR[b] IgG1 (etanercept [Enbrel])	RA, JRA[c], psoriatic arthritis, ankylosing spondylitis	Immunex-Wyeth	1998
Anti-TNF antibody (adalimumab [Humira], infliximab [Remicade])	RA, Crohn's disease	Abbott, Centocor	2002
CD-11a (efalizumab [Raptiva])	Psoriasis	Genentech	2003
LFA-3–IgG (alefacept [Amevive])	Psoriasis	Biogen	2003
IL-1 (anakinra [Kineret])	RA	Amgen	2001
G-CSF (pegfilgrastim [Neulasta], filgrastim [Neupogen])	Reconstitution after chemotherapy	Amgen	1991

[a]GM-CSF, granulocyte-macrophage colony-stimulating factor.
[b]TNFR, TNF receptor.
[c]JRA, juvenile RA.
[d]G-CSF, granulocyte colony-stimulating factor.

are equally able to neutralize yet have little or no effect. Although there are a number of hypotheses (e.g., decreased expression of adhesion molecules or acceleration of apoptosis of TNF-α-bearing cells), none have been widely accepted, and the explanation for differences in efficacy of the various TNF-α-lowering agents is not known.

Monitoring of CBT Effect: General Principles

There are two major types of laboratory measures used to monitor CBTs: biomarkers of disease and cytokine-induced molecules. Biomarkers of disease are assays used to monitor disease activity, are not specific for the CBT, and can be used to monitor any therapy for the disease. Examples include
FIGURE 1 Diagram of cellular effects of IFN-β as a prototype of a CBT. The cellular response to IFN-β is a prototype system in which receptor binding by the cytokine results in upregulation of a host of early, intermediate, and late genes, with complex downstream effects.

sedimentation rate and rheumatoid factor measurement in RA or C-reactive protein in inflammatory bowel disease (23). Biomarkers of disease are extensively dealt with in other chapters of this manual and are not discussed here. Cytokine-induced molecules are relatively specific markers of cytokine induction and represent expected responses ideally linked to the therapy's mode of action. MxA is such a marker in IFN-β therapy for MS.

Most cytokines during their natural function have their effect over a short distance. In other words, they are released by one cell and act upon a nearby cell so that their concentrations in serum are low or not measurable. Thus, when CBTs are injected it is assumed that they will achieve effective concentrations at the appropriate location of optimal action, and that these concentrations will be uniform from individual to individual. Unfortunately, with many CBTs, the subject of therapy is a black box in which a drug is injected and a clinical effect is assessed; this "black box" nature of therapy presents serious problems in identifying biomarkers. An example is IFN-β therapy for MS. Within an hour after injection the drug is not detectable in blood. The target cell mediating the drug effect is unknown; many different cell types have IFNARs and can respond to IFN-β. These facts, combined with the fact that MS is a highly variable disease requiring hundreds of trial subjects to show a therapeutic effect for a given treatment, make it very difficult to assess the drug's effect in any one patient, and they underline the need for biomarkers of drug efficacy.

Because of this lack of a firm understanding of the mechanism of action of CBTs, efficacy monitoring is not highly developed for most biologicals. Ideally, we would be able to measure multiple products of genes which (i) are sensitive and specific for the CBT, (ii) are highly correlated with the expected molecular effect of the cytokine on gene products critical for the disease, and (iii) represent bioactivity of the CBT at various levels of its mechanism, from interaction with cell surface receptors to activation of necessary downstream gene products. This ideal has not been reached for any CBTs, but the currently available monitoring assays closest to the ideal involve monitoring of genes upregulated after injection of IFN-β, described at length below.

Monitoring of Immunogenicity: General Principles

During development of biologicals by pharmaceutical companies, efforts are made to minimize immunogenicity. However, as summarized recently by Schellekens (41), the immunogenicity of a product in humans is not predictable from structural analyses and animal studies. Even during clinical trials, immunogenicity may be underestimated if the antibody assays are not reliable. Such a situation occurred for anti-IFN-β therapy in the treatment of MS. In the pivotal study of IFN-β therapy for MS (19), anti-IFN-β antibodies were measured but the assays used were unreliable, and there was considerable variability in readings. This resulted in a highly confusing picture, and the problems with immunogenicity of the product were thus overlooked.

The need for high quality in assays for antibiological antibodies induced during therapy cannot be overstated, since both underdiagnosis and overdiagnosis create problems for clinicians. Antibodies to recombinant proteins used in therapy can cause serious side effects by inactivating both the injected and the native protein. This was demonstrated to be potentially fatal in pure red cell aplasia

in patients treated with recombinant erythropoietin who developed antierythropoietin antibodies (5, 46). At a minimum, antibodies can lead to loss of bioactivity of the injected CBT, a state known as antibody-mediated decreased bioactivity (ADB) (25). Assays for antibodies to CBTs are generally developed to address two different aspects of antibody function: binding and neutralization.

Binding-antibody (BAb) assays are generally faster, more sensitive, and more inexpensive than other assays. Enzyme-linked immunosorbent assay (ELISA) technology can be used, which allows for the screening of hundreds of samples in a few hours in an automated fashion. Other methodologies to detect BAbs include immunoprecipitation assays and blotting methods. Careful attention must be paid in the development of these assays to a number of factors which contribute to imprecision in BAb assays, especially in ELISAs. These have been well summarized recently by Bendtzen (1). For instance, some cytokines which are adhered to solid phase become partially denatured, creating neoepitopes not found in the recombinant molecule. These neoepitopes will then serve as antigens in ELISAs, creating false positivity. Conversely, partial denaturation of the antigen will also result in destruction of some epitopes for true BAbs, leading to potential false negativity. For instance, in ELISAs measuring anti-IFN-β BAbs, adhering IFN-β directly to plastic plates by using highly alkaline coating buffers results in both false positivity and false negativity (31), making this method of coating plates for anti-IFN-β ELISAs highly unreliable. However, the many advantages of ELISA technology make this technique highly desirable if methodologically feasible. Thus, a modified ELISA has proven to be highly useful in the monitoring of MS patients treated with IFN-β (27); in this assay, IFN-β is captured in liquid phase by a monoclonal anti-IFN-β antibody adhered to the plate (4) and then reacted with the patient's serum and developing reagents. BAb assays are ideal for screening for biologically relevant antibodies, but they tend to detect low-affinity antibodies. Thus, BAb assays can be positive for patients in whom there is no interference with CBT therapeutic effect, i.e., false positive.

For an antibody assay that more closely correlates with ADB, neutralizing-antibody (NAb) assays are used. NAbs are unlikely to be false positive; i.e., patients in whom NAbs are positive are likely to be receiving incomplete benefit from the medication. They measure the ability of the patient's serum to neutralize a biological effect of the CBT. For IFN-β, the standard NAb assay is performed by adding serum to IFN-β and then to a layer of IFN-β-responsive cells, with subsequent exposure to a virus which kills unprotected cells, described at more length below. For the TNF blocker infliximab, no NAb assay is available. NAb assays are advantageous in being more highly correlated with clinical measures, but they tend to be difficult and much more expensive than BAb assays.

