# Fluid and electrolyte therapy

Anthony Delaney and Simon Finfer

The management of patients' fluid and electrolyte status requires an understanding of body fluid compartments as well as an understanding of water and electrolyte metabolism. These principles will be considered along with the commonly encountered fluid and electrolyte disturbances. Recent evidence for the use of fluid therapy in a number of common clinical scenarios will also be presented.

## FLUID COMPARTMENTS (TABLE 85.1, FIGURE 85.1)

### TOTAL BODY WATER

In humans, water contributes approximately 60% of body weight, with organs varying in water content (Table 85.2). The variation of the percentage of total body weight as water, between individuals, is largely governed by the amount of adipose tissue. The average water content as a percentage of total body weight is 60% for males and 50% for females. Total body water as a percentage of total body weight decreases with age, due to a progressive loss of muscle mass, causing bone and connective tissue to assume a greater percentage of total body weight<sup>1-3</sup> (Table 85.3).

Total body water is commonly divided into two volumes, the extracellular fluid (ECF) volume and the intracellular fluid (ICF) volume.<sup>2</sup> Sodium balance regulates the ECF volume, whereas water balance regulates the ICF volume. Sodium excretion is normally regulated by various hormonal and physical ECF volume sensors, whereas water balance is normally regulated by hypothalamic osmolar sensors.<sup>4</sup>

### EXTRACELLULAR FLUID

ECF is defined as all body water external to the cell, and is commonly subdivided into plasma and interstitial fluid volumes. The ECF is normally 40% of total body water and 25% of total body weight. With acute or chronic illness, ICF volume is reduced, and ECF volume is increased and may even exceed the ICF volume. The ECF volume can be divided into the plasma volume, the extracellular fluid volume, and the interstitial volume.

### INTRACELLULAR FLUID

ICF is defined as all the body water within cells and, unlike the ECF compartment, is an inhomogeneous, multicompartmental entity, with different pH and ionic composition depending upon the organ or tissue being considered. The ICF volume is often determined by inference from the difference in measurements of the total body water and ECF spaces. This estimation suffers from the inaccuracies inherent in both ECF and total body water measurements. In general, the ICF is considered to be 60% of total body water and 35% of total body weight.

### TRANSCELLULAR FLUID

Fluids in this compartment have a common characteristic of being formed by transport activity of cells. The fluid is extracellular in nature and will be considered as part of the interstitial volume. It may vary from 1 to 10 l, with larger volumes occurring in diseased states (e.g. bowel obstruction or cirrhosis with ascites), and is formed at the expense of the remaining interstitial and plasma volumes.

### WATER METABOLISM

Water balance is maintained by altering the intake and excretion of water. Intake is controlled by thirst, whereas excretion is controlled by the renal action of antidiuretic hormone (ADH). In health, plasma osmolalities of about 280 mOsm/kg suppress plasma ADH to concentrations low enough to permit maximum urinary dilution.<sup>5</sup> Above this value, an increase in ECF tonicity of about 1–2% or a decrease in total body water of 1–2 l, causes the posterior pituitary to release ADH, which acts upon the distal nephron to increase water reabsorption. Maximum plasma ADH concentrations are reached at an osmolality of 295 mOsm/kg.<sup>5</sup> The osmotic stimulation also changes thirst sensation and, in the conscious ambulant individual, initiates water repletion (drinking), which is more important in preventing dehydration than ADH secretion and action. Thus, in health, the upper limit of the body osmolality (and therefore serum sodium) is determined by the osmotic threshold for thirst, whereas the lower limit is determined by the osmotic threshold for ADH release.<sup>6</sup>

**Table 85.1** Body fluid compartments

Fluid compartment	Volume (ml/kg)	% Total body weight
Plasma volume	45	4.5
Blood volume	75	7.5
Interstitial volume	200	20
Extracellular fluid volume	250	25
Intracellular fluid volume	350	35
Total body fluid volume	600	60

Increase in osmolality caused by permeant solutes (e.g. urea) does not stimulate ADH release. ADH may also be released in response to hypovolaemia and hypotension, via stimulation of low and high pressure baroreceptors. ADH release is extremely marked when more than 30% of the intravascular volume is lost. ADH may also be stimulated by pain and nausea, which are thought to act through the baroreceptor pathways.<sup>4</sup> ADH release may also be stimulated by a variety of pharmacological agents (Table 85.4). Renal response to ADH depends upon an intact distal nephron and collecting duct, and a hypertonic medullary interstitium. The capacity to conserve or excrete water also depends upon the osmolar load presented to the distal nephron.<sup>4</sup>

### WATER REQUIREMENTS

Water is needed to eliminate the daily solute load, and to replace daily insensible fluid loss (Table 85.5). With a

**Table 85.2** Water content of various tissues

Tissue	% Water content
Brain	84
Kidney	83
Skeletal muscle	76
Skin	72
Liver	68
Bone	22
Adipose tissue	10

normal daily excretion of 600 mOsm solute, maximal and minimal secretions of ADH will cause urine osmolality to vary from 1200 to 30 mOsm/kg respectively, and the urine output to vary from 500 ml to 20 l/day respectively. Skin and lung water losses vary, and may range from 500 ml to 8 l/day depending on physical activity, ambient temperature and humidity.

### DISORDERS OF OSMOLALITY

#### TONICITY

Osmolality is a measure of the number of osmol/kg water. The osmolality of the ECF is due largely to sodium salts. Clinical effects of hyperosmolality, due to excess solute, depend upon whether the solute distributes evenly throughout the total body water (e.g. permeant solutes of alcohol or urea) or distributes in the ECF only (e.g. impermeant solutes of mannitol or glucose). With impermeant solutes, hyperosmolality is associated with a shift of fluid from the ICF to the ECF compartment. Hyperosmolality due to increased impermeant solutes is known

**Figure 85.1** Body fluid compartments.

**Table 85.3** Water content as a percentage of total body weight

Age (years)	Males (%)	Females (%)
10–15	60	57
15–40	60	50
40–60	55	47
> 60	50	45

**Table 85.4** Drugs affecting ADH secretion

Stimulate	Inhibit
Nicotine	Ethanol
Narcotics	Narcotic antagonists
Vincristine	Phenytoin
Barbiturates	
Cyclophosphamide	
Chlorpropamide	
Clofibrate	
Carbamazepine	
Amitriptylline	

as hypertonicity. This condition may also be associated with a reduction in the serum sodium concentration (see below).

#### WATER EXCESS

In a 70-kg man, for every 1 l excess water, ECF increases by 400 ml and ICF increases by 600 ml, on average. The osmolality also decreases by 6–7 mOsm/kg and the serum sodium falls by 3.0–3.5 mmol/l.

#### WATER DEFICIENCY

In a 70-kg man, for every 1 l water loss, 600 ml is lost from the ICF and 400 ml from the ECF. The osmolality

also increases by 7–8 mOsm/kg and the serum sodium rises by 3.5–4.0 mmol/l.

### ELECTROLYTES

Chemical compounds in solution may either:

- Remain intact (i.e. undissociated), in which case they are called non-electrolytes (e.g. glucose, urea)
- Dissociate to form ions, in which case they are called electrolytes. Ions carry an electrical charge (e.g. Na<sup>+</sup>, Cl<sup>-</sup>). Ions with a positive charge are attracted to a negative electrode or cathode, and hence are called 'cations'. Conversely, ions with a negative charge travel towards a positive electrode or anode and are called 'anions'. Each body water compartment contains electrolytes with different composition and concentration (Table 85.6)

### SODIUM

Sodium is the principal cation of the ECF and accounts for 86% of the ECF osmolality. In a 70-kg man, total body sodium content is 4000 mmol (58 mmol/kg) and is divided into a number of compartments (Table 85.7). ECF concentration of sodium varies between 134 and 146 mmol/l. The intracellular sodium concentration varies between different tissues, and ranges from 3 to 20 mmol/l.

The standard Western society dietary sodium intake is about 150 mmol/day, but the daily intake of sodium varies widely, with urinary losses ranging from < 1 to > 240 mmol/day.<sup>7</sup> Sodium balance is influenced by renal hormonal and ECF physical characteristics. The complete renal adjustment to an altered sodium load usually requires 3–4 days before balance is restored.

#### HYPONATRAEMIA

Hyponatraemia is defined as a serum sodium less than 135 mmol/l and may be classified as isotonic, hypertonic or hypotonic, depending upon the measured serum osmolality (Table 85.8).

**Table 85.5** Daily fluid balance (for a 70-kg man at rest in a temperate climate)

	Input (ml)			Output (ml)	
	Seen	Unseen		Seen	Unseen
Drink	1000	–	Urine	1000	–
Food	–	650	Skin	–	500
Water of oxidation	–	350	Lungs	–	400
			Faeces	–	100
Total	1000	1000	Total	1000	1000

**Table 85.6** Electrolyte composition of body fluid compartments

Electrolyte	ICF (mmol/l)	ECF (mmol/l)	
		Plasma	Interstitial
Sodium	10	140	145
Potassium	155	3.7	3.8
Chloride	3	102	115
Bicarbonate	10	28	30
Calcium (ionized)	< 0.01	1.2	1.2
Magnesium	10	0.8	0.8
Phosphate	105	1.1	1.0

**Table 85.7** The sodium compartments in a 70-kg man

	Total (mmol)	(mmol/kg)
Total body sodium	4000	58
Non-exchangeable bone sodium	1200	17
Exchangeable sodium	2800	40
Intracellular sodium	250	3
Extracellular sodium	2400	35
Exchangeable bone sodium	150	2

**Table 85.8** Common causes of hyponatraemia

<b>1. Spurious result</b>
Isotonic
Hyperlipidaemia
Hyperproteinaemia
Hypertonic
Hyperglycaemia
Mannitol, glycerol, glycine or sorbitol excess
<b>2. Water retention</b>
Renal failure
Hepatic failure
Cardiac failure
Syndrome of inappropriate ADH secretion
Drugs
Psychogenic polydipsia
<b>3. Water retention and salt depletion</b>
Postoperative, post trauma or patients with excess fluid losses given inappropriate fluid replacement
Adrenocortical failure
Diuretic excess

**Isotonic hyponatraemia**

Plasma normally contains 93% water and 7% solids (5.5% proteins, 1% salts and 0.5% lipids). If the solid phase is elevated significantly (e.g. in hyperlipidaemia or hyperproteinaemia), any device which dilutes a specific amount of plasma for analysis will give falsely lower values for all measured compounds. This effect produces 'fictitious hyponatraemia' and is associated with a normal measured serum osmolality.<sup>8</sup> Measurement of plasma sodium by an ion-selective electrode is not affected by the volume of plasma 'solids' and therefore 'pseudohyponatraemia' will not occur with this method.<sup>8</sup>

**Hypertonic hyponatraemia**

In patients who have hypertonicity due to increased amounts of impermeant solutes (e.g. glucose, mannitol, glycerol or sorbitol), a shift of water from the ICF to the ECF occurs to provide osmotic equilibration, thus diluting the ECF sodium. Such resultant hyponatraemia is often associated with an increased measured osmolality. For example, in the presence of hyperglycaemia, for every 3 mmol/l rise in glucose, the serum sodium decreases by 1 mmol/l.<sup>9</sup>

**Hypotonic hyponatraemia**

Hyponatraemia is almost always caused by an excess of total body water, due to excessive hypotonic or water-generating i.v. fluids (e.g. 1.5% glycine, 0.45% saline or 5% glucose) or excessive ingestion of water, particularly in the presence of high circulating ADH concentrations. It may rarely be caused by loss of exchangeable sodium or potassium. In the latter circumstances, a loss of approximately 40 mmol of sodium or potassium, without a change in total body water content, is required to lower the serum sodium by 1 mmol/l. As hyponatraemia may be associated with an alteration in both total body water and total body sodium, the ECF may be increased (hypervolaemia), decreased (hypovolaemia) or exhibit no change (isovolaemia).<sup>5</sup>

In health, a fluid intake up to 15–20 l may be tolerated before water is retained and hyponatraemia occurs. In psychogenic polydipsia, if the water intake exceeds the renal capacity to form dilute urine, water retention and hyponatraemia will occur. With this disorder, the plasma osmolality exceeds urine osmolality. In circumstances where ADH is increased (e.g. hypovolaemia, hypotension, pain or nausea), or where renal response to ADH is altered (i.e. in renal, hepatic, pituitary, adrenal or thyroid failure), water retention occurs with lower intakes of fluid.

**Transurethral resection of prostate (TURP) syndrome**

**Clinical features** The TURP syndrome consists of hyponatraemia, cardiovascular disturbances (hypertension, hypotension, bradycardia), an altered state of consciousness (agitation, confusion, nausea, vomiting, myoclonic and generalised seizures) and, when using glycine solutions, transient visual disturbances of blurred vision, blindness and fixed dilated pupils, following TURP. It has also been described following endometrial ablation.<sup>10</sup> It may occur

within 15 minutes or be delayed for up to 24 hours postoperatively,<sup>11</sup> and is usually caused by an excess absorption of the irrigating fluid which contains 1.5% glycine with an osmolality of 200 mosm/kg. Hyponatraemic syndromes have also been described when irrigating solutions containing 3% mannitol or 3% sorbitol have been used. Symptomatology usually occurs when > 1 l of 1.5% glycine or > 2–3 l of 3% mannitol or sorbitol are absorbed.<sup>12</sup>

The excess absorption of irrigating fluid causes an increase in total body water (which is often associated with only a small decrease in plasma osmolality), hyponatraemia (as glycine, sorbitol or mannitol reduces the sodium component of ECF osmolality) and an increase in the osmolar gap.<sup>12,13</sup> When glycine is used, other features include hyperglycinaemia (up to 20 mmol/l; normal plasma glycine concentrations range from 0.15 to 0.3 mmol/l), hypserinaemia (as serine is a major metabolite of glycine), hyperammonaemia (following deamination of glycine and serine), metabolic acidosis and hypocalcaemia (due to the glycine metabolites glyoxylic acid and oxalate). Because glycine is an inhibitory neurotransmitter, and as it passes freely into the intracellular compartment when glycine solutions are used, hyperglycinaemia may be more important in the pathophysiology of this disorder than a reduction in body fluid osmolality and cerebral oedema.<sup>14</sup>

**Treatment** Treatment is largely supportive with the management of any reduction in plasma osmolality being based on the measured plasma osmolality and not the plasma sodium. If the measured osmolality is > 260 mOsm/kg and mild neurological abnormalities exist, and if the patient is haemodynamically stable with normal renal function, close observation and reassurance (e.g. the visual disturbances are reversible and will last for less than 24 hours) are usually all that is needed. If the patient is hypotensive and bradycardic with severe and unresolving neurological abnormalities, haemodialysis may be warranted. Hypertonic saline is only used if the measured osmolality is < 260 mOsm/kg and severe non-visual neurological abnormalities exist.<sup>15</sup>

#### Syndrome of inappropriate ADH secretion (SIADH)

This syndrome is a form of hyponatraemia in which there is an increased concentration of ADH inappropriate to any osmotic or volume stimuli that normally affect ADH secretion.<sup>16</sup> Diagnostic criteria and common causes are listed in Tables 85.9 and 85.10, respectively.

**Table 85.9** Criteria for the diagnosis of syndrome of inappropriate antidiuretic hormone (SIADH)

Hypotonic hyponatraemia
Urine osmolality greater than plasma osmolality
Urine sodium excretion greater than 20 mmol/l
Normal renal, hepatic, cardiac, pituitary, adrenal and thyroid function
Absence of hypotension, hypovolaemia, oedema and drugs affecting ADH secretion
Correction by water restriction

**Table 85.10** Aetiologies of syndrome of inappropriate antidiuretic hormone (SIADH)

Ectopic ADH production by tumours
Small cell bronchogenic carcinoma
Adenocarcinoma of the pancreas or duodenum
Leukaemia
Lymphoma
Thymoma
Central nervous system disorders
Cerebral trauma
Brain tumour (primary or secondary)
Meningitis or encephalitis
Brain abscess
Subarachnoid haemorrhage
Acute intermittent porphyria
Guillain–Barré syndrome
Systemic lupus erythematosus
Pulmonary diseases
Viral, fungal and bacterial pneumonias
Tuberculosis
Lung abscess

**Clinical features** While cerebral manifestations are usually absent when the sodium concentration exceeds 125 mmol/l, progressive symptomatology of headache, nausea, confusion, disorientation, coma and seizures are often observed when plasma sodium is below 120 mmol/l.<sup>17</sup>

**Treatment** Initial treatment should be fluid restriction with close monitoring of serum sodium. If serum sodium concentration is not increasing with fluid restriction, judicious administration of sodium as intravenous normal or hypertonic saline may be required. As the true duration and rapidity of onset of hyponatraemia is often unclear, the presence and severity of symptoms may be used as the trigger for active correction of hyponatraemia.<sup>17</sup> The evidence base available to guide therapy is limited and there is consequently no consensus on the optimum rate at which to correct the serum sodium concentration. The major concern is to avoid neurological damage from untreated seizures or cerebral oedema and from myelolysis.<sup>17</sup> In the absence of good evidence, recommended rates at which to increase the sodium concentration vary from 0.5 to 2 mmol/l per hour. Unless the treating clinician feels that more rapid correction is indicated, it seems prudent to correct the serum sodium concentration at a slower rather than a faster rate.

#### Cerebral salt wasting

Cerebral salt wasting (CSW) is a syndrome occurring in patients with a cerebral lesion and an excess renal loss of sodium and chloride.<sup>18</sup> The exact aetiology of the syndrome remains unclear. Although hyponatraemia is not necessary for the diagnosis, the syndrome is commonly associated with hyponatraemia.<sup>19</sup> The diagnosis of CSW is suspected in patients with a cerebral lesion, such as

subarachnoid haemorrhage, traumatic brain injury or a cerebral tumour, when there is an elevated urine output, with elevated urinary sodium in the absence of a physiological cause for increased sodium excretion.<sup>19</sup> The syndrome can be differentiated from the SIADH, as patients with CSW will have evidence of ECF depletion (e.g. negative fluid balance, tachycardia, increased haematocrit, increased urea, low central venous pressure) as opposed to the SIADH where ECF volume will be normal or slightly expanded.<sup>20</sup> Treatment of patients involves exclusion of other causes of hyponatraemia and increased urine output, replacement of sodium and fluid losses, and possibly fludrocortisone.<sup>21</sup>

### Hypertonic saline

Hypertonic saline, most commonly as 3% saline, is used as a therapy for patients with symptomatic hyponatraemia. Due to the osmolarity (1000 mosm/l) of 3% saline, it must be given through a central line, and care must be taken to avoid the known complications of its use. Complications reported with hypertonic saline therapy include congestive cardiac failure and central pontine and extrapontine myelinolysis (osmotic demyelination syndrome).<sup>22,23</sup> Careful haemodynamic and electrolyte monitoring throughout saline administration is required. There is still no uniform agreement that osmotic demyelination is produced by a rapid correction of hyponatraemia.

While hypertonic saline has been proposed as a therapy for raised intracranial pressure in a number of clinical settings,<sup>24</sup> its use remains controversial.<sup>25</sup> In a recent methodologically sound (adequate allocation concealment, blinded and using intention to treat analysis) randomised clinical trial, which included 229 patients with severe traumatic brain injury, resuscitation with 250 ml of 7.5% saline was not associated with improved mortality or functional outcomes compared to Hartmann's solution.<sup>26</sup>

### Vasopressin receptor antagonists

V<sub>2</sub> receptor antagonists, such as lixivaptan, tolvaptan and OPC-31260, have recently been developed. These agents come from a novel class of non-peptide agents that bind to V<sub>2</sub> receptors in the distal tubule of the kidney and prevent vasopressin-mediated aquaporin mobilisation, and thus promote an aquaresis.<sup>27</sup> These agents have been trialled as therapeutic options for the treatment of hyponatraemia in a number of clinical settings including hyponatraemia associated with cardiac failure, cirrhosis and SIADH.<sup>27,28</sup> At present the role of V<sub>2</sub> receptor antagonists in the management of hyponatraemia in the critically ill remains uncertain.

### HYPERNATRAEMIA

Hypernatraemia, defined as a serum sodium greater than 145 mmol/l, is always associated with hyperosmolality and may be caused by excessive administration of sodium salts (bicarbonate or chloride), water depletion or excess sodium and loss of water (Table 85.11).

**Table 85.11** Causes of hypernatraemia

Water depletion
Extrarenal loss
Exposure
GIT losses (often with excess saline replacement)
Renal loss
Osmotic diuresis – urea, mannitol, glycosuria
Diabetes insipidus
Neurogenic
Post traumatic, fat embolism
Metastatic tumours, craniopharyngioma, pinealoma, cysts
Meningitis, encephalitis
Granulomas (TB, sarcoid)
Guillain–Barré syndrome
Idiopathic
Nephrogenic
Congenital
Hypercalcaemia, hypokalaemia
Lithium
Pyelonephritis
Medullary sponge kidney
Polycystic kidney
Post obstructive uropathy
Multiple myeloma, amyloid, sarcoid
Salt gain
Hypertonic, saline or sodium bicarbonate

Excessive ingestion of sodium salts is rare but intravenous infusion of large volumes of sodium-containing fluids is common in the management of hospitalised patients. Hypernatraemia often occurs in the recovery phase of acute illness when spontaneous diuresis or diuretic therapy results in more rapid clearance of free water than sodium. Pure water depletion is uncommon, unless water restriction is applied to a patient who is unconscious or unable to obtain or ingest water, as the thirst response normally corrects water depletion. If it occurs, the serum sodium concentration increases, in association with loss of both ECF and ICF.

### Clinical features

Hypernatraemia usually produces symptoms if the serum sodium exceeds 155–160 mmol/l (i.e. osmolality > 330 mOsm/kg). The clinical features include increased temperature, restlessness, irritability, drowsiness, lethargy, confusion and coma.<sup>29</sup> Convulsions are uncommon. The diminished ECF volume may reduce cardiac output, thereby reducing renal perfusion, leading to pre-renal renal failure.

### Treatment

For pure water depletion, this consists of water administration. If i.v. fluid is required, 5% glucose or hypotonic saline solutions (0.45% saline) are often used, as sterile water infusion causes haemolysis. In rare cases, i.v. sterile water may be used, by administering through a central venous catheter.<sup>30</sup> Since rapid rehydration may give rise

to cerebral oedema, the change in serum sodium should be no greater than 0.5 mmol/l per hour.<sup>29</sup>

### POTASSIUM

Potassium is the principal intracellular cation and accordingly (along with its anion) fulfils the role of the ICF osmotic provider. It also plays a major role in the functioning of excitable tissues (e.g. muscle and nerve). As the cell membrane is 20-fold more permeable to potassium than sodium ions, potassium is largely responsible for the resting membrane potential. Potassium also influences carbohydrate metabolism and glycogen and protein synthesis.

Total body potassium is 45–50 mmol/kg in the male (3500 mmol/70 kg) and 35–40 mmol/kg (2500 mmol/65 kg) in the female; 95% of the total body potassium is exchangeable. As ECF potassium ranges from 3.1 to 4.2 mmol/l, the total ECF potassium ranges from 55 to 70 mmol. About 90% of the total body potassium is intracellular: 8% resides in bone, 2% in ECF water and 70% in skeletal muscle. With increasing age (and decreasing muscle mass), total body potassium decreases.

#### FACTORS AFFECTING POTASSIUM METABOLISM

The potassium content of cells is regulated by a cell wall pump-leak mechanism. Cellular uptake is by the  $\text{Na}^+/\text{K}^+$  pump which is driven by  $\text{Na}^+/\text{K}^+$  ATPase. Movement of potassium out of the cell is governed by passive forces (i.e. cell membrane permeability and chemical and electrical gradients of the potassium ion).

Acidosis promotes a shift of potassium from the ICF to the ECF, whereas alkalosis promotes the reverse shift. Hyperkalaemia stimulates insulin release, which promotes a shift of potassium from the ECF to the ICF, an effect independent of the movement of glucose.  $\beta_2$ -adrenergic agonists promote cellular uptake of potassium by a cyclic AMP-dependent activation of the  $\text{Na}^+/\text{K}^+$  pump, whereas  $\alpha$ -adrenergic agonists cause a shift of potassium from the ICF to the ECF.<sup>31</sup> Aldosterone increases the renal excretion of potassium; glucocorticoids are also kaliuretic, an effect which may be independent of the mineralocorticoid receptor.

Normally, mechanisms to reduce the ECF potassium concentration (by increasing renal excretion and shifting potassium from the ECF to the ICF) are very effective. However, mechanisms to retain potassium in the presence of potassium depletion are less efficient, particularly when compared to those of sodium conservation. Even with severe potassium depletion, urinary loss of potassium continues at a rate of 10–20 mmol/day. Metabolic alkalosis also enhances renal potassium loss, by encouraging distal nephron  $\text{Na}^+/\text{K}^+$ , rather than  $\text{Na}^+/\text{K}^+$  exchange.

#### HYPOKALAEMIA

Hypokalaemia is defined as a serum potassium of less than 3.5 mmol/l (or plasma potassium less than 3.0 mmol/l). It may be due to decreased oral intake, increased renal or

**Table 85.12** Causes of hypokalaemia

Inadequate dietary intake (urine $\text{K}^+ < 20$ mmol/l)
Abnormal body losses
Gastrointestinal (urine $\text{K}^+ < 20$ mmol/l)
Vomiting, nasogastric aspiration
Diarrhoea, fistula loss
Villous adenoma of the colon
Laxative abuse
Renal (urine $\text{K}^+ > 20$ mmol/l)
Conn's syndrome
Cushing's syndrome
Bartter's syndrome
Ectopic ACTH syndrome
Small cell carcinoma of the lung
Pancreatic carcinoma
Carcinoma of the thymus
Drugs
Diuretics
Corticosteroids
Carbapenems, amphotericin B, gentamicin
Cisplatin
Renal tubular acidosis
Magnesium deficiency
Compartmental shift
Alkalosis
Insulin
$\text{Na}^+/\text{K}^+$ ATPase stimulation
Sympathomimetic agents with $\beta_2$ effect
Methylxanthines
Barium poisoning
Hypothermia
Toluene intoxication
Hypokalaemic periodic paralysis
Delayed following blood transfusion (see Chapter 88)

gastrointestinal loss, or movement of potassium from the ECF to the ICF (Table 85.12).

#### Clinical features

These include weakness, hypotonicity, depression, constipation, ileus, ventilatory failure, ventricular tachycardias (characteristically torsades de pointes), atrial tachycardias, and even coma.<sup>32</sup> With prolonged and severe potassium deficiency, rhabdomyolysis and thirst and polyuria, due to the development of renal diabetes insipidus, may occur. The ECG changes are relatively non-specific, and include prolongation of the PR interval, T-wave inversion and prominent U-waves.

#### Treatment

Intravenous or oral potassium chloride will correct hypokalaemia, particularly if it is associated with metabolic alkalosis. If the patient has renal tubular acidosis and hypokalaemia, potassium acetate or citrate may be preferred to potassium chloride. Intravenous administration of potassium should normally not exceed 40 mmol/hour, and plasma potassium should be monitored at 1–4-hourly

**Table 85.13** Causes of hyperkalaemia

Collection abnormalities
Delay in separating RBC
Specimen haemolysis
Thrombocythemia
Excessive intake
Transiently following blood transfusion (see Chapter 88)
Exogenous (i.e. i.v. or oral KCl, massive blood transfusion)
Endogenous (i.e. tissue damage)
Burns, trauma
Rhabdomyolysis
Tumour lysis
Decrease in renal excretion
Drugs
Spironolactone, triamterine, amiloride
indomethacin
Captopril, enalapril
Renal failure
Addison's disease
Hyporeninaemic hypoaldosteronism
Compartmental shift
Acidosis
Insulin deficiency
Digoxin overdosage
Succinylcholine
Arginine hydrochloride
Hyperkalaemic periodic paralysis
Fluoride poisoning

intervals.<sup>33</sup> In patients with acute myocardial infarction and hypokalaemia, some recommend i.v. potassium to maintain the serum potassium at 4.0 mmol/l.<sup>34</sup> The plasma concentration should be monitored closely.

### HYPERKALAEMIA

Hyperkalaemia is defined as a serum potassium greater than 5.0 mmol/l or plasma potassium greater than 4.5 mmol/l. It may be artifactual (from sampling errors such as in vitro haemolysis); true hyperkalaemia may be due to excessive intake, severe tissue damage, decreased excretion or body fluid compartment shift (Table 85.13).

#### Clinical features

These include tingling, paraesthesia, weakness, flaccid paralysis, hypotension and bradycardia. The characteristic ECG effects include peaking of the T-waves, flattening of the P-wave, prolongation of the PR interval (until sinus arrest with nodal rhythm occurs), widening of the QRS complex, and the development of a deep S-wave. Finally, a sine wave ECG pattern which deteriorates to asystole may occur at serum potassium levels of 7 mmol/l or greater.

#### Treatment

This is directed at the underlying cause, and may include dialysis. Rapid management of life-threatening hyperkalaemia may be achieved by:<sup>35</sup>

- Calcium chloride 5–10 ml i.v. of 10% (3.4–6.8 mmol, which is used to reduce the cardiac effects of hyperkalaemia)
- Sodium bicarbonate, 50–100 mmol i.v.
- Glucose, 50 g i.v. with 20 units of soluble insulin
- Oral and rectal resonium A, 50 g
- Diuresis with furosemide, 40–80 mg i.v.

### CALCIUM

Almost all (99%) of the body calcium (30 mmol or 1000 g or 1.5% body weight) is present in bone. A small but significant quantity of ionised calcium exists in the ECF, and is important for many cellular activities, including secretion, neuromuscular impulse formation, contractile functions and clotting. Normal daily intake of calcium is 15–20 mmol, although only 40% is absorbed. The average daily urinary loss is 2.5–7.5 mmol. The total ECF calcium of 40 mmol (2.20–2.55 mmol/l) exists in three forms: 40% (1.0 mmol/l) is bound to protein (largely albumin), 47% is ionised (1.15 mmol/l) and 13% is complexed (0.3 mmol/l) with citrate, sulphate and phosphate. The ionised form is the physiologically important form, and may be acutely reduced in alkalosis which causes a greater amount of the serum calcium to be bound to protein.<sup>36</sup> While the serum ionised calcium can be measured, total serum calcium is usually measured, which can vary with the serum albumin concentrations. A correction factor can be used to offset the effect of serum albumin on serum calcium. This is 0.02 mmol/l for every 1 g/l increase in serum albumin (up to a value of 40 g/l), added to the measured calcium concentration. For example, if measured serum calcium is 1.82 mmol/l, and serum albumin is 25 g/l, corrected serum calcium =  $1.82 + [(40-25) \times 0.02]$  mmol/l = 2.12 mmol/l. It has been suggested that ionised calcium, where available, is a better indicator of calcium status in the critically ill.<sup>37</sup>

### HYPOCALCAEMIA

Common causes of hypocalcaemia include hypoparathyroidism and pseudohypoparathyroidism, septic shock, acute pancreatitis and rhabdomyolysis.<sup>38</sup> Clinical features of a reduced serum ionised calcium include tetany, cramps, mental changes and decrease in cardiac output. Symptomatic hypocalcaemia should be treated with i.v. calcium, either as calcium chloride or calcium gluconate. It should be remembered that 1 ml of calcium chloride has three times as much elemental calcium as 1 ml of calcium gluconate, and so the former is the preferred formulation in acute situations. Calcium should be administered via a central vein when practical due to the risk of tissue damage if extravasated.<sup>38</sup>

### HYPERCALCAEMIA

The clinical features of hypercalcaemia include nausea, vomiting, pancreatitis, polyuria, polydipsia, muscular weakness, mental disturbance and ectopic calcification. Some of the common causes of hypercalcaemia include

endocrine diseases such as hyperparathyroidism and thyrotoxicosis, renal failure, malignancy, thiazide diuretics and prolonged immobilisation.<sup>38</sup>

Severe hypercalcaemia (> 3.3 mmol/l) or more moderate symptomatic hypercalcaemia will require specific therapy. A cause for the elevated calcium concentration should be sought, and specific treatment may be warranted. General measures include restoration of intravascular volume with normal saline, followed by the use of a loop diuretic such as furosemide to promote calcium excretion. The use of bisphosphonates, such as pamidronate (30–90 mg by i.v. infusion), is recommended for severe cases.<sup>39</sup> Other therapies to consider include steroids, calcitonin and mithramycin.

## MAGNESIUM

Magnesium is primarily an intracellular ion which acts as a metallo-coenzyme in numerous phosphate transfer reactions. It has a critical role in the transfer, storage and utilisation of energy.

In humans, the total body magnesium content is 1000 mmol, and the plasma concentrations range from 0.70 to 0.95 mmol/l. The daily oral intake is 8–20 mmol (40% of which is absorbed) and the urinary loss, which is the major source of excretion of magnesium, varies from 2.5 to 8 mmol/day.<sup>40</sup>

### HYPOMAGNESAEMIA

Hypomagnesaemia is caused by decreased intake or increased loss (Table 85.14). Clinical features include

**Table 85.14** Causes of magnesium deficiency

Gastrointestinal disorders
Malabsorption syndromes
GIT fistulas
Short-bowel syndrome
Prolonged nasogastric suction
Diarrhoea
Pancreatitis
Parenteral nutrition
Alcoholism
Endocrine disorders
Hyperparathyroidism
Hyperthyroidism
Conn's syndrome
Diabetes mellitus
Hyperaldosteronism
Renal diseases
Renal tubular acidosis
Diuretic phase of acute tubular necrosis
Drugs
Aminoglycosides
Carbenicillin, ticarcillin
Amphotericin B
Diuretics
Cis-platinum
Cyclosporin

neurological signs of confusion, irritability, delirium tremors, convulsions and tachyarrhythmias. Hypomagnesaemia is often associated with resistant hypokalaemia and hypocalcaemia. Treatment consists of i.v. magnesium sulphate as a bolus of 10 mmol, administered over 5 minutes, followed by 20–60 mmol/day.

### HYPERMAGNESAEMIA

Hypermagnesaemia is often caused by excessive administration of magnesium salts or conventional doses of magnesium in the presence of renal failure. Clinical features include drowsiness, hyporeflexia and coma, vasodilatation and hypotension, and conduction defects of sinoatrial and atrioventricular nodal block and asystole may occur. Treatment is directed towards increasing excretion of the ion, which may require dialysis. Intravenous calcium chloride may be used for rapidly treating the cardiac conduction defects.<sup>40</sup>

### MAGNESIUM THERAPY

There are increasing reports of the use of magnesium as a therapy for a variety of conditions. A randomised control trial of over 10 000 women with pre-eclampsia demonstrated the efficacy of magnesium in the prevention of eclampsia,<sup>41</sup> and it is also a recommended treatment for established eclampsia. It has been used to treat atrial fibrillation, to achieve both rate control and reversion to sinus rhythm in a number of settings, including post cardiac surgery, and in the emergency department.<sup>42,43</sup> Magnesium, given either intravenously or nebulised, may be beneficial for patients with acute severe asthma.<sup>44,45</sup> There are also preliminary trials to suggest that magnesium may prevent delayed cerebral ischaemia due to vasospasm in patients with subarachnoid haemorrhage.<sup>46</sup>

## PHOSPHATE

While most of the body phosphate exists in bone, 15% is found in the soft tissues as ATP, red blood cell 2,3-DPG, and other cellular structural proteins, including phospholipids, nucleic acids and phosphoproteins. Phosphate also acts as a cellular and urinary buffer.<sup>40</sup>

### HYPOPHOSPHATAEMIA

Hypophosphataemia may be caused by a decreased intake, increased excretion or intracellular redistribution (Table 85.15). While hypophosphataemia may be

**Table 85.15** Causes of hypophosphataemia

Hyperparathyroidism
Vitamin D deficiency
Vitamin D resistant rickets
Renal tubular acidosis
Alkalosis
Parenteral nutrition
Alcoholism
Refeeding syndrome

symptom-free, clinical features have been described which include paraesthesia, muscle weakness, seizures, coma, rhabdomyolysis and cardiac failure. Hypophosphataemia may be a prominent feature of the refeeding syndrome when it may be accompanied by other electrolyte disturbances such as hypokalaemia and hypomagnesaemia. Treatment consists of close monitoring and replacement as oral or i.v. sodium or potassium phosphate, 50–100 mmol/24 hours.

### HYPERPHOSPHATAEMIA

Hyperphosphataemia is usually caused by an increased intake or decreased excretion (Table 85.16). Clinical features include ectopic calcification of nephrocalcinosis, nephrolithiasis and band keratopathy. Treatment may require haemodialysis; otherwise oral aluminium hydroxide and even hypertonic glucose solutions to shift ECF phosphate into the ICF can be used.

## FLUID AND ELECTROLYTE REPLACEMENT THERAPY

### GENERAL PRINCIPLES

In critical illness many of the body's normal homeostatic mechanisms are deranged and basic life-preserving senses such as hunger and thirst may be abolished by disease processes or by treatments such as the use of sedation. As a result, the survival of critically ill patients depends on the administration of appropriate volumes of fluids, and appropriate quantities of electrolytes and nutrition

**Table 85.16** Causes of hyperphosphataemia

Rhabdomyolysis
Renal failure (acute or chronic)
Vitamin D toxicity
Acidosis
Tumour lysis
Hypoparathyroidism
Pseudohypoparathyroidism
Diphosphonate therapy
Excess i.v. administration

by their medical and nursing attendants. Basal requirements for water, electrolytes and nutrients are discussed in Chapter 87. In addition to basal requirements, many critically ill patients have abnormal fluid and electrolyte losses that must be replaced; examples are discussed below.

### GASTROINTESTINAL LOSSES

The daily volumes and composition of gastrointestinal tract (GIT) secretions in mmol/l are shown in Table 85.17. Clinical effects of fluid loss from the GIT are largely determined by the volume and composition of the fluid, and therapy is usually directed at replacing the losses. Gastric fluid loss (e.g. from vomiting and nasogastric suction) results in water, sodium, hydrogen ion, potassium and chloride depletion. Hence, metabolic alkalosis, hypokalaemia, hypotension and dehydration develop if the saline and potassium chloride losses are not correctly replaced.

#### *Pancreatic and biliary fluid losses (e.g. pancreatic or biliary fistula)*

These may result in hyperchloraemic acidosis with hypokalaemia, hypotension and dehydration if the losses of bicarbonate, potassium and saline are not correctly replaced.

#### *Intestinal losses (e.g. fistula or ileostomy losses, diarrhoea and ileus)*

These result in hypokalaemia, hypotension and dehydration if the saline and potassium losses are not replaced.

### RESUSCITATION FLUIDS

Systemic hypotension is a common feature of acute critical illness and first-line treatment is usually the administration of intravenous resuscitation fluid. The fluids available to clinicians to maintain or expand intravascular volume are crystalloids, colloids and blood products; the properties of colloid solutions and blood products are discussed in Chapter 89.

Whether the choice of resuscitation fluid influences patients' outcomes has been the subject of long-running debate. The debate has been fuelled by the conflicting

**Table 85.17** Daily volume and electrolyte composition of GIT secretions

Electrolytes (mmol/l)	Vol (l)	H <sup>+</sup>	Na <sup>+</sup>	K <sup>+</sup>	Cl <sup>-</sup>	HCO <sub>3</sub> <sup>-</sup>
Saliva	0.5–1.0	0	30	20	10–35	0–15
Stomach	1.0–2.5	0–120	60	10	100–120	0
Bile	0.5	0	140	5–10	100	40–70
Pancreatic	0.75	0	140	5–10	70	40–70
Small and large gut	2.0–4.0	0	110	5–10	100	25

and inconclusive results of a number of meta-analyses.<sup>47-50</sup> At present, the published data do not provide unequivocal support for either side of the debate. The only adequately powered trial to date, the Saline versus Albumin Fluid Evaluation Study, found that saline and albumin produced comparable outcomes in a heterogeneous population of adult patients.<sup>51</sup> Whether specific fluids are beneficial or harmful in more highly selected subpopulations of critically ill patients is not yet clear. A number of investigator-initiated trials are currently underway and are expected to report their results in the next few years. These trials may provide clinicians with the data needed to make rational fluid choices.

# Metabolic response to injury and infection

Ian K S Tan

Injury and infection evoke in the host a hypermetabolic inflammatory response and a compensatory hypometabolic hypoimmune response. The magnitude of the response is proportional to the extent of injury. Additional components of illness, such as ischaemia and reperfusion or resuscitation, nutritional status, surgical procedures, transfusions, drugs and anaesthetic techniques, genetic polymorphisms and concurrent diseases, impact on the response. Some components of the metabolic response, or the failure to regulate the response, are destructive, and its modulation may improve patient survival.<sup>1</sup>

## MEDIATORS OF THE METABOLIC RESPONSE

Following directed adhesion to endothelium and migration into tissue, neutrophils undergo an oxidative burst, producing a large variety of free radicals (species with one or more unpaired electrons) and reactive oxygen species (ROS), overwhelming natural scavenging and antioxidant defences, such as superoxide dismutase and glutathione peroxidase. These free radicals and ROS directly damage cells. Proteases, arachidonic acid metabolites (leukotrienes, thromboxanes and prostaglandins) and adhesion molecules are produced, amplifying the inflammatory cascade. Inducible nitric oxide synthase is activated, and nitric oxide is produced. Tissue macrophages become primed and activated.

## CYTOKINES

Cytokines are soluble, non-antibody, regulatory proteins released from the activated immunocytes, and are responsible primarily for the inflammatory and counter-inflammatory response. Injury and infection cause cytokine release from activated leukocytes, endothelial cells and fibroblasts. T-helper type 1 (TH1) lymphocytes primarily impact cell-mediated immunity and secrete tumour necrosis factor- $\alpha$  (TNF- $\alpha$ ), interleukin-2 (IL-2) and interferon- $\gamma$  (IFN- $\gamma$ ), while TH2 lymphocytes impact antibody-mediated immunity and secrete IL-4 and IL-10. The TH1/TH2 cytokine profile determines the immunostimulatory/immunosuppressive balance. Cytokines generally exert their effects in a paracrine

fashion, but in severe injury and infection, they enter the circulation and act as hormones. The following are major cytokines involved in the response to stress:

- TNF- $\alpha$  is a necessary and sufficient proximal mediator. After endotoxin challenge, TNF- $\alpha$  concentrations peak before other mediators. TNF- $\alpha$  administration reproduces all features of septic shock, including hypermetabolism, fever, anorexia, hyperglycaemia, decreased lipogenesis, marked protein catabolism and lactic acidosis. TNF- $\alpha$  activates the hypothalamic–pituitary–adrenal (HPA) axis. Soluble TNF- $\alpha$  receptors, a natural antagonist to TNF- $\alpha$ , also increase; this may be a regulatory response which contributes to later immunosuppression.
- IL-1 $\beta$  (endogenous pyrogen) produces much the same metabolic effects as TNF- $\alpha$ , and the combined effect of the two cytokines is greater than the effect of either alone. IL-1 $\beta$  is a potent inducer of the HPA axis as well as central and peripheral noradrenergic neurons. IL-6 is the main mediator of the acute phase response. Similar to TNF- $\alpha$  and IL-1 $\beta$ , IL-6 levels correlate with severity of illness and outcome. IL-8 induces neutrophil adhesion, chemotaxis and enzyme release. IL-2 generation is decreased. Anti-inflammatory cytokine (IL-4, IL-10, transforming growth factor- $\beta$ ) and antagonist (IL-1 receptor antagonist) levels increase. IL-4 activates B lymphocytes.
- Colony-stimulating factors stimulate the proliferation of haemopoietic cells, superoxide and cytokine production by neutrophils and macrophages. Disproportionate monocytopoiesis over granulocytopoiesis occurs. Erythropoietin production is suppressed.
- IFN- $\gamma$  stimulates fibroproliferation, upregulates TNF receptors and induces TNF synthesis. IFN- $\gamma$  production is synergistically induced by IL-12 and IL-18. IFN- $\alpha/\beta$  secretion is induced in viral infections and is proinflammatory.
- High mobility group box 1 (HMGB1) is a late pro-inflammatory mediator. It induces the expression of adhesion molecules in endothelial cells, increases enterocyte permeability, and further release of pro-inflammatory cytokines from leukocytes.
- Counter-inflammatory cytokines accumulate at the site of injury. Prostaglandin E<sub>2</sub> inhibits further synthesis of inflammatory cytokines, and spermine inhibits

their release. Transforming growth factor- $\beta$  inhibits monocyte activation.

### NEUROENDOCRINE MEDIATORS

Cytokine release from the site of injury or infection triggers vagal afferent impulses to the dorsal vagal complex (DVC) in the medulla oblongata. Synaptic connections with the rostroventral medulla and locus ceruleus, and the hypothalamic nuclei, activate the sympathetic nervous system and the HPA axis respectively.<sup>2</sup> High circulating cytokine levels may also cross the blood–brain barrier, or affect neurons at circumventricular organs lacking a blood–brain barrier, such as the area postrema. In general, a biphasic response is observed following injury and infection: an initial neuroendocrine ‘storm’ followed by a decrease. The following are some neuroendocrine mediators involved in the response to stress:

- *Reflex vagal efferent nerves* secrete acetylcholine, which by binding to  $\alpha_7$  subunits of the nicotinic receptor, suppresses proinflammatory cytokine synthesis from immunocytes.
- *Reflex sympathetic efferents* increase catecholamine levels, causing tachycardia and calorogenesis with increased oxygen consumption. Blood flow redistribution occurs depending on tissue receptor balance. Glycogenolysis, gluconeogenesis and lipolysis are stimulated. Activation of  $\beta_2$ -adrenergic receptors decreases synthesis of proinflammatory cytokines and increases the synthesis of anti-inflammatory cytokines. However,  $\alpha_2$ -adrenoreceptor activation may increase TNF production.
- *HPA axis* activation results in high adrenocorticotropin hormone (ACTH) and cortisol levels, driving gluconeogenesis, proteolysis and lipolysis. Primarily by suppressing the nuclear factor (NF)- $\kappa$ B pathway, cortisol attenuates damage from excessive proinflammatory cytokine synthesis, while activating synthesis of anti-inflammatory IL-4 and IL-10. With prolonged critical illness, ACTH levels fall, but cortisol remains elevated with persistent loss of diurnal variation in secretion. Corticosteroid-binding globulin levels fall, and free cortisol levels may be increased. TNF decreases glucocorticoid response, and peripheral glucocorticoid resistance may vary between tissues.
- *Growth hormone* (GH) levels increase acutely with increased pulsatile frequency, but concomitant peripheral GH resistance occurs initially with low levels of GH-binding protein (GHBP) and insulin-like growth factor (IGF-1). Levels of the inversely regulated IGF-binding protein (IGFBP-1) increase, which correlates with mortality. Subsequently, loss of hypothalamic stimulation, as well as decreased ghrelin (a potent growth hormone secretagogue) levels, causes greatly reduced GH burst amplitudes, but peripheral GH sensitivity recovers.<sup>3</sup>
- *The thyroid axis* behaves in a similar fashion, with transient increases in thyrotropin (TSH) and thyroxine ( $T_4$ ) levels, and reduced conversion of  $T_4$  to tri-iodothyronine ( $T_3$ ). Chronically, reduced thyrotrophin-releasing hormone (TRH) secretion leads to low/normal levels and pulsatility in TSH, low  $T_4$  levels and further falls in  $T_3$  levels, termed the ‘sick euthyroid syndrome’.
- *Prolactin* (PRL) levels increase transiently, followed by reduced pulsatile amplitudes. As T-lymphocyte function is prolactin-dependent, this contributes to late loss of immune competence.
- *Luteinising hormone* (LH) levels increase transiently, followed by reduced pulsatile amplitudes. Low testosterone and high estradiol levels occur.<sup>4</sup> Dehydroepiandrosterone levels are low. Estrogens inhibit proinflammatory cytokine production.
- *$\alpha$ -Melanocyte stimulating hormone* ( $\alpha$ -MSH) levels increase, leading to immunosuppression via inhibition of the NF- $\kappa$ B pathway.
- *Insulin and glucagon* levels are increased but the insulin levels are inappropriately low for the level of hyperglycaemia. Insulin resistance is characterised by impaired glycogen synthesis. The increased glucagon:insulin ratio augments gluconeogenesis. Insulin has anti-inflammatory properties by inhibiting the NF- $\kappa$ B pathway, and prevents mitochondrial ultrastructural abnormalities, possibly by inhibiting hyperglycaemia-induced production of superoxide. Leptin levels increase acutely, then decrease.
- *Procalcitonin* levels increase and remain high, and its level correlates with severity of illness, so that procalcitonin has become a useful marker of systemic infection and a guide to therapy. Calcitonin levels, however, are variable and not necessarily elevated. Of the other members of the calcitonin superfamily, calcitonin gene-related peptide (CGRP) and adrenomedullin levels greatly increase; they are anti-inflammatory and contribute to vasodilatation.
- *The renin-angiotensin-aldosterone axis* is activated, causing fluid retention. Subsequently, aldosterone levels fall while renin remains elevated.
- *Arginine vasopressin* (AVP) levels increase initially, then return to normal or low levels despite persistent shock, in part due to depletion of stored hormone. Downregulation of  $V_1$  receptors (which mediate AVP’s vasoconstricting effect) occurs in sepsis.
- *Vasoactive intestinal peptide* secretion is induced, probably by nitric oxide, inhibiting production of proinflammatory cytokines and stimulating secretion of IL-10.

### THE METABOLIC RESPONSE

The metabolic response to injury and infection begins with the activation of receptors throughout the body by the above mediators. These receptors include toll-like receptors (TLR)-2 and TLR-4, and the receptor for advanced glycation end products (RAGE). Subsequent intracellular

activation of the NF- $\kappa$ B pathway leads to gene induction and production of mRNA for the synthesis of proinflammatory cytokines. Catecholamines can initiate rapid functional changes via protein phosphorylation, which does not require gene induction. Behavioural effects such as anorexia, possibly due to elevated leptin levels, also affect the metabolic response. The metabolic effects may be described at three levels.

### CELLULAR METABOLIC EVENTS

Intracellularly, heat shock protein (HSP) synthesis is induced. Many HSPs are also expressed constitutively. HSPs act as 'chaperones', assisting in the assembly, disassembly, stabilisation and internal transport of other intracellular proteins. HSPs facilitate translocation of the glucocorticoid-receptor complex from the cytosol to the nucleus, and inhibit NF- $\kappa$ B activity. HSPs have cellular protective roles in sepsis and ischaemia-reperfusion.<sup>5</sup>

Mitochondrial dysfunction limits cell metabolism and may be responsible for the ensuing multiorgan dysfunction of severe injury and infection. Electron transport chain complexes are inhibited by excessive nitric oxide and peroxynitrite generated during sepsis.<sup>6</sup> Additionally, poly (ADP-ribose) polymerase-1 (PARP-1) is activated, reducing cell nicotinamide adenine dinucleotide (NADH) content, a substrate for ATP generation. The reduced ATP production may have functional consequences, such as diaphragmatic dysfunction.<sup>7</sup> It has been hypothesised that this 'metabolic shutdown' is an adaptive response similar to hibernation.<sup>8</sup>

Apoptosis, or programmed cell death, may finally be induced when death receptors are engaged by their ligands, or by mitochondrial-mediated pathways.<sup>9</sup> Death receptors include Fas and TNF receptor type I (TNFRI), and this pathway activates caspase. The mitochondrial pathway, mediated in part by glycogen synthase kinase-3 $\beta$  activation, causes activation of caspase. Caspases 8 and 9 activate caspase 3, which commits the cell to death. TNF- $\alpha$ , IL-10, cortisol and nitric oxide all induce apoptosis. Apoptosis further augments immunosuppression. It is probable that bioenergetic failure and the apoptotic death of immune cells are the major causes of death in late sepsis.

### INTERMEDIARY METABOLISM

*Protein metabolism:* IL-1, TNF, related cytokines and hormonal changes trigger an extreme protein catabolism. Glutamine, alanine and other amino acids are mobilised from skeletal muscle and taken up by hepatocytes and gut mucosa. Glutamine depletion may occur. Increased ureagenesis and nitrogen loss occurs. Levels of branch chained amino acids (leucine, isoleucine, valine) fall with peripheral oxidation. The fraction of energy expenditure derived from glucose is reduced, while that derived from amino acid oxidation in the Krebs cycle is increased.

*Carbohydrate metabolism:* hyperglycaemia results from glycogenolysis, accelerated gluconeogenesis and peripheral

insulin resistance. Lactate production increases from peripheral tissue, areas of injury and the white cell mass, and serves as substrate for gluconeogenesis in hepatocytes. In the terminal phase of severe illness, hypoglycaemia may occur.

*Fat metabolism:* lipolysis is increased with increased turnover of triglycerides and fatty acids, and plasma free fatty acid levels are high. TNF, IL-1 and IL-6 decrease lipoprotein lipase activity, contributing to hypertriglyceridaemia. Both high- and low-density lipoprotein (HDL and LDL) cholesterol levels are low. Ketosis is suppressed, indicating that fat is not a major calorie source. Glycerol generated from lipolysis further contributes to gluconeogenesis. The action of cyclooxygenase and lipoxygenase on arachidonic acid (a tissue phospholipid) produces inflammatory leukotrienes, thromboxanes and prostaglandin E<sub>2</sub>.

*Electrolyte and micronutrient metabolism:* salt and water retention occurs, with hyponatraemia, masking the loss of lean tissue. Protein loss is accompanied by potassium, magnesium and phosphate loss. Serum hypocalcaemia with increased intracellular calcium commonly occurs. Zn redistributes to liver and bone marrow. Zn deficiency is associated with impaired IL-2 production and wound healing. Selenium levels are low and correlate with mortality. Selenium is required by glutathione peroxidases and thioredoxin reductases to prevent oxidative damage. Fe levels decrease.

### SYSTEMIC PROTEIN SYSTEM RESPONSES

The acute phase response is a systemic response to injury characterised by redirection of hepatic protein synthesis and haematological alterations. Production of proteins involved in defence is increased (protease inhibitors, fibrinogen, C-reactive protein, haptoglobin, complement C3), while synthesis of serum transport and binding molecules is reduced (albumin, transferrin). Serum levels of acute phase reactants such as C-reactive protein can be used for diagnostic, monitoring and prognostic purposes.

Complement cascade triggering produces the membrane attack complex, chemoattractants (C3a, C5a), vasoactive anaphylatoxins (C3a, C4a, C5a), opsonins (C3b), stimulation of neutrophil and monocyte oxidative burst (C3b) and neutrophil adherence to endothelium (C5a).

TNF- $\alpha$  induces the expression of tissue factor on leukocyte and endothelial cell surfaces, triggering the coagulation cascade. Depletion of endogenous anticoagulants such as antithrombin, protein C, and tissue factor pathway inhibitor (TFPI) occurs. In turn, activated coagulation factors amplify inflammation.

## FACTORS AFFECTING THE METABOLIC RESPONSE

### ENERGY BALANCE AND OXYGEN DELIVERY

Hypermetabolism increases oxygen demand and consumption. Capillary permeability increases, causing reduced intravascular filling, and inadequate oxygen delivery can

lead to anaerobic metabolism and inadequate production of high-energy phosphates. In adequately resuscitated patients, aerobic glycolysis with lactate production rather than anaerobic glycolysis is characteristic of the metabolic response to stress.<sup>10</sup> Subsequent cell swelling from injury and resuscitation activates phospholipase A<sub>2</sub>, augmenting the inflammatory cascade.<sup>11</sup>

### SURGICAL PROCEDURES AND ANAESTHETIC TECHNIQUES

Total afferent neuronal blockade (somatic and autonomic block) (e.g. by epidural anaesthesia), and minimally invasive surgery, both of which greatly attenuate the metabolic changes of surgical injury, have been associated with reduced morbidity.<sup>12,13</sup> Improved analgesia, avoidance of endotracheal intubation and maintenance of consciousness may also contribute to the effect.

### STARVATION AND NUTRITION

Starvation alone produces adaptive hypometabolism with the use of fat as the primary fuel, sparing protein. In contrast, injury and infection result in hypermetabolism with prominent protein catabolism. Starvation in combination with the metabolic changes of stress produces a hypoalbuminaemic malnourished state. Malnutrition clearly contributes to morbidity and mortality. However, current forms of nutrition do not adequately reduce protein catabolism or promote protein synthesis, so that a positive energy balance often results in fat and fluid gain instead.<sup>14</sup>

### DRUGS AND DISEASE

Adverse effects of steroids include increased infection rates and myopathy (particularly in conjunction with the use of neuromuscular blocking drugs). Commonly used intensive care unit (ICU) drugs such as the catecholamines, dopamine, corticosteroids, theophylline, calcium-channel blockers, antibiotics and blood transfusions all have immunomodulatory effects. Diseases such as diabetes will clearly impact on the metabolic response to stress. Apart from concurrent disease, the inciting organism may itself modulate its host response by affecting cytokine mediators, their production, secretion and elimination, or by interacting with their receptors.<sup>15</sup>

### GENETIC POLYMORPHISMS

From epidemiological studies, a large genetic influence on the outcome of sepsis can be found.<sup>16</sup> Unfortunately, studies on specific genetic polymorphisms involving mediators of the metabolic response have generally been underpowered, and the evidence is conflicting.

### SECONDARY INSULTS

Secondary insults, such as device-related sepsis, the use of bioincompatible membranes for renal support, mechanical

ventilator-induced lung injury, pain and hypothermia, will increase the severity and duration of the metabolic response.

### VALUE OF THE METABOLIC RESPONSE

The cytokines and neuroendocrine mediators reprioritise metabolic processes, increasing the supply of substrates to active tissues involved in defence against injury. Inflammation localises the area of injury. Cardiovascular changes divert blood flow to inflamed areas and vital organs, while salt and water retention maintains overall perfusion. Sympathectomised and adrenalectomised animals fare poorly when stressed. Etomidate, which blocks cortisol synthesis, was associated with increased mortality when used for ICU sedation.<sup>17</sup>

Disadvantages of the metabolic response include increased oxygen consumption and myocardial work, which is detrimental to patients with marginal cardiovascular reserves. The redistribution of blood flow away from the 'non-vital' gut organ may result in translocation of bacteria and endotoxin into the circulation. High catecholamine levels are arrhythmogenic to the compromised heart. Systemic inflammation can result in systemic tissue destruction. Hyperglycaemia is associated with an increased incidence of infection.

### MODULATING THE METABOLIC RESPONSE

Modulation of the metabolic response in order to accelerate recovery and improve morbidity and mortality is an expanding area of research. Large multicentre trials have failed to show consistent benefits with therapies targeted at specific cytokine components of the metabolic response to infection. This has led to the development of therapies providing non-specific suppression or elimination of circulating mediators, or monitoring the state of 'immunologic dissonance' in order to provide individualised therapy.

Antioxidants show promise in improving survival. The substitution of omega-3 fatty acids for omega-6 fatty acids in inflammatory mediators modulates the metabolic response. Clinically, enteral nutrition with eicosapentaenoic acid (EPA or fish oil),  $\gamma$ -linolenic acid (GLA or borage oil) and antioxidant vitamins<sup>18</sup> has been shown to reduce mortality. Selenium prevents excessive oxidative damage, but was not shown to reduce mortality when supplemented in pharmacological doses, and a larger trial is needed.<sup>19</sup> Ethyl pyruvate is another promising antioxidant able to directly neutralise peroxides and peroxy-nitrite non-enzymatically. Statins decrease the activation of the NF- $\kappa$ B pathway, and inhibit superoxide production. Experimentally, statins have been shown to prolong survival time in sepsis,<sup>20</sup> but randomised controlled trials in humans are required.<sup>21</sup>

Protein catabolism leading to loss of muscle has functional consequences such as respiratory muscle weakness. A 25% body weight loss in the presence of injury may be

fatal. Wound healing and multiple facets of host defence are impaired, increasing the risk of nosocomial infection. Parenteral glutamine supplementation has been reported to reduce mortality.<sup>22</sup> Of the anabolic agents (GH, IGF-1 and testosterone derivatives), GH has received the most attention in the setting of critical illness. GH increased mortality in a heterogeneous group of critically ill patients.<sup>23</sup> It is possible that patient selection, unmasking of glutamine deficiency and high GH doses (mean 0.1 mg/kg per day) resulted in the adverse outcome. Combined GH, IGF-1 and glutamine-supplemented parenteral nutrition has been shown to produce net protein gain.<sup>24</sup>

'Intensive insulin therapy' to attain a glucose of 4.4–6.1 mmol resulted in significant prevention of acute renal failure, and shortened time to weaning from mechanical ventilatory support.<sup>25</sup> The mortality benefit shown in a previous trial could not be corroborated. Frequent hypoglycaemia may accompany the technique and further studies are underway.

A meta-analysis of steroid usage in septic shock found that high-dose steroids given over a short time increased mortality, while lower doses of hydrocortisone for 5–7 days and subsequently tapered resulted in improvement in survival and shock reversal.<sup>26</sup> In the largest trial, the benefit was found only in patients who had a less than 9 µg/dl increase in cortisol after 250 µg tetracosactrin intravenously.<sup>27</sup> Given the difficulties in free cortisol kinetics and definition of 'relative adrenal insufficiency' in the critically ill, this finding requires external validation.

The extracellular fluid is the aqueous medium within which the mediators of the metabolic response function, so that blood purification may modulate the intensity of the metabolic response and hence influence outcome. A randomised trial of 425 ICU patients with acute renal failure to ultrafiltration doses of 20 ml/hour per kg, 35 ml/hour per kg and 45 ml/hour per kg by continuous veno-venous haemofiltration resulted in survival at 15 days after treatment discontinuation of 41%, 57% and 58% respectively.<sup>28</sup> Extension of the above approach leads to the inference that high volume haemofiltration (i.e. intensive plasma water exchange) may further improve survival.<sup>29</sup>

In an initial trial, activated protein C (APC) was found to reduce 28-day mortality in patients with severe sepsis. Longer term follow-up did not reveal an overall improvement in survival, although the study was not powered to detect this end-point.<sup>30</sup> In less severely ill patients, APC did not influence outcome, and increased the rates of serious bleeding.<sup>31</sup> APC is not indicated in paediatric severe sepsis.

The most logical approach is to monitor the host response so as to provide individualised therapy. Although IFN-γ did not reduce infection or mortality in burns patients,<sup>32</sup> it is hypothesised that monitoring HLA-DR expression may be used to identify immunosuppressed patients who may benefit most from IFN-γ.<sup>33</sup>

# Enteral and parenteral nutrition

Richard Leonard

It is standard practice to provide nutritional support to critically ill patients, in order to

- treat existing malnutrition
- minimise wasting of lean body mass

However, despite the universality of this practice, the evidence underlying it is often conflicting and of disappointingly poor quality.<sup>1</sup> The failings in the evidence seem to extend to some of the resulting debates, in which certainty appears inversely proportional to justification.<sup>2</sup> Inevitably, these difficulties have led many to seek clarity in meta-analysis; perhaps equally inevitably,<sup>3</sup> they have usually been disappointed. On so basic a question as the relative merits of enteral and parenteral routes of feeding, the two most recent meta-analyses have produced conflicting results.<sup>4,5</sup> Instead of choosing on which trials to base patient care, it seems the clinician must now decide which meta-analysis to believe.

The problem persists with the publication of numerous clinical practice guidelines,<sup>6–11</sup> which differ in important areas, although one at least has been used in a cluster randomised trial showing a 10% reduction in mortality that just failed to reach statistical significance in those intensive care units (ICUs) randomised to use the guideline – the ACCEPT study.<sup>6</sup> While such validation does not mean that each component of the ACCEPT guideline (Figure 87.1) is optimal, it does at least provide some support.

## NUTRITIONAL ASSESSMENT

Objective assessment of nutritional status is difficult in ICU, because disease processes confound methods used in the general population. Anthropometric measures such as triceps skin-fold thickness and mid-arm circumference may be obscured by oedema. Voluntary handgrip strength, a test of functional capacity, is impractical in unconscious patients. Laboratory measures, including transferrin, pre-albumin and albumin levels, lymphocyte counts and skin-prick test reactivity, are abnormal in critical illness. Clinical evaluation – the so-called Subjective Global Assessment – is better than objective measurement at predicting morbidity.<sup>12</sup> Historical features of

malnutrition include weight loss, poor diet, gastrointestinal symptoms, reduced functional capacity and a diagnosis associated with poor intake. Physical signs include loss of subcutaneous fat, muscle wasting, peripheral oedema and ascites.

While laboratory measures are of little value in assessing nutritional status in critically ill patients, intensivists are increasingly involved in preoperative assessment of patients undergoing major surgery. In these patients the serum albumin and operative site were closely associated with the risk of postoperative complications.<sup>13</sup> This raises the possibility that outcomes may be improved by treating preoperative malnutrition identified by a simple screening test.

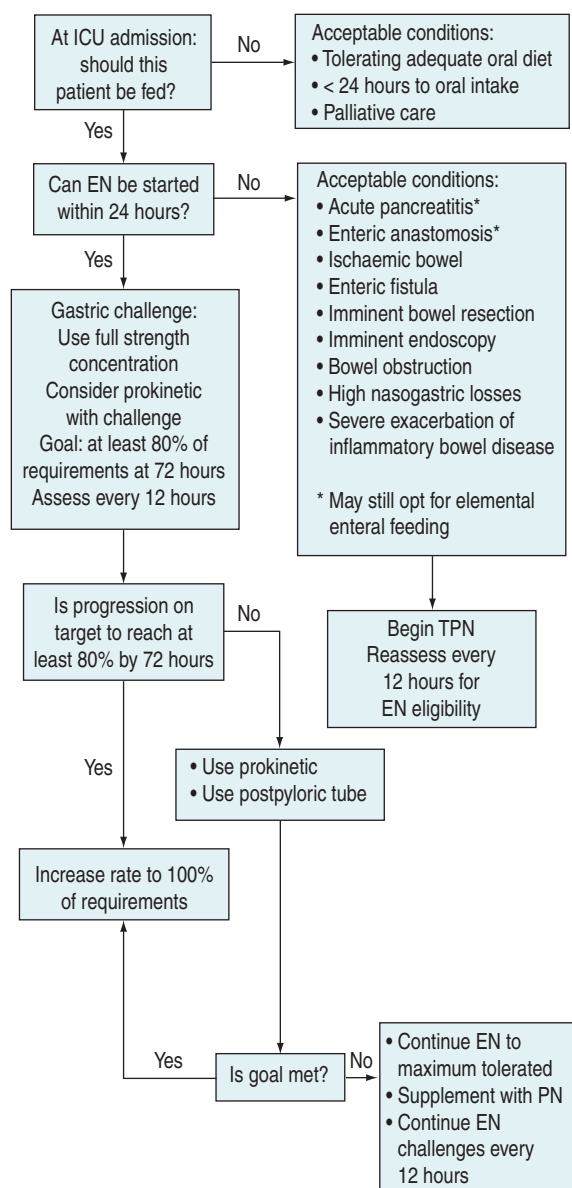

## PATIENT SELECTION AND TIMING OF SUPPORT

There are reasonable grounds to believe that it is better to provide nutritional support to critically ill patients than not to do so. This belief is based on the close association between malnutrition, negative nitrogen and calorie balance and poor outcome, and the inevitability of death if starvation continues for long enough. In otherwise healthy humans this takes several weeks to occur. There is also some direct evidence from small studies of parenteral nutrition in patients with severe head injuries<sup>14</sup> and of jejunal feeding in those operated on for severe pancreatitis,<sup>15</sup> in which the control groups received little or no nutritional support. Both studies showed decreased mortality in the groups receiving adequate nutrition.

Two questions arise from this, relating to the important problem of when nutritional support should start:

- How long is it safe to leave a critically ill patient without nutrition? In other words, which patients need to be fed artificially because they will be starved for too long, and which can safely wait until they are able to eat?
- If the patient will clearly exceed whatever period is deemed reasonable, is it better to begin feeding immediately? In other words, when should we start to feed?

Quite good evidence now supports the early institution of nutritional support, and the trend is both to tolerate

**Figure 87.1** Algorithm for nutritional support used in the ACCEPT trial.<sup>6</sup> EN, enteral nutrition, PN, parenteral nutrition.

much shorter periods without nutrition and to begin feeding more rapidly after initial resuscitation.

In 1997, recommendations from a conference sponsored by the US National Institutes of Health, the American Society for Parenteral and Enteral Nutrition and the American Society for Clinical Nutrition suggested that nutritional support be started in any critically ill patient unlikely to regain oral intake within 7–10 days.<sup>10</sup> The basis for this was that at a typical nitrogen loss of 20–40 g/day dangerous depletion of lean tissue may occur after 14 days of starvation. Others have suggested a

maximum acceptable delay of 7 days. A meta-analysis comparing early (first 48 hours after admission to ICU) with late enteral feeding revealed a reduction in infectious complications.<sup>16</sup> Two subsequent meta-analyses comparing early enteral feeding with no artificial nutritional support, and early parenteral feeding with delayed enteral feeding, both found a reduction in mortality with early support.<sup>17</sup> Finally, early institution of enteral feeding was an important component of the ACCEPT study guideline.<sup>6</sup> Patients in this study received nutritional support if they were thought unlikely to tolerate oral intake in the next 24 hours, and the goal was to start feeding within 24 hours of admission to ICU. The weight of evidence is presently in favour of this more aggressive approach.<sup>18</sup>

## NUTRITIONAL REQUIREMENTS OF THE CRITICALLY ILL

### ENERGY

Some muscle wasting and nitrogen loss are unavoidable in critical illness, despite adequate energy and protein provision.<sup>19</sup> This fact, coupled with the realisation that caloric requirements had previously been overestimated, has led to downward revision of intake, a process which may still be ongoing. In 1997, the American College of Chest Physicians (ACCP) published guidelines recommending a daily energy intake of 25 kcal/kg,<sup>9</sup> and this has remained the standard target energy intake for critically ill patients. More recently, concerns have been raised that this may be excessive. An observational study found lower mortality in those patients who received 9–18 kcal/kg/day than in those with higher and lower intakes.<sup>20</sup> However, meaningful benefits of hypocaloric feeding have yet to be demonstrated in prospective trials. It is, moreover, extremely important to realise that enterally fed patients frequently fail to achieve their target intake, and that significant underfeeding is certainly associated with worse outcomes.<sup>20–22</sup>

Attempts have also been made to tailor the energy provided to critically ill patients to their individual needs. Two methods are commonly used, indirect calorimetry and predictive equations.

Indirect calorimetry is the gold standard, and its use is becoming easier with the availability of devices designed for ICU patients. It permits measurement of the resting energy expenditure (REE). This value excludes the energy cost of physical activity, which increases later in the course of an ICU admission.<sup>23</sup> Calorimetry reveals deviations from values predicted by equations, such that two thirds of patients in one study were being either under- or overfed.<sup>24</sup> On the other hand, it could not be shown that outcomes are improved by the use of calorimetry.<sup>25</sup> Moreover, there are no clear data to relate measured REE to total energy expenditure in the individual patient. As a result, many units do not use calorimetry; in those that do, a target energy provision of  $1.3 \times$  measured REE is usual.<sup>22</sup>

There are a large number of equations claiming to predict basal metabolic rate (BMR) on the basis of weight, sex and age. The best known is the Harris-Benedict equation, which dates back more than 80 years. Schofield's equations were derived anew in the 1980s.<sup>26</sup> Correction factors exist to convert predictions of BMR into estimated energy expenditure by adjusting for such variables as diagnosis, pyrexia and activity. In the past these correction factors have been excessive and may have contributed to overfeeding; a more conservative approach is now advocated. The recommendations of the British Association for Parenteral and Enteral Nutrition are:<sup>27</sup>

1. Determine BMR from Schofield equations (Table 87.1)
2. Adjust BMR for stress (Table 87.2)
3. Add a combined factor for activity and diet-induced thermogenesis
  - bed-bound, immobile +10%
  - bed-bound, mobile/sitting +20%
  - mobile around ward +25%

Despite the popularity of measurements or estimates of energy expenditure it is not clear that their routine use improves outcome. Many clinicians dispense with both and simply aim to deliver the ACCP's recommended target of 25 kcal/kg per day.

**Table 87.1** Basal metabolic rate in kcal/day by age and gender<sup>26</sup>

Age	Female	Male
15–18	13.3 W + 690	17.6 W + 656
18–30	14.8 W + 485	15.0 W + 690
30–60	8.1 W + 842	11.4 W + 870
> 60	9.0 W + 656	11.7 W + 585

W = weight in kg.

**Table 87.2** Stress adjustment in the calculation of basal metabolic rate<sup>27</sup>

Partial starvation (>10% weight loss)	Subtract 0–15%
Mild infection, inflammatory bowel disease, postoperative	Add 0–13%
Moderate infection, multiple long bone fractures	Add 10–30%
Severe sepsis, multiple trauma (ventilated)	Add 25–50%
Burns 10–90%	Add 10–70%

## PROTEIN

Assessment of nitrogen balance by measuring urinary urea nitrogen is too variable to be useful in estimating protein requirements in ICU.<sup>28</sup> As there is an upper limit to the amount of dietary protein that can be used for synthesis,<sup>29</sup> there is no benefit from replacing nitrogen lost in excess of this. A daily nitrogen provision of 0.15–0.2 g/kg per day is therefore recommended for the ICU population; this is equivalent to 1–1.25 g protein/kg per day. Severely hypercatabolic individuals, such as those with major burns, are given up to 0.3 g nitrogen/kg per day, or nearly 2 g protein/kg per day.<sup>27</sup>

## MICRONUTRIENTS

Critical illness increases the requirements for vitamins A, E, K, thiamine (B<sub>1</sub>), B<sub>3</sub>, B<sub>6</sub>, vitamin C and pantothenic and folic acids.<sup>30</sup> Thiamine, folic acid and vitamin K are particularly vulnerable to deficiency during total parenteral nutrition (TPN). Renal replacement therapy can cause loss of water-soluble vitamins and trace elements. Deficiencies of selenium, zinc, manganese and copper have been described in critical illness, in addition to the more familiar iron-deficient state. Subclinical deficiencies in critically ill patients are thought to cause immune deficiency and reduced resistance to oxidative stress. Suggested requirements for micronutrients in critically ill patients vary between authors and depending on route of administration; the most comprehensive guidance<sup>30</sup> is reproduced in Tables 87.3 and 87.4. More recent but broadly similar recommendations for some compounds are also available.<sup>31</sup>

Commercial preparations of both enteral and parenteral feeding solutions contain standard amounts of micronutrients. Supplementation of intake of certain antioxidant vitamins and trace elements above these levels is discussed below.

## WATER AND ELECTROLYTES

Water and electrolyte requirements vary widely depending on the patient's condition; typical basal intakes are shown in Table 87.5.

## ROUTE OF NUTRITION

When possible patients should be fed enterally. The advantages over the parenteral route are:

- lower cost
- greater simplicity
- possibly fewer infective complications

These appear to be the only advantages of the enteral route. Despite the fervour with which some pursue the debate,<sup>2</sup> there is little basis for the widespread belief that the enteral route provides a clear benefit in terms

**Table 87.3** Vitamin requirements in critical illness<sup>30</sup>

Vitamin	Function	Dose
Vitamin A	Cell growth, night vision	10000–25000 IU
Vitamin D	Calcium metabolism	400–1000 IU
Vitamin E	Membrane antioxidant	400–1000 IU
β-Carotene*	Antioxidant	50 mg
Vitamin K	Activation of clotting factors	1.5 µg/kg per day
Thiamine (vitamin B <sub>1</sub> )	Oxidative decarboxylation	10 mg
Riboflavin (vitamin B <sub>2</sub> )	Oxidative phosphorylation	10 mg
Niacin (vitamin B <sub>3</sub> )	Part of NAD, redox reactions	200 mg
Pantothenic acid	Part of coenzyme A	100 mg
Biotin	Carboxylase activity	5 mg
Pyridoxine (vitamin B <sub>6</sub> )	Decarboxylase activity	20 mg
Folic acid	Haematopoiesis	2 mg
Vitamin B <sub>12</sub>	Haematopoiesis	20 µg
Vitamin C	Antioxidant, collagen synthesis	2000 mg

\*Not strictly a vitamin.

**Table 87.4** Trace element requirements in critical illness<sup>30</sup>

Element	Function	Dose
Selenium	Antioxidant, fat metabolism	100 µg
Zinc	Energy metabolism, protein synthesis, epithelial growth	50 mg
Copper	Collagen cross-linking, ceruloplasmin	2–3 mg
Manganese	Neural function, fatty acid synthesis	25–50 mg
Chromium	Insulin activity	200 mg
Cobalt	B <sub>12</sub> synthesis	
Iodine	Thyroid hormones	
Iron	Haematopoiesis, oxidative phosphorylation	10 mg
Molybdenum	Purine and pyridine metabolism	0.2–0.5 mg

**Table 87.5** Water and electrolyte requirements/kg per day

Water	30 ml
Sodium	1–2 mmol
Potassium	0.7–1 mmol
Magnesium	0.1 mmol
Calcium	0.1 mmol
Phosphorus	0.4 mmol

of outcome, and that the advantages of enteral feeding are unassailable.

Two hypotheses are commonly advanced in support of the putative superiority of enteral feeding. First, it appears that the lipid contained within TPN is immunosuppressive. Intravenous lipid is known to suppress neutrophil and reticuloendothelial system function, and a comparison of TPN with and without lipid in critically ill trauma patients showed a lower complication rate in those not receiving lipid.<sup>32</sup> Second, enteral feeding may protect against infective complications. Absence of complex nutrients from the intestinal lumen is followed in rats by villus atrophy and reduced cell mass of the gut-associated lymphoid tissue (GALT). Starved humans show these changes to a much lesser extent. Lymphocytes produced in the GALT are redistributed to the respiratory tract, and contribute heavily to mucosal immunity. In mice, this contribution is lost during TPN.

The possibility that multiple organ failure may be driven by translocation of bacteria or endotoxin across an impaired mucosal barrier has been extensively investigated in animals. While it is known that TPN is associated with increased gut permeability to macromolecules in humans, this does not seem to result in translocation.<sup>33</sup> Although translocation does occur following surgery, and seems to be associated with sepsis,<sup>34</sup> a causal relation with multiple organ failure is unproven. In fact, a reduction in septic morbidity has only been found in certain groups, primarily abdominal trauma victims,<sup>35,36</sup> in whom parenteral nutrition was associated with a higher incidence of abdominal abscess and pneumonia. A third study found no difference.<sup>37</sup> In head-injured patients there is one trial showing no effect and one each supporting either route; however in the study favouring TPN the enteral nutrition group were grossly underfed.<sup>14,38,39</sup>

None of these studies is less than 15 years old, and the techniques of both enteral and parenteral feeding have changed a great deal in that time. Reductions in septic complications have also been found using enteral feeding in pancreatitis.<sup>40</sup> In contrast, no benefit was found in sepsis, though enteral feeding was instituted late.<sup>41</sup> A review of 31 clinical trials comparing enteral with parenteral feeding found no consistent difference.<sup>42</sup>

More recent systematic analyses have, as mentioned earlier, produced conflicting results. One found a reduction in infectious complications with enteral feeding, but no difference in mortality.<sup>5</sup> The most recent and most robust meta-analysis considered only high-quality trials using an intention-to-treat principle. It showed a clear reduction in mortality in patients fed parenterally.<sup>4</sup>

The same authors performed a prospectively defined subgroup analysis comparing early enteral with parenteral feeding, which showed no difference in mortality. Another recent meta-analysis of this question reached the same conclusion.<sup>43</sup> On this basis, as in the ACCEPT study, the authors recommended early use of the enteral route, with rapid recourse to parenteral nutrition if this was not possible.<sup>6,17</sup> At present it appears that timing of nutritional support matters as much as the route used.

A well-powered randomised study comparing early parenteral with enteral feeding will soon start.<sup>18</sup> However, in view of the practical and financial advantages of enteral feeding, it will probably need to find a significant mortality difference in favour of the parenteral route if it is to change the present preference for enteral feeding.

## ENTERAL NUTRITION

### ACCESS

Nasal tubes are preferred to oral, except in patients with a basal skull fracture, in whom there is a risk of cranial penetration. A large-bore (12–14 Fr) nasogastric tube is usually used at first. Once feeding is established and gastric residual volumes no longer need to be checked this can be replaced with a more comfortable fine-bore tube. A stylet is needed to assist in passage of fine-bore tubes. The position of all tubes must be checked on X-ray before feeding is started, as misplacement is not uncommon and intrapulmonary delivery of feed is potentially fatal.

Nasojejunal tubes are beneficial if impaired gastric emptying is refractory to prokinetic agents<sup>6</sup> (see below) or in pancreatitis. Spontaneous passage through the pylorus following blind placement is not reliable, but may be increased by the administration of single doses of 200 mg erythromycin or 20 mg metoclopramide.<sup>44</sup> However endoscopic or fluoroscopic assistance is needed for truly reliable transpyloric tube placement, although new developments in tube technology may soon obviate the logistic difficulties these methods entail. Unsurprisingly, two meta-analyses of various inconclusive studies have produced conflicting results on the question of whether nasojejunal feeding reduces the risk of aspiration or ventilator-associated pneumonia.<sup>7,45</sup> At present, the uncertain quality of the evidence concerning their benefits, coupled with the cost and logistic difficulty of placing them, precludes the routine use of nasojejunal tubes for all patients.

An alternative method of access in those needing long-term enteral feeding is percutaneous gastrostomy, which is usually performed endoscopically. Percutaneous jejunal access can be obtained either via a gastrostomy or by direct placement during incidental laparotomy.

### REGIMEN

Slowly building up the rate of feeding is not proven to avoid diarrhoea or high gastric residual volumes. Head-injured patients fed with target intake from the outset have fewer infective complications.<sup>46</sup> Nonetheless, it is presently common practice to start delivering around 30 ml/hour and build up to the target intake depending on tolerance, as judged by gastric residual volumes. These are assessed by aspiration of the tube every 4 hours. Gastric residual volumes over 150 ml on two successive occasions have been associated with an increased incidence of ventilator-associated pneumonia;<sup>47</sup> contrastingly, others have found no link between high residual volumes and the risk of aspiration.<sup>48</sup> Nevertheless, if the residual volume is consistently greater than 200 ml, treatment with prokinetic agents (metoclopramide 10 mg every 8 hours or erythromycin 250 mg every 12 hours intravenously) appears to increase tolerance of feeding, though there is no discernible effect on mortality or morbidity.<sup>44</sup> In refractory cases a nasojejunal tube often permits successful enteral feeding, because small bowel function is resumed quicker than gastric emptying. A nasogastric tube is still needed to drain the stomach. Diarrhoea, abdominal distension, nausea and vomiting may suggest intolerance, despite low gastric volumes. Absence of bowel sounds is common in ventilated patients and should not be taken to indicate ileus.

Fine-bore tubes should not be aspirated as this causes them to block. Various folk remedies have been tried for unblocking tubes, including instillation of Coca-Cola<sup>TM</sup> fruit juice and pancreatic enzyme supplements. The instillates should be left in situ for an hour or more.

### COMPOSITION

Commercially available enteral feeding solutions vary widely in composition. Polymeric feeds contain intact proteins (derived from whey, meat, soy isolates and caseinates) and carbohydrates in the form of oligo- and polysaccharides. These require pancreatic enzymes for absorption.

Elemental feeds with defined nitrogen sources (amino acids or peptides) are not of benefit when used routinely, but may enable feeding when small bowel absorption is impaired, for instance in pancreatic insufficiency or following prolonged starvation. Lipids are usually provided by vegetable oils consisting mostly of long-chain triglycerides, but some also contain more easily absorbed medium-chain triglycerides. The proportion of non-protein calories provided as carbohydrate is usually two thirds.

Electrolyte composition varies widely, with sodium- and potassium-restricted formulations available. Vitamins and trace elements are usually added by the manufacturers so that daily requirements are present in a volume containing roughly 2000 kcal. The possible benefits of providing additional doses of some of these substances to critically ill patients are considered below.

### COMPLICATIONS

Enteral feeding is an independent risk factor for ventilator-associated pneumonia.<sup>49</sup> Sinusitis due to nasogastric intubation may necessitate changing to an orogastric tube. Fine-bore tubes are vulnerable to misplacement in the trachea or to perforation of the pharynx, oesophagus, stomach or bowel. Percutaneous endoscopic gastrostomy is associated with a high 30-day all-cause mortality in acutely ill patients, in whom it may be best avoided.<sup>50</sup> Other complications include insertion site infection, serious abdominal wall infection and peritonitis. Surgically placed jejunostomies can cause similar problems, and may also obstruct the bowel.

Diarrhoea is common in ICU patients, particularly those being fed enterally. It is often multifactorial and causes considerable distress and morbidity, particularly when the patient is repeatedly soiled with watery stool. Common causes include antibiotic therapy, *Clostridium difficile* infection, faecal impaction and a non-specific effect of critical illness. Malabsorption, lactose intolerance, prokinetic agents, magnesium, aminophylline, quinidine and medications containing sorbitol (e.g. paracetamol syrup and cimetidine) are occasional culprits. Rate of administration of enteral feed also plays a role. Faecal impaction, medication-induced diarrhoea and *C. difficile* infection must be excluded or treated, while malabsorption may respond to elemental diet. Slowing the rate of feeding sometimes helps; diluting the formula does not.

Metabolic complications include electrolyte abnormalities and hyperglycaemia. Severely malnourished patients are at risk of refeeding syndrome (see below) if nutritional support is begun too rapidly.

### PARENTERAL NUTRITION

Parenteral nutritional support is indicated when adequate enteral intake cannot be established within an acceptable time. In some cases, absolute gastrointestinal failure is obvious, while in others it only becomes apparent after considerable efforts to feed enterally have failed. As discussed above, there is increasing evidence that if enteral feeding cannot be established early, then the parenteral route should be used until it can. Nevertheless, the aim in all patients fed intravenously should be to revert to enteral feeding as this becomes possible.

Parenteral feeding solutions may be prepared from their component parts under sterile conditions. Ready-made

**Table 87.6** Minimum monitoring during total parenteral nutrition. Less stable patients may require more intensive surveillance

<b>Nursing</b>	Temperature Pulse Blood pressure Respiratory rate Fluid balance Blood sugar (4 hourly when commencing feed)
<b>Daily</b> (at least)	Review of fluid balance Review of nutrient intake Blood sugar Urea, electrolytes and creatinine
<b>Weekly</b> (at least)	Full blood picture Coagulation screen Liver function tests Magnesium, calcium and phosphate Weight
<b>As indicated</b>	Zinc Uric acid

solutions also exist, but any necessary additions must be made in the same way.

In ICU patients the daily requirements are infused continuously over 24 hours. Careful biochemical and clinical monitoring is important, particularly at the outset (Table 87.6).

### ACCESS

The major concern with central venous access for TPN is prevention of infection. The following considerations apply:<sup>51</sup>

- *insertion site*: subclavian lines have lower infection rates than internal jugular or femoral lines
- *tunnelling* may reduce infection rates in internal jugular lines but apparently not in short-term subclavian lines. It is not recommended for routine use
- *expertise* of operator and adequacy of ICU *nurse staffing levels* affect infection rate
- *skin preparation*: 2% chlorhexidine in alcohol is the most effective
- *sterile technique*: maximal sterile barrier procedures (mask, cap, gown, gloves, and large drape) are known to reduce catheter-related bacteraemia rates sixfold. There is a bewildering resistance to use of these precautions outside ICUs
- *dressings*: permeable polyurethane transparent dressings are superior to impermeable
- *antimicrobial catheters*: catheters coated with either chlorhexidine and silver sulfadiazine or rifampicin and minocycline are several times less likely to cause bacteraemia than standard polyurethane catheters.

The duration of the anti-infective effect appears to be longer with the antibiotic-coated catheters (2 weeks versus 1 week)

- *scheduled exchange* has not been proven to reduce catheter-related sepsis
- *guide-wire exchange* is associated with increased bacteraemia rates, which in routine use outweigh the reduced mechanical complications

In practice, pre-existing central access is used in the first instance. If a multilumen catheter is used, one lumen should be dedicated to administration of TPN and not used for any other purpose. Three-way taps should be avoided and infusion set changes carried out daily under sterile conditions. For long-term TPN (more than 2 months) specialised catheters with a tunnelled cuff or a subcutaneous port are recommended.

## COMPOSITION

### ENERGY

Energy is provided by a combination of carbohydrate and lipid. The optimal balance between the two is unknown; often 30–40% of non-protein energy is given as lipid. Alternatively, glucose may be relied upon for almost all the energy, with lipid being infused once or twice a week to provide essential fatty acids.

Glucose is the preferred carbohydrate and is infused as a concentrated solution. Exceeding the body's capacity to metabolise glucose (4 mg/kg per min in the septic patient) can lead to hyperglycaemia, lipogenesis and excess CO<sub>2</sub> production. Endogenous insulin secretion increases to control blood sugar levels. However, many patients require additional insulin, particularly diabetics. This may be infused separately, but when requirements are stable it is more safely added to the TPN solution. Persistent hyperglycaemia is better addressed by reducing the glucose infusion rate than by large doses of insulin.

Lipid provides essential fatty acids (linoleic and linolenic acids) and a more concentrated energy source than glucose. It may thus avoid the complications of excess glucose administration. However, there are concerns of immunosuppression from lipid infusion, as discussed above. Current lipid preparations consist of soybean oil emulsified with glycerol and egg phosphatides.

### NITROGEN

Nitrogen is supplied as crystalline solutions of L-amino acids. Commercially available preparations vary in their provision of conditionally essential amino acids. Glutamine, tyrosine and cysteine are absent from many because of instability.

### MICRONUTRIENTS

Vitamin and trace element preparations are added to TPN solutions in appropriate amounts. Thiamine, folic acid and vitamin K are particularly vulnerable to depletion and additional doses may be necessary.

### ELECTROLYTES

Amino acid preparations contain varying quantities of electrolytes; additional amounts may need to be added to the solution.

### COMPLICATIONS

Parenteral nutrition has the potential for severe complications.

- *Catheter-related sepsis* is addressed above. Other complications of central venous cannulation are discussed elsewhere
- *Electrolyte abnormalities* include hypophosphataemia, hypokalaemia and hypomagnesaemia, especially in the first 24–48 hours
- *Hyperchloraemic metabolic acidosis* may result from amino acid solutions with a high chloride content. Replacing some chloride with acetate in the TPN solution will resolve this where necessary
- *Rebound hypoglycaemia* may occur when TPN is discontinued suddenly. TPN should be weaned over a minimum of 12 hours. If it cannot be continued, an infusion of 10% dextrose should be started and blood sugars closely monitored
- *Refeeding syndrome* may occur when normal intake is resumed after a period of starvation. It is associated with profound hypophosphataemia, and possibly hypokalaemia and hypomagnesaemia. With the restoration of glucose as a substrate, insulin levels rise and cause cellular uptake of these ions. Depletion of ATP and 2,3-DPG results in tissue hypoxia and failure of cellular energy metabolism. This may manifest as cardiac and respiratory failure, with paraesthesiae and seizures also reported. Thiamine deficiency may also play a part
- *Liver dysfunction* is common during TPN. Causes include hepatic steatosis, intrahepatic cholestasis and biliary sludging from gallbladder inactivity. The problems necessitating TPN in the first place may also cause liver dysfunction
- *Deficiencies* of trace elements and vitamins (especially thiamine, folic acid and vitamin K) may occur

## NUTRITION AND SPECIFIC DISEASES

### ACUTE RENAL FAILURE

The advent of continuous renal replacement therapy means that dietary fluid and protein restriction is rarely necessary in ICU. Use of specialised lipid or amino acid formulations in TPN is not supported by evidence, and in general normal nutritional support is appropriate in acute renal failure.

### LIVER DISEASE<sup>10,52</sup>

Energy requirements in ICU patients are not altered by the presence of chronic liver disease. Lipolysis is

increased, so lipid must be used with caution to avoid hypertriglyceridaemia (not more than 1 g/kg per day). Protein restriction may be required in chronic hepatic encephalopathy; starting with 0.5 g/kg per day, the dose may be cautiously increased towards a normal intake. Hepatic encephalopathy may in part be due to depletion of branched-chain amino acids (BCAAs) permitting increased cerebral uptake of aromatic amino acids, which produce inhibitory neurotransmitters. In protein-intolerant patients the use of feeds enriched with BCAAs may permit greater protein intake without worsening encephalopathy. Their routine use is not indicated.<sup>17</sup> Thiamine and fat-soluble vitamin deficiencies are common in patients with chronic liver disease.

Fulminant hepatic failure reduces gluconeogenesis; hypoglycaemia is a common problem necessitating glucose infusion. Lipid is well tolerated. Energy and protein requirements are similar to those above. BCAAs have not been shown to be superior to standard amino-acid solutions.

### RESPIRATORY FAILURE

Oxidation of fat produces less carbon dioxide than glucose. There have been attempts to use this to assist in weaning from mechanical ventilation by providing 50% of energy intake as lipid, with mixed results. Avoidance of overfeeding is much more important.

### ACUTE PANCREATITIS

Until recently, TPN was a cornerstone of the management of severe acute pancreatitis to minimise pancreatic stimulation. This has changed with the publication of studies showing jejunal feeding to be safe, effective and associated with reductions in infective complications compared with TPN.<sup>40</sup> Elemental feeds and pancreatic enzyme supplements are logical if malabsorption is a problem. Despite the shift towards enteral feeding of patients with pancreatitis, some can only be fed intravenously.

### OBESITY

The possibility that obese patients specifically may benefit from hypocaloric feeding was assessed by comparing 40 obese patients fed target intakes of <20 or 25–30 kcal/kg per day.<sup>53</sup> Other than a reduction in ICU stay, no benefit was shown. At present there is insufficient evidence to justify feeding obese patients differently from others.

### ADJUNCTIVE NUTRITION

Certain substances have been used as adjuncts to feeding solutions, in attempts to modulate the metabolic and immune responses to critical illness. While this is an area of much promise, in general no conclusive benefit has yet been shown in unselected critically ill patients. The situation has been complicated by a tendency to study

several compounds simultaneously, at arbitrary doses and in heterogeneous populations, then to perform retrospective subgroup analysis in order to demonstrate an effect. The evidence would be a great deal clearer if supplements with an established therapeutic window were evaluated individually. Such interventions are at least as much matters of pharmacology as of nutrition, and should be investigated as such.

### GLUTAMINE

Glutamine serves as an oxidative fuel and nucleotide precursor for enterocytes and immune cells, mainly lymphocytes, neutrophils and macrophages. It also appears to regulate the expression of many genes related to signal transduction and to cellular metabolism and repair. During catabolic illness glutamine is released in large quantities from skeletal muscle, in order to supply this need. In these circumstances it may become 'conditionally essential' and is vulnerable to depletion, with potentially adverse effects on gut barrier and immune function, which may in turn impair the ability to survive a sustained period of critical illness once glutamine stores are depleted.

The evidence on glutamine supplementation in critical illness is as contradictory as in other areas of nutritional support. Reductions in infectious complications and length of ICU stay were shown in small early studies of enterally fed trauma and burns patients, but a much larger study in unselected ICU patients found no effect on any outcome.<sup>54</sup> TPN solutions have historically contained no glutamine because of problems with stability and solubility. These are now being overcome by use of dipeptides, but clinical studies of intravenous glutamine supplementation during TPN have also been conflicting. One early trial in ICU patients requiring TPN showed a reduction in late mortality which only became apparent after 20 days, and which persisted at 6 months.<sup>55</sup> There are suggestions from meta-analysts that there is now a demonstrable mortality benefit from higher doses of parenteral glutamine;<sup>56</sup> this awaits confirmation in a prospective trial. In the meantime, it seems that the patients most likely to benefit are those requiring TPN for more than 10 days.<sup>55</sup>

### SELENIUM

Selenium is crucial to the regulation of glutathione peroxidase, the major scavenging system for oxygen free radicals. Low plasma selenium levels are common in ICU patients, and a number of small studies have shown potential benefits, again mostly when larger doses are given intravenously. A very recent large randomised trial of selenium 1000 µg intravenously for 14 days has shown a reduction in mortality when patients breaching trial protocols were excluded, but the intention-to-treat analysis did not reach statistical significance.<sup>57</sup> Parenteral selenium supplementation may well soon be proven to be beneficial in unselected ICU patients.

### ANTIOXIDANT VITAMINS

Vitamins A, C and E are also involved in systemic defence against oxidant stress, and have been studied in various combinations and doses, with and without selenium. Of the trials not using selenium, only one has shown a reduction in deaths using large enteral doses of vitamins C and E; the control group, however, had a very high mortality rate.<sup>58</sup> It is hard to recommend routine supplementation with antioxidant vitamins on present evidence.

### ARGININE AND IMMUNONUTRITION

Arginine is a non-essential amino acid which acts as a precursor of nitric oxide, polyamines (important in lymphocyte maturation) and nucleotides. Animal studies suggest enhanced cell-mediated immunity and survival when arginine is supplemented. Several commercially available enteral feeding solutions combine omega-3 fatty acids, arginine, nucleotides and in one case glutamine to produce so-called immune-enhancing diets. They have been assessed in a number of trials, few of them in patient groups likely to be admitted to ICU outside North America. Meta-analysis has suggested reductions in hospital stay and infections, but not in mortality.<sup>59,60</sup> Subgroup analysis revealed an increase in mortality when arginine supplementation was given to septic patients;<sup>60</sup> interim safety assessment of a randomised controlled trial<sup>61</sup> led to its early cessation when this finding was replicated in the subgroup of patients with sepsis, though this may have been a chance effect.<sup>17</sup>

At present it appears that such diets should not be used in septic patients. While there are suggestions of benefit in other groups, notably patients undergoing major surgery or suffering a burn injury, there is little basis for their general use in ICU patients unless it is justified by future adequately powered prospective trials comparing their individual components with meaningful controls.

# Blood transfusion

James P Isbister

Blood component therapy has a central therapeutic role in clinical medicine, but blood banking and transfusion medicine has tended to focus on the blood component supply rather than the demand/patient perspective. The clinical focus should naturally be on ‘what is best for the patient?’ not, ‘what is best for the blood supply?’

Demand for blood components continues to increase. Reasons include the greater burden of chronic disease due to ageing of the population, increasing severity of illness of intensive care unit (ICU) patients and both a widening range of clinical indications for blood components and newer blood-intensive surgical procedures. This is tempered by greater focus on appropriate use.

When prescribing blood component therapy, the clinical problem and patient’s needs must be accurately identified and clearly understood. Often therapy is required for haematological deficiencies until the basic disease process can be corrected (e.g. surgical control for acute haemorrhage, or support for bone marrow suppression until the marrow recovers). Therapy may be aimed at controlling the effects of a deficiency or preventing secondary problems. Alternatively, the indication is passive immunotherapy (e.g. Rhesus prophylaxis) or high-dosage intravenous immunoglobulin as immunomodulatory therapy.

In recent years the role of blood transfusion in a wide range of clinical settings is being critically reassessed. Careful risk assessment and the use of blood conservation techniques have made ‘bloodless’ surgery possible in most elective surgical settings. Added to the uncertainty about the indications and benefits of allogeneic blood transfusion is the accumulating evidence that blood transfusion is an independent risk factor for poorer clinical outcomes. Clearly many transfusions are both indicated and lifesaving, but it is appropriate that there is greater focus on transfusion alternatives, techniques to minimise exposure and closer attention to the quality and immediate efficacy of blood components.

Traditionally, transfusion has been regarded as the ‘default’ decision when there is clinical uncertainty. The benefits of transfusion have been assumed with little or no evidence to support the assumption and patients are thereby unnecessarily exposed to potential morbidity or even mortality. Given that the decision-making process for using blood component therapy can be difficult, that

indications may be controversial or when there is no evidence for potential benefit, there are good common sense and scientifically evidence-based reasons to adopt a non-transfusion default position.<sup>1,2</sup> If allogeneic blood component therapy can be avoided, the potential hazards cease to be an issue.

Both evidence-based transfusion medicine and the fact that blood is altruistically donated should ensure that blood is seen as a valuable and unique natural resource that should be conserved and managed appropriately. It should only be used as therapy when there is evidence for potential benefit, when alternatives have been considered and potential harm has been minimised. Potential hazards must be balanced against benefits and wherever possible the benefits and risks should be explained to the patient/relatives.

In considering the use of allogeneic blood transfusion the following questions need to be addressed:

- What is the timeframe of the decision-making process?
- Is it an elective decision?
- What is the haemopoietic defect?
- What is the most appropriate therapy for the patient?
- Are there alternatives to allogeneic transfusion?
- What component is indicated and where should it be obtained?
- How should the component be administered and monitored?
- What are the potential hazards of the blood component therapy?
- Can the risk of adverse effects be avoided or minimised?
- What is the cost of the haemotherapy?
- Is the patient fully informed of the medical decisions?

Safe and effective transfusion requires attention to the following details (Figure 88.1):

- Clearly defined indication and benefits of blood components
- Accurate patient identification for blood group compatibility
- Identification and careful management of high-risk patients
- Appropriate handling, administration and monitoring

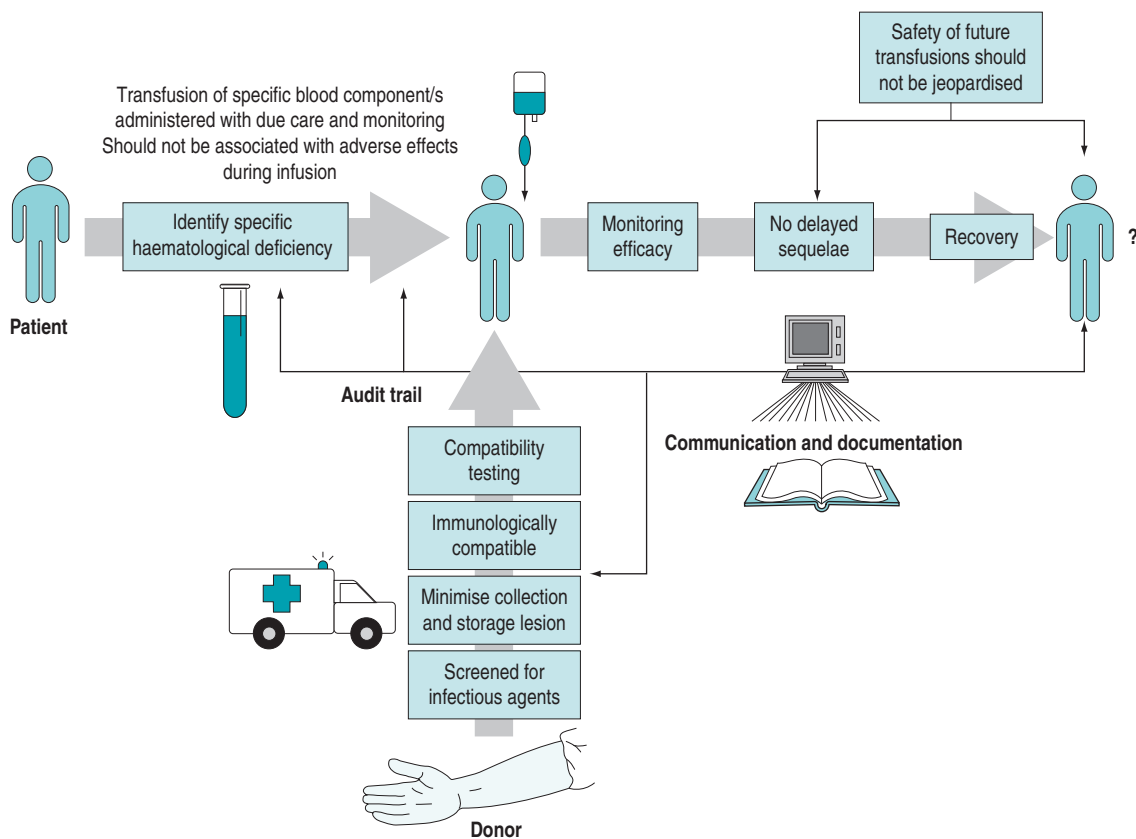

Figure 88.1 What is a safe transfusion?

- Provision of adequate amounts and quality of component(s)
- Communication of benefits and risk to the patient/relatives
- The infusion should not be associated with preventable ill effects
- Awareness of possible transfusion-related complications
- Early diagnosis and prompt action in relation to adverse events of transfusion
- Accurate documentation
- Input into quality assurance programmes

### BLOOD STORAGE AND THE STORAGE LESIONS

Blood is altered from the moment of collection and the 'lesions' of collection – anticoagulation, separation, cooling, preservation and storage – compound and progressively increase until the date of expiry.<sup>3</sup> The extent of these changes is determined by collection technique, the specific blood component, the preservative medium, the container, storage time and storage conditions. The threshold storage time for blood components has generally been arbitrarily determined by *in vitro* studies

and assessment of *in vivo* survival. In the case of red cell concentrates, greater than 75% of transfused cells should survive post transfusion.

Storage results in quantitative and/or qualitative deficiencies in blood components, which may reduce the immediate efficacy of a transfusion. In parallel with these storage changes is an accumulation of degenerate material (e.g. microaggregates and procoagulant material), release of vasoactive agents, cytokine generation and haemolysis.<sup>4</sup> Many of the changes occurring during storage are related to the presence of leukocytes and can be minimised by pre-storage leukoreduction.<sup>5</sup> Red cells undergo a change from their biconcave disc shape to spiky spherocytes (echinocytes) and in so doing lose their flexibility. There are also changes in the red cell membrane resulting in an increased tendency to adhere to endothelial cell surfaces in the microcirculation, especially if there is activation of endothelial cells, for example in the presence of the systemic inflammatory response (e.g. with shock or sepsis).<sup>6</sup> There is evidence that the immediate post-transfusion function of stored red cells and haemoglobin in delivering oxygen to the microcirculation and unloading is questionable, and several hours are required for red cell oxygen carriage and delivery to return to normal.<sup>7,8</sup> It is important to differentiate between the storage

**Figure 88.2** The storage lesions. ARDS, adult respiratory distress syndrome; GIT, gastrointestinal tract; MOF, multiorgan failure; RES, reticuloendothelial system; TRALI, transfusion-related acute lung injury.

lesion being responsible for failure to achieve clinical/laboratory end-points due to reduced survival and/or qualitative defects in cellular function and the 'toxic' effects of blood storage (Figure 88.2).

The use of blood filters has been an acknowledgement of the existence of the blood storage lesion and its possible clinical significance. The 170  $\mu\text{m}$  blood-giving filters were first introduced into transfusion medicine to stop the occlusion of blood-giving sets. Ironically, there was little concern that the fibrin clots may harm the patient but fortunately the lung is one of nature's remarkable filters. Adult respiratory distress syndrome (ARDS) and the Vietnam War increased interest in unfiltered microaggregates accumulating during storage. Both logic and animal data suggested their implication in ARDS and that microfilters to remove microparticles 20–40  $\mu\text{m}$  in size may be protective. This proved difficult to confirm but microaggregate filters do not adequately address the problem of the storage lesion and its clinical significance. Using pre-storage leukodepletion filters, and preventing the development of the storage lesion in both blood and platelets from its inception, is more logical and scientific. Universal pre-storage leukoreduction is now standard practice in many countries, although it was primarily introduced as a precautionary measure against the possible transmission of variant Creutzfeldt–Jakob disease (vCJD) and not to address the numerous other indications for the removal of leukocytes.<sup>9</sup>

The clinical significance of blood storage lesions is still controversial. Further studies are needed to assess their

relevance in conditions such as ARDS, multiorgan failure (MOF), vasoactive reactions and alterations in laboratory parameters.<sup>7,10,11</sup> It is assumed that blood components have been appropriately collected, processed, stored, transported and transfused, but despite much greater attention to standard operating procedures and regulation generally, the quality of the final product cannot be guaranteed.<sup>12</sup> The 'assumed' quality of labile cellular blood products is based on research data and monitoring of standard operating procedures. There is rarely detailed individual product assessment prior to transfusion.<sup>8</sup> It is accepted that the adverse effects of storage increase with time and an arbitrary 'cut off' is mandated on the basis of research studies.

In relation to the possible clinical significance of the storage lesion, the following should be considered:

- Quantitative and qualitative deficiency of blood component
  - Failure to achieve anticipated end-points due to reduced quantity and/or quality of the blood product
  - Exposure to excessive numbers of donors in achieving efficacy
- Physical characteristics
  - Hypothermia
  - Chemical characteristics
  - Citrate toxicity
  - Acid–base imbalance
  - Glucose

- Contamination
  - Bacterial resulting in endotoxaemia or septicaemia
  - Plasticisers
- Accumulation of 'toxic' or degenerate products
  - Role of the storage lesion in transfusion-related immunomodulation
  - Role of cytokines
  - Role of reticuloendothelial system blockade
  - Accentuation of free radical pathophysiology due to free iron
- Effects of transfusion on laboratory parameters (e.g. elevations in bilirubin, neutrophils, serum iron and lactic dehydrogenase) which may lead to incorrect interpretation
- Large volume transfusions (proportional to storage age) as a risk factor for MOF and ARDS
- Early hyperkalaemia, late hypokalaemia
- Activation and consumption of the haemostatic factors with possible contribution to disseminated intravascular coagulation (DIC) and venous thromboembolism
- Non haemolytic, non-febrile transfusion reactions
- Hypotension and circulatory instability due to vasoactive substance (kinins, histamine)

#### THE ROLE OF LEUKOCYTES AS A 'CONTAMINANT' IN LABILE STORED BLOOD AND THE ROLE OF PRE-STORAGE LEUKODEPLETION

There are several difficulties assessing potential adverse effects of leukocytes as they may be responsible for a wide range of blood component quality and safety issues.<sup>9</sup> The presence of leukocytes has been shown to be responsible for specific adverse outcomes in some patients (e.g. non-haemolytic febrile transfusion reaction, platelet refractoriness and transfusion-associated graft-versus-host disease, TAGVHD), but this is the minority. In the larger context the overall available evidence, in the absence of adequate large randomised clinical trials, suggests that universal pre-storage leukodepletion may reduce transfusion-related morbidity and mortality as well as generating cost savings.<sup>13</sup> Leukodepletion of red cell and platelet concentrates minimises the clinical consequences of the immunomodulatory effects of allogeneic transfusion. Hence it may decrease the incidence of recurrence of some cancers, of postoperative infections, of blood stream infections and reduce ICU and hospital length of stay. In many patients transfusion-related acute lung injury (TRALI) is a multifactorial disorder and in 'at risk' patients non-leukodepleted blood may be a risk factor. Patients in whom there is activation of the systemic inflammatory response syndrome (SIRS) are at risk of developing the multiorgan failure syndrome.<sup>5,14</sup> Patients at particular risk include those with trauma, burns, critical bleeding, shock, sepsis and those undergoing cardiopulmonary bypass.<sup>15-19</sup> The quality and function of pre-storage leukodepleted red cell concentrates is better maintained on storage, ensuring better post-transfusion efficacy and survival.<sup>6,20</sup>

#### CLINICAL GUIDELINES FOR BLOOD COMPONENT THERAPY

The following is a brief summary of the clinical guidelines for the use of commonly used blood components. The use of specific concentrates or recombinant products is beyond the scope of this book.

#### RED CELL TRANSFUSIONS

What constitutes appropriate use of red cell transfusions in acute medicine is contentious because of the difficulties in identifying the benefits of red cell transfusion in many circumstances.<sup>21</sup> Pursuit of the lowest safe haematocrit continues to receive considerable attention, but pushing any aspect of a system to its limits risks 'sailing too close to the wind' which may be appropriate in some situations, but potentially hazardous in others.<sup>22,23</sup>

In an otherwise stable patient, the transfusion of red cell concentrates is likely to be inappropriate when the hemoglobin level is  $> 100$  g/l. On the other hand, their use may be appropriate when haemoglobin is in the range 70–100 g/l if there are other defects in the oxygen transport system, such as cardiorespiratory dysfunction. The decision to transfuse should be supported by the need to relieve clinical signs and symptoms of impaired oxygen transport and prevent morbidity and mortality. The transfusion of red cell concentrates is likely to be appropriate when hemoglobin is  $< 70$  g/l and the anaemia is not reversible with specific therapy in the short term, but lower levels may be acceptable in patients who are asymptomatic, especially in the younger age group.

#### PLATELET TRANSFUSIONS

Platelet transfusion therapy may benefit patients with platelet deficiency or dysfunction. The following are the indications for platelet transfusions:<sup>24</sup>

#### PROPHYLAXIS

- Bone marrow failure when the platelet count is  $< 10 \times 10^9/l$  without associated risk factors for bleeding or  $< 20 \times 10^9/l$  in the presence of additional risk factors
- To maintain the platelet count at  $> 50 \times 10^9/l$  in patients undergoing surgery or invasive procedures
- In qualitative platelet function disorders, depending on clinical features and setting (platelet count is not a reliable indicator for transfusion)

#### BLEEDING PATIENT

- In any haemorrhaging patient in whom thrombocytopenia secondary to marrow failure is considered a contributory factor
- When the platelet count is  $< 50 \times 10^9/l$  in the context of massive haemorrhage/transfusion and  $< 100 \times 10^9/l$  in the presence of diffuse microvascular bleeding

The transfusion of platelet concentrates is not generally considered appropriate:

- when thrombocytopenia is due to immune-mediated destruction
- in thrombotic thrombocytopenic purpura and haemolytic uraemic syndrome
- in uncomplicated cardiac bypass surgery

### FRESH FROZEN PLASMA

There are few specific indications for fresh frozen plasma, but its use may be appropriate.<sup>25</sup>

- for replacement of single factor deficiencies where a specific or combined factor concentrate is not available
- for treatment of the multiple coagulation deficiencies associated with acute DIC
- for treatment of inherited deficiencies of coagulation inhibitors in patients undergoing high-risk procedures where a specific factor concentrate is unavailable
- in the presence of bleeding and abnormal coagulation parameters following massive transfusion or cardiac bypass surgery or in patients with liver disease
- for immediate reversal of warfarin-induced anticoagulation in the presence of potentially life-threatening bleeding when prothrombin concentrates (PCC) are not available<sup>26–28</sup> (see Chapter 91)

The use of fresh frozen plasma is generally not considered appropriate in cases of:

- hypovolaemia
- plasma exchange procedures unless post exchange invasive procedures are planned
- treatment of immunodeficiency states

### CRYOPRECIPITATE

Cryoprecipitate is prepared from freshly collected plasma and contains factor VIII, fibrinogen, von Willebrand factor, factor XIII and fibronectin. Cryoprecipitate was originally developed for treatment of haemophilia due to factor VIII deficiency, but is now prescribed to treat congenital or acquired hypofibrinogenaemia, usually in the context of liver disease, trauma, DIC, hyperfibrinolysis or massive transfusion.

### IMMUNOGLOBULIN

Normal human immunoglobulin is available in intramuscular and intravenous forms for the treatment or prevention of infection in patients with proven hypogammaglobulinaemia.<sup>29</sup> Intravenous immunoglobulin G has been recommended as adjunctive therapy in patients with fulminant sepsis syndrome, especially those with toxic shock syndrome caused by group A streptococci.<sup>30</sup>

Intravenous immunoglobulin therapy also has a role in therapy of some autoimmune disorders, such as idiopathic thrombocytopenic purpura, autoimmune polyneuropathy and others (see Chapter 90).

### FACTOR CONCENTRATES

There is an increasing number of plasma protein concentrates available for clinical use. Some are prepared from donor plasma and some by recombinant technology. Factor VIII and factor IX concentrates have an established role in the management of haemophilia, but others are in the process of establishing their clinical efficacy and indications. Antithrombin III (ATIII) concentrates are available for thrombophilia due to ATIII deficiency and are increasingly recommended in other disorders where ATIII may be depleted (e.g. DIC, MOF).<sup>31</sup> Recombinant human activated protein C has antithrombotic, anti-inflammatory and profibrinolytic properties but its role in the treatment of patients with severe sepsis remains controversial.<sup>32</sup>

Of recent interest is the use of the recombinant activated haemostatic proteins and inhibitors. Recombinant activated factor VII (rFVIIa) was developed for the management of haemophilic patients with coagulation factor inhibitors. rFVIIa is now being widely used 'off label' for controlling haemorrhage in the non-haemophilic setting and there is considerable controversy as to its benefits and risks.<sup>33</sup> There are an increasing number of case reports and series reporting on the use of rFVIIa in critical life-threatening haemorrhage. Patients with uncontrolled critical bleeding and coagulopathy, despite large transfusions and surgical intervention, have significant mortality rates and rFVIIa in these clinical situations is used as salvage therapy. rFVIIa is now being studied in controlled trials where there is critical bleeding in various clinical settings. rFVIIa initiates the extrinsic coagulation pathway when complexed to tissue factors at sites of injury and on activated platelet surfaces. It potentially has a role in a wide range of haemostatic disorders (e.g. massive blood transfusion, liver disease, uraemia, severe thrombocytopenia and platelet disorders).<sup>34</sup>

### POTENTIAL ADVERSE EFFECTS OF ALLOGENEIC TRANSFUSION

The pathophysiology of blood transfusion reactions can broadly be divided into five categories (Figure 88.3):

- Reactions may occur due to *immunological differences* between the donor and recipient, resulting in varying degrees of blood component incompatibility. In general, in order for a reaction to occur, the recipient needs to have been previously immunised to a cellular or plasma antigen.<sup>35</sup>
- A wide range of *infectious agents* may be transmitted by homologous blood component therapy.

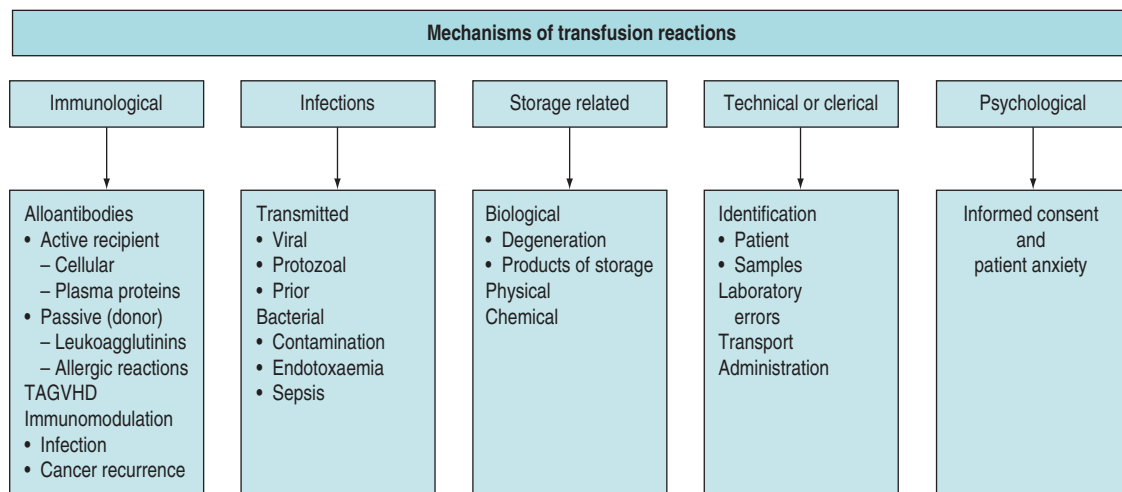

Figure 88.3 Possible mechanisms of adverse effects to blood transfusion. TAGVHD, transfusion-associated graft-versus-host disease.

- *Alterations in blood products due to preservation and storage* may result in quantitative and/or qualitative deficiencies in the blood components which will reduce transfusion efficacy and expose the patient to potentially adverse consequences from storage accumulants in the component.
- *Technical or clerical errors* that may result in adverse events in all the above categories.
- *Psychological* – informed consent issues and patient anxiety compatibility.

In terms of causation of an adverse clinical event, the possible role of blood transfusion can be classified into three categories on the basis of probability (Figure 88.4):

- *Definite – unifactorial – transfusion caused:* The well-understood and reported hazards of transfusion (i.e. immunological, technical, infectious) are generally unifactorial with a 1:1 causal relationship between the blood component transfused (usually a specific individual unit) and the adverse consequence for the patient. ABO blood group incompatibility, transfusion-related infection transmission, TAGVHD and TRALI due to donor leukoagglutinins are examples in this category.
- *Probable – oligofactorial – transfusion related:* Some adverse consequences of transfusion result from interaction with other insults, pathophysiology or host factors, but the contribution of the transfusion can usually be specifically identified. Fever, allergic reactions, hypotensive reactions, pulmonary oedema, some cases of TRALI, hyperbilirubinaemia and cytomegalovirus (CMV) transmission are examples in this category.
- *Possible – multifactorial – transfusion associated:* Transfusion may be a contributor to a complication or poor clinical outcome. In these circumstances it may be difficult to implicate transfusion directly in an individual case, nor is it necessarily the major factor. Transfusion-induced immunomodulation (TRIM) and the clinical

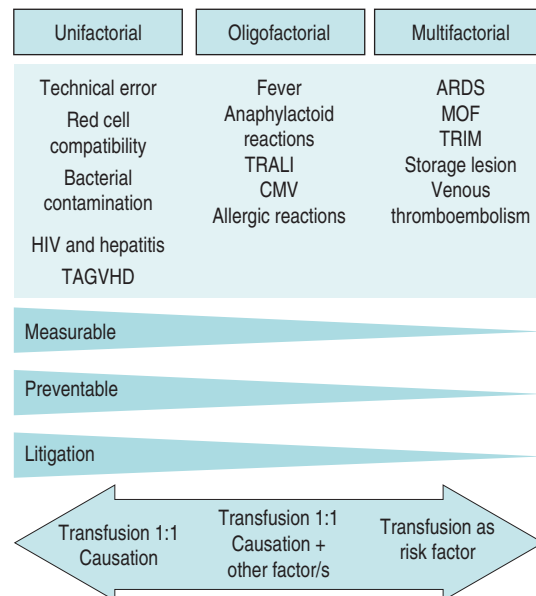

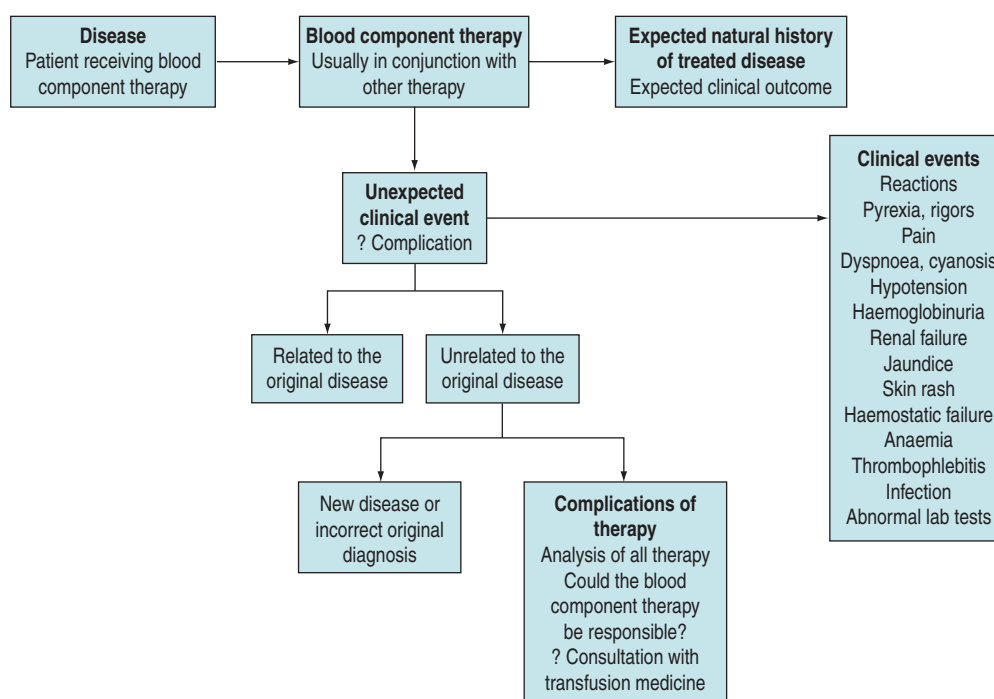

Figure 88.4 Algorithm for analysis for the possibility of a transfusion reaction. ARDS, adult respiratory distress syndrome; CMV, cytomegalovirus; MOF, multiorgan failure; TAGVHD, transfusion-associated graft-versus-host disease; TRIM, transfusion-induced immunomodulation; TRALI, transfusion-related acute lung injury.

consequences of storage lesions fall into this category. The role of transfusion being associated with adverse consequences has been established in observational studies, but causation cannot be confidently concluded. Accumulating evidence, in the absence of randomised clinical trials, supports causation, thus demanding a more precautionary approach to allogeneic blood

**Figure 88.5** Adverse reactions to blood component therapy may just be one of the contributory factors in the differential diagnosis of any unexpected clinical presentation.

transfusion, examination of alternatives to transfusion and implementation of methods to improve the quality of transfused blood components (especially red cell and platelet concentrates). Universal pre-storage leukodepletion is currently the most important and effective strategy for minimising the clinical impact of TRIM and the blood storage lesions.

Adverse reactions to blood component therapy may present in a wide range of ‘guises’ and transfusion must always be considered in the differential diagnosis of any unexpected clinical presentation or indeed as a contributory factor to a clinical picture that may have several contributory factors (Figure 88.5).

### PYREXIA

Mild febrile reactions are not usually a matter of concern, but rigors and temperatures above 38°C should not be ignored. The majority of febrile reactions are now considered to be an immunological reaction against one or more of the transfused cellular or plasma components, usually leukocytes.

### TRANSFUSION-RELATED INFECTIONS

#### HEPATITIS

Post-transfusion hepatitis is a potential complication of allogeneic transfusion; donor selection, serological and

nucleic acid tests ensure exclusion of infective donors. Hepatitis B and C are now almost totally preventable transfusion-transmitted diseases.

#### HUMAN IMMUNODEFICIENCY VIRUS

Donor selection, antibody screening and nucleic acid testing of blood donors has almost eliminated transfusion-associated HIV infection.

#### MONONUCLEOSIS SYNDROMES

The development of swinging pyrexia with varying degrees of peripheral blood atypical mononucleosis, 7–10 days following transfusion, can cause diagnostic confusion. Abnormalities in liver function are common. CMV infection is the commonest cause of this syndrome.

### OTHER TRANSFUSION-TRANSMISSIBLE INFECTIONS

There is an increasing range of agents that have the potential to be transmitted by blood transfusion, the most recent one of concern being vCJD. The reader is referred to reviews for further information.<sup>36,37</sup>

#### BACTERIAL CONTAMINATION

Bacterial contamination of stored blood has always been recognised as a potential cause of fulminant endotoxic shock. Although a rare complication, continuing reports

of its occurrence, especially in relation to platelet concentrate transfusion, have increased awareness.<sup>38,39</sup> The clinical features of transfusion-related bacterial sepsis in the non-anaesthetised patient include rigors, fever, tachycardia and vascular collapse, with prominent nausea, vomiting and diarrhoea. Anaesthetised patients may have a delayed onset of symptoms (fever, tachycardia, hypotension and cyanosis), followed by DIC, renal failure and sometimes ARDS. The requirement to store platelet concentrates at room temperature increases the risks of bacterial contamination. Pre-release bacterial testing is being more widely advocated as a measure to minimise the problem.

### HAEMOLYTIC TRANSFUSION REACTIONS

Most severe acute haemolytic transfusion reactions are due to ABO incompatibility, have an identifiable cause and are avoidable, in contrast to delayed haemolytic reactions which are immune in nature and usually cannot be prevented.

#### INITIAL SYMPTOMS AND SIGNS

The classic symptoms and signs of an acute haemolytic transfusion reaction, typical of ABO incompatibility, include apprehension, flushing, pain (e.g. at infusion site, headache, chest, lumbosacral and abdominal), nausea, vomiting, rigors, hypotension and circulatory collapse.

#### HAEMOSTATIC FAILURE

Haemorrhagic diathesis due to DIC may be a feature, resulting in severe generalised haemostatic failure, with haemorrhage and oozing from multiple sites.<sup>40</sup> As the responsible transfusion is likely to have been administered for haemorrhage, increasing severity of local bleeding may be the first clue to an incompatible transfusion, especially if the patient is unconscious or anaesthetised in the operating room.

#### OLIGURIA AND RENAL IMPAIRMENT

Renal impairment may complicate a haemolytic transfusion reaction and its prevention or the appropriate management of established renal failure is important. If circulating volume and urinary output are rapidly restored, established renal failure is unlikely to occur. Death from acute renal failure directly caused by an incompatible blood transfusion is preventable, and there are usually other poor prognostic factors.

#### ANAEMIA AND JAUNDICE

A severe haemolytic transfusion reaction may be suspected from the development of jaundice or anaemia.

### ALLERGIC AND ANAPHYLACTOID REACTIONS

Non-cellular blood (plasma and plasma derivatives) components are rarely considered to be a major cause for

adverse reactions to transfusion therapy. However, the complexity of plasma and its various components and the effects from component processing results in a broader spectrum of potential adverse effects than frequently recognised. The antigenic heterogeneity of plasma proteins and the presence of antibodies make the non-cellular components of blood responsible for a range of adverse effects, many of which remain poorly understood and commonly pass unrecognised in clinical practice.<sup>41</sup>

There has been debate over the years as to the classification of allergic reactions to blood components. Clinical severity may range from minor urticarial reactions or flushing through to fulminant cardiorespiratory collapse and death. Some of these reactions are probably true anaphylaxis, but in others, mechanisms have been less clear and the term anaphylactoid has been used. To avoid implying the mechanism of the reaction, the term immediate generalised reaction has been used.

The clinical syndromes of immediate reactions have been classified as follows:

- Grade I
  - skin manifestations
- Grade II
  - mild to moderate hypotension
  - gastrointestinal disturbances (nausea)
  - respiratory distress
- Grade III
  - severe hypotension, shock
  - bronchospasm
- Grade IV
  - cardiac and/or respiratory arrest

### PLASMA AND PLASMA COMPONENTS MAY CAUSE ADVERSE EFFECTS BY SEVERAL PATHOPHYSIOLOGICAL MECHANISMS

Immunological reactions to normal components of plasma may occur in two ways:

- Plasma proteins being antigenic to the recipient; they may contain epitopes on their molecules different from those on the recipient's functionally identical plasma proteins (e.g. anti-IgA antibodies)
- Antibodies in the donor plasma reacting with cellular components of the recipient's blood cells or plasma proteins

Physicochemical characteristics and contaminants of donor plasma, such as temperature, chemical additives, medications and micro-organisms may be responsible for recipient reactions.

The preparation techniques and storage conditions of blood and blood products may potentially cause adverse reaction through:

- *accumulation of metabolites* or cellular release products
- *plasma activation*, i.e. activation of some of the proteolytic systems. Importantly, the complement and

kinin/kininogen systems may generate vasoactive substances and anaphylatoxins which may be responsible for reactions. Some apparently allergic reactions to blood products may be due to vasoactive substances in the infusion. Subjective sensations may be missed in an unconscious patient. Hypotension occurring during rapid infusion of a hypovolaemic patient is likely to be interpreted as further volume loss, particularly with some plasma protein fractions that have been reported as consistently producing a transient fall in blood pressure, and a situation fraught with risk of overload can be produced

- *histamine generation*: histamine levels increase in some stored blood components and levels may be correlated with non-febrile, non-haemolytic transfusion reactions. Histamine release may be stimulated in the patient by plasma components, synthetic colloids and various medications
- *generation of cytokines* during storage may be responsible for non-haemolytic transfusion reactions
- *chemical additives*: there are various chemical additives (ethylene oxide, formaldehyde, drugs, latex) which may be responsible for immunological or non-immunological recipient reactions.

#### TRANSFUSION-ASSOCIATED GRAFT-VERSUS-HOST DISEASE (TAGVHD)

Graft-versus-host disease, classically observed in relationship to allogeneic bone marrow transplantation, may occur following a blood transfusion due to the infusion of immunocompetent lymphocytes precipitating an immunological reaction against the host tissues of the recipient.<sup>42</sup> It is most commonly observed in immunocompromised patients, but may also be seen in recipients of directed blood donation from first-degree relatives, and occasionally where donor and recipient are not related, due to homozygosity for HLA haplotypes for which the recipient is heterozygous. The syndrome usually occurs 3–30 days post allogeneic transfusion with fever, liver function test abnormalities, profuse watery diarrhoea, erythematous skin rash and progressive pancytopenia.

#### TRANSFUSION-RELATED ACUTE LUNG INJURY (TRALI)

TRALI is receiving a great deal of attention as a potentially serious complication of blood transfusion.<sup>43–46</sup> In the classic plasma neutrophil antibody-mediated form of the disease symptoms usually arise within hours of a blood transfusion.<sup>47</sup> In contrast to most patients with ARDS, recovery usually occurs within 48 hours. The underlying pathophysiology of ‘classic’ TRALI is due to the presence of leukoagglutinins in donor plasma. When complement is activated, C5a promotes neutrophil aggregation and sequestration in the microcirculation of the

lung, causing endothelial damage leading to an interstitial oedema and acute respiratory failure. This classic form of transfusion-related acute lung injury has been recognised for over five decades, but was thought to be a rare complication of allogeneic plasma transfusion. As leukoagglutinins occur typically in plasma from multiparous females there is a move to using male donor only fresh frozen plasma.

It is now accepted that there has been underrecognition and underdiagnosis of TRALI, partly due to a lack of clinical awareness, but also to a broader understanding of mechanisms by which blood transfusion may cause or be a contributory factor to lung injury.<sup>48,49</sup> The term TRALI is now being expanded to include cases in which transfusion is identified as an independent risk factor predisposing patients to lung injury.<sup>50,51</sup> The reader is referred to recent reviews addressing the expanding area of concern in which transfusion, per se, is being identified as an independent risk factor for poor clinical outcomes, of which TRALI is only one.

#### TRANSFUSION-RELATED IMMUNOMODULATION (TRIM)

There is evidence that allogeneic blood transfusion is immunosuppressive in the recipient that has implications in relation to resistance to infection and the likelihood of cancer recurrence.<sup>52–54</sup> Donor leukocytes probably play the most important role in this immunomodulation. TRIM, along with the clinical effects of the blood storage lesion, is probably the mechanism by which allogeneic blood transfusion is responsible for poorer clinical outcomes discussed in the next section.

#### ALLOGENEIC TRANSFUSION AS AN INDEPENDENT RISK FACTOR FOR POORER CLINICAL OUTCOMES

Over the last decade experimental and clinical studies have identified blood transfusion as an independent risk factor for morbidity and mortality as well as increased admission rates to ICUs, increased length of hospital stay and additional costs.<sup>18,19,55–57</sup> Blood transfusion being implicated as part of the problem rather than optimal therapy has been a surprise to many clinicians, health administrators and patients, as it has always been assumed that blood transfusion can only be of benefit to the bleeding or anaemic patient. This long-standing belief is now being effectively challenged and currently the debate on the management of the acutely haemorrhaging or anaemic patient has moved significantly from a paradigm with a focus on transfusion to one in which the urgent control of critical bleeding is the paramount priority, with avoidance and/or minimisation of blood transfusion. There is thus increasing evidence that transfusion-related immunomodulation (TRIM) and the transfusion effects of storage lesions are responsible for poorer clinical outcomes in a range of clinical settings.<sup>18,19,55,58–63</sup>

However, it is not possible to categorically conclude causation and that pre-storage leukoreduction will eliminate or

minimise the risk. While the case for causation is strengthened, it is important to be aware that there is minimal evidence for the efficacy or appropriateness of many transfusions, and there is evidence that restrictive red cell transfusion policies do not jeopardise clinical outcomes; indeed, the reverse may be the case.<sup>64,65</sup> Thus, until these issues are resolved, a precautionary approach should be adopted, with the *modus operandi* being to avoid or minimise allogeneic transfusion and use appropriate patient blood conservation techniques.<sup>66</sup> An additional association with transfusion is the higher incidence of venous thromboembolism if patients are transfused.<sup>67</sup>

### CRITICAL HAEMORRHAGE AND MASSIVE BLOOD TRANSFUSION

There is a reappraisal of clinical practice guidelines for the use of blood components in the bleeding patient.<sup>21,68</sup> The guidelines are no longer for the management of massive blood transfusion, but rather for the management of critical bleeding and avoiding getting into the massive transfusion coagulopathy quagmire in which the patient can spiral down into the 'triad of death' – coagulopathy, acidosis and hypothermia.

This reappraisal of management of patients with acute haemorrhage is resulting in the challenging of long-standing dogmas. There is greater tolerance of hypotension until haemorrhage is controlled, and lower haemoglobin levels are tolerated with closer attention to the clinical context of the anaemia and its impact on systemic and local oxygen delivery, especially if there are any compromises in cardiorespiratory function. More attention and research is being directed toward the role of clear fluids and the importance of plasma viscosity, colloid oncotic pressure and functional capillary density.<sup>69</sup> The search for safe and effective haemoglobin-based oxygen carriers continues.<sup>70-72</sup>

If blood loss has been massive or there are defects in the haemostatic system, specific component therapy may be indicated. Advances in patient retrieval, resuscitation protocols, techniques for rapid and real-time diagnosis, trauma teams and early 'damage control' surgery have improved the management of acutely haemorrhaging patients. Patients are now surviving with larger volumes of blood transfusion, but sepsis, acute lung injury and multiorgan failure remain major challenges, and blood transfusion is increasingly being recognised as a two-edged sword and probably a contributory factor to these complications in which microcirculatory dysfunction is recognised as central in the pathophysiology. As already discussed, the evidence that the immediate post-transfusion ability of stored red cells and haemoglobin to deliver and unload oxygen to microcirculation may be impaired is resulting in stored red cell concentrates not being automatically the first therapy for acutely enhancing oxygen delivery. Indeed, recent animal data indicate that the immediate clinical benefit of transfused red cells in

treating hypovolaemic shock relates to reconstitution of the macrocirculation, with adverse effects on the functional capillary density in the microcirculation.<sup>73</sup>

In previously healthy patients who have suffered an acute blood loss of less than 25% of their blood volume, restoring volume is more important than replacing oxygen-carrying capacity. Plasma volume expanders may preclude the necessity for allogeneic transfusion, especially if bleeding can be controlled. Clear fluids also allow time for transfusion compatibility testing. In the context of acute bleeding and hypovolaemic shock, the haemoglobin level is not the primary indicator for determining the need for allogeneic red cell transfusion. A normal human may survive a 30% deficit in blood volume without fluid replacement, in contrast to an 80% loss of red cell mass if normovolaemia is maintained. Minimisation of allogeneic blood transfusion is important and haemodilution with tolerance of anaemia is now accepted clinical practice. However, there are limits to haemodilution, not only from the oxygen-carrying capacity perspective. Marked reduction in blood viscosity is counterproductive as reactive peripheral vasoconstriction to maintain total peripheral resistance results in reduction in functional capillary density in the microcirculation. The role of clear fluids and the importance of plasma viscosity, colloid oncotic pressure, electrolyte composition and functional capillary density is the subject of current research.<sup>74</sup>

A protocol approach to blood component therapy is generally not recommended, as each patient should be treated individually. However, this remains a controversial issue with advocates for 'blind', up-front component therapy with red cell and haemostatic components, especially fresh frozen plasma and cryoprecipitate or fibrinogen concentrates. With better understanding of coagulopathy in the critical haemorrhage setting and the importance of hypofibrinogenaemia and hyperfibrinolysis there is a reanalysis of the approach to blood component therapy.<sup>75</sup> In an elective situation in which normovolaemia is generally maintained from the outset, defects can be predicted and appropriate blood components prescribed, a protocol approach may be justified. This should be done in close consultation with the haematologist and hospital transfusion service.

Failure of haemostasis is common in critically bleeding patients and may be complex and multifactorial in pathogenesis.<sup>76,77</sup> The importance of avoiding acidosis and hypothermia cannot be overemphasised as the triad of coagulopathy, acidosis and hypothermia has an extremely poor prognosis. Coagulopathy associated with critical haemorrhage is related to other aspects of the pathophysiology of the clinical setting. The assumption that there is a 'generic coagulopathy' vaguely referred to as DIC is incorrect and can result in inappropriate therapeutic decisions. The reader is referred to an expanding literature on this topic where it will be seen that there can be no standard approach to therapy.<sup>77</sup> This author is increasingly convinced that the pathophysiology of coagulopathy, when occurring in the context of critical haemorrhage,

should be viewed as related to the primary insult/initiating event, and that a 'secondary' coagulopathy (e.g. massive stored blood transfusion, haemodilution, hypothermia, continuing tissue hypoxia, etc.) may compound the problem in the resuscitated patient. The primary mechanisms of coagulopathy relating to the initiating event may relate to trauma, hypoxia, pregnancy, microbial infection, envenomation or iatrogenic (antithrombotic) agents. In all circumstances there is activation or inhibition of some aspect of the haemostatic system, and therapy is better informed if the varied mechanisms are understood. Frequently, complex tests are required for definitive diagnosis, but the urgency of the situation cannot always await the results, and therapy may be initiated on clinical evidence with minimal laboratory information.

Many trauma patients have coagulopathy at presentation that is more related to hypovolaemic shock and not consumption or dilution. Recent evidence indicates that excessive activation of the protein C system and hypofibrinogenaemia secondary to secondary hyperfibrinolysis are important.<sup>78</sup> Except for severe abnormalities, haemostatic laboratory parameters correlate poorly with clinical evidence of haemostatic failure. In the massively transfused patient thrombocytopenia and impaired platelet function are the most consistent significant haematological abnormalities, correction of which may be associated with control of microvascular bleeding. Coagulation deficiency from massive blood loss is initially confined to factors V and VIII. Activated partial thromboplastin time (APTT), prothrombin time (PT) and fibrinogen assay should be performed, but the urgency of the situation does not usually allow for other specific factor assays.

A problem with the standard screen tests of coagulation function is that they do not give information about the actual formation of the haemostatic plug, its size, structure or stability. For this reason there is increasing interest in global tests of haemostatic plug formation and stability such as thromboelastography, thrombin generation tests and clot waveform analysis in which changes in light transmission in routine APTT are measured.<sup>79</sup> Fresh frozen plasma should be infused if the test results are abnormal, including cryoprecipitate or fibrinogen concentrates if the fibrinogen level is < 1 g/l. A case can be made for prophylactic fresh frozen plasma in infusions in patients with massive blood loss which has been replaced with red cell concentrates and plasma substitutes.

With ongoing bleeding with associated microvascular oozing various approaches may be taken. Having ensured that all identifiable haemostatic defects have been corrected, questions arise as to the role of fresh blood and, more recently, recombinant activated factor VII (rFVIIa).<sup>80</sup> The use of freshly collected whole blood remains controversial and is an 'emotive' subject needing some comment. The provision of fresh whole blood can present logistic, ethical and safety problems needing consideration. Many transfusion medicine specialists categorically state that there is never an indication for fresh whole blood. Such dogma can be difficult to defend in the

clinical setting of the massive haemorrhage and transfusion syndrome where pathophysiology remains poorly understood and specific blood component therapy may be ineffective.

The following statements reasonably summarise the current status of fresh blood transfusion:

- Fresh blood provides immediately functioning oxygen-carrying capacity, volume and haemostatic factors in the one product
- The number of allogeneic donors to whom a patient is exposed can be reduced
- Problems associated with infusion of massive volumes of stored blood can be minimised/avoided
- The risk of transfusion-related viral infections is possibly higher than fully tested and stored blood
- The benefit in controlling haemorrhage probably relates to the presence of immediately functioning platelets

#### SPECIFIC HAZARDS OF MASSIVE BLOOD TRANSFUSION

Massive blood transfusion may be defined in several ways:

- replacement of the circulating volume in 24 hours
- > 4 units of blood in 1 hour with continuing blood loss
- loss of 50% of circulating blood volume within 3 hours

Any patient receiving massive blood component therapy is likely to be seriously ill and have multiple problems. Many adverse effects must be considered in conjunction with the injuries and multiorgan dysfunction. It is not always possible to define the complications caused or aggravated by massive blood transfusion.

#### CITRATE TOXICITY

A patient responds to citrate infusion by the removal of citrate and mobilisation of ionised calcium. Citrate is metabolised by the Krebs cycle in all nucleated cells, especially the liver. A marked elevation in the citrate concentration is seen with transfusion exceeding 500 ml in 5 minutes; the level rapidly falls when the infusion is slowed. Citrate metabolism is impaired by hypotension, hypovolaemia, hypothermia and liver disease. Toxicity may also be potentiated by alkalosis, hyperkalaemia, hypothermia and cardiac disease. The clinical significance of a minor depression of ionised calcium remains ill-defined, and it is accepted that a warm, well-perfused adult patient with normal liver function can tolerate a unit of blood each 5 minutes without requiring calcium. The rate of transfusion is more significant than the total volume transfused. Common practice is to administer 10% calcium gluconate 1.0 g i.v. following each 5 units of blood or fresh frozen plasma. Such a practice remains controversial as there is increasing concern regarding calcium homeostasis and cell function in acutely ill patients.

**ACID–BASE AND ELECTROLYTE DISTURBANCES****Acid–base**

Stored bank blood contains an appreciable acid load and is often used in a situation of pre-existing or continuing metabolic acidosis. The acidity of stored blood is mainly due to the citric acid of the anticoagulant and the lactic acid generated during storage. Their intermediary metabolites are rapidly metabolised with adequate tissue perfusion, resulting in a metabolic alkalosis. Hence the routine use of sodium bicarbonate is usually unnecessary and is generally contraindicated. Alkali further shifts the oxygen dissociation curve to the left, provides a large additional sodium load, and depresses the return of ionised calcium to normal following citrate infusion. Acid–base estimations should be performed and corrected in the context of the clinical situation. With continuing hypoperfusion, however, metabolism of citrate and lactate will be depressed, lactic acid production will continue, and there may be an indication for i.v. bicarbonate and calcium to correct acidosis and low ionised calcium.

**Serum potassium**

Although controversial, it is unlikely that the high serum potassium levels in stored blood have pathological effects in adults, except in the presence of acute renal failure. However, hypokalaemia may be a problem 24 hours after transfusion as the transfused cells correct their electrolyte composition and potassium returns into the cells. Thus, although initial acidosis and hyperkalaemia may be an immediate problem with massive blood transfusion, the net result of successful resuscitation is likely to be delayed hypokalaemia and alkalosis. With CPD (citrate–phosphate–dextrose) blood, the acid load and red cell storage lesion is less. Constant monitoring of the acid–base and electrolyte status is essential in such fluctuating clinical situations.

**Serum sodium**

The sodium content of whole blood and fresh frozen plasma is higher than the normal blood level due to the sodium citrate. This should be remembered when large volumes of plasma are being infused into patients who have disordered salt and water handling (e.g. renal, liver or cardiac disease).