MONITORING OF IFN-β THERAPY

Monitoring of Efficacy

Activation of the IFNAR as a Measure of Effect of Anti-IFN-β Antibodies

Neurologists prescribe IFN-β for their MS patients with the assumption that bioactivity of the drug will be maintained with repeated injection. However, many patients injecting the drug

develop anti-IFN-β antibodies, and these anti-IFN-β antibodies can interfere with bioactivity, inducing a state known as ADB. In this situation, antibodies developed against the drug prevent the binding of the drug to its specific receptor, leading to lack of activation of the IFNAR after the patient injects the drug. Because of this, in those patients in whom ADB is suspected, bioactivity measurements, measuring activation of IFN-β-inducible genes, are increasingly being used as a direct measure of whether IFN-β is stimulating the IFNAR, the receptor critical for IFN-β function. IFNAR binding with subsequent signal transduction is a necessary first step for IFN-β action in MS. If bioactivity is maintained, each injection of IFN-β results in the strong upregulation of the MxA gene, which is IFN-β inducible, in the blood. MxA is a cytoplasmic protein (47) with a molecular mass of about 75 kDa which has intrinsic GTPase activity blocking viral replication, and it is encoded by the Mx1 gene, located on chromosome 21q22.3. Other genes, such as those for 2′,5′-oligoadenylate synthetase (28), neopterin (8), and viperin (7), are also upregulated after IFN-β injection, but MxA has proven to be the most robust and widely used marker.

Bioactivity measurements using IFN-β-induced MxA mRNA or MxA protein have been performed in both cross-sectional and longitudinal studies of MS patients (2, 3, 9, 10, 27, 28, 32, 43). Blood is obtained 12 h after IFN-β injection, at which time a strong MxA mRNA signal is detectable in patients without high levels of anti-IFN-β antibodies. The three commercially IFN-β preparations have similar doses of IFN-β with each injection, approximately 6 to 9 mIU of IFN-β, so the MxA mRNA levels induced are similar. RNA is obtained as whole RNA, and the reliability of the assay is dependent on the quality of the RNA, since RNA is an unstable molecular species. Thus, the methodology of RNA purification for these assays is critical. In order to ensure optimal RNA quality, we have utilized the PAXgene purification system, developed by Becton Dickinson, for our version of the MxA mRNA measurement, which we call the gene expression of MxA.

Once RNA is purified, reverse transcription is performed using the SuperScript First-Strand Synthesis System for reverse transcription-PCR (Life Technologies, Grand Island, N.Y.). cDNA is then subjected to real-time PCR analysis using the PE Applied Biosystems Taqman system; a 6-carboxyfluorescein- or 6-carboxytetramethylrhodamine-labeled probe is used for either MxA or glyceraldehyde-3-phosphate dehydrogenase (GAPDH) in separate tubes. We have utilized plasmids containing the sequence of MxA and GAPDH in order to standardize our assay. We then express the values obtained for any particular patient as a normalization ratio, a ratio of expression of MxA of the patient relative to that of a healthy control, with each measurement indexed to the GAPDH RNA level.

When this method is used for a large group of healthy controls, a normal distribution of values is obtained with the mean at 1 (Fig. 2A). When this method is used for a large group of MS patients with low or absent anti-IFN-β antibody levels in blood samples obtained 12 h after injection, a normal distribution of values is obtained with the mean at 17 (27) (Fig. 2B). GEM values expressed as the normalization ratios obtained for the same patient over time are very stable as long as anti-IFN-β antibody levels are absent or low.

The results of the GEM assay are highly dependent on the level of anti-IFN-β antibodies. Four stages of the relationship between antibody assays and bioactivity measured by GEM can be identified (Fig. 3) in those patients who develop significant levels of antibodies. In the first stage, which occurs in the first few months after initiation of therapy, NAbs are absent, and bioactivity is normal. In the second stage, as NAbs rise, bioactivity decreases. In the third stage, which can last for years if the patient continues IFN-β injections, NAbs remain positive and bioactivity is decreased or absent. In the fourth stage, which occurs in an unknown but significant percentage of patients with ADB, usually those taking IFN-β-1b rather than IFN-β-1a, NAb levels spontaneously decrease and bioactivity increases despite continued injection.

Prolonged periods of ADB result in a loss of clinical efficacy of IFN-β, particularly in those measures of MS activity responsive to IFN-β therapy, such as gadolinium-enhancing lesions on magnetic resonance imaging or relapse rates (20, 34, 39). The clinical effects of the loss of efficacy are much more difficult to identify in MS relative to other diseases in which CBTs have been used, because of the incomplete response of patients to IFN-β and the highly variable progression and relapse rate in MS. This has prompted some clinicians to claim that "the effects of IFNβ NAb on clinical efficacy are incompletely understood" (50). However, most investigators in the field believe that adequate evidence exists to conclude that levels of NAbs high enough to substantially lower bioactivity as measured by MxA assays will lead to significant diminution or loss of therapeutic efficacy (13, 25).

Monitoring of IFN-β-Induced Genes Important in MS Pathogenesis

Although the MxA gene is an IFN-β-induced gene in MS patients, there is no evidence that MxA is important in MS pathogenesis. Thus, the MxA gene is an excellent gene for measuring IFNAR activation and monitoring the effect of anti-IFN-β antibodies, and its induction is a necessary condition for effect of IFN-β in MS, but it may not be a sufficient condition for treatment effect. Other molecules, like IL-10 (37, 38, 49), may be directly linked to the therapeutic effect. Efforts are underway to identify IFN-β-inducible genes important for the therapeutic effect (22, 48).

Immunogenicity

Assays for antibodies which neutralize the ability of IFN-β to protect susceptible cell lines from viral lysis were the first antibody assays to be used for MS patients treated with IFN-β. Such assays, called cytopathic-effect assays (14, 15), are currently the standard in the field. In the most popular version of this assay, the A549 cell line, a human lung carcinoma line, is the target, and encephalomyocarditis virus is used to lyse the cells. Cell death is measured using a vital dye, and the assay is considered positive when addition of a 1:20 dilution of patient serum is able to result in cell death by interfering with the protective effect of IFN-β. An alternative assay which is increasingly being used is the NAb-MxA test (36). In this more recently developed assay, the readout is measurement of production of an IFN-β-inducible protein, MxA, by a cell line; A549 cells can also be used as the cell line for this assay. Cells exposed to IFN-β preincubated with serum devoid of NAbs will make high levels of MxA, while cells exposed to IFN-β preincubated with serum with NAbs present will not produce MxA. In both assays, the NAbs exert their effect by binding to IFN-β in such a way as to prevent its ability to bind to the IFNAR; IFNAR-activated signal transduction leads to both protection from viral lysis and production of MxA. NAb assays, like all antibody assays, have both strengths and weaknesses. Positives are that these
FIGURE 2   Histograms of gene expression of MxA (GEM) in controls without IFN-β injection (top) and MS patients 12 h after IFN-β injection (bottom). The x axis represents $\log_2$ of normalization ratios, i.e., 2 to the power (ΔΔCt) where ΔΔCt is (Ct of MxA – Ct of GAPDH) for sample minus (Ct of MxA – Ct of GAPDH) for normal control. The y axis represents number of patients. The expected response after injection is a strong increase in level of MxA mRNA as detected by real-time reverse transcription-PCR. In this group of patients the MS patients had a mean of over 16-fold increase in MxA mRNA after injection.

assays are now relatively well standardized and correlate quite well with loss of clinical efficacy. However, disadvantages are that they are difficult technically, cumbersome, and quite expensive. Also, because they are based on responses of cell lines, any serum constituents that affect the cells will lead to problems in the assay.

Increasingly, BAb assays for anti-IFN-β antibodies are being used as screening assays. BAb assays test for all antibodies that bind at a range of affinities to IFN-β; serum samples that have low or absent binding levels are negative for NAbs and do not require further analysis (31, 33). In the capture ELISA technique initially developed by Brickelmaier
FIGURE 3 Stages of ADB in IFN-β-treated MS patients. Four stages can be identified in the interplay between antibody and bioactivity of IFN-β as measured by the GEM assay. ◆, Nab level (%); ■, bioactivity (%). The *y* axis represents percent maximal response, and the *x* axis represents months post initiation of therapy.

et al. (4), a monoclonal anti-IFN-β antibody, adhered to the plate, is used to capture the antigen, IFN-β, and then the solid phase is incubated sequentially with serum, conjugated antibody, and the developing reagent. The test was initially shown to be reliable for a small number of samples from patients treated with Avonex, an IFN-β-1a preparation. Our laboratory subsequently demonstrated that the assay could accurately assess antibody response in a large number of patients treated with all three IFN-β preparations (31). BAb assays have also been used successfully in screening for NAbs in clinical trial specimens (35, 39).

MONITORING OF INFLIXIMAB THERAPY

Infliximab-Sensitive Genes
Unlike IFN-β, infliximab, as a monoclonal antibody to TNF-α, does not have a receptor for its action and thus does not directly upregulate gene expression. Because it is designed to block TNF-α, one might assume that its effect can be measured by documenting decreased expression of TNF-α in the peripheral blood, but this assumption would not be correct. TNF-α, IL-6, and IL-1β were not significantly decreased by infliximab therapy, but acute-phase proteins such as cyclic AMP receptor protein and haptoglobin were decreased (24). At this point, there are no well-accepted biomarkers for infliximab direct action, either for assessment of the effect of anti-infliximab antibodies or for therapeutic effect.

Recent reports on infliximab in Crohn's disease provided an interesting potential biomarker. Ten Hove et al. (42) found that infliximab induced apoptosis of lamina propria T lymphocytes in patients with Crohn's disease but did not influence expression of activation markers, homing receptors, memory cells, Fas expression, or Bax/Bcl-2 expression on peripheral blood T lymphocytes from these patients. In an extension study from this group, Van den Brande et al. (44) investigated why infliximab is clinically effective in

Crohn's disease, while a related TNF blocker, etanercept (Enbrel), is not; etanercept is a dimeric fusion protein consisting of the extracellular portion of the p75 TNF receptor linked to the Fc domains of human IgG1. They found the two drugs to be equally effective in in vitro bioassays of TNF neutralization; however, infliximab was able to induce apoptosis of lamina propria T lymphocytes, while etanercept was not. These data indicate that biomarkers of drug efficacy may need to utilize biopsies of inflamed tissue rather than peripheral blood lymphocytes, a not-surprising situation when one considers the compartmentalization of the immune response and the normally short range of action of cytokines.

Infliximab Immunogenicity
The immunogenicity problems with infliximab (17, 40) are not as well studied as with IFN-β, possibly because of the very different ways in which these CBTs are used. Antibodies to infliximab are measured using a double-antigen ELISA in which infliximab serves as the detection and capture reagent. All immunoglobulin isotypes and subclasses can be detected. Anti-infliximab antibodies can occur in as many as 30% of patients, despite the concurrent use of immunosuppressives such as methotrexate in these patients. Antibodies to infliximab are associated with a more rapid reduction in serum infliximab concentrations from postinfusion peak levels and an impaired clinical response. Also, delayed infusion reactions, characterized by myalgias, arthralgias, fever, rash, pruritus, dysphagia, urticaria, sore throat, headache, and facial, hand, or lip edema, may occur 3 to 12 days after infusion; these reactions are felt to be likely due to anti-infliximab antibodies (16).

SUMMARY
CBTs are a subclass of biologicals that have profound biological effects, many of which are poorly understood. These drugs are recent additions to therapy, and consequently, we are still relatively early in a growth curve about their optimal use. Monitoring of their effects is going to be important for many reasons. One of the major reasons is that these therapies tend to be highly immunogenic and the optimal approach for identification of antidrug antibodies and their potential to neutralize drug effects needs to be identified. Another reason is the high cost of these biologicals, which makes optimal use critical. Unfortunately, pharmaceutical companies which invest a great deal in the development of these drugs are reluctant to invest even more in working on optimal techniques for monitoring immunogenicity and drug effect. This situation leaves a vacuum after these drugs become available, which is filled only very slowly as problems with the therapies surface and the medical community attempts to solve them. For example, in 2005, 12 years after IFN-β came to the market in the United States for therapy of MS, there is still no standardized assay for anti-IFN-β antibodies and no clearly effective treatment options for the many patients who have high titers of NAbs with no therapeutic effect (26, 29, 30). It is hoped that robust assays for therapeutic efficacy and for immunogenicity will be developed more effectively in the future after the launch of other CBTs.

Introduction

RUSSELL H. TOMAR

44

The contemporary practice of anatomic pathology is intertwined with and unthinkable without the contributions of immunohistochemistry. Since our last edition, more antigens have been shown to add value to the diagnosis, prognosis, and treatment processes associated with more tissues and more diseases. The techniques have been refined and increasingly standardized; the instrument continues to improve; the interpretations are more precise and sophisticated.

Major enhancements are on the immediate horizon. The instrumentation not only to perform immunohistochemical assays but also to evaluate histopathological slides in general is becoming more automated, which has shortened turnaround times. Enhancements in the technology will increase the utilization and value of the assays discussed in this section. The increased understanding and application of molecular methods will undoubtedly alter the practice not only of pathology but also of many other subspecialty areas, including surgery, gynecology, oncology, hematology, and gastroenterology.

Section G provides an overview of present practice and insights into the future of immunohistology and immunopathology measurements. The chapter by Roche et al. reviews general immunohistochemistry principles. Setty et al. then discuss the use of molecular biology methods on tissues. The chapter by Shidham and Kajdacsy-Balla covers the diagnostic and prognostic applications of immunohistochemistry. Finally, Collins et al. discuss immunofluorescence methods for the diagnosis of renal and skin diseases.

Immunohistochemistry: Principles and Advances

PATRICK C. ROCHE, ERIC D. HSI, AND BOURKE L. FIRFER

45

Immunohistochemistry (IHC) has become indispensable for detection, classification, and management of neoplasms in the daily practice of surgical pathology and increasingly so in cytopathology. Automation and the increasing availability of primary and secondary antibodies have augmented this revolution. In addition, tissue may now be examined for nucleic acid components, thereby enhancing diagnostic sensitivity and specificity.