**HYPOTHERMIA**

Blood warmed from 4°C to 37°C requires 1255 kJ (300 kcal), the equivalent heat produced by 1 hour of muscular work, with an oxygen requirement of 62 l. Hypothermia impairs the metabolism of citrate and lactate, shifts the oxygen dissociation curve to the left, increases intracellular potassium release, impairs red cell deformability, delays drug metabolism, masks clinical signs, increases the incidence of arrhythmias, reduces cardiac output and impairs haemostatic function. Thus a thermostatically controlled blood-warming device should be routinely used when any transfusion episode requires the rapid infusion of more than 2 units of blood.

**HYPERBILIRUBINAEMIA**

Jaundice is common following massive blood transfusion as a significant amount of transfused stored blood may not survive, resulting in varying degrees of hyperbilirubinaemia. During hypovolaemia and shock, liver function may be impaired, particularly in the presence of sepsis or multiorgan failure. An important rate-limiting step in bilirubin transport is the energy-requiring process of transporting conjugated bilirubin from the hepatocyte to the biliary canaliculus. Thus, although an increased load of bilirubin from destroyed transfused red cells may be conjugated, there may be delayed excretion, leading to a conjugated hyperbilirubinaemia. This ‘paradoxical’ conjugated hyperbilirubinaemia may be misinterpreted, leading to unnecessary investigations. The effect of resorbing haematoma and the possibility of an occult haemolytic transfusion reaction should also be considered.

**BASIC IMMUNOHAEMATOLOGY**

Red cell serology is a highly specialised area of knowledge and it is not possible to expect clinicians to have more than a basic working knowledge essential for patient safety. The following is a summary of core knowledge for the clinician.

**SALINE AGGLUTINATION**

Safe red cell transfusion has revolved around this traditional serological technique. A saline suspension of red cells is mixed with serum and observed for agglutination. Saline agglutination is used for ABO blood grouping and is one of the techniques for compatibility testing of donor blood.

**THE DIRECT AND INDIRECT ANTIGLOBULIN TEST**

In red cell serology, the antiglobulin test (Coombs test) is used to detect IgG immunoglobulins or complement components. The direct antiglobulin test (DAT) detects immunoglobulin or complement components present on the surface of the red cells circulating in the patient. The result is positive in autoimmune haemolytic anaemia and haemolytic disease of the newborn and during a haemolytic transfusion reaction. The indirect antiglobulin test (IAT) detects the presence of non-agglutinating antibodies in the patient’s plasma, usually IgG type. Antibody screening for atypical antibodies and pretransfusion compatibility testing are the main applications of the IAT.

**REGULAR AND IRREGULAR (ATYPICAL) ANTIBODIES**

The regular alloantibodies (isoagglutinins) of the ABO system are naturally occurring agglutinins present in all ABO types (except AB), depending on the ABO group. Group O people have anti-A and anti-B isoagglutinins,

group A have anti-B and Group B have anti-A. Group A cells are the cause of the commonest and most dangerous ABO incompatible haemolytic reactions. Atypical antibodies are not normally present in the plasma, but may be found in some people as naturally occurring antibodies or as immune antibodies. Immune antibodies result from previous exposure due to blood transfusion or pregnancy. Naturally occurring antibodies more frequently react by saline agglutination and, although they may be stimulated by transfusion, are usually of minimal clinical significance. In contrast, many of the immune atypical antibodies are of major clinical significance and their recognition is the *raison d'être* for pretransfusion compatibility testing and antenatal antibody screening. Most of the clinically significant immune atypical antibodies are detected by the IAT.

Blood group antigens vary widely in their frequency and immunogenicity. The D antigen of the Rhesus blood group system is common and highly immunogenic. Thus, when a Rh-negative (i.e. D-negative) patient is exposed to D-positive blood there is a high likelihood of forming an anti-D antibody. It is for this reason that the D antigen is taken into account when providing blood for transfusion, in contrast to the numerous other red cell antigens that are less common or less immunogenic. Beyond the Rh (D), and sometimes the Kell (K) blood group antigens, it is not practical, or necessary, to take notice of other blood group antigens unless an atypical antibody is detected during antibody screening procedures.

### THE ANTIBODY SCREEN

On receipt of a blood sample by the transfusion service the red cells are ABO and Rh D typed and the serum is screened for atypical antibodies. This screen consists of testing the patient's serum with group O screening cells. The screening panel consists of red cells obtained usually from two group O donors containing all common red cell antigens occurring with a frequency of greater than approximately 2% in the community. If an atypical antibody is detected on the antibody screen, further serological investigations are carried out to identify the specificity of the antibody. These investigations are time consuming and when possible should be carried out electively.

### THE CROSSMATCH (COMPATIBILITY TEST)

The crossmatch is the final compatibility test between the donor cells and the patient's serum. The crossmatch test tends to be overemphasised to the detriment of the antibody screen. With sophisticated knowledge of serology the emphasis in the supply of compatible blood is now concentrated on the steps prior to the final compatibility crossmatch.

### THE TYPE AND SCREEN SYSTEM

As precompatibility testing has assumed the major role in the selection of blood for transfusion, there has been a

rethinking of policies relating to the supply of blood for elective transfusions. Whenever elective surgery is planned for a patient who is likely to require blood transfusion, the transfusion service must receive a clotted blood sample well before the anticipated time of surgery. The precompatibility testing should be carried out during the routine working hours when facilities are geared for large workloads and enough staff is available to handle all contingencies.

### THE PROVISION OF BLOOD IN EMERGENCIES

When quick clinical and laboratory decisions are made under conditions of stress it is frequently difficult for all involved personnel to appreciate the difficulties of others. The decision to give uncrossmatched, partially crossmatched or wait for crossmatched compatible blood is not easy, and certain basic serological considerations may clarify for the clinician some of the problems faced by the serologist. Depending upon the degree of urgency and the extent of previous knowledge about the patient's red cell serology, blood can be provided with varying degrees of safety. However, it should be emphasised that when a patient is exsanguinating and likely to die, the giving of ABO compatible uncrossmatched blood, especially if the antibody screen is negative, is safe and appropriate therapy.

### UNIVERSAL DONOR GROUP O BLOOD

Group O blood under normal circumstances will be ABO compatible with all recipients. The transfusions should be given as red cell concentrates screened for high titre A or B haemolysins and only used in extreme emergencies. If the recipient is in the childbearing age every attempt should be made to give Rh-D negative blood until the patient's blood group is known.

### ABO GROUP SPECIFIC BLOOD

Transfusion of blood of the correct ABO type circumvents the isoagglutinin problems alluded to above. Simple as this approach may seem, its safety is dependent on meticulous attention to grouping. Previous blood group information, such as a 'bracelet' group or 'unofficial' group written in the patient's records may be incorrect, and there may be considerable risk if blood is administered on the basis of this information.

### SALINE-COMPATIBLE BLOOD

The administration of saline-compatible blood is, for practical purposes, the administration of ABO group specific blood.

# Colloids and blood products

Michael Mythen

Colloids are plasma expanders used to expand the blood volume. Hydrostatic and osmotic forces dictate movement of fluid between the different compartments of the body across semipermeable membranes (Starling's forces).

The osmotic pressure generated by a solute is proportional to the number of molecules or ions of solute and independent of solute molecular size.

Colloid osmotic pressure (COP) is the osmotic pressure exerted by the macromolecules (the colloid molecules).<sup>1,2</sup> This can be measured using a membrane transducer system in which the membrane is freely permeable to small ions and water but largely impermeable to the colloid molecules.<sup>3</sup> The membrane pore size and the molecular size distribution of the colloid being studied will dictate the measured value (see Figures 89.2 and 89.3).<sup>2,3</sup> Capillary walls are made up of endothelial cells, which are freely permeable to small ions such as  $\text{Na}^+$  and  $\text{Cl}^-$ , but are relatively impermeable to larger molecules such as colloids (Figure 89.3). A colloid is a homogeneous non-crystalline substance consisting of large molecules or ultramicroscopic particles of one substance dispersed through a second substance – the particles do not settle and cannot be separated out by ordinary filtering or centrifuging like those of a suspension such as blood.<sup>2</sup>

In practical terms, it is a fluid that when infused into the intravascular space should expand the blood volume by the volume infused.<sup>3,4</sup> Crystalloids have larger volumes of distribution dependent on their composition (Figure 89.1 and Table 89.1). Colloids or plasma substitutes have molecular weights (MW)  $> 35$  kDa, and infusion results in an initial increase in blood osmotic pressure. The ideal properties of a colloid are:

- stable with a long shelf life
- pyrogen, antigen and toxin free
- free from risk of disease transmission
- plasma volume expanding effect lasts for several hours
- metabolism and excretion do not adversely effect the recipient
- no direct adverse effects, e.g. causing a coagulopathy

## COLLOID SOLUTIONS

There are two major groups of colloids – plasma derivatives or semisynthetics.<sup>5</sup> Plasma derivatives include human

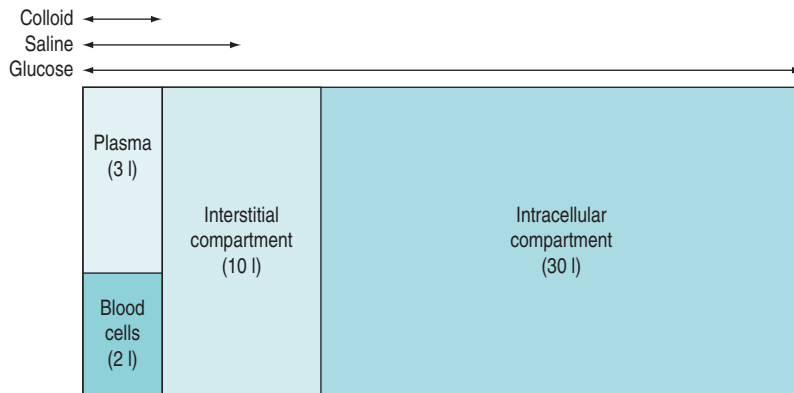

albumin solutions, plasma protein fraction, fresh frozen plasma and immunoglobulin solutions. Three principal types of semisynthetic colloid molecule are commonly used in intravenous solutions – gelatins, dextrans and hydroxyethyl starches. All colloids are presented dissolved in a crystalloid solution. Isotonic saline is still the most commonly used carrier solution but isotonic glucose, hypertonic saline and isotonic balanced electrolyte solutions are also used.

Colloids often do not consist of uniform sized molecules. Human albumin solution contains more than 95% albumin with a uniform molecular size. This is described as monodisperse. Conversely, all the semisynthetic colloids have a distribution of molecular sizes and are described as polydisperse.<sup>1,2</sup> The size–weight relationship is relatively constant although some colloids can have equivalent MW with different molecular size – succinylated and urea-linked gelatins have almost identical molecular weights but the succinylated product undergoes conformational change due to an increase in negative charge and is physically larger.<sup>2,3</sup>

## HUMAN ALBUMIN SOLUTION

Human albumin is thought of as an ideal colloid and is commonly the reference solution against which other colloids are judged. Human albumin is a naturally occurring monodisperse colloid. Solutions (5% and 20%) are prepared from human plasma and heat treated to ensure that neither hepatitis nor HIV can be transmitted. It has a relatively short (~1 year) shelf life at room temperature, but a 5-year shelf life at 2–8°C. Human albumin 5% is used for the treatment of hypovolaemia in a wide variety of clinical conditions. Concentrated salt-poor 20% human albumin is used for the treatment of hypoalbuminaemia in the presence of salt and water overload (e.g. hepatic failure with ascites). Albumin has putative advantages that include limiting free radical-mediated damage but the importance of a normal serum albumin level remains uncertain.<sup>6–8</sup>

Human-derived colloid has a number of significant disadvantages. These are expensive products and concerns have been raised about transmission of infectious agents, such as new variant Creutzfeldt–Jakob disease (nvCJD)

associated with bovine spongiform encephalopathy (BSE), that are not removed by currently available techniques. Concerns have also been raised by the conclusions of a highly controversial meta-analysis suggesting that the use of human albumin solution may be associated with increased mortality in the critically ill. These conclusions were probably unjustified,<sup>8,9</sup> but there is certainly no evidence that the use of human albumin has any advantages over less expensive semisynthetic alternatives<sup>10,11</sup> or indeed crystalloids. However, the latter applies to all colloids.<sup>12–14</sup>

### GELATINS

Gelatins are prepared by hydrolysis of bovine collagen.<sup>15</sup> The commonly available preparations are succinylated gelatin (Gelofusine) and urea-linked gelatin–polygeline (Haemaccel).<sup>1,2</sup> Because of the significant calcium content of Haemaccel, citrated blood should not be infused through a giving set that has been previously used for this product; however, this does not apply to SAGM (saline–adenine–glucose–mannitol) blood. Gelatins are relatively inexpensive and stable, with long shelf lives. The gelatins' plasma volume expanding effect only lasts about 90–120 minutes.<sup>3,4</sup> They are mainly eliminated by renal excretion.

Incidence of reactions to gelatins are acceptable (<0.5%) and range from mild skin rash and pyrexia to life-threatening anaphylaxis. The reactions appear to be related to histamine release, which is probably the result of a direct effect of gelatin on mast cells. The gelatins appear to have the least impact on haemostasis and it is not clear whether they have any impact over and above simple haemodilution of clotting factors. A specific safety issue has arisen with bovine-derived gelatin products since the advent of sporadic cases of nvCJD associated with exposure to tissue infected with BSE. The gelatin used in the commercially available products in the UK, for example, is sourced from the US (which is regarded as BSE free) or from certified BSE free herds in France. The UK Spongiform Encephalopathy Advisory Committee concluded that gelatin was safe to use in this context.

### DEXTRANS

Dextran are polysaccharides biosynthesised commercially from sucrose by the bacterium *Leuconostoc mesenteroides* using the enzyme dextran sucrose.<sup>1,2</sup> This produces a high molecular weight dextran that is then cleaved by acid hydrolysis and separated by repeated ethanol fractionation to produce a final product with a relatively narrow molecular weight range. The products in current clinical use are described by their MW, Dextran 40 and Dextran 70 having MWs of 40 000 and 70 000 Da, respectively.

Dextran preparations are stable at room temperature and have long shelf lives. Dextran 70 is used as a plasma

substitute for the treatment of hypovolaemia and has an intravascular volume-expanding effect that lasts at least 6 hours. Dextran 40 is used for its effects on micro-circulatory flow and blood coagulation in some types of surgery (e.g. vascular, neuro and plastic surgery). The beneficial effects on outcome when Dextran 40 is used as an 'anti-sludging agent' remain controversial. Dextran 40 should not be used as a plasma substitute for the treatment of hypovolaemia as although it produces an immediate plasma volume expansion as a result of its small molecular weight it may obstruct renal tubules and produce renal failure.<sup>5</sup>

Dextrans can precipitate true anaphylactic reactions, as anti-dextran antibodies may be present due to synthesis of dextrans by lactobacilli that occur naturally as gut commensals. Dextran infusion, particularly of the high molecular weight products, can also precipitate anaphylactoid reactions. The risk of true anaphylactic reactions can be decreased about 10-fold by pretreatment with monovalent hapten-dextran. The dextrans are also associated with significant haemostatic derangements. These include:

- simple haemodilution of clotting factors
- reduction in factor VIII activity
- increase in plasminogen activation
- increase in fibrinolysis
- reduction in clot strength
- impairment of platelet function

Red cell aggregation is also reduced with the lower molecular weight dextrans. In patients whose haemostatic function is normal prior to infusion, a maximum dose of 1.5 g/kg is often recommended to avoid risk of bleeding complications. The anticoagulant effects of dextrans can be utilised perioperatively as a prophylaxis against thromboembolism.<sup>1,2,5</sup>

### HYDROXYETHYL STARCHES

Hydroxyethyl starches (HES) are produced by hydroxyethyl substitution of amylopectin, a D-glucose polymer, obtained from sorghum or maize.<sup>1,2</sup> The pattern of hydroxyethyl substitution on glucose moieties influences the susceptibility to hydrolysis by non-specific amylases in the blood. A high C2 to C6 substitution ratio and a high overall degree of substitution (the proportion of glucose moieties that have been substituted) both protect against enzymatic breakdown and prolong the effective activity of HES as a plasma volume expander. The different HES products are commonly described by their weight-averaged molecular weight (MW<sub>w</sub>, number of molecules at each weight times the particle weight divided by the total weight of all the molecules). They are also described by their degree of substitution.<sup>1,2–5</sup> Hetastarches (C2/C6 ratio 0.6–0.7), pentastarches (C2/C6 ratio ≈0.5) and tetrastarches (C2/C6 ratio ≈0.4). Starch usage varies between countries.

In the USA, the only starches available for clinical use are high molecular weight (>450 kDa) hetastarches presented in either normal saline or a lactate-buffered, glucose-containing, balanced electrolyte solution (Hex-tend).<sup>16,17</sup> There is a move towards the use of the non-saline based starch as the administration of high volumes of normal saline to humans has been associated with clinically significant acid–base disturbances.<sup>18–21</sup> In particular, normal saline infusion has been shown to cause a hyperchloraemic metabolic acidosis; however, the pathogenesis and significance of this phenomenon remains controversial.<sup>18–22</sup> Colloids presented in balanced electrolyte solutions are becoming available outside the USA. In Europe, the trend over the past 5 years has been towards the use of lower molecular weight (130 kDa) tetrastarches presented in saline and more recently in balanced electrolyte solutions.<sup>23</sup> Starch preparations are stable at room temperature and have long shelf lives. The duration of intravascular retention is proportional to molecular weight<sup>3,4,24</sup> but is > 6 hours even for the 130 kDa tetrastarches.

HES products are associated with an acceptable incidence of adverse events including anaphylactoid reactions. Tissue deposition may result in intractable itching if large volumes of HES are infused over several days.<sup>25</sup> Whether the administration of large volumes of HES may cause some renal dysfunction remains controversial.<sup>26</sup> HES products can cause a coagulopathy.<sup>27,28</sup> In particular, HES products cause a reduction in factor VIII (FVIII) levels and impair platelet function causing a von Willebrand-like syndrome. These effects are greater with high molecular weight HES molecules infused at large volumes. The effects of the high molecular weight starches on coagulation seemed to be lessened in the reformulated balanced electrolyte alternative cited above.<sup>16</sup>

### THE ROLE OF HYPERTONIC SOLUTIONS

In recent years hypertonic (600–1800 mosmol) crystalloid and colloid solutions have been introduced for certain clinical indications.<sup>29–33</sup> The theoretical advantage of these solutions is that a small volume of administered fluid will provide a significant plasma volume expansion. The high osmolarity of these solutions draws tissue fluid into the intravascular space and thus should minimise tissue oedema for a given plasma volume increment. Hypertonic crystalloids and colloids presented in a hypertonic saline carrier have been shown to achieve adequate resuscitation in a number of clinical settings. A smaller volume of hypertonic solution is normally required to achieve similar plasma volume expansion. In particular, these solutions are thought to result in reduced cerebral oedema in those patients at risk of this complication and indeed these solutions may have a place in treating refractory cerebral oedema.<sup>31–33</sup> Outside the perioperative arena they are finding use in the management of burns patients and in prehospital resuscitation of trauma victims. They are limited at present to single dose administrations.

### BLOOD SUBSTITUTES – PERFLUOROCARBON AND HAEMOGLOBIN THERAPEUTICS

In future, the use of artificial or semisynthetic oxygen-carrying solutions will become increasingly common.<sup>34</sup> A number of products have been and are currently under evaluation: perfluorocarbon, modified human haemoglobin (Hb), modified bovine Hb and recombinant Hb solutions. These products not only function as oxygen carriers but are also capable of sustained plasma volume expansion. Unlike Hb present in intact red cells, these products often have a linear O<sub>2</sub>Hb dissociation profile and the effects of this on O<sub>2</sub> uptake in the lungs and release in the tissues are not yet clearly defined. Additionally, they may have specific pharmacological effects – for example, with stroma-free haemoglobin nitric oxide scavenging resulting in vasoconstriction is well recognised. A modified bovine haemoglobin solution (Hemopure) has been licensed for clinical use in South Africa since 2001 but is still not approved for use elsewhere in the world.

### PLASMA DERIVATIVES

#### FRESH FROZEN PLASMA

Fresh frozen plasma (FFP) contains normal plasma levels of all the clotting factors, albumin and immunoglobulin. A unit is typically 200–250 ml and has a FVIII level of at least 0.7 IU/ml (i.e. 70% of normal levels) and about 0.5 g of fibrinogen. It is kept at a temperature of –50°C in order to preserve coagulant levels. FFP is indicated for the replacement of multiple clotting factor deficiencies (e.g. liver disease, coumarin anticoagulant overdose and coagulopathy associated with massive blood transfusion).<sup>35–37</sup> An initial dose of 12–15 ml/kg (four packs for a 70-kg adult) is appropriate. Although it is effective, FFP should not be used as a plasma volume expander solely for the treatment of hypovolaemia.

#### CRYOPRECIPITATE

Cryoprecipitate is usually supplied as a pool of six or so single donor units in one pack. It is prepared from FFP by using a freeze thaw method, collection of the precipitate and then resuspending it in about 20 ml of plasma. It contains about 50% of the coagulant factor activity of the original unit (e.g. fibrinogen 250 mg, FVIII 100 IU). Cryoprecipitate is stored at –30°C and remains stable for up to a year.<sup>35</sup> It is indicated in the treatment of coagulation defects, including massive haemorrhage and DIC if there is microvascular bleeding associated with a fibrinogen level < 0.5 g/l and as an alternative to FVIII concentrate in the treatment of inherited deficiencies of von Willebrand factor, FVIII and FXIII.<sup>36,37</sup> For an adult, transfusion of 3–4 g of fibrinogen (about 16 packs) should raise the fibrinogen level by 1 g/l.

### FACTOR VIII

Factor VIII concentrate is prepared from large pools of donor plasma. One freeze-dried vial contains about 300 FVIII units.<sup>35</sup> The concentrates are heat or chemically treated to inactivate HIV-1. It is stable for 2 years when stored at 4°C. Further purification of the concentrate by chromatography results in high-purity FVIII and the relative merits of high- and intermediate-purity products are being investigated.

Recombinant FVIII is being used increasingly commonly in many parts of the world. Indications are the treatment of haemophilia A and von Willebrand's disease.<sup>38</sup> A dose of about 10–15 U/kg may be given, depending on the severity of bleeding and repeated 12 hourly, as required.

### FACTOR IX

Factor IX concentrate (prothrombin concentrate) contains factors II, VII, IX and X in varying amounts, and is prepared from pools of plasma.<sup>35</sup> It is available as a freeze-dried preparation, and is reconstituted with water immediately before use. Factor IX concentrate of intermediate purity is used to treat haemophilia B and to correct bleeding disorders due to an overdose of coumarin anticoagulants in patients who cannot tolerate large volumes of FFP.<sup>35</sup> Purified factor IX concentrates are now available and are 100 times purer than the traditional concentrate, with 75% of total protein being factor IX.

### OTHER PLASMA CONCENTRATES

Activated factor VII concentrate can be used in patients with inhibitors to factor VIII or IX, as it bypasses the requirement for these factors.<sup>35</sup> Activated factor VII has also been used in the treatment of severe life-threatening haemorrhage but this remains controversial.<sup>39</sup> Other concentrates, such as antithrombin III, C1 esterase inhibitor, and proteins C and S, are available for treating deficient patients at times of risk, such as surgery. Most of these concentrates have been used experimentally with varying success for the treatment of DIC and septic shock.

Recombinant versions of most plasma factors are either clinically available or in development and will probably become the standard of care. Recombinant activated protein C has been shown to be beneficial in a large human study for the treatment of septic shock<sup>40</sup> (see Chapter 11).

### IMMUNOGLOBULINS (GAMMAGLOBULINS)

Normal human immunoglobulin preparation is made from plasma pools obtained from normal blood donors. It contains antibodies to hepatitis A, measles, mumps, varicella, polio and prevalent bacteria.<sup>35</sup> Immunoglobulins are indicated in the prevention or treatment of

patients with hypogammaglobulinaemia, and may have a role in the treatment of autoimmune diseases, such as thrombocytopenic purpura and myasthenia gravis. Specific immunoglobulins are available for a range of infectious agents including tetanus, hepatitis B, rubella, measles, rabies and varicella zoster. They are made from donor plasma known to contain high levels of the specific IgG antibodies and are used for prophylaxis and treatment in patients who have not been actively immunised. Rhesus-D immunoglobulin is prepared from plasma containing high levels of anti Rh-D antibodies and it prevents sensitisation of Rh-negative mothers to Rh-D positive cells that may enter their circulation. The principal use of Rh-D immunoglobulin is in the prevention of haemolytic disease of the newborn.<sup>41</sup>

# Therapeutic plasma exchange and intravenous immunoglobulin immunomodulatory therapy

James P Isbister

Bloodletting to remove 'evil humours' has a long history of over 2000 years. Although not based on logic in the past, the removal of 'noxious' agents from the blood remains the rationale, but now there is scientific understanding of the pathophysiology of the diseases treated by plasma exchange.<sup>1</sup> Exchange transfusions revolutionised the management of haemolytic disease in the newborn, and paved the way for therapeutic plasmapheresis and plasma exchange – the removal of plasma, with replacement by albumin-electrolyte solutions or fresh frozen plasma.

Plasma exchange was initially used in the management of hyperviscosity associated with malignant paraproteinaemia, but is now also used in the treatment of a wide range of autoimmune disorders (now > 100). Nevertheless, plasma exchange is expensive and not risk-free, and debate continues on its therapeutic role in many diseases.

For the past two decades, intravenous immunoglobulin (IVIG) has increasingly been used as an immunomodulatory agent beyond its original primary use as replacement therapy in patients with humoral immune deficiency. The use of this agent will also be referred to in this chapter as it is now being used in many disorders in which plasma exchange is effective, but the convenience and safety of IVIG therapy is preferred as an alternative. However, the underlying principles in managing autoimmune diseases in which IVIG is used are similar to those of therapeutic plasma exchange. The mechanism of action of IVIG as an immunomodulatory agent remains controversial and it is likely, as fine plasma exchange, that there is more than one mechanism in play. Therapeutic efficacy of IVIG has been established in controlled trials for a range of diseases including idiopathic thrombocytopenic purpura, Kawasaki disease, Guillain-Barré syndrome, dermatomyositis, and others. There is compelling evidence that IVIG can modulate immune reactions of T-cells, B-cells and macrophages, not only interfering with antibody production and degradation, but also modulating the complement cascade and cytokine networks.

## RATIONALE FOR PLASMA EXCHANGE

Theoretically, plasma exchange should be effective to treat any disorder in which there is a pathogenic circulating factor responsible for the disease. However, this premise is probably too simplistic, and other mechanisms may contribute to its beneficial effects (Table 90.1). It is a non-specific procedure, which brings about numerous, potentially undesirable, alterations in the plasma's *milieu interieur*.

## PATHOPHYSIOLOGY OF AUTOIMMUNE DISEASE

Autoimmune disease originates from the breakdown of immunoregulation (i.e. immune tolerance), allowing the immune system to become autoaggressive. Autoimmune diseases having underlying humoral mechanisms result from either a circulating autoantibody against a self-antigen (alone or in combination with an environmental antigen) or circulating immune complexes (which may be deposited in the microcirculation of various organs, resulting in end-organ damage). Cellular and tissue damage is affected by the autoantibody or immune complexes activating the cellular and humoral components of the inflammatory response. The circulating proteolytic systems involved include the complement, coagulation, fibrinolytic and kinin systems. On the cellular side, neutrophils and macrophages are involved, with eosinophils and basophils also playing a part.

The varied clinical manifestations of autoimmune disorders relate more to the cell, tissue or organ involved, rather than the pathophysiological process. However, basic pathophysiological mechanisms by which autoimmune diseases occur need to be understood in order to standardise treatment. Although some cells of the host defence system, in particular the macrophages and lymphocytes, may have special differentiation appropriate to individual organs, their basic functional processes are not all that dissimilar between different organs.

**Table 90.1** Rationale for plasma exchange

Removal of circulating toxic factor antibodies
Monoclonal antibodies
Autoantibodies
Alloantibodies, immune complexes, chemicals, drugs
Depletion of the mediators of inflammation
Replacement of deficient plasma factor(s)
Potiation of drug action
Enhanced reticuloendothelial function
Altered immunoregulation
Potentiating effects of plasma exchange on other modes of therapy

In general, autoimmune disease can be an acute, self-limiting ('one hit') disorder, intermittent or a chronic perpetuating disorder. Acute autoimmune disease may have an identifiable trigger, such as an infection, followed by a 10-day to 3-week gap until the pathogenic humoral or cellular factors appear in the circulating blood. At this point, end-organ damage commences, and clinical features of the disease appear.

The course of the disease will be determined by several factors:

- biological function and importance of the system involved
- extent of damage
- replaceability or otherwise of the cells under attack
- time course of the damaging insult

The extent of damage is a product of the:

- characteristics of the antibodies or lymphocytes involved (e.g. antibody affinity, complement fixing capabilities and titre)
- function of other components of the host defence system (e.g. neutrophils, platelets, proteolytic systems and reticuloendothelial system)
- presence of other aggravating factors (e.g. infection, hormonal responses and circulatory responses)

The kinetics of the end-cell involved in the immunological damage is relevant in determining the final outcome of the disease. Ultimate recovery of organ function after 'burn out' of a self-limiting autoimmune disease, or control of a chronic autoimmune disease, is determined by the ability of the cell to replace and restore function to normal.

Cells are broadly divided into three kinetic characteristics:

- *Continuous replicators*: these cells are continuously replaced in the normal state. They are readily replaced when damaged, and if the immunological insult is removed or controlled, full replacement of the end-cells occurs. This is typically seen with the haemopoietic system, the cells lining the gut and skin cells.
- *Discontinuous replicators*: these are cells that are not being constantly replaced in the normal state, but

when damaged, cell division is initiated and replacement occurs. This is seen with hepatocytes, renal tubular cells and the neuronal Schwann cells.

- *Non-replicating cells*: when damaged, these cells are irreplaceably destroyed with permanent loss of function. This is seen with neuronal cells, muscle cells and renal glomeruli.

The clinical features and final outcome of any autoimmune disease can thus be seen to be determined by many different factors, including the ability of the end-organ to repair following removal or control of the immunological insult. In many self-limiting autoimmune diseases, if the end-cell is a continuous or intermittent replicator, full recovery can be expected, as long as appropriate support to end-organ function and life support is given during the acute phase of the illness. Examples are acute tubular necrosis, acute demyelination, acute hepatic failure and some forms of marrow aplasia. However, in disorders with non-replicating cells such as acute glomerulonephritis, therapy must be aimed at removing the immunological insult or dampening its damaging effects as soon as possible, so as to minimise irreparable damage to the end-cells and thus long-term organ function. Immunological mediators may also produce disease without direct destruction of end-cells. This occurs when autoantibodies develop against cell receptors, with blocking or destruction of the receptor as is typically seen in myasthenia gravis and thyrotoxicosis.

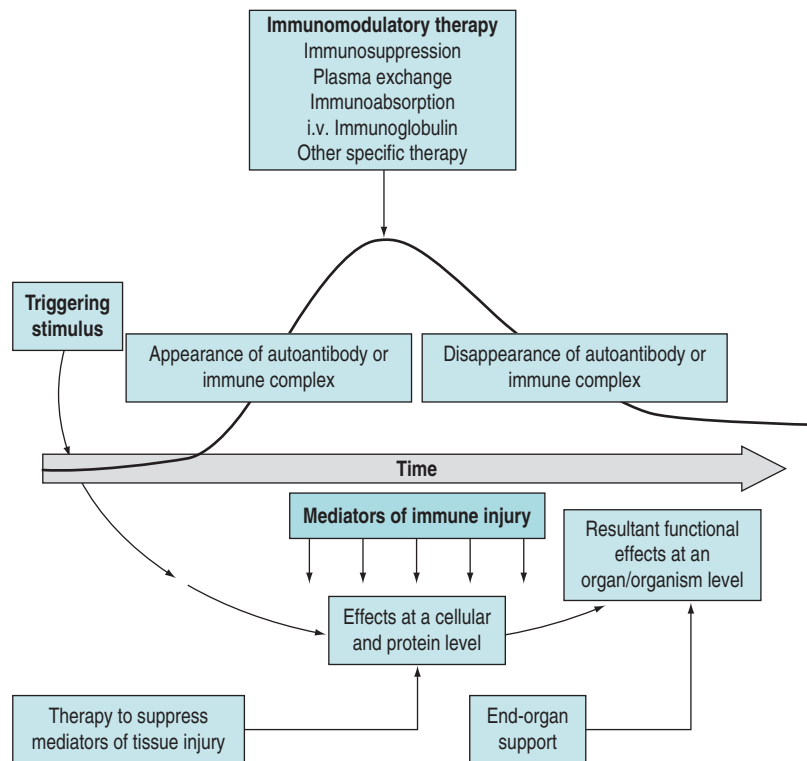

Therapy in acute and chronic autoimmune disease aims to minimise irreparable end-organ damage and support patients during the acute illness. This therapy may include:

- non-specific therapy to suppress the effector mechanisms, e.g. corticosteroids, antiplatelet therapy, non-steroidal anti-inflammatory drugs, anticoagulation and depletion of humoral effector mechanisms by plasma exchange or defibrination
- therapy to reduce the circulating levels of a humoral factor is achieved with plasma exchange or immunoadsorption technique
- specific or broad-spectrum immunosuppressive agents to suppress or block the immune response, e.g. corticosteroids, cytotoxic agents, antilymphocyte globulin, high-dose intravenous gammaglobulin therapy
- therapy directed at altering reticuloendothelial function, which may then have effects on autoantibody and immune complex clearance, or clearance of circulating damaged cells
- intravenous immunoglobulin immunomodulatory therapy

As most disorders are multifactorial, it is unlikely that a single form of therapy will be successful. A multipronged approach to therapy needs to be planned following an analysis of the basic underlying pathophysiology. The stage of the disease is also important (Figure 90.1). Clearly, plasma exchange will have a different response when autoantibody production is rising rapidly, compared with a stage when

**Figure 90.1** The therapy of ‘one hit’ autoimmune disease.

autoantibody has ceased production. Also, immunoregulation is a complex process, and therapies may interfere at different points in the immune mechanisms.

In some circumstances, specific and directed therapy may attack the most relevant link in the pathophysiological chain, but overall multiple approaches to therapy may be required. In general, plasma exchange is a temporising procedure and concomitant immunosuppressive therapy is required to maintain control. Plasma exchange for autoimmune disease should generally be regarded as a first step in immunomodulatory therapy, and restricted to acute or fulminant situations in which autoantibodies or immune complexes are responsible for life-threatening or end-organ damaging complications. There are some situations in which the humoral factor may be only transient (‘one antigen hit’ disorders), and no follow-up immunosuppression is required (e.g. acute postinfectious polyneuritis). Increasing monoclonal antibody therapy with rituximab (an anti-CD20 antibody) is finding a role in the longer term management of autoimmune diseases.<sup>2,3</sup>

The availability and recognition of the immunomodulatory effects of intravenous immunoglobulin has resulted in an exponential increase in its use in immune and inflammatory disorders, with its availability being one of the main drivers of the supply of human-derived plasma products. In most of the immune and inflammatory disorders in which plasma exchange has been used, intravenous

immunoglobulin has been used. The mechanisms of action of intravenous immunoglobulin remain controversial. Intravenous immunoglobulin, fractionated from normal human plasma, was introduced as a replacement therapy for humoral immunodeficiency disorders, but is now widely used for a range of autoimmune and inflammatory diseases. Progress is being made in understanding the complex mechanisms by which IVIG has immunomodulatory actions. The mechanisms of action of IVIG involve modulation of expression and function of immunoglobulin Fc receptors, interference with activation of the complement system and the cytokine and immunoglobulin idiotype networks, and regulation of cell growth. There is also evidence for effects on activation, differentiation and effector functions of dendritic cells and T and B lymphocytes.<sup>4</sup>

**TECHNICAL CONSIDERATIONS**

Cell separators available for plasma exchange therapy are broadly divided into two groups:<sup>5</sup>

- machines which use centrifugation for the separation and are also suitable for specific separation and removal of blood components (e.g. plasmapheresis, thrombopheresis and leukopheresis)
- machines which separate by membrane filtration and can only be used for separation of plasma components

Either of these techniques for plasma exchange can be combined with immunoabsorption techniques, in which immunoglobulins are specifically or non-specifically removed.<sup>6</sup>

As plasma is removed, it is replaced volume for volume with a solution of adequate colloid activity (e.g. 5% albumin) and appropriate electrolyte composition. Although the levels of other plasma proteins are reduced by plasma exchange, there are rarely clinically significant effects. However, if extremely large volumes are exchanged, or exchanges are done frequently, it may be necessary to replace some plasma proteins. In patients with coagulation factor deficiencies or immunodeficiency, fresh frozen plasma is usually required.

### INDICATIONS (TABLE 90.2)

Plasma exchange is most beneficial for immunoproliferative and autoimmune diseases. In some conditions with unclear pathophysiology, beneficial effects of plasma exchange may be due to infusion of a deficient

**Table 90.2** Acute diseases in which plasma exchange may be beneficial\*

#### Immunoproliferative diseases with monoclonal immunoglobulins

- Hyperviscosity syndrome
- Cryoglobulinaemia
- Renal failure in multiple myeloma

#### Autoimmune diseases due to autoantibodies or immune complexes

- Goodpasture's syndrome
- Myasthenia gravis
- Guillain-Barré syndrome
- Chronic inflammatory demyelinating polyneuropathy (CIDP)
- Stiff-man syndrome
- Systemic lupus erythematosus
- Fulminant antiphospholipid syndrome
- Thrombotic thrombocytopenic purpura
- Haemolytic uraemic syndrome
- Rapidly progressive glomerulonephritis
- Coagulation inhibitors
- Autoimmune haemolytic anaemia
- Pemphigus
- Paraneoplastic syndromes

#### Conditions in which replacement of plasma may be beneficial ± removal of toxins

- Disseminated intravascular coagulation
- Multiorgan dysfunction syndrome
- Overwhelming sepsis syndromes (e.g. meningococcaemia)

#### Conditions in which the mechanisms are unknown

- Reye's syndrome

#### Removal of protein-bound or large molecular weight toxins

- Paraquat poisoning
- Envenomation?

\*This is an incomplete list and only includes disorders that are relatively common or in which plasma exchange has a definitive role to play.

component in the replacement plasma, rather than removal of a circulating factor.

### MONOCLONAL ANTIBODIES ASSOCIATED WITH IMMUNOPROLIFERATIVE DISEASES

Monoclonal immunoglobulins are a classic feature of multiple myeloma and Waldenström's macroglobulinaemia, but may also be associated with other lymphoproliferative disorders. These monoclonal proteins may be associated with numerous clinical effects, many of which may be reversed by plasma exchange.

#### HYPERVISCOSITY SYNDROME

Characteristic clinical features of hyperviscosity in association with monoclonal proteins include visual disturbance, neurological dysfunction and hypervolaemia, all of which can be rapidly relieved by plasma exchange.<sup>7</sup>

#### HAEMOSTATIC DISTURBANCES

Monoclonal proteins may impair haemostasis by adversely affecting platelet function or by inhibitory effects on coagulation factors. Plasma exchange is usually effective in controlling haemorrhage and may also be helpful in preparing patients for surgery.

#### RENAL FAILURE

The development of renal failure in the course of multiple myeloma is generally regarded as a sign of poor prognosis. In most cases, the renal failure is multifactorial in origin, but some of these factors may be reversible by plasma exchange. Patients presenting acutely with hyperviscosity, dehydration and hypercalcaemia may show recovery of renal function following adequate hydration, alkaline diuresis and plasma exchange.

### IMMUNOLOGICAL DISEASES

#### DISEASES MEDIATED BY SPECIFIC AUTOANTIBODIES

##### Goodpasture's syndrome

Circulating antiglomerular basement membrane antibodies can be demonstrated in most cases of Goodpasture's syndrome. The disease classically has a fulminant presentation with rapidly progressive renal failure and life-threatening pulmonary haemorrhage. Early diagnosis and intensive plasma exchange may be necessary to preserve renal function and control pulmonary haemorrhage. Patients who are already in anuric renal failure rarely show improvement in renal function.<sup>8</sup>

##### Myasthenia gravis

Removal of the acetylcholine receptor autoantibody is associated with clinical improvement in the majority of patients with this disorder. The beneficial effects of plasma exchange are usually transient, and the procedure should normally be used in conjunction with other forms of therapy (see Chapter 49). The major role for plasma exchange is usually in myasthenic crisis, in patients whose

condition is resistant to other forms of therapy, and prior to surgery. Therapy can be monitored by acetylcholine receptor autoantibody assays and respiratory function tests. Patients undergoing plasma exchange may transiently deteriorate during the procedure, due to a combination of the physical exertion and removal of medication from the circulation, and adequate ventilatory support should be available. IVIG may also be used in myasthenia gravis.<sup>9–11</sup>

#### **Stiff-man syndrome**

Stiff-man syndrome (STS) is a rare neurological disorder characterised by involuntary axial and proximal limb rigidity and continuous motor unit activity on electromyography. Autoantibodies to glutamic acid decarboxylase are usually demonstrable. Although plasma exchange is successful in STS, those who are autoantibody negative are less likely to respond.<sup>12,13</sup>

#### **Autoimmune haematological disorders**

Haemostatic failure due to autoantibodies directed against coagulation factors may present a major management problem. Antibodies directed against factor VIII are the commonest, occurring spontaneously or in association with replacement therapy in haemophiliacs. First-line therapy in patients with coagulation factor inhibitors usually requires activated factor VII therapy with recombinant FVIIa or appropriate prothrombin concentrates.<sup>14</sup>

#### **IMMUNE COMPLEX DISEASE**

##### **Rapidly progressive glomerulonephritis**

Immune complex-induced rapidly progressive glomerulonephritis may occur by itself or be associated with several systemic disorders (e.g. systemic lupus erythematosus, polyarteritis nodosa and Wegener's granulomatosis).<sup>15–17</sup> Plasma exchange may result in improvement in renal function even in patients who present with anuria. The decomplementing and defibrinating effects of plasma exchange may be partly responsible for clinical improvement. The therapeutic role of plasma exchange in rapidly progressive glomerulonephritis is difficult to assess, but most experienced physicians feel that the procedure leads to a more rapid and complete recovery of renal function in fulminant, rapidly deteriorating cases. However, the ultimate prognosis of the disease depends on adequate immunosuppression to inhibit immune complex formation, or spontaneous disappearance of the inciting antigen.

##### **Systemic lupus erythematosus (SLE)**

Plasma exchange has a role in acute life-threatening or organ-damaging relapses of SLE. Rapid deterioration in renal function, cerebritis and acute fulminant lupus pneumonitis are clinical situations in which plasma exchange should be considered.<sup>18</sup>

##### **Cryoglobulinaemia**

The various forms of cryoglobulinaemia may be associated with vasculitis or hyperviscosity. In some cases, there may

be an acute fulminant presentation with cutaneous vasculitis, renal failure and neurological impairment. In this situation, plasma exchange should be considered an urgent definitive form of therapy.

#### **OTHER IMMUNE-MEDIATED DISEASES**

##### **Renal transplant rejection**

Humoral mechanisms appear to play a part in hyperacute renal allograft rejection. Plasma exchange  $\pm$  IVIG may be useful in tiding patients over episodes of acute graft rejection, but results of clinical trials have been conflicting.<sup>19,20</sup> General opinion is that plasma exchange helps in a limited number of patients who cannot be currently preselected by any clinical or laboratory criteria.

##### **Thrombotic thrombocytopenic purpura**

Thrombotic thrombocytopenic purpura (TTP) is a potentially fulminant and life-threatening disorder characterised by platelet microthrombi in small vessels, resulting in microangiopathy. The clinical syndrome is manifest by the pentad of thrombocytopenia, microangiopathic haemolytic anaemia, fever, renal dysfunction and neurological abnormalities. Abdominal symptoms, hepatic dysfunction and pulmonary abnormalities may also occur. With the appropriate clinical features, thrombocytopenia and a microangiopathic blood film, diagnosis is established.

TTP has been linked to a severe deficiency in ADAMTS13 with metalloprotease activity, with its target cleavage sequence in von Willebrand factor (vWF). The presence of an autoantibody inhibitor to this vWF reducing metalloproteinase has been documented in patients with both acute TTP and those with chronic relapsing forms. In normal plasma, vWF undergoes proteolysis by a specific protease, and deficiency of this cleaving protease reduces or abolishes the plasma clearance of ultralarge vWF multimers, resulting in intravascular aggregation of platelets, particularly at sites of intravascular shear stress. The inhibitor to the metalloproteinase has been demonstrated to be an IgG autoantibody.

There is a primary idiopathic form of the disease that usually has an acute presentation and probably has an underlying autoimmune mechanism. This form may be associated with a variety of prodromal infections (viral or bacterial). Bacterial cytotoxins, produced by *Shigella dysenteriae* type 1 and certain *Escherichia coli* serotypes, have been related to TTP and haemolytic uraemic syndrome (HUS), probably by initiating damage to vascular endothelial cells, possibly via cytokine mechanisms. TTP may be associated with various drugs (cytotoxic agents), toxins and bites. Cytomegalovirus (CMV), human immunodeficiency virus (HIV) and herpes viruses have also been implicated. Chemotherapy-associated TTP/HUS is being increasingly recognised and may be associated with a range of cytotoxic medications. Severe microangiopathy resembling TTP has also been reported as a complication of acute graft-versus-host disease in patients receiving ciclosporin prophylaxis following allogeneic bone marrow transplant.

TTP used to be a fatal disease in 90% of patients, but dramatic improvement in its outcome has occurred over the past two decades with the development of effective therapy. Plasma exchange has become the cornerstone of the treatment with fresh frozen plasma replacement.<sup>21,22</sup> Cryoprecipitate-poor plasma (depleted in vWF) may offer advantages over whole fresh frozen plasma. It is now possible to achieve remissions in the majority of patients and cures are now common, though unfortunately relapse may occur. The clinical course at relapse is usually milder than the disease at presentation and less aggressive therapy may be needed.

#### **Haemolytic uraemic syndrome (HUS)**

This syndrome has many similarities to TTP, but renal involvement in contrast to cerebral in TTP is the hallmark in association with microangiopathy and thrombocytopenia.<sup>23</sup> The prognosis and approach to management of HUS is similar to TTP. It usually occurs in children (related to bacterial or viral infections), but may rarely be seen in adults, in whom the disease may take a more chronic and sinister course. In adult cases medications are commonly implicated.

#### **Inflammatory demyelinating neuropathies and the Guillain-Barré syndrome (GBS)**

This acute self-limiting disease in which an acute demyelinating neuropathy occurs (usually following a viral infection) commonly results in admission to the intensive care unit (ICU) (see Chapter 49). There is demyelination due to postinfectious autoimmunity, with both cellular and humoral arms of the immune system attacking myelin. There is now wide experience in the use of plasma exchange and IVIG therapy in GBS, with controlled trials substantiating its benefits of shortening of the illness and complications. Therapy should be instituted early.<sup>11,24</sup> As GBS also responds to high-dose IVIG there is debate as to which should be the first line of therapy. Decisions are usually made on the basis of local logistics and economics as the therapies are comparable in relationship to efficacy and safety.<sup>25</sup> In some cases the onset of recovery after therapy may be delayed, probably due to time for remyelination to occur. Some patients show rapid improvement after plasma exchange, suggesting the presence of neuronal blocking factors. Chronic inflammatory demyelinating peripheral neuropathy (CIPD) is related to GBS, and plasma exchange and/or IVIG have important roles in treatment, in many cases requiring long-term therapy.

### **COMPLICATIONS**

Plasma exchange is a relatively safe procedure, but close supervision by experienced physicians and apheresis operators is essential. A sound understanding of the haemodynamic, biochemical, haematological and immunological effects of plasma exchange is of paramount importance.

Potential complications of plasma exchange include fluid imbalance, reactions to replacement fluids, vasovagal reactions, pyrogenic reactions, hypothermia, embolism (air or microaggregates), hypocalcaemia, anaemia, thrombocytopenia, haemostatic disturbances, hepatitis, hypogammaglobulinaemia, and altered pharmacokinetics of drugs. Prevention and treatment of most of these complications are usually obvious, but specific mention should be made of the following.

#### **CIRCULATORY EFFECTS**

Any extracorporeal procedure is likely to lead to problems of circulatory instability. Intravascular volume changes, vasovagal reactions, medications and infusion fluids may all alone, or in combination, be responsible for circulatory problems. If there are no associated oxygen transport defects, the patient will usually be able to compensate. However, if there are pre-existing defects (e.g. altered blood volume, vascular disease or renal failure), close monitoring is essential. A strict fluid and electrolyte balance should be kept at all times, both during the plasma exchange and as a daily tally.

#### **PLASMA ONCOTIC PRESSURE**

Most patients compensate for minor fluctuations in plasma oncotic pressure (COP). Patients who have oedema or local factors predisposing to interstitial fluid accumulation (e.g. raised intracranial pressure, interstitial pulmonary oedema, deep-venous thrombosis and renal impairment) need close attention.

#### **INFECTION**

Many patients who are undergoing plasma exchange are already immunosuppressed, either due to their disease or secondary to drug therapy. In patients requiring recurrent and frequent plasma exchange, attempts should be made to maintain serum immunoglobulin levels. When fresh frozen plasma is not used as replacement fluid, the bactericidal and opsonic activities of blood are probably impaired, and it is probably advantageous to infuse at least 2 units of fresh frozen plasma at the conclusion of the procedure. At the completion of a course of plasma exchange consideration may need to be given to a dose of intravenous gammaglobulin.

#### **HAEMOSTASIS**

Plasma exchange causes perturbations in the haemostatic system which may result in either bleeding or thrombosis. The significance of these alterations will depend largely on the volume and frequency of exchange, pre-existing defects in the system, anticoagulation, other risk factors for thrombosis, replacement fluids and invasive procedures.

### REACTIONS TO REPLACEMENT FLUIDS

The rapid infusion of any blood component may be associated with allergic or vasomotor reactions. Plasma exchange is a rather unique situation in which blood or blood products and plasma substitutes are being infused at resuscitation rates into normovolaemic, normotensive patients.

### EFFECTS OF INTRAVASCULAR PROTEINS

If plasma protein fractions or albumin are being used for replacement fluids, not only will coagulation and complement components be depleted, but various transport and binding proteins in the circulation will be significantly reduced. These may have significant effects on drug activity and elimination (e.g. antithrombin III levels may have effects on heparin activity). The effects of corticosteroids may be potentiated after plasma exchange owing to a reduction in binding proteins.

# Haemostatic failure

James P Isbister

Failure of haemostasis is common in critically ill patients and may be complex and multifactorial in pathogenesis. As haemostatic failure may complicate a wide range of medical, surgical and obstetric disorders, definitive diagnosis and specific therapy can significantly impact on outcome. Frequently, complex tests are required for definitive diagnosis, but the urgency of the situation cannot always wait for the results, and therapy may be initiated on clinical evidence with minimal laboratory information. Consultation with a clinical haematologist is strongly recommended.

## NORMAL HAEMOSTASIS

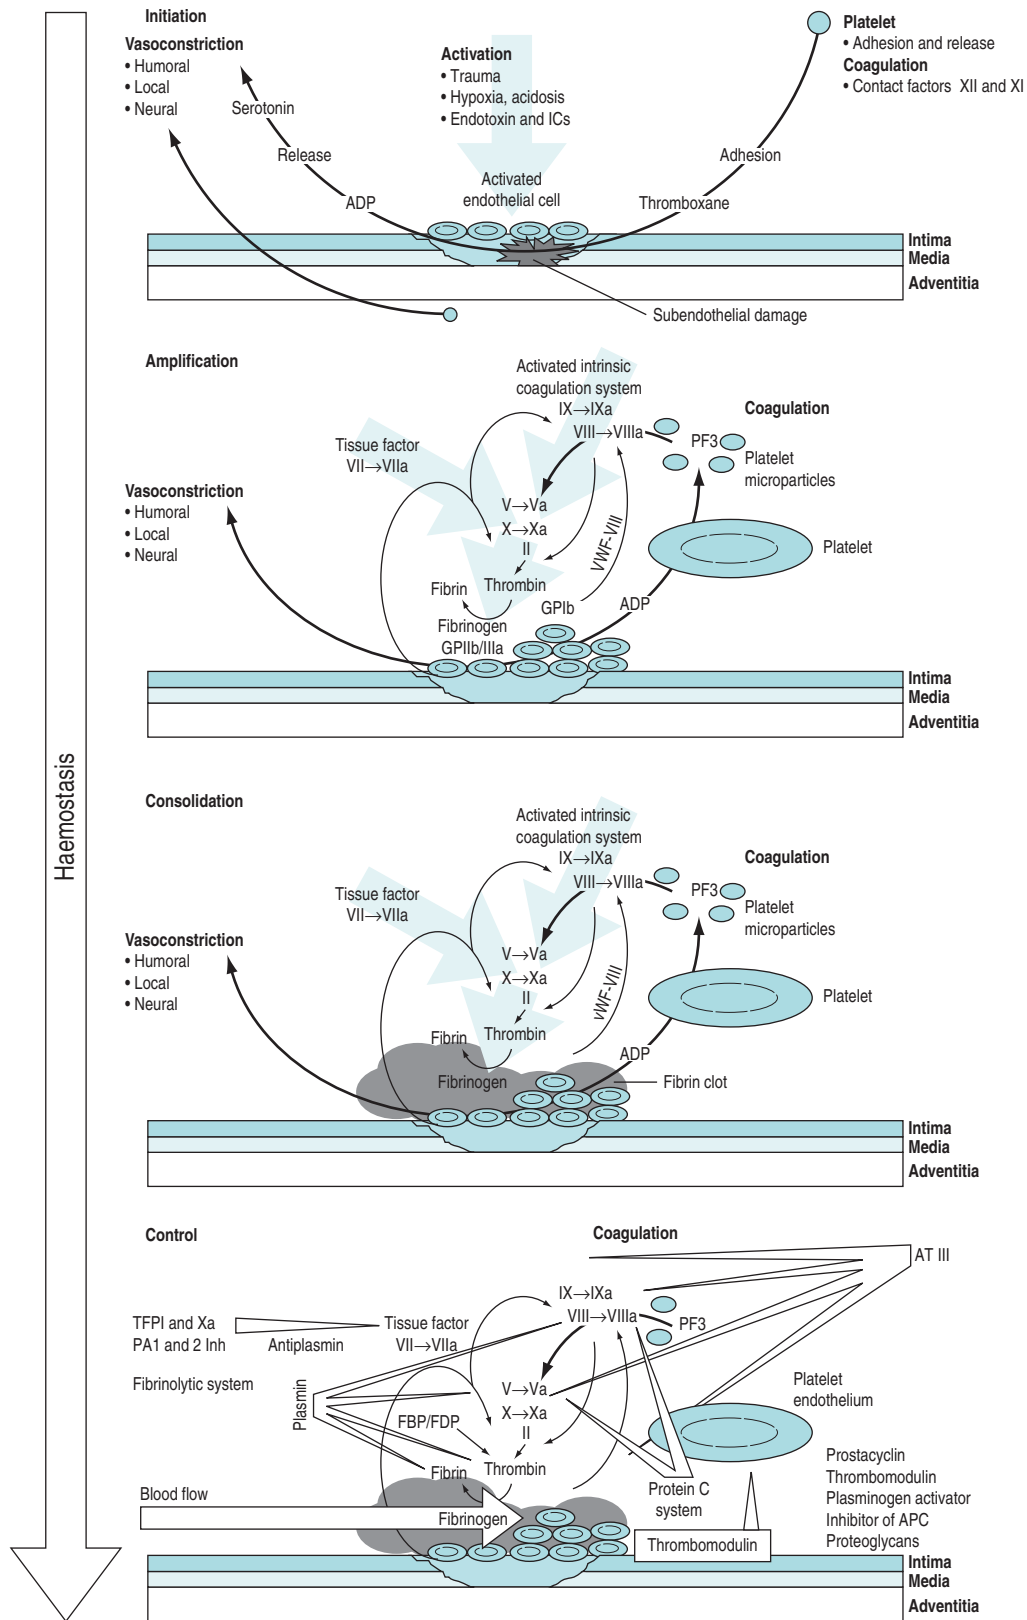

The haemostatic system is a delicately controlled component of the host defence system, the role of which is to initiate haemostasis where and when required and in adequate, but not in excessive, amounts. The system closely interacts with other components of the host defence system, including the acute stress responses, inflammation, healing and immune functions. There has been a paradigm shift in our understanding of the haemostatic system from one of interacting humoral factors to an integrated cell-based system.<sup>1,2</sup> In view of the increasing range of focused therapies available that act on the haemostatic system to modulate its activity, it is important that core aspects of the structure and function of the system are summarised.

The conversion of blood from its fluid to solid state is an increasingly understood physiological process. The triad of vascular constriction, platelet plugging and fibrin clot formation forms haemostatic plugs and provides the framework on which haemostasis operates (Figure 91.1) and sets the scene for healing to occur. Thrombin is the potent proteolytic enzyme of the coagulation sequence converting fibrinogen to fibrin-soluble monomers, which subsequently polymerise to form the fibrin clot. Fibrinogen is the bulk protein of the coagulation system and fibrin is the end-product of this cascade of proteolytic activity, in which precursor coagulation proteins are activated to potent proteolytic enzymes, with the aid of cofactors, to produce active precursors further down the coagulation 'amplifier'. The polymerised fibrin is further

acted on by factor XIII to form a stable fibrin clot. The process of thrombin generation in small amounts initially occurs in relationship to tissue factor-bearing cells and the process is subsequently transferred to the activated platelet surface where amplification occurs.

Following injury, vascular constriction reduces bleeding, and allows time to initiate haemostasis. With large volume haemorrhage, resulting systemic hypotension is an important physiological mechanism to minimise blood loss and facilitate stabilisation of the haemostatic plug. Controlled or 'tolerated' hypotension is now accepted as an important aspect of managing critical haemorrhage.<sup>3,4</sup> This vascular constriction is further accentuated by vasoconstrictors released in association with platelet plug formation. Vascular endothelial cells play an active part by synthesising substances which act at the membrane surface and/or interact with platelets and the coagulation system (e.g. prostacyclin, antithrombin III, plasminogen activator, von Willebrand factor, thrombomodulin, heparin cofactor II and nitric oxide).<sup>5</sup> Following the initial vascular reactions, successful haemostasis depends on adequate numbers of functioning platelets, coagulation cascade function, and poorly understood contributions from red cells and leukocytes.

The coagulation system is triggered via the extrinsic pathway, by which damaged tissues expose tissue factor (TF). Tissue factor is a membrane-bound protein present in cells surrounding the vascular bed. Factor VII and VIIa (a small amount circulates normally in the blood) are bound to TF activating factor X. Factor Xa interacts with the cofactor Va to form prothrombinase complexes with the generation of a small amount of thrombin on the cell surface. Factor IX is also activated by the TF/VIIa complex; it does not play a significant role in the initiation phase of coagulation, but diffuses across to platelets in the vicinity that have adhered in proximity to the site of the TF-bearing cells binding to a specific platelet surface receptor and interacting with cofactor factor VIIIa, leading to activation of factor X directly on the platelet surface. The concept of the intrinsic and extrinsic systems is more of historical and laboratory significance as it is now clear that such a division is artificial, but the concept still has value in performing and assessing haemostatic laboratory tests.

**Figure 91.1** Overview of the haemostatic system. APC, activated protein C; AT III, antithrombin III; FBP, fibrinogen breakdown product; FDP, fibrinogen degradation product; ICs, immune complexes; TFPI, tissue factor pathway inhibitor; vWF, von Willebrand factor.

Von Willebrand factor (vWF) is a multimeric glycoprotein that plays a central role in haemostasis by mediating adhesion of platelets to the exposed subendothelium and linking the primary vascular/platelet phase with coagulation by being the carrier protein for coagulant factor VIII which dissociates from vWF to form a complex on the activated platelet surface with IXa (tenase complex) to activate factor X to Xa. Further vWF is released from Weibel–Palade bodies in nearby endothelial cells and platelet  $\alpha$ -granules. Platelets interact with vWF via their surface glycoprotein Ib-IX-V complexes. This slows their motion along the subendothelium, allowing receptor interaction leading to platelet binding to collagen. Adhesion to collagen is facilitated by the GPIa-IIa receptor. GPIIb-IIIa can then bind vWF, fibrinogen, fibronectin, vitronectin and thrombospondin, providing further important sites of anchorage for the spreading platelet. The initiation phase of platelet plug formation leads to the development of a platelet monolayer over the injured subendothelium. With the concomitant activation of the coagulation cascade there is local generation of thrombin. Thrombin is a potent platelet agonist via the protease-activated receptor (PAR) to produce a haemostatic plug. Further extension occurs by platelet recruitment by platelet agonists, such as thrombin and mediators, adenosine 5-diphosphate (ADP) and thromboxane A<sub>2</sub> released directly from platelets. P-selectin is expressed during activation and also plays a role in platelet-to-platelet cohesion.

Parallel to and within the coagulation system are complex feedback mechanisms to ensure fine-tuning and protection against inappropriate and excessive activation.<sup>6–8</sup> There are several inhibitory proteins, including antithrombin III, thrombomodulin, proteins C and S, tissue factor pathway inhibitor as well as the fibrinolytic system, which are all important in controlling the degree and site of fibrin formation. Indeed, thrombin itself acts as either a procoagulant or an anticoagulant depending on context. Massive activation, as may be seen in trauma and severe infections, can precipitate systemic activation, but in general, the system is well controlled and activity is localised to the area of the stimulus. Perturbations in this complex defence system can produce a wide range of clinical disorders from excessive arterial or venous thrombosis, microvascular obstruction and atheroma to haemostatic failure.

#### SYSTEMIC HAEMOSTATIC ASSESSMENT

There may be clinical features suggesting local or generalised failure of the haemostatic system (Figure 91.2). Clinical history is important, especially with respect to previous bleeding problems, family history, comorbid medical conditions and medications. The nature of surgery or an invasive intervention may have haemostatic issues that need specific consideration.

#### TESTS OF THE HAEMOSTATIC SYSTEM

Tests of whole blood clotting time and clot observation do not generally have a role in assessing haemostasis. However, in emergency settings, while waiting for laboratory results, observation of blood collected into a glass tube and maintained at 37°C for clot formation, size, retraction and possible lysis may provide crude information of a possible coagulopathy. The thromboelastogram is a more accurate and controlled procedure for ‘holistic’ assessment of the haemostatic system at the bedside, but requires close attention to technique and quality control. In most clinical settings, laboratory haemostatic screening tests are readily available, with near-patient testing techniques continuing to improve. A full blood count, prothrombin time (PT), activated partial thromboplastin time (APTT), fibrinogen level, D-Dimer  $\pm$  thrombin clotting time (TCT) provide a broad screen for most clinically significant haemostatic disorders<sup>9–11</sup> (Figure 91.3). Based on these results, and following consultation with a haematologist, further specific tests of haemostasis may be performed (e.g. mixing studies, factor assays, platelet function tests and test of fibrinolytic function). In broad terms:

- PT tests the integrity of the extrinsic system
- APTT the intrinsic system
- TCT fibrinogen conversion
- D-Dimer assay measures the breakdown products from lysis of fibrin

The haemostatic system optimally functions at 37°C and laboratory coagulation tests are performed at 37°C. Hypothermia may severely impair a patient’s systemic and local haemostasis despite the system being structurally intact and laboratory tests normal.

The laboratory investigation of a patient with a potential haemostatic defect depends on the degree of urgency. It may be necessary to administer blood component therapy without a definitive haemostatic defect being established. In elective settings, the defect can be accurately identified, problems pre-empted and specific blood component therapy administered prophylactically or therapeutically. A detailed clinical history and screening laboratory investigations prior to elective procedures will often avert undiagnosed emergency haemostatic crises.

There are several important principles in the collection of blood samples for haemostatic investigations. Most samples are collected into citrated tubes and the amount of anticoagulant in the tube is related to the intended amount of blood to be collected into the tube. It is important that the correct amount of blood is added to the tube and gently mixed. Attention to venepuncture technique is crucial and rapid transfer of the sample to the laboratory is important. Contamination of the sample with tissue factor due to traumatic venepuncture will activate the sample and invalidate results. Collection from vascular access lines may result in diluted or heparin-contaminated samples. Incorrect

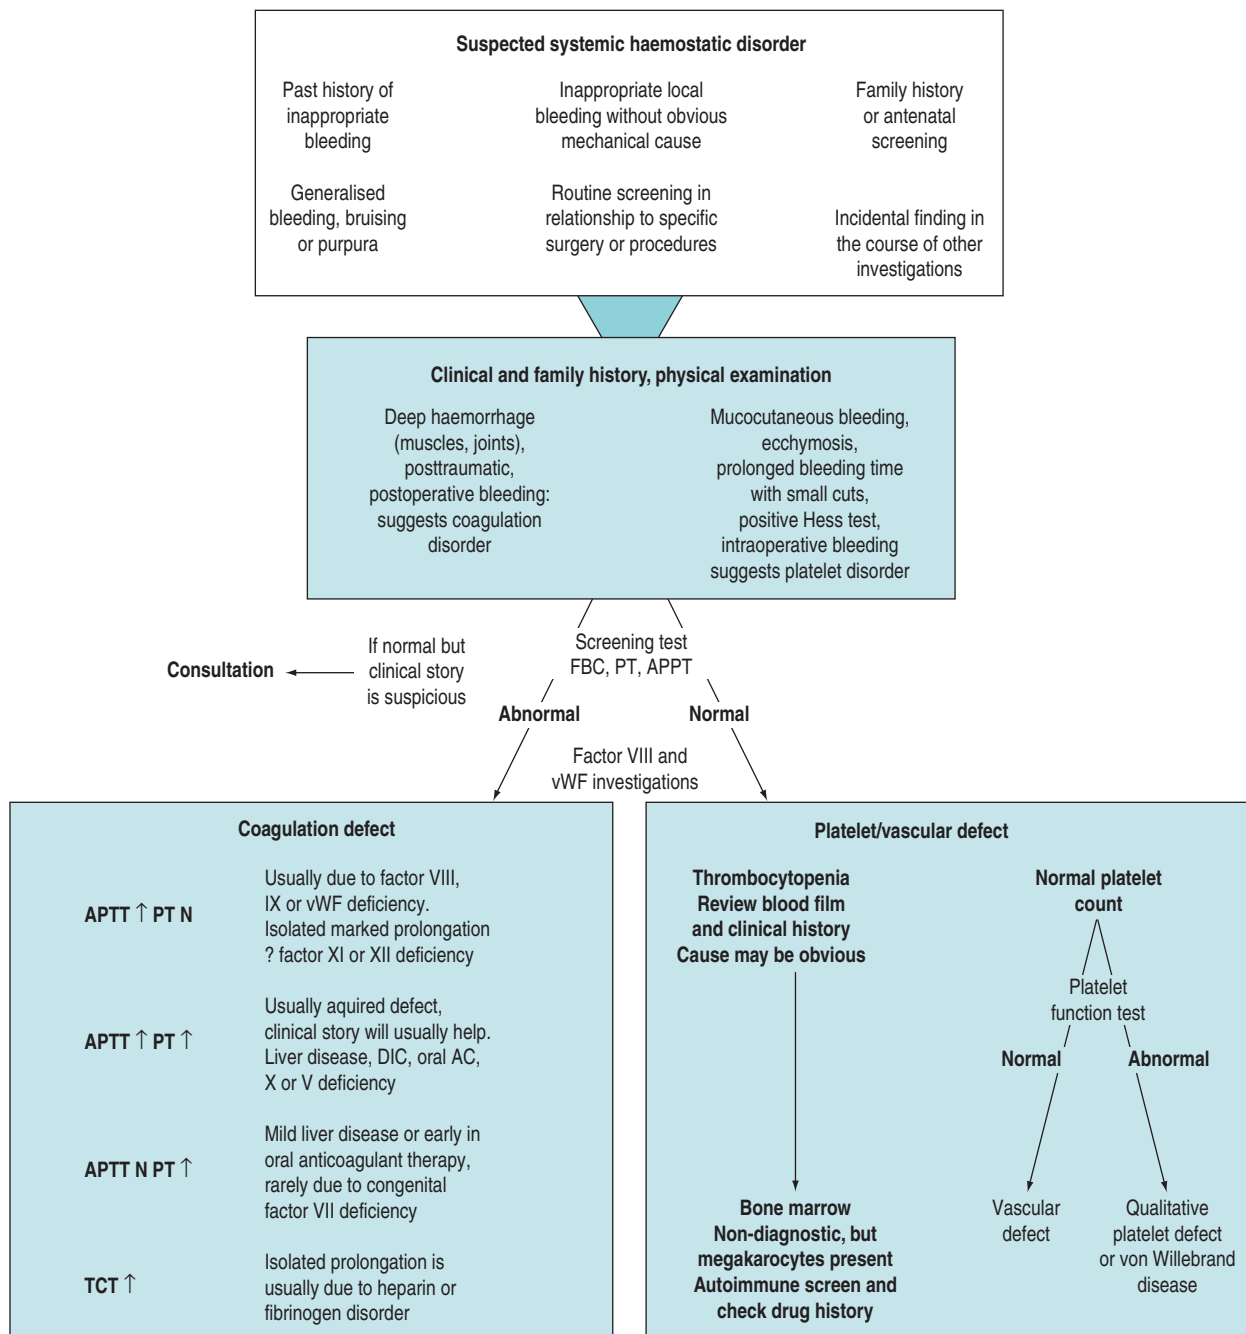

Figure 91.2 Coagulation tests.

laboratory results may be more dangerous to a patient than no results at all.

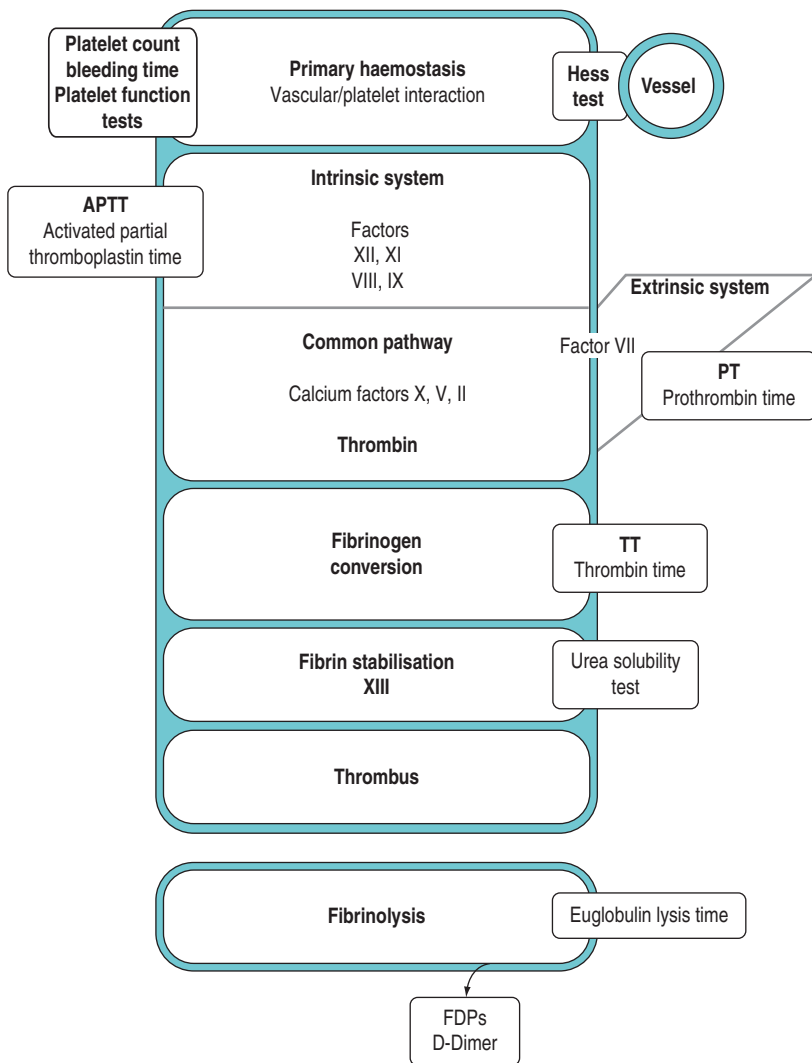

**PLATELET COUNT (PC) (NORMAL 150–400 × 10<sup>9</sup>/l)**

The counting of platelets is performed as part of the full blood count by automated cell counters. It is not possible to perform accurate platelet counts on ‘fingerprick’ blood.

**BLEEDING TIME (BT) (NORMAL 3–9 MINUTES)**

The bleeding time is progressively prolonged when the platelet count falls below 75–100 × 10<sup>9</sup>/l assuming platelet function is normal. It is also prolonged when platelet function is defective, in capillary/vascular disease and in some coagulation defects. The bleeding time is an invasive and operator-dependent test. It is not good for

**Figure 91.3** Investigations for a suspected haemostatic defect. FDPs, fibrinogen degradation products.

screening unselected patients and has generally been replaced by the platelet function analyser, PFA-100(R).

**PROTHROMBIN TIME (PT) (NORMAL RANGE < 3 SECONDS ABOVE THE CONTROL)**

The PT is a test of the extrinsic coagulation and prolongation may be caused by factor VII deficiency, liver disease, vitamin K deficiency or oral anticoagulant therapy. The PT is also expressed as the international normalised ratio (INR), especially when used for anticoagulant control.

**ACTIVATED PARTIAL THROMBOPLASTIN TIME (APTT) (< 6 SECONDS ABOVE CONTROL)**

The APTT is a test of the intrinsic coagulation system and the result must be interpreted with caution as there may be significant variation in sensitivity and specificity of the test between laboratories. In unselected patients there is poor

correlation between the APTT prolongation and the presence of haemostatic failure or the likelihood of a patient bleeding. In the context of a patient suspected of having a systemic haemostatic defect, an isolated prolongation of the APTT may represent deficiency or an inhibitor of factor VIII or IX. If there is a marked isolated prolongation there may be a deficiency in the contact phase of the coagulation cascade and there is poor correlation with a bleeding tendency. Prolongation of APTT and PT may be due to deficiencies of factors X, V or II. A lupus anticoagulant may prolong the APTT and represent a prothrombotic state.

**THROMBIN CLOTTING TIME (TCT) (NORMAL < 2 SECONDS LONGER THAN CONTROL)**

This is a test of the final conversion of fibrinogen to fibrin. Prolongation of TCT is due to hypofibrinogenaemia, dysfibrinogenaemia, heparin, and fibrin degradation products.

**D-DIMER (NORMAL < 0.25 ng/L)**

The D-Dimer assay measures cleavage fragments resulting from the proteolytic action of plasmin of fibrin. Elevation of D-Dimer may be seen in the postoperative state, trauma, renal impairment, sepsis and venous thrombosis. High levels of D-Dimer suggest excessive fibrinolysis, as seen in disseminated intravascular coagulation. The test is specific for fibrinolysis and not primary fibrinogenolysis.

**SPECIFIC COAGULATION FACTOR ASSAYS**

Fibrinogen is the commonest routinely measured coagulation factor in patients suspected of systemic haemostatic failure. Fibrinogen concentration can be measured using clottable protein methods, end-point detection techniques or immunochemical tests. The method of Claus is the most common fibrinogen assay used. Other assays are usually performed in the investigation for specific defects, usually after consultation with a haematologist.

**EUGLOBULIN LYSIS TIME (ELT) (NORMAL RANGE > 90 MINUTES)**

This test mainly reflects the presence of plasminogen activators. A shortened time is indicative of systemic fibrinolytic activation.

**PLATELET FUNCTION TESTS**

Platelet function tests are used for the diagnosis of platelet disorders.<sup>12,13</sup> In recent years there has been increasing interest in the use of platelet function tests to monitor antiplatelet therapy. Unfortunately, platelet function testing is poorly standardised and good quality control is commonly lacking. The diagnostic utility of some of the newer simpler assays of platelet function have been evaluated in a range of clinical settings, but their value remains controversial.

A popular technology is the platelet function analyser (PFA-100) in which citrated whole blood is placed in a disposable cartridge containing a membrane coated with collagen/adrenaline or collagen/ADP into which a microscopic aperture has been cut. With high shear rates contact of blood with the membrane causes platelets to aggregate and occlude the aperture. The time to occlude the aperture is recorded as the end-point and referred to as the closure time.<sup>14</sup> The technique is simple and rapid, but subject to a number of variables such as the platelet count, haematocrit, ABO blood group and plasma vWF levels. A normal result has a high negative predictive value and is increasingly becoming popular as a screening test for platelet dysfunction; however, false positive and negative results may occur. The test is more sensitive than the bleeding time which is now generally regarded as an obsolete test.

**THROMBOELASTOGRAM (TEG)**

Thrombelastography was originally described 50 years ago, but failed to establish a role in routine laboratory haemostasis testing. Improvements in the technology, especially standardisation and computerisation, have now made the TEG

a valuable tool for monitoring haemostasis as a holistic dynamic process supplementing the long-standing conventional coagulation screens. The TEG measures the viscoelastic properties of blood as it clots under low shear conditions. The patterns of changes in shear elasticity provide information about the kinetics of clot formation, growth, strength and stability of the formed clot. The TEG is increasing being used as a point of care test, providing 'real time' information about a patient's haemostatic function.<sup>15</sup>

**CONGENITAL HAEMOSTATIC DEFECTS**

Congenital bleeding disorders are relatively uncommon and are usually confined to a single defect. It is important to identify the defect so that specific replacement therapy can be given preoperatively or to arrest a particular episode of bleeding.

**THE HAEMOPHILIAS****HAEMOPHILIA A (CLASSIC HAEMOPHILIA)**

Haemophilia A is an X-linked disorder due to a deficiency of factor VIII. The mainstay of haemophilia treatment is coagulation factor replacement.<sup>16,17</sup> Coagulation factor concentrates or recombinant factor VIII are given to prevent bleeding and to control existing haemorrhage. The dose of clotting factor is calculated on the basis that one unit of coagulation factor is that amount present in 1 ml of pooled normal plasma. An individual with a plasma volume of 3000 ml would have 3000 U of the clotting factor in the circulation. If such person was a haemophiliac with <1% factor VIII level in the plasma, a dose of 3000 U of factor VIII would be required to raise the plasma level to 100% of normal.

Experience has demonstrated that doses of 15–20 U/kg body weight will control most haemarthroses, but doses of up to 30 U/kg are required for muscle haematomas or for the prevention of dental bleeding. Raising clotting factor levels to 100% of normal is indicated for severe bleeding (e.g. intracranial or intra-abdominal haemorrhage), but there is considerable patient variation in response to specific doses, and empirical 'dose-finding' may be necessary. Measurement of factor VIII levels following replacement therapy is helpful. A factor VIII concentration of 25%, usually achieved with a dose of 15 U/kg, controls joint bleeding, whereas a level of 50%, generally obtained with a dose of 30 U/kg, prevents bleeding following tooth extraction. Clotting factor is given when a haemophiliac undergoes invasive procedures, including minor invasions such as arterial blood gas sampling.

The half-life of factor VIII in the circulation is approximately 12 hours. On this basis, doses are repeated 12-hourly if it is necessary to maintain a specific plasma concentration of the factor. Clotting factor assays are performed near the end of this 12-hour period in order to confirm that adequate levels for haemostasis are being achieved. Concentrate may also be given by continuous infusion.

**HAEMOPHILIA B (CHRISTMAS DISEASE)**

Haemophilia B due to factor IX deficiency is less common than classic haemophilia. The general principles of management are similar, with factor IX concentrates or recombinant products being used.

**VON WILLEBRAND'S DISEASE**

Von Willebrand's disease (vWD), the commonest of the hereditary haemostatic disorders, with a prevalence of approximately 100 symptomatic persons per million, is due to a quantitative or qualitative defect in von Willebrand factor (vWF). Patients with defective vWD may have mucocutaneous bleeding consistent with platelet dysfunction, or spontaneous deep tissue bleeding similar to that of haemophiliacs.

Classification of vWD is complex and controversial. Therapy may be determined by the specific subtype and expert haematological consultation is important.<sup>18,19</sup> Clinical heterogeneity is reflected in the classification of subtypes corresponding to specific pathophysiological mechanisms.

In most cases desmopressin (DDAVP) is effective therapy, but replacement therapy may be needed for the rarer severe subtypes. DDAVP induces a haemostatic state via release of factor VIII and vWF; 0.3 µg/kg is infused slowly over 30 minutes immediately prior to surgery or to establish haemostasis in the bleeding patient. Antifibrinolytic agents may also be useful when not contraindicated as a thrombotic risk. If replacement therapy is indicated, cryoprecipitate or factor VIII concentrates containing vWF should be administered.

**CONGENITAL PLATELET DISORDERS**

Congenital platelet disorders are rare, the commonest severe disorder being Glanzmann's thrombasthenia.<sup>20</sup> Platelet transfusions may be required for acute bleeds or in relation to elective surgery; DDAVP ± antifibrinolytic therapy and recombinant factor VIIa may all have a role.

**ACQUIRED HAEMOSTATIC DISORDERS**

The acquired disorders of coagulation are usually more complex and multifactorial than the hereditary disorders. A unified approach is essential for the successful management of these potentially life-threatening situations, and transfusion therapy cannot be isolated from other treatment.

**CRITICAL HAEMORRHAGE AND MASSIVE BLOOD TRANSFUSION**

The nature and management of haemostatic defects secondary to acute and/or massive blood loss and transfusion remains poorly understood.<sup>21</sup> The coagulopathy of trauma is characterised by non-surgical bleeding from

mucosal lesions, serosal surfaces, wounds and vascular access sites. Hypothermia, acidosis and haemodilution are commonly present, occasionally with features of disseminated intravascular coagulation (DIC). DIC typically occurs acutely after trauma when brain, fat, amniotic fluid or other potent thromboplastins enter the circulation. It may occur less acutely when endothelial inflammation or failure reduces clearing of activated coagulation factors. The coagulopathy of trauma should be anticipated in massive transfusion situations and there is increasing support for early treatment with plasma, which may prevent or delay its onset.

Further aggravation of the complications of massive blood transfusion can be avoided or minimised if correctable defects in the haemostatic system are identified (Table 91.1). The relative importance of the different potential mechanisms responsible for haemostatic failure is difficult to determine, but the identification of correctable defects will avoid or minimise complications. Haemostatic failure correlates poorly with the volume of transfusion or components administered, but better with the nature of the insult, degree of hypovolaemia, and time to resuscitation. Trauma patients with major coagulopathy and microvascular haemorrhage usually have abnormal laboratory parameters prior to massive blood transfusion. Except for severe abnormalities, haemostatic laboratory parameters correlate poorly with clinical evidence of haemostatic failure. Thrombocytopenia and impaired platelet function are probably the most consistent significant haematological abnormalities, correction of which may be associated with control of microvascular bleeding.

Coagulation deficiency from massive blood loss is initially confined to factors V and VIII. APTT, PT and fibrinogen assay should be performed, but the urgency of the situation does not usually allow for other specific factor assays, and fresh frozen plasma (FFP), cryoprecipitate or factor concentrates should be infused if the test results are abnormal. Correction of hypofibrinogenaemia is probably more important than thought previously.<sup>22</sup>

**Table 91.1** Possible factors contributing to haemostatic failure following massive blood transfusion

Pre-existing haemostatic defect
Loss of coagulation factors, platelets and inhibitors
Dilution of coagulation factors, platelets and inhibitors
Impaired synthesis due to effects of shock on liver and bone marrow function
Effects of trauma: disseminated intravascular coagulation (DIC) and fibrinolysis
Effects of blood storage lesion: depletion of coagulation factors and platelets, aggravation or precipitation of DIC
Depletion of modulators of haemostasis (e.g. antithrombin III, fibronectin and protein C)
Incompatible transfusion reaction: DIC
Hypothermia
? Citrate toxicity

**Table 91.2** Potential problems with stored blood components

Failure to correct deficiency
Inadequate correction of deficiency
Blockade of reticuloendothelial system (microaggregates, coagulation)
Microvascular pathophysiology (ARDS, MSOF)
Accentuation of free radical pathology (leukocytes, iron)
Activation and consumption of the haemostatic system
Hyperkalaemia, hypocalcaemia, hypothermia
Vasoactive effects (hypotension)
Hyperbilirubinaemia

A case can be made for prophylactic FFP in infusions in patients with massive blood loss which has been replaced with red cell concentrates and plasma substitutes. Hypothermia must be avoided, recognised and treated rapidly.<sup>23</sup> Potential problems associated with large volume stored blood replacement are summarised in Table 91.2.

With ongoing bleeding with associated microvascular oozing, various approaches may be taken. Having ensured that all identifiable haemostatic defects have been corrected, questions arise as to the roles of fresh blood and, more recently, recombinant activated factor VII (rFVIIa).<sup>24</sup> The use of freshly collected whole blood remains controversial and is an 'emotive' subject needing some comment.<sup>25,26</sup> The provision of fresh whole blood can present logistic, ethical and safety problems needing consideration. Many transfusion medicine specialists categorically state that there is never an indication for fresh whole blood. Such dogma can be difficult to defend in the clinical setting of the massive haemorrhage and transfusion syndrome where pathophysiology remains poorly understood and specific blood component therapy may be ineffective. The current author, from his own experience and on the basis of current evidence, feels that the following statements reasonably summarise the current status of fresh blood transfusion:

- Fresh blood provides immediately functioning oxygen-carrying capacity, volume and haemostatic factors in the one product
- The number of allogeneic donors to whom a patient is exposed can be reduced
- Problems associated with infusion of massive volumes of stored blood can be minimised/avoided
- The risk of transfusion-related viral infections is potentially higher than fully tested and stored blood
- The benefit in controlling haemorrhage probably relates to the presence of immediately functioning platelets

#### HAEMOSTATIC FAILURE ASSOCIATED WITH LIVER DISEASE

The liver is the production site of nearly all the factors involved in the formation and control of coagulation (Table 91.3). Bleeding in association with liver disease can be difficult to manage. There may be a combination of

**Table 91.3** Haemostatic disturbances in liver disease

Deficiency of vitamin K-dependent clotting factors II, VII, IX, X
Deficiency of fibrinogen and factor V
Dysfibrinogenaemia
Disseminated intravascular coagulation
Excessive fibrinolytic activity
Circulating anticoagulants
Platelet abnormalities

excessive consumption of coagulation factors and impaired synthesis of both clotting factors and coagulation inhibitor proteins. Excessive activation of fibrinolysis may occur and defective clearing of activated clotting factors compounds the problem. Moreover, the effects of massive blood loss, shock and transfusion must also complicate the problem.

Haemostatic defects due to deficient vitamin K-dependent coagulation factors (in patients with predominantly cholestatic liver disease) may be rapidly reversed with vitamin K therapy, and blood transfusion may not be required. If the abnormality is not reversed by vitamin K, hepatocellular damage is likely to be present and FFP is appropriate replacement therapy.<sup>27</sup> When an elective procedure is planned, prophylactic FFP is appropriate. Low fibrinogen levels in liver disease usually indicate advanced disease and are associated with a poor prognosis, or the presence of DIC. Cryoprecipitate is generally the most readily available form of fibrinogen if concentrates are not available.

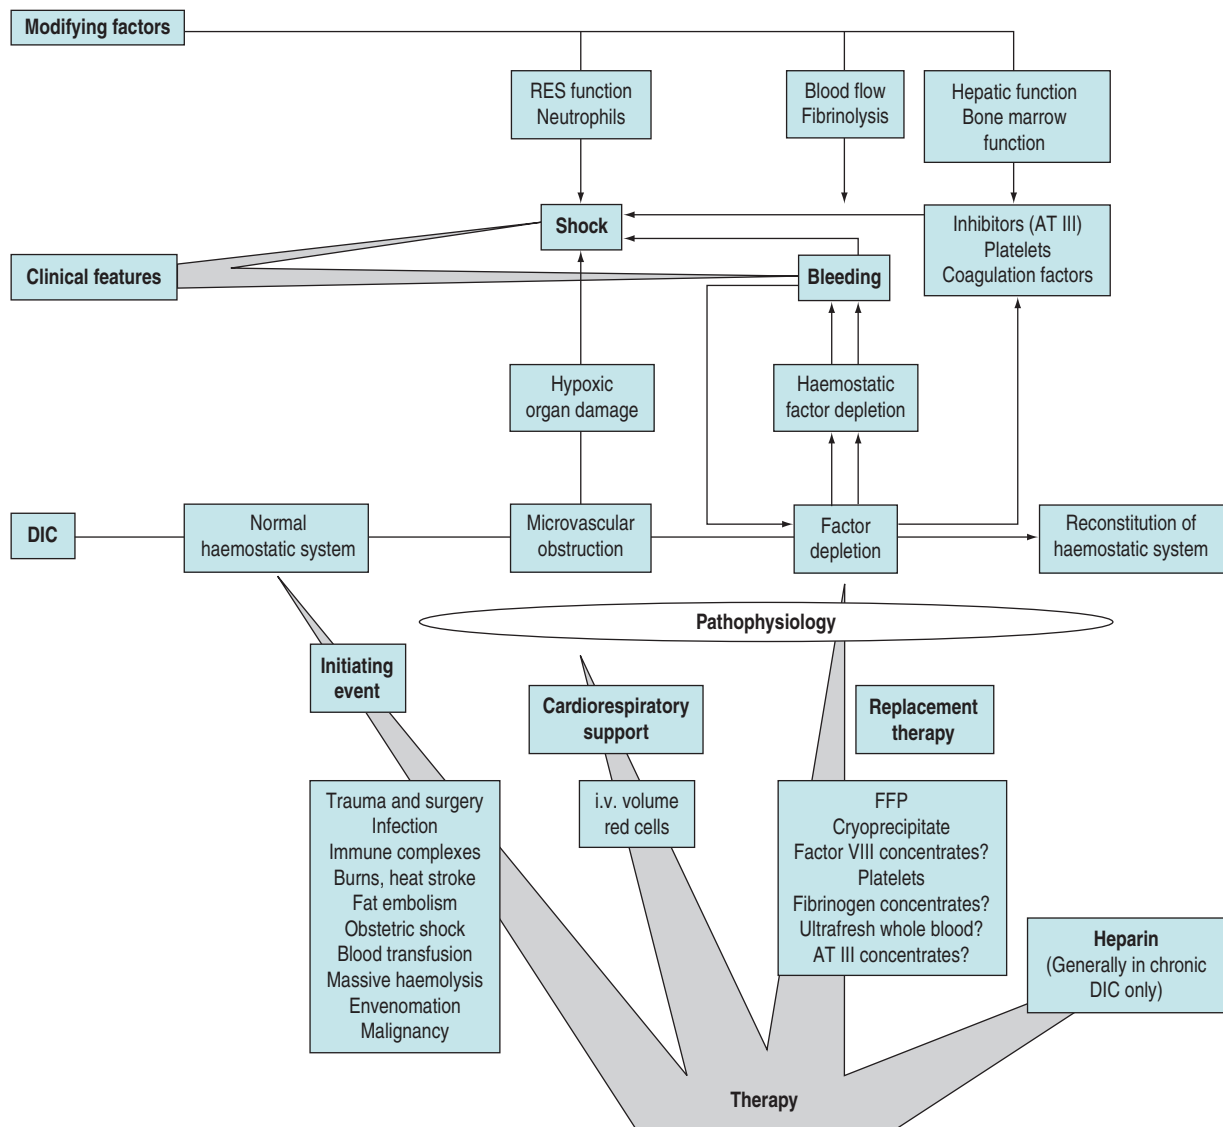

#### DISSEMINATED INTRAVASCULAR COAGULATION<sup>28</sup>

Disseminated intravascular coagulation (DIC) is a pathophysiological process and not a disease in itself. Clinical manifestations of DIC relate to occlusion of the microvessels during the obstructive phase of the syndrome and haemorrhage secondary to consumption of plasma and cellular components of the haemostatic system.<sup>29</sup>

Perpetuation of the process may be due to continuation of the stimulus and/or consumption of the natural inhibitors of haemostasis. DIC thus results, due to inappropriate, excessive and uncontrolled activation of the haemostatic process. This may initially occur with adequate compensation when defects may only be demonstrable in laboratory tests. If the initiating disorder is severe enough, the clinical syndrome of uncontrolled acute DIC will result with a systemic bleeding state, usually with associated end-organ failure. A compensatory secondary fibrinolysis occurs, which in some cases may accentuate the bleeding.

#### PATHOPHYSIOLOGY

DIC is characterised by the consumption of clotting factors and platelets within the circulation, resulting in varying degrees of microvascular obstruction due to fibrin deposition (Figure 91.4). When significant platelet and coagulation factor consumption occurs, bleeding may become a major feature.

**Figure 91.4** The pathophysiology and management of disseminated intravascular coagulation (DIC). AT III, antithrombin III; FFP, fresh frozen plasma; RES, reticuloendothelial system.

Mechanisms which may inappropriately activate the haemostatic system include:

- Activation of the coagulation sequence by release of tissue thromboplastins into the systemic circulation, e.g. following extensive tissue trauma, during surgery, malignancy and during an acute intravascular haemolysis.
- Vessel wall endothelial injury causing platelet activation followed by activation of the haemostatic system, predominantly via the intrinsic pathway (e.g. Gram-negative sepsis from endotoxin release, viral infections, extensive burns, prolonged hypotension, hypoxia or acidosis).
- Induction of platelet activation (e.g. septicaemia, viraemia, antigen-antibody complexes and platelet activation).

### CLINICAL FEATURES

The clinical presentation of DIC varies, with patients showing thrombotic, haemorrhagic or mixed manifestations in various organ systems. The major clinical problem and presenting feature of acute DIC is bleeding. This may manifest as generalised bruising or bleeding at sites of therapeutic or traumatic invasion (venepuncture sites and surgical wounds). DIC may occur in association with a wide range of clinical disorders (see Table 91.5). When DIC occurs in acutely ill patients with multisystem organ failure the prognosis is poor. DIC may, in some patients, be an agonal event and should not be treated.

**LABORATORY FINDINGS**

Results of tests may be variable and difficult to interpret. Significant DIC can be present despite normal standard coagulation tests (i.e. PT, APTT and TCT). The key tests in diagnosis are those that provide evidence for excessive conversion of fibrinogen to fibrin within the circulation and its subsequent lysis. Platelet–fibrin clots create a mesh in the microcirculation in which passing red cells may be traumatised, resulting in red cell fragmentation and haemolysis. The blood film may demonstrate fragmentation of the red cells (microangiopathic haemolytic anaemia), but this is more commonly seen in chronic DIC, especially in association with malignancy.

The diagnosis is usually based on a combination of the appropriate clinical picture with a supportive pattern of laboratory tests of the haemostatic system<sup>27</sup> (Table 91.4). Thrombocytopenia and hypofibrinogenaemia with prolongation of the APTT, PT and TCT in conjunction with an elevation of fibrin degradation products (D-Dimer test) are supportive evidence for the diagnosis. The D-Dimer test is specific for fibrin breakdown versus primary fibrinogenolysis. More specialised test such as elevation of fibrinopeptide A and reduced levels of antithrombin III add further weight to the diagnosis.

In chronic DIC the laboratory findings are different from those in acute DIC. Many of the usual tests of haemostasis are normal or near normal. The platelet count may be normal, as may many of the haemostatic factors. However, this is a compensated state in which there is increased turnover of each of the haemostatic components. D-Dimer is elevated in this setting and a microangiopathic red cell picture is seen on the peripheral blood film.

**DISORDERS ASSOCIATED WITH DIC**

DIC may occur in association with a wide range of clinical disorders (Table 91.5).

**THERAPY**

The management of DIC remains controversial, but removal or treatment of the initiating cause is important in conjunction with general resuscitation. The early recognition of DIC and initiation of management may allow the patient to survive hours or days, granting sufficient time for definitive diagnosis and treatment of the inciting disorder. Blood component therapy should be given to the haemorrhaging patient, but the use of heparin should only be considered in selected cases.

- Fresh frozen plasma (FFP) contains all the coagulation factors and the main inhibitors, antithrombin III and protein C, in near-normal quantities and should be used if haemorrhage is occurring.<sup>30,31</sup>
- Cryoprecipitate contains all the components of the factor VIII complex, as well as fibrinogen, factor XIII and fibronectin in concentrated form. Between 5 and 10 units should be infused in conjunction with the fresh frozen plasma.
- Platelet transfusion may be indicated in the presence of life-threatening haemorrhage; however, this is a controversial subject and the patients tend to be resistant if the initiating cause of the DIC has not been controlled.
- It is likely that replacement therapy with antithrombin III concentrates and possibly other inhibitors of haemostasis will find a greater role in therapy.<sup>30</sup> Successful treatment of the bleeding phase of DIC probably

**Table 91.4** Laboratory test for the diagnosis of disseminated intravascular coagulation

Analysis	Early	Late
Platelet count	↓	↓↓
Activated partial thromboplastin time (APTT)	↑	↑↑
Prothrombin time (PT)	↑	↑
Thrombin clotting time (TCT)	↑	↑
Fibrin degradation products (D-Dimer assay)	↑	↑↑
Hypofibrinogen	↓	↓↓
Other coagulation factors II, VII, VIII, X	↓	↓↓
Coagulation inhibitors: antithrombin III, protein C	↓	↓↓↓
Blood film	Usually normal in early stages	Fragmented red cells + in subacute or chronic cases
Supplementary and research tests: prothrombin fragment 1+2, thrombin–antithrombin complex (TAT complex), procalcitonin (PCT), plasmin–antiplasmin complexes (PAP complex)	↑	↑

**Table 91.5** Conditions associated with disseminated intravascular coagulation

Infection
Bacterial sepsis
Viral haemorrhagic fevers
Protozoal (malaria)
Trauma
Extensive tissue injury
Head injury
Fat embolism
Malignancy
Carcinoma
Leukaemia (especially promyelocytic)
Immunological disorders
Transplantation rejection
Incompatible haemolytic blood transfusion reactions
Severe allergic reaction
Drug reactions
Extracorporeal circulations
Snake bite envenomation
Vascular disorders
Giant haemangioma
Aortic aneurysm
Pregnancy associated
Septic abortion
Abruptio placentae
Eclampsia
Amniotic fluid embolism
Placenta praevia
Burns
Hyperthermia
Liver disease and acute hepatic necrosis

depends to a variable degree on the patient being able to 'switch off' the coagulation system. Correction of depleted coagulation inhibitor levels, reticuloendothelial blockade and impaired or excessive fibrinolysis may be important.

- In general, heparin should only be used after initial adequate replacement therapy has failed to control bleeding. The decision to use heparin should not be undertaken lightly, or without due consultation. Small doses should be used initially (e.g. 50–100 units/kg body weight followed by 10–15 units/kg per hour), adjusted according to the clinical and laboratory response. Heparin is especially valuable in certain specific clinical situations, including acute promyelocytic leukaemia, the early stages of amniotic fluid embolism and immediately following a severe incompatible blood transfusion.

Management of sudden massive obstetric haemorrhage is similar to other cases of DIC except that the onset is more likely to be fulminant and unexpected and associated with greater depletion of coagulation factors, especially fibrinogen, due to marked fibrinolysis. Fresh blood is possibly warranted in some of these cases where bleeding does not stop quickly. Once the uterus has been emptied and contracted,

the haemostatic failure quickly resolves. There is increasing interest in a possible role for rFVIIa in this setting.

### OUTCOME

Factors which may affect the outcome of DIC include:

- the nature of the initiating event
- the host factors (e.g. state of reticuloendothelial system, levels of inhibitors of coagulation and fibrinolytic activity, hepatic synthetic function)
- the extent of end-organ damage sustained during the thrombotic phase and from shock caused during the haemorrhagic phase

### ANTITHROMBOTIC THERAPY

The availability of an increasing variety of antithrombotic agents, and wider clinical use of antithrombotic therapy generally, has inevitably resulted in an increase in iatrogenic bleeding in patients presenting with other medical conditions (e.g. trauma, surgery and invasive procedures) and intensivists must be aware of the methods for rapid reversal of therapy.<sup>32,33</sup> Bleeding problems in patients on well-controlled anticoagulation are usually due to surgery, trauma or a local lesion (e.g. peptic ulceration). Otherwise, bleeding is due to over-anticoagulation, sometimes as a result of drug interactions. Elective surgery in this group of patients needs careful planning if haemorrhagic and thrombotic complications are to be avoided. Patients on antithrombotic therapy involved in traumatic events are a challenge in whom there is the risk of progression of the original insult, increased risk of posttraumatic complications, and mortality.

### ORAL ANTICOAGULANT AGENTS

Oral anticoagulant agents induce a controlled deficiency of the vitamin K-dependent clotting factors (II, VII, IX and X), the anticoagulant action being measured by prolongation of PT (INR). The indications for reversing vitamin K antagonists depend on the clinical situation and the indication for therapy. Reversal of over-anticoagulation depends on the degree of overactivity and on the presence, or not, of haemorrhage. In most cases vigorous intervention is unnecessary and the oral anticoagulation can be temporarily ceased. Short-term reversal or temporary reversal is achieved by administration of FFP. Prothrombin complex concentrate will effectively and rapidly reverse the anticoagulant effects of warfarin, including protein C correction, and have a role in anticoagulant overdose. Previous concerns about coagulation activation do not appear to be a problem with current products.

Long-term reversal requires vitamin K, but care must be taken not to give an excessive dose if it is planned that the patient needs to return to oral anticoagulation in the long term. For most surgical interventions or invasive procedures an INR of 1.5 or less is accepted as safe. This can usually be achieved by temporarily ceasing medication.

**HEPARINS**

With the wide clinical use of fractionated low molecular weight (LMW) heparins, this subject has become more complex. Heparins act by potentiating the action of anti-thrombin III, a natural coagulation inhibitor. Unfractionated heparin acts in neutralising both thrombin and factor Xa, in contrast to the LMW heparins which predominantly neutralise factor Xa. The anticoagulant effect of unfractionated heparin is usually measured by prolongation of the APTT. LMW heparins do not prolong the APTT, are generally administered on weight basis and are not routinely monitored by a laboratory test. When monitoring is required, the anti-Xa assay is used.

**ANTIPLATELET AGENTS**

Antiplatelet agents are being used increasingly for prophylaxis and therapy of arterial disease, and many of the non-steroidal anti-inflammatory agents are also platelet-inhibitory drugs. Aspirin has an irreversible effect on platelet function and platelet function tests may show abnormalities for up to 10 days after medication. Most of the other non-steroidal anti-inflammatory drugs have a reversible effect lasting a matter of hours or occasionally days. Perioperative bleeding is usually mild, but occasionally may be serious, depending on the surgery, and in some situations a platelet transfusion may be necessary. In other cases, the patient may already have a mild haemostatic defect (e.g. von Willebrand's disease) and aspirin may have a synergistic effect, leading to major haemostatic failure.

Agents such as clopidogrel act as inhibitors of platelet aggregation by selectively inhibiting the binding of ADP to its platelet receptor by irreversibly modifying the platelet ADP receptor and, as a result, ADP-mediated activation of the GPIIb/IIIa complex. As with aspirin, platelets exposed to clopidogrel are affected for their lifespan and recovery of normal platelet function occurs as new platelets are produced.

**REVERSAL OF ANTITHROMBOTIC AGENTS**

Life-threatening bleeding in patients on warfarin requires urgent reversal and this is best achieved with prothrombin concentrate (PCC) administration in conjunction with FFP depending on the factor VII level of the PCC.<sup>34–36</sup> The advantages of PCC over FFP include more timely correction, absence of volume overload and potentially better restoration of the vitamin K-dependent coagulation factors. Vitamin K<sub>1</sub> is essential for sustained reversal, but the dose should be determined on the basis of whether temporary reversal is indicated. When there is an indication to continue warfarin therapy, vitamin K<sub>1</sub> should be administered in a dose that will lower or maintain the INR to a safe, but not subtherapeutic, range and will not cause resistance once warfarin is reinstated.

Immediate reversal of heparin activity can be achieved with protamine sulphate. Although formulas have been quoted for the reversal of heparin (e.g. 1 mg protamine sulphate will neutralise 100 units of heparin), it is better

to titrate the dose using APTT after an initial empirical dose of 50 mg. Protamine sulphate should be injected slowly by the intravenous route. Protamine is not without risk, as it may itself impair coagulation and be associated with anaphylactoid reactions. It is not possible to reverse the effects of LMW heparins, and rFVIIa may have role in critical bleeding settings.

Antiplatelet agents, particularly acetylsalicylic acid, clopidogrel and GPIIb/IIIa inhibitors, now have a central role in preventing arterial thrombosis. Clinicians are now regularly confronted by balancing the haemorrhagic risks associated with these agents, especially in the peri-surgical setting, against the thrombotic risks associated with their discontinuation. It is generally agreed that continuing acetylsalicylic acid during vascular surgery procedures and in most other settings in which the bleeding risk is likely to be low is acceptable. It is generally recommended that clopidogrel be ceased 5 days before surgery to allow regeneration of half the platelet pool. Although withdrawal of the competitive GPIIb/IIIa inhibitors at the beginning of surgery will decrease the risk of bleeding, it should be emphasised that thrombotic events in patients waiting for urgent myocardial revascularisation are a significant risk and acceptance of perioperative bleeding risk may take priority. Patient blood management techniques to minimise blood loss and transfusion should be used.<sup>37</sup> Platelet concentrate transfusions may be indicated in the acute setting.

**NEWER ANTITHROMBOTIC AGENTS**

Limitations of the currently available antithrombotic agents continue to stimulate research into new anticoagulants with improved pharmacological activity and safety.<sup>38</sup>

Targets of action include:

- the factor VIIa/tissue factor pathway inhibition – recombinant nematode anticoagulant peptide c2 and tissue factor pathway inhibitor
- factor Xa inhibitors – fondaparinux, idraparinux, razaxaban
- factor Va and VIIIa pathway inhibition with recombinant activated protein C, soluble thrombomodulin
- thrombin inhibitors – hirudin, bivalirudin, argatroban, ximelagatran, dabigatran

Independent of their mode of action, these agents all have the potential to cause bleeding complications.

Reversal agents do not exist for the majority of these newer agents. Recombinant activated factor VIIa may have a role in controlling bleeding, but more experience will be needed with the use of these newer agents and their bleeding risks.

**ACQUIRED INHIBITORS OF COAGULATION**

Major haemostatic failure may be seen with rare inhibitors of coagulation factors. Autoantibodies against factors VIII (commonest), IX, X, V and vWF have been reported. A coordinated approach to haemotherapy is

essential if bleeding is to be arrested. The patients are relatively resistant to factor replacement therapy and removal of the offending autoantibody by plasma exchange and replacement with FFP  $\pm$  factor concentrates is indicated. Recombinant activated factor VII may have a role yet to be defined.

### PRIMARY FIBRINOLYSIS

This rare acquired disorder of haemostasis is in reality primary fibrinogenolysis because circulating plasmin is responsible for an uncontrolled proteolytic attack on the coagulation system (particularly factor VIII and fibrinogen). The disorder may complicate specific types of surgery (e.g. neurosurgery, pulmonary and prostate) or malignancy. Rapid recognition of this potentially devastating failure of haemostasis is essential if appropriate antifibrinolytic and blood component therapy (FFP and cryoprecipitate) is to be effective. With streptokinase and tissue plasminogen activator therapy of arterial and venous disease, problems of excess lysis may occur.

### EXTRACORPOREAL CIRCULATION CARDIAC SURGERY

A range of haemostatic disturbances may be associated with extracorporeal circulation, most commonly cardiopulmonary bypass, and the clinician must constantly balance the risks of bleeding versus thrombosis.<sup>39</sup> The abnormalities are generally directly related to the time on bypass and are more likely to be seen in multiple valve replacements or re-operations. Fresh blood components have generally been advocated in cardiac bypass surgery to ensure optimal oxygen delivery and function of the haemostatic components of blood. Haemostatic failure usually becomes apparent in the operating room or soon after and appropriate laboratory investigations should be performed to allow logical therapy. It is pointless infusing large volumes of plasma products or platelets if heparin has not been adequately reversed. Increased fibrinolytic activity may in some cases also contribute to bleeding.

A predictable thrombocytopenia occurs after extracorporeal blood circulation. The postoperative platelet count in the majority of cardiac bypass patients is seldom below 100 000/ $\mu$ l, but platelet functional defects may contribute to bleeding and occasionally platelet concentrates are indicated. Increasingly, rFVIIa is being used to control bleeding associated with cardiac surgery. More evidence is required before definitive recommendations can be made.<sup>40</sup>

### THROMBOCYTOPENIA AND QUALITATIVE PLATELET DEFECTS

#### IDIOPATHIC THROMBOCYTOPENIC PURPURA (ITP)

ITP is an autoimmune disorder where autoantibodies (IgG) are directed against the platelets, which are subsequently destroyed by the monocyte-macrophage system, predominantly in the spleen. ITP is typically a disease of

children and young adults. The acute form is more commonly identifiable as postinfectious, and recovery over weeks to months is the usual natural history. The course of the chronic form is variable and may spontaneously recover, but more commonly needs specific intervention.

Therapy of ITP remains controversial.<sup>41</sup> Corticosteroids should generally be regarded as short-term therapy. In adults, the majority of patients respond with a rise in the platelet count. After an initial high dose (50–75 mg) of prednisolone a day until response occurs, the dose is gradually reduced. There is little evidence that corticosteroids will raise the platelet count in acute disease. However, their short-term role in reducing the incidence of bleeding, which is highest in the first weeks, may be important. High dose i.v. immunoglobulin is effective in most patients and is specifically indicated in fulminant acute disease, preoperatively and in pregnancy.

#### THROMBOTIC THROMBOCYTOPENIC PURPURA

Thrombotic thrombocytopenic purpura (TTP) is a disorder in which platelet aggregates form within the microvasculature, resulting in tissue ischaemia and infarction. Red blood cell fragmentation occurs, resulting in haemolysis, and the systemic platelet clumping leads to thrombocytopenia. This condition and its management are discussed in more detail in Chapter 90.

#### DRUG-INDUCED THROMBOCYTOPENIA

The clinical presentation of drug-induced thrombocytopenia may be as variable as ITP. Some may have a dramatic and fulminant presentation with marked haemostatic failure. Drugs with a particular reputation for inducing thrombocytopenia include quinine (also in bitter drinks), quinidine, antituberculous drugs, heparin, sedormid, thiazide diuretics, penicillins, sulphonamides, rifampicin and anticonvulsants.

Heparin-induced thrombocytopenia and thrombosis syndrome (HITTS) is an important and potentially life-threatening complication of heparin therapy.<sup>42–44</sup> An immune reaction occurs to heparin after 7–10 days of therapy, at which time the patient's platelets aggregate and thrombocytopenia develops; this reactivity can be demonstrated by a variety of laboratory tests. In contrast to other causes of drug-induced thrombocytopenia, there may be arterial, microvascular or venous thrombosis associated with the platelet aggregation. The best way to avoid this potentially devastating complication is to keep heparin therapy as brief as possible, and be always alert to the diagnostic possibility. The incidence is less with the use of LMW heparins, and if cross-reactivity is not demonstrated in the heparin antibody test, LMW heparins or heparinoids may have a part to play in therapy.

Quinine-induced immune thrombocytopenia with haemolytic uraemic syndrome (HUS) can be a severe drug reaction, characterised by the onset of chills, sweating, nausea and vomiting, abdominal pain, oliguria and petechial rash following quinine or quinidine exposure. Quinine-dependent platelet-reactive antibodies can usually be identified. Plasma exchange in conjunction with

renal dialysis has been found to be a beneficial adjunct to therapy.

### SEPSIS

Platelets play an important role in the inflammatory response and a reactive thrombocytosis is usually seen in infection. However, if there is overwhelming sepsis, associated DIC or marrow suppressive influences, thrombocytopenia may be seen. The combination of sepsis, shock, DIC, alcoholism and nutritional deficiency are common factors contributing to thrombocytopenia in critically ill patients.

### QUALITATIVE PLATELET DEFECTS

The effects of aspirin and other antiplatelet agents are discussed above. Haemostatic failure is a common manifestation of renal failure. Its mechanism is not fully elucidated, but the defect can be substantially corrected by dialysis. Prolongation of the bleeding time, defects in aggregation responses, diminished adhesion and reduced platelet factor 3 availability have all been demonstrated. A relationship between the degree of anaemia and prolongation of bleeding is usually demonstrable; increasing the haemoglobin level reduces the bleeding time. Patients with the myelodysplastic syndrome may not only have thrombocytopenia, but also a qualitative platelet function defect. They are thus at high risk of bleeding in relation to any surgery or invasive procedure.  $\beta$ -Lactam antibiotics may also be responsible for a platelet function defect.

# Haematological malignancies

James P Isbister

The treatment of haematological malignancy has been an evolving success story. In recent years, the prognosis for patients with acute leukaemia has changed from death within 1–3 months without effective therapy to long-term survival and cure in many cases.<sup>1,2</sup> In some diseases the potential for regular cure of patients has been realised, including Hodgkin's disease, childhood acute lymphoblastic leukaemia, some high-grade lymphomas and some adult leukaemias.<sup>3</sup> These advances have predominantly resulted from the introduction of a wide range of cytotoxic chemotherapeutic regimens which permit obliteration of the disease in conjunction with comprehensive supportive therapy. In some cases, 'supralethal' therapy is necessary, with bone marrow transplantation (autologous or allogeneic) being used as marrow 'rescue' therapy. The development of 'engineered' highly specific and targeted drugs is offering further promise (e.g. monoclonal antibodies, tyrosine kinase inhibitors for chronic myeloid leukaemia).<sup>1</sup>

It is important that clinicians not regularly involved in the care of these patients do not take a nihilistic approach to management of patients with haematological malignancy. If patients can be adequately supported and complications treated during the severe neutropenic stage of chemotherapy, clinical improvement may occur rapidly following marrow recovery. However, in patients requiring prolonged ventilatory support and/or dialysis, the prognosis is poor and intensive supportive therapy can usually only be justified if marrow recovery is imminent and there is a reasonable anticipated life expectancy if the crisis can be survived.

## CLASSIFICATION AND PATHOPHYSIOLOGY

The heterogeneous nature of the haemopoietic and lymphoid cells, their individual kinetic characteristics and the disseminated nature of haemopoietic and lymphoid tissue explains the complexity of haematological malignancy. The numerous confusing classification systems advocated to 'clarify' understanding have in many cases increased the confusion for the non-expert. In broad terms, the haematological malignancies with origins in the marrow are classified as leukaemia or multiple myeloma, and those

arising in the peripheral lymphoid tissues as Hodgkin's and non-Hodgkin's lymphomas (nodal and extranodal).

The leukaemias are divided into acute and chronic, generally according to the time span of their clinical course. In general, a leukaemia that is blastic in appearance behaves in an acute and malignant manner with a rapidly fatal outcome without therapy. This is in contrast to the chronic leukaemias in which the cells are more differentiated ('benign'), with the disease following a more indolent course. Leukaemias are classified on the basis of their cell of origin with broad division into those of myeloid origin (i.e. of haemopoietic marrow origin) and those of lymphoid origin (i.e. arising from the cells of the immune system).

Most patients with acute myeloid leukaemia present with features of bone marrow failure. Acute promyelocytic leukaemia is a unique subtype of acute myeloid leukaemia which may typically present with disseminated intravascular coagulation (DIC) requiring expert haematological management.<sup>4</sup> Acute lymphoblastic leukaemia is the commonest encountered in children. The lymphomas are a complex and heterogeneous group of malignancies ranging from highly malignant disorders through to low-grade indolent disease not requiring therapy.

The myelodysplastic syndromes are a group of disorders in which the main feature is bone marrow dysplasia. They are a heterogeneous group of potentially malignant haematological disorders which may be the harbingers of more classic leukaemic states or may behave as slowly evolving marrow failure syndromes. They usually occur in the elderly, have an insidious onset and may have a variety of clinical manifestations.

Dysplasia may affect any of the haemopoietic elements, with the patient presenting with a range of peripheral blood abnormalities, most commonly including anaemia, thrombocytopenia and neutropenia. Diagnosis, classification, understanding of pathophysiology and therapy have undergone enormous changes in recent years and the non-specialist can be excused for feeling confused.<sup>5,6</sup> There is a rising prevalence and incidence of the myelodysplastic syndromes. Epidemiological data indicate that they are more common than initially thought and probably on the increase, especially due to the ageing population and their occurrence as a late complication of cytotoxic chemotherapy.

Awareness of these relatively common disorders is important as undiagnosed patients with relatively normal blood counts may present de novo with life-threatening infection or haemorrhage in a postoperative or trauma setting.

## COMPLICATIONS OF HAEMATOLOGICAL MALIGNANCY AND ITS THERAPY

### METABOLIC DISTURBANCES

At presentation, haematological malignancy may be associated with a range of metabolic derangements.<sup>7</sup> Hyperuricaemia and hypercalcaemia are well-recognised complications which may be associated with renal failure.<sup>8</sup> The tumour lysis syndrome is a rarer complication which may occur spontaneously or shortly after the initiation of therapy.<sup>9,10</sup> There is sudden liberation of intracellular contents in quantities that overwhelm the excretory capacity of the kidneys, resulting in hyperkalaemia, hyperphosphataemia, hypocalcaemia and occasionally lactic acidosis. Pre-empting the development of this syndrome usually allows control of the metabolic effects, especially with the maintenance of high intravenous fluid intake, alkalinising the urine and administration of allopurinol. More recently, intravenous rasburicase – a recombinant uricolytic agent which, in contrast to allopurinol, acts on existing uric acid concentrations – is being used for the management of anticancer therapy-induced hyperuricaemia.<sup>11</sup> Rasburicase is contraindicated in patients with methaemoglobinaemia and glucose-6-phosphate dehydrogenase deficiency.

Multiple myeloma may be complicated by renal insufficiency, hypercalcaemia, hyperviscosity and hyperuricaemia. Most of these can be managed conventionally; however, with large amounts of monoclonal protein, fluid management can be difficult due to the hypervolaemia with or without hyperviscosity and plasma exchange may be indicated (see Chapter 90).

### COAGULOPATHIES

A range of haemostatic disturbances may occur in association with haematological malignancy and its therapy. Most of these are considered in general terms in Chapter 91 which outlines the general principles of diagnosis and management.

### ACUTE RESPIRATORY DISTRESS SYNDROME

Acute (or adult) respiratory distress syndrome (ARDS) remains a potentially lethal complication of autoaggressive inflammation. As most of the mediators (cytokines, neutrophils and endothelial adherence molecules) initiating the disease process are haemopoietic in origin it is not surprising that ARDS may occur in haemopoietic malignancies. However, ARDS is relatively uncommon in the neutropenic septic patient, probably due to the fact that the neutrophil under normal circumstances is one of the central mediators of this syndrome. ARDS and interstitial pneumonitis may be a problem due to hyperleukocytosis, transfusion-related acute lung injury (TRALI; see

Chapter 88), cytomegalovirus (CMV) infection, DIC, post marrow transplantation, and sometimes in relation to chemotherapy and radiotherapy. The use of all-trans retinoic acid (ATRA) may be associated with the development of a potentially lethal ARDS/pulmonary leukostasis syndrome (retinoic acid syndrome), usually in association with a rising leukocyte count.<sup>12</sup> In all the settings mentioned, early recognition of the symptom complex of fever and dyspnoea (with or without pulmonary infiltrates) is important and therapy with high-dose corticosteroids decreases morbidity and mortality.

### SIDE-EFFECTS OF CHEMOTHERAPY

The wide range of cytotoxic chemotherapeutic agents used in the management of haematological malignancy may be responsible for a plethora of toxicities other than bone marrow suppression. The haematologists will be aware of these and should communicate necessary information to the intensive care unit (ICU) staff.

### BONE MARROW FAILURE

Most of the acute leukaemias present with clinical and laboratory features of marrow failure with anaemia, bleeding or infection. If not a problem at presentation, marrow failure is almost universal during remission induction and subsequent chemotherapy.

### Neutropenia

Neutropenia should be considered in the following terms:

- Absolute neutrophil count, the rate of fall, the nadir and duration.
- Duration of the neutropenia is a critical factor determining the management and outcome. Patients with profound prolonged neutropenia of  $< 0.1 \times 10^9/l$  granulocytes for  $> 10$  days require special attention and they may require different initial therapy.

For practical purposes neutropenia has been divided into the following groups:

- Neutropenia  $< 0.5 \times 10^9/l$
- Neutropenia between  $0.5$  and  $1.0 \times 10^9/l$  and potentially falling
- Neutropenia  $0.5$ – $1.0 \times 10^9/l$  and stable or rising
- Profound prolonged neutropenia

Figure 92.1 illustrates the numerous interacting factors to be considered when managing patients with neutropenia in association with haematological malignancy and its therapy. Table 92.1 lists the organisms which may be associated with various defects in the host defence system.

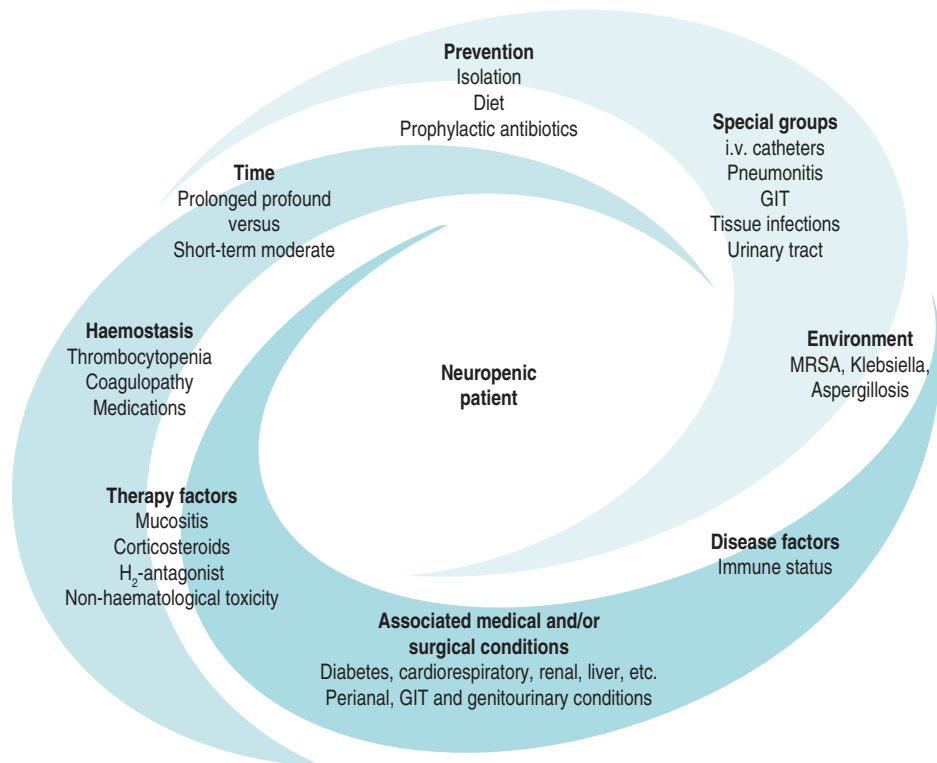

## PRINCIPLES OF MANAGEMENT OF HAEMATOLOGICAL MALIGNANCIES

### ICU ADMISSION

Patients with haematological malignancy may be critically ill from their disease or therapy, for brief or long

**Figure 92.1** The neutropenic patient. GIT, gastrointestinal tract; MRSA, meticillin-resistant *Staphylococcus aureus*.

periods. At times during therapy they may require intensive supportive therapy and can develop a range of life-threatening complications. Rarely, it is necessary to admit critically ill patients with haematological disorders to the ICU. Under normal circumstances, admission of such patients is to be avoided as they have severely impaired host defences and poor tolerance for invasive procedures. However, mechanical ventilation may be required for severe respiratory infections or pneumonitis. Such patients may present specific problems for the ICU staff. Most patients have severe marrow failure requiring intensive transfusion support. Severe neutropenia is the main, and most life-threatening, defect in the host defence system. Nutrition can be a challenge in these patients due to a multitude of factors. The anorexia, nausea and vomiting with chemotherapy, oral mucositis, hypermetabolism, malabsorption and diarrhoea are only some of the factors mitigating against maintaining an adequate nutritional state, and parenteral nutrition may be needed if the period of therapy is prolonged.

There must be good communication between the ICU staff and clear policies on admission and treatment. If the patient's ultimate prognosis is poor, extraordinary invasive measures cannot be justified. A palliative approach will be instituted if the patient does not respond to treatment within a specific period of time. However, if the

haematological malignancy has a high likelihood of cure or long-term good-quality survival, more strenuous and extended intensive care support can be justified.

### INFECTION PREVENTION

Prevention of infection is extremely important and meticulous attention to sterility with invasive procedures (e.g. i.v. line insertions) is essential. Infection may be endogenously or exogenously acquired. Most patients when they are admitted to hospital become colonised with the hospital flora. The major sources of infecting organisms, however, are the patients themselves (e.g. from the oropharynx, the gastrointestinal tract, i.v. line sites, lung and local lesions).

All ICUs must demand strict adherence to infection control guidelines. The most effective procedure is hand-washing by all health care workers involved in the care of the immunocompromised patient.

Other preventive measures include sterile techniques for invasive procedures by experienced staff, maintaining a clean environment, cooked patient meals, and limited use of prophylactic antibiotics. Needless to say, excessive use of antibiotics is a major factor in the emergence of resistant strains and the susceptibility to colonisation with hospital-acquired organisms. Many would argue that the efficacy of empirical therapy in the neutropenic patient

**Table 92.1** Organisms associated with immune deficiency states

<b>Neutropenia</b>

<b>Humoral immune dysfunction</b>
<b>Bacteria</b>
<i>Streptococcus pneumoniae</i>
<i>Haemophilus influenzae</i>

is such that prophylaxis may be unnecessary. Reverse barrier nursing is instituted in order to minimise exposure to exogenous infection. This can be difficult in a critical care setting and will not prevent infections of endogenous origin.

#### INVASIVE PROCEDURES

Invasive procedures should be kept to a minimum and, when performed, appropriate steps should be taken to minimise bleeding and the risk of infection. Endotracheal intubation should be avoided or minimised if at all possible. Biopsy procedures, arterial access, and other invasive procedures should be well planned and discussed with the haematologists.

#### BLOOD COMPONENT THERAPY

During the period of marrow suppression red cell concentrates may need to be administered to maintain oxygen-carrying capacity at a satisfactory level. There is much debate as to the appropriate trigger for red cell transfusion. The decision is essentially a clinical one that takes into account the numerous comorbidities that may occur in these patients, such as cardiorespiratory compromise, thrombocytopenia and physical activity. In general, a fixed haemoglobin level trigger is no longer appropriate. In some patients a higher oxygen delivery may be necessary (i.e. acute respiratory failure) and a higher haemoglobin level may be required (> 120 g/l). Maintenance of a higher haemoglobin may avoid the requirement for intubation and assisted ventilation.

Regular platelet concentrates are required. In the presence of sepsis platelets are consumed rapidly and transfusions may be necessary on a daily basis, otherwise every second day is usually adequate. The patient should be examined daily for evidence of haemostatic failure (e.g. purpura, ecchymoses, mouth, fundoscopy). Granulocyte transfusion may have a role in patients with proven unresponsive bacterial sepsis.<sup>13</sup>

#### ANTIMICROBIAL THERAPY

##### The febrile neutropenic patient

After resistance of the malignant cell to therapy, infection is the commonest cause of death in patients with haematological malignancy. Patients usually tolerate neutropenia without developing infection until the count is <  $1.0 \times 10^9/l$  and it is not until the neutrophil count falls to <  $0.2 \times 10^9/l$  that spontaneous overwhelming sepsis becomes a major potentially life-threatening problem. These patients must be watched closely for infection and treated early if necessary. When the neutrophil count is <  $0.5 \times 10^9/l$  any temperature above 38°C should be regarded as representing serious sepsis until proven otherwise. High-risk patients include those with pneumonitis, severe mucositis, an infected i.v. catheter and evidence of local sepsis. In patients with haematological malignancy and in allogeneic marrow transplant patients there may be pre-existing immunodeficiency.

The role of prophylactic antibiotic therapy has been controversial due to concerns related to the development of antibiotic resistant micro-organisms, but there is evidence to support their use.<sup>14,15</sup> Early empirical antibiotic therapy, without microbiological proof of cause, may be life-saving.<sup>16</sup> With most patients fever resolves, especially if marrow function returns in the short term. Ultimate proof of infection is frequently not established. Patients with agranulocytosis will not show the typical features of inflammation. For example, lung consolidation may not occur, cellulitis or sputum may not be clinically obvious, and urinary tract symptoms may be minimal. The role of steroids in suppressing temperature and clinical features of inflammation must also be considered. Non-infectious fever should be borne in mind (e.g. malignancy or drugs).

The presence of rigors, hypotension and shock may point more towards Gram-negative sepsis. The value of combination therapy with a  $\beta$ -lactam antibiotic in combination with an aminoglycoside has been demonstrated in patients with prolonged and severe neutropenia with Gram-negative septicaemia. Gram-negative sepsis is potentially rapidly fatal in the neutropenic patient, but is less common than in the past as the less virulent Gram-positive organisms now predominate. This may be related to several factors including the increased use of permanent indwelling intravenous devices, mucositis,  $H_2$  antagonists and the use of quinolones as antibiotic prophylaxis. However, both streptococcal and staphylococcal sepsis can be severe and empiric use of vancomycin in high-risk patients is justified. *Staphylococcus epidermidis* is an indolent form of sepsis and time is usually available for adjustment of therapy, with most patients recovering.

### The choice of empirical antibiotic therapy

Empirical antibiotic therapy should be aggressive with cover against Gram-negative sepsis as this is potentially lethal for the neutropenic patient.<sup>17</sup> Anaerobic cover may need to be included when there is any problem with the gastrointestinal tract (e.g. intra-abdominal or perianal problems). This is not usually necessary when problems are confined to the mouth.

The nature and site of infection is determined by a range of factors including:

- the host defence defect
- time course of neutropenia
- local microbiological ecology
- antibiotic usage (e.g. prophylaxis)
- haemostasis
- presence of indwelling lines (i.v., endotracheal, urinary)
- type of chemotherapy
- nature of disease
- patient factors (e.g. hepatic, renal, respiratory or other factors)

### Antibiotic regimens

Empirical antimicrobial regimens for neutropenic patients remain a constant changing and controversial issue.<sup>17,18</sup> Initial empirical antibiotic therapy should cover *Pseudomonas aeruginosa*, *Escherichia coli*, *Klebsiella* species, *Streptococcus viridans*, *Staphylococci* (coagulase negative and coagulase positive) depending on clinical circumstances. Other organisms should be covered after the results of cultures have been assessed or it is known that a specific organism is present in the ward (e.g. *Streptococcus viridans*) or on surveillance cultures. Coverage against *Staphylococcus epidermidis* is not necessary until bacteraemia is demonstrated.

**Single-drug therapy** Single-agent therapy with a third-generation cephalosporin (e.g. cefotaxime, ceftriaxone, ceftazidime, cefepime) may be adequate therapy in low-risk patients, i.e. neutrophil count  $> 0.5 \times 10^9/l$  and expected to stay above  $0.5 \times 10^9/l$  or neutropenia

expected to last less than 7 days. The carbapenems (e.g. imipenem and meropenem) are alternative choices to third-generation cephalosporins, having good *Pseudomonas* cover, and can also be used as monotherapy in low-risk individuals.

**Two-drug therapy** Two-drug therapy with an added aminoglycoside (gentamicin, tobramycin, amikacin, netilmicin) is recommended as standard initial empirical regimen in patients with prolonged and profound neutropenia and no additional risk factors.

**Three-drug therapy** Three-drug therapy with a glycopeptide (vancomycin, teicoplanin) added to the aminoglycoside and cephalosporin is indicated for patients who are particularly likely to be infected with coagulase-negative staphylococci, methicillin-resistant *Staphylococcus aureus*, *Corynebacterium* species and penicillin-resistant *Streptococcus viridans* (e.g. infected indwelling central venous catheter, pneumonitis, rash and severe mucositis).

Daily clinical assessment and review of microbiological results is essential. Antibiotic therapy is modified according to microbiological results. If no helpful microbiological information is forthcoming in the case of single- or two-drug therapy, the antibiotic regimen should be re-evaluated at 48 hours and if there has been no response, a glycopeptide added. If the fever has resolved and the cultures are negative, the aminoglycoside may be ceased.

Multiresistant Gram-negative organisms occasionally cause problems (e.g. some species of *Acinetobacter*) and need treatment with amikacin. Vancomycin-resistant *Enterococcus* is also occasionally seen although it may only be a 'commensal' rather than actual cause of infection. Therapy with a new antibiotic of the oxazolidinone class, such as linezolid, may be necessary.

With patients on three-drug therapy, antibiotic reassessment at 72 hours is appropriate. If there is no response, further investigation such as a CT chest and bronchoalveolar lavage may be indicated. Depending on the clinical state of the patient the introduction of antifungal therapy should be considered. Fungal infections are an increasing problem in patients with profound prolonged neutropenia.<sup>19</sup> There is an increasing range of antifungals available, including voriconazole and the echinocandins (casposungin, micafungin). Standard amphotericin is now rarely used. Prophylaxis with new azoles such as posaconazole may reduce the incidence of *Aspergillus* as fluconazole has with *Candida* infection. The use of potent anti-*Aspergillus* agents seems to be resulting in the emergence of breakthrough fungal infections with *Mucormycosis*, *Scedosporium* and *Fusarium*. These are uncommon fungal infections which were only rarely seen previously.

### Haemopoietic growth factors, immunotherapy and granulocyte transfusions

Genetically engineered haemopoietic growth factors are now widely used to minimise the degree and time of neutropenia. Granulocyte and granulocyte-macrophage colony-stimulating factors are glycoproteins which stimulate

the proliferation and maturation of bone marrow progenitor cells, and increase the number and function of these committed cell populations. Treatment reduces the duration and severity of neutropenia in patients receiving chemotherapy and after haemopoietic stem cell transplantation.<sup>20</sup> Growth factors do not prevent neutropenia, but do shorten its duration, and their use has been associated with fewer infectious febrile episodes. Intravenous immunoglobulin should be infused in patients with hypogammaglobulinaemia. Granulocyte transfusion may have a role if bacterial-proven sepsis is not resolving or there is evidence of spreading local bacterial infection.

#### Patient subgroups

**Indwelling intravenous catheters** Indwelling intravenous silastic catheters provide a nidus for both infectious and non-infectious complications. The incidence of catheter-associated infections varies. Indwelling i.v. catheters present an increased risk of infection for both neutropenic and non-neutropenic patients. Coagulase-negative staphylococci are the most common cause of catheter-associated bacteraemia, but *Staphylococcus aureus*, *Bacillus* species, *Corynebacteria* and Gram-negative organisms (especially species of *Acinetobacter* and *Pseudomonas*) can also cause catheter infections and *Candida* infection can be catheter related. Exit-site infections and infections along the subcutaneous tunnel of the catheter can be caused by aerobic bacteria, *Mycobacteria* and fungi.

If bacteraemia is thought to be catheter related, it may be possible to avoid removal of the catheter, particularly if the infection is caused by coagulase-negative staphylococci. Even patients with Gram-negative infections can often be successfully treated with antibiotics infused through the catheter. In patients with multiple-lumen catheters, the administration of antibiotics should be rotated through all the lumens, as infection may be restricted to only one. However, removal of the catheter is usually necessary for bacteria (e.g. species of bacillus) that may not be eradicated even though sensitive to antibiotics and with candidaemia in which there is a high incidence of dissemination. Patients with tunnel infections usually require catheter removal.

**Lung infiltrates** Lung infiltrates in febrile patients with neutropenia represent a high risk of treatment failure. Prolonged neutropenia has a significantly adverse effect on the outcome of infection. Incorporation of systemic antifungal agents into first-line therapy, particularly in selected high-risk subgroups, may improve the outcome. Involvement of a respiratory physician with experience in managing immunocompromised patients is important. Pulmonary investigations such as fine-cut chest CT, bronchoscopy, bronchoalveolar lavage  $\pm$  transbronchial biopsy may be required. Pulmonary haemorrhage can be a sudden and life-threatening cause of pulmonary infiltration and respiratory insufficiency. This usually occurs in severe thrombocytopenia associated with infection, and in patients who have become resistant to platelet transfusions.

## HAEMOPOIETIC STEM CELL TRANSPLANTATION

Haemopoietic stem cell transplantation therapy is increasingly establishing a role in the treatment of a wide range of malignant and non-malignant disorders.<sup>21</sup> Allogeneic haemopoietic stem cell transplantation has been used as an adjunct to the treatment of acute leukaemia with an impressive success rate, which is translating into long-term survival and cure. This success is now being extended to the management of a wider range of haematological malignancies and some solid tumours. Haemopoietic stem cells can be obtained from either marrow aspiration or from the peripheral blood by apheresis using a blood cell separator following stimulation of the marrow with haemopoietic growth factors  $\pm$  cytotoxic chemotherapy. Allogeneic transplantation brings with it a range of potentially serious and potentially fatal complications related to graft-versus-host disease (GVHD).<sup>22</sup> It does, however, have the advantage of using normal stem cells which need not be stored and a limited degree of GVHD may have a beneficial anti-tumour effect. Autologous stem cell transplantation is of particular advantage when relatively normal bone marrow can be obtained, in which case GVHD is not a problem.

The principles for the use of bone marrow transplantation in the management of malignancy include the following:

- The tumour must be responsive to chemotherapy and/or radiotherapy.
- The dose limitation of the chemotherapeutic agents used relate to marrow toxicity and not other end-organs.
- There should be a source of uncontaminated, or minimally contaminated, haemopoietic stem cells.
- Appropriate haemopoietic supportive therapy must be available during the marrow aplastic period.
- High-quality clinical and laboratory facilities must be available for the collection and preservation of haemopoietic stem cells.
- An integrated team of medical and nursing and scientific staff is essential.
- The preparation of a well-documented clinical protocol and effective implementation, with appropriate monitoring, is essential for success. The general management of the patient during the procedure is similar to the management of other patients receiving high-dose chemotherapy who will have prolonged neutropenic periods.

### COMPLICATIONS OF HAEMOPOIETIC CELL TRANSPLANTATION

#### Respiratory failure in haemopoietic cell transplant patients

Respiratory failure is the commonest cause of death in patients undergoing bone marrow transplantation. Both CMV-induced interstitial pneumonia and the idiopathic pneumonia syndrome rarely occur in the early cytopenic phase post transplantation. Haematological reconstitution with donor-type cells seems to be a prerequisite to

the development of these pulmonary complications, suggesting a key role of immunological reactions. While CMV pneumonia can be effectively treated or prevented by ganciclovir, the idiopathic syndrome is usually fatal. Due to improved prophylaxis and therapy, lethal interstitial pneumonia due to *Pneumocystis jiroveci* (formerly *P. carinii*), *herpes simplex*, *varicella zoster* or *Toxoplasma gondii*, as well as lethal pneumonia caused by bacteria or *Candida* species, is generally less common. However, *Aspergillus* species have emerged as frequent causative pathogens. Prolonged granulocytopenia and prolonged medication with corticosteroids are major risk factors for pulmonary aspergillosis, which is commonly fatal, but prophylaxis may be achieved by sterile air supply during the hospital stay and by prophylactic inhalation of amphotericin B. Pulmonary haemorrhage, diagnosed by bronchoalveolar lavage, may develop due to the toxicity of the conditioning regimen, or may be secondary to infectious pneumonia of various kinds. Congestive heart failure might give rise to the development of pulmonary oedema. Patients with hepatic veno-occlusive disease have a high risk of subsequent pulmonary complications.

#### Graft-versus-host disease (GVHD)

GVHD is a major complication of allogeneic haemopoietic stem cell transplantation, especially with the increasing use of unrelated and mismatched donors.<sup>22</sup> The target of the immune response in GVHD has long been regarded to be histocompatibility antigens possessed by the host, but not the donor. However, it is now recognised that self-antigens have been documented in GVHD, confirming that it is more complex than simple alloreactivity. Cytokines play a central role in mediating many of the manifestations of GVHD.

Nearly all patients with GVHD have a rash. Other features include liver and gastrointestinal dysfunction. Initial therapy for low-grade disease is systemic corticosteroids. Treatment for more severe disease may include a range of therapies, including ciclosporin, anti-thymocyte globulin, tacrolimus, methotrexate, PUVA and thalidomide.

#### Veno-occlusive disease of the liver

Veno-occlusive disease can be a major complication of haemopoietic stem cell transplantation, predominantly seen in allogeneic transplants, and is a major contributor to mortality.<sup>23</sup> The disorder is due to thrombotic occlusion in the small hepatic vessels, probably as a result of endothelial damage associated with high-dose chemotherapy. The problem manifests as weight gain, oedema, ascites, tender hepatomegaly, jaundice and may proceed to liver failure. Prophylaxis with low-dose heparin or prostaglandins may be useful. Treatment is predominantly supportive with fluid management a critical aspect. Treatment with tissue plasminogen activator and anti-thrombin III concentrates has been successful.

# Organ donation

Stephen J Streat

Intensivists often have responsibility for the care of organ transplant recipients and have seen the benefits they obtain from transplantation. Clinical results continue to improve, despite increasing recipient case complexity and increasing use of organs from extended-criteria deceased donors, and this success continues to drive demand for transplantation.<sup>1</sup> At the same time, deaths from road trauma (once the most common cause of death in deceased-donor organ donation) continue to fall in many countries as a result of both primary prevention and better treatment of traumatic brain injury. Decompressive craniectomy in particular is effective in controlling refractory intracranial hypertension<sup>2</sup> (and thereby reducing brain death), although whether outcomes are improved overall await the results of two ongoing clinical trials. Similarly, population-based studies have shown falls in the incidence and mortality of subarachnoid haemorrhage<sup>3</sup> and perhaps also intracerebral haemorrhage. Treatments for some other conditions which uncommonly contribute to deceased-donor donation (e.g. hypoxic-ischaemic encephalopathy, meningitis) have also improved.

With the exception of the USA, many countries are now experiencing a fall in brain dead organ donation. Transplant numbers have been maintained, or only modestly increased, by other strategies, including donation after cardiac death (DCD, formerly called non-heart beating donation), live donors (including altruistic donors) and the use of split livers for two recipients. There is considerable pressure on intensivists and others to provide a solution to the 'organ donor shortage', but less consideration given to restricting access to waiting lists. Despite widespread condemnation of the practice, desperate recipients from wealthy countries take part in 'transplant tourism'<sup>4,5</sup> in Asia (particularly in China, including organs from executed prisoners), Africa and South America. The internet has facilitated a form of altruistic but directed live donation which also is potentially vulnerable to commercial exploitation (e.g. <http://www.matching-donors.com>). Slow progress continues in alternative approaches to end-stage organ failure, including artificial organs, xenotransplantation and the engineering of organs and tissues from stem cells, but none is yet available for routine clinical use.

## RESPONSIBILITIES OF THE INTENSIVIST

Most intensivists are supportive of deceased-donor organ donation.<sup>6</sup> Those who are not should make arrangements with other intensivist colleagues for the care of potential organ donors and discussions with their families.<sup>7</sup> Intensivists' responsibilities include the care of dying patients and of their families in the intensive care unit – the location of organ donation itself. Intensivists therefore must either define and take responsibility for good practice in organ donation, or accept that these processes will be taken over by others with the objective of 'transforming the greatest possible number of cadavers into real donors'.<sup>8</sup> This personal epiphany<sup>9,10</sup> is not yet widely shared in intensive care medicine.

Intensivists must ensure that the processes involved in deceased-donor organ donation, now including DCD, continue to be publicly seen to be of the highest standard. These processes include the care of the dying patient and their family, determination of death, identification of the potential for organ donation to occur, offering the opportunity for organ donation to the family, maintenance of physiological stability after brain death throughout the time until organ retrieval, withdrawal of treatment and determination of death in DCD, and after-care for the family of the deceased, irrespective of whether organ donation took place

## CARE OF THE DYING PATIENT AND THEIR FAMILY

Intensivists are familiar with the care of the dying patient, including the need to avoid suffering and maintain patient dignity. The respect of the intensive care unit (ICU) staff for the humanity of the dying person is expressed in the 'patient comfort care' provided by the nursing staff, the continued involvement and attentiveness of the medical staff, and in evident compassion of all staff for the family.<sup>11</sup>

On behalf of all the treating team, an intensivist should establish rapport during an early meeting (e.g. the morning after admission) with the family of every intensive care patient. This is particularly important for families of patients at high risk of death or disability with whom

there will often need to be several ‘bad news’ meetings over several days. Family meetings should be attended by whomsoever the family defines itself to include, by the intensivist, and by a member of the nursing staff supporting the family (preferably the ‘bedside nurse’ looking after the patient). If the family wishes, the meeting might include a chaplain, social worker or cultural health worker. The ‘support’ role should be kept separate from the ‘bearer of bad news’ role. Family meetings should be held in a separate private room large enough to accommodate all the participants, away from the bedside and protected from interruption. With evident compassion<sup>11</sup> the intensivist should convey an accurate account of the sequence of events, a realistic prognosis (in as much as this is possible) and the immediate treatment plan. Some families find CT or other visual information helpful. There must be enough time to answer any questions that the family may have. At the end of the meeting the intensivist should ascertain that the family understands what has been said<sup>11</sup> and agrees with the immediate plan. Ensuring that all team members give the family congruent messages is an essential part of maintaining the trust of the family in the ICU team. Ideally, one intensivist should speak with the family but where this is impractical it is vital that there be detailed and explicit discussions between one intensivist and another before the next family meeting. A relationship of mutual understanding and trust will enable the ICU team and the family to work together through difficult and painful issues, including withdrawal of intensive therapies,<sup>12</sup> death of the patient and consideration of organ donation.

Many patients who develop apparent loss of brainstem function do so despite continuance of all available surgical and medical therapy. In these circumstances, brain-oriented intensive therapies (including sedatives, opioids, neuromuscular blockers, hypothermia and osmotherapy) should be withheld pending formal assessment of brain death. In order to meet the preconditions for brain death assessment,<sup>7</sup> extracranial homeostasis must be maintained, and these conditions also preserve the possibility of organ donation in the future.