The implementation of the Food and Drug Administration (FDA) ruling on the classification of immunohistochemical reagents and kits (1) is a significant occurrence that is familiar to many who deal with IHC and other areas such as flow cytometry. This ruling has led to the classification of the majority of immunohistochemical reagents as "analyte-specific reagents" (32, 33) and as class I medical devices, exempting them from premarket notification. This is permitted because IHC staining results are incorporated into the surgical pathology report as one part of the entire diagnostic evaluation. The IHC results are not stand-alone results. A few immunostains such as estrogen receptor (ER) and progesterone receptor are considered class II devices. These immunostains have no routine morphologic correlates but do have substantial and accepted scientific validation. Class III devices include immunostains that are not considered part of the surgical pathology diagnostic process and may result in a stand-alone report to a physician. Such tests require premarket notification and specific FDA approval. An example is the FDA-approved HercepTest for determination of Her2 protein overexpression as an indication for trastuzumab (Herceptin) therapy.

The FDA ruling essentially permits IHC laboratories to continue operating as they have been. Manufacturers must now label the antibody reagents they sell for diagnostic use (but for which they have not sought FDA clearance) as analyte-specific reagents. The manufacturers have the responsibility of following "good manufacturing practices" to ensure that antibodies are of consistent high quality and have the specificity that is claimed. However, all surgical pathology reports that incorporate IHC results are required to contain a statement indicating that the individual laboratory (not the manufacturer of the reagent) has the ultimate responsibility for ensuring the quality of the immunostaining (31). Thus, the laboratory director has the responsibility to utilize high-quality immunostains and to document their performance.

The intention of this chapter is to present current, practical methods that are applicable for performance of quality immunostains in the modern automated IHC laboratory. A review of the many different staining systems available today is beyond the scope of this chapter, although some are specifically mentioned by way of example.

SPECIMEN PROCESSING FOR PARAFFIN SECTION IHC

The importance of tissue fixation for the outcome of immunohistochemical staining is commonly recognized but cannot be overemphasized. In most pathology laboratories, neutrally buffered formalin is the routine fixative of choice. It is relatively inexpensive, easy to prepare, and produces excellent morphological preservation without shrinkage artifacts. The exact mechanism by which formaldehyde fixes tissues is not fully known but does involve cross-linking of reactive sites within and between protein molecules via hydroxymethylene bridges (41). Calcium ions have also been implicated in cross-link formation (20). The cross-links are believed to be responsible for masking antibody-binding epitopes and to be a major cause of lack of sensitivity in paraffin section IHC. Other fixatives (such as alcohol) that are considered less damaging to tissue antigenicity have been promoted as substitutes for formalin (4), but there has been little movement away from neutrally buffered formalin as the routine fixative in the daily practice of pathology. Instead, there have been increasing research and development focused on antigen recovery in formalin-fixed tissues in order to improve immunohistochemical staining.

In spite of its inherent detrimental effects on antigenicity and IHC, a proper and consistent protocol for fixation with neutrally buffered formalin is imperative for high-quality IHC. Formaldehyde is commercially available as a concentrated (37 to 40%) solution, and 10% neutrally buffered formalin is made by 1:10 dilution of the concentrate with phosphate-buffered saline (PBS; 50 mM phosphate, 0.9% NaCl [pH 7.2 to 7.4]), resulting in a final formaldehyde concentration of 3.7 to 4.0%. Ideally, tissue samples that are approximately 1.0 by 1.0 by 0.3 cm are placed in a cassette and immersed in 20 times the volume of freshly prepared formalin buffer for a minimum of 12 h and a maximum of 24 h. In practice, larger pieces are usually processed, but the tissue should not be forced into the cassette, and the smaller the size, the better

and more thorough the fixation. If the specimens cannot be processed into paraffin blocks after 24 h of fixation in formalin, they should be transferred into 70% ethanol for holding until the tissue can be put on the processor. Prolonged exposure to formalin results in excessive cross-link formation and increasing loss of antigenicity (2, 3, 10). After they are properly fixed and embedded in a paraffin block, tissue specimens appear to retain antigenicity for decades (25).

Paraffin tissue sections for IHC are usually cut at a thickness of 4 to 6 μm. In order to retain sections on the glass microscope slide throughout the staining process, it is necessary to use slides that have been specially treated to increase their adhesive properties. Erie Scientific Company (Portsmouth, N.H.) produces slides that are treated with aminoalkyl silane and known as SuperFrost Plus. These slides are also generically referred to as charged or silanized slides and adhere to tissue sections through a combination of electrostatic and hydrophobic interactions. Although not used as commonly, glass slides treated with poly-L-lysine to increase their adhesive properties are another option. Storage of cut sections on microscope slides for use in IHC is still a subject of debate. At issue is the reported loss of reactivity of certain antigens, including p53 and Her2, when cut sections have been stored at room temperature. This phenomenon may be more pronounced when tissue is fixed in alcohol-supplemented formalin (14). For some laboratories, positive control sections or sections for research studies must be cut in advance and stored for subsequent use. If for practical reasons this is the case, sections should not be heated or melted down but just allowed to air dry on the slides. They should be stored in a closed slide box in a cool location or at 4°C if possible. Immediately prior to staining, slides can be placed in a 60°C oven for 60 min to melt excess paraffin and promote stronger adherence to the slides. Sections are then deparaffinized, hydrated through graded ethanols, and blocked for endogenous peroxidase.

SPECIMEN PROCESSING FOR FROZEN-SECTION IHC

Optimal preservation of cellular antigens and tissue morphology occurs if tissue is frozen rapidly, in a relatively cryoprotected fashion, and ice crystal formation is prevented. Properly snap-frozen tissue can also be used for molecular genetic studies and for mRNA extraction and analysis. Since all fresh tissue should be considered infectious, it should be handled with gloves in a biological hood with universal precautions. Specimens for freezing should first be trimmed of excess adipose and connective tissue and then divided with a scalpel or scissors into pieces that are no larger than 1.5 cm^2 in surface area and 0.5 cm in thickness. Prior to freezing, tissue specimens can be collected and transported in 4°C balanced salt solution or tissue culture medium such as minimal essential medium or RPMI 1640. Specimens in such liquid media must be handled and transported at 4°C to slow autolysis of the tissue and should be delivered to the laboratory for freezing within 1 h of surgical excision.

In preparation for freezing and storage, prepare all containers and slides (i.e., imprints) as needed with patient name, identification number, date, and tissue source. A 24-by-24-mm disposable base mold (Allegiance Healthcare Corporation, McGaw Park, Ill.) can be used for actual tissue freezing, and PolyCons (4-cm diameter by 1.5-cm height; Madan Plastics, Inc., Cranford, N.J.) can be used for storage of frozen specimens. Rapid freezing is accomplished by immersion of the specimen in an isopentane (2-methylbutane) bath that has been precooled with either liquid nitrogen (−135 to −140°C) or dry ice (−30°C). Alternatively (and more conveniently), a refrigerated (lowest temperature, −52°C) quick-freezing tissue bath (Histobath; Shandon, Inc., Pittsburgh, Pa.) containing isopentane can be used and is designed for constant operation.