Withdrawal of intensive therapies is common practice in Australasian ICUs.<sup>12–14</sup> In the setting of severe brain damage this first involves assembling definitive prognostic information. Although neurophysiology and imaging provide important supportive information, a sedative-free clinical assessment of CNS function is an essential aspect of prognostication. During the period of sedative-free CNS assessment, some patients will suffer apparent loss of brainstem function. If brain death does not occur, but devastating brain damage has clearly occurred, those treating the patient (e.g. intensivists, neurosurgeons and others) should achieve a consensus view of prognosis and a recommended treatment plan, which might include withdrawal of intensive treatments (e.g. artificial airway, ventilatory or inotropic support, further neurosurgery). The intensivist should then discuss the prognosis and recommended plan with the family and facilitate a

consensus. Withdrawal of treatment may subsequently occur, either because death is seen to be imminent and inevitable or because the likely survival outcome would not be in accord with the patient’s previously expressed wishes or inferred best interests. Such a decision to limit or withdraw treatment is guided by the principles of non-maleficance and respect for autonomy.<sup>15</sup> It is appropriate to withdraw all intensive therapies from such patients, while continuing to provide ‘comfort care’ to the patient and support to the family.<sup>15</sup>

The possibility of future organ donation must have no influence on a decision to limit or withdraw specific brain-oriented therapies. A minority of patients having intensive treatments withdrawn will die within a short period of time (i.e. under 1 hour) and it is in such circumstances that DCD is possible. Some families of dying patients volunteer the view that they (and/or the patient) would wish for organ donation to take place, if that is possible. Such views are commonly conveyed prior to the determination of brain death in patients who seem very likely to become or may already be brain dead, but can also be made when the patient retains brainstem function, and sometimes even prior to a decision that intensive treatments will be withdrawn. They should be sensitively acknowledged by the intensivist, and assurances given that the intensivist will revisit this issue without prompting with the family if and when the clinical circumstances are appropriate. However, the possibility of DCD must not be raised by the treating team prior to a consensus decision of the family and treating team that treatment will be withdrawn.

#### IDENTIFICATION OF THE POTENTIAL FOR ORGAN DONATION TO OCCUR

Most ICUs admit patients with very severe brain damage whose probability of recovery is low. The rationale for this practice is to identify any (small) subgroup of patients with reversible conditions and provide them with the necessary treatment to facilitate their recovery. There are, however, more extreme situations when the chance of recovery is thought so remote that admission of the patient to ICU would not ordinarily occur. Some intensivists advocate admitting these patients to ICU solely to allow for the future possibility that organ donation may occur, sometimes with accompanying explicit discussion and agreement of the family to such a plan.<sup>16</sup> Although it seems likely<sup>16</sup> that such an utilitarian approach might increase the number of organs available for transplant, ethical,<sup>17</sup> legal<sup>18</sup> and clinical<sup>17</sup> objections to the practice have all been raised.

Organ donation is possible in most situations where brain death has been confirmed. The absolute general contraindications to organ donation are few and present in a small minority of brain-dead patients. They include situations where there is an unacceptably high risk of transmission of malignancy or infection to the recipient, or where the function of the possible donor organs is

**Table 93.1** Information likely to be required by transplant teams

Age, sex, weight, approximate height
Medical and social history (including comorbidity, surgery, medication, alcohol, smoking, illicit drug use, tattoos, body piercing, sexual history and allergies)
Detailed clinical history of fatal illness (including history of cardiac arrest, periods of hypotension or hypoxia, evidence of aspiration or sepsis)
Current clinical status (including physiological parameters and the extent of ventilatory and inotropic support)
Current investigations (including blood group, arterial blood gases, chest X-ray, ECG, serum urea, creatinine, electrolytes, glucose, bilirubin, transaminases, alkaline phosphatase and gamma-glutamyl transpeptidase, prothrombin ratio, activated partial thromboplastin time, haemoglobin, white cell count, platelets and all microbiology results)
Other investigations may be required later (e.g. echocardiogram or bronchoscopy)

likely to be unacceptably poor. Most extracerebral malignancies and certain infections (e.g. HIV) are likely to remain absolute contraindications but other donor factors (e.g. advanced age, recent bacterial sepsis,<sup>19</sup> treated HSV encephalitis, positive HCV<sup>20</sup> or HBV<sup>20</sup> serology, some 'apparently cured' malignancies) are no longer absolute contraindications. Intensivists should discuss the specific issue with the appropriate agency (donor coordinator or organ procurement organisation) rather than decide that organ donation is contraindicated on medical grounds. Similarly, the organ-specific contraindications to organ donation have reduced in recent years as the outcomes of recipients transplanted with donor organs formerly rejected have been found to be acceptable.<sup>21</sup> Finally, all contraindications vary somewhat between transplant centres and continue to change in a more permissive direction. Intensivists should discuss these organ-specific issues with the donor coordinator or appropriate agency before deciding that any particular organ is unsuitable for possible donation and subsequent transplantation. In most jurisdictions an appropriate authority (e.g. a coroner or medical examiner) may legally interdict organ donation under certain circumstances (e.g. homicide) and this issue must also be clarified with the donor coordinator. The donor coordinator will clarify with the transplant teams whether any organ donation is possible and whether particular organs may not be suitable, and the intensivist should ensure that the information (Table 93.1) necessary for these decisions is provided.

### DETERMINATION OF BRAIN DEATH

This is a clinical responsibility of the intensivist and must be carried out according to appropriate codes of practice or clinical guidelines (see Chapter 46). The determination of brain death<sup>7,22,23</sup> involves several stages:

1. establishing the presence of a condition known to produce severe and irreversible structural brain damage
2. exclusion of possible confounding factors
3. determination by two independent clinical examinations that there is profound unresponsive coma and persistent absence of brainstem function

The examination and determination of brain death is facilitated by a proforma and should be documented in the medical record. When clinical examination is confounded (e.g. by barbiturate coma), then absent cerebral blood flow must instead be demonstrated by reliable imaging.<sup>7</sup>

The intensivist should convey the fact of brain death and its medical and legal implications to the family. It can be difficult to accept brain death as death, given the life-like appearance of the skin, the rise and fall of the chest and the warmth of the hands that are preserved by ventilatory and circulatory support.<sup>24</sup> Some family members appreciate an offer to view the (second) clinical examination for brain death (taking care to explain beforehand the possibility of spinal reflexes), or the cerebral blood flow study when clinical examination is confounded. This may help them to understand and accept the final awful implication of this diagnosis. Intensivists should be open to offering these options.

In the absence of organ donation, it is appropriate to remove ventilatory support at a time that allows for family needs.

### DONATION AFTER CARDIAC DEATH

Donation after cardiac death (DCD), previously known as non-heart-beating donation, is increasing in many countries but is not yet practised worldwide. Kootstra and colleagues from Maastricht have long been advocates for DCD, and described four categories of 'non-heart-beating' donors; this terminology remains in common use.

- Category I: those who are dead on arrival
- Category II: those in whom cardiopulmonary resuscitation is ceased
- Category III: those in whom cardiac arrest is expected to soon occur
- Category IV: those who have cardiac arrest while brain dead

In all but Category III the situation is 'uncontrolled'.<sup>25</sup>

DCD practice varies considerably worldwide. Category II donors are most common in the Dutch experience but donation does occur from all categories. Almost all DCD donors in the UK, USA, Canada and Australasia are Category III (and a very few are Category IV). By contrast, in Spain, although withdrawal of treatment in ICU is far less common than in Holland or the UK,<sup>26,27</sup> and Category III donors are rare, immediate postmortem organ preservation measures (including cardiopulmonary bypass) can be implemented with prior consent and most DCD donors are Category I and II.<sup>28</sup>

Recent advocates for DCD commonly assert that ‘all organ donation occurred this way’ before brain death was accepted as legal death. Although organs were removed after circulatory arrest, there are differences which are not discussed and which negate the assertion that the processes are identical. Although brain death was not accepted as legal death, the syndrome had been recognised many years earlier (e.g. absent cerebral blood flow<sup>29</sup> was reported in 1956 and the clinical syndrome<sup>30</sup> in 1959). The final awful meaning of the brain death syndrome (‘apnoea, fixed dilated pupils, polyuria, hyperglycaemia and spontaneous hypothermia’<sup>31</sup>) was understood by intensivists and nephrologists and conveyed to families at that time, prior to a discussion of organ donation (PB Doak, RV Trubuhovich, personal communications). Organ donation was not discussed with the family if some brainstem function (usually only a tracheal reflex) was known to be present. Apnoea at hypercarbia was not specifically tested for but the shared expectation of the family and the treating team was that the patient would not breathe after withdrawal of ventilatory support (although a few did, for a short time and inadequately). Cardiac arrest usually occurred in 15–20 minutes, at which point death was declared and the kidneys were removed.

In contrast to organ donation after brain death, in (Category III) DCD the patient is known not to be brain dead at the time of organ donation discussion, may well breathe after extubation and may not die in the timeframe where organ donation is possible. These differences have ethical and clinical consequences for intensivists which are discussed below.

Delayed graft function is more common (~40% vs. ~20%) in recipients of DCD kidney grafts,<sup>32</sup> but long-term recipient outcomes are equivalent to those who receive a graft from a brain-dead donor.<sup>33</sup> Both graft and patient survival after DCD liver grafts are lower than after grafts from brain-dead donors (e.g. 5-year graft survival 52% vs. 66%, 5-year patient survival 65% vs. 72%),<sup>34,35</sup> probably reflecting both intolerance of the liver to more than 15 minutes of warm ischaemia and impaired small vessel washout of the biliary system. Less viscous preservation solutions may ameliorate this latter problem. Patient survival is less impacted than graft survival but at the expense of an increased frequency of retransplantation. Recipient and graft outcomes after pancreas transplantation with grafts from DCD donors are similar to those from brain-dead donors.<sup>36</sup> Although successful lung and even heart transplantation from DCD donors is being reported, experience so far is insufficient to characterise the long-term recipient outcomes.

Following the Institute of Medicine report<sup>37</sup> in 1997 there has been an explosion of publications on the legal, ethical and medical issues raised by DCD<sup>25,38,39</sup> and more recently several national guidelines or recommendations have been produced which address these issues.<sup>35,40,41</sup> Recommendations for Australasia have been developed by the Australian and New Zealand Intensive Care Society.<sup>7</sup>

There are many potentially contentious issues, including ensuring that there has been a consensus decision to withdraw treatment before the family are presented with the option of possible organ donation after death, estimating the probability of death soon after withdrawal of treatment, use of agents (e.g. heparin) and procedures (e.g. instrumentation) prior to death that are for ‘organ benefit only’, location of withdrawal of treatment (ICU or operating room), presence of the family after withdrawal of treatment, use of opioids and sedatives after withdrawal of treatment, separation of clinical responsibility for end-of-life care (including opioids, sedatives and determination of death) from responsibility for organ procurement, timing of organ removal after death, abandoning the procedure (but continuing comfort care) if the patient does not die within a predetermined time (usually 1 hour) after withdrawal of treatment, ensuring that the family are fully informed and supported throughout the process, ensuring that all participating personnel are familiar with, and accepting of, DCD procedures and ensuring that appropriate protocols which explicitly address all of these issues are in place in each participating hospital. DCD should only take place in the context of such protocol wherein broad clinical, ethical and societal consensus has been achieved after wide consultation. Where this has been done, DCD has been viewed favourably by both families and hospital staff, has compensated for the fall in brain-dead donors in Holland and the UK, and has modestly increased the number of organs (particularly kidneys) available for transplant in the USA.

#### OFFERING THE OPPORTUNITY FOR ORGAN DONATION TO THE FAMILY

Organ donation (from deceased donors) is an activity that takes place at the end of life, usually involving an intensive care unit. It is separate from transplantation which is concerned with the care of patients with end-stage organ failure who may receive donated organs. Appreciating this distinction is fundamental to an understanding of important issues that are often ignored or dismissed in transplant-oriented publications. Organ donation fundamentally modifies human rituals at the time of death, even of death in the ICU. Organ retrieval is an invasive procedure carried out in the operating room. Although it is done respectfully and with identical surgical processes to those used on living people, it is nevertheless viewed by some<sup>42</sup> as ‘mutilating’. Discussion of organ donation is an emotionally intense activity involving a newly bereaved family and a health professional, and requires very clear and sensitive communication. This discussion takes place when family members are experiencing the death of their family member. They must consider the issue amidst their intense grief – there is no other time. Knowledge of transplantation varies widely in the community and there is even less knowledge of organ donation processes. Some families may not previously have known that organ donation and transplantation occur! Similarly, discussion of organ donation and willingness to be part of it vary

widely in the community. There is greater support of 'organ donation in principle' than either individual willingness to donate or willingness to agree to donation on behalf of a family member. Discussion of organ donation among families is promoted as a way of increasing organ donation rates and it may do so. However, some family members hold strong views against organ donation based on spiritual, religious or cultural beliefs.<sup>42</sup>

There are several utilitarian attitudes about organ donation including the notion that organ donation is the only possible positive outcome that can occur in the setting of brain death,<sup>43</sup> that it is appropriate to refer to dead or dying persons in a utilitarian way as sources of organs for transplant,<sup>44</sup> that for many families organ donation can assist with easing the pain of loss, and that fulfilling the previously expressed wishes of the donor should be the primary or indeed the only<sup>45</sup> consideration. In some jurisdictions these wishes have indeed been defined to be legally sufficient for organs to be retrieved, and are often assumed to be a means of increasing the organ donation rate<sup>46</sup> by excluding the family from the opportunity to prohibit organ donation and 'returning control to the individual'. This assumption may well be erroneous.<sup>47,48</sup> Although many countries (including Australia) have defined the status of an individual's wishes about organ donation after their death to constitute legally sufficient 'consent', it is contentious whether the word itself is appropriate in this context<sup>10</sup> as the person is dead at the time that the issue becomes 'live' and further, it is unlikely that any current 'register-based' record of such wishes would meet standards for informed consent<sup>49</sup> in a personal health care context.<sup>50</sup>

Implicit in a 'transplant-oriented' moral economy<sup>51</sup> is the judgement that for a family to agree to organ donation is both desirable and of greater moral value ('the right thing to do') than the contrary decision, particularly if organ donation was the previously expressed wish of the dead person. This judgement implicitly denies the legitimacy of the close human relationship between the family and the deceased to determine what should happen to their loved one after death,<sup>52</sup> but is now explicitly acknowledged, practised and advocated by many USA organ procurement organisations (S Gunderson, personal communication). Even in countries that legally allow the previously expressed wishes of the deceased to determine whether organ donation may take place, usual practice continues to both involve the family and not to proceed against family objection – accepting that the impact on the deceased's family is the most important factor determining consent practice.<sup>53</sup> However, in many countries this has resulted in the evolution, exposition and advocacy of strategies 'to overcome family objections'. The likely injurious effect of such 'strategies' on family bereavement<sup>54</sup> is not considered or reported by those who advocate for it, and whose sole measure of 'quality' or 'success' in organ donation practice is the proportion of situations in which donation occurs.

Intensivists should be aware of their own views on these matters, and indeed the views of others that might discuss organ donation with family members. Whilst

intensivists most often initiate discussion of organ donation with families in Australasia, this is increasingly unusual elsewhere. Whoever undertakes this discussion should be skilled in communication with grieving people. In Australasian clinical practice, the intensivist has already established a relationship with the family, involving mutual trust and respect, in prior family meetings during the patient's final illness. This relationship naturally allows the intensivist to initiate and facilitate discussion of organ donation. Defining the discussion as 'offering the option of organ donation' rather than 'obtaining consent' (or even 'persuasion'<sup>55</sup>) is not coercive in language and enables the intensivist to provide complete and unbiased information, support the family in their decision-making and thank them for their consideration, whatever the decision about organ donation might be.

The intensivist must ensure that the fact of death (in the situation of brain death) is understood. When (Category III) DCD is a possibility, there must be prior consensus agreement by the family and the treating team that treatment must be withdrawn before the option of possible organ donation is raised by the intensivist. The patient is clearly not dead at this time, although death is certainly anticipated to be imminent. This imminent death should also be understood by the family before the option of DCD is offered.

In either situation there must be sufficient time for the intensivist to inform the family of the option of organ donation and what it entails, to answer any questions and if necessary to facilitate decision-making by the family. The discussion may take into account previously expressed wishes, previous family discussions, values and beliefs of the patient and of family members. This discussion must not be coercive. Language that is potentially coercive (e.g. 'fulfilling the deceased's wishes', 'doing what he would have wanted', 'something good may come of this') can redefine the situation in terms of the family coming to fulfil the intensivist's wishes and should be avoided. Finally, some language is particularly insensitive from the perspective of grieving families and should be avoided (e.g. the use of the term 'harvest' rather than 'organ retrieval' to describe the process of organ retrieval, or 'the body' rather than the person's name to describe the brain-dead person). The intensivist should facilitate the family spending time at the bedside prior to organ retrieval if they wish. Some investigations (e.g. echocardiography or bronchoscopy) may be performed during this time and the family should be informed about these. The intensivist should ensure that the family is offered the opportunity to spend time with the deceased after organ retrieval.

#### MAINTENANCE OF EXTRACEREBRAL PHYSIOLOGICAL STABILITY IN BRAIN DEATH

Immediately prior to brain death there is usually a period of hypertension, tachycardia and occasionally dysrhythmia, mediated by both autonomic activity and catecholamine

secretion. Pulmonary oedema, biventricular dysfunction and myocardial injury may develop but there is debate about the implications of these for subsequent cardiac graft function.<sup>56</sup> If treatment of this adrenergic phenomenon is thought essential, then a short-acting  $\beta$ -blocker (e.g. esmolol) or only 'moderating' doses of a conventional  $\beta$ -blocker should be used. Cardiac arrest can rarely occur during this phase, usually due to tachydysrhythmia, but is often reversible. Hypertension is soon followed by hypotension, associated with marked reduction in sympathetic activity and catecholamine secretion. Hypotension may be profound in the presence of simultaneous hypovolaemia or cardiac dysfunction and can lead to cardiac arrest or loss of donor organ viability, and should be promptly treated by volume expansion and inotropic support.

Diabetes insipidus due to loss of ADH production soon follows in most but not all brain-dead persons and is manifest by brisk hypo-osmolar polyuria, which untreated will quickly lead to hyperosmolality and later to hypovolaemia. Other hormone abnormalities occur but do not have serious implications in the short term. Associated with the loss of cerebral blood flow there is loss of cerebral metabolism and a fall of around 25% in oxygen consumption and carbon dioxide production.<sup>57</sup> This leads to a fall in the necessary ventilatory minute volume necessary for normocarbica. The fall in resting energy expenditure (heat production) together with loss of vasomotor tone and the possibility of shivering-induced thermogenesis exacerbate the risk of hypothermia developing.

Spontaneous movements and spinal motor reflexes commonly persist in brain death.<sup>58</sup> These rarely include bizarre movements<sup>22,59</sup> which are often reproducible. Family members may be offered the opportunity to view the (perhaps second) clinical examination for brain death and should be warned about the possibility of these responses (which may not have occurred at the first examination) and given a prior explanation of them. These movements and sympathetic circulatory responses can also occur during organ retrieval in the operating room. The use of neuromuscular blockade and opioids is recommended in the operating room<sup>60</sup> although catecholamine responses are not suppressed by opioids in this situation.<sup>61</sup>

#### SUGGESTED STRATEGIES FOR MAINTAINING PHYSIOLOGICAL STABILITY

The onset of brain death is usually heralded by rises in intracranial pressure (if measured) and signs of progressive loss of brainstem function (coma, pupillary dilatation) and these features should initiate preparation for specific support strategies. This preparation should include ensuring that central venous access for inotropic support (and perhaps pressure measurement), intravenous access for rapid volume expansion and a source of external heat (e.g. a warming blanket) are all available.

#### VENTILATORY MANAGEMENT

The aims of ventilatory management are to maintain good oxygenation and normocarbica, minimise circulatory depression and maintain, if possible, sufficiently good lung function to allow for future lung donation to occur. The use of moderate tidal volumes (10–12 ml/kg) and addition of a low level of positive end-expiratory pressure (PEEP) (5 cmH<sub>2</sub>O) may prevent atelectasis. Originally a  $P_{aO_2}$  of more than 350 mmHg on 100% oxygen and 5 cmH<sub>2</sub>O PEEP was thought a necessary criterion for lung donation but  $P_{aO_2}/F_{iO_2}$  ratios of 300 or 250 have been found to be acceptable.<sup>62</sup> Peak airway pressures above 30 cmH<sub>2</sub>O should be avoided if possible. Usual pulmonary care including changes of position and sterile endotracheal suctioning must continue. When pulmonary dysfunction is severe, higher levels of PEEP may be required to prevent airway frothing or provide adequate oxygenation. The determination of apnoea during brain-death testing in such patients may require a period of mechanical hypoventilation prior to apnoea and continuation of continuous positive airway pressure (CPAP) during apnoea in such patients if serious hypoxaemia and circulatory depression are to be avoided.

#### CIRCULATORY MANAGEMENT

The aims of circulatory management are to maintain adequate organ perfusion and arterial pressure without producing fluid overload or excessive vasoconstriction, and without prejudicing future cardiac donation. Reasonable initial haemodynamic goals include normotension (a mean arterial pressure over 70 mmHg), heart rate of 100 beats per minute or less, and central venous pressure of 8 mmHg. Some inotropic support is almost always given (e.g. 92% of the 227 donors in 2006 in Australia and New Zealand<sup>63</sup>). Having established normotension with an inotrope infusion, the haemodynamic response to a controlled volume challenge should be assessed.

The choice of inotrope is the subject of more controversy than evidence. Dobutamine is not recommended. Noradrenaline (norepinephrine), usually less than 500  $\mu$ g/hour, is preferred in Australasia (85% of 208 donors in 2006 who received inotrope infusions<sup>63</sup>) without apparent harm to organ function in recipients. Dopamine may exacerbate tubular polyuria and is not commonly used in Australasia (8% of 208 donors in 2006 who received inotrope). Adrenaline (epinephrine) may have specific benefit on renal blood flow in brain death<sup>64</sup> but may also increase glycaemia and thereby osmotic diuresis. Catecholamine infusion may reduce the upregulation of organ immunogenicity that occurs in brain death and lower the incidence of acute rejection in subsequent recipients of kidney grafts.<sup>65</sup> Although levels of thyroid hormones fall after brain death, this is probably the 'sick euthyroid syndrome' and replacement of thyroid hormone does not improve the circulation after brain death.<sup>66–68</sup>

Corticosteroids are often given just prior to organ removal from brain-dead donors and commonly recommended

(on the basis of retrospective analyses) to increase the number of organs, particularly thoracic organs<sup>69</sup> that are retrieved and transplanted. Although steroids improve haemodynamics in an experimental model,<sup>70</sup> an early randomised human study<sup>71</sup> did not show any benefit in kidney graft outcomes. There are no other trials of steroids alone in human brain death and a single small trial of the combination of steroid and tri-iodothyronine ( $T_3$ ) similarly did not show beneficial circulatory effects.<sup>72</sup>

Vasopressin infusion, at least in low doses, reduces the amount of catecholamine required to support arterial pressure<sup>73</sup> without apparent detriment to subsequently transplanted organs. Whether this translates into improved outcome is uncertain. Following reports using retrospective analysis with multiple logistic regression,<sup>74,75</sup> many authors now advocate the use of so-called 'hormonal resuscitation' (combined use of  $T_3$ , steroid and vasopressin), although these authors of papers themselves cautioned that their results 'are based on a retrospective analysis and the finding should be confirmed in future prospective randomised clinical studies'.<sup>75</sup>

Control of excessive polyuria will minimise the risks of developing hyperosmolality,<sup>76</sup> hypovolaemia or hyperglycaemia secondary to infusion of large amounts of dextrose-containing fluids. Synthetic desmopressin (1-D amino-8 D arginine vasopressin) is commonly given to control diabetes insipidus and appears safe and effective.<sup>62,77</sup>

Control of diabetes insipidus is an essential aspect of rational fluid therapy, and hypovolaemia should be corrected with resuscitation fluids. Haemoconcentration occurs early after experimental brain death. Crystalloid infusion has been reported to worsen pulmonary function in brain death and somewhat larger volumes will be required than if colloid is used.<sup>78</sup> At least moderate anaemia is well tolerated in brain death but red cells may be given if needed to maintain packed cell volume around 0.25 pending organ retrieval. Free water should be given as necessary (1–2 ml/kg per hour as 5% dextrose) to maintain serum osmolality in the range of 280–310 mosm/kg, corresponding to serum sodium below 155 mmol/l. Severe hyperosmolality (probably a marker of inadequate donor care) is associated with poor graft function in subsequent liver recipients.<sup>76</sup> Failure to control diabetes insipidus will lead to increased requirements of free water to control serum osmolality. If 5% dextrose is used for this then hyperglycaemia and osmotic diuresis may result.

#### METABOLIC MANAGEMENT

Oxygen consumption, carbon dioxide production, heat production and glucose oxidation all fall in brain death due to the loss of cerebral metabolic activity.<sup>57</sup> Hypothermia may easily develop in association with vasoparesis, loss of shivering, exposure to room temperature, warm polyuria and infusion of room temperature intravenous fluids. Core temperature should be kept above the 35°C

required to confirm brain death.<sup>7,22</sup> Keeping the ambient temperature high (24°C) and using infusion fluid warmers, heated humidifiers and external warming systems may be required. Low-dose insulin infusion is occasionally required to prevent hyperglycaemia. Serum potassium should be kept above 3.5 mmol/l but potassium replacement should be given with caution as hyperkalaemia is not uncommon after brain death. Correction of hypophosphataemia does not improve haemodynamics in brain death.<sup>79</sup>

#### AFTERCARE OF THE DONOR FAMILY

Routine aftercare is increasingly recommended<sup>80</sup> for all families of patients who die in ICUs. Aftercare programs are well received<sup>11</sup> and have the potential to improve the care of subsequent families by revealing areas of inadequate or inappropriate communication.

There may be issues specific to organ donation that need to be addressed, sometimes by way of a family meeting with an intensivist at some later stage. Most organ donation agencies provide donor families with ongoing emotional support (which may extend over many years), provide them with limited anonymous information about recipients, and accept and facilitate limited anonymous communication (i.e. by letter) between recipients and donor families by mutual consent; direct contact is not recommended.

# Liver transplantation

Elizabeth Sizer and Julia Wendon

Liver transplantation has revolutionised the care of patients, with both acute and chronic end-stage liver disease becoming the treatment of choice in the absence of contraindications. It has become an almost routine procedure, with the majority of patients having a short postoperative intensive care unit (ICU) stay and 1-year survival > 90%.<sup>1–4</sup> Indications have widened, and contraindications decreased. As a consequence, the number of patients awaiting transplantation continues to outstrip cadaveric donor rates; waiting times lengthen, hence patients become critically ill before receiving a transplant, increasing risk and perioperative complications, and impairing long-term outcome.<sup>5</sup> Innovative strategies have evolved as possible solutions to the lack of cadaveric donor organs, including widening the donor pool to include previously unsuitable donors (so called marginal donors), paediatric and adult living-related donation, reduced size and splitting techniques and the use of ‘non-heart beating donation’.

## PATIENT SELECTION

There are currently relatively few absolute contraindications to liver transplantation and no specific age limitation. Guidelines are available in regard to hepatocellular carcinoma and liver transplant. Such patients increasingly, if not inevitably, require disease-modifying treatments, (transarterial chemoembolisation and radio frequency ablation) whilst waiting for a suitable cadaveric donor.

Portopulmonary and hepatopulmonary syndromes are now an active indication for transplantation as opposed to a contraindication.<sup>6</sup> Such patients are likely to have a more complex postoperative course, especially if graft function is borderline or they develop sepsis. Monitoring of patients whilst on the waiting list is essential to ensure that their disease does not progress such that transplantation is no longer a feasible option. Patients must have the required cardiorespiratory reserve to tolerate the procedure. Much work has gone into the development of prognostic tools to allow accurate prediction of the need and timing for transplantation, and increasingly the model used is the model for end-stage liver disease (MELD) system. This system was initially developed for predicting survival following transjugular intrahepatic portosystemic

shunt (TIPS) but has been shown to be equally useful in predicting survival in those awaiting liver transplantation. Once multiorgan failure has developed in a debilitated patient awaiting transplantation, survival rates decrease to 20–30% and these patients often require weeks to months of postoperative hospitalisation.<sup>2,7</sup>

## PERIOPERATIVE ASPECTS

### OPERATIVE TECHNIQUE

Orthotopic liver transplantation (OLT) involves recipient hepatectomy, revascularisation of the donor graft and biliary reconstruction.

Two main techniques are used in adult liver transplantation – those with vena cava preservation (‘piggyback technique’) and those using portal bypass (either internal, temporary portocaval shunt or external, veno-venous bypass). The advantages of the piggyback technique include haemodynamic stability during the anhepatic phase, without large volume fluid administration, and the negation of the need for veno-venous bypass with its associated risks and complications. Decreased transfusion requirements, shorter anhepatic time and shorter total operating time are also observed. There is no observed difference in renal function between the two techniques.<sup>8–10</sup> The donor hepatic artery is directly anastomosed, utilising an ‘end-to-end’ technique, or a conduit is constructed. Portal venous anastomosis must also be undertaken. In most patients this is an end-to-end anastomosis; however, portal venous thrombosis is no longer a contraindication to transplantation. These patients may under go a re-cannulisation procedure or require a jump graft technique. Such conduits and grafts are normally fashioned from donor vessels.

It is imperative that all those caring for the patients are aware of the surgical technique undertaken, as complications may vary. The radiologist must be aware of the technique used to allow appropriate interpretation of subsequent investigations and vascular imaging. This applies not just to the vascular anastomosis but also to the presence of a full graft, reduced size graft, right or left split graft or indeed an auxiliary graft. The biliary anastomosis is normally also undertaken as an end-to-end procedure, the

donor bile duct being directly joined to the recipient duct. It is no longer standard for this to be undertaken over a T-tube, but this may be required where there is marked discrepancy between donor and recipient duct size. Some conditions (e.g. extrahepatic biliary atresia, primary sclerosing cholangitis) may preclude end-to-end anastomosis and formation of choledochojejunostomy may be required.

Split-liver grafts allow one liver to provide an organ for two recipients. Initially comprised of a child receiving the left lateral segment and an adult the remaining liver, nowadays two adults may receive grafts from one liver if the anatomy and size match allow. Such splits may be less than ideal when the recipient has a high MELD score, as is increasingly the case with the prioritisation of sick patients awaiting liver grafts. Such grafts are at increased risk of postoperative complications such as bile leaks from the cut surface and haematoma/collections at the cut surface.<sup>3,11</sup>

Auxiliary liver transplantation is a technique that involves subtotal recipient hepatectomy and implantation of a reduced size graft. It is a technically difficult procedure, as both portal and arterial supplies have to be constructed de novo. In addition, a duplicate biliary drainage system needs to be constructed. Hepatic venous outflow is anastomosed as usual. In acute liver failure, it has significant potential, since regeneration of the native liver may obviate the need for donor function, potentially allowing withdrawal of immunosuppression. It also has application in the treatment of some hereditary metabolic disorders where adequate metabolic function may be achieved with an auxiliary graft. The major advantage is withdrawal of immunosuppressive therapy if the patient develops severe complications, or when applicable gene therapy becomes available. The disadvantage of auxiliary transplantation in the face of acute liver failure is that the postoperative course is frequently more complicated; reasons are multifactorial, and can be due to the continued presence of a regenerating native liver or due to a smaller donor graft attempting to cope with a critical illness.

Non-heart beating transplantation (NHBD) has emerged in recent times as a potential way of increasing organs for transplantation.<sup>12,13</sup> The success in renal transplantation has led to exploration of its application in the fields of liver, pancreas and lung retrieval. Most retrievals are undertaken in the context of controlled NHBD, i.e. in the context of planned withdrawal of care. Warm ischaemia can be accurately assessed and cold ischaemia minimised. Early experience with NHBD was associated with inferior survival for patients and grafts but recent experience suggests that survival is approaching that for heart beating donation. There are, however, continuing concerns over biliary and vascular complications. Prolonged cold ischaemia is associated with poor graft function and biliary complications, as are warm ischaemia times of greater than 30 minutes.<sup>14</sup> With regard to postoperative care, an understanding of the pre- and perioperative factors is essential in anticipating potential complications, initiation of monitoring and proactive management.

Living donor-related transplantation (LDLT) is now a routine undertaking in paediatric liver transplantation. It is becoming increasingly utilised in adult liver transplantation although its application in countries with good cadaveric donor pools is less established. Adult LDRT using right lobe grafts is an effective procedure with good survival outcomes but is associated with significant complications. From a postoperative perspective the intensive care team may be responsible for the management of both the donor and the recipient. Morbidity rates for donors are significantly higher with use of a right lobe donation compared with a left lobe graft. Mortality for donors has been reported. Survival rates now reported for living related recipients are good, with rates of 80% at 12 months.<sup>15,16</sup>

Adequate function of undersized transplanted liver grafts is essential to successful outcome. Primary graft non-function is relatively rare and one of the main areas of concern is that of the so-called 'small for size syndrome'.<sup>15,17</sup> This was first recognised in the post transplant setting but also occurs following liver resection. It is still an area under discussion but the clinical entity is that of hyperbilirubinaemia, graft dysfunction, ascites, and portal hypertension with associated end-organ dysfunction/failure. The clinical picture is that of portal hyperaemia, with portal flow passing into a small liver remnant/graft with associated pathophysiological consequences, and at a histological level there is evidence of arteriolar constriction. In some patients consideration should also be given to the potential compounder of hepatic venous outflow limitation.<sup>18,19</sup> Other factors that predispose to the syndrome are an inappropriate graft weight to recipient and steatotic grafts. In regard of management of this syndrome most trials have focused on optimising venous outflow and limiting/preventing portal hyperaemia and limiting portal hypertension.<sup>15,20</sup> Animal studies have also examined the role intrahepatic vasodilators with good effect. Management of the syndrome remains controversial but its early consideration allows the clinical team time to consider therapeutic options and interventions.

#### BLOOD LOSS AND COAGULOPATHY

Orthotopic liver transplantation may be associated with massive blood loss. The causes of this are multifactorial and include preoperative coagulation disorders secondary to end-stage liver disease, portal hypertension, surgical technique, adhesions related to previous surgery and intraoperative changes in haemostasis. Activation of the fibrinolytic system, especially during the anhepatic and post-reperfusion phases, occurs in some recipients. Platelet dysfunction, both quantitative and qualitative, is also common. The consequences of massive bleeding and replacement are significant, not only in terms of postoperative morbidity and mortality, but also intraoperatively, when issues such as acute hypovolaemia, reduced ionised calcium due to citrate intoxication,

hyperkalaemia, acidosis and hypothermia become important. Transfusion-related acute lung injury (TRALI) is a potentially devastating complication. It is believed to result from neutrophil antibodies preformed in donor serum. The immunosuppressive effects of large volume blood transfusions are well recognised and pertinent in a group of patients who are already functionally immunosuppressed. In addition to these immediate problems is the risk of transmission of, as yet, unidentified viral infections.

Much effort has gone into reducing the amount of exogenous blood products required intraoperatively. This includes the use of cell salvage techniques with autologous transfusion, near patient testing of haemostasis, utilising both laboratory-based tests and thromboelastography. The appropriate use of antifibrinolytic drugs such as aprotinin and tranexamic acid may then be considered. These therapies appear to reduce intraoperative blood loss and transfusion requirements and possibly reduce the reperfusion injury sustained without increasing the incidence of thromboembolic complications or renal impairment.

Although it is assumed that all patients with liver disease are subject to an increased risk of bleeding there are some subgroups that are prothrombotic. Patients with preoperative portal or hepatic venous thrombosis appear to carry a higher incidence of prothrombotic mutations than the general population, and patients with primary biliary cirrhosis and primary sclerosing cholangitis are frequently prothrombotic. Such patients may require anticoagulation in the early postoperative period. Other patient groups such as those with Budd–Chiari syndrome may have a recognised prothrombotic condition with a resultant early requirement for anticoagulation.

### POST-REPERFUSION SYNDROME

The post-reperfusion syndrome is a poorly understood phenomenon that occurs after reperfusion of the portal vein through the donor graft. It is characterised by hypotension, bradycardia, vasodilatation, pulmonary hypertension, hyperkalaemia and in some cases cardiac arrest. The aetiology is unclear, but a sudden increase in venous return, release of vasoactive substances, and cold potassium-rich preservation fluids are potentially implicated. The syndrome usually resolves within the first 5 minutes of reperfusion with appropriate fluid loading and electrolyte management. However, in approximately 30% of patients it lasts for significantly longer, necessitating the use of inotropes and/or vasopressors. The post-reperfusion syndrome seems more common in organs with longer preservation times and may well be associated with initial poor graft function.

### POSTOPERATIVE CARE

The postoperative care of the recipient depends to some extent on preoperative comorbidity, the presence of any of the immediate complications listed above, recipient

stability during the procedure and lastly the pretransplant cause of liver failure.

Straightforward recipients who return to the ICU in a stable condition with good graft function may be woken up and weaned immediately. The tracheal tube and some of the invasive monitoring lines should be removed as soon as no longer required to reduce the risk of infection and encourage mobility. Close monitoring of all physiological systems is important in the early postoperative period (Tables 94.1 and 94.2).

### EARLY COMPLICATIONS

As with all postoperative surgical intensive care admissions some complications are applicable to all patients. These include haemorrhagic and pulmonary complications of any prolonged procedure in addition to specific complications pertinent to liver transplantation. These can be subdivided into technical complications, conditions and complications associated with pre-existing liver disease, and complications associated with immunosuppressive agents, graft function and massive transfusion.

#### CARDIOVASCULAR

End-stage liver disease is characterised by a hyperdynamic circulation, with low systemic vascular resistance, high cardiac index and a relatively reduced circulating volume. The majority of patients can be managed with adequate volume loading with or without vasopressor inotropes to maintain adequate perfusion pressures. However, in some patients this state may compensate for degrees of cardiomyopathy (which may be difficult to detect with non-invasive preoperative investigation).<sup>21–23</sup> The massive increase in the volume of liver transplants performed in the last decade has revealed cardiac failure as an important cause of morbidity and mortality in the transplant recipient. So-called cirrhotic cardiomyopathy, quite independent of the effects of alcohol, may be multifactorial in nature, possibly due to overproduction of nitric oxide, abnormal  $\beta$ -adrenoceptor structure and/or function, or the presence of some as yet unidentified myocardial depressant factor. Whatever the cause, OLT can impose severe stresses on the cardiovascular system: haemorrhage, third-space loss, impaired venous return due to caval clamping, hypocalcaemia and acidosis all impair myocardial contractility. Reperfusion can also be a time of profound circulatory instability, as discussed above. In addition, the impaired exercise tolerance of the pretransplant recipient may have limited the clinical importance of coronary ischaemia which becomes pertinent in the posttransplant period.

Haemodynamic changes after OLT are also common; hypertension with an increased systemic vascular resistance is frequent and may be due to the restoration of normal liver function and portal pressure, as well as the hypertensive effect of the calcineurin immunosuppressants. The increased afterload in the early posttransplant period may unmask cardiac dysfunction. Management of

**Table 94.1** Routine investigation of posttransplant patient in the ICU

	FBC	LFTs	Coagulation	Drug levels	Cultures	Ultrasound
Day 1	✓	✓	✓		As indicated	Routine ultrasound including hepatic artery, hepatic veins and portal vein flow between D1 and D5 unless clinically indicated at other time
Day 2	✓	✓	✓	✓		
Day 3	✓	✓	✓	✓		

**Table 94.2** Monitoring of graft function in ICU

	Parameter	Comment
General	Liver perfusion Bile production Haemodynamics	Characteristics at surgery Quality ± volume if T-tube in situ Stabilisation, with cessation of vasopressor requirements
Coagulation	INR/Prothrombin time (hours)	8-hourly for the first 24 hours, thereafter daily unless indicated. The fall in PT is more important than the actual value. FFP should be withheld to assess graft function although platelet support should be provided as usual
Biochemistry	Glucose	Hypoglycaemia is an ominous sign. 4-hourly measurement in the first 24 hours. Euglycaemia or hyperglycaemia requiring insulin infusion is the norm
	Arterial blood gases and lactate	4–6-hourly depending on ventilatory requirement. Hyperlactataemia and acid–base disturbance should rapidly resolve. Other causes of base deficit such as renal tubular acidosis and hyperchloraemia should be excluded and managed appropriately
	AST	Should fall steadily (50% fall each day). The first measurement may reflect washout and thus the next may be higher. Daily measurements. The initial measurement reflects the degree of preservation injury.
	Bilirubin	Early increases may reflect absorption of haematoma and do not reflect graft function. Haemolysis should be considered if the graft is not blood group matched, termed passenger lymphocyte syndrome
	ALP/GGT	Usually normal; increases may reflect biliary complications or cholestasis of sepsis

myocardial dysfunction post OLT is largely empirical; diuretics, afterload reduction and positive-pressure ventilation may all be required. In the longer term, control of cardiovascular risk factors is required and many of these patients may over the years return to the intensive care environs with other system failures and considerable burdens of hypertension, coronary ischaemia, diabetes, hyperlipidaemia and renal dysfunction.

### PULMONARY

Pulmonary complications are common and occur in 40–80% of recipients. The presence of preoperative impairment (e.g. pleural effusions, hypoxaemia, pulmonary hypertension or the hepatopulmonary syndrome) is strongly associated with postoperative complications. Specific conditions related to liver transplantation include right hemidiaphragm palsy as a result of phrenic nerve damage, which can occur if suprahepatic caval clamping is used intraoperatively. The commonest postoperative problems are pleural effusions, ongoing shunting secondary to the hepatopulmonary syndrome, atelectasis and, over subsequent days, infection. De novo acute lung injury and the acute respiratory distress syndrome are relatively uncommon at this stage. Other complications such

as TRALI and pulmonary oedema are almost certainly underrecognised and underreported.

Specific management of portopulmonary syndrome may be required in the postoperative period if right-sided pressures are elevated, to ensure that liver congestion and graft dysfunction do not ensue.<sup>6,24,25</sup> Control of pulmonary pressures may require a variety of therapeutic options, with the treatment options being similar to those utilised in primary pulmonary hypertension. Concern about potential hepatotoxicity needs to be balanced against the need to control right-sided pressures and provide optimal graft function. Similarly, hepatopulmonary syndrome may take a variable time to resolve and hypoxia during this period will require management and recognition.

Respiratory complications are also seen in patients with poor muscle bulk and subsequent weakness. Similarly, the presence of osteoporosis in the pretransplant patient is frequently associated with postoperative pain and poor cough. The role of adequate analgesia is important, as in all patients, in promoting mobilisation and adequate respiratory function. In general, the management of a protracted respiratory wean follows conventional lines.

### NEUROLOGICAL

The quoted incidence of central nervous system (CNS) complications varies widely from 10 to 40% in the published series. Most neurological complications occur within the first month of transplant. The commonest causes relate to persistent encephalopathy post transplant in a patient with pre-existing encephalopathy.<sup>26,27</sup> The causes are multiple, including hepatic, metabolic, infectious, vascular and pharmacological. A patient with acute liver failure will remain encephalopathic in the immediate posttransplant period, and is at risk for intracranial hypertension for 48 hours following transplantation, or longer in the face of graft dysfunction. De novo hepatic encephalopathy may develop in patients with severe graft dysfunction and/or primary graft non-function; again the patient is at risk of cerebral oedema. The effects of sepsis, rejection (and its treatment with high-dose steroids), drug therapy (especially the sedatives and analgesics used in the ICU setting) and the presence of renal failure may all contribute to the presence of altered conscious level. The calcineurin inhibitors are particularly associated with seizures and altered conscious level. All such patients will require brain imaging to further define the aetiology of their impaired neurology.

Other possible neurological complications are those of intracerebral haemorrhage. Such bleeds may relate to arteriovenous malformations, may be spontaneous or may be a complication of intracranial pressure monitoring, particularly in patients with acute liver failure. CNS infection normally presents later than the immediate postoperative period but should always be considered, especially in those patients with a prolonged and complicated postoperative course. All possible infecting agents, including bacterial, viral, fungal and opportunistic, should be considered. Central pontine myelinolysis is a rare but potentially devastating complication associated with rapid sodium shifts. Modern technology and the use of haemofiltration techniques allow tight control of sodium shifts in the majority of patients, and this has become a rare neurological complication.

### RENAL DYSFUNCTION

Despite intraoperative efforts, renal dysfunction can be exacerbated and acute renal dysfunction is a relatively common complication, with an incidence of between 12 and 50%<sup>28–30</sup> and a multifactorial aetiology. Risk factors include the presence of pretransplant comorbidity (e.g. hypertension, diabetes mellitus, hepatorenal syndrome), severity of underlying liver disease, intraoperative instability, blood product requirement, drug toxicity and graft dysfunction. Mortality in those who require renal replacement is high, and graft survival is lower. To avoid exacerbation of existing renal impairment, agents with inherent nephrotoxicity, such as the calcineurin inhibitors, may be omitted or their dose significantly reduced in the early pretransplant period. There must be a balance between the risk of rejection and that of side-effects of drug therapies. Mycophenolate mofetil, a cytotoxic

immunosuppressant, may be substituted in the posttransplant course to limit or mitigate against renal dysfunction, and increasingly agents such as interleukin-2 (IL-2) blockers are utilised to decrease renal dysfunction.<sup>31</sup>

Hepatorenal syndrome is a reversible entity following establishment of normal liver function post transplantation. There are considerable data in the literature to suggest that such patients do well with no prolongation of care or increase in mortality. Some data suggest that combined renal and liver transplant is associated with improved outcome. Patients with significant intrinsic renal dysfunction, as compared to those with functional hepatorenal dysfunction, may be offered combined liver–kidney transplantation.<sup>32,33</sup> Interestingly, the risk of acute rejection for combined liver–kidney grafts is as for liver transplantation as compared to the higher rate of rejection that is seen for sole renal transplant.

Intra-abdominal hypertension should always be considered in the posttransplant setting as a potential contributor to not only renal dysfunction but also cardiorespiratory dysfunction. Early consideration should be given to laparostomy in patients with elevated intra-abdominal pressures and associated organ dysfunction.<sup>34,35</sup>

### PRIMARY NON-FUNCTION (PNF)/INITIAL POOR FUNCTION

This is a spectrum occurring in 2–23% of cases, which at worst requires urgent retransplantation. It is characterised by poor graft function from the time of reperfusion, with hyperlactataemia, coagulopathy, metabolic acidosis, hypoglycaemia, hyperkalaemia and a rapid elevation in aminotransferase concentrations, accompanied by a systemic inflammatory response.

A major reason for the initial graft dysfunction is ischaemic injury to the graft, which depends on the type of preservation fluid used, and the duration of cold and warm ischaemia time. The aetiology of primary non-function remains unclear.<sup>36</sup>

Vasodilator prostaglandins and antioxidants may have a role in ‘rescue therapy’, but controlled data are lacking.

### SURGICAL PROBLEMS

Anastomotic thromboses are uncommon complications of liver transplantation, but can cause significant morbidity, which may require further invasive procedures and even urgent retransplantation. Hepatic artery thrombosis occurring in the early postoperative period is associated with a similar picture to PNF. Small vessel calibre is a risk factor, and is more prevalent in the paediatric recipient where it has also been associated with prothrombotic states such as protein C deficiency. Ultrasound is the first-line screening test and is undertaken both routinely in the immediate postoperative period and if there is a sudden rise in transaminase measurements. If the vessel is not visualised, the patient should proceed to CT angiography. If diagnosed quickly, emergency intervention

can be undertaken to re-establish arterial flow; however, emergency retransplantation may be required.

Venous complications such as portal thrombosis are even more uncommon, and are usually associated with intraoperative technical difficulty, recurrence of preoperative disease or undiagnosed thrombophilia. Portal thrombosis is normally associated with portal hypertension and massive ascites, but may also be associated with graft dysfunction, especially in the paediatric population. CT scanning will interrogate the vessels and also provide information on graft perfusion: regional ischemia may be identified that may have presented as a transaminitis. Treatment is dependent on the severity of the injury but ranges from diuretics to angioplasty, surgical reconstruction or ultimately retransplantation. Regional ischaemia and areas of poor perfusion should be actively sought in patients with a transaminitis and especially in those who had received a reduced size or split-liver graft.

Biliary complications post liver transplant are relatively common. The bile duct normally receives two-thirds of its arterial supply from the gastroduodenal artery and one-third from the hepatic artery. Post transplant, the only supply is from the hepatic artery, making it vulnerable to ischaemic injury whether that be at the time of retrieval, reperfusion or postoperatively. The resulting complication depends on the type of biliary anastomosis and the timing of the insult. Strictures are more commonly observed than leaks. Management of biliary complications is in the first instance endoscopic, with stent placement and/or balloon dilatation. In patients with a T-tube in situ, cholangiography may be undertaken by that route. Open reconstruction in the early postoperative period is uncommon (Tables 94.3, 94.4 and 94.5). Bile leaks may also be seen in the postoperative period from the cut surface of a split graft. Bile leaks are associated with an increased risk of infection and potentially of pseudoaneurysm formation.

## ACUTE REJECTION

Acute cellular rejection becomes a risk from approximately 5–7 days post transplant; the clinical signs of rejection are non-specific and include fever, deterioration in graft function, and a rapid rise in serum aminotransferase concentration. Liver biopsy is the only reliable diagnostic tool; however, biopsy may be relatively contraindicated due to coagulopathy. In some circumstances transjugular biopsy offers a solution to this problem. The normal management regime for an episode of acute rejection is that of pulsed methylprednisolone, 1 g for 3 days. The differential diagnosis may be that of sepsis, or problems with vascular integrity; there are some data to suggest that procalcitonin may be of use in the differentiation (Table 94.6).

## SEPSIS AND FEVER

Transplant recipients are uniquely vulnerable to bacterial infection: preoperative colonisation, prolonged and technically difficult surgery, large wounds, urinary catheterisation and the frequent need for central venous access postoperatively all combine to make them at vastly increased risk. However, compared with a decade ago, the overall incidence is reduced, probably due to improved and patient-tailored immunosuppressive regimens. Sepsis remains an important and life-long complication of liver transplantation, which may require readmission to intensive care.<sup>37,38</sup>

The epidemiology of pathogens is evolving; the incidence of Gram-positive bacterial infection (enterococci and staphylococci) is now more common than Gram-negative sepsis. More concerning is the emergence of multiple antibiotic-resistant bacteria, in particular meticillin-resistant *Staphylococcus aureus* (MRSA), vancomycin-resistant enterococci (VRE) and extended-spectrum  $\beta$ -lactamase (ESBL)

**Table 94.3** Technical complications of OLT

Complication	Comment
Abdominal bleeding	
Anastomosis	Immediate
Graft surface (if cut down)	Immediate
General ooze secondary to coagulopathy	Immediate
Pseudo-aneurysm formation	Can present early or late and is usually associated with intra-abdominal sepsis and biliary leaks
Vascular complications	
Hepatic artery thrombosis	Early and late
Portal vein thrombosis	Early and late; there may also be a stenosis of the portal vein rather than thrombosis
Inferior vena caval obstruction	May be infra-, supra- or retrohepatic in site
Biliary complications	
Biliary leak	Usually early
Biliary stricture	Usually late
Papillary dysfunction	Late
Roux-en-Y dysfunction	Usually late

**Table 94.4** Biochemical and clinical features of technical problems

Complication	Features	Investigation	Management
Hepatic artery thrombosis	Early: rapid rise in transaminase, coagulopathy, graft failure Differential diagnosis: hyperacute rejection, primary graft non/dysfunction	Ultrasound, angiogram	Thrombectomy, retransplantation
	Late: biliary complications, strictures, sepsis, liver abscess	Ultrasound, angiogram	Angioplasty
Portal vein thrombosis	Early: rapid deterioration in graft function, acute liver failure, ascites, variceal bleeding Late: mildly abnormal LFTs, portal hypertension, varices	Ultrasound, CT, angiography, MRA Investigation as for acute portal vein thrombosis	Thrombectomy, retransplantation, conservative management

**Table 94.5** Differential diagnosis of graft dysfunction in ICU

Primary non-function
Preservation injury
Rejection – hyperacute/acute
Vascular complications
Biliary complications
Drug-induced liver dysfunction
Infection – viral, bacterial, fungal
Recurrent disease (normally late)

producing Gram-negative organisms. Mortality associated with infection caused by these multiply resistant organisms is significantly greater compared with other organisms.

A decline in the incidence of both *Pneumocystis jirovecii* (formerly *P. carinii*) and cytomegalovirus infection is probably a result of both modulating immunosuppressive regimens and more effective prophylaxis. Patients should be screened for viral infections, including herpes simplex virus (HSV) and cytomegalovirus (CMV) utilising polymerase chain reaction (PCR) techniques. Opportunistic fungal

infection still remains problematic, especially in the context of environmental risk factors<sup>39,40</sup> (Table 94.7).

### FEVER

In transplant recipients, 76% of febrile episodes have a documented infectious aetiology, but acute rejection needs to be considered in the differential diagnosis. In the ICU transplant recipient the aetiology is even more likely to be infectious – often nosocomial and bacterial. In one study, pneumonia, catheter-related bacteraemia and the biliary tree were the three most common sources in the ICU population (41%). Viral infections accounted for 9% of febrile episodes, fungal infections 3% and endocarditis 3%. As mentioned above, the epidemiology of pathogens is changing and it is important to have thorough knowledge of local problem pathogens on which to base meaningful antibiotic policy.

These data have implications for the threshold to investigate febrile episodes, suspect bacterial infection and commence appropriate empirical antibiotic therapy. However, it should also be appreciated that immunosuppressed recipients do not always produce a febrile response to infection.

**Table 94.6** Management of rejection in intensive care

	Comment	Characteristics	Liver biopsy	Differential diagnosis	Treatment options
Hyperacute rejection	Rare in OLT 1–10 days post transplant	Rapid deterioration in graft function: AST > 1000, Coagulopathy, acidosis	Haemorrhagic necrosis	Primary non-function/ delayed function Hepatic artery thrombosis	Retransplantation Rarely: OKT3, Cyclophosphamide, plasmapheresis (unproven)
Acute rejection	30–70% Occurs at mean of 7–9 days	Often clinically silent apart from fever and RUQ pain High AST and bilirubin Coagulation and acid– base undisturbed	Portal inflammation Endothelitis Bile duct damage	Sepsis Vascular Viral	Methylprednisolone 1 g daily for 3 days

In those who do not respond: Consider diagnosis; if correct, consider tacrolimus if induction agent is cyclosporin A, OKT3 or MMF/sirolimus if other new agents.

Table 94.7 Infection in the intensive care unit

Aetiology	Bacterial	Viral	Fungal	Protozoal
	Wound Nosocomial pneumonia Line sepsis UTI Liver Biliary	HSV CMV EBV Varicella	Candida Aspergilla PCP Cryptococcus	Toxoplasmosis Strongyloides
Timing	Any time	HSV in first few weeks CMV 3–10 weeks EBV from 4 weeks Varicella later All may be earlier in ALF or retransplantation	Usually after 4 weeks	After 3 weeks

### MANAGEMENT OF CMV INFECTION AFTER LIVER TRANSPLANTATION

CMV infection is rarely associated with symptomatic illness in healthy hosts, but is a major cause of morbidity and mortality in transplant recipients; it is the single most common opportunistic infection after solid organ transplantation. In the absence of antiviral prophylaxis the overall incidence of CMV infection after OLT ranges from 23 to 85%, with approximately 50% of those developing clinical disease.

CMV infection most commonly occurs in the first 3 months after OLT, with a peak incidence in the third and fourth week. Infection may be asymptomatic or it may cause a spectrum of illness including fever, thrombocytopenia, neutropenia, pneumonia and hepatitis. The indirect effects of infection probably contribute more to the adverse effects on graft function than direct effects. CMV infection further immunosuppresses the recipient, leading to increased opportunistic fungal infection and also increased risk of Epstein–Barr virus (EBV) infection which can go on to be associated with posttransplant lymphoproliferative disease (PTLD). CMV infection is also implicated in increased rejection, although this is controversial. In those patients who proceed to transplant who are already receiving immunosuppressive agents, or in those with acute liver failure, CMV disease may present earlier in the clinical course.

The risk of CMV infection post transplant is dependent on the serological status of both the donor and recipient; the highest risk is associated with donor positive/recipient negative. Proven prophylactic strategies in the high-risk groups include long-term intravenous (i.v.) or oral (po) ganciclovir. Currently, 3 months of ganciclovir remains the gold standard in the treatment of CMV disease. In many patients, therapy will commence i.v. and then convert to oral to facilitate discharge from hospital and rehabilitation. There is no evidence to support specific immunoglobulin in addition, but it is frequently added in the management of CMV pneumonitis.

The monitoring of posttransplant patients in the intensive care and ward environment should allow for HSV, CMV and EBV PCR; treatment options can then be tailored to individual patient needs.

### MANAGEMENT OF VIRAL HEPATITIS

Hepatitis C (HCV) related cirrhosis is the commonest indication for transplantation in both Europe and the USA. Post transplant, HCV viraemia is universal. Recurrent liver disease, with a more accelerated and aggressive course, is often observed; indeed, 20% are cirrhotic at 5 years post transplant.<sup>41</sup> Those with histological evidence of recurrence also have a greater incidence of acute rejection. Immunosuppression, especially with steroids, directly increases the HCV RNA serum load. Most transplant programmes therefore convert to single- or double-agent immunosuppression regimens as soon as possible post transplant.<sup>42</sup> Yet to be fully elucidated is the role of antiviral therapy (interferon and ribavirin) in both the pre- and post-transplant period. Provisional data are optimistic, although it requires considerable workload and supportive drug therapy. It would not normally be undertaken in the intensive care setting. Theoretically, early antiviral therapy is attractive as viral load is low, immunosuppressive therapy has just started and acute rejection necessitating pulsed steroids is relatively common. However, risk of infection and thrombocytopenia often contraindicates antiviral therapy in the early postoperative period.

Initial results of transplantation for hepatitis B infection (HBV) were discouraging, largely due to recurrent disease with rapid and fatal progression. Passive immunoprophylaxis with hepatitis B immune globulin (HBIG) during and after transplant and the use of antiviral agents pretransplant to suppress viral replication dramatically reduce reinfection rate. However, such therapy must be continued indefinitely following transplant to prevent disease recurrence. In respect of modulation of immunosuppression regimens, the comments made with respect to HCV are similarly applicable.

### IMMUNOSUPPRESSION

As the field of transplantation evolves, new immunosuppressive regimens and drugs become available. For all combinations, however, there is a balance to be struck between the optimal prevention of rejection and the toxicity and

unwanted effects of the drugs. The incidence of acute rejection rises at about 1 week after OLT; it resembles a delayed-type hypersensitivity reaction, and immunosuppressive agents are highly effective at treating it. Chronic rejection occurs over months to years and is characterised by the 'vanishing bile-duct' syndrome, pathological mechanisms are poorly understood and immunosuppressant agents are largely ineffective.<sup>31</sup> Currently, calcineurin inhibitors such as ciclosporin and tacrolimus, along with steroids, form the mainstay drugs after liver transplantation, certainly in the early stages. They have revolutionised the outcome of solid-organ transplantation, but both drugs are limited by their side-effects, predominantly nephro- and neurotoxicity, necessitating drug level monitoring.

These manifestations of toxicity can be difficult in the management of posttransplant immunosuppression in patients who exhibited encephalopathy or renal dysfunction pretransplant; the use of agents without renotoxic profiles may be considered in this context. It is usual to have an induction regimen beginning in the perioperative period; this usually involves a calcineurin inhibitor and steroids, which are administered in a high-dose taper regime. With time after transplantation, the level of immunosuppression required decreases and drug doses may be reduced further. Cytotoxic drugs such as azathioprine or mycophenolate mofetil (MMF) may also allow further reduction of steroids and calcineurin inhibitors. The long-term effects of immunosuppression have to be considered but are less pertinent in the immediate postoperative period.

Another variation in the regimen is the introduction of antilymphocyte antibodies (ALA) for 10–14 days in order to delay the introduction of calcineurin inhibitors: this may be desirable in patients with impaired renal function. ALA interferes with lymphocyte function in several ways: enhanced removal of activated lymphocytes by the reticuloendothelial system, downregulation of lymphocyte-binding cell surface receptors, with decreased lymphocyte activation and proliferation.

Recently, several monoclonal antibodies have been introduced. They bind to IL-2 receptors, which are only present on activated T-cells, and hence they have a more specific mode of action. The role of such agents, especially in those with renal dysfunction, is gaining greater recognition.

Sirolimus is a novel immunosuppressant that has been used extensively in renal transplantation and more recently in liver transplant recipients in whom the calcineurin inhibitors are contraindicated.<sup>31</sup> It resembles tacrolimus structurally, and binds to the same protein, but whereas ciclosporin and tacrolimus act by inhibiting IL-2 gene transcription, sirolimus acts by blocking post-receptor signal transduction and IL-2 dependent proliferation. In addition to its immunosuppressive actions, sirolimus is also an antifungal and antiproliferative agent. Sirolimus lacks neuro- and nephrotoxicity. However, it can raise the intracellular concentrations of ciclosporin A and tacrolimus, indirectly potentiating their toxicity. Hyperlipidaemia has also been noted although this may

be a reflection of the often higher dose steroid regimens used in combination with sirolimus. Because of its antiproliferative effects, sirolimus can also cause thrombocytopenia, neutropenia and anaemia; there have also been concerns about its effects on wound healing. Sirolimus also requires therapeutic drug level monitoring, not only because serum concentrations have a high level of intra- and interindividual variability, but also because there are significant interactions with drugs that use the cytochrome P-450 3A system.

All immunosuppressive regimens should be tailored to individual patient needs and a balance struck between side-effects (short and long term) and risk of rejection.

#### READMISSION TO ICU/LATE COMPLICATIONS

The cause of readmission to ICU after liver transplantation varies in relation to time after transplantation. Approximately 20% of recipients require readmission, and this correlates with actuarial reduced patient and graft survival. In the period immediately after transplantation, cardiorespiratory failure is the commonest reason for readmission, due to both fluid overload and infection. Indeed, an abnormal pre-discharge chest X-ray is predictive of readmission as is high central venous pressure and tachypnoea. Other predictors of readmission are age, pretransplant synthetic function, bilirubin, amount of intraoperative blood products and renal dysfunction. Graft dysfunction, severe sepsis and postoperative care of surgical complications are other important causes of readmission. Bleeding and biliary anastomotic leaks represent the commonest surgical causes for readmission.

#### LIVER TRANSPLANTATION FOR ACUTE LIVER FAILURE

Acute liver failure is a syndrome associated with an acute onset coagulopathy, jaundice and encephalopathy; the causes are many and the syndrome is notable for its high morbidity and mortality. The acceptance of emergency liver transplantation in selected cases has revolutionised the clinical course, but outcome is sometimes disappointingly poor, often due to the rapid development of uncontrollable cerebral oedema, sepsis and multiorgan failure. There is also a short window of opportunity in listing these patients; despite highest priority listing they may receive 'marginal' organs or even ABO blood group incompatible organs. Early determination of prognosis and appropriate listing for transplant are clearly important. The King's College Hospital prognostic criteria for non-survival among patients with acute liver failure is a tool used to identify those at high risk while sparing those in whom spontaneous recovery will otherwise occur. It has been validated both in Europe and the USA (Table 94.8). Several advances in the supportive management of these patients have occurred since the original criteria were developed but their prognostic value holds true.

**Table 94.8** King's College Hospital prognostic criteria for non-survival among patients with acute liver failure

Paracetamol induced	Non-paracetamol induced
pH < 7.3 (irrespective of grade of encephalopathy), following volume resuscitation and > 24 hours post ingestion	PT > 100 seconds (INR > 6.5) irrespective of grade of encephalopathy
or	or
PT > 100 seconds (INR > 6.5) and creatinine > 300 µmol/l in patients with grade III–IV encephalopathy, occurring within a 24-hour timeframe	pH < 7.3 following volume resuscitation
	or
	any three of the following variables (in association with encephalopathy):
	Age < 10 years or > 40 years
	Aetiology: non-A, non-B or drug induced
	Jaundice to encephalopathy > 7 days
	PT > 50 seconds (INR > 3.5)
	Serum bilirubin > 300 µmol/l

### EXTRACORPOREAL HEPATIC SUPPORT

The liver has metabolic, excretory and synthetic functions, all of which need to be maintained in a patient who has liver failure until either an organ becomes available or regeneration takes place. The major components of a bioartificial liver include hepatocytes able to perform some of the functions of normal liver, a delivery system to bring blood to and from the patient, and a membrane designed to allow adequate exchange between blood and hepatocytes.

Clinical trials are in progress to evaluate the place for these devices and there has been some success with using them as a bridge to transplantation, and in acute liver failure in particular an improvement in neurological status and reduced cerebral oedema.<sup>43</sup> Still to be elucidated is the timescale on which these devices can be used and whether they can bridge the gap to regeneration, thus sparing the patient from transplantation.

### PAEDIATRIC LIVER TRANSPLANTATION

OLT is the treatment of choice for children with end-stage liver disease. Cholestatic disorders make up the largest indication for transplantation, with extrahepatic biliary atresia plus or minus previous Kasai porto-enterostomy accounting for over 50% of paediatric transplants. Metabolic diseases and primary hepatic tumours are also common indications. As in adult recipients, multisystem effects of end-stage liver disease are common, and the occurrence of liver disease as part of a congenital syndrome (e.g. Alagille's) may warrant invasive preoperative evaluation of extrahepatic manifestation. Patient and graft survival have improved over the last decade such that 5-year patient survival is over 80%. Scarce availability of paediatric donors has driven innovations such as reduced size grafts, split-liver techniques and living donor programmes which have all contributed to expand the pool of available donors and reduce the mortality for those children waiting for suitable organs.

One of the biggest problems associated with paediatric transplantation is the relatively high incidence of vascular

complications such as hepatic artery thrombosis, portal vein thrombosis and venous outflow obstruction. Risk factors for these conditions include fulminant hepatic failure, long operation time, donor/recipient age and weight discrepancies, young recipient age, low recipient weight and arterial reconstruction techniques. In order to minimise these often devastating complications, strategies to minimise the risk include delayed primary closure of the abdominal wall, maintaining the haematocrit at 22–25% to ensure laminar flow, and avoidance of platelets and blood components combined with considered use of anticoagulants.

Associated cardiac, pulmonary or renal abnormalities observed in some paediatric syndromes with liver disease may require particular attention and management such as the pulmonary stenosis seen in association with Alagille's.

### HEPATOPULMONARY SYNDROMES

Changes in the cardiovascular system associated with chronic liver disease may contribute to the spectrum of cardiopulmonary disease associated with chronic liver disease and portal hypertension. A hyperdynamic state with high cardiac output, long-standing portal hypertension with the development of collateral flows, together with an imbalance of vasoactive mediators either synthesised or metabolised by the liver, may lead to characteristic changes in both flow and pressure through the pulmonary vasculature. This may be associated with hypoxia and orthodeoxia. Two ends of the spectrum are hepatopulmonary syndrome (HPS) and portopulmonary hypertension (PPH). The two conditions are rare but important, as they have vastly different impacts on risk associated with liver transplantation and long-term outcome (Table 94.9). The role of agents used in the management of primary pulmonary hypertension is yet to be examined in a controlled manner in liver disease but data thus far suggest benefit.

Diagnostic criteria for both conditions are summarised in the table.

**Table 94.9** Diagnostic criteria for hepatopulmonary syndrome and portopulmonary hypertension

Hepatopulmonary syndrome	Portopulmonary hypertension
Chronic liver disease (± cirrhosis)	Portal hypertension
Arterial hypoxaemia	Mean pulmonary artery pressure > 25 mmHg
$P_{aO_2} < 75$ mmHg (10 kPa) or A-a $O_2$ gradient > 20 mmHg	Pulmonary artery occlusion pressure < 15 mmHg
Intrapulmonary vascular dilatation	Pulmonary vascular resistance > 120 dynes/s per $cm^{-5}$

### HEPATOPULMONARY SYNDROME

It can be seen from Table 94.9 that hypoxia is a characteristic finding in this condition. It results from intrapulmonary vascular dilatation at the pre- and postcapillary level, leading to decreased ventilation/perfusion ratios; more uncommonly, anatomical shunt is present with atrioventricular communication. One of the postulated mechanisms of this vasodilatation is overactivity of pulmonary vasculature nitric oxide synthetase; pretransplant patients have raised levels of exhaled nitric oxide that decrease post transplant with resolution of the syndrome. Medical treatment of the syndrome has been disappointing; indeed, most transplant centres agree that the syndrome is an indication for transplantation in itself, as resolution is reported in up to 80% after transplantation.

Risk stratification based on severity is important, as vastly increased peritransplant mortality is associated with severe hypoxia and high levels of vascular shunt. Mortality overall is 16% at 90 days and 38% at 1 year. Refractory hypoxia is the indirect cause of death, which may be due to multiorgan failure, intracerebral haemorrhage and sepsis due to bile leaks. Resolution of the syndrome can take months, lending support to the theory that it is vascular remodelling rather than just acute reversal of vasodilatation that reverses hypoxia.<sup>25,44</sup>

### PORTOPULMONARY HYPERTENSION

Up to 20% of pretransplant patients have pulmonary hypertension; this probably constitutes increased flow through the pulmonary vasculature and is not associated with increased resistance. These patients do well after transplantation. A much more ominous syndrome is the presence of pulmonary hypertension with high pulmonary vascular resistance (seen in < 4%). The aetiology of this syndrome is complex but it is characterised by a hyperdynamic high flow state with excess central volume and non-embolic pulmonary vasoconstriction. The pathological changes associated with this syndrome match

those associated with primary pulmonary hypertension except that cardiac output is high in this group.

In comparison to HPS, there are several differences in terms of response to medical treatment and outcome after transplantation. The response to epoprostenol, a PGI<sub>2</sub> analogue, is encouraging. Decreases in pulmonary artery pressure but more importantly transpulmonary gradient (TPG) have been noted, although at least 3 months' treatment seems necessary, suggesting remodelling rather than vasodilatation is the important mechanism. A limiting factor in the treatment may also be progressive thrombocytopenia and splenomegaly. Another difference is the perioperative risk and posttransplant prognosis, Resolution is not associated with transplantation and progression can be a feature. Perioperatively, the higher the mean pulmonary artery pressure (MPAP), pulmonary vascular resistance (PVR) and TPG the greater the risk of death, usually due to acute right ventricular decompensation. If the MPAP is >35 mmHg or the PVR is >250 dyne/s per cm, mortality reaches 40%. If MPAP is >50 mm Hg some have even suggested delisting or even intraoperative cancellation as the mortality may be as high as 100%.<sup>24</sup>

# Heart and lung transplantation

Cliff J Morgan

The first successful cardiac transplantation was performed at Groote Schuur, South Africa in 1967 and was followed by operations in other pioneer cardiac centres worldwide. However, it was not until the introduction of ciclosporin (cyclosporine) in 1979 that consistently improved long-term survival was achieved. To date, more than 70 000 cardiac transplantations have been performed in over 200 centres. Further improvements in immunosuppression therapy, surgical technique, detection and treatment of rejection, and general improvements in anaesthesia and postoperative care contributed to the sustained improvements, especially in centres concentrating experience and expertise above a critical mass. Typical survival figures following cardiac transplantation are in the order of 80% survival at 1 year, 70% after 5 years and 50% at 10 years.

The first successful heart and lung transplantation was performed in Stanford, USA in 1981 and was followed by successful heart–lung, single-lung and double-lung transplantations, mostly at the same centres that had led the way in cardiac transplantation.

With cardiac and lung transplantation accepted as standard treatment for a range of end-stage cardiopulmonary diseases, a large number of recipients may potentially develop critical illness, unrelated or directly related to their original condition. Around 40% of cardiac transplant recipients are readmitted to hospital within 1 year, at least a third requiring admission to intensive care units (ICUs).<sup>1</sup> Many of these patients present to the ICUs of non-transplant centres, especially as the number of centres performing transplantation is apparently falling. Therefore, all critical care practitioners need to be aware of the principles of management of the transplant recipient.

## CARDIAC TRANSPLANTATION

The main issue with cardiac transplantation revolves around donor availability (Table 95.1). The numbers of potential recipients who fulfil internationally accepted criteria<sup>2</sup> (Table 95.2) vastly outnumber the available donors, so the great majority of patients with severe end-stage heart failure inevitably die before a suitable donor heart becomes available.

The cardiac equivalent of dialysis, for the maintenance of the potential renal transplant recipient until an organ is available, is simply not feasible. However, there has been progress in the medical and surgical management of severe heart failure, some of which are highly specialised treatments with limited availability and some more routine and commonplace (Table 95.3). The use of inotropic drugs such as  $\beta$ -agonists (e.g. dobutamine), catecholamines (e.g. epinephrine) and phosphodiesterase inhibitors (e.g. milrinone) to support the failing heart and circulation is widely practised, as is the use of intra-aortic balloon pump (IABP) counterpulsation. These treatment options are, of course, highly invasive but may be used as rescue therapy in a patient with severe or end-stage cardiac failure who may be waiting for a transplant but in whom some event such as infection or worsening myocardial ischaemia has resulted in a catastrophic deterioration. The response of the failing heart to  $\beta$ -agonists may be disappointing because of the tendency to  $\beta$ -receptor downregulation from chronic overstimulation. In these cases the phosphodiesterase inhibitor drugs such as milrinone and enoximone may have greater and more sustained potency because of their intracellular site of action.

Some patients who have been deemed inoperable in conventional terms may still benefit from cardiac surgical interventions, though in the setting of severe chronic cardiac failure the risk of death, serious morbidity and prolonged postoperative critical illness may be considered prohibitive. Sometimes a degree of reversible myocardial ischaemia may be demonstrated by thallium scanning and guide subsequent coronary artery bypass grafting. In some cases, the degree of secondary mitral valve regurgitation caused by dilatation of the left ventricle may become a haemodynamically significant lesion of itself and reconstruction of the mitral valve or remodelling of the left ventricle may prove beneficial. In extreme cases of cardiac decompensation and where other organ functions are maintained (an unusual combination) the use of mechanical assistance<sup>4</sup> to support the heart and buy time for a donor heart to become available ('bridge to transplant') or to provide support while a severe but temporary process (such as some viral myocarditis episodes) subsides ('bridge to recovery') may be undertaken in

**Table 95.1** Illustration of the disparity between transplant operations and numbers of patients on the UK transplant registry

Organ transplanted	UK recent annual total	UK registered potential recipients
Heart	50–60	90–100
Lung	50	275
Heart and lung	5	20

Source: www.uktransplant.org.uk.

**Table 95.2** Criteria to select cardiac transplant recipients

<b>Clinical</b>
Heart failure survival score (HFSS), <sup>3</sup> high risk
NYHA class III/IV heart failure refractory to maximal medical treatment
Severely limiting angina not suitable for revascularisation – surgical or medical
Recurrent symptomatic ventricular arrhythmias refractory to medical, surgical or electrophysiological treatments
<b>Physiological</b>
Peak oxygen consumption less than 10 ml/kg per min after reaching anaerobic threshold
<b>Exclusion criteria</b>
Age greater than 65 years
Transpulmonary gradient (mean PAP – mean PAOP) > 15 mmHg (2.0 kPa) or PVR > 5.0 Wood Units despite standardised reversibility testing with nitrates or inhaled nitric oxide
Insulin-dependent diabetes mellitus with end-organ dysfunction
Severe psychiatric disturbance or intellectual retardation
Current alcohol or drug abuse
Morbid obesity
Concurrent malignancy
Severe hepatic or renal disease, unrelated to cardiac disease (unless being considered for combined organ transplant)
Immunodeficiency disease
Active systemic infection

NYHA, New York Heart Association; PAOP, pulmonary artery occlusion pressure (or 'wedge' pressure); PAP, pulmonary artery pressure; PVR, pulmonary vascular resistance.

highly specialised centres. The logical conclusion is to develop permanent mechanical support devices obviating the need for transplantation but this goal appears to be a long way in the future. The cost of such therapy in both financial and human terms has to be considered in the context of general health economics. These episodes are still at best pioneering, extremely invasive, draining on the resources of critical care, blood transfusion and pharmacy, and of limited outcome benefits. On the other hand, it can be argued that earlier use of potent mechanical assistance at a stage that other organs have yet to be irretrievably damaged should be more widely attempted and, by inference, outside the major cardiac specialist centres.

## DONORS AND RECIPIENTS

Most countries have seen a progressive gradual decline in the numbers of cardiac transplantations performed as a result of decreasing donor availability. Measures to optimise the donor pool for all solid organ transplants and care of potential donors are discussed elsewhere. Donor selection criteria are summarised in Table 95.4.

Matching of a potential cardiac donor with a recipient is determined by weight within 80–120% of each other, ABO blood group compatibility and negative lymphocyte crossmatch. HLA tissue type comparisons are only available after the event generally and are of prognostic and theoretical interest only.

## THE TRANSPLANT PROCEDURE

The care of the cardiac transplant recipient is multifaceted and should take the following principles into account:

- General preparation of a patient (and relatives) who has suffered severe chronic illness and has been under the shadow of impending death
- Perioperative care for major cardiac surgery
- Management of specific early postoperative complications, e.g. control of rejection, containment of side-effects of immunosuppression and prompt treatment of infection
- Reintegration of the patient into society

The anaesthetic and perioperative care of these patients is not materially different from any major cardiac surgery and the important principles are well described in the literature.<sup>11–13</sup> However, the coordination of the timing of surgery with the arrival of the donor heart, management of the excised donor graft and the immunosuppression protocol are all crucial factors. Organ preservation after harvesting from the donor is especially important and the main factor appears to be limiting the total ischaemic time to less than 4 hours (6 hours at the extreme). The recipient may have to be called in from home and may have a full stomach. The recipient may be elated or extremely anxious, or both.

Details of perioperative care will vary from centre to centre, e.g. the timing of components of the immunosuppression regimen, exact choice of antibiotics for prophylaxis and whether or not the right internal jugular vein has to be left virgin by the anaesthetic and postoperative team so that endomyocardial biopsies may be more conveniently performed. The striking difference of the cardiac transplant recipient compared to other postoperative cardiac surgical patients is the consequences of the grafted donor heart having no nervous control. It is denervated at excision from the donor and reinnervation in the recipient does not occur.

**Table 95.3** Non-transplant or bridge to transplant treatment of severe cardiac failure

Treatment modality	Notes	Applicability
Angiotensin-converting enzyme (ACE) inhibitors	Reduce cardiac work and improve output – beware exacerbation of renal failure	Ward setting to establish, then as outpatient
$\beta$ -Blockers <sup>5,6</sup>	Improve $\beta$ -receptor numbers and function	Ward setting to establish, then as outpatient
Inotropic support	Rescue therapy – rescue and restabilisation sometimes possible – requires central vascular access	CCU or ICU
Intra-aortic balloon pump counterpulsation	Rescue therapy combined with inotropes – may restabilise and thus temporary but invasive	CCU or ICU
Antiarrhythmic treatments – implantable defibrillators and advanced pacing, e.g. resynchronisation <sup>7</sup>	Where recurrent or severe arrhythmias threaten life or cause general destabilisations	Cardiac centre with facilities for electrophysiology
Surgical interventions	Routine (e.g. coronary artery bypass) or complex (e.g. anterior ventricular remodelling, mitral reconstruction where severe mitral regurgitation complicates cardiomyopathy)	Specialised cardiac centre
Ventricular assist devices (VAD) <sup>8</sup>	Short- and medium-term mechanical support for the failed heart – extremely invasive – usually holding stage or bridge to transplant	Specialised cardiac centre
Totally implanted artificial heart <sup>9,10</sup>	Longer term version of VAD – ultimately may be instead of transplant	Specialised cardiac centre, then possibly home

CCU, coronary care unit; ICU, intensive care unit.

**Table 95.4** General criteria to select cardiac transplant donors

Age under 60 years
Brain death criteria fulfilled
Family consent obtained
Absence of infection
Absence of chest trauma
Absence of prolonged cardiac arrest
Minimal inotropic support
Viral markers (hepatitis B, C and HIV) negative
No malignancy (except primary cerebral tumour)

### PHYSIOLOGY AND PHARMACOLOGY OF THE DENERVATED HEART (TABLE 95.5)

At surgery, the sinoatrial (SA) node of the recipient is retained but does not activate the grafted heart across the suture line. The donor heart has its own SA node but this is not innervated. It may be possible to discern two discrete P waves on the electrocardiogram (ECG). The donor SA node controls the graft heart rate. In the absence of autonomic innervation, only drugs or

manoeuvres that act directly on the heart will have an effect. For example, the Valsalva manoeuvre or carotid sinus massage will not affect heart rate, but drugs such as adrenaline (epinephrine), noradrenaline (norepinephrine) and isoprenaline (isoproterenol) exert a positive inotropic and chronotropic effect and  $\beta$ -adrenergic blockers will depress myocardial function. Quinidine and digoxin will influence conductivity through their direct effects only.

The denervated heart retains its intrinsic control mechanisms,<sup>14</sup> e.g. a normal Frank–Starling response to volume loading, normal conductivity and intact  $\alpha$ - and  $\beta$ -adrenergic receptors, possibly with enhanced responsiveness.

The coronary arteries retain their vasodilatory responsiveness to nitrates and metabolic demands. They can develop atherosclerosis in the long term, but the patient experiences no anginal pain with ischaemia or infarction because of the denervation.

Denervation results most importantly in an atypical response to exercise, hypovolaemia and hypotension. Any increase in cardiac output from increased heart rate or contractility depends on an increasing venous return and circulating catecholamines, and the response may be delayed. During exercise, muscle contraction increases venous return and the increased circulating catecholamines

Table 95.5 The pharmacology of the denervated heart

Drug	Effect on recipient	Mechanism
Digoxin	Normal increase in contractility; minimal effect on AV node	Direct myocardial effect; denervation
Adenosine	Fourfold increase in sinus and AV node blocking effect	Denervation supersensitivity
Atropine	None	Denervation
Epinephrine	Increased contractility and chronotropy	Denervation supersensitivity
Norepinephrine	Increased contractility and chronotropy	Denervation supersensitivity
Isoprenaline	Normal chronotropic effect	
Glyceryl trinitrate	No reflex tachycardia	Baroreflex disruption
Quinidine	No vagolytic effect	Denervation
Verapamil	AV block	Direct effect
Nifedipine	No reflex tachycardia	Denervation
$\beta$ -Blockers	Increased antagonistic effect	Denervation
Pancuronium	No tachycardia	Denervation
Neostigmine, succinylcholine	No bradycardia	Denervation

increase the heart rate. This is a gradual response and, as exercise ceases, the heart rate and cardiac output slowly fall as the catecholamine and the response levels decrease.<sup>15</sup> In pathological states, the transplanted heart is especially dependent on adequate filling volumes, and attention to preload is critical.

The denervated heart is also sensitive to extremes of heart rate; arrhythmias are unusual but may cause serious haemodynamic problems. Cardiac arrhythmias can be atrial, junctional or ventricular, and may be a sign of rejection. These may resolve if the rejection is adequately treated. Occasionally, antiarrhythmic drugs that act directly on the conduction system (e.g. quinidine, disopyramide and procainamide) or electrical cardioversion are required. Verapamil and nifedipine have enhanced effects in the transplanted heart. Hypotension and bradycardia may be profound because of the absence of the normal cardiac sympathetic-mediated response to vasodilatation. Adenosine used for supraventricular tachycardias may induce asystole and cause profound hypotension in the transplanted heart. Amiodarone has been used successfully for ventricular and atrial arrhythmias, but its mild negative inotropy and vasodilatation can cause hypotension. Lidocaine is normally effective in the treatment of ventricular arrhythmias.

### POSTOPERATIVE CARE

In the majority of cases the immediate postoperative course is uneventful and very similar to 'routine' cardiopulmonary bypass surgery requiring sternotomy with similar duration of postoperative ventilation and ICU length of stay, with hospital discharge being at around

10–14 days if all goes well. All the usual principles of care apply with the additional concerns regarding denervation, immunosuppression, infection, and detection and treatment of rejection.

The transplanted heart may have suffered from ischaemic damage before successful reperfusion in the recipient and may require inotropic, chronotropic or even temporary mechanical support. The severity of recipient pulmonary vascular disease may have been underestimated and even modest elevations of pulmonary vascular resistance combined with a degree of graft right ventricular myocardial dysfunction may prove troublesome or result in haemodynamic instability or catastrophic low cardiac output states. It may be necessary therefore to tide the patient over this temporary setback with a combination of various therapeutic options selected on the basis of careful clinical examination and investigation (Table 95.6). Most complex situations are assisted by or absolutely require the use of echocardiography.

### IMMUNOSUPPRESSION

The details of the immunosuppression regimen will differ between transplant centres but the principles are the same.<sup>16</sup> Immunosuppression is induced just prior to transplantation and then maintained permanently with a combination of drugs aimed at maximal effect and minimal toxicity. Episodes of suspected or proven rejection prompt additional temporary treatment.

Since the early 1980s the regime used by most centres has been triple therapy with ciclosporin, azathioprine and corticosteroids. The initial introduction of ciclosporin in 1979 was a major step, but the drug has significant

**Table 95.6** Possible support options for postoperative care of the complicated cardiac transplant recipient

Treatment	Directed at	Based on
Inotropic support, e.g. milrinone or epinephrine	Poor contractility of LV, RV or both LV and RV	Elevated filling pressures, low cardiac output, echocardiography (TTE or TOE)
Pressor support, e.g. norepinephrine	Low systemic arterial blood pressure despite adequate filling pressures and supported contractility	Arterial pressure monitoring, cardiac output and TTE or TOE
Heart rate support with chronotropic drugs (e.g. isoprenaline or milrinone) or pacing	Low intrinsic grafted heart rate	Heart rate less than 90 in the first 48 hours usually symptomatic and indication for support
Mechanical support, e.g. IABP	Poor LV function not responsive to other measures	Elevated LAP, low cardiac output, poor response to drugs, TTE or TOE
Temporary ventricular assistance – RVAD, LVAD or BiVAD	Very poor RV, LV or biventricular function	As above, no response to less invasive measures and where recovery or retransplantation may be an option
Inhaled nitric oxide	RV failure combined with reversible elevation of PVR	Filling pressures, PAP, TTE or TOE
Resternotomy	Catastrophic states where excessive bleeding or tamponade is suspected	Combination of observations but particularly TOE

IABP, intra-aortic balloon pump counterpulsation; LAP, left atrial pressure (direct or indirect); LV, left ventricle; PAP, pulmonary arterial pressure; PVR, pulmonary vascular resistance; RV, right ventricle; RVAD, LVAD, BiVAD, right, left or biventricular assist device support; TOE, transoesophageal echocardiography; TTE, transthoracic echocardiography.

problems; in addition to renal and hepatic toxicity, there is uncertain gut absorption and bioavailability (at best only 30%) which can be exacerbated by many commonly prescribed drugs.<sup>17</sup> Alterations in gut function may seriously reduce plasma levels to the point at which rejection may occur. Drug interactions may result in toxic levels. Plasma levels of the drug should be monitored frequently, especially in the early perioperative phase and during any complicating illness. When the gut cannot be relied upon the intravenous formulation may be used with one-third of the oral dose given by intravenous injection over 2–6 hours. Modified formulations of the drug have allegedly improved bioavailability and stability of plasma levels.<sup>18</sup>

Ciclosporin works through interleukin-2 (IL-2) inhibition in T lymphocytes so its action is fairly specific. Tacrolimus is an alternative to ciclosporin and has similar potency, toxicity and monitoring requirements. Azathioprine is the other commonly used drug. It has a much broader T and B lymphocyte depression effect so marrow suppression is not surprisingly a major potential side-effect. The intravenous alternative to the commonly used oral preparation is highly irritant and when the oral route is not available it is usually best omitted or an alternative used. Mycophenolate is often substituted for azathioprine. It has a much more specific effect through suppression of purine synthesis in lymphocytes, and achieves lower incidence of rejection, but at the expense of greater risk of infections.<sup>19</sup> Corticosteroids are very important at induction and for treatment of rejection episodes but otherwise the dose is tapered to minimise all the usual steroid side-effects.

Immunological treatment with antithymocyte globulin (ATG) derived from various species was traditionally reserved for the treatment of rejection episodes but newer monoclonal ATG-type drugs<sup>20</sup> may prove more effective and less allergenic. Newer approaches with the promise of greater specificity and lower toxicity include agents such as daclizumab<sup>21</sup> which appears to reduce episodes of rejection, but so far no convincing evidence of improved survival. The complexity of these issues makes it vital that all relevant treatment decisions are made by, or discussed with, the relevant transplant centre.

### REJECTION

One or more episodes of rejection are experienced by the majority of recipients within the first 3 months after transplantation. The risk is subsequently negligible in successful grafts. The diagnosis may be suggested on clinical grounds but the gold standard remains histological examination of an endomyocardial biopsy. In some centres biopsies are performed on a routine basis, as well as when rejection is suspected. The right internal jugular vein is the preferred vascular access site for performing the biopsy so this should be considered when selecting line sites for general critical care purposes. The clinical indications or suggestions of rejection are very non-specific and include dyspnoea, weight gain, malaise, atrial arrhythmias, low voltage ECG and echocardiographic evidence of declining cardiac function. The biopsy is graded according to an internationally accepted system, but some centres have moved to a more algorithm-based approach to the patient where clinical

features and monitoring of the immune response help to determine the frequency of biopsies.<sup>22,23</sup>

#### OTHER COMPLICATIONS

The other main complications include infection, malignancy and graft atherosclerosis or cardiac allograft vasculopathy (CAV).

#### Infection

Opportunistic infections (commonly lung) account for many of the complications and for a significant proportion of readmissions. A recent study reported that 45% of infections were bacterial and less than 10% fungal; however, the associated mortalities were 40% for fungal and less than 10% for bacterial infections.<sup>24</sup> Opinions vary as to the current significance of cytomegalovirus (CMV) infection. Some centres believe that CMV is a problem of the past because of better matching of CMV status, and more effective and potent prophylaxis and treatment with ganciclovir when indicated.<sup>25</sup> However, there is still significant risk of severe acute viral illness,<sup>26</sup> and a possible link between acute viraemic episodes and subsequent damage to the graft and CAV.<sup>27</sup>

#### Malignancy

The transplant recipient has a hundredfold increased risk of new malignancy (around 1–2% per year) compared to age-matched controls. The majority are skin tumours (with substantially increased susceptibility to solar radiation) and lymphomas but any neoplasm may occur. Malignancy is one of the leading causes of death or late readmission to hospital and the risk of subsequent malignancy is a significant and complex factor in the selection of optimum immunosuppression.<sup>28</sup>

#### Cardiac allograft vasculopathy (CAV)

This is the main cause of death in the long term after heart transplantation and is a multifactorial process resulting in diffuse obliterative coronary atherosclerosis.<sup>29</sup> The diffuse nature of the lesions makes revascularisation by angioplasty and stent, or by surgical bypass, difficult. Perhaps improvements in the control of rejection, management of CMV and drugs such as statins, calcium channel blockers and specific growth regulatory factors such as hepatocyte growth factor<sup>30</sup> may help.

### HEART-LUNG TRANSPLANTATION

The first heart–lung transplant (HLT) was performed in Stanford in 1981. HLT was then performed for both parenchymal lung disease and pulmonary hypertension. With the advent of single- or double-lung transplantations, there is overlap between indications for these procedures. The present indications for HLT are primary pulmonary hypertension, Eisenmenger's syndrome, end-stage suppurative pulmonary disease or end-stage bilateral lung disease

**Table 95.7** Heart–lung transplantation: donor selection criteria

Age and ABO blood group compatibility as per heart donors
Close size match of donor to recipient to avoid lung restriction (donor lung too big) or persistent residual space between lung and chest wall (donor lung too small)
Donor $Pao_2 > 100$ mmHg (13.3 kPa) on $Fio_2 = 0.3$ or $> 300$ mmHg (39.9 kPa) on $Fio_2 = 1.0$
Normal chest X-ray

associated with significant cardiac failure, generally right ventricular failure.

#### SELECTION CRITERIA (TABLE 95.7)

These are similar to those for heart transplantation, except that an elevated pulmonary vascular resistance tips clinical judgement towards HLT. Exclusion criteria for recipients are also similar but probably should include a stricter age limit (i.e. 45 years), high-dose corticosteroid therapy (relative contraindication), active bronchopulmonary fungal disease, and prior sternotomy, thoracotomy or mediastinal irradiation.

#### THE TRANSPLANT PROCEDURE

Heart–lung transplantation is by any definition a massive procedure. The combination of cardiopulmonary bypass with full anticoagulation and significant likelihood of pleural adhesions tethering the explanted lungs to the chest wall make for a substantial risk of major intraoperative haemorrhage and this may continue into the postoperative phase. Preservation of nerves such as the vagus, phrenic and recurrent laryngeal may be difficult and result in significant morbidity when unsuccessful.

#### POSTOPERATIVE CARE

This is similar to that for cardiac transplant patients, with some differences. The patient is without a bronchial arterial supply or pulmonary innervation. Lymphatic drainage of the lungs is lost. Thus patients are kept in a negative fluid balance in the early postoperative period. Active physiotherapy is required, sometimes with bronchoscopic toilet to clear secretions, as denervation prevents reflex coughing of secretions below the anastomosis (usually at around five tracheal rings above the carina). Once secretions reach the native trachea, coughing may result. Immunosuppression is given as for cardiac transplantation. Antibiotic prophylaxis will depend on local policies and results of cultures of recipient and donor sputum or secretions. Rejection is more likely to manifest first in the lungs rather than the heart graft so rejection surveillance includes frequent reassessment of pulmonary status, possibly with transbronchial biopsies.

**COMPLICATIONS**

Bleeding may occur due to extensive dissection and systemic pulmonary collaterals in congenital heart disease. Other early complications include tracheal anastomotic dehiscence, acute reperfusion lung injury (i.e. pulmonary oedema) due to long ischaemic times and infection. Heart–lung recipients have three times as many infections as heart recipients, and this contributes significantly to their higher mortality rate. Infection is the major cause of mortality in the first 6 months, and rejection thereafter.

**IMMUNOSUPPRESSION**

This is very similar to that used in heart transplantation, and also similar in single- and double-lung transplantation.

**SINGLE- OR DOUBLE-LUNG TRANSPLANTATION**

Early attempts at single-lung transplantation (SLT) yielded only short-term survival.<sup>31</sup> However, subsequent successes by the Toronto Group encouraged the development of double-lung transplantation,<sup>32</sup> initially by the en bloc method with tracheal anastomosis. The extensive dissection required in the recipient and the high incidence of anastomotic problems encouraged development of bilateral sequential lung transplantation (BSLT), which has found wide favour.<sup>33</sup> SLT is indicated for non-suppurative lung disease in a patient who does not have cardiac disease (e.g. emphysema from smoking or  $\alpha_1$ -antitrypsin deficiency, or fibrosing alveolitis). Whilst these conditions can also be managed by BLST, SLT provides satisfactory results and makes more efficient use of a limited donor pool. BSLT is indicated for suppurative and/or bilateral lung disease (e.g. cystic fibrosis and bilateral bronchiectasis). The merits of BSLT or HLT for these conditions are controversial. With HLT, the recipient's heart may be used in a 'domino' procedure as a donor heart for a second recipient.<sup>34</sup> Either BLST or a domino HLT allows the most efficient use of donor organs. Lung transplantation can be combined with kidney or liver transplantation.

Recipients are accepted for lung transplantation up to age 55 years. It is usually possible to perform SLT without cardiopulmonary bypass (CPB). The requirement for CPB is higher in BSLT (approximately 5–10%) because the first lung transplanted (usually the right) must immediately provide ventilation and gas exchange whilst the other side is transplanted. CPB increases the amount of operative blood loss and the volume of colloid required in the postoperative period. The incidence of non-cardiogenic pulmonary oedema is also increased.

**PHYSIOLOGY OF THE DENERVATED LUNGS**

The lungs appear to remain permanently denervated. There is evidence that the bronchial artery circulation and lymphatic system regenerate after several weeks.

Control of respiration is not affected by the loss of pulmonary afferent nerves. Regulation of breathing is through chest wall afferents. Patients regain spontaneous breathing early, and are usually able to be weaned off ventilation and extubated within 48 hours.

Patients who were dependent on their hypoxic drive may take time to achieve normocarbica. Arterial blood gases otherwise tend to remain normal. On exercise, minute volume, tidal volume and respiratory rate are able to increase appropriately. Bronchomotor tone is retained. The cough response is lost below the anastomosis.

**POSTOPERATIVE CARE**

Patients require a period of postoperative ventilation for reasons similar to all major pulmonary surgery. However, there are additional concerns regarding the temporary lung injury which almost inevitably results from the procedure, and the worry that this injury may be compounded by infection, overgenerous fluid therapy, pulmonary oxygen toxicity and barotrauma or 'volutrauma' from injudicious ventilator settings. Some degree of impaired gas transfer or widened alveolar to arterial oxygen tension gradient ( $A-a$ ) $DO_2$  is very common and may further widen as a result of the following complications.

**IMPLANTATION RESPONSE**

This manifests within a few hours. Infiltrates in the transplanted lung or lungs appear on chest X-ray, and the lungs may appear to be oedematous with increased peribronchial cuffing. In severe cases, a picture suggestive of severe acute respiratory distress syndrome is seen with widespread loss of translucency. There is an association between ischaemic time and the severity of the response. Management is supportive with fluid restriction if tolerated.

**HYPERACUTE REJECTION**

This is fortunately rare. It usually results in acute graft failure with a very poor prognosis for recovery of function. Management requires continued respiratory support and consideration of retransplantation.

**EARLY REJECTION**

Episodes of rejection of the transplanted lung occur in almost all recipients in the first 3 months, but may occur very early in some recipients. Deterioration in  $P_{aO_2}$  and pulmonary infiltrates after 48–72 hours should favour a suspicion of rejection rather than implantation response. It may be difficult to distinguish between early rejection and bacterial infection. Bronchoscopic washings may be helpful and transbronchial biopsy is essential in doubtful cases. In suspicious cases, a course of pulsed steroids is appropriate with concurrent antibiotics.

**SPUTUM RETENTION**

Effective analgesia, aggressive physiotherapy and early mobilisation are essential to minimise this problem. Secretions

below the anastomoses do not elicit a cough reflex and voluntary coughing is important.

#### PULMONARY INFECTION

Early pulmonary bacterial infection is common, and infection with other micro-organisms can occur later. Initially, bronchitis is more common than pneumonia. Patients with resident micro-organisms are given prophylactic antibiotics. Samples of the donor's pulmonary secretions are taken at the time of lung harvesting and may be useful in guiding the selection of antibiotics.

#### ANASTOMOTIC PROBLEMS

Ischaemic anastomotic ulceration is usually superficial, but occasionally deeper tissue loss eventually produces bronchial or tracheal stenosis requiring dilatation and/or stent insertion in the early months. Anastomotic dehiscence is rare but often fatal. It may be preceded by fungal invasion of the anastomosis. Fibreoptic bronchoscopy to inspect the anastomoses and remove residual secretions is performed at the conclusion of surgery or after return to the ICU. This is repeated as indicated.

#### LONG-TERM COMPLICATIONS

Obliterative bronchiolitis<sup>35</sup> which may be a manifestation of chronic rejection may eventually lead to graft failure. Recurrent infections with *Pseudomonas* or methicillin-resistant *Staphylococcus* can be serious. After the first 6 weeks, infection with CMV, any fungus, protozoan or virus presents potential hazards. Chronic renal failure due to ciclosporin therapy may persist, but is not usually a major problem unless other complications occur. Most patients have a good quality of life with few complications. The improvement in quality of life after lung transplantation may be more important as a marker of success than bald survival figures.<sup>36</sup>

#### RESULTS OF CARDIOPULMONARY TRANSPLANTATION

A very good source of information on the results of intrathoracic transplantation can be found at [www.ishlt.org](http://www.ishlt.org) and in more traditional publications<sup>37</sup> such as the recent summary of results of transplantation in the UK.<sup>38</sup> These figures indicate that survival is considerably better after heart transplantation than heart–lung or lung. Almost 90% of heart recipients are alive at 3 months as compared to around 75% of heart–lung and lung recipients. Around 70% of heart recipients are still alive after 5 years; 50% or less of heart–lung and lung recipients survive this long. While these figures are quite impressive and could improve with current trends in immunosuppression and general care, the main issue remains the gross disparity between the number of patients with end-stage cardiopulmonary disease and the ever-shrinking supply of donor organs. This is all the more reason to ensure that those

patients who have got as far as to benefit from such a rare and precious opportunity receive high standards of medical care throughout their remaining life.

# The critically ill child

Alan W Duncan

The chapters on paediatric intensive care are intended to help intensivists outside specialised paediatric centres manage common paediatric emergencies. They should be read in conjunction with relevant adult chapters, as there are areas of common interest. Some common neonatal emergencies are also presented.

The differences between neonates and infants from adults render them susceptible to critical illness and alter their response to disease processes. Nevertheless, there are also similarities and many aspects of organ monitoring and support in adult intensive care units (ICUs) have been successfully modified for use in children and are applicable to even the smallest infants.

The major differences between paediatric and adult patients are described below.

## ADAPTATION

Dramatic physiological adaptation takes place as the fetus adjusts to extrauterine life. Many changes are incomplete until some time after birth and, until then, reversion to fetal physiology may occur. Classically, this applies to the cardiorespiratory events at birth and the subsequent development of a transitional pattern of circulation (see below).

## GROWTH AND DEVELOPMENT

There is progressive growth and development of all organ systems throughout childhood. 'Small-body technology' has evolved to cope with the technical aspects of paediatric critical care. Some aspects of growth are non-linear and contribute to the reduced cardiorespiratory reserve of the infant. Physiological differences that influence disease processes and their management are discussed in respective chapters in this section.

## MATURATION

At birth, the immaturity of many systems and biochemical processes alters the response to pathophysiological stress and drugs. Thermoregulation, immune function

and renal function are immature at birth, even in the full-term infant. Such immaturity is magnified in the premature infant; for example, surfactant deficiency in the lung causing hyaline membrane disease and liver glucuronyl transferase deficiency causing jaundice.

## DIVERSE PATHOPHYSIOLOGICAL STATES

Developmental anomalies, inborn errors of metabolism, susceptibility to infection and various accidents and trauma provide a wide spectrum of paediatric critical illnesses. The response to these illnesses is modified by various aspects of adaptation, growth and development and maturation.

## PAEDIATRIC INTENSIVE CARE

The development of separate paediatric ICUs recognised the unique problems and requirements of critically ill children. The paediatric ICU (PICU) should not be seen in isolation, but as part of a tertiary paediatric centre, with well-defined prehospital care, emergency medical services and retrieval teams. Minimum standards should be adopted. In general, a PICU should provide:

- a specialist trained in paediatric intensive care available at short notice
- a range of paediatric subspecialty support
- immediately available junior medical staff with advanced life support skills
- nursing staff with experience in paediatric intensive care
- allied health professionals and ancillary support staff
- specialised advanced life support equipment for children ranging in age from neonates to adolescents
- 24-hour laboratory, radiological and pharmacy services
- purpose-built PICU, recognising the special physical and emotional needs of critically ill children and their families
- a programme for teaching, continuing education, research and quality assurance

Neonatal ICUs have their own particular requirements.

### CARDIORESPIRATORY EVENTS AT BIRTH

During intrauterine life, 60% of blood returning to the right atrium passes directly through the foramen ovale into the left ventricle and ascending aorta. As most of this blood is from the umbilical arteries, the heart and brain are perfused with better-oxygenated blood. Pulmonary vascular resistance (PVR) is high and most of the blood reaching the right ventricle passes through the ductus arteriosus to the descending aorta. Only 10% of right ventricle output passes to the lungs which, although non-functional, require a blood supply for nutrition, growth and development of the lung vasculature.

At birth, closure of the umbilical vessels increases systemic vascular resistance (SVR) and lung expansion leads to the dramatic fall in PVR. Pulmonary blood flow increases, leading to a rise in left atrial pressure and functional closure of the foramen ovale. The ductus arteriosus subsequently constricts and eventually thromboses.

Following the dramatic fall in PVR at birth, there is a gradual regression in muscularisation of the pulmonary arterioles over the following weeks to months. This regression is prevented if high pulmonary blood flow occurs, due to congenital heart lesions (e.g. ventricular septal defect, large patent ductus arteriosus and truncus arteriosus) or lesions associated with persistent hypoxaemia (e.g. transposition of great vessels). With these lesions, progression to irreversible pulmonary vascular disease may occur at an early age.

### TRANSITIONAL CIRCULATION

Haemodynamic adaptation at birth may be delayed or reversed by a number of factors. Persistent pulmonary hypertension and patency of the fetal channels result in right-to-left shunting through the foramen ovale and ductus arteriosus (termed persistent fetal circulation or more correctly transitional circulation). A vicious cycle may develop, with increasing hypoxaemia and acidosis, increased PVR and further shunting. Unless the underlying disturbance is treated and the pulmonary hypertension is corrected, progression to death is likely. Pulmonary circulation pathophysiology is probably related to abnormalities of endogenous nitric oxide production and manipulation of this agent is proving useful in therapy.

### CAUSES OF TRANSITIONAL CIRCULATION

A 'fetal' pattern may persist due to:

- low lung volume states (e.g. hyaline membrane disease and perinatal asphyxia)
- pulmonary hypoplasia (e.g. diaphragmatic hernia and Potter's syndrome)
- meconium aspiration syndrome
- chronic placental insufficiency

- perinatal hypoxia and acidosis from any cause
- sepsis (e.g. group B streptococcal infection)
- hyperviscosity syndrome

### CLINICAL FEATURES

Hypoxaemia disproportional to the degree of respiratory distress is typical of transitional circulation and suggests the possibility of congenital cyanotic heart disease. In cases without significant lung disease, echocardiography may be necessary to exclude a structural cardiac lesion. Severe respiratory distress is present in cases secondary to pulmonary disease. Differential cyanosis (i.e. increased cyanosis affecting the lower limbs when compared with the head, neck and right arm) may be seen with the right-to-left shunting at ductal level. This may be confirmed by simultaneous pre- and postductal arterial blood sampling, transcutaneous  $P_{O_2}$  monitoring or oximetry.

### TREATMENT

It is important to treat the underlying cause (e.g. surfactant therapy for hyaline membrane disease) in addition to therapy to reduce PVR. The main steps employed are:

- maintenance of high inspired oxygen. Alveolar oxygen tension is an important determinant of pulmonary arteriolar resistance. Sudden reductions in inspired oxygen may increase shunting through fetal channels (so-called flip-flop phenomenon)
- correction of low lung volume states with continuous positive airway pressure (CPAP) or positive-pressure ventilation with positive end-expiratory pressure (PEEP)
- correction of both metabolic and respiratory acidosis
- deliberate hyperventilation using muscle relaxants to lower  $P_{aCO_2}$  and generate a respiratory alkalosis. This manoeuvre is limited by lung immaturity and risk of barotrauma. Rapid rates of ventilation (> 60 breaths/min) may prove beneficial
- maintenance of systemic arterial pressure with volume expanders and inotropic agents to reduce the pressure gradient favouring ductal shunting
- isovolaemic haemodilution with colloid, if indicated, to reduce hyperviscosity
- administration of pulmonary vasodilators, e.g. inhaled nitric oxide<sup>1</sup>

Many centres successfully employ extracorporeal membrane oxygenation (ECMO) in this situation.

### THERMOREGULATION IN THE NEWBORN

Human body temperature is maintained within narrow limits. This is achieved most easily in the thermoneutral zone – the range of ambient temperature within which the metabolic rate is at a minimum. Once ambient

temperature is outside the thermoneutral zone, heat production (shivering or non-shivering thermogenesis) or evaporative heat loss processes are required to maintain body temperature within normal limits. Regulatory mechanisms are less effective in the neonate (there is no shivering or sweating), who is otherwise disadvantaged by a high surface area to body weight ratio and lack of subcutaneous tissue.

The thermoneutral zone is higher in premature infants and falls with increasing postnatal age. Oxygen consumption is minimal, with an environmental or abdominal skin temperature of 36.5 °C. Oxidation of brown fat found in the interscapular and perirenal areas (non-shivering thermogenesis) is the major source of heat production when 'cold-stressed'.

Alteration of body temperature above or below normal leads to increased or decreased metabolism respectively. Attempts by the body to maintain body temperature within normal limits are associated with increased metabolism and cardiorespiratory demands. Radiation is a major source of heat loss in the neonate and is effectively minimised by double-walled incubators or by servo-controlled radiant heaters. The latter allows better access to critically ill babies for monitoring and procedures. Cold stress per se increases neonatal mortality. In the presence of respiratory or cardiac disease, it may lead to decompensation.

### IMMUNOLOGY OF THE INFANT

The immunological system consists of:

- non-specific mechanisms, including phagocytosis and the inflammatory response
- specific immune responses, consisting of cell-mediated (T-cell) and humoral (B-cell) systems (see Chapter 59). These two components are intimately related and both may be abnormal in the newborn infant

The inflammatory response of the newborn is attenuated. Febrile response to infection may be lacking and both cellular (chemotaxis and phagocytosis) and humoral (complement activity and opsonisation) responses may be impaired. Cell-mediated immunity is completely absent in infants born without thymic function (DiGeorge syndrome). In the normal newborn, however, T-cell function appears to be quite well developed. Rejection of skin allografts is slower in the newborn but this seems to be related mainly to the attenuated inflammatory response.

The B-cell system, responsible for antibody production, is immature at birth. The neonate has passive immunity against some infections because of transplacental transfer of maternal antibodies. Natural immunity is acquired as a result of immunoglobulin A (IgA) in breast milk and protects against some acquired gastrointestinal infections. Overall, the immaturity and inexperience of the immune system result in a markedly increased susceptibility to infection in the first 6 months of life.

### RESUSCITATION OF THE NEWBORN

Some newborn infants fail to adapt from fetal to extra-uterine life and require immediate cardiopulmonary and cerebral resuscitation. The Apgar scoring system (Table 96.1) scored after 1 minute, remains the most widely accepted method of assessment. The best Apgar score is 10 and the worst is 0. There is an inverse relationship between the Apgar score and the degree of hypoxia and acidosis. It has been suggested that the 5-minute score is a guide to ultimate prognosis but this is questioned. Collection of sequential scores must not delay the institution of resuscitation.

### BIRTH ASPHYXIA

The causes of birth asphyxia may be:

- placental failure – acute or chronic (e.g. toxæmia, diabetes and antepartum haemorrhage)
- drug depression due to maternal analgesics or sedatives administered immediately prior to delivery
- obstetric complications (e.g. difficult forceps, breech, caesarean section and prolapsed cord)
- fetal conditions (e.g. multiple births and prematurity)
- postnatal problems (e.g. respiratory distress immediately after birth from any cause)

### MANAGEMENT

The principles of resuscitation are identical to those employed in other situations. Resuscitation must be started immediately after delivery. Although some cerebral insult may have occurred in utero or intrapartum, secondary insults from postpartum asphyxia must be avoided.

Babies suffering mild asphyxia immediately before birth with Apgar scores between 5 and 7 usually respond to stimulation and gentle suction to the nose, mouth

Table 96.1 Apgar scoring system

Score	0	1	2
Heart rate	Absent	< 100 beats/min	> 100 beats/min
Respiratory effort	Absent	Weak cry	Strong cry
Muscle tone	Limp	Some flexion	Active motion
Reflex irritability (in response to catheter in nose)	No response	Grimace	Grimace and cough or sneeze
Colour	Blue, pale	Body pink, extremities blue	Pink

and pharynx although oxygen therapy is occasionally required. Babies with moderate asphyxia (Apgar 3–4) usually respond to bag-and-mask ventilation with oxygen. Acid–base status should be determined and sodium bicarbonate administered to restore pH > 7.25. Severely asphyxiated infants (Apgar 0–2) need urgent cardiopulmonary resuscitation (CPR). After airway suction, bag-and-mask ventilation should be followed by rapid orotracheal intubation and positive-pressure ventilation with oxygen. Fear of complications of oxygen therapy must not mitigate against the administration of 100% oxygen at this stage. If the liquor contains thick meconium, it is vital that the pharynx and trachea be suctioned prior to the onset of respiration or application of positive pressure. Meconium aspiration syndrome is a preventable condition that is often difficult to manage.

Venous access via umbilical or peripheral veins must be established immediately and followed by the administration of 1–2 mmol/kg of sodium bicarbonate. Subsequent buffer therapy should be based on arterial acid–base status if available. Rapid or excessive infusions of hypertonic solutions (e.g. sodium bicarbonate or hypertonic dextrose) or volume expanders may precipitate intracranial haemorrhage, particularly in premature infants.

Asphyxiated infants are usually volume-depleted at birth and blood pressure should be immediately restored with colloids (10 ml/kg in the first instance). External cardiac massage and additional drug therapy (see below) should be employed, if necessary, to restore cardiac rhythm. Postresuscitative care to maintain cerebral perfusion pressure, correct abnormal serum biochemistry and control seizures is required to prevent secondary cerebral insults. Myocardial dysfunction may occur secondary to asphyxia. Dopamine or dobutamine (5–10 µg/kg per min) may prove useful.

The orotracheal tube should be changed to nasotracheal to enable secure fixation once a degree of stability is attained. Radiological confirmation of tube position should be made as soon as possible. The trachea is very short in the newborn and endobronchial intubation is a particular risk.

Approximate nose to mid-trachea (T2) distances are:

- 28 weeks' gestation: 7 cm
- 33 weeks' gestation: 9 cm
- term infant: 10.5 cm

### CARDIORESPIRATORY ARREST IN CHILDREN

The vast majority of children lack intrinsic myocardial disease and when cardiac arrest occurs, it is usually the end result of hypoxaemia and acidosis. The most common predisposing causes are rapidly progressive upper-airway obstruction, near drowning, sudden infant death syndrome, pneumonia, sepsis, gastroenteritis and major

trauma. Such children invariably arrest in asystole and this should be assumed if an electrocardiogram (ECG) is not immediately available.

Ventricular fibrillation (VF) may be anticipated in the following situations:

- congenital heart disease
- cardiomyopathies
- myocarditis
- poisoning (e.g. tricyclic antidepressant ingestion)
- hereditary prolongation of QT interval (Romano–Ward syndrome)

The International Liaison Committee on Resuscitation (ILCOR) has developed a consensus statement detailing the science underpinning paediatric and neonatal basic and advanced life support.<sup>2</sup> The management of paediatric cardiopulmonary resuscitation is discussed in detail elsewhere in this volume.

### VASCULAR ACCESS

Venous access may be difficult, particularly in the collapsed, hypovolaemic or hypothermic child. The external jugular vein may be prominent when usual sites are inaccessible. Cannulation of central veins, apart from via the femoral and external jugular veins, is hazardous even in ideal situations and should not be attempted during cardiac arrest in small children and babies. Two may be considered: intraosseous access or endotracheal instillation.

### INTRAOSSIOUS ACCESS<sup>3</sup>

This involves infusion into bone marrow – a non-collapsible venous system in direct communication with the circulation. In dog experiments, drugs infused in this way reach the central circulation as rapidly as those injected into a central vein. The effect of equal doses of adrenaline (epinephrine) given by intraosseous and i.v. routes is identical in shocked dogs. The technique is simple and quick to learn.

Intraosseous infusion has been successfully used in CPR.<sup>4</sup>

Potential complications include:

- osteomyelitis: conventional venous access should be established after resuscitation
- compartment syndromes requiring limb amputation: these have resulted from needle misplacement in muscle or administration of fluids into muscle through another bone perforation<sup>5</sup>

Careful placement is essential, and close observation of the limb and early removal once alternative access is achieved are recommended.

### ENDOTRACHEAL INSTILLATION

Endotracheal instillation is, at best, a poor substitute for the above methods. Do not use bicarbonate and calcium

as they will cause direct lung damage and cannot be administered by this route.

Epinephrine, lidocaine and atropine may be diluted in saline (newborn 1 ml, infants and preschool children 3 ml, older children 5 ml) and delivered into the bronchi through a catheter passed down the endotracheal tube.

### PAEDIATRIC MONITORING

Technology has allowed most aspects of adult monitoring to be applied to neonatal and paediatric practice. The ideal paediatric haemodynamic and respiratory monitoring system should:

- be non-invasive, painless and readily interfaced with the child
- constitute minimal risk to the child
- provide specific data relevant to the child's status that are reproducible and readily understood
- respond rapidly to changes in status
- provide continuous visual and/or auditory display of data
- have appropriate alarms
- have facilities for recording data
- be inexpensive and require low maintenance

### ARTERIAL CANNULATION AND PRESSURE MONITORING

Arterial cannulation is routine practice in paediatric intensive care, even in infants weighing < 1 kg. It is indicated in all critically ill infants for continuous blood pressure monitoring and accurate blood gas sampling. In the neonate, difficult 'stabs' may lead to significant errors in  $P_{aO_2}$  and  $P_{aCO_2}$ . Umbilical arterial catheters are commonly used in newborn infants, although users must be aware of the potential vaso-occlusive complications (e.g. lower limb ischaemia, renal thrombosis, necrotising enterocolitis and rarely, paraplegia).

Peripheral arteries used include radial, ulnar, brachial, femoral, posterior tibial and dorsalis pedis. Radial and ulnar or posterior tibial and dorsalis pedis vessels must never be cannulated sequentially in the same limb. The safety of brachial and femoral cannulation lies in the presence of rich collateral vessels around the elbow and hip joints. Arterial lines are kept patent by continuous flushing with 1–2 ml/hour of heparinised normal saline (5 units heparin/ml flushing solution) or 5% dextrose. Complications include distal ischaemia, infection, retrograde embolisation and haemorrhage. Retrograde embolisation occurring with flushing is a particular risk in the small infant, depending on the length and volume of the vessel and volume and speed of injection. In a 1.5 kg infant, as little as 0.5 ml of fluid injected rapidly into the right radial artery will reach the cerebral circulation. Haemorrhage from accidental disconnection can be significant because of the relatively small blood volume. Meticulous fixation is therefore required.

### CENTRAL VENOUS CANNULATION AND PRESSURE MONITORING

All routes of central venous cannulation are applicable to infants and children and must be within the skills of paediatric intensivists. The femoral route is sometimes the safest in emergency situations. Catheters utilising the Seldinger technique have greatly increased successful placement. Ultrasonography is useful to determine the exact location of veins. Multilumen catheters are recommended when infusing multiple drugs and for parental nutrition. Complications including catheter-related sepsis are the same as in adults. This risk can be reduced by adherence to a bundle of measures.<sup>6</sup> The need for prolonged venous access may warrant regular catheter changes, or surgical implantation of a central venous device (e.g. Infusaport, Broviac or Hickman catheter). Umbilical venous cannulation and passage of the catheter through the sinus venosus to the right atrium is useful in neonatal emergencies.

### PULMONARY ARTERY PRESSURE MONITORING

Pulmonary artery (PA) pressure monitoring using flow-directed 4 and 5 FG catheters is feasible even in neonates; however, it is invasive, technically more difficult and has greater risks than in the adult. It is rarely required in the neonate, as the pulmonary circulation and response to therapy can usually be gauged indirectly from the magnitude of right-to-left shunting. Systemic levels of PA pressure are usually found in neonates with severe lung disease.

The major indication for PA pressure monitoring is following surgery for congenital heart disease (e.g. repair of ventricular septal defect with pulmonary hypertension, truncus arteriosus and obstructed total anomalous pulmonary venous drainage). A catheter is inserted directly into the PA or via the right ventricular outflow tract at the time of surgery. It is most useful in guiding weaning from mechanical ventilation.

### LEFT ATRIAL PRESSURE MONITORING

Left atrial pressure monitoring is often useful after open heart surgery for congenital heart disease, and is achieved by means of a catheter placed directly in the left atrium during surgery.

### CARDIAC OUTPUT MEASUREMENT

Cardiac output determination can be performed in small children by dye dilution, thermodilution or Doppler techniques. Unfortunately, errors have been substantial, and the first two techniques are invasive, intermittent and only repeatable within finite limits. Interpretation of results is made difficult or impossible in the presence of

intracardiac shunts or valvular incompetence. The dye curve may, in fact, be useful in demonstrating residual intracardiac shunts. Calculation of derived variables is only as accurate as the flow measurement.

A recently developed system (PiCCO, Pulsion Medical Systems AG, Munich, Germany) provides continuous cardiac monitoring even in small infants. Cardiac output is determined both intermittently by transpulmonary thermodilution<sup>7</sup> and continuously through arterial pulse contour analysis.<sup>8</sup> The system also derives cardiac preload volume, an index of left ventricular contractility, and an estimate of intrathoracic blood volume and extravascular lung water.

### TEMPERATURE MONITORING

Temperature monitoring is important in neonatal and paediatric intensive care. Prevention of cold stress requires accurate measurement of core and skin temperature. Core-toe-ambient temperature gradients provide a sensitive, albeit indirect index of cardiac output and peripheral perfusion and are useful in managing fever. Toe temperature normally lies between core temperature (tympanic or oesophageal) and ambient temperature. The toe-core temperature gradient increases with low cardiac output or vasoconstriction from any cause. Toe temperature is a useful guide to the efficacy of vasodilator therapy.

### PULSE OXIMETRY

Pulse oximetry provides continuous non-invasive measurement of arteriolar saturation ( $SaO_2$ ) and provides a rapid indication of hypoxaemia. Accurate information is given:

- when the oxyhaemoglobin dissociation curve is shifted to the left (e.g. fetal haemoglobin and alkalosis) or to the right (e.g. sickle-cell disease and acidosis)
- in the presence of carboxyhaemoglobin (functional saturation is accurate)
- with moderately severe desaturation (e.g. cyanotic heart disease)
- with anaemia (haemoglobin concentrations above 5 g/dl)
- when skin is pigmented

Errors occur with extreme hypoperfusion, excessive movement and rapidly changing ambient light. A range of sensors is now available to monitor children of all ages.

### TRANSCUTANEOUS $P_{O_2}$ AND $P_{CO_2}$ MONITORING

Oxygen and carbon dioxide diffuse through well-perfused skin from the superficial capillary network and can be measured using modified polarographic and glass electrodes respectively. The electrodes are heated to 43–45°C to arterialise the capillary blood and maximise

capillary blood flow. Under optimal conditions, there is good correlation between arterial and transcutaneous gas tensions. Hence continuous monitoring of blood gas tensions is possible in a non-invasive way. The  $P_{tCO_2}$ – $P_{tO_2}$  gradient and the output of the heating element have been used as indices of microcirculation. The accuracy of these devices is mainly confined to the neonatal period.

### DRUG INFUSIONS

All drugs used in cardiovascular and respiratory support are administered according to body weight; accurate delivery is crucial. Accurate drug infusions require accurate devices, of which syringe pumps are the most useful. Potentially lethal errors in calculating drug dilutions are minimised by the use of dose/dilution/infusion rate guidelines (Table 96.2).<sup>9</sup>

### PAIN RELIEF AND SEDATION IN CHILDREN

Management of pain and agitation in children has received inadequate attention and has tended to be underestimated and underrated. Infants and children are often unable or unwilling to complain of pain. In the past, some believed that the neonate could not perceive pain. It is now clear that even neonates possess all the anatomical and neurochemical systems necessary for pain perception and exhibit physiological and behavioural responses to pain.<sup>10</sup> Stress responses associated with pain and agitation may increase morbidity and mortality in critically ill patients. Analgesia can be provided by narcotic infusions, local blocks and regional techniques in children of all ages. Painful procedures in the ICU must always be accompanied by appropriate analgesia. The addition of sedative agents such as benzodiazepines can reduce agitation, minimise harmful stress responses and result in narcotic sparing.

### NEONATAL AND PAEDIATRIC EMERGENCY TRANSPORT

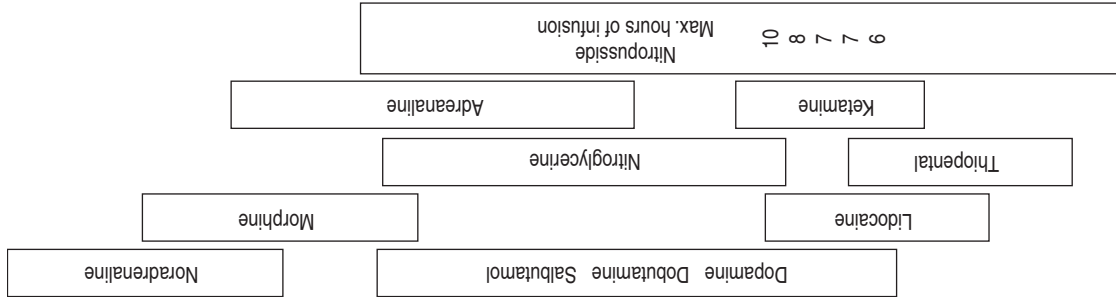

Care of critically ill neonates and children necessitates the use of specialised retrieval services linked to neonatal and paediatric ICUs. Retrieval services should offer facilities for specialist consultation in addition to secondary transport. Careful audit of such services is necessary to improve patient outcome.<sup>11</sup> The aim of retrieval services is to extend the intensive care facility to peripheral hospitals, allowing stabilisation by experienced personnel prior to rapid transport to a regional centre in the most appropriate vehicle (see Chapter 4). Special considerations such as thermoregulation and oxygen monitoring must be provided for in neonatal transport. Well-designed neonatal emergency transport services have resulted in significant reductions in morbidity and mortality.

**Table 96.2** Calculation of drug infusion dilutions

1. Select desired drug dosage to be delivered in  $\mu\text{g}/\text{kg}$  per min
2. Select infusion rate of syringe pump in ml/h (from centre of table)
3. Calculate number of milligrams of drug to be mixed in 50-ml syringe e.g.: 10-kg child, 0.1–2  $\mu\text{g}/\text{kg}$  per min, infusion 1–20 ml/h:  
put 0.3 ml/kg (= 3 mg) in 50 ml

$\mu\text{g}/\text{kg}$ per min	0.15 mg/kg in 50 ml	0.3 mg/kg in 50 ml	0.6 mg/kg in 50 ml	1.5 mg/kg in 50 ml	3 mg/kg in 50 ml	6 mg/kg in 50 ml	15 mg/kg in 50 ml	30 mg/kg in 50 ml	60 mg/kg in 50 ml

### OUTCOME OF PAEDIATRIC INTENSIVE CARE

Depending on admission criteria, mortality in paediatric ICUs ranges from 5 to 15%. If patients with pre-existing severe disabilities are excluded, the majority of survivors have a normal or near-normal life expectancy. A number of scoring systems have been developed or modified for paediatric application to predict ICU mortality. These scoring systems allow comparison between different ICUs, internal audits, stratification of patients for research purposes and analysis of cost benefit. The paediatric risk of mortality (PRISM) score<sup>12,13</sup> and the paediatric index of mortality (PIM) score<sup>14</sup> are applicable to a wide range of critically ill infants and children. Although PRISM performs marginally better, PIM is easier to collect and hence less prone to errors in data collection. PIM also has the advantage that it predicts mortality based on admission parameters whereas PRISM is based on the worst variables in the first 24 hours. As many paediatric ICU deaths occur in the first 24 hours, PRISM is often recording the dying process rather than predicting it. Specialised scores have been developed for specific problems, e.g. the modified injury severity scale (MISS) and paediatric trauma score (PTS) for paediatric trauma, and the modified Glasgow Coma Scale (GCS) for neurological insults. Numerous scoring systems have been developed for meningococcaemia, the best validated being the Glasgow meningococcal septicaemia prognostic score (GMSPS).<sup>15</sup>

Compared with adult intensive care, children with equivalent therapeutic intervention scores (TISS) have a lower in-hospital and 1-month mortality.<sup>16</sup> In addition, non-survivors do not consume a disproportionate amount of resources. While multiple organ failure increases mortality, the prognosis is considerably better than for adults.<sup>17</sup> There is evidence that mortality is lower in specialist paediatric ICUs,<sup>18</sup> and that paediatric ICUs with a larger workload have better outcomes than those looking after fewer children.<sup>19</sup> General hospitals should therefore have facilities for urgent resuscitation of children prior to early transport to a specialised paediatric ICU. Unless unavoidable, critically ill children, particularly those requiring mechanical intervention, should not be cared for in an adult ICU for longer than 24 hours. The American Academy of Pediatrics, the Society of Critical Care Medicine, the British Paediatric Association and the Australian National Health and Medical Research Council have all stated that children should receive intensive care in specialist paediatric units.

# Upper respiratory tract obstruction in children

Alan W Duncan

Upper respiratory tract obstruction (URTO) is a common cause of respiratory failure in infants and children. This reflects the frequency of upper respiratory tract abnormalities and disorders, the presence of narrow airways and the structural inefficiencies of the lung and chest wall. The majority of children with critical airway obstruction are otherwise healthy, and expert management results in a normal life expectancy. Poor management can lead to cardiopulmonary arrest and hypoxic cerebral damage.

## ANATOMICAL DIFFERENCES AND CLINICAL RELEVANCE

Differences in the anatomy and function of the airway are important considerations in airway maintenance, laryngoscopy and intubation. In the newborn, the nose contributes approximately 42% of total airways resistance, which is considerably less than the adult's 63%. Thus, infants are obligatory nose-breathers. The epiglottis is longer, U-shaped and floppy, and may need to be lifted with a straight-bladed laryngoscope for visualisation of the larynx and intubation. The larynx is higher in the neck (C3–4) in the neonate, and has an anterior inclination.<sup>1</sup> It descends over the first 3 years of life, and again at puberty, to ultimately lie opposite C6. The length of the trachea varies from 3.2 to 7.0 cm in babies weighing less than 6 kg. Accurate positioning of the tracheal tubes is required to prevent accidental extubation or endobronchial intubation. The narrowest part of the airway until puberty is the cricoid ring. This part of the airway is most vulnerable to trauma and swelling. The narrow cricoid ring also dictates tube size, and allows use of uncuffed tubes in infants and children.

## PATHOPHYSIOLOGY

Although the ratio of airway diameter to body weight is relatively large in the infant, in absolute terms airway diameter is small, and a minimal reduction causes a devastating increase in airway resistance. For example, the

diameter of the newborn's cricoid ring is 5 mm. A 50% reduction in radius will result in turbulent flow, and increases the pressure (and work) required to maintain breathing 32-fold.<sup>2</sup>

Symptoms and signs vary with the level of obstruction, the aetiology and the age of the child. Airway obstruction may be extrathoracic, intrathoracic or a combination. Extrathoracic obstruction is more pronounced during inspiration and is characterised by inspiratory stridor and prolongation of inspiration. Intrathoracic obstruction affecting either large or small airways is more pronounced during expiration and is characterised by expiratory stridor, prolonged expiration, wheeze and air trapping. Biphasic stridor is characteristic of mid tracheal lesions. These features mirror the intrapleural and airway pressure changes of the respiratory cycle (Figure 97.1). Retraction of the chest wall, an important sign of respiratory distress, reflects the negative intrapleural pressures generated combined with the compliance of the chest wall. Large negative intrapleural pressures are also transmitted to the interstitium of the lung, and may result in pulmonary oedema.<sup>3,4</sup> Cor pulmonale may develop secondary to chronic obstruction, hypoxia and pulmonary hypertension.<sup>5,6</sup>

## CLINICAL PRESENTATION

Stridor is noisy breathing due to turbulent air flow. It is the cardinal feature of URTO. Parents complain that their child has noisy breathing and of 'sucking the chest in'. The pitch and timing of stridor provide information about the degree and level of obstruction.

Voice sounds may also be informative. Nasal obstruction results in hyponasality. Oropharyngeal obstruction may cause a 'hot potato' voice. Supraglottic obstruction is characterised by a muffled voice. Children with glottic lesions may be hoarse or aphonic.

Retraction of the chest wall develops as obstruction progresses. Retraction is less prominent in older children, as the chest wall is more stable. As obstruction worsens, the work of breathing increases and the accessory muscles become active. The alae nasi (vestigial muscles of ventilation) begin

**Figure 97.1** Dynamics of (a) extrathoracic and (b) intrathoracic airways obstruction.

to flare. Fever increases minute volume and magnifies any degree of obstruction. Whereas infants and older children can maintain an increased work of breathing, premature infants and neonates rapidly fatigue, and may develop apnoeic episodes.<sup>7,8</sup>

Auscultation over the neck and larynx may identify the site of obstruction. A foreign body in the airway may produce a mechanical or slapping sound. Decreased or absent breath sounds may occur with greater degrees of obstruction. Chronic URTO is a cause of failure to thrive, chest deformity (pectus excavatum) and cor pulmonale.<sup>5,6</sup> Some infants present with recurrent chest infections. Abnormal posturing (head retraction) may also be a feature, particularly in infants.

Initially, the child with airway obstruction exhibits tachypnoea and tachycardia. If obstruction is severe and persistent, exhaustion eventually occurs, and the child exhibits decreased respiratory effort, decreased stridor and breath sounds, restlessness, cyanosis, pallor and eventually bradycardia.

## AETIOLOGY

A classification of the causes of URTO is presented in Table 97.1. The neonatal causes are predominantly due to congenital structural lesions. Acute inflammatory lesions, foreign bodies and trauma predominate in older infants and children.

## DIAGNOSIS

The cause of URTO can often be determined from the history and clinical features. Radiographic examination of the upper and lower airways with anteroposterior and lateral views may show soft-tissue swelling or the presence of foreign bodies.<sup>9</sup> Air shadows may indicate fixed stenotic or compressive lesions. In children with significant respiratory distress, these investigations should be undertaken in the intensive care unit (ICU) rather than the radiology department.

Previously, barium swallow and aortography have been used to confirm the diagnosis of vascular compression of the trachea. Computed tomography (CT) has assumed importance in the assessment of fixed lesions such as intrinsic stenosis and extrinsic compression. Echocardiography, magnetic resonance imaging (MRI) and CT with contrast are useful to assess vascular anomalies.<sup>10</sup> Tracheobronchography may provide excellent anatomical delineation of the proximal tracheobronchial tree and allow dynamic assessment of airway calibre.

Direct visualisation of the airway may be necessary, and may also prove therapeutic (e.g. removal of a foreign body). Nasoscopy, flexible fiberoptic and rigid laryngoscopy and bronchoscopy all have a place in assessing the

**Table 97.1** Causes of upper airway obstruction in children

Level	Newborn	Older infant and child
Nasal	Choanal atresia	
Oropharyngeal	Facial malformations (e.g. Pierre Robin syndrome, Treacher Collins syndrome) Macroglossia Cystic hygroma Vallecular cyst	Macroglossia/postglossectomy Angioedema Retropharyngeal abscess Tonsillar and adenoidal hypertrophy Obstructive sleep apnoea
Laryngeal	Infantile larynx Bilateral vocal cord palsy Congenital subglottic stenosis Subglottic haemangioma Laryngeal web Laryngeal cysts	Acute laryngotracheobronchitis (croup) Bacterial tracheitis Acute epiglottitis Postintubation oedema and stenosis Laryngeal papillomata Laryngeal foreign body Inhalation burns Caustic ingestion External trauma
Tracheal	Tracheomalacia Vascular ring	Foreign body Anterior mediastinal tumours (e.g. lymphoma)

paediatric airway. Investigation of the child's airway should only be undertaken in specialised centres by experienced endoscopists, radiologists and anaesthetists.

Blood gas determination is rarely useful in assessment or monitoring of URTO. An exception to this is in very young infants where hypercapnic respiratory failure may occur early and insidiously in URTO. It is dangerous practice to await respiratory failure before intervention. Mild hypoxaemia only may be present until fatigue, hypoventilation, cyanosis and hypercapnia occur. Pulse oximetry may provide useful warning information. An oxygen saturation less than 90% in a patient with pure URTO (without lung disease) is a reason for concern.

## SPECIFIC AIRWAY OBSTRUCTION

### EPIGLOTTITIS

Epiglottitis is a life-threatening supraglottic lesion which, prior to vaccination, was caused almost exclusively by *Haemophilus influenzae* type b. The prevalence of epiglottitis has fallen dramatically with the uptake of *H. influenzae* vaccination. It still occurs due to failure to vaccinate or vaccine failure. Occasional cases are caused by *Streptococcus*, *Staphylococcus*, *Pneumococcus* and *Meningococcus*, as well as by viruses. Non-infective causes include corrosive ingestion and thermal injury.

The diagnosis is usually obvious from history and clinical features. There is an acute onset of high fever, toxæmia and noisy breathing. The child adopts a characteristic posture, preferring to sit with mouth open, drooling saliva. The tongue is often proptosed and immobile. Cough is usually absent. These features are the legacy of an intensely painful pharynx. Due to the accompanying septicaemia, the severity of illness often appears out of proportion to the degree of airway obstruction. Typically, a low-pitched inspiratory stridor is present, accompanied by a characteristic expiratory snore. Atypical cases with cough and without fever may obscure the diagnosis.

Sudden total obstruction is not infrequent, and may be precipitated by examination of the pharynx, by placing the child in the supine position or stressful procedures (e.g. cannula insertion). When the diagnosis is in doubt, a lateral X-ray of the neck in the sitting position should be taken in the emergency department or ICU, provided that staff capable of securing the airway remain in attendance. Examination of the pharynx must not be undertaken unless personnel and facilities are available for immediate intubation.

### MANAGEMENT

#### PARENTERAL ANTIBIOTICS

Third-generation cephalosporins are the preferred antibiotics because of emerging resistance to ampicillin and, to a lesser extent, chloramphenicol. Appropriate regimens include cefotaxime 200 mg/kg per day i.v. for

5 days, or ceftriaxone 100 mg/kg i.v. statim followed by 50 mg/kg i.v. after 24 hours. Co-trimoxazole is usually an effective enteral antibiotic if more prolonged therapy is required.

#### RELIEF OF AIRWAY OBSTRUCTION

All but the mildest cases require insertion of an artificial airway under anaesthesia (see below). Nasotracheal intubation is the optimal management,<sup>11</sup> although, depending on the available personnel, tracheostomy is a satisfactory alternative. Anaesthesia for relief of airway obstruction is described below. A tube of size appropriate for age is chosen (see Chapter 104). Extubation can be undertaken when fever subsides and the child no longer appears toxic. Most cases can be extubated in less than 18 hours. Only those complicated by pulmonary oedema, pneumonia or cerebral hypoxia (from delayed therapy) will require intubation for longer than 24 hours. It is not necessary to re-examine the larynx prior to extubation. Nebulised adrenaline (epinephrine) is of no benefit in this condition and may aggravate the situation.<sup>12</sup> Pulmonary oedema, when it occurs, is due to airway obstruction, septicaemia and increased lung capillary permeability.<sup>3,13,14</sup> It is managed according to conventional principles.

#### PROPHYLAXIS

Most invasive infections due to *H. influenzae* occur in children under 5 years of age. The risk of infection in close contacts is about 500-fold higher than in the general population. It is thus recommended that all members (including adults) of any household with *H. influenzae* type b infection and with another child under 4 years should be given prophylactic antibiotics. An accepted regimen is oral rifampicin 20 mg/kg per day (maximum 600 mg) for 4 days. An alternative is a single dose of ceftriaxone 100 mg/kg i.m. or i.v.

### CROUP

Croup or acute laryngotracheobronchitis is due to inflammation and oedema of the glottic and subglottic regions. The narrowest part of the child's upper airway is the subglottic region, the point at which critical narrowing occurs. Retained secretions due to the bronchitic component may compound the obstruction. Croup is uncommon in children under 6 months of age, and an underlying structural lesion such as subglottic stenosis or haemangioma with superimposed infection should be suspected. Endoscopy is warranted if the child has a prior history of stridor or if symptoms persist beyond the acute episode.

Three subgroups are recognised: viral croup, spasmodic croup and bacterial tracheitis.

#### VIRAL CROUP

Viral croup, most commonly due to parainfluenza virus, respiratory syncytial virus and rhinovirus, is characterised by a coryzal prodrome, low-grade fever, harsh barking

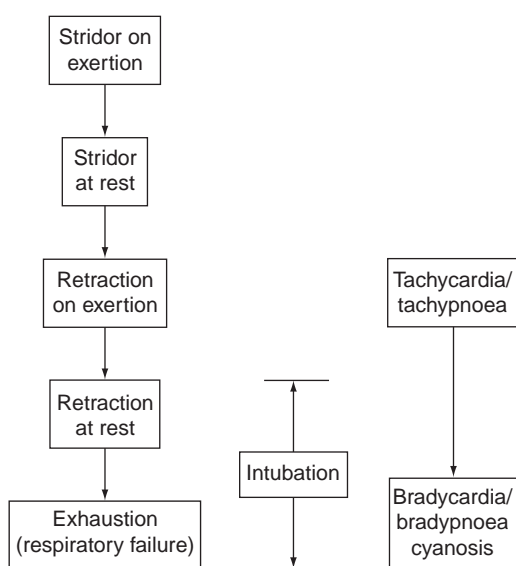

Figure 97.2 Features of progressive upper-airway obstruction.

(croupy) cough and hoarse voice. Progression of airway obstruction in severe cases is shown in Figure 97.2.

#### SPASMODIC CROUP

Spasmodic or recurrent croup occurs in children with an allergic predisposition.<sup>15,16</sup> It usually develops suddenly, often at night, and without prodromal symptoms. Endoscopy reveals pale, watery oedema of the subglottic mucosa. Such children probably represent part of the asthma spectrum, and wheeze, due to small airway flow limitation, may be a feature.

#### BACTERIAL TRACHEITIS

Bacterial tracheitis is uncommon but should be suspected in children exhibiting the usual features of croup, but accompanied by high fever, leukocytosis and copious purulent secretions.<sup>17</sup> There is a greater risk of sudden, severe obstruction from purulent secretions. *Staphylococcus aureus* is usually the cause, although *H. influenzae* and group A *Streptococcus* have also been isolated in some cases.

#### MANAGEMENT

*Minimal disturbance* is important, as restlessness will increase minute ventilation, oxygen consumption and signs of obstruction.

*Adequate hydration:* oral fluid intake must be encouraged to avoid dehydration. Nasogastric feeding is contraindicated, and i.v. fluids may occasionally be necessary. Overhydration must also be avoided. Hyponatraemia and convulsions due to inappropriate antidiuretic hormone secretion have been observed with prolonged, severe airway obstruction.

*Oxygen therapy* may mask signs of respiratory failure, but should be given to treat hypoxaemia. Its use can be guided by pulse oximetry (i.e. keep  $SaO_2 > 90\%$ ). Oxygen administration may further stress the young child. The need for oxygen therapy is often an indication that the child is progressing towards intubation.

*Corticosteroids* have dramatically reduced the need for intubation in children with croup. They are effective in both viral and spasmodic croup.<sup>18,19</sup> Steroids will also shorten the duration of intubation and increase the success rate of extubation.<sup>20,21</sup> The dose of dexamethasone is 0.6 mg/kg statim (maximum dose 10 mg) followed, if necessary, by 0.15 mg/kg 6-hourly. In very distressed children, it is best administered i.m. or i.v. to ensure absorption. Inhaled steroids are also effective in milder cases.<sup>22</sup>

*Humidification* of inspired gases was the mainstay of supportive care for decades. Controlled studies showing efficacy are lacking. A study by Bourchier *et al.* failed to demonstrate benefit and its use has been abandoned in many centres.<sup>23</sup>

*Nebulised adrenaline* will usually provide temporary relief of acute obstruction.<sup>24</sup> Historically, racemic adrenaline (2.25% solution, i.e. 1:88 L-adrenaline), developed for use in asthma, was employed. Indications for adrenaline nebulisation are:

- acute laryngotracheobronchitis, where relief usually lasts 1–2 hours, but may be longer if it facilitates secretions to be expelled. It is debatable whether the natural history of the disease is altered. It is an effective temporising measure until steroids have time to work. If given prior to induction, it will facilitate inhalational anaesthesia for intubation
- spasmodic croup, where one or two inhalations may produce lasting relief of airway obstruction
- post endoscopy or intubation oedema, where the benefit is often dramatic
- during transport, where administration may render the child safe for interhospital transfer without intubation

The empirical dose of racemic adrenaline is 0.05 ml/kg diluted to 2 ml with saline and nebulised with oxygen. The same dose of a strong preparation (1%) of the L-isomer can also be used. The same mass of L-adrenaline is also provided by 0.5 ml/kg (max 5 ml) of the standard 1:1000 solution of adrenaline, and this is equally effective. Antibiotics are indicated only for bacterial tracheitis where anti-staphylococcal cover is recommended.

*Mechanical relief of airway obstruction:* this requirement has been greatly reduced by early use of steroids. Increasing tachycardia, tachypnoea and restlessness indicate the need for tracheal intubation. An  $SaO_2$  persistently less than 90% is another reason for concern. It is important not to wait for the development of bradycardia, bradypnoea, cyanosis, exhaustion and respiratory failure. Blood gases are not a useful guide for intubation.

**Table 97.2** Nasotracheal tube size in croup

Age	Size
Less than 6 months	3.0 mm
6 months to 2 years	3.5 mm
2–5 years	4.0 mm
Over 5 years	4.5 mm

Nasotracheal intubation is preferred. An orotracheal tube, size (inner diameter) 1 mm less than that predicted by age (Table 97.2) is first inserted under anaesthesia (see below). A stylet through the tube is recommended to overcome the resistance of the subglottic region. The tube is changed to a nasotracheal tube immediately after clearance of secretions.

Extubation can be performed when the child is afebrile, secretions have diminished and a leak is audible around the tube with coughing or application of positive pressure (25 cmH<sub>2</sub>O or less). The duration of intubation averages 5 days. Children under 1 year have a higher incidence of requiring intubation and a longer duration of intubation. Reintubation may be required in some cases. Endoscopy should be performed in cases that require repeated intubation to exclude underlying lesions and subglottic injury. Tracheostomy is a suitable alternative for some situations, although complications are more significant.

### OTHER SUPRAGLOTTIC LESIONS

Retropharyngeal abscess, tonsillitis, peritonsillar abscess, infectious mononucleosis and Ludwig's angina may all mimic epiglottitis. Local features will usually indicate the diagnosis. A retropharyngeal abscess can be detected by palpation and is obvious on a lateral X-ray of the neck. Airway relief, antibiotics, drainage and, rarely, neck incision form the basis of treatment for these disorders. A nasopharyngeal tube will provide relief of obstruction in most supraglottic lesions. In an emergency situation, placement of a laryngeal mask airway may be life-saving. Tonsillectomy, although best performed electively, is occasionally indicated in the acute phase of tonsillar obstruction. Steroids appear to be effective in reducing cervical lymphadenopathy and tonsillar enlargement in cases of infectious mononucleosis and the response is rapid.