Prior to freezing, blot the tissue on a fresh absorbent towel (do not use gauze) to remove excessive liquid medium. Dispense a small amount of Tissue-Tek optimal cutting temperature (OCT) compound (Sakura Finetek U.S.A., Inc., Torrance, Calif.) into the bottom of a disposable base mold, place the tissue in the OCT layer, and then cover the entire specimen with OCT compound until the base mold's lower chamber has been completely filled. Grasp the edge of the base mold with a surgical clamp or forceps, and slowly submerge the base mold into precooled isopentane until it is completely immersed. Allow to freeze for 20 to 30 s and remove from the isopentane bath, then pop the frozen OCT compound-tissue block out of the base mold by using a twisting action at the ends of the base mold. Excess freezing compound can be trimmed away with a scalpel or single-edged razor blade. The frozen OCT compound-tissue block can then be placed into a labeled PolyCon for storage in a −70 to −80°C ultracold freezer until sectioned.

Cut frozen sections on a cryostat at a thickness of 4 to 5 μm and place on appropriately labeled charged (silanized) slides. Dry the sections in a 37°C oven for 15 min and then place in 4°C high-performance liquid chromatography-grade acetone (in a refrigerator or cooler) for 10 min. Remove slides from the acetone and fan dry for 10 min. If immunostaining is not to be performed immediately, the dried sections can be placed in a storage box and kept at room temperature in an electronic desiccator for up to 7 days. If longer storage of sections is required, the slides should be tightly wrapped in aluminum foil and stored at −70 to −80°C. When ready for staining, slides that have been stored in the freezer must be allowed to come to room temperature BEFORE they are unwrapped. Equilibration to room temperature prior to unwrapping prevents condensation from accumulating or freezing on the section, either of which can compromise morphology and immunoreactivity.

Immediately before immunostaining, sections are fixed in a freshly prepared 1% paraformaldehyde–PBS solution for 10 min. This fixative solution is prepared from a stock 10% solution of paraformaldehyde. Proper preparation of the 10% paraformaldehyde solution is critical and should be performed as detailed in Table 1.

A 1% paraformaldehyde solution is made by dilution of the 10% stock with PBS. All sections for immunostaining, EXCEPT those that are to be stained for κ and λ light chains, are fixed for 10 min at room temperature in the 1% paraformaldehyde solution. Slides are then rinsed in several changes of tap water and placed in a Tris-buffered saline solution for 5 min. Sections that are to be immunostained for κ and λ light chains are fixed a second time in 4°C acetone for 5 min, air dried with a fan for 10 min, and hydrated for 1.5 min in PBS. Sections are then fixed in 1% paraformaldehyde for **1 min**, rinsed in tap water, and placed in Tris-buffered saline for 5 min. The shorter fixation time for slides destined to be immunostained for κ and λ light chains is necessary for optimal detection of cell surface-associated immunoglobin. Both manual and automated IHC can be performed with frozen sections, but the buffers that are used must contain only a minimal amount (0.025%) of nonionic detergent (e.g., Tween 20) in order to maintain nuclear and cellular detail.

TABLE 1 Protocol for preparation of 10% paraformaldehyde stock solution[a]

1. Weigh out 100 g of paraformaldehyde powder into a 2-liter beaker.
2. Add 800 ml of distilled water to the beaker.
3. Place the beaker on a hot plate or stirrer. Slowly heat to 58°C (about 30 min), stirring constantly. Heat for 15 min at 58°C. DO NOT OVERHEAT.
4. Add **2 to 5 drops of 5N NaOH.** The solution will clear. Let cool for 30 min.
5. Pour the solution into a graduated cylinder. Add distilled water to 1 liter. Mix by inversion three times.
6. Filter the solution into a dark reagent bottle. This solution is good for 1 month at room temperature.

[a] This entire procedure should be done in a fume hood.

HEAT-INDUCED EPITOPE AND ANTIGEN RETRIEVAL TECHNIQUES

The most significant advance in the field of IHC in the past decade is perhaps the development and refinement of heat-induced epitope retrieval, also referred to as antigen retrieval. In the first application of antigen retrieval to tissue sections in 1991, Shi et al. (30) showed that the sensitivity of immunohistochemical staining could be increased by high-temperature heating of sections in a heavy-metal solution by using a microwave. Since that initial report, a variety of different retrieval solutions and sources have been used to enhance the immunoreactivity of formalin-fixed paraffin sections. Excellent reviews and reports have been published on this subject in the past 5 years (7, 11, 18, 27, 28, 35), and readers are referred to these for comprehensive discussions regarding the different permutations of this important technique.

Analogous to formaldehyde fixation, the mechanism for heat-induced antigen retrieval is also not completely established. A high temperature (100°C) is necessary for epitope unmasking and reportedly may work by disrupting of protein-protein cross-links (30, 34, 42) and/or cross-links involving calcium ions (20), increasing tissue permeability, and unfolding or refolding protein antigens (6, 19). The source of heating does not appear to be critical as successful results have been obtained with microwave ovens, water baths, autoclaves, pressure cookers, and vegetable steamers (35). What does appear to be important is the maximum temperature achieved and the length of time sections are exposed to that temperature. In general, exposure of sections to 100°C for a minimum of 20 min is recommended and will produce adequate immunohistochemical staining for most antibodies. Surprisingly, this treatment does not significantly change tissue morphology but can cause a decrease in the intensity of hematoxylin staining of nuclei (18). A protocol for heat-induced antigen retrieval using a vegetable steamer is presented in Table 2.

A variety of antigen retrieval solutions have been used successfully, and include citrate buffer at pH 3 to 6, Tris-HCl at pH 8 to 10 (with or without urea), and EDTA solutions at pH 8 to 9 (21, 27-29). For most antibodies, the staining intensity changes little over a pH range of 2 to 10, and therefore, 10 mM citrate buffer, pH 6.0, or 100 mM Tris-HCl, pH 8, is commonly used. In our experience, antigen retrieval in 1 mM EDTA, pH 8.0, produces superior staining of most nuclear antigens, including ER, progesterone receptor, p53, MIB-1, TdT, MLH-1, MSH-2, and MSH-6. Others have reported similar findings for a variety of cytoplasmic antigens (23). However, EDTA solutions also tend to cause increased cytoplasmic background staining in some tissues, especially liver, kidney, and adrenal cortex, presumably due to retrieved endogenous biotin (5). This increased staining can be eliminated by a biotin blocking step.

EVALUATION OF PRIMARY ANTIBODIES

Frequently, different antibodies from several different sources are available for use against a particular antigen, and selection of a particular antibody clone should be an informed choice. Often there are assessments in the literature that can provide guidance in this decision. As an example, comparison of different antibodies against p53 in fixed tissues has demonstrated differences in reactivities that impact the prognostic significance of p53 expression in breast cancer (12), with the pAb1801 and DO7 antibodies reported to be more effective than others tested. A comprehensive review of differences in reactivities of antibody clones with particular antigens is beyond the scope of this chapter. However, it is critical that the user be familiar with the recent literature regarding specific antibodies in order to avoid, or at least be informed of, potential problems specific to an individual clone.

Most antibodies used in a clinical IHC laboratory are commercially available and have well-characterized specificities. For analyte-specific reagents, it is assumed that good manufacturing practices have been followed and that the antibody will likely perform as advertised. Usually, prior peer-reviewed literature also exists and can be used to acquire a realistic review of the performance of the antibody in a particular diagnostic setting. This information will provide the user with a good foundation from which to start antibody dilutions and antigen retrieval methods. The manufacturer's technical service representatives can also be contacted for this information, but details on diagnostic utility will not be available. Many vendors now offer their analyte-specific reagent antibodies as prediluted reagents optimized for immunohistochemical staining. The use of prediluted reagents is becoming a common practice and can limit the flexibility when the stain is being established in a particular laboratory. One concern related to the antibody is that it may be diluted so that it works on optimally fixed tissues in the manufacturer's own immunostaining system but it may be too diluted for cases in which suboptimally processed tissue is evaluated or a less-sensitive detection system is used. Whenever possible, undiluted primary antibody is preferable.

The immunohistochemist should also note whether the antibody is polyclonal versus monoclonal and pay attention to the species and isotype of the primary antibody. Polyclonal antibodies have high-affinity clones within them, allowing for substantial dilution (often greater than 1:1,000), but also can have problems with increased background, requiring extra blocking steps. Knowing the species and isotype will prevent problems in which an inappropriate suboptimal secondary antibody is used. An example in which the isotype makes a difference is the LeuM1 clone (anti-CD15), an immunoglobulin M mouse monoclonal antibody that has been shown to have superior performance when anti-immunoglobulin M is used as the secondary antibody.

TABLE 2 Protocol for steam heat-induced antigen retrieval

1. Sections are mounted on charged slides, deparaffinized, hydrated through graded alcohols, and blocked for endogenous peroxidase activity.
2. Ten to fifteen minutes prior to the completion of step 1, the lower chamber of a Black & Decker Handy Steamer Plus is filled with 1,000 ml of distilled water. A reagent reservoir containing 200 ml of 10 mM sodium citrate, pH 6.0, or 1 mM EDTA, pH 8.0, is placed in the upper chamber of the steamer, and the timer is turned to the maximum time setting.
3. After the distilled water in the lower chamber has reached a full boil (usually 10 to 15 min), carefully open the steamer cover by holding it with both hands, rotating it clockwise one-quarter turn and draining, and then pulling back slowly away from the steamer.
4. Place the slides into the hot antigen retrieval solution and cover the steam chamber.
5. Steam slides for 30 min without opening the steamer cover. Time the steaming period with an independent lab timer (the timer on the steamer is inaccurate).
6. Open the steamer cover by holding it with both hands, rotating it clockwise one-quarter turn and draining, and then pulling back slowly away from the steamer.
7. Remove the reagent reservoir containing slides and place the reservoir with slides on the counter. Allow to stand for 5 min.
8. Rinse slides in cool running tap water for 1 min or long enough to thoroughly rinse slides free of retrieval solution.
9. Begin the immunohistochemical staining protocol.

CONTROL TISSUES

Selection of appropriate positive and negative control tissues is critical for evaluation and validation of immunohistochemical stains. The lack of standardized tissue makes it important for the immunohistochemist to select specimens that reflect the intended diagnostic use of the antibody and also the different fixation and processing conditions that are used in the laboratory. This point is made abundantly clear to us on a daily basis. The Cleveland Clinic, Cleveland, Ohio, uses Hollande's fixative and Mayo Clinic, Rochester, Minn., uses B-5 fixative for lymphoid tissues and bone marrow core biopsy specimens due to the excellent detailing of nuclear morphology that these fixatives produce. However, problems can arise when IHC is attempted with these tissues and the staining protocols have been optimized for formalin-fixed tissues. Therefore, we must also procure positive and negative control tissues fixed in Hollande's or B-5, as well as tissue fixed in neutrally buffered formalin. Positive control tissue is easy to obtain if the target antigen is present in normal tissues but can be difficult to find when the antigen is expressed only in certain tumors. An example of the latter case is the anaplastic lymphoma kinase protein recognized by anaplastic lymphoma kinase 1. This antigen is present in only a percentage of anaplastic large-cell lymphomas (9), and therefore a laboratory may be obligated to obtain control material from other accredited laboratories or to use cell lines known to overexpress the protein in order to establish conditions for diagnostic use (detection of anaplastic large-cell lymphoma).

OPTIMIZING CONDITIONS FOR IMMUNOREACTIVITY

Numerous factors can be manipulated and adjusted in order to optimize immunohistochemical staining. Some of the most commonly altered variables are antibody dilution, duration of primary antibody incubation, choice and concentration of secondary reagent, antigen retrieval buffer, incubation temperature, choice of detection system, and addition of amplification steps. Checkerboard approaches to optimizing staining have been advocated in which each variable is systematically altered while all other variables remain constant (28). However, the large number of variables just listed would require an unrealistic number of slides to be stained and evaluated. Since most automated stainers have limited temperature control and have optimized secondary reagents and detection chemistries, the immunohistochemist is left

primarily with adjustments of antibody dilution, primary incubation time, and antigen retrieval method. These limitations dramatically decrease the number of test slides required to evaluate a particular antibody.

In general, the lower the dilution, the more intense the staining for a given incubation time. However, use of highly concentrated antibodies may result in a prozone effect, causing a decreased intensity of staining. Nonspecific staining can also become a problem at higher concentrations of primary antibody. Longer incubation times (1 h to overnight) may permit greater dilutions of primary antibodies. However, since some automated stainers operate in a batch mode, the adjustments that can be made to incubation times may be limited (<30 min). If prolonged incubations are required, they are best performed "off-line."

As discussed previously, the most significant advance in IHC in the last 10 years is the development of heat-induced antigen retrieval (27, 30). Antigen retrieval enables antibodies that might previously have performed only in frozen tissues to be reactive in fixed tissues and has greatly expanded the number of antibodies that can now be applied to paraffin-embedded tissue (8). The increase in sensitivity afforded by antigen retrieval also can result in cost savings for the laboratory since higher dilutions of primary antibody may be used and more tests per vial can be performed with this technique than with previous methods. Most antibodies demonstrate an increase in staining intensity when antigen retrieval is used. However, some antibodies may perform better in acidic citrate-based buffers and many perform better in alkaline EDTA-based buffers (21). Further, some antibodies such as Epstein-Barr Virus latent membrane protein 1 and CD21 perform best with the use of enzyme digestion as the method of antigen retrieval. There appears to be no way to predict the behavior of a particular antibody, and conditions must be determined empirically. Several studies have looked at a fairly broad range of antibodies and can serve as a guide to the immunohistochemist (6, 8, 21, 40).