### TONSILLAR AND ADENOIDAL AIRWAY OBSTRUCTION

The contemporary conservative surgical approach to tonsillectomy and adenoidectomy has led to an increased incidence of hypertrophy and untreated chronic upper-airway obstruction.<sup>25</sup> Such children may present with

severe, acute exacerbations due to intercurrent infection (e.g. tonsillitis). They may present in a toxic state with drooling, thereby mimicking acute epiglottitis. Obstruction is most marked during sleep. In the most severe cases, it may be necessary to relieve the obstruction with a nasotracheal tube or a nasopharyngeal tube positioned beyond the tonsillar bed. Tonsillectomy and adenoidectomy are generally contraindicated in the acute phase, because of increased risk of bleeding, but are performed when infection has settled.

### OBSTRUCTIVE SLEEP APNOEA SYNDROME

Obstructive sleep apnoea (OSA) syndrome is characterised by intermittent upper-airway obstruction during sleep, with heavy snoring, stertorous breathing and an abnormal, irregular respiratory pattern.<sup>26</sup> Frequent episodes of chest-wall motion with inadequate airflow (hypopnoea) or absent airflow (obstructive apnoea) are a feature. These episodes are most frequent during rapid eye movement sleep. They are accompanied by variable degrees of oxygen desaturation. OSA may be associated with enlarged tonsils and adenoids, a large uvula or long soft palate, macroglossia, retrognathia or various neurological disorders. Obesity is a common finding.

If OSA is severe and protracted, cardiac and pulmonary decompensation may occur. Chronic hypoxia and hypercarbia lead to pulmonary hypertension and cor pulmonale.<sup>5,6</sup> There may also be evidence of left ventricular failure and pulmonary oedema. Urgency of treatment is dictated by the mode of presentation. Critically ill children may require immediate relief of airway obstruction (nasopharyngeal or nasotracheal tube), oxygen therapy and diuretics. Antibiotics are indicated if there is bacterial superinfection. Surgical intervention is required after stabilisation. Tonsillectomy and adenoidectomy are often dramatically beneficial. They are best removed even when not grossly enlarged. Postoperative observation in a paediatric ICU or high-dependency unit is required for those with severe OSA. Other surgical procedures, such as uvulopalatopharyngoplasty or tracheostomy, may be required when this fails. The use of nocturnal continuous positive airway pressure (CPAP) is an option in long-standing, refractory conditions, e.g. neurological disorders. It is often not feasible because it is difficult to interface CPAP masks in young and uncooperative children.

### PIERRE ROBIN SYNDROME

This sequence consists of a posterior cleft palate, retrognathia and relative macroglossia. It is the cause of airway obstruction, feeding difficulties and failure to thrive in the newborn. Differential growth eventually reduces the significance of the deformity. Acute airway obstruction may be relieved by nursing the infant in the prone position, by passage of a nasopharyngeal tube or insertion of a laryngeal mask airway.<sup>27</sup> Occasionally, nasotracheal

intubation or tracheostomy is required. Tongue–lip anastomosis has been used in the past but is now rarely performed.

### CYSTIC HYGROMA

Although often conspicuous at birth, cystic hygroma is a relatively rare cause of upper-airway obstruction in infancy. The tumours consist of masses of dilated lymphatic channels. They usually occur in the neck and may involve tissues of the tongue and larynx. Occasionally, extension into the mediastinum occurs. Airway obstruction may be due to infection or haemorrhage into the lesion. Surgical excision has been the mainstay of treatment, although complete removal is difficult and recurrence is common. Treatment using sclerosing therapy is now used. Compounds used include bleomycin emulsion or OK 432.<sup>28,29</sup> OK 432 is produced by lyophilisation of cultures of a low virulent strain of group A *Streptococcus pyogenes* (human origin). In severe cases, long-term tracheostomy is required.

### INHALATION BURNS

Inhalational injury should be suspected with burns occurring in a closed space, and when facial burns, singed nasal hairs and oropharyngeal carbonaceous material are present. Respiratory complications are the major cause of mortality in children who are burnt. Direct airway burns or inhalation of products of combustion may lead to rapidly progressive oedema. The situation may be compounded by small airway and lung injury and by the need to provide adequate analgesia. Early intubation is strongly recommended prior to an emergency situation developing. Tracheal tube fixation is critical and may be problematic with extensive facial burns; it may require suturing of the tube to the nasal septum.

### SUBGLOTTIC STENOSIS

Neonates with congenital subglottic stenosis may present with severe obstruction requiring intubation at birth. Other infants present with persistent stridor or recurrent croup due to superimposed infection. Subglottic stenosis may also occur as a complication of prolonged or traumatic intubation, the result of tube pressure, mucosal ischaemia and healing by fibrosis. Prolonged intubation or tracheostomy may be required. Surgical techniques such as the cricoid split procedure or laryngotracheoplasty may be required to enlarge the airway.

### SUBGLOTTIC HAEMANGIOMA

Haemangiomas are common in infancy and occur in many parts of the body. Subglottic lesions often present in the second or third month of life and owe their importance to the anatomical location. Stridor is usually both inspiratory and expiratory. A hoarse cry is indicative of

vocal cord involvement. Obstruction may be severe and is aggravated by crying, struggling or superimposed infection. Cutaneous haemangiomas are seen in 50% and, if present, provide a clue to diagnosis. Definitive diagnosis rests on endoscopy. The natural history is of spontaneous resolution between the first and second years of life. Meanwhile, tracheostomy or periods of intubation may be indicated to cover episodes of obstruction. Encouraging results are being obtained with laser surgery. Intralésional injection of steroids may be of benefit.

### FOREIGN BODY OR CHOKING

A foreign body must be suspected in any acute obstruction occurring in an infant or child between 6 months and 2 years of age. Older children with neurological impairment are also at risk. A foreign body lodged in the pharynx results in gagging, respiratory distress and facial congestion. Laryngeal impaction usually produces stridor, a distressing cough and aphonia. Sudden total obstruction may occur. Symptoms usually develop while the child is playing or eating.

The technique for removal of a pharyngolaryngeal foreign body without equipment in infants and children is controversial and difficult. The American Academy of Paediatrics has made recommendations to cover various ages.<sup>30</sup> Gravity should be utilised by placing the child prone, straddled over the arm with the head down and a hand supporting the jaw. Four back blows between the shoulder blades should be administered. If this fails, chest thrusts or finger sweep across the pharynx should be attempted. There is some risk that the latter manoeuvre may impact the foreign body in the larynx. Abdominal thrusts (the Heimlich manoeuvre) are not recommended in infants but may be useful in children older than 1 year. Expired air resuscitation should be attempted in an emergency, although the risk of gastric distension is great. The best method of removal is extraction under direct vision using a laryngoscope, forceps, suction or a finger.

Tracheal or bronchial foreign bodies produce persistent cough and wheeze, and recurrent pneumonia. A foreign body lodged in the upper oesophagus may compress the trachea and present with either acute or, more commonly, persistent stridor. Radiopaque materials are easily shown radiologically, but both anteroposterior and lateral views may be necessary. Barium studies may prove useful for non-radiopaque material in the oesophagus. Treatment is removal at bronchoscopy or oesophagoscopy.

### ANTERIOR MEDIASTINAL TUMOURS

Anterior mediastinal tumours, such as lymphoma, may compress the trachea or bronchi, causing symptoms such as dry cough, stridor or wheeze. Airway compression may become severe enough to cause hyperinflation or atelectasis. Pleural effusions are common and may add to the respiratory distress. This is a high-risk situation. Symptoms may be aggravated by the supine position, especially

during anaesthesia for a biopsy procedure. This is likely in patients with superior vena caval syndrome. Postural symptoms or findings on flow–volume loops may allude to this risk. Echocardiography may also provide evidence of cardiac compression which increases the risks associated with anaesthesia. Sudden complete obstruction that cannot be bypassed by a standard tracheal tube has been described. The use of armoured tubes or a rigid bronchoscope may be required. Consideration should be given to leaving the tracheal tube in situ postoperatively until corticosteroids and chemotherapy reduce the tumour mass.

### ANAESTHESIA FOR RELIEF OF AIRWAY OBSTRUCTION

Inhalational induction and anaesthesia with oxygen and halothane or sevoflurane is the preferred technique for intubation. The use of muscle relaxants is hazardous if the ability to maintain a patent airway is doubtful.

Important points are:

- A prepared induction should be undertaken with efficient suction apparatus, a range of tracheal tubes, suitable stylets and bougies. Preparations must be made to intubate without deep anaesthesia if sudden obstruction occurs.
- Inhalational anaesthesia is slow in upper-airway obstruction, particularly when accompanied by lower airway or lung disease.
- Induction in the sitting position is advocated with epiglottitis. The child is laid flat after induction and prior to intubation.
- CPAP or assisted ventilation will reduce obstruction (minimise the dynamic component) and hasten induction. Care must be taken not to distend the stomach.
- Laryngoscopy is performed, and the child intubated, only when adequate depth of anaesthesia is achieved (e.g. approximately 8–10 minutes of 4% halothane in oxygen). Others recommend 6–8% sevoflurane.
- Orotracheal intubation is quickest and safest, and should be performed initially. After good tracheal toilet, the tube is changed to a nasotracheal one. Muscle relaxants may be used at this point if the operator is confident of the ability to intubate and/or ventilate.

### CARE OF NASOTRACHEAL TUBE

Successful management of URTO in children requires optimal care of the nasotracheal tube. Such children must always be nursed in an ICU with adequate nursing ratios. The nasotracheal tube must be positioned at the level of the clavicular heads (T2) on an anteroposterior chest X-ray. Length of the tube from 1 to 6 years of age

(in cm measured at the nose) is given by age in years + 13 cm. A meticulous technique of fixation must be employed to prevent accidental extubation.

Adequate humidification is difficult in the active child. Nevertheless, it is important to prevent obstruction of narrow tubes by inspissated secretions. Lightweight heat and moisture exchangers (HME) are very useful (e.g. Thermovent, Gibeck, and Humivent, Portex). The HME should be changed every 24 hours to reduce contamination and increased resistance. Oxygen supplementation can be provided, if necessary. Some children will tolerate connection of a humidified T-piece.

Effective bagging and tracheal toilet is vital, and should be repeated until the airway is clear. Instillation of saline (0.5–1.0 ml) prior to suction may be necessary to remove secretions. Light sedation is used to improve tolerance of the tracheal tube and to reduce the risk of self-extubation. Midazolam, 0.1–0.2 mg/kg statim, followed by continuous infusion (0.05–0.2 mg/kg per hour) is effective. Arm restraints may also be advisable, particularly in very young children. In some restless young children, it may be safer to use heavy sedation and mechanical ventilation. Signs of obstruction are usually relieved by intubation. Mild retraction may persist in children with high fever and increased minute ventilation in the presence of a smaller than predicted tube. Fibreoptic bronchoscopy can be performed to confirm patency. The tracheal tube must be changed or removed if there is doubt about its patency.

Nasogastric tube feeding should be commenced in children who require intubation longer than 24 hours.

### TRACHEOSTOMY

Tracheostomy remains a life-saving procedure and must be undertaken if tracheal intubation is impossible, or if appropriate equipment and personnel to facilitate intubation are unavailable. For chronic airway problems, it is more comfortable, allows better nasopharyngeal toilet and permits the child to leave the ICU and eventually return home. It is best performed under endotracheal anaesthesia with the neck extended. When intubation is impossible, the tracheostomy can be performed under anaesthesia via a laryngeal mask airway. A longitudinal slit is made through the second and third tracheal rings without removal of cartilage. Stay sutures in the tracheal wall lateral to the incision aid recannulation if accidental dislodgement occurs prior to formation of a well-defined tract (after 4 days). A postoperative chest X-ray should be obtained to check the position of the tip of the tracheostomy tube and to exclude pneumothorax or other complications.

Care of a newly created tracheostomy is similar to that of an endotracheal tube, with the additional problem of some discomfort and the likelihood of fresh blood in the airway. The first tracheostomy tube change is undertaken once a tract has been established, usually between 5 and 7 days.

**CRICOTHYROTOMY**

A wide-bore plastic i.v. cannula (14- or 16-gauge) passed into the trachea via the cricothyroid membrane may be life-saving if alternative procedures are unavailable. This should be performed with the neck extended as for tracheostomy. A system of connection to a low-pressure oxygen supply must be planned in advance. One method is to attach the hub of the cannula to the sleeve of a plastic 2–3 ml syringe (without plunger) to an adaptor from a 7.5 mm outer diameter tracheal tube, and then to a breathing circuit (e.g. Jackson Rees modification of Ayres T-piece). Jet ventilation has also been performed through a narrow cannula in this situation.

# Acute respiratory failure in children

Alan W Duncan

Established or imminent respiratory failure is the commonest reason for admission to neonatal and paediatric intensive care units (ICUs). A number of structural and functional factors contribute to the high incidence of respiratory failure, particularly in the first year of life. In addition, respiratory failure is frequently a consequence of pathology primarily affecting other organ systems, e.g. congenital heart disease or central nervous system (CNS) disease.

## PREDISPOSING FACTORS

Respiratory function must equate with metabolic demands. Oxygen consumption in the infant is approximately 7 ml/kg per min (compared with 3–4 ml/kg per min in the older child and adult). Fever, illness and restlessness dramatically increase demands; during periods of apnoea or respiratory depression,  $P_{aCO_2}$  rises at twice the rate of older children and adults. Respiratory reserve is reduced in infants and neonates due to the following factors.

## STRUCTURAL IMMATURITY OF THE THORACIC CAGE<sup>1</sup>

The ribs are short and horizontal and the bucket motion that increases the anteroposterior and lateral dimensions of the thorax is minimal. Thus, the infant is dependent on diaphragmatic displacement of abdominal contents to increase the length and volume of the thorax. Rib cage structure and function alter between 12 and 18 months, as the child develops the erect posture. The consequence is that any impairment of diaphragmatic function (e.g. phrenic nerve palsy, abdominal distension) may precipitate respiratory failure.

The chest wall is soft and provides a poor fulcrum for respiratory effort. Retraction of bony structures and soft tissues, a prominent sign of respiratory distress, occurs with reduced lung compliance and increased airway resistance. Infant intrapleural pressure is  $-1$  to  $-2$  cmH<sub>2</sub>O ( $-0.1$  to  $-0.2$  kPa) compared with  $-5$  to  $-10$  cmH<sub>2</sub>O ( $-0.5$  to  $-1.0$  kPa) in the adult. This is due to the higher compliance of the chest wall (which tends to collapse in) and lower

elastic recoil of the lung. The result is an increased tendency to airway closure, atelectasis and intrapulmonary shunting.

In the neonate, the diaphragm and intercostal muscles have a lower percentage of type I (slow twitch and high oxidative) muscle fibres and therefore fatigue more readily. Diaphragmatic muscle mass is relatively reduced. Intercostal muscle activity is inhibited during rapid eye movement sleep, further reducing ventilatory efficiency. Increased respiratory work is poorly sustained in the face of increased load and may culminate in exhaustion and apnoea.<sup>2</sup>

## INFANT AIRWAYS

Although relatively large compared with the adult, airways of infants in absolute terms are small and more prone to obstruction. Trachea and bronchiole diameters of a 3 kg neonate are one-third and one-half respectively of those of a 60-kg adult. However, any degree of oedema or airway mucus will have a more profound effect on airway resistance in the infant.

## LUNG STRUCTURE

Although the number of alveoli in the infant lung is proportionate to body size, the diffusion area is relatively small. The alveolar surface area is approximately 2.8 m<sup>2</sup> at birth, 32 m<sup>2</sup> at 8 years and 75 m<sup>2</sup> in the adult. Alveolar number and surface area may be reduced by in utero or early postnatal insults, including ventilator-induced injury. The infant lung also lacks the anatomical channels that allow 'collateral ventilation', putting the infant at greater risk of atelectasis, emphysematous changes and ventilation/perfusion abnormalities. The interalveolar pores of Kohn appear between the first and second years of life, while Lambert's channels provide communication between bronchi and adjacent alveoli beginning at 6 years.

## INCREASED SUSCEPTIBILITY TO INFECTION

The immaturity and inexperience of the immune system (cellular and humoral) result in a markedly increased susceptibility to infection in the first 6 months of life. The neonate's T-cells are unable to produce certain cytokines

which compromises the interaction between T-cells and B-cells. There is greater reactivity of T-suppressor cells to T-helper cells. Complement activation is impaired in premature and full-term neonates. The neonate's phagocytes have diminished motility, adherence and chemotaxis but bacterial killing by polymorphonuclear leukocytes is intact. In addition, there are many immune deficiency syndromes that may first reveal themselves early in postnatal life.

### IMMATURITY OF LUNG FUNCTION

Premature infants in particular may have surfactant deficiency, resulting in alveolar instability, atelectasis, intrapulmonary shunting and reduced lung compliance.

### IMMATURITY OF RESPIRATORY CONTROL

Inadequate respiratory drive from immaturity of the respiratory centre is a factor leading to apnoeic spells, particularly in premature infants. Opioid analgesics are associated with greater respiratory depression in young infants.

### CONGENITAL ABNORMALITIES

Congenital defects of the respiratory system (lower airways, lungs, chest wall, diaphragm) or associated organs (e.g. heart, great vessels) often present with respiratory failure shortly after birth.

### PERINATAL ASPHYXIA OR INJURIES

Asphyxia or intracranial haemorrhage associated with birth may result in seizures and respiratory depression.

### CLINICAL PRESENTATION

Respiratory distress is manifested by tachypnoea, distortion of the chest wall (i.e. sternal and rib retraction, recession of intercostal, subcostal and suprasternal spaces) and use of accessory muscles (e.g. flaring of alae nasi and use of neck muscles).

In young infants, lethargy, pallor, apnoea, bradycardia and hypotension may be the first signs of hypoxia. The physiological anaemia of infancy may delay recognition of cyanosis, and major signs are those of CNS and cardiovascular depression. Increased work of breathing, marked by tachypnoea and chest-wall retraction, is poorly sustained; bradypnoea and apnoea are evidence of respiratory fatigue. Expiratory 'grunting' is a sign of respiratory distress that represents an attempt to maintain a positive expiratory airway pressure to prevent airway closure and alveolar collapse, the equivalent of pursed-lip breathing in the adult.

The older child with acute hypoxia, like the adult, demonstrates tachycardia, hypertension, mental confusion

and restlessness prior to CNS and cardiovascular depression. Sweating occurs with CO<sub>2</sub> retention – a feature lacking in the newborn.

In the newborn, the effects of hypoxia and acidosis may be compounded by the development of pulmonary hypertension and reversion to a transitional circulation, with right-to-left shunting through a patent ductus arteriosus and foramen ovale. If untreated, increasing hypoxaemia, progressive acidosis and death may occur.

Conventional clinical examination of the chest should be performed. It is, however, of limited value in the neonate, as breath sounds may be transmitted uniformly through the chest, even in the presence of tension pneumothorax, lobar collapse or endobronchial intubation. The chest X-ray is an essential part of the assessment.

### AETIOLOGY

Acute respiratory failure may result from upper or lower airway obstruction, alveolar disease, pulmonary compression, neuromuscular disease or injury (Table 98.1). Upper respiratory tract obstruction is discussed in Chapter 97.

### TRACHEOMALACIA, TRACHEAL STENOSIS AND VASCULAR COMPRESSION

Instability of the tracheal wall (tracheomalacia) is most commonly associated with oesophageal atresia, tracheo-oesophageal fistula and various vascular anomalies. The most common causes of vascular compression are a double aortic arch and the complex of a right-sided aortic arch, left ductus arteriosus and an aberrant left subclavian artery. These produce a true vascular ring, with encirclement of the trachea and oesophagus. Anterior tracheal compression may also be due to an anomalous innominate artery. Lower tracheomalacia or tracheal stenosis may occur in association with an anomalous left pulmonary artery (pulmonary artery sling). The problem may extend to the major bronchi (bronchomalacia). Tracheomalacia and bronchomalacia also occur as isolated airway anomalies. In this situation, the severity of dynamic airway obstruction is aggravated by any condition that results in reduced lung compliance.

Division of the vascular ring and ligation or repositioning of the aberrant vessel, while removing the cause of the obstruction, do not immediately re-establish normal airway dimensions or stability. Although severity of symptoms may be alleviated by surgery, problems may persist for some years. Tracheomalacia may sometimes be stabilised by a prolonged period of nasotracheal intubation or tracheostomy with continuous positive airway pressure (CPAP). Tracheopexy, which suspends the anterior tracheal wall from the posterior sternal surface and great vessels, is occasionally useful. A slide tracheoplasty may be required to correct tracheal stenosis associated with

Table 98.1 Causes of respiratory insufficiency in infancy and childhood

		Envenomation

complete tracheal rings.<sup>3</sup> A range of stenting devices have also been developed for complex airways and employed with mixed success.

### MECONIUM ASPIRATION SYNDROME

Meconium aspiration is seen in 0.3% of live births, and is most common in term or postterm infants. There is usually a history of fetal distress in labour, or prolonged and complicated delivery. Asphyxia during labour results in the expulsion of meconium into the liquor. With the first few breaths, material in the upper airway (i.e. amniotic fluid, meconium, vernix and squames) is inhaled, obstructing small airways and producing atelectasis and obstructive emphysema. Meconium also causes a chemical pneumonitis and surfactant abnormalities. During recovery, the aspirated material is absorbed and phagocytosed.

Clinical signs include tachypnoea, retraction and cyanosis. The chest may become hyperexpanded and pneumomediastinum or pneumothorax is a frequent complication. Pulmonary hypertension and persistent fetal circulation are common.

The chest X-ray confirms the diagnosis, with coarse mottling and streakiness radiating from the hila. Lungs are overexpanded, with flattened diaphragms and an increase in the chest anteroposterior diameter. The condition is largely preventable if the airway can be aspirated rapidly and completely following delivery of the head and before the first breath.

Most of these infants require oxygen therapy. Severely affected infants require controlled mechanical ventilation (CMV), which may be difficult because of the high pressures required, the non-uniformity of ventilation, and danger of pneumothorax. Improved outcomes are now achieved using surfactant (may cause transient deterioration), inhaled nitric oxide and high-frequency oscillation.<sup>4</sup> Extracorporeal membrane oxygenation (ECMO) is also effective in those centres that have the facility, although its use has declined since the introduction of the above therapies. Cerebral effects of severe intrapartum asphyxia contribute to overall morbidity and mortality.

### CONGENITAL CYSTIC ADENOMATOID MALFORMATION

Congenital cystic adenomatoid malformation (CCAM) of the lung results from abnormal mesenchymal proliferation and failure of maturation of bronchiolar structures early in gestation. The result is multiple lung cysts, usually within a single lobe. CCAM is often diagnosed on antenatal ultrasound. Other cases present with respiratory distress due to obstruction whilst others present with infection in the cysts and recurrent lobar pneumonia. Some cases are diagnosed incidentally on chest radiographs taken for another reason. Some cases are associated with renal dysplasia. Even asymptomatic infants

are at risk of cyst expansion or infection and lobectomy is the treatment of choice for all cases.

### LOBAR EMPHYSEMA

Congenital lobar emphysema is characterised by overdistension of a pulmonary lobe caused by air trapping. Most cases present in the first month of life, with tachypnoea, wheezing, grunting and cough. Signs include hyperresonance, decreased air entry and deviation of the trachea and heart away from the affected lobe. There may be asymmetry of the chest due to bulging of the affected hemithorax. Cyanosis may be associated with periods of increased respiratory distress. There may be associated cardiovascular abnormalities, rib cage abnormalities or renal dysplasia.

Radiologically, the affected lobe is overdistended with compression and deviation of the surrounding structures. The pathogenesis is unknown in over 50%, 25% have localised bronchial cartilaginous dysplasia, and the remainder have obstruction of a lobar bronchus from a mucous plug, redundant mucosa, aberrant vessels or localised stenosis. Lobectomy is the definitive surgical treatment. Care must be taken with positive airway pressure because of the risk of further overdistension.

### ASPIRATION PNEUMONIA

In the newborn, aspiration may result from pharyngeal incoordination or lack of protective reflexes, due to prematurity, birth asphyxia or intracranial haemorrhage. It is particularly likely to occur with abnormalities of the alimentary tract, such as oesophageal atresia, tracheo-oesophageal fistula and oesophageal reflux. Large and small airway obstruction and pneumonia may occur.

### HYALINE MEMBRANE DISEASE

This is due to deficiency of lung surfactant. Predisposing factors are prematurity, maternal diabetes and intranatal asphyxia. Postnatal hypoxia and acidosis also inhibit surfactant production. Lack of surfactant results in alveolar instability, atelectasis, intrapulmonary shunting and increased work of breathing.

Clinical signs appear shortly after birth and consist of tachypnoea, chest-wall retraction, expiratory grunting and a progressive increase in oxygen requirements. The chest X-ray reveals a reticulogranular pattern (ground-glass appearance) with air bronchograms. In uncomplicated cases, the disease is self-limiting and resolves in 4–5 days. Respiratory failure may require increasing inspired oxygen concentrations ( $F_{iO_2}$ ), CPAP, intermittent mandatory ventilation (IMV) or CMV. CPAP is known to improve oxygenation, the pattern and regularity of respiration, retard the progression of the disease and reduce

morbidity, particularly with early application in the extremely preterm infant. In infants with persistent pulmonary hypertension, transitional circulation and requiring high airway pressures, the use of inhaled nitric oxide and high-frequency oscillatory ventilation are beneficial.

Instillation of surfactant into the trachea has been shown to improve oxygenation and compliance (despite some initial deterioration) and reduce the risk of pneumothorax, early mortality and morbidity.<sup>5-8</sup> Two types of surfactant are used: synthetic (Exosurf), and bovine (Survanta) or porcine (Curosurf).

### BRONCHOPULMONARY DYSPLASIA

Bronchopulmonary dysplasia (BPD), or chronic lung disease, may occur in survivors of neonatal lung disease. Its occurrence correlates with lung immaturity, high airway pressures and barotrauma. The lung architecture is abnormal with widespread fibrosis and cystic changes. There is often a reactive component to the airway disease that may be responsive to bronchodilator and anti-inflammatory therapy, such as steroids. It is a cause of chronic respiratory failure in infancy, and in severe cases progresses to cor pulmonale and death in the first 2 years of life. Prolonged low-flow home oxygen therapy may be necessary to reduce the risk of pulmonary hypertension. Superimposed bacterial and viral infection may exacerbate chronic respiratory failure and lead to further lung injury.

### PNEUMONIA

Perinatal pneumonia may occur as a result of transplacental spread of a maternal infection, prolonged rupture of membranes, passage through an infected birth canal or cross-infection in the nursery. The immunoparalytic state of the newborn and the need for invasive procedures increase the risk.

Clinical and radiological features may be indistinguishable from hyaline membrane disease. Antibiotics (e.g. penicillin and gentamicin) should be given until negative cultures exclude the diagnosis. The most common organisms include group B haemolytic *Streptococcus*, *Escherichia coli*, *Pseudomonas aeruginosa*, *Klebsiella pneumoniae* and *Staphylococcus aureus*. Group B haemolytic streptococcal infection is frequently associated with septic shock and persistent fetal circulation. Failure to suspect group B haemolytic streptococcal infections (and hence treat promptly with penicillin) will result in poor outcome. Multiresistant staphylococcal and Gram-negative bacillary infections must be suspected in longer-stay patients in neonatal ICUs.

Most pneumonia in infants and young children is of viral origin. Viruses commonly implicated are respiratory syncytial virus (RSV), influenza A1, A2 and B, and parainfluenza types 1 and 3. Adenovirus and rhinovirus are less common

causes. The spectrum of illness is wide. Many infants and children have cough, fever and tachypnoea, with X-ray evidence of patchy consolidation, all of which resolve rapidly. Occasionally, infants develop life-threatening respiratory illness with extensive pneumonic changes and marked necrosis. Permanent lung damage with bronchiolitis obliterans and pulmonary fibrosis may occasionally complicate severe adenoviral pneumonia in particular.

Bacterial pneumonia also occurs. Pneumococcal pneumonia is common and usually responds dramatically to appropriate antibiotic therapy. Staphylococcal pneumonia is relatively uncommon, but may result in life-threatening respiratory failure, and is often associated with complications (e.g. empyema, pneumatocele, tension pneumothorax and suppuration in other organs). Aspiration of an effusion may be useful for diagnostic purposes. Parapneumonic effusions (empyema) may require tube thoracostomy or video-assisted thoracoscopic drainage. Resolution of the effusion can be enhanced by the instillation of thrombolytic agents such as urokinase or tissue plasminogen activator.<sup>9</sup> In severe cases with bronchopleural fistula, surgical resection of the necrotic area offers the best chance of survival.

Pneumonia due to *Haemophilus influenzae* may also occur and be associated with epiglottitis, meningitis, pericarditis or middle-ear disease. The prevalence of *H. influenzae* infection has reduced dramatically since the introduction of HiB immunisation.

Gram-negative pneumonia is seen mostly in infants with debilitating conditions who are hospitalised for prolonged periods. It is a particular risk for patients in ICUs with endotracheal or tracheostomy tubes. Other opportunistic infections, such as *Pneumocystis jirovecii* (formerly *P. carinii*), *Candida albicans*, *Aspergillus* and cytomegalovirus, may occur in immune deficiency states.

### MASSIVE PULMONARY HAEMORRHAGE

This usually presents as acute cardiorespiratory collapse, accompanied by outpouring of bloodstained fluid from the trachea, mouth and nose. It is seen in association with severe birth asphyxia, hyaline membrane disease, congenital heart disease, erythroblastosis fetalis, coagulopathy and sepsis. Hypoxia is often a precipitating factor. The condition in the newborn is believed to represent haemorrhagic pulmonary oedema due to acute left ventricular failure. Treatment is that of the underlying condition with oxygenation, CMV and correction of any coagulation disturbance.

### PULMONARY OEDEMA

Pulmonary oedema in the newborn period is due mostly to congenital heart disease, especially coarctation of the aorta, patent ductus arteriosus, critical aortic stenosis and, rarely, obstructed total anomalous pulmonary venous drainage.

Pulmonary oedema due to circulatory overload may also occur in erythroblastosis fetalis, the placental transfusion syndrome, or as a result of inappropriate fluid therapy. Myocarditis is a further cause seen throughout infancy and childhood. Prolonged supraventricular tachycardia may result in ventricular dysfunction and biventricular failure, including pulmonary oedema.

In the newborn period, pulmonary oedema manifests as respiratory distress and feeding difficulty and specific features of congenital heart lesions may be evident. There is a spectrum of severity, from tachypnoea with a widened alveolar–arterial oxygen gradient to life-threatening respiratory failure requiring urgent support. Chest X-ray usually shows an enlarged heart (except in total anomalous pulmonary venous drainage) and a ground-glass appearance fanning out from the hilar regions.

### PULMONARY HYPOPLASIA

This is seen most often in association with congenital diaphragmatic hernia, but bilateral pulmonary hypoplasia may also occur in association with renal agenesis or dysgenesis (Potter's syndrome), in babies with severe Rhesus isoimmunisation, and in the presence of chronic amniotic fluid leak. It may also present as an isolated malformation. Unilateral hypoplasia can occur as an isolated anomaly or in association with cardiovascular defects.

### DIAPHRAGMATIC HERNIA

Congenital diaphragmatic hernia (most commonly left-sided) results in respiratory failure, partly due to lung compression but mainly related to the associated pulmonary hypoplasia (both ipsilateral and contralateral). The degree of pulmonary hypoplasia is most severe in infants with absence of the diaphragm. The disturbance of pulmonary function ranges from mild to severe. In severe cases, life-threatening respiratory distress is present from birth, with cyanosis, intercostal retraction, mediastinal displacement, and poor or absent breath sounds on the affected side. The abdomen is usually scaphoid, due to much of its usual contents being in the chest. Chest X-ray shows loops of bowel in the affected hemithorax, with pulmonary compression and mediastinal displacement to the contralateral side.

Neonates presenting in the first 4 hours of life have major degrees of lung hypoplasia and have a mortality of 40% despite maximal supportive therapy. Those presenting after 4 hours of age should all survive. CMV may be complicated by tension pneumothorax and bronchopleural fistula on either side. Pulmonary hypertension with persistent fetal circulation and difficulties of CMV present major challenges. Many centres use ECMO or high-frequency ventilation in these infants. Nitric oxide is a useful pulmonary vasodilator in this condition.<sup>4</sup> Prolonged ventilatory support is often required but the outlook for survivors is excellent.

### PNEUMOTHORAX

Spontaneous pneumothorax may occur during the birth process in normal newborns, or secondary to hyaline membrane disease or meconium aspiration. Tension pneumothorax is particularly likely to occur when CMV is required in the presence of lung immaturity, lung hypoplasia, non-uniform lung disease (e.g. staphylococcal pneumonia) and diseases characterised by air trapping (e.g. meconium aspiration, bronchiolitis and asthma).

Tension pneumothorax should be suspected with any sudden deterioration of an infant on a ventilator. Classic clinical signs are evident in older children, but are of limited value in neonates. Circulatory embarrassment may be profound and rapidly progressive. Abdominal distension due to depression of the diaphragm and congestion of intra-abdominal organs, and unilateral chest hyperexpansion are useful signs. Transillumination of the thorax using a bright light source is a sensitive guide in newborn infants. A chest X-ray is mandatory, but should be preceded by needle aspiration or drainage if the infant's condition is critical. Pre-existing pulmonary interstitial emphysema in one lung may also point to the likely side of the pneumothorax.

### REPAIRED EXOMPHALOS OR GASTROSCHISIS

Complete repair of abdominal wall defects may cause marked elevation of intra-abdominal pressure when the intestines are then enclosed in a poorly developed peritoneal cavity. The diaphragm is elevated, compressing the lungs. In addition, compression of the inferior vena cava may lead to peripheral oedema, reduced cardiac output and oliguria (abdominal compartment syndrome). The associated paralytic ileus may further increase intra-abdominal pressure.

Disturbed lung function with inadequate gas exchange may require postoperative ventilation for several days. With large defects, it may be necessary to house the abdominal contents in a prosthesis to allow gradual reduction into the abdominal cavity.

### DIAPHRAGMATIC PALSY

Phrenic nerve palsy is a relatively common complication of cardiothoracic surgery. It occasionally occurs as a congenital abnormality, or may result from birth trauma. Paralysis and paradoxical movement of the affected diaphragm lead to reduced lung and tidal volumes, hypoxaemia and increased work of breathing. A chest X-ray taken without positive airway pressure reveals the elevated hemidiaphragm (positive pressure may mask the radiological diagnosis). Screening with ultrasound or fluoroscopy confirms the paradoxical movement.

Paralysis of the hemidiaphragm may cause respiratory failure in infants, particularly if associated with another

disorder affecting lung function. Problems are greatest in children under 3 years, due to the poor stability of the chest wall. CPAP may be an effective method of increasing lung volume, stabilising the rib cage and reducing paradoxical movement. Surgical plication of the diaphragm is usually effective in cases that fail to resolve with conservative management.

### BIRTH ASPHYXIA

Birth asphyxia may result from placental failure, obstetric difficulties or maternal sedation. The resulting central respiratory depression, convulsions, intracerebral haemorrhage, meconium aspiration and transitional circulation contribute to respiratory failure. The Apgar score at 1 minute is an objective means of evaluating the degree of asphyxia; the score at 5 minutes is a guide to prognosis. Delayed spontaneous respiration (> 5 minutes) is also a poor prognostic sign. Further postnatal hypoxaemia, hypercapnia and brain ischaemia must be avoided. Severely asphyxiated infants need CMV after delivery, with correction of acidosis and hypovolaemia; inotropic drugs may be needed to maintain cerebral blood flow. It is important to prevent hypoglycaemia and control convulsions. A recent randomised control trial has shown improved cerebral outcomes with the use of early topical hypothermia, although the benefit is probably restricted to infants with less severe degrees of hypoxic-ischaemic encephalopathy.<sup>10</sup>

### CONVULSIONS

Convulsions in the newborn are most frequent in the first 3 days of life. They are commonly due to birth asphyxia, trauma, intracranial haemorrhage and metabolic abnormalities such as hypoglycaemia or hypocalcaemia and meningitis. Seizures in older children commonly occur with fever, idiopathic epilepsy, CNS infection, poisoning, trauma and metabolic disturbances (e.g. hypoglycaemia, hyponatraemia and hypocalcaemia).

Generalised seizures may cause respiratory failure from airway obstruction, aspiration, apnoea or central respiratory depression. During grand mal seizures, ventilation may be inadequate, and oxygen consumption and CO<sub>2</sub> production may be increased by associated muscle activity. Anticonvulsant drugs may further depress respiration.

Initial management consists of ensuring a clear airway, adequate oxygenation and ventilation, and administering anticonvulsants. Oxygen should be given, because cerebral and total body oxygen consumption is increased, and it is difficult to assess adequacy of ventilation. Urgent control of seizures is important, as protracted seizures (longer than 1 hour) cause cerebral oedema and may result in permanent neurological sequelae, even if hypoxaemia is avoided. The underlying cause must then be determined and treated.

### APNOEA OF PREMATURITY

Recurrent apnoeic episodes (> 20 seconds) are common in premature infants, and relate to immaturity of the brainstem, hypoxia, altered chemoreceptor responsiveness, diaphragmatic fatigue and the active (rapid eye movement) sleep state. Underlying causes such as hyaline membrane disease, hypoglycaemia, aspiration, sepsis, anaemia and intracranial haemorrhage should be sought. Mild episodes revert either spontaneously or with tactile stimulation. Severe episodes may require bag-and-mask ventilation. Apnoeic episodes may be reduced or prevented by theophylline or caffeine (central respiratory stimulants) or CPAP. IMV is necessary in some cases.

Many premature infants also suffer obstructive or mixed (central and obstructive) apnoea, both disorders of respiratory and airway musculature control. The infant airway collapses easily, and this is aggravated by neck flexion. Ex-premature infants may develop recurrent apnoea with intercurrent infection or following general anaesthesia and surgical procedures. This risk may persist until a postconceptual age of 46 weeks, and demands close monitoring.<sup>11</sup> The risk may be greater in infants with a history of apnoeic episodes, bronchopulmonary dysplasia, anaemia or neurological disease. This is transient and remarkably responsive to theophylline or caffeine loading. Ongoing maintenance therapy is often unnecessary.

### STATUS ASTHMATICUS

Asthma is the commonest reason for admission to most paediatric hospitals. Asthma is an inflammatory disease affecting the airways. Airway obstruction is due to mucosal oedema, mucus plugging and bronchiolar muscle spasm. Under 2 years of age, bronchiolar muscle is poorly developed, and muscle spasm is probably of less importance, with poor response to bronchodilator therapy.

Clinical and radiological features and management of asthma in small children are similar to that in adults (see Chapter 35). Blood gas estimation is indicated for any child with acute severe asthma, if pulsus paradoxus greater than 20 mmHg (2.6 kPa) is present, or if the child fails to respond to optimal drug therapy. Hypoxaemia due to intrapulmonary shunt and  $\{\dot{V}\}/\{\dot{Q}\}$  mismatching is the usual finding, and is the main cause of morbidity and mortality. High inspired oxygen therapy is therefore important. Hypocapnia in response to hypoxic drive is the rule; normocapnia or a rising *P*<sub>a</sub>CO<sub>2</sub> are signs of worsening asthma or fatigue and require increased medical therapy or mechanical ventilation.

Nebulised and/or i.v.  $\beta_2$ -sympathomimetic amines, i.v. aminophylline and corticosteroids form the mainstay of drug therapy; maximal therapy should be introduced early. Salbutamol is nebulised with oxygen as 0.05 mg/kg of 0.5% solution diluted to 4 ml with sterile water, given 2–4-hourly initially, or more frequently in severe

cases. A greater and more sustained response may be achieved by more frequent or continuous salbutamol nebulisation.<sup>12</sup> Inhaled ipratropium may have additional benefit, even in patients receiving maximal therapy with  $\beta_2$ -sympathomimetic amines.

Some centres abandoned the use of aminophylline because of its narrow therapeutic range and because of the belief that it did not add benefit to maximal therapy with salbutamol. There is evidence, however, that aminophylline does have a place in the management of severe acute asthma in children that is unresponsive to initial treatment.<sup>13</sup> Aminophylline is also known to possess anti-inflammatory properties. A loading dose of 5–10 mg/kg aminophylline over 1 hour produces serum levels in the therapeutic range; lower loading doses may be employed to reduce the occurrence of nausea and vomiting. Children under 9 years have increased metabolism, and require higher doses of theophylline (0.85 mg/kg per hour, equivalent to an aminophylline infusion of 1.1 mg/kg per hour). Serum concentrations should be measured (therapeutic range is 60–110  $\mu\text{mol/l}$ ).

Continuous infusion of salbutamol has been shown to reduce the need for CMV. It should be added when  $P_{aCO_2}$  is rising or is greater than 60 mmHg (8 kPa), as an infusion of 5–10  $\mu\text{g/kg}$  per min for 1 hour and then reduced to 1–2  $\mu\text{g/kg}$  per min. An adrenaline (epinephrine) or isoprenaline infusion (0.05–2  $\mu\text{g/kg}$  per min) may be useful in refractory cases.

Lactic acidosis may occur as a result of hypoxaemia and increased work of breathing. Adrenaline by infusion is also associated with lactic acidosis. Cautious bicarbonate therapy is recommended to improve cardiovascular function and bronchomotor responsiveness to theophylline and sympathomimetic agents. Isoprenaline and theophylline may both override pulmonary hypoxic vasoconstrictor responses and thereby increase intrapulmonary shunt and worsen hypoxaemia. Salbutamol is believed to be preferable in this respect.

Particular attention should be paid to fluid balance. Dehydration may lead to inspissation of secretions, but the risks of inappropriate antidiuretic hormone (ADH) secretion and pulmonary oedema must be noted.<sup>14,15</sup>

With aggressive medical therapy, the need for CMV should be rare. Its use should be based predominantly on clinical features rather than solely on blood gas analysis. It should not, however, be withheld out of fear of difficulties. CMV may worsen air trapping and lead to hypotension or pneumothorax. Controlled hypoventilation (permissive hypercapnia) with a long expiratory time is advocated to minimise airway pressures and air trapping. A trial of positive end-expiratory pressure (PEEP) may be justified to reduce intrinsic (auto) PEEP and air trapping, although evidence in adults suggests that PEEP may be associated with increased air trapping.<sup>16</sup>

## ACUTE VIRAL BRONCHIOLITIS

Most cases of bronchiolitis occur in the first 6 months of life and are caused by RSV. Other viruses now identified as causing bronchiolitis include rhinovirus and human metapneumovirus. Cough, low-grade fever, tachypnoea and wheeze are the cardinal signs. Some infants, particularly ex-premature, develop apnoeic episodes. The chest is hyperinflated with rib retraction and widespread crepitations. Clinical features are due to small airways obstruction from oedema and exudate.

Management consists of minimal handling and oxygen therapy. If respiratory distress is marked, feeds should be withheld and fluids administered i.v. Progression of the disease leads to exhaustion and respiratory failure in 1–2% of cases. CPAP and/or aminophylline therapies are reported to reduce the work of breathing, lower  $P_{aCO_2}$  and eliminate recurrent apnoea. Nebulised adrenaline may also be beneficial.<sup>17</sup> CMV is required in some cases, particularly when the disease occurs in association with congenital heart or chronic lung disease. High airway pressures may be required, increasing the risk of pneumothorax. The antiviral agent ribavirin is difficult to administer and has not been shown to improve outcome. Bacterial coinfection is common, and justifies the use of broad-spectrum antibiotics in severe cases.<sup>18</sup>

## RESPIRATORY FAILURE SECONDARY TO CONGENITAL HEART DISEASE

Infants with congenital heart disease may develop respiratory failure for a number of reasons.

### TYPE OF CARDIAC LESION

Congenital heart lesions producing acute respiratory failure fall into four main groups.

1. *Left heart obstruction* (e.g. critical aortic stenosis, interrupted aortic arch and coarctation of aorta). In this group, left ventricular failure leads to pulmonary oedema, reduced pulmonary compliance and respiratory failure.
2. *Large left-to-right shunts* (e.g. ventricular septal defect and patent ductus arteriosus). Respiratory failure in this group with excessive pulmonary blood flow results from volume overloading of the left ventricle, with pulmonary oedema, small airways obstruction, bronchial compression or intercurrent infection. Correction of the defect is associated with improved lung mechanics.<sup>19</sup>
3. *Hypoxaemic lesions*, where:
  - (a) there is obstruction to pulmonary blood flow (e.g. tetralogy of Fallot and critical pulmonary stenosis)
  - (b) the pulmonary and systemic circuits are in parallel (e.g. transposition of the great vessels)

- (c) there is complete mixing of systemic and pulmonary venous blood (e.g. single ventricle and truncus arteriosus).

In lesions associated with reduced pulmonary blood flow, lung compliance is high. High-pressure ventilation may further impede pulmonary blood flow, leading to increased hypoxaemia and, occasionally, CO<sub>2</sub> retention. Hypoxaemic lesions associated with increased pulmonary blood flow have problems of reduced lung compliance and air trapping (due to small airways disease and bronchial compression) in addition to hypoxaemia (due to mixing).

4. Vascular lesions associated with compression or stenosis of large airways (e.g. vascular rings and anomalous left pulmonary artery).

### INTERCURRENT INFECTION

Recurrent pneumonia and bronchiolitis are common in infants with congenital heart disease, particularly those associated with increased pulmonary blood flow.

### POSTOPERATIVE

Respiratory failure may occur following repair of cardiac lesions due to low cardiac output state and pulmonary oedema, acute respiratory distress syndrome (ARDS), lobar collapse, pleural effusions, pneumonia, phrenic nerve palsy, respiratory depressant drugs, abdominal distension and ascites.

### NEAR DROWNING

Respiratory failure after near drowning may result from aspiration pneumonitis or CNS depression from hypoxic–ischaemic encephalopathy. Acute gastric dilatation (associated with the immersion or resuscitation) is common and may be a contributing factor. Pulmonary oedema may be secondary to water and particulate matter inhaled, or to chemical pneumonitis from aspiration of gastric contents. Secondary infection occasionally leads to necrotising pneumonia. Prophylactic antibiotics are not of proven benefit, but there are occasional reports of fulminant ARDS associated with infection after immersion. Broad spectrum antibiotic therapy should be administered early if there is significant pulmonary disease. Ongoing therapy should be guided by culture of tracheal aspirate.

Patients with both fresh- and salt-water drowning are usually hypovolaemic, hypoxic and acidotic at the time of admission. Oxygen therapy is mandatory, even in so-called ‘dry drowning’. Resuscitation usually requires volume expansion, correction of acidosis and inotropic support. Immersion hypothermia may afford some protection to the brain. Complete rewarming should not be undertaken until circulatory resuscitation is achieved. Resuscitation

attempts should be sustained in the presence of severe hypothermia; in warmer climates, however, severe hypothermia implies a longer period of immersion and carries a very poor prognosis. In such circumstances it may be appropriate to cease resuscitative efforts prior to rewarming. CMV usually produces a dramatic improvement in gas exchange.

### TRAUMA

Respiratory failure may follow trauma to the brain, spinal cord, chest or abdomen. High spinal cord injuries may be difficult to detect in the presence of severe brain injury. Presence of rhythmic flaring of the alae nasi without accompanying respiratory excursion is a useful sign (Duncan’s sign). As the chest wall is compliant, severe pulmonary contusion can occur from blunt trauma with minimal chest-wall injury. Fractured ribs, haemothorax and pneumothorax may all precipitate respiratory failure. The diagnosis of a ruptured diaphragm is often delayed as the clinical signs are easily confused with a tension pneumothorax. CMV will effectively displace abdominal contents from the thorax and improve gas exchange prior to surgery. The chest X-ray is a mandatory investigation during resuscitation.

Acute gastric dilatation is almost invariable in the traumatised child, may mimic an acute abdomen and may exacerbate respiratory failure. Emergency decompression with a wide-bore gastric tube improves cardiorespiratory function and reduces the risk of aspiration.

### ACUTE RESPIRATORY DISTRESS SYNDROME

Acute respiratory distress syndrome (ARDS) may occur in children of all ages from a variety of direct and indirect lung insults. ARDS is characterised by respiratory distress or failure, diffuse pulmonary infiltrates, reduced pulmonary compliance and hypoxaemia in the presence of a known precipitating cause and in the absence of left ventricular failure. In children, common causes include shock from any cause, pneumonia, sepsis, near drowning, aspiration and pulmonary contusion.

### POISONING

Accidental poisoning is a common but preventable cause of respiratory failure, particularly in the first 4 years of life. Deliberate overdose is seen in children beyond 8 years. Tricyclic antidepressants, antihistamines, anti-convulsants and attention deficit hyperactivity disorder (ADHD) medications (clonidine, methylphenidate, dexamfetamine) are now the commonest CNS-affecting drugs ingested. Convulsions may aggravate the situation.

### MENINGITIS AND ENCEPHALITIS

Meningitis is common in the early years of life. After the neonatal period, the usual causative organisms are *Haemophilus influenzae*, *Neisseria meningitidis* and *Streptococcus pneumoniae*. Immunisation has markedly reduced the incidence in developed countries. Rapid diagnosis and appropriate antibiotic therapy form the cornerstone of treatment. Respiratory failure is mainly associated with uncontrolled convulsions, altered conscious state or raised intracranial pressure (ICP).

Encephalitis may also cause unconsciousness and raised ICP. Associated problems are upper airway obstruction, pulmonary aspiration and central respiratory depression. In many cases of encephalitis, a causative organism is not found although viral or postinfective causes are suspected. The antiviral agent, aciclovir, should be administered until herpes encephalitis is excluded. Hyperpyrexia, convulsions and cerebral oedema may complicate encephalitis.

### GUILLAIN-BARRÉ SYNDROME

This is the most common polyneuritis in childhood. Ascending paralysis may involve the intercostal muscles, the diaphragm and bulbar muscles. The onset may be rapid, with respiratory failure occurring within 48 hours. Intervention is based on clinical assessment of cough reflex and bulbar function, a measured vital capacity < 15 ml/kg, and evidence of hypoxaemia ( $SaO_2$  < 90%). Hypoxaemia occurs relatively early due to reduced functional residual capacity, atelectasis and intrapulmonary shunting. An elevated  $Paco_2$  is a late feature, suggesting a vital capacity in the tidal range, i.e. < 5–7 ml/kg. CMV is usually necessary if intubation is required. Unless rapid recovery is anticipated, early tracheostomy is advocated for patient comfort, to allow speech and to facilitate mobilisation. The condition is often improved by the early use of i.v. immunoglobulin therapy or plasmapheresis. Immunoglobulin is easier to deliver and probably safer. Other complications relate to autonomic involvement (arrhythmias, blood pressure lability) and ileus. Muscle pain may require analgesic relief.

Transverse myelitis may present in a similar manner and the principles of management are the same. Nerve conduction studies and MRI may be necessary to distinguish between the two conditions. Immunoglobulin therapy and plasmapheresis, however, are not effective. There are some reports of benefit from steroid therapy.

### ENVENOMATION

Some animal venoms, such as those of some snakes, ticks and blue-ringed octopus, are neurotoxic and may cause muscle weakness and respiratory insufficiency. The Sydney funnel-web spider causes widespread acetylcholine release and symptoms similar to anticholinesterase poisoning. These

symptoms include intense salivation, lacrimation, sweating, laryngeal and muscle spasm and pulmonary oedema. Paralysis due to tetrodotoxin may rapidly follow puffer-fish ingestion. In Australia and many other countries, specific antivenom therapy is available for most potentially lethal envenomations. Supportive therapy is required until antivenom is administered and recovery occurs.

### MANAGEMENT OF ACUTE RESPIRATORY FAILURE

In some cases, definitive treatment of the underlying cause will lead to resolution of respiratory failure (e.g. relief of upper airway obstruction or reversal of drug depression). Where this is not possible, mechanical ventilatory support is required until the underlying process has resolved.

### GENERAL MEASURES

#### GENERAL NURSING CARE

Critically ill children require a nurse:patient ratio of 1:1 and it is important that the nurses are skilled in the care of a ventilated child. This is one of the important differences between a paediatric intensive care unit and a general unit that only occasionally looks after children.

#### THERMAL ENVIRONMENT

Maintenance of body temperature is of major importance. The immature newborn is particularly vulnerable to cold stress, which increases metabolism, rapidly depletes carbohydrate stores and causes cardiorespiratory deterioration. In a normal newborn, oxygen consumption may rise threefold on exposure to environmental temperatures of 20–25°C. Conditions are optimal when the abdominal skin temperature is 36–36.5°C.

The most satisfactory devices to maintain temperature homeostasis are servo-controlled infrared-heated open cots. These allow for observation of and access to the exposed infant. In an incubator, the environmental temperature is less stable and access is difficult. Double-glazed incubators reduce radiant heat loss. Older infants and children can be nursed in standard cots and beds.

#### POSTURE

Neonates are best nursed prone with the hips and knees flexed and the head turned regularly. This posture may abolish apnoeic episodes in premature infants. It also decreases gastric emptying time, making aspiration of vomitus less likely. However, if the neonate is unstable and interventions are likely, the supine position is preferred. Older infants and young children are usually nursed in the position they find most comfortable although, as in adults, there is evidence that gas exchange is improved by prone positioning in at least some ventilated children.

### PHYSIOTHERAPY

The role of conventional chest physiotherapy with posturing, percussion and vibration in the paediatric ICU setting is unproven. Physiotherapy must be applied cautiously in children with cardiovascular instability or raised ICP. Chest compression and vibration in the newborn may result in rib fractures and possibly intracranial haemorrhage. Physiotherapy may cause a significant fall in  $P_{aO_2}$ .  $F_{iO_2}$  should be increased in anticipation (caution is required in premature infants who are at risk of retinopathy of prematurity). In infants, periodic gentle pharyngeal suction removes pharyngeal secretions and may stimulate coughing. Effective bagging, tracheal suction and positioning are the most useful techniques in the intubated patient.

### FLUID THERAPY

Oral feeding should be suspended with severe respiratory distress, because of the difficulty in oxygen administration and the risk of abdominal distension, vomiting and aspiration. Nasogastric feeding may be cautiously employed in infants with mild to moderate respiratory distress.

Lung and airway disease is often associated with increased secretion of ADH, leading to fluid retention. Increased airway pressure (e.g. CMV and CPAP) may also increase ADH secretion. Efficient humidification via a tracheal or tracheostomy tube prevents insensible water loss from the airway, and diminishes fluid requirements. Most patients with acute lung disease benefit from some degree of fluid restriction. Fluid balance and biochemical status must be monitored carefully. In prolonged respiratory failure, it is essential to minimise wasting of the respiratory muscles and to provide energy for increased work of breathing. High-calorie oral or nasogastric feeding may be tolerated. Parenteral nutrition is particularly useful when fluid restriction is necessary, and should be commenced early if prolonged interruption to enteral feeding is likely.

### MONITORING AND ASSESSMENT

Repeated clinical observation by skilled staff is necessary to detect early signs of hypoxia, increasing respiratory distress, or onset of fatigue. Deterioration may represent a progression of disease state, development of fatigue or the presence of complications. Monitoring of cardiorespiratory parameters and respiratory therapy is imperative for optimal respiratory care.

### PULSE OXIMETRY

Pulse oximetry provides essential information about the state of oxygenation (i.e.  $S_{aO_2}$ ) on a continuous basis. It is applicable to children of all sizes and can obviate the need for arterial cannulation in some cases. It forms part of a minimum standard for monitoring critically ill infants and children. Surprising degrees of desaturation, undetectable clinically, may be identified and treated.

### BLOOD GASES

Measurement of blood gases and acid–base status is essential in cardiorespiratory assessment. Arterial blood is obtained from an indwelling cannula or by direct puncture of peripheral arteries. The latter may be distressing to the child. Results from difficult collections may not accurately reflect the true blood gas status. Topical anaesthesia using EMLA cream should be considered for non-urgent percutaneous sampling.

Peripheral arterial cannulation is routine practice in paediatric intensive care, even in infants weighing less than 1 kg. It allows continuous blood pressure monitoring and reduces sampling errors. The radial, ulnar, brachial, femoral, posterior tibial and dorsalis pedis arteries are suitable. Radial artery cannulation by cut-down should be considered when the percutaneous method fails. Radial and ulnar or posterior tibial and dorsalis pedis vessels must not be cannulated in the same limb, even at different times, because of the danger of distal limb ischaemia. The safety of brachial and femoral cannulation lies in the collateral vessels around the elbow and hip joints. Complications of arterial cannulation include distal ischaemia, infection, haemorrhage and retrograde embolisation when the cannula is flushed. Central venous blood gases provide information on the adequacy of cardiac output (mixed venous oxygen saturation) as well as trends in  $P_{CO_2}$ .

In the neonate with acute respiratory failure, a preductal vessel, such as the right radial artery, is preferred. Preductal sampling is important in premature infants, because it indicates the  $P_{aO_2}$  of blood perfusing the retina. Knowledge of the  $F_{iO_2}$  is essential to interpret information from all forms of oxygen monitoring.

### CAPNOGRAPHY

Measurement of the end-tidal  $P_{CO_2}$  in the intubated patient provides a continuous guide to the adequacy of alveolar ventilation. In severe lung disease, the value does not reflect arterial  $P_{CO_2}$  (due to a wide alveolar–arterial gradient). It may still provide valuable trend information, and is also an additional means of warning of sudden reductions in cardiac output.

### CHEST X-RAY

Clinical examination of the thorax may be misleading in the small infant and serial chest X-rays form a vital part of assessment. Anteroposterior supine films usually provide the necessary information. Lateral or decubitus views may be useful to localise lung pathology, or to confirm air or fluid collections. Examination should look for focal or generalised lung disease, pleural effusions, evidence of barotrauma, the size and shape of cardiac contour and the position of invasive devices. The tracheal tube should be level with the second thoracic vertebra or the ends of the clavicles, and take account of the neck posture. A change from extension to flexion may advance the endotracheal tube by 1 cm in the term neonate. As the trachea in the neonate is only 4 cm long, accurate placement is critical. Multiple chest X-rays may be required with rapidly changing clinical situations.

**TRANSILLUMINATION**

Transillumination of the thorax with a cold fibreoptic light source is a useful technique to detect pneumothorax in newborn infants. Transillumination occurs on the side of pneumothorax, but does not quantify the amount of air present. Bilateral pneumothoraces may cause confusion. In severe pulmonary interstitial emphysema, increased transillumination may be seen. A chest X-ray should be performed to confirm the pneumothorax when time permits.

**VITAL CAPACITY AND MAXIMUM INSPIRATORY FORCE**

In diseases such as Guillain–Barré syndrome, measurements of vital capacity and maximum inspiratory force are useful in older cooperative children. A vital capacity < 15 ml/kg or an inability to generate a maximum inspiratory force of less than  $-25$  cmH<sub>2</sub>O ( $-2.5$  kPa) is an indication for intubation and assisted ventilation. These parameters are also useful to guide weaning and extubation or decannulation.

**SPECIFIC MEASURES****OXYGEN THERAPY**

Mode of administration is guided by patient size and required  $F_{iO_2}$ . Neonates requiring less than 40% oxygen can be nursed in an incubator. Plastic headboxes are used to deliver higher concentrations to neonates and infants.

Older children tolerate appropriately sized facemasks but  $F_{iO_2}$  is rarely known. Masks incorporating a reservoir bag will deliver high concentrations in young children. Restless children do not tolerate facemasks and oxygen delivery may become intermittent. Once positioned, nasal cannulae are usually well tolerated. A single catheter in the postnasal space (1–2 l/min) is also an effective method of delivery. With nasal cannulae,  $F_{iO_2}$  depends on flow rate, size of the nasopharynx, the presence or absence of mouth-breathing and peak inspiratory flow rate. Using a single nasal cannula, a flow rate of 150 ml/kg per min provides  $F_{iO_2}$  about 0.5 in children under 2 years.<sup>20</sup> Effective humidification is difficult with nasal cannulae, and drying of mucosa and secretions may be a problem.

Therapeutic procedures, physiotherapy and handling may all increase oxygen consumption and lead to hypoxaemia and deterioration. Timing of these manoeuvres is important and a prior increase in  $F_{iO_2}$  may be justified.

**COMPLICATIONS OF OXYGEN THERAPY IN NEONATES****RETINOPATHY OF PREMATURITY**

Retinal vessels of premature infants are susceptible to the vasoconstrictive effects of high arterial oxygen tension. Visual impairment is due to retinal fibroproliferative changes or to subsequent retinal detachment. While the

absolute safe maximal level and duration of hyperoxia are unknown, maintenance of a  $P_{aO_2}$  between 50 and 80 mmHg (6.6 and 10.6 kPa) is recommended.

**BRONCHOPULMONARY DYSPLASIA**

The development of chronic pulmonary insufficiency in mechanically ventilated neonates correlates best with lung immaturity, peak inspiratory pressures and other evidence of barotrauma or volutrauma. Pulmonary oxygen toxicity is probably a contributory factor. Chronic hypoxaemia, on the other hand, is a factor in the development of cor pulmonale.

**INTUBATION**

Tracheal intubation relieves airway obstruction, and allows accurate control of inspired oxygen, application of positive airway pressure and tracheal toilet. Nasotracheal intubation is preferred, as it allows better fixation. Implant-tested polyvinyl chloride tubes may be left in place indefinitely. For long-term use, however, tracheostomy is indicated. Disadvantages of nasotracheal intubation include bypassing nasal humidifying mechanisms, sinusitis, increased airway resistance, risk of subglottic stenosis, impaired cough reflex, loss of physiological PEEP and impaired pulmonary defence mechanisms. In neonates, the risk of laryngeal injury correlates with duration of intubation and repeated intubation trauma. The correct tracheal tube size permits a small leak when a positive pressure of less than 25 cmH<sub>2</sub>O (2.5 kPa) is applied. Exceptions to the rule are:

- neonates: for unknown reasons, absence of leak rarely results in complications
- croup, where a smaller tube than predicted for age is passed, and subsequent development of a leak indicates resolution of subglottic oedema and is an indication for extubation
- mechanical ventilation in the presence of poorly compliant lungs, where an airtight seal may be required for effective ventilation – a risk of subglottic stenosis occurs. Alternatively, cuffed endotracheal tubes are increasingly used in children

**MECHANICAL VENTILATORY SUPPORT****MECHANICAL VENTILATION**

Paediatric ventilators are discussed elsewhere in this volume. The risks of barotrauma, volutrauma and oxygen toxicity demand that specific ventilator settings be prescribed for rate, peak inspiratory pressure, PEEP, CPAP, flow rate, inspiratory time, minute volume and inspired oxygen. If pulmonary function progressively deteriorates, a stepwise increase of each setting should be considered. The least harmful alternative should be undertaken first (e.g. increasing  $F_{iO_2}$  is probably a safer alternative than increasing PEEP). Unless contraindicated, a PEEP of 3–5 cmH<sub>2</sub>O (0.3–0.5 kPa) is recommended in all ventilated infants to prevent airway closure. In the presence of reduced cerebral

compliance, PEEP may be associated with increased intracranial pressure. Oxygenation is a priority, however, and other means of maintaining cerebral perfusion pressure should be employed if PEEP is required. Removing or reducing PEEP must be considered if there is evidence of barotrauma. Increased PEEP demands a similar increase in peak inspiratory pressure if the same tidal volume is to be maintained. Mean airway pressure is the main determinant of oxygenation. It is dependent on rate, peak inspiratory pressure, flow rate, inspiratory time and PEEP.

In general, slow ventilatory rates (e.g. neonates 30 breaths/min, infants under 12 months 25 breaths/min, children 16–20 breaths/min) and an inspiratory time of about 1 second provide optimal gas exchange. Infants under 1 kg may benefit from faster ventilatory rates and shorter inspiratory times. Short inspiratory times may, however, be associated with loss of lung volume and increased intrapulmonary shunting. Strategies to recruit alveoli are important with many lung diseases, particularly after disconnection for suction and other procedures.

#### CONTINUOUS POSITIVE AIRWAY PRESSURE

Continuous positive airway pressure (CPAP) applies a constant pressure gradient to the spontaneously breathing patient via a special circuit. The T-piece system requires a fresh gas flow of two to three times the predicted minute ventilation to prevent rebreathing. For CPAP to be well sustained, either the flow rate must exceed peak inspiratory flow or a reservoir bag must be incorporated into the system.

Nasotracheal intubation is the safest and most efficient method of applying CPAP, although masks, nasal cannulae or a nasopharyngeal tube may be used. These latter techniques rely on neonates being obligatory nose breathers; positive pressure is lost during crying or mouth breathing, and abdominal distension may occur. Blood gas sampling during mouth breathing may lead to errors in oxygen therapy. The stomach should be decompressed continuously with a nasogastric tube.

Benefits of CPAP include the following:

- CPAP increases functional residual capacity (FRC), recruits alveoli, promotes alveolar stability and reduces intrapulmonary shunt. An increased  $PaO_2$  results and allows a reduction in  $\dot{V}iO_2$ .
- CPAP promotes the stability of large and small airways. This splinting effect is useful in airway obstruction, bronchomalacia and tracheomalacia. CPAP has also been recommended in croup, bronchiolitis and even asthma.
- In neonates, CPAP may abolish or reduce apnoeic episodes and improve the rhythmicity of spontaneous breathing. Physiological amounts of CPAP (2–5 cmH<sub>2</sub>O, 0.2–0.5 kPa) should be applied to intubated children whenever practical to prevent airway closure.

Because of the resistance of the endotracheal tube and respiratory circuit, the use of low levels of pressure support ventilation (PSV) is often more effective in minimising the work of breathing.

CPAP may reduce cardiac output or cause barotrauma. Increased ADH secretion and fluid retention are also seen, although the exact mechanism is disputed. If CPAP results in hyperinflation it may also increase pulmonary vascular resistance and right ventricular afterload. This effect is often balanced by the beneficial effect of CPAP in preventing atelectasis, optimising lung volume and thereby reducing pulmonary vascular resistance. It is often difficult to interface CPAP and other non-invasive respiratory techniques to non-sedated infants and children without causing excessive restlessness.

#### SEDATION AND ANALGESIA

Sedation and analgesia should be used to reduce restlessness and discomfort, and to minimise the work of breathing (see Chapter 100). In the brain injured, sedation prevents coughing, straining, unwanted autonomic responses and increases in intracranial pressure. Heavy sedation (with or without muscle relaxants) is recommended, provided supervision and monitoring facilities are adequate.

#### COMPLICATIONS

Complications of mechanical ventilatory support include:

- *Reduced cardiac output*: circulatory effects of increased airway pressure may be less marked in young children.<sup>21</sup> Nevertheless, volume expansion (e.g. with 10–20 ml/kg of colloid) may be required at the start of CMV, particularly if muscle relaxants are employed
- *Barotrauma, volutrauma* may present as:
  - (a) *pulmonary interstitial emphysema* (PIE) with gas in the lung interstitium, outside the alveoli. This is most common in premature infants, although protective lung ventilation strategies have probably reduced the incidence. PIE is deleterious to gas exchange and is not readily amenable to drainage. It may produce intrapulmonary tension and mediastinal shift. Unfortunately, the initiating factor, positive pressure, may need to be increased further to restore gas exchange. It is a forerunner of pneumothorax. Management is to limit or remove positive pressure as early as possible. High-frequency oscillatory ventilation may be advantageous. Occasionally, decompression of the lung by needling or via thoracotomy may be required
  - (b) *pneumothorax*
  - (c) *pneumomediastinum*
  - (d) *tension pneumopericardium* occasionally occurs in neonates on ventilation and may require decompression by pericardiocentesis or limited sternotomy and drainage
  - (e) *pneumoperitoneum*, where a differential diagnosis from ruptured viscus may be difficult. Occasionally, drainage is required to reduce intra-abdominal tension and respiratory embarrassment.

Mechanical ventilation must be approached cautiously if air leak is a particular risk (e.g. in immature lungs and diseases characterised by air trapping). Permissive hypercapnia can often be tolerated, provided that oxygenation, perfusion and acid–base balance are acceptable.

### WEANING

The risks of prolonged ventilation (ventilator-induced lung injury, ventilator-associated pneumonia, airway injury, cost) must be balanced against the risk of premature weaning and extubation. Particular risks such as those associated with pulmonary hypertension, myocardial dysfunction and the difficult airway should be considered. Weaning commences when the underlying process necessitating ventilation has resolved sufficiently, the cardiovascular system is stable and the child is awake and has sufficient respiratory drive. It is unlikely to be successful if an  $F_{iO_2}$  over 0.5 or peak airway measures greater than 25 cmH<sub>2</sub>O (2.5 kPa) are required. PEEP should be reduced to 5 cmH<sub>2</sub>O (0.5 kPa) or less prior to intubation. The rate of weaning is determined by the underlying pathology and the expected response.

Progression through IMV and PSV or CPAP is usually advised. Attention to the status of all organ systems must be meticulous, and some degree of fluid restriction is usually indicated. Other forms of circulatory support such as inotropic agents and vasodilators should be maintained during the weaning period. Increased work of breathing places additional demands on the cardiovascular system and may divert blood flow from other vital organs. The patient should be fasted and the abdomen decompressed prior to extubation. A period of fasting before and after long-term intubation is recommended (e.g. up to 24 hours in some cases), to allow for return of laryngeal competence.

### HIGH-FREQUENCY OSCILLATORY VENTILATION

High-frequency ventilation (HFV) refers to ventilation at respiratory rates between 4 and 15 Hz, with tidal volumes close to or less than anatomical dead space. Methods of HFV most commonly used are high-frequency jet ventilation, high-frequency flow interruption and high-frequency oscillatory ventilation (HFOV). Most interest has centred on HFOV (10–15 Hz), with tidal volumes well below anatomical dead space. All three can produce adequate oxygenation and CO<sub>2</sub> removal in infants, children and adults with restrictive lung disease, often using lower peak and mean airway pressures than in CMV. In HFOV CO<sub>2</sub> removal is very efficient and occurs by a combination of accelerated diffusion and cardiogenic mixing. Oxygenation is maintained by keeping mean airway pressure above the critical opening pressure for the alveoli. High volume cycling is avoided, thereby limiting further lung injury as a result of repeated shear stress.

Animal studies using HFOV and an ‘open lung strategy’ have convincingly demonstrated less of the histological changes of ARDS and less barotrauma.<sup>22,23</sup> Although

a multicentre trial of HFOV in preterm infants failed to show benefit, a number of single centre randomised or rescue studies have demonstrated less barotrauma in very low birth weight infants, a decreased incidence of chronic lung disease (BPD) and reduced requirement for ECMO.<sup>24,25</sup> The combined use of HFOV and nitric oxide therapy has led to reduced use of ECMO in many centres. HFOV has an important role in the management of severe pulmonary air leak syndromes.

# Paediatric fluid and electrolyte therapy

Frank A Shann

Children need a much higher intake of water and electrolytes per kilogram of body weight than adults; this makes children more susceptible to dehydration if they have abnormal losses of water or a reduced intake. On the other hand, an inability to excrete a water load, due to immature kidneys (in neonates) or high levels of anti-diuretic hormone (ADH), means that children can easily be given too much water intravenously. There are good reviews of fluid and electrolyte therapy in paediatric and neonatal intensive care.<sup>1–5</sup>

## WATER

The full-term neonate is 80% water; this figure falls to about 60% by 12 months of age, and then remains almost constant throughout childhood. The intravenous (i.v.) fluid requirements for children in hospital are shown in Tables 99.1 and 99.2. The widely used formula for an active child shown in Table 99.1 was published in 1957,<sup>6</sup> and some of the measurements of energy expenditure were made almost 100 years ago. The formula is a compromise between the requirements of a fully active child and the much lower requirements at basal metabolic rate – for example, the estimate of 100 ml/kg per day for an active 10-kg child in hospital is double the 50 ml/kg per day needed for a sick child at basal state (Table 99.1).<sup>6,7</sup>

Table 99.3 shows that very ill children in intensive care often need much less water than the ‘standard’ amounts that are often given. For example, if a 15-kg child (‘standard’ maintenance fluid of 50 ml/hour,<sup>6</sup> Table 99.2) sustains a head injury and has evidence of high levels of ADH (maintenance fluid  $\times 0.7$ ),<sup>8</sup> is ventilated with humidified gas (maintenance  $\times 0.75$ ),<sup>9</sup> is paralysed (basal state, maintenance  $\times 0.7$ ),<sup>6</sup> and is maintained at a rectal temperature of 36°C (maintenance – 12%),<sup>1</sup> then his actual full maintenance fluid requirement is  $(50 \times 0.7 \times 0.75 \times 0.7) - 12\% = 16$  ml/hour. Even less water should be given initially if the child is overhydrated.

In very small children, all fluid administered has to be taken into account, including the volume of drugs (bicarbonate, dextrose and antibiotics) and ‘flushes’ used to clear i.v. lines (after blood sampling or administration of drugs).

The estimates of water requirements in Tables 99.1–99.3 are only approximate, and water balance must be

monitored closely in any child in intensive care. Unfortunately, regular, accurate weighing of very sick children is often impractical, and hydration has to be assessed using:

- the serum sodium concentration
- skin turgor
- urine output (minimum 0.5–1.0 ml/kg per hour)
- central venous pressure

In a child with oliguria following a severe ischaemic or hypoxic insult (such as birth asphyxia, near drowning or cardiac arrest), it may be helpful to measure the urine sodium concentration.<sup>10</sup> In oliguria due to acute tubular necrosis, where restriction of fluid intake may be necessary, the urine sodium is usually more than 40 mmol/l. In oliguria due to hypovolaemia, the urine sodium is usually less than 20 mmol/l.