Increased sensitivity for detecting antigens can also be associated with increased detection of false-positive signals due to nonspecific staining. In particular, endogenous biotin or biotin-binding activity can be retrieved, causing false-positive granular cytoplasmic reactions (5). An example was the erroneous report of inhibin staining in hepatocellular carcinomas that was subsequently demonstrated to be due to endogenous biotin (13, 17). Biotin or biotin-binding activity can be eliminated by a blocking step consisting of the application of free avidin after that of primary antibody followed

by the application of free biotin (5, 42). Blocking kits are available from several commercial vendors, including Dako Corporation (Carpenteria, Calif.) and Vector Laboratories (Burlingame, Calif.). Other potential causes of false-positive staining include endogenous peroxidase activity in horseradish peroxidase-based systems and endogenous phosphatase in alkaline phosphatase-based systems. Both activities can be minimized by blocking steps with hydrogen peroxide and levamisole, respectively (16, 22).

DETECTION SYSTEMS

Numerous methods are presently available for detecting bound primary antibodies. Most are enzyme-based techniques using either horseradish peroxidase or alkaline phosphatase, but peroxidase methods appear to be favored for most automated immunostainers in clinical laboratories. Examples include the peroxidase-antiperoxidase (PAP) method, the enzyme-labeled streptavidin-biotin (LSAB) technique, and the avidin-biotin complex (ABC) method. These are three-layer techniques involving a primary antibody, an appropriately specific secondary antibody, and the enzyme-containing tertiary reagent. In the case of the PAP method, the secondary antibody is unlabeled and added in excess so that it binds both the primary antibody and the soluble enzyme-antibody (PAP) complex that comprises the third layer. The antibody species in the PAP complex must therefore be the same as the primary antibody. For the LSAB and ABC techniques, the secondary antibody is covalently conjugated with biotin (biotinylated) and must recognize and bind only the primary antibody. The third layer of LSAB or ABC then binds tightly to the biotin.

The long-established indirect method uses secondary antibodies directly conjugated with peroxidase or alkaline phosphatase to bind primary antibody. This two-step method is simple and quick but also considerably less sensitive than the three-step detection systems described above. More recently, secondary antibodies conjugated to a dextran polymer backbone containing a large number of enzyme molecules (~100) have become commercially available (EnVision Systems; Dako Corporation). This new generation of secondary antibody conjugates permit two-step techniques that have sensitivities approaching those of the three-layer methods (26). The system is biotin free and therefore does not display nonspecific staining associated with biotin-binding proteins or endogenous biotin.

Newer catalyzed signal amplification or catalyzed reporter deposition techniques generate extreme sensitivity to which most users are not accustomed (15). Typically, these are five-step, peroxidase-based procedures that involve (i) application of primary antibody, (ii) application of a biotinylated secondary antibody, (iii) application of ABC-peroxidase, (iv) application of biotinyl tyramide and hydrogen peroxide (H_2O_2), and (v) application of peroxidase-labeled streptavidin. In the presence of the free radicals generated by ABC-peroxidase and H_2O_2, the biotinyl tyramide is activated and covalently attaches to locally available free amino groups. The reaction essentially results in a biotin "lawn" in the vicinity of the antigen and primary antibody. Peroxidase-labeled streptavidin binds to the numerous attached biotin molecules, and the slide is then routinely developed with chromogen and H_2O_2. A drawback to this methodology relative to other techniques is the additional time required for multiple incubation steps and the higher level of nonspecific staining that may accompany the dramatic increase in sensitivity.

Chromogen selection is also important. Peroxidase systems generally use 3,3′-diaminobenzidine (DAB; brown) or 3-amino-9-ethylcarbazole (AEC; red) chromogens. For alkaline phosphatase systems, BCIP (5-bromo-4-chloro-3-indolylphosphate)-nitroblue tetrazolium may be used to yield a blue-purple product or fast red–naphthol AS-TR phosphate may be used to produce a red-pink product. Choice may be influenced by personal preference (red versus blue versus brown), contrast with the counterstain (hematoxylin versus methyl green), incubation time (peroxidase-DAB reacts faster, allowing for a shorter incubation time, than phosphatase-fast red), sensitivity, safety issues (DAB is a carcinogen), and technical issues (AEC is soluble in organic solvents and cannot be used with xylene-based permanent mounting medium). DAB is a reliable chromogen that produces crisp, well-localized reactions that are permanent. At Mayo Clinic, DAB is used for nuclear antigens in paraffin sections and for all antigens in frozen-section immunostains related to lymphoma phenotyping. AEC (red) has traditionally been the chromogen of choice at Mayo Clinic for membrane and cytoplasmic antigens in paraffin sections because of the excellent color contrast with a light hematoxylin counterstain. A drawback to the use of AEC, however, is the solubility of AEC in organic solvents and the requirement for aqueous mounting media.

Techniques for performing double and triple immunoenzyme staining on tissue specimens can also be useful for the simultaneous visualization of two or more different antigens in paraffin-embedded or frozen tissue. Two or more different chromogen substrates are used to detect multiple cellular epitopes present in a tissue specimen. This technique can be particularly useful in applications involving quantitative analysis, for example, comparing the ratio of two cell populations in tissues (39), determining the spatial or morphometric relationships of disparate cell lines in tissue, and confirming the presence of coexpression of certain antigens within a single cell population. The details of the procedures and protocols for multiple immunoenzyme staining techniques are available from other sources (36–38).

SUMMARY

In this chapter, we have focused on present methods of IHC that are essential to the generation of quality stains. We have also discussed recent advances that have improved the sensitivity and versatility for paraffin section immunostains. Chief among these is the incorporation of antigen retrieval techniques into the daily practice of the IHC laboratory. With the increasing utilization of automated immunostainers, a moderate amount of standardization is now possible, both within an individual laboratory and among laboratories using similar reagents and equipment. Encouraging data are emerging from the United Kingdom's national external quality assessment scheme for immunocytochemistry (23). Using fixed breast tumors from multiple different laboratories, we found that in a central laboratory, routine procedures could be 90 to 100% efficient at demonstrating ER expression. The assay made use of the anti-ER 1D5 clone with pressure cooker antigen retrieval. Thus, variations in tissue processing at different laboratories did not seem to be a limiting factor in accurately determining ER statuses of breast cancers. In a companion study (24), there was good concordance among different laboratories when tumors expressed high or moderate levels of ER. Most participating laboratories used either the 1D5 or 6F11 clones with heat-induced antigen retrieval. However, there was still considerable interlaboratory variation for

tumors that expressed low levels of ER, with significant false-negative rates (30 to 60%). Ultimately, the performance of a particular immunostain is the responsibility of the medical director of the laboratory. National proficiency testing programs such as those conducted by the CAP can be helpful with issues related to standardization of staining procedures (including specimen processing, antigen retrieval, detection systems, and antibody selection) and interpretation.

Use of Molecular Biology Methods on Tissues

SUMAN SETTY, CHUNG-CHE (JEFF) CHANG,
AND ANDRÉ A. KAJDACSY-BALLA

46

Molecular diagnostic techniques have become important tools in pathology over the last decade, and giant strides are expected to continue to occur during the next few years as well. Tumors that appear to be very similar by light microscopy and immunohistochemistry analyses can still have very divergent outcomes and responses to therapy. The burgeoning field of molecular biomarkers has helped differentiate malignancies that need more aggressive or more specific therapy. Pathology has finally arrived at a point where the first tumor-specific molecular therapeutic targets have been identified. This chapter does not cover the details of most of these methods, but it will provide an overview of several examples of molecular biology applications in this rapidly advancing field.

Not all present biomarkers can be detected in tissues that are routinely available in pathology laboratories. There is an ongoing effort to adapt techniques that work well with fresh, unfixed tissues to specimens such as formalin-fixed paraffin-embedded needle biopsy material and cytology smear material. Fluorescent in situ hybridization (FISH) is an example of a test that has been successfully used in the clinical laboratory.

Today, most leukemias and lymphomas are characterized by specific chromosomal translocations or chromosomal lesions (Table 1). Molecular methodologies such as Southern blotting, PCR, FISH, reverse transcription PCR (RT-PCR) including real-time PCR, and molecular arrays have been applied to detect genetic lesions and to aid in the detection, determination of prognoses, and classification of malignancies. FISH and RT-PCR are particularly good for the detection of chromosomal lesions with widely dispersed breakpoints within large introns (3). For example, t(2;5) and t(9;22) translocations of chromosomes are found in anaplastic large-cell lymphoma and chronic myelogenous leukemia, respectively.

Additionally, molecular diagnostic techniques facilitate the detection and determination of prognoses of solid tumors. For example, detection of the t(X;18) translocation facilitates the diagnosis of synovial sarcoma. FISH for *HER-2/neu* gene amplification in breast carcinoma facilitates therapeutic decision making. In recent times, the thrust has been towards detecting markers of genetic susceptibility function by detecting polymorphisms associated with disease predisposition. For example, genetic polymorphism in the cytochrome P-450 gene CYP1A can explain higher-than-average individual ability to metabolize procarcinogens in cigarette smoke, leading to a greater risk of carcinoma.

About a quarter of patients with mammary carcinoma have up-regulated expression of the HER-2/neu gene and protein (20). Semiquantitation by immunohistochemistry detects a large percentage of these cases. However, a small fraction of the results of protein studies fall into the equivocal category and require in situ hybridization (ISH) studies to detect amplification when present. ISH assays can be performed on archival paraffin-embedded tissues (17, 23). ISH is a morphologic approach to genetic testing in which a fluorochrome (FISH)- or chromogen (chromogenic ISH [CISH])-tagged DNA probe is hybridized either to a metaphase or interphase preparation of chromosomes released from cells or to a tissue section. A fluorescent microscopic signal is obtained when the probe selectively attaches to the gene-specific complementary DNA. A second probe labeled with a different color attaches to the chromosome 17 centromere. The presence of only two signals for *HER-2/neu* per cell is indicative of an unamplified state. The presence of more than two signals argues for amplification. A control probe for chromosome 17 is used to rule out aneuploidy in the tumor by determining the ratio of the *HER-2/neu* to the chromosome 17 signals. The use of various fluorophores or chromogens on the same section facilitates the reading of the slides. For example, in breast cancer, two signals for chromosome 17 and five signals for *HER-2/neu* in the same cell are interpreted to indicate *HER-2/neu* amplification.

Additionally, ISH assays can detect deletions, amplifications, or duplications of chromosomal loci. ISH studies can also detect disease recurrence in cytological material and body fluids. For example, the Vysis Urovision test detects aneuploidy for chromosomes 3, 7, and 17 in urine specimens as an adjunct to detection of cytologic atypia that occurs in bladder cancer.

The CISH method using type-specific primers or pools of high-risk-associated and low-risk-associated primers for human papillomavirus (HPV) detects intracellular virus. CISH is commonly performed on residual material from liquid-based cervical Papanicolaou test material.

HPV-associated carcinomas of the head and neck, lung, and cervix have different mechanisms associated with carcinogenesis, but they may have a common feature, the presence of HPV DNA integrated into the host cell genome. The resulting up-regulation of viral E6 and E7 proteins leads to immortalization of the cells and resulting HPV-associated dysplasia or cancer (14). Detection of HPV in precursor

TABLE 1 Correlation of genetic lesions and immunohistochemical (IHC) markers

Type of lymphoma	Genetic lesion(s)	IHC marker(s)[a]	Reliability of IHC marker(s)
Mucous-associated lymphoid tissue lymphoma	t(1;14) (*BCL10/IGH*), t(11;18) (*API2/MALT1*)	BCL-10	Variable
Mantle cell lymphoma	t(11;14) (*BCL1/IGH*)	Cyclin D1 (Bcl-1)	Variable
Follicular lymphoma	t(14;18) (*BCL2/IGH*)	Bcl-2	Excellent
Burkitt's lymphoma	t(8;14) (c-*MYC/IGH*), variants	CD10$^+$ phenotype, MIB1 100%, Bcl-2$^-$ phenotype	Excellent
Anaplastic large-cell lymphoma	t(2;5) (*ALK/NPM*), variants	ALK (cytoplasmic and nuclear), ALK (only cytoplasmic)	Excellent

[a]ALK, anaplastic lymphoma kinase; MIB1, approaching 100% of neoplastic cells with nuclear graining of MIB1 (a polycation marker).

lesions is a screening tool for bringing women with a predisposition for cervical carcinoma to attention. The screening of cervical cytology (Papanicolaou smear) has led to early detection and treatment of squamous lesions (21). One of the clinical algorithms calls for DNA testing for the high-risk HPV types that are associated with a higher-than-average likelihood of development of carcinoma. The "gold standard" is the PCR-based assay using consensus-degenerate MY09-MY11 or GP5+-GP6+ primers followed by restriction digestion for typing of the HPV (19). The ISH method provides the pathologist with a visual tool to complete a cytological interpretation. A nonvisual method which uses RNA-DNA hybridization is commercially available (Digene Corp., Gaithersburg, Md.).

Molecular techniques are used for detecting the presence of and quantitating the sequences found in organisms responsible for predisposition to disease. They may also be used for predicting drug responses (pharmacogenomics), detecting carrier states and the presence of genetic conditions, tumor typing, determining prognoses, detecting tumors, and assessing tumor responses to drugs. PCR may be used for detection of *Mycobacterium tuberculosis* in tissues and quantitation of target molecules such as human immunodeficiency virus and hepatitis C virus DNA.

Ligase chain reaction and similar techniques are presently used for the detection of microorganisms in tissues by labeling the oligonucleotides with organism-specific sequences. This process can also be used for detection and quantitation of the expression of specific genes in tissues.

OTHER EXAMPLES OF MOLECULAR TESTING FOR HISTOLOGIC DIAGNOSIS

Detection of polymorphic genomic DNA with differences in restriction fragment lengths is the basis of the tests used by forensic laboratories and those used for the study of disease-causing mutations. This method may also be used for the identification of the tissue of origin of "floaters" in surgical pathology blocks. Floaters are small fragments of tissue that accidentally float from one specimen to another during gross tissue sectioning, processing, and slide preparation. Sometimes it becomes impossible to distinguish a floater from tissue that really belongs to the patient in question. Comparison of the patterns of DNA digestion with a panel of restriction enzymes reveals a distinctive pattern for the tissue in question. It is possible to determine whether the tissue in question belongs to the patient or to a different patient being studied in the same histology batch.

Mutation Analysis