## SODIUM<sup>11,12</sup>

Sodium is predominantly an extracellular ion, so total body sodium is well represented by the serum concentration. It must be interpreted in the context of both total hydration and the relative amounts of water and sodium. Acute changes in serum sodium are usually due to changes in body water rather than changes in body sodium.

In the first 1–2 days of life, small preterm babies often have poor urine output and high transcutaneous fluid losses. They are therefore prone to hypernatraemia and hyperkalaemia, and such infants should usually be given 5% or 10% dextrose without sodium or potassium. From 2 days of age, 2–4 mmol/kg per day of sodium and potassium will usually be sufficient, but much higher intakes of sodium are needed in some preterm neonates due to their impaired renal conservation of sodium.

*Hyponatraemia* may be due to:<sup>11</sup>

- increased body water due to excessive water intake, especially in the presence of high levels of ADH (CNS disease, intermittent positive-pressure ventilation (IPPV), lung disease, vomiting, stress)
- low body sodium due to diuretic therapy, poor renal conservation of sodium, or a low sodium intake (e.g. breast milk)

**Table 99.1** Approximate intravenous fluid requirements for children (ml/kg per day)

Active child in hospital	
< 10 kg	100 ml/kg per day
10–20 kg	1000 ml + (50 ml/kg per day for each kg over 10 kg)
> 20 kg	1500 ml + (20 ml/kg per day for each kg over 20 kg)
Sick, but not intubated	
< 10 kg	50 ml/kg per day
10–20 kg	500 ml + (30 ml/kg per day for each kg over 10 kg)
> 20 kg	800 ml + (20 ml/kg per day for each kg over 20 kg)
Intubated, with humidified inspired gases	
< 10 kg	35 ml/kg per day
10–20 kg	350 ml + (20 ml/kg per day for each kg over 10 kg)
> 20 kg	550 ml + (12.5 ml/kg per day for each kg over 20 kg)

Acute hyponatraemia causes cerebral oedema, with a grave risk of cerebral herniation and death or severe brain damage.<sup>13</sup> Hyponatraemia due to sodium deficit should be corrected by careful administration of sodium (Table 99.4). However, hyponatraemia is usually due to water excess rather than sodium deficiency, and this should be treated with restriction of water intake. If symptomatic, it can be corrected by careful administration of 3% sodium at 0.5 ml/kg per hour (Table 99.4), and furosemide 0.5 mg/kg i.v. if there are high ADH levels. Hyponatraemia must be corrected slowly: the serum sodium should increase by no more than 8 mmol/l each 24 hours, and even less in patients with long-standing hyponatraemia.<sup>11</sup>

*Hypernatraemia* may be due to:<sup>12</sup>

- reduced body water (dehydration) from a large insensible fluid loss (caused by radiant heaters or phototherapy), diarrhoea, osmotic diuresis (caused by glycosuria) or inadequate fluid intake
- increased body sodium from administration of large amounts of sodium (e.g. sodium bicarbonate) or salt poisoning

With hypernatraemic dehydration, shock should be treated with boluses of 10 ml/kg of 0.9% saline. The water deficit should then be corrected very slowly using 0.9% saline so that the serum sodium falls no faster than

**Table 99.3** Modifications to the fluid intakes for active children shown in Table 99.2

Decrease	Adjustment
Humidified inspired air	× 0.75
Basal state (e.g. paralysed)	× 0.7
High ADH (IPPV, brain injury)	× 0.7
Hypothermia	– 12% per °C
High room humidity	× 0.7
Renal failure	× 0.3 (+ urine output)
Increase	
Full activity + oral feeds	× 1.5
Fever	+ 12% per °C
Room temperature > 31°C	+ 30% per °C
Hyperventilation	× 1.2
Neonate preterm (1–1.5 kg)	× 1.2
radiant heater	× 1.5
phototherapy	× 1.5
Burns first day	+ 4% per 1% area burnt
subsequently	+ 2% per 1% area burnt

ADH, antidiuretic hormone; IPPV, intermittent positive pressure ventilation.

0.5 mmol/l per hour to prevent cerebral oedema.<sup>12</sup> If salt ingestion causes severe acute hypernatraemia without dehydration, peritoneal dialysis or haemofiltration may be indicated.

## POTASSIUM<sup>14</sup>

Potassium is predominantly an intracellular ion, so total body potassium is poorly represented by the serum concentration. The concentration of potassium in the serum depends on pH as well as the total body potassium (which is usually about 50 mmol/kg). A child may have hypokalaemia without a deficit of total body potassium in the presence of alkalosis and, conversely, there may be a large deficit of potassium without hypokalaemia in the presence of acidosis. Potassium should rarely be infused at more than 0.3 mmol/kg per hour, and it should not normally be given to a patient with severe oliguria or anuria.

**Table 99.2** Approximate intravenous fluid requirements for children (ml per hour)

	Weight in kg											
	3	5	7	10	15	20	25	30	40	50	60	70
Active	12	20	30	40	50	60	65	70	80	90	95	100
Sick	6	10	14	20	25	30	35	40	45	55	60	70
Intubated	4	7	10	14	17	21	25	28	32	40	45	50

Table 99.4 Doses and formulae in paediatric fluid and electrolyte therapy

<b>Albumin 20%</b>	undiluted: 2–4 ml/kg 5% in 5% dextrose or saline: 10–20 ml/kg
<b>Bicarbonate (number of mmol of deficit)</b>	under 5 kg: base excess $\times$ wt(kg) $\times$ 0.5 (give half of this) over 5 kg: base excess $\times$ wt(kg) $\times$ 0.3 (give half of this)
<b>Blood volume</b>	85 ml/kg in neonate 70 ml/kg in older children
<b>Calcium</b>	chloride 10% (0.7 mmol/ml Ca <sup>++</sup> ): maximum 0.2 ml/kg i.v. stat, requirement 1.5 ml/kg per day gluconate 10% (0.22 mmol/ml Ca <sup>++</sup> ): maximum 0.5 ml/kg i.v. stat, requirement 5 ml/kg per day
<b>Dextrose</b>	for hypoglycaemia: 1 ml/kg 50% dextrose i.v. in neonate: 4 mg/kg per min (2.4 ml/kg per hour 10% dextrose) day 1, increasing to 8 mg/kg per min (up to 12 mg/kg per min with hypoglycaemia) for hyperkalaemia: 0.1 U/kg insulin and 2 ml/kg 50% dextrose i.v. stat
<b>Magnesium</b>	chloride 0.48 g/5 ml (1 mmol/ml Mg <sup>++</sup> ): 0.4 mmol (0.4 ml)/kg per dose slow i.v. 12-hourly sulphate 50% (2 mmol/ml Mg <sup>++</sup> ): 0.4 mmol (0.2 ml)/kg per dose slow i.v. 12-hourly
<b>Mannitol</b>	0.25–0.5 g/kg per dose i.v. (1–2 ml/kg of 25%) 2-hourly, provided serum osmolality < 330 mosm/kg
<b>Packed cells</b>	10 ml/kg raises Hb 3 g%, 1 ml/kg raises PCV 1%.
<b>Potassium</b>	maximum 0.3 mmol/kg per hour, requirement 2–4 mmol/kg per day, 1 g KCl = 13.3 mmol K <sup>+</sup> . Hyperkalaemia: see dextrose
<b>Sodium</b>	depletion: 3% saline at 0.5 ml/kg per hour (maximum Na rise 8 mmol/l in 24 hours); requirement 2–6 mmol/kg per day, 1 g NaCl = 17.1 mmol/Na <sup>+</sup>
<b>Urine</b>	minimum acceptable is 0.5–1.0 ml/kg per hour

PCV, packed cell volume.

### CALCIUM, MAGNESIUM AND PHOSPHATE

Hypocalcaemia in children occurs in:

- sick neonates in the first two days of life
- infants of diabetic mothers
- exchange transfusion with citrated blood (a temporary effect)
- magnesium deficiency
- infants fed cows' milk (which has a high phosphate content)

Hypocalcaemia and hypomagnesaemia cause jitters, tetany, cardiac arrhythmias and convulsions. The doses of calcium and magnesium are given in Table 99.4. The normal intravenous maintenance requirements in infants are 1 mmol/kg per day of calcium and 0.3 mmol/kg per day of magnesium.

### STANDARD PAEDIATRIC MAINTENANCE FLUIDS

'Maintenance solution' is an unfortunate term, since these solutions do not provide maintenance calorie or protein requirements (see Parenteral nutrition, below). Until recently, it was common practice to give children a hypotonic maintenance solution of approximately 0.2%

saline in 4% dextrose in generous amounts, based on the water requirements of an active child.<sup>6</sup> This policy resulted in a high incidence of hyponatraemia – and far too many children developed cerebral oedema that resulted in death or severe brain damage.<sup>13,15–18</sup>

Several factors have contributed to the high incidence of hyponatraemia in children.

- The amount of dehydration present is often overestimated,<sup>19</sup> and rapid administration of an excessive amount of fluid will cause hyponatraemia, even if 0.9% saline is given, because the increase in intravascular volume will cause the production of urine containing more than 154 mmol/l of sodium (the amount present in 0.9% saline).<sup>20</sup>
- The formula that is widely used to calculate maintenance water requirements is based on the needs of active children, and prescribes too much fluid for a sick child (Table 99.1).<sup>13</sup>
- Many sick children have increased secretion of anti-diuretic hormone even in the absence of hypovolaemia,<sup>21,22</sup> so they are unable to excrete the excess water when they are given large amounts of fluid.
- Some sick children lose substantial amounts of sodium in their urine, perhaps due in part to the excretion of ketones as sodium salts.<sup>18</sup>

There is general agreement that an isotonic fluid such as 0.9% saline should be used to correct hypovolaemia, but there has been spirited debate about whether hypotonic 0.2% saline or isotonic 0.9% saline should be used for maintenance.<sup>5,23,24</sup> The supporters of using 0.2% saline argue that it is logical and safe providing the volume of fluid given is never in excess of actual requirements,<sup>25–27</sup> but there is limited empirical evidence to support this theory.<sup>27</sup> The supporters of using 0.9% saline for initial maintenance therapy in sick children (with careful monitoring of the serum sodium) argue that, in practice, this has been preferable,<sup>13,15–18</sup> because it is difficult to ensure that no excess fluid is administered, and there is a lower risk of hyponatraemia and cerebral oedema if any excess fluid that is given is isotonic. It is especially important to use isotonic fluid during and after surgery, and whenever there is a high risk of cerebral oedema (e.g. amongst children with diabetic ketoacidosis or brain injury).<sup>5,15–18,23,24</sup>

All children with clear signs of hypovolaemia should be treated with 5–10 ml/kg boluses of 0.9% saline until the intravascular volume has been restored, and then given 0.9% saline (with potassium and dextrose as required) in the volumes shown in Tables 99.1 and 99.2 (or calculated from Table 99.3). The serum sodium concentration should be monitored carefully. If the serum sodium is less than 138 mmol/l and falling, then less 0.9% saline should be infused. If the serum sodium is more than 142 mmol/l and rising, then 0.45% or 0.2% saline should be infused with a cautious increase in the rate.

Great care should be taken to avoid hypoglycaemia in children. Hypoglycaemia is particularly dangerous in young infants,<sup>28</sup> while hyperglycaemia is probably less dangerous in children than it is in adults in intensive care.<sup>29</sup>

The key messages are:

- correct hypovolaemia using 10 ml/kg boluses of 0.9% saline
- most sick children need far less maintenance fluid than previously thought (Table 99.2)
- use isotonic maintenance fluid for the first few days of treatment with careful monitoring of the serum sodium
- avoid hypoglycaemia

## DEHYDRATION AND SHOCK

Weight loss is the best guide to the degree of dehydration, if a recent weight is known. Many of the commonly used clinical signs of dehydration in children are inaccurate, and this leads to dehydration being diagnosed when it is not present, and to overestimation of the degree of dehydration.<sup>19</sup> The clinical signs of mild to moderate dehydration become apparent with only 3–4% dehydration in children.<sup>19</sup> The most reliable signs are:<sup>30</sup>

- decreased peripheral perfusion (as shown by pallor or reduced capillary return)
- deep breathing
- decreased skin turgor

In children with shock, intravenous access may be difficult. In these circumstances, parenteral fluid can be given rapidly into the bone marrow, which is an intravascular compartment.<sup>31</sup> The usual sites chosen are the junction of the upper and middle third of the tibia (0–12 months of age), the medial malleolus (1–5 years) and the iliac crest (over 5 years). A 0.9 mm (20 gauge) lumbar puncture needle or an intraosseous needle can be used; the needle is held perpendicular to the bone and pushed in *gently* with a rotary motion about its long axis – a slight decrease in resistance will be felt as the needle enters the medulla. In infants with a patent anterior fontanelle, the superior sagittal sinus is an excellent way to gain intravenous access in an emergency.<sup>32</sup>

Shock should be treated with an initial bolus of 10 ml/kg of 0.9% saline, followed by further boluses of 10 ml/kg until the intravascular volume has been restored.<sup>33</sup> After shock has been corrected with a rapid infusion of fluid, the remainder of the deficit is replaced over the next 48–72 hours, while giving maintenance requirements using 0.9% saline with dextrose and potassium chloride. Thus, a 5-kg child with 10% dehydration from diarrhoea (500 ml deficit) might receive 100 ml (20 ml/kg) of isotonic saline rapidly to restore the circulation, leaving a 400 ml deficit to be replaced over 48 hours. If the maintenance requirement is 250 ml/day (Table 99.1), then the child should be given a further 450 ml of 0.9% saline per day for the next 2 days (approximately 20 ml/hour) in addition to the initial 100 ml. Further abnormal fluid losses should be replaced with an appropriate fluid (see Table 99.5).

With hypernatraemic dehydration, shock should be treated as above, with rapid infusion of 10–20 ml/kg of isotonic saline. The remaining deficit should then be replaced *slowly* with 0.9% saline so that the serum sodium falls no faster than 0.5 mmol/l per hour to prevent cerebral oedema.<sup>12</sup>

In dehydration due to pyloric stenosis there is a deficit of water, hydrogen ion, chloride and potassium. Hypovolaemia should be treated by rapid infusion of 10–20 ml/kg of 0.9% saline, then 0.9% saline in 5% dextrose with 40 mmol/l of potassium chloride should be given at 50 ml/kg per day with careful monitoring of the serum electrolytes and blood glucose.

## OEDEMA

Oedema is common in children in intensive care units. It may be due to:

- excess water intake, often with high levels of ADH (from CNS disease, IPPV or lung disease)
- capillary leak (due to the effects of hypoxia, ischaemia, acidosis or sepsis)
- hypoalbuminaemia
- heart failure or renal failure

**Table 99.5** Composition of some body fluids in children

Fluid	Na <sup>+</sup> mmol/l	K <sup>+</sup> mmol/l	Cl <sup>-</sup> mmol/l	HCO <sub>3</sub> <sup>-</sup> mmol/l	Other
Gastric fluid	20–80	10–20	100–150	0	H <sup>+</sup> 30–120
Bile	140–160	3–15	80–120	15–30	
Pancreatic fluid	120–160	5–15	75–135	10–45	Basal state
Jejunal fluid	130–150	5–10	100–130	10–20	
Ileal fluid	50–150	3–15	20–120	30–50	
Diarrhoeal fluid	10–90	10–80	10–110	20–70	
Sweat					
Normal	10–30	3–10	10–35	0	
Cystic fibrosis	50–130	5–25	50–110	0	
Burn exudate	140	5	110	20	Protein 30–50 g/l
Saliva	10–25	20–35	10–30	2–10	Unstimulated

Several possible causes are often present in one child, and it can be difficult to decide which is the most important. Children with oedema and high levels of ADH will have a serum osmolality less than 270 mmol/kg (with hyponatraemia) and a urine osmolality greater than 270 mmol/kg; the appropriate treatment is fluid restriction. On the other hand, in children with oedema due to capillary leak, fluid restriction and attempts to remove water (diuretics, dialysis) are unlikely to cure the oedema, and often cause hypovolaemia; in fact, large amounts of fluid (e.g. blood and normal saline) may be needed to preserve the intravascular volume in these children – the oedema will only disappear when the capillary damage resolves.

### CRYSTALLOID OR COLLOID

There have been many reviews of the contentious issue of the relative merits of crystalloid or colloid fluids in critically ill patients. A widely quoted review concluded that, compared to crystalloids, albumin increased mortality by 6% (95% CI, 3–9%).<sup>34</sup> However, a subsequent large study in 6997 adults in Australia found no significant difference in overall mortality between normal saline and 4% albumin;<sup>35</sup> the mortality with albumin tended to be lower in sepsis and higher in trauma, but the differences just failed to reach statistical significance in both subgroups. The current Cochrane analysis is heavily influenced by the large Australian study, and it concludes that there is no evidence that albumin reduces mortality when compared with cheaper alternatives such as saline.<sup>36</sup>

There have been very few studies comparing crystalloid to colloid fluids in children, so most of the evidence comes from studies in adults. The use of albumin in paediatric and neonatal intensive care has been reviewed.<sup>37,38</sup> The meta-analyses do not suggest that colloid is better

than crystalloid, and colloid is more expensive and carries a small risk of transmitting infection. Until more evidence is available, it seems sensible to use crystalloid as routine, but give concentrated albumin to children with severe hypoalbuminaemia (perhaps if their serum albumin is less than 25 g/l), unless the low albumin is caused by chronic malnutrition, when albumin should *not* be given.<sup>39</sup>

### PARENTERAL NUTRITION<sup>40–42</sup>

‘Maintenance solution’ is an unfortunate medical term, particularly when small children are concerned – a solution of 5% dextrose with sodium and potassium chloride provides maintenance amounts of water, sodium, potassium and chloride, but little or no calories, protein, trace elements or vitamins. For example, 100 ml/kg per day of 5% dextrose provides 20 cal/kg per day (84 kJ/kg per day), which is only 20% of the requirement of a normal infant (let alone a child with increased calorie requirements). It has been estimated that, although an adult has the energy reserve to survive for about a year on 3 litres of 10% dextrose a day, a small preterm infant will survive only 11 days on 75 ml/kg per day of 10% dextrose.<sup>43</sup>

Many children in intensive care units are unable to absorb adequate amounts of food from the gut, and their nutritional reserves are small, so they often need parenteral nutrition. However, parenteral nutrition is difficult to administer and dangerous in small children – such patients should be referred to a specialist paediatric unit as soon as possible.

The usual requirements for amino acids, dextrose and fat in parenteral nutrition in children are shown in Table 99.6. The amino acid solution can be mixed with dextrose in the Pharmacy Department to make a ‘nutrient solution’. A standard nutrient solution might provide 4 mmol/kg per day of sodium, 3 mmol/kg per day of potassium, and 7.5 mmol/

Table 99.6 Approximate requirements in paediatric parenteral nutrition

	Total fluid ml/kg per day*	Amino acids (g/kg per day) Day			Dextrose (g/kg per day) Day			Lipid (g/kg per day) Day				Total calories (kcal) needed (1 kcal = 4.2 kJ)
		1	2	3+	1	2	3+	1	2	3	4+	
Neonates	100	1.5	2	2	10	10–15	15–20	1	2	2	2–3	100/kg
Under 10 kg	100	1.5	2	2	10	10	15–20	1	2	2	2–3	100/kg
10–15 kg	90	1	1.5	2	5	10	15	1	1.5	2	2–3	1000 + (50/kg over 10 kg)
15–20 kg	80	1	1.5	1.5–2	5	10	10–15	1	1	1.5	2–3	1000 + (50/kg over 10 kg)
20–30 kg	65	1	1	1–2	5	10	10–15	1	1	1	1–2	1500 + (20/kg over 20 kg)
30–50 kg	50	1	1	1–2	5	5–10	10	1	1	1	1–2	1500 + (20/kg over 20 kg)

\*1 ml/kg per day of fluid is needed for each kcal/kg per day; for adjustments to requirements, see Table 99.3 [Total kcal/kg per day equals g/kg per day of (amino acids × 4) + (dextrose × 4) + (lipid × 10)].  
Calorie requirement of an active child in hospital.

day of calcium and phosphate (with up to 12 mmol/l for neonates). The standard solution should also contain 4 mmol/l of magnesium, 0.2 µmol/kg per day of manganese, 3 µmol/kg per day of zinc, 0.5 µmol/kg per day of copper, 0.04 µmol/kg per day of iodide, 0.005 µmol/kg per day of chromium, 20 µg/l of hydroxycobalamin, 2 mg/l of phytomenadione, 1 mg/l of folic acid, and a multivitamin preparation. For short-term nutrition, the solution need not provide fluoride, iron or vitamins A, D and E, but a paediatric multivitamin preparation should be given to children on long-term parenteral nutrition. Fat can be given as a 20% emulsion, either through a separate i.v. line or alternating with the nutrient solution. Nutrient solutions for paediatric use contain high concentrations of calcium, magnesium and phosphorus, and they should not be mixed with the fat emulsion, even in a Y-connection placed just before the cannula.

In a child on parenteral nutrition, it is important that abnormal fluid losses (Table 99.5) be replaced with an appropriate solution (in addition to the nutrient solution), and that parenteral nutrition always be introduced and withdrawn slowly. A dislodged i.v. cannula should be replaced immediately in a child on parenteral nutrition to prevent rebound hypoglycaemia. If nutrient solution is not available at any time, it should be replaced with an infusion of a similar amount of dextrose (e.g. 20% dextrose with 40 mmol/l of sodium chloride and 20 mmol/l of potassium chloride).

Children receiving parenteral nutrition are liable to develop:

- hyperglycaemia (with glycosuria and dehydration)
- hypoglycaemia

- sepsis
- extravasation of solutions with necrosis of tissue
- thrombocytopenia
- hypoproteinaemia
- electrolyte imbalance
- acidosis
- anaemia
- hyperlipaemia
- uraemia
- cholestatic jaundice

Frequent, careful monitoring is essential (Table 99.7). Initially, monitoring may need to be more frequent than suggested in Table 99.7, particularly in preterm babies. Monitoring can be less frequent once a child is stabilised on parenteral nutrition.

Table 99.7 Monitoring in paediatric parenteral nutrition

Daily: inspect i.v. site, electrolytes, acid–base, serum triglyceride (reduce lipid infusion rate if triglyceride is greater than 2–2.5 mmol/l)
Twice weekly: haemoglobin (transfuse if anaemia develops), platelets, proteins
Weekly: creatinine, magnesium, calcium, phosphate, bilirubin, aspartate aminotransferase
Blood glucose 8-hourly until the dextrose intake is stable
Test urine for glucose 8-hourly (reduce dextrose intake if more than trace)
Weigh frequently (daily if possible)

# Sedation and analgesia in children

Geoff Knight

All children, including preterm infants, feel and remember pain and discomfort.<sup>1</sup> Provision of adequate sedation and analgesia should therefore be a priority in the management of all critically ill children.

## INDICATIONS AND BENEFITS

Pain in the paediatric intensive care unit (PICU) may be surgical in origin or due to the underlying illness or to procedures (e.g. central venous catheterisation, lumbar puncture and removal of drains). Sedation is frequently necessary to allow a child to tolerate an endotracheal tube and mechanical ventilation. It may also be needed to allow sleep in a brightly lit, noisy environment. As young children are unlikely to cooperate during investigations, such as an echocardiogram or computed tomographic (CT) scan, sedation is often necessary to prevent excessive movement.

In addition to its humane benefits, sedation and analgesia can suppress non-advantageous physiological responses to noxious stimuli. Analgesic suppression of the marked postsurgery stress response has been associated with significant improvements in postoperative morbidity and mortality.<sup>2-4</sup>

## ASSESSMENT

Adequacy of pain relief and sedation is dependent on an accurate assessment of the degree of discomfort. This is particularly difficult in the critically ill child who may be preverbal, developmentally delayed, intubated and/or paralysed, or simply uncooperative. Thorough assessment requires careful and frequent consideration of a number of factors. These include the nature of the noxious stimulus, variations in physiological parameters (e.g. heart rate and blood pressure) and interpretation of subjective clues (e.g. facial expressions and posture). Parental interpretations are reliable and should be included in the overall assessment.

Pain and sedation assessment tools should also be utilised. Neonates and infants are particularly difficult to assess and validated assessment tools, including the

Premature Infant Pain Profile (PIPP) and CRIES scale, are helpful objective measures of pain in this group.<sup>5</sup> The Multidimensional Assessment of Pain Scale (MAPS) has recently been validated as a tool for assessing postoperative pain in preverbal children.<sup>6</sup> Established tools such as the Face, Legs, Activity, Cry and Consolability (FLACC) Scale have been modified to enhance the pain assessment of children with cognitive impairment.<sup>7</sup> The COMFORT and the modified COMFORT 'Behavior' are validated observer reported sedation scales for children 1-3 years.<sup>8</sup> In older children, self-reporting measurement scales can be used but these require a degree of patient cooperation.

The most challenging group of patients to manage optimally are those receiving muscle paralysis. Attempts to enhance the limited clinical parameters available for interpretation with an objective measure have centred on the bispectral index (BIS). Validation studies in the paediatric intensive care environment are limited and highlight the probable inaccuracy of current methods of assessing sedation in paralysed patients.<sup>9</sup> In general it is preferable to err on the side of over- rather than under-sedation in the paralysed patient.

## APPROACH TO MANAGEMENT

The management of discomfort, anxiety and pain should be multifaceted. Recently published consensus guidelines from the United Kingdom Paediatric Intensive Care Society present a detailed analysis of the evidence for assessment and management strategies.<sup>10</sup>

Management can and should, whenever possible, begin prior to the child's admission to intensive care. Orientation to the unit should be accompanied by a clear, age-appropriate explanation of the planned procedure or operation and the expected postoperative course. Parental presence during this phase and at other critical times is also important to help allay anxiety and fear. Close attention should also be paid throughout a child's admission to potentially distressing physiological factors, such as hunger and urinary retention. In addition to these supportive measures, many paediatric patients require a pharmacological form of analgesia or sedation.

**Table 100.1** Single dose and infusion rates of sedative and analgesic drugs\*

Drug	Bolus dose	Infusion rate
Morphine	0.1–0.2 mg/kg i.v.	10–40 µg/kg per hour
Fentanyl	1–2 µg/kg i.v.	1–10 µg/kg per hour
Remifentanyl	0.1–0.5 µg/kg i.v.	0.1–0.5 µg/kg per min
Midazolam	0.1–0.2 mg/kg i.v. 0.5 mg/kg (oral)	50–200 µg/kg per hour
Ketamine	1–2 mg/kg i.v.	10–20 µg/kg per min (sedation) 4 µg/kg per min (analgesia)
Propofol	1–3 mg/kg i.v.	< 4 mg/kg per hour (short term)
Clonidine	1–2 µg/kg i.v. 4 µg/kg (oral)	0.1–2 µg/kg per hour
Dexmedetomidine	0.5–1 µg/kg i.v.	0.2–1.0 µg/kg per hour

Note: Some infusion rates are described per minute and others per hour.

Sedation and analgesia should be tailored to the patient's particular requirements. It is vital that there be continuous assessment and frequent adjustment of regimes so that optimal levels of sedation and adequate analgesia are delivered at all times. This requires a clear understanding by medical and nursing staff of the aims of management and of the pharmacology of the agents being administered. Relief of pain should be achieved with analgesic agents and care must be taken to avoid the overadministration of sedative agents when the patient's primary need is for pain relief (Table 100.1). While emphasis should be on optimal comfort, consideration should also be given to minimising side-effects. A single drug may be effective but often a combination of medications and a combination of delivery methods (e.g. i.v./oral, i.v./epidural) will be useful and may avoid the side-effects of high doses of a single agent. A recent trend towards analgesia-based sedation, as an approach to managing the ventilated adult patient, has shown benefits when compared to hypnotic-based regimes.<sup>11</sup>

#### PAEDIATRIC PHARMACOLOGICAL CONSIDERATIONS

Differences in drug handling between children and adults should be considered. Drug distribution, rates of drug metabolism and relative organ blood flows differ in

children, particularly in young infants. These differences may result in greater concentrations of free drug and differing volumes of distribution. Neonates have relatively larger total body water, extracellular fluid volume, blood volume and cardiac output and significantly less body fat than adults. Their blood–brain barrier is less efficient and allows more ready entry of some drugs to the brain. Mixed-function oxidases mature quickly to adult levels by 6 months of age, and acetylation and glucuronidation mechanisms mature by about 3 months. Renal blood flow and glomerular filtration rate are low in the immediate neonatal period. However, both increase significantly in the first 2–3 days and reach adult values by around 5 months. Tubular secretory capacity reaches adult levels by 6 months of age. In general therefore, drug metabolism and clearance are relatively mature by 6 months of age but great care is required when dealing with the neonate and young infant.

#### NON-OPIOID AGENTS

##### MIDAZOLAM

Midazolam is water soluble, and has a rapid onset of action. Metabolism occurs in the liver and by 6 months of age is comparable to that of an adult. The standard i.v. sedative dose is 0.1–0.2 mg/kg and this is effective for uncomfortable procedures, such as echocardiography and cardioversion. The oral route (0.5 mg/kg) may also be useful though there is a 15-minute delay to onset of sedation. Nasal administration (0.2 mg/kg) can be useful in children who do not have established i.v. access and in whom oral agents are not appropriate. Although midazolam may be effective as the sole sedative agent for ventilated patients, higher doses, and often additional agents, are commonly required in young children (1–4 years).<sup>12</sup> 50–200 µg/kg per hour, in combination with an opioid (morphine 10–40 µg/kg per hour), is usually effective in facilitating mechanical ventilation. Dose-related respiratory depression occurs and hypotension can be significant in hypovolaemic patients and in those with depressed myocardial function. During continuous infusion, accumulation can occur, particularly in young infants (under 6 months) and in patients with liver dysfunction. The use of midazolam in neonatal intensive care is controversial as there are concerns regarding its safety and effectiveness as a long-term sedative in the newborn.<sup>13</sup>

##### KETAMINE

Ketamine is a dissociative anaesthetic agent with sedative, analgesic and amnesic properties. Biotransformation occurs by the microsomal enzyme system. Thus, there is little metabolism in the newborn and clearance is less and elimination half-life greater in infants than in older children and adults.<sup>14</sup> Ketamine's usefulness in preterm infants, to

a postconceptual age of 51 weeks, is limited because of an increased risk of postanaesthetic apnoea. An initial i.v. dose of 1–2 mg/kg is usually adequate to induce deep sedation. Cardiovascular disturbance is minimal and ketamine is therefore particularly useful as the induction agent in status asthmaticus and in patients with a compromised haemodynamic state, such as tamponade. Prolonged sedation for ventilated children can be achieved with a continuous infusion of 10–15 µg/kg per min and analgesia can be provided by an infusion of 4 µg/kg per min. Concomitant use of an antisialogogue, such as glycopyrrolate, helps control the often seen increase in respiratory tract secretions. The unpleasant emergent phenomena, seen frequently in adults, probably occur less often in children. The traditional practice of concurrently administering a benzodiazepine with the aim of minimising these effects has minimal demonstrable benefit.<sup>15</sup>

### PROPOFOL

Propofol is a rapidly acting hypnotic agent that is widely used in paediatric anaesthesia and intensive care for short- and longer-term sedation.<sup>16,17</sup> Although it has no analgesic properties its short half-life makes it an attractive agent for sedation. The half-life decreases with age, probably due to development of metabolising capacity and increasing hepatic flow.<sup>18</sup> Sedation can be achieved in the spontaneously breathing patient, with an induction dose of 1 mg/kg, followed by intermittent smaller doses: 2–3 mg/kg per hour has delivered uncomplicated satisfactory sedation to ventilated children.<sup>19</sup> However, propofol should be used with caution for sedation in the PICU because of the reported association between high dose (> 4 mg/kg per hour), prolonged (> 29 hours) infusions and a clinical syndrome (propofol infusion syndrome) consisting of metabolic acidosis, lipaemia, cardiac failure, arrhythmias and death.<sup>20</sup> The pathogenesis of this syndrome remains unclear, although it has been postulated that a disturbance of mitochondrial function leading to disordered hepatic lipid regulation underlies the disorder.<sup>21</sup> Lipaemia may be an early indicator of developing problems and successful use of haemodialysis in the early phase is the only therapy described.<sup>22</sup> There are sufficient concerns to limit the use of propofol in the PICU to short-term sedation in the stable ventilated child. Administration of propofol in the presence of shock, hypoxaemia or acute liver dysfunction, or for long-term, high-dose sedation cannot be recommended. It should be noted that the manufacturers advise against the use of propofol for sedation of children during intensive care.

### THIOPENTAL

Thiopental is useful as an anaesthetic induction agent in critically ill children, although its hypotensive effects limit its use in shocked patients. The standard dose is 5 mg/kg,

and this should be reduced to 2–3 mg/kg when hypotension is a risk. Thiopental is useful in the management of refractory status epilepticus and may have a role in difficult cases of raised intracranial pressure. In such cases, it is administered by continuous infusion (1–5 mg/kg per hour). Accumulation can lead to prolonged sedation.

### CHLORAL HYDRATE

Chloral is an effective oral hypnotic and sedative agent with no analgesic effect. The hypnotic dose is 50 mg/kg and appropriate sedation may be achieved with lower doses. Gastric irritation can be a problem in some children. Toxic doses produce depression of respiration and cardiac contractility. Despite the disadvantage of delayed onset, chloral can be useful given prior to procedures, or as a supplemental sedative agent in the ventilated child and it can effectively induce nocturnal sleep. On a cautionary note, there is some evidence that it may not be suitable in acutely wheezing infants.<sup>23</sup>

### CLONIDINE AND DEXMEDETOMIDINE

Clonidine is an  $\alpha_2$ -adrenoreceptor agonist with significant neurological, neuroendocrine and cardiovascular effects that result in sedation, analgesia and reduced sympathetic outflow. It is rapidly absorbed after oral administration and has a half-life of 9–12 hours. Metabolism is via the liver and kidney and approximately 50% is excreted unchanged in the urine. A single oral dose (4 µg/kg) can provide both preoperative sedation and postoperative analgesia following moderately painful surgery.<sup>24</sup> An i.v. infusion (0.1–2 µg/kg per hour) in combination with midazolam (50 µg/kg per hour) has been shown to produce effective sedation in ventilated children without haemodynamic disturbance.<sup>25</sup> Clonidine can also have a role in the management of the autonomic storms seen following severe traumatic brain injury and in the management of opioid withdrawal.

Dexmedetomidine is a selective  $\alpha_2$ -agonist that has many of the properties of clonidine and may produce less respiratory depression. It is metabolised in the liver and, in adults, has an elimination half-life of 2 hours. It has provided satisfactory sedation and analgesia with minimal respiratory or haemodynamic disturbance in postoperative ventilated and spontaneously breathing adult patients. Respiratory stability during infusion has been sufficient to allow successful extubation of patients who had previously failed because of agitation.<sup>26</sup> Use is approved and recommended by the manufacturer for the sedation of adult patients for up to 24 hours. In the paediatric population studies are limited. 0.5–1 µg/kg followed by an infusion of 0.5–1 µg/kg per hour has provided adequate sedation for non-invasive procedures.<sup>27</sup> 1 µg/kg followed by 0.1–2 µg/kg per hour, added to an opioid/benzodiazepine regime, has also

been shown to improve patient comfort without significant respiratory depression.<sup>28</sup> As with clonidine, bradycardia has been seen during continuous infusion.<sup>25,29</sup>

## OPIOID ANALGESICS

### MORPHINE

Morphine is frequently used to provide analgesia and as part of a sedative regime for children on mechanical ventilation. Marked variation in pharmacokinetics in the neonatal period has been demonstrated, but infants over 1 month of age eliminate morphine efficiently and should not be more sensitive to respiratory depression than adults. Clearance and half-life (2 hours) are at adult values by 6 months of age.<sup>30</sup> The active metabolite is renally excreted and can therefore accumulate in renal failure. The standard i.v. dose is 0.1–0.2 mg/kg and an infusion rate of 20–40 µg/kg per hour provides safe postoperative pain relief in spontaneously breathing patients. With careful titration of dose to effect, higher rates can be administered, particularly to the child on mechanical ventilation. Patient-controlled analgesia devices delivering fixed doses of opioid, with or without a background infusion, can be used successfully by the majority of school-aged children and may occasionally be appropriate in intensive care. Histamine-related side-effects, in particular nasal itch, may warrant a change of opioid and fentanyl is an alternative.

### FENTANYL AND ALFENTANIL

Fentanyl has theoretical advantages over morphine in certain situations because of its rapid onset and its systemic and pulmonary hemodynamic stability. Termination of the effects of a single dose is by redistribution. Clearance is more rapid in neonates and infants compared to adults and does not change with time during continuous infusion. However, after prolonged infusion, unchanged fentanyl is returned to the circulation from peripheral compartments, resulting in a prolonged terminal elimination half-life of approximately 21 hours.<sup>31</sup> The effective dose for painful procedures is 1–2 µg/kg. Fentanyl is useful as an anaesthetic agent in patients with labile pulmonary vasculature, as it can blunt changes in pulmonary vascular resistance seen with stimulation.<sup>4</sup> However, it does not prevent the increase in pulmonary vascular pressure caused by hypoxia.<sup>32</sup> Infusions of 1–5 µg/kg per hour produce effective sedation in neonates on mechanical ventilation; 1–10 µg/kg per hour is required for analgesia in older children. Tolerance, noted in both neonates and older children, can develop rapidly.<sup>33</sup> Fentanyl's short duration of action makes it suitable for use in epidural regimens.

Alfentanil, because of its shorter duration of action, may have advantages for analgesia or sedation for very short procedures.

### REMIFENTANIL

Remifentanyl is a synthetic opioid with potent analgesic properties, rapid onset of action, and, following initial redistribution, a short half-life of around 8 minutes. Metabolism occurs via non-specific esterases and is therefore relatively independent of renal and hepatic mechanisms. The short duration of action allows rapid emergence from general anaesthesia, thereby facilitating extubation or assessment of the patient's neurological state.<sup>34</sup> Postoperative pain needs to be managed with an alternative analgesic regime and an opioid should be administered prior to discontinuing remifentanyl.

Infusions of 0.1–0.5 µg/kg per min have produced satisfactory analgesia and sedation in ventilated adult patients and there is evidence that ventilation times are shorter and weaning from ventilation more rapid in comparison to standard sedation regimes.<sup>11,35</sup> Although remifentanyl is widely used in paediatric anaesthesia there are few data available on its use in children in intensive care. Uncomplicated and successful use in the induction and sedation of a ventilated preterm neonate has been described.<sup>36</sup> As metabolism is relatively independent of renal and hepatic mechanisms, remifentanyl could be considered for use in patients with liver and/or renal impairment who do not have continuing pain and in whom rapid termination of sedation is required.

### PARACETAMOL AND NON-STEROIDAL ANTI-INFLAMMATORY DRUGS

The addition to an analgesic regime of either paracetamol or a non-steroidal anti-inflammatory drug (NSAID) should be considered provided there are no contraindications.

Paracetamol is useful for mild to moderate pain and is an effective supplement to opioids for more severe pain. Enteral preparations, though useful, are prone to erratic absorption. The intravenous preparation *Perfalgan* is a more useful drug in the intensive care setting and has been shown to reduce opioid requirements in adults with few side-effects following orthopaedic surgery.<sup>37</sup> Data in children and neonates are limited. The recommended initial i.v. dose is 15 mg/kg (30 mg/kg p.o. or rectal) and the total daily i.v. dose should be limited to 60 mg/kg (90 mg/kg p.o.). Lower i.v. doses (7.5 mg/kg 6-hourly) are recommended for neonates. Contraindications to paracetamol include liver dysfunction and care must be taken to avoid liver injury in all children.

NSAIDs should also be considered as supplemental analgesics. Care should be taken, however, regarding the risk of bleeding, particularly in the postoperative period and in the highly stressed patient in whom gastric bleeding is more likely. *Ketorolac* (0.6 mg/kg) can be given i.v. and therefore has the potential to reduce the dose of opioid required in the immediate postoperative period when enteral medications are not appropriate.

## INHALED AGENTS

### NITROUS OXIDE

Nitrous oxide is a potent analgesic agent. It is useful in intensive care during short painful procedures such as removal of surgical drains. A mixture of 50% nitrous oxide with oxygen provides analgesia in awake and cooperative patients. It is unsuitable for repeated or continuous use because of toxicity and administration to younger children may cause distress because of the need for application of a mask.

### ISOFLURANE

Isoflurane has been used for long-term sedation in intensive care in adults. As elimination is independent of hepatic and renal mechanisms, there are theoretical advantages in many critically ill patients. However, an association between isoflurane sedation and neurological abnormalities has been reported in children.<sup>38</sup> These abnormalities, although reversible, were a considerable clinical problem and make this technique unsuitable.

## DRUG WITHDRAWAL SYNDROMES

Opioid withdrawal is a recognised problem and symptoms include poor feeding, tremors, agitation, poor sleeping, tachycardia, diarrhoea, sweating, increased muscle tone, dystonic posturing and seizures. It occurs particularly following prolonged high-dose infusions. The risk of withdrawal following a fentanyl infusion is associated with the duration of infusion and the total dose. Infusion for > 5 days or a total dose > 1.5 mg/kg was associated with greater than 50% incidence.<sup>39</sup>

Benzodiazepine withdrawal (agitation, anxiety, sweating, tremor) is also seen and the risk following a midazolam infusion is associated with a total dose > 60 mg/kg.<sup>40</sup> Careful attention to weaning an infusion in high-risk patients can minimise withdrawal symptoms. Longer-term pharmacological management is occasionally required and is best managed by administering the agent from which the patient is withdrawing. Methadone, benzodiazepines and clonidine have been used via i.v., oral and subcutaneous routes.<sup>41</sup> Recent evidence suggests that short-term (5-day) opioid weaning programmes can be successful.<sup>42</sup> Although withdrawal can be a significant problem, adequate sedation or analgesia should not be withheld because of fears of the development of drug dependence.

## LOCAL ANAESTHESIA

Local anaesthesia can produce effective analgesia without systemic effects and therefore has significant advantages in many patients, particularly the postoperative group. In the intensive care setting, it can be used as the sole

method of providing analgesia or in combination with i.v. agents. The risk of toxicity is related both to the dose and to the rapidity of absorption, which is dependent on local blood flow. Metabolism of the amide local anaesthetics (lidocaine, bupivacaine) is via the cytochrome P-450 system and their half-life is longer in infants less than 6 months of age. Unbound drug does not produce analgesia but is potentially toxic as infants have lower levels of the binding protein  $\alpha$ -glycoprotein.<sup>43</sup> The use of local anaesthesia in infancy therefore requires careful assessment and close monitoring.

### EMLA

EMLA, an emulsion of lidocaine and prilocaine, is effective in reducing the pain associated with percutaneous procedures.<sup>44</sup> It needs to be applied to the skin 60 minutes beforehand and thus is unsuitable for urgent procedures. Systemic absorption of the prilocaine component and subsequent methaemoglobinaemia can occur. Neonates, because of their relative deficiency of methaemoglobin reductase, are particularly at risk and EMLA should be used with caution in this group.

### LOCAL INFILTRATION

Optimal analgesia for some painful procedures is possible, particularly in older children, with careful local infiltration and minimal sedation. The total dose of local anaesthetic agent infiltrated must be monitored and maximum doses not exceeded. The total dose of lidocaine should not exceed 4 mg/kg (7 mg/kg if combined with adrenaline).

### NERVE BLOCKS

Femoral nerve blockade is a simple technique that produces effective analgesia in cases of femoral shaft fracture. A single injection is effective for approximately 3 hours and longer term analgesia can be provided by a continuous infusion of bupivacaine (0.125%) at 0.2–0.3 ml/kg per hour through a fine catheter placed adjacent to the femoral nerve.<sup>45</sup> As this technique can decrease opioid requirements, it is particularly useful in trauma patients who have suffered a coexistent head injury.

Intercostal nerve blocks may be useful after thoracotomies and liver transplants in children.<sup>46</sup> A single dose of 0.125% bupivacaine (maximum single dose 2 mg/kg) can produce up to 8 hours of analgesia. The dose must be carefully limited, because the relatively high blood flow to the area increases the risk of toxicity. Continuous infusions via an intercostal catheter can provide ongoing pain relief. These require careful monitoring in the PICU, particularly regarding maximal dose. There is a risk of pneumothorax with this technique and it should therefore be avoided when there is significant coexistent lung disease.

## EPIDURAL ANALGESIA

Caudal, lumbar and thoracic epidural anaesthesia can provide effective control of postoperative pain in children.<sup>47,48</sup> The procedures must be performed by skilled experienced staff who clearly understand the risks and benefits. A complication rate of 1.5 per 1000 has been reported, with dural puncture and intravascular injection seen most commonly.<sup>49</sup> Other risks include cord injury, epidural infection and excessive motor blockade. Infants under 6 months are at highest risk because of their size and immature metabolism.

Many epidural catheter insertions are performed in the operating theatre and general anaesthesia is a prerequisite in most paediatric patients. PICU care may subsequently be required because of the nature of the surgery (e.g. thoracotomy, liver transplant) or because of underlying patient factors (e.g. neurological disorders, morbid obesity, age). Epidurals have been used in paediatric cardiac surgery without clear benefit over conventional postoperative analgesia.<sup>50</sup> Particular indications for commencing epidural analgesia in the PICU include burns in a suitable distribution (e.g. abdomen and lower limbs) and blunt chest trauma with rib fractures. Contraindications include shock, hypovolaemia, meningitis, coagulopathy and local skin infection.

Bupivacaine is the most commonly used local anaesthetic. A single dose should not exceed 2.5 mg/kg and the maximum infusion rate is 0.4 mg/kg per hour (0.2 mg/kg per hour in infants). Opioids (morphine and fentanyl) may be added and have a synergistic effect, thereby allowing less local anaesthetic agent to be used. Epidural opioids can cause sedation and respiratory depression.

# Shock and cardiac disease in children

Robert D Henning

Most cases of shock in childhood are caused by hypovolaemia (Table 101.1) or sepsis. The causes, clinical course, management and complications of shock differ from those in adults: severe diarrhoeal disease and congenital abnormalities are common in childhood but abdominal sepsis, pancreatitis and obstructive vascular disease are uncommon.

The following factors affect the epidemiology of shock in children:

## SMALLER BODY FLUID COMPARTMENTS

A small volume of blood or diarrhoeal fluid loss, or of fluid leakage into the extravascular space may represent a large percentage loss of blood or extracellular fluid (ECF) volume in a small child (Table 101.2).

## IMMATURE IMMUNE SYSTEM IN INFANTS AND TODDLERS<sup>2</sup>

The innate host defences of the small child are immature: the skin and the respiratory and gut mucosae are more permeable to bacteria and their toxins, and secretory IgA levels remain low throughout childhood. There is increased susceptibility to severe bacteraemias due to:

- low IgM and IgG levels
- deficient neutrophil adhesion, migration and respiratory burst activity, combined with lower levels of complement (especially C3, C9 and factor B)
- low cytokine production by monocytes

Antibody response to bacterial polysaccharide capsular antigens (e.g. *Streptococcus pneumoniae*, *Haemophilus* spp. and *Neisseria meningitidis*) remains poor in the pre-school years. Low IgG concentrations, immunological naivety and reduced natural killer (NK) cell activity predispose young children to frequent viral infections, and the newborn to severe herpes simplex infection.<sup>3</sup>

Reduced cytokine production, especially in the immunologically naive, may alter the features and duration of the shock syndrome, including the ability to develop a fever, and causes deficiency in most T-cell functions, including cytotoxicity and augmentation of B-cell differentiation.<sup>4</sup>

## MICROBIOLOGY

In the newborn, septic shock is most often caused by *Staphylococcus aureus*, group B  $\beta$ -haemolytic streptococci, Enterobacteriaceae, *Listeria monocytogenes*, enteroviruses (e.g. Echo or Coxsackie viruses) or herpes simplex virus.

Later in childhood, *Strep. pneumoniae*, *N. meningitidis*, *Haemophilus influenzae*, *Staph. aureus* and Enterobacteriaceae cause most cases of septic shock. Although severe sepsis due to *H. influenzae* type b (Hib) and *N. meningitidis* group C has been almost completely eradicated among immunised children, cases of severe sepsis involving these organisms still occur in non-immunised children, and cases of sepsis due to other serotypes are seen in immunised children.

In immunodeficient children, *Staph. aureus*, Enterobacteriaceae, *Pseudomonas* spp., *Candida albicans*, fungi and viruses such as cytomegalovirus and varicella frequently cause septic shock.

## SEVERE CONGENITAL ABNORMALITIES

Children with congenital heart, lung or neurological diseases, multiple congenital abnormalities, inborn errors of metabolism and the inherited immunodeficiency syndromes are prone to develop cardiogenic, hypovolaemic or septic shock, especially in the first 2–3 years of life.

## OTHER CHILDHOOD CONDITIONS THAT PREDISPOSE TO SEVERE SEPSIS

These include:

- cancer and its chemotherapy
- organ transplantation (especially bone marrow)
- multiple trauma
- burns
- prolonged paediatric intensive care unit (PICU) stay
- the presence of implanted therapeutic devices including intravascular catheters

**Table 101.1** Causes of hypovolaemic shock in childhood

Bleeding
Revealed (external or into the gastrointestinal tract)
Concealed (scalp, intracranial, trunk or limbs)
Water and electrolyte loss
Bowel
Renal
Skin
Plasma loss (capillary leak)
Water deprivation (absolute or relative to losses)

**Table 101.2** Body fluid compartments during childhood (ml/kg)<sup>1</sup>

	Total body water	Extracellular fluid	Intracellular fluid	Blood
Preterm newborn	800	550	300	95
Birth	750	450	300	85
1 year	700	350	350	80
5 years	650	250	400	75
Adult	600	200	400	70

## **PATHOPHYSIOLOGY**

The pathophysiology of shock is described in Chapter 11 which should be read in conjunction with this chapter. The following aspects of a child's physiology affect the response to insults.

### **IMMATURE CARDIOVASCULAR SYSTEM<sup>5,6</sup>**

#### **LESS CAPABLE OF DEVELOPING CONTRACTILE FORCE**

The immature myocardium has more loose connective tissue than the adult, but fewer sarcomeres per gram of tissue. The arrangement of myofibrils in the myocyte, and of myocytes in the myocardium, is less parallel than in the adult. Intracellular desmin fibrils which link the contractile elements are more randomly arranged in the infant heart. Less efficient calcium uptake, storage and release from sarcoplasmic reticulum (SR) and a higher density of cell membrane Na/Ca exchangers mean that excitation-contraction coupling is more dependent on trans-sarcolemmal Ca<sup>++</sup> flux, and on ECF Ca<sup>++</sup> concentration than the adult.

#### **LESS DIASTOLIC COMPLIANCE THAN THE ADULT HEART**

- Limited calcium uptake and storage into SR, more slow skeletal troponin I and more  $\beta$ -tropomyosin relative to  $\alpha$ -tropomyosin mean slower diastolic relaxation of the ventricles.
- Greater myocardial collagen content and immaturity of the cytoskeleton and intercellular matrix increase the diastolic elastic recoil of the infant ventricular wall.
- Increases in end-diastolic volume of either ventricle cause greater reduction of compliance of the opposite ventricle than in the adult: when right ventricle (RV) afterload rises acutely, the consequent increase in RV end-diastolic volume distorts the left ventricle (LV) and impairs LV filling and emptying more than in the adult.

#### **MORE TOLERANT OF HYPOXAEMIA**

Although the infant heart has fewer mitochondria per gram of tissue, and a lower oxidative capacity, it has a lower oxygen demand per gram, larger glycogen reserves and a higher capacity for anaerobic glycolysis.<sup>7</sup> Glucose is the major myocardial energy source (rather than long chain fatty acids as in older children) and hypoglycaemia causes severe myocardial depression.

#### **IMMATURE AUTONOMIC INNERVATION**

Parasympathetic innervation of the heart is more complete than sympathetic in infants, and the infant response to severe stress (e.g. hypoxia) tends to be bradycardia rather than tachycardia.

The infant myocardium has fewer  $\beta$ -receptors, more  $\alpha$ -receptors, and is more sensitive to noradrenaline (nor-epinephrine) than the adult. Stimulation of myocardial  $\alpha$ -receptors in the infant is more likely to cause tachycardia than bradycardia.<sup>8</sup>

#### **HIGH PULMONARY VASCULAR RESISTANCE<sup>8</sup>**

In the fetus, the small pulmonary arteries are narrow, the pulmonary vascular resistance is high, and pulmonary blood flow is less than one-tenth of systemic flow. A thick layer of smooth muscle, which extends further out into the vascular tree than in the adult, is highly sensitive to hypoxia, hypercarbia, acidemia, sepsis and central neural stimuli such as pain.

At birth, after the first breaths are taken, the smooth muscle cells gradually relax and become more fusiform in shape. Pulmonary vascular resistance falls immediately, then gradually declines to adult levels by 6–8 weeks of age, and smooth muscle bulk falls to adult levels by 3–4 months.<sup>9</sup> In the presence of lung disease, high pulmonary venous pressures (e.g. due to aortic stenosis or stenosis of the pulmonary veins) or large left-to-right shunts (e.g. ventricular septal defect (VSD) or truncus arteriosus), the high pulmonary vascular resistance and the extensive

and bulky vascular smooth muscle fail to decline normally. The infant is then vulnerable to episodes of acute right heart failure whenever the pulmonary vascular resistance increases abruptly.

## CLINICAL PRESENTATION OF SHOCK IN CHILDHOOD

### HYPOVOLAEMIC SHOCK (SEE TABLE 101.1)

The child may have a history of fluid or blood loss, reduced fluid intake or bowel-related illness. Signs of dehydration (see Chapter 99), external bleeding or haematoma may be present. The presence of hypovolaemic shock implies a blood volume deficit greater than 30 ml/kg.

Signs of homeostatic compensation, such as tachycardia (Table 101.3), narrow pulse pressure, cool mottled limbs and slow capillary refill usually precede the onset of hypotension, which tends to occur late (after loss of 15–20% of blood volume) and precipitously in young children. In severe shock of any cause, signs of multiple organ hypoperfusion (e.g. oliguria of less than 0.5 ml/kg per hour, lethargy or coma, hypothermia, tachypnoea and increasing lactic or other metabolic acidosis) are found. Bleeding due to disseminated intravascular coagulation and liver dysfunction may occur in the first 6 hours.

In early shock, these changes are reversible by plasma volume expansion with boluses of 20 ml/kg 0.9% saline or blood, repeated as necessary. Failure to respond to two such boluses with a decrease in heart rate and capillary refill time (normal < 2 seconds after 5 seconds' pressure over the sternum) indicates refractory shock requiring more aggressive treatment (see below).

**Table 101.3** Normal blood pressure, heart rate and respiratory rate in childhood<sup>10</sup>

Age	Blood pressure (mmHg (kPa))	Heart rate (beats/min) (2nd–98th centile)	Respiratory rate (breaths/min)
Birth	75/40 (10.0/5.3)	125 (94–155)	50
1 year	95/60 (12.6/8.0)	120 (108–168)	35
2 years	96/60 (12.8/8.0)	110 (90–152)	25
6 years	98/60 (13.0/8.0)	110 (64–133)	16
10 years	110/70 (14.6/9.3)	90 (63–130)	16
14 years	118/75 (15.7/10.0)	80 (61–120)	16

**Table 101.4** Investigation of shock in children

#### All shocked children

Arterial blood gases  
Plasma electrolytes, urea, creatinine, glucose, liver function tests, lactate  
Haemoglobin, platelet count, total and differential white cell count  
Coagulation screen including fibrin degradation products  
Blood group (hold serum)

#### If the cause of shock is unknown

##### Exclude sepsis:

Several sets of blood cultures, percutaneous and via vascular catheters  
Culture and Gram stain pus  
Urine cultures from mid-stream sample or suprapubic aspirate of urine  
Urine, stool and nasopharyngeal aspirate for virology  
CSF bacterial and viral culture plus PCR for specific organisms

##### Urine bacterial antigens

To exclude cardiogenic shock: echocardiography, ECG, cardiac catheter

Drug screen: urine, gastric aspirate, blood

Metabolic screen: urinary amino acids and organic acids, plasma ammonia and glucose

Short Synacthen test

CSF, cerebrospinal fluid; ECG, electrocardiogram; PCR, polymerase chain reaction.

Investigations (see Table 101.4) include:

- daily weighing and comparison with pre-illness weight
- close monitoring of fluid balance
- stool culture and examination for occult blood
- imaging of body cavities by CT or ultrasound for evidence of fluid or blood accumulation
- repeated full blood examination and coagulation screen
- plasma urea and electrolytes
- serum and urine osmolality

## CARDIOGENIC SHOCK

Tachycardia, hypotension, low volume pulses and signs of homeostatic compensation and poor organ perfusion (see above) are usually present. Cardiomegaly, muffled heart sounds and a gallop rhythm may be found. New murmurs may appear (e.g. mitral systolic murmur due to left ventricular dilatation with consequent mitral regurgitation, or aortic diastolic murmur due to endocarditis). Chest rales, tachypnoea and wheezing indicate left heart failure, while in right heart failure, oedema appears first in the eyelids and dorsum of hands and feet. Hepatomegaly develops rapidly in children, and is a more reliable sign of right heart failure than a raised jugular venous pressure (JVP) which may be hard to detect in infants.

**Table 101.5** Causes of cardiogenic shock in childhood

Structural congenital heart disease (qv)
Post cardiac surgery
Arrhythmia (qv)
Myocardial hypoxia/ischaemia
Cardiomyopathy
Congenital
Metabolic
Infective
Hypertrophic
Endocardial fibroelastosis
Valvular heart disease
Congenital
Infective
Rheumatic
Traumatic
Sepsis
Drug intoxication
Cardiac tamponade
Constrictive pericarditis
Trauma to myocardium or coronary arteries

Combinations of signs specific to individual congenital heart lesions are described below. Such signs when present (e.g. absent femoral pulses in aortic coarctation, or skull, liver or renal bruits of arteriovenous fistulae) may indicate the cause of the shock (Table 101.5), while diagnostically useful murmurs are not always present.

Investigations (see Table 101.4) should include:

- chest X-ray to assess heart size and lung vascularity and oedema, and to exclude pneumothorax
- electrocardiogram (ECG)
- echocardiography
- in some cases, CT or MR angiography or cardiac catheterisation

### SEPTIC SHOCK

Septic infants usually present with a hypodynamic circulation, low cardiac output and cool extremities. Early septic shock in older children may be hypodynamic, or may be similar to that in adults, in which tachycardia, tachypnoea and hypotension are accompanied by warm extremities, wide pulse pressure and increased cardiac output. Lethargy or stupor, oliguria and Kussmaul breathing characteristic of metabolic acidosis indicate inadequate tissue oxygenation.

Severely septic children are often hypothermic rather than febrile.

As shock progresses, myocardial depression by endotoxin, tumour necrosis factor- $\alpha$  (TNF- $\alpha$ ) and interleukin-1 $\beta$  (IL-1 $\beta$ ) (see Chapter 11) decreases the cardiac output earlier than is the case in adults, as the less compliant infant ventricle cannot dilate to sustain the stroke volume in the face of a reduced ejection fraction.<sup>11,12</sup> Furthermore, the rapid and severe capillary leak that is characteristic of

paediatric sepsis leads to hypovolaemia in the underresuscitated child, further reducing preload and cardiac output. For this reason, septic children often respond well to aggressive fluid resuscitation (> 60 ml/kg in the first hour). Peripheral oedema caused by leakage of proteinaceous fluid from injured capillary endothelia exacerbates cellular hypoxia by increasing the diffusion distance for oxygen between capillaries and cells.

### MULTIPLE ORGAN FAILURE IN SHOCKED CHILDREN

Shock of any cause leads to multiple organ failure, the clinical course and outcome of which differ from those in shocked adults:

- Myocardial depression, reduced ventricular diastolic compliance<sup>13</sup> and low cardiac output. Clinically important arrhythmias rarely occur.
- Acute lung injury can occur in a shocked child of any age, including the newborn. Respiratory muscle fatigue due to impaired muscle blood flow and oxygenation further reduces gas exchange.
- Acute renal failure occurs frequently, is usually reversible within 50 days, may require haemodiafiltration or peritoneal dialysis, and is rarely a significant contributor to mortality in shocked children.
- Disseminated intravascular coagulation occurs very commonly, due to activation of the coagulation pathway, increased production of plasminogen activator inhibitor-1 and reduced levels of proteins C and S, antithrombin III and thrombomodulin.<sup>14</sup> This contributes to failure of other organs, and combines with impaired liver function and clotting factor dilution by fluid resuscitation to cause bleeding from puncture sites and sometimes from the upper gastrointestinal tract.
- Bone marrow failure, with anaemia, granulocytopenia and thrombocytopenia, implies severe shock and is associated with a poor outcome, especially in sepsis.
- Gastrointestinal failure with paralytic ileus is often present. Significant upper gastrointestinal bleeding occurs less commonly in shocked children than in adults. The source is usually generalised oozing from gastric mucosa which responds to proton pump inhibitors and replacement of platelets and clotting factors.
- Plasma concentrations of liver enzymes and bilirubin are often raised but return to normal over a few days in survivors.
- Acalculous cholecystitis due to splanchnic ischaemia is sometimes found in older children.
- Encephalopathy with stupor or coma occurs commonly. The appearance of seizures suggests some complication of sepsis, such as glucose or electrolyte abnormality, meningitis, septic embolus or intracranial bleeding.

### DISTRIBUTIVE SHOCK

The main features are hypotension, vasodilatation and hypovolaemia due to plasma leakage from capillaries. The child's extremities are warm and pink, the blood

**Table 101.6** Causes of distributive shock in childhood

Sepsis
Anaphylaxis
Drugs
Neurogenic: spinal cord injury

pressure is low and the pulse pressure is wide. There is tachycardia, oliguria and stupor. Other evidence of anaphylaxis (wheezing, urticaria, swollen face or tongue), spinal cord injury (bradycardia, quadriplegia, lax anal sphincter) or drug intoxication (history, tablets, coma out of proportion to shock) may be present (Table 101.6).

#### INVESTIGATION

See Table 101.4.

#### MANAGEMENT

The child's airway, breathing (see Chapter 98) and circulation should be secured during the initial assessment. The priorities in management of the circulation are to achieve:

1. adequate perfusion of the brain and heart
2. adequate perfusion of kidneys, liver and gut
3. adequate perfusion of muscle and other tissues

#### ADEQUATE PERFUSION OF THE BRAIN AND HEART

This requires systolic and diastolic blood pressures of 80% of normal for age (see Table 101.3), achieved by aggressive early blood volume expansion and by pressor drugs. The conscious state is the best index of adequate brain perfusion, while improved coronary perfusion is shown by rising blood pressure with falling central venous pressure.

#### Preload

Intravenous fluid is given in boluses of 20 ml/kg 0.9% saline or 10 ml/kg blood or colloid, repeated every 5–10 minutes until blood pressure, heart rate and skin vasoconstriction (capillary refill time: normal < 2 seconds after 5 seconds' pressure over the sternum) and indices of organ perfusion (i.e. urine output, conscious state, blood pH and lactate) improve. Heart and liver size and increases in central venous pressure (CVP) are used to assess hypovolaemia. If more than 40 ml/kg crystalloid is given:

- consider starting an infusion of a pressor drug (sepsis and other distributive shock) or an inotrope (see below)
- monitor central venous pressure
- insert an arterial cannula for blood pressure and biochemical monitoring

Pulmonary artery catheterisation for measurement of wedge pressure and cardiac output is rarely justified in children: evidence that it improves outcome is lacking,<sup>15</sup> and side-effects occur commonly.<sup>16</sup> Non-invasive monitoring of left and right ventricular preload by transthoracic

echocardiography may be more useful than atrial pressure measurement, in that it removes the confounding factors of diastolic compliance and atrioventricular (AV) valve dysfunction, but it is subjective and operator dependent.<sup>17</sup>

#### Systemic vascular resistance

In septic or hypovolaemic shock, infusion of noradrenaline (0.05–2.0 µg/kg per min) should be started (via an intraosseous cannula when no central venous cannula is in place) if volume expansion does not achieve 80% of normal systolic blood pressure for age within 10 minutes. In septic shock, vasopressin (0.0003–0.0006 U/kg per min), the action of which does not depend on downregulated α<sub>1</sub>-receptors, may be used to reduce the dose of noradrenaline required. Vasopressin deficiency occurs commonly in septic shock<sup>18</sup> and in irreversible shock of other causes.<sup>19</sup>

#### Contractility

If the blood pressure then remains low despite CVP = 12 mmHg or 'adequate' LV filling on transthoracic echo, an inotrope such as adrenaline (0.05–2.0 µg/kg per min), dobutamine or dopamine (5–15 µg/kg per min) should be added. Dobutamine and dopamine downregulate β-adrenergic receptors, and dopamine depletes myocardial noradrenaline stores, so the dose of these drugs should be minimised as soon as possible. β-Agonists increase oxygen consumption (and therefore oxygen demand) by increasing free fatty acid cycling and by increasing glycogenolysis and glycolysis.<sup>20</sup> Dopamine suppresses prolactin, thyroid-stimulating hormone and growth hormone secretion in infants and children.<sup>21</sup>

In infants with cardiogenic shock, infusion of 10% calcium gluconate (0.2–0.5 ml/hour) can increase blood pressure and cardiac output. Serum ionised calcium should be monitored.

#### ADEQUATE PERFUSION OF KIDNEYS, LIVER AND GUT

Bowel and liver ischaemia in a shocked child impairs detoxification of drugs and toxic metabolites and may increase the risk of bacteraemia and endotoxaemia of bowel origin.<sup>22</sup> Hypovolaemia and low cardiac output must be corrected by blood volume expansion and inotropic drugs such as dobutamine. Vasoconstricting drugs (vasopressin, noradrenaline and dopamine doses > 5 µg/kg per min) should be reduced or stopped once heart and brain perfusion are secured.

Urine output > 0.5 ml/kg per hour and a normal (or falling) plasma creatinine concentration are the best indices of adequate renal perfusion. Monitoring of splanchnic perfusion remains unreliable. Gastric pH and gastric–arterial P<sub>CO<sub>2</sub></sub> difference correlate somewhat with outcome in septic children (though not as well as plasma lactate)<sup>23</sup> and are not consistently improved by measures to restore bowel perfusion.<sup>24</sup> Oesophageal–arterial P<sub>CO<sub>2</sub></sub> difference<sup>25</sup> and near-infrared spectroscopy of the liver<sup>26</sup> may offer more accurate monitoring of the adequacy of splanchnic blood flow.

**ADEQUATE PERFUSION OF MUSCLE AND OTHER TISSUES**

Further volume expansion and infusion of vasodilators such as milrinone may be needed to improve circulation to these tissues in shock states where myocardial depression is prominent, provided an adequate blood pressure (80% normal for age; see Table 101.3) can be sustained. Maintaining a supranormal cardiac output and oxygen delivery has not been shown to improve survival in paediatric shock, although the ability to do so may predict survival.

In the absence of a pulmonary artery catheter, the adequacy of upper or lower body blood flow is conventionally assessed by monitoring changes in central venous saturation<sup>27</sup> and plasma lactate, though the oxygen excess factor  $\Omega$  ( $SaO_2/(SaO_2 - SpO_2)$ ) has been used in children with intracardiac shunts.<sup>28</sup>

**Afterload reduction in cardiogenic shock**

Vasoconstrictors and blood transfusion (to achieve a haemoglobin concentration of 120 g/l) may be required at first to ensure adequate coronary and cerebral perfusion pressure. When blood pressure is adequate (see Table 101.3), the cardiac output may be improved by afterload reduction. Short-acting drugs such as milrinone or sodium nitropruside (SNP) are preferable.

Inhaled nitric oxide (NO) 1–10 ppm via the ventilator circuit may improve RV output in children with cardiogenic shock due to pulmonary hypertension (primary or after cardiac surgery or in persistent pulmonary hypertension of the newborn). Sildenafil and bosentan have been shown to reduce pulmonary vascular resistance and to permit weaning from NO in this group of children.<sup>29</sup>

Infusion of vasodilators such as nitroglycerin, prostacyclin (PGI<sub>2</sub>) and SNP reduces systemic as well as pulmonary vascular resistance. These drugs are easier to administer than NO, but are less effective pulmonary vasodilators, and they (and sildenafil and bosentan) often cause systemic hypotension.

After appropriate samples are taken for investigations (see Table 101.4), possible sepsis is treated aggressively with appropriate antibiotics (Table 101.7), replacement of invasive lines and drainage of collections of pus.

**Supportive measures**

Early mechanical ventilation secures adequate oxygenation and pH of arterial blood. It also reduces the work

**Table 101.7** Initial antibiotic therapy in children with septic shock

**Up to 8 weeks of age**

Flucloxacillin 50 mg/kg i.v. 6-hourly *plus*  
Gentamicin 6 mg/kg i.v. per day *plus*  
Cefotaxime 50 mg/kg i.v. 6-hourly

**Older child**

Flucloxacillin 50 mg/kg i.v. 6-hourly  
Gentamicin 6 mg/kg i.v. per day

of breathing and muscle oxygen demand, diverting the limited cardiac output away from muscles to vital organs. Airway pressures and tidal volumes should be limited to the minimum needed, as impaired venous return from positive-pressure ventilation will exacerbate hypotension.

Other measures include administration of platelets and fresh frozen plasma in consumptive coagulopathy, early commencement of renal support with haemodiafiltration or peritoneal dialysis in established acute renal failure and the use of H<sub>2</sub> antagonists or proton pump inhibitors to prevent upper gastrointestinal bleeding.

**Controversial measures**

- *Stress dose of hydrocortisone (4 mg/kg per day for ~5 days)*: Reduced 28-day all-cause mortality and ICU and hospital mortality in septic shock.<sup>30</sup>
- *Granulocyte-macrophage colony-stimulating factor*: A randomised trial found that it reduced mortality in severely ill septic, neutropenic newborns.<sup>31</sup>
- *Intravenous pooled polyclonal immunoglobulin (IVIG)*: Some evidence of reduced mortality from controlled trials in severe sepsis.<sup>32</sup>
- *Recombinant bactericidal permeability-increasing protein (rBPI<sub>21</sub>)*: Trend to improved functional outcome in a small trial in children with severe meningococcal sepsis.<sup>33</sup>
- *Granulocyte transfusions for severe sepsis with neutropenia*: Trend to improved outcome when combined with IVIG in a controlled trial in septic newborns.<sup>34</sup>
- *High-dose steroids after antibiotics started*: Pre-1992 trials showed no benefit.<sup>30</sup>
- *Monoclonal anti-endotoxin, anticytokine antibodies or IL-1 receptor antagonists*: No evidence of efficacy in controlled trials.<sup>32</sup>
- *Activated protein C*: No evidence of improved outcome in a controlled trial in severely septic children.<sup>35</sup>
- *Tri-iodothyronine (T<sub>3</sub>)*: No convincing evidence of improved outcome in trials in children with low cardiac output after cardiac surgery despite evidence that T<sub>3</sub> is deficient in these patients.<sup>36</sup>
- *Circulatory support with extracorporeal membrane oxygenation (ECMO)*: ECMO has been employed in children moribund with septic shock, with some survivors, but there is no convincing evidence of its efficacy.<sup>37</sup>
- *Close control of blood glucose using insulin infusion*: There is no evidence in children that it improves outcome. Infants are very vulnerable to hypoglycaemia and are sensitive to low insulin doses. Blood glucose should be monitored frequently in shocked children.

**HEART FAILURE IN CHILDREN**

In cardiac failure, the cardiac output is insufficient to meet the metabolic needs of the tissues without development of abnormally high ventricular end-diastolic volumes.<sup>38</sup>

Table 101.8 shows the main causes of heart failure in children. In many cases, several factors combine to produce heart failure (e.g. sepsis plus valve regurgitation and amiodarone).

- *Preload* may be:
  - excessive: volume loading, e.g. systemic arteriovenous malformation, large ventricular septal defect, aortopulmonary window, AV valve regurgitation or excessive fluid administration
  - inadequate: e.g. mitral stenosis, pericardial tamponade, hypertrophic cardiomyopathy or congenital hypoplasia of the left or right ventricle. Ventricular diastolic compliance may be reduced by ischaemia, postoperative myocardial oedema, sepsis, heart transplant rejection or cardiomyopathy (infiltrative or hypertrophic).
- *Excessive afterload* (ventricular systolic wall tension) may be caused by pulmonary valve stenosis or pulmonary hypertension (right ventricle); by aortic valve stenosis, aortic coarctation or hypoplasia or systemic hypertension (left ventricle); or by ventricular dilatation. (Laplace's Law:  $T = P \times R/2H$ , where T is systolic wall tension, P is ventricular pressure during systole, R is ventricular radius and H is ventricular wall thickness.)
- *Inadequate contractility*: e.g. due to myocarditis, sepsis or ischaemia.
- *Heart rate* may be:
  - too fast (e.g. in supraventricular tachycardia or atrial flutter, ventricular filling time is inadequate and myocardial work is excessive).
  - too slow (e.g. complete heart block).

### PRESENTING SIGNS

In childhood, heart failure may present with growth failure. Feeding is slow and may cause sweating and dyspnoea. Useful signs are tachypnoea, cardiomegaly, hepatomegaly, gallop rhythm, tachycardia and cool, mottled extremities. There may be clinical and X-ray signs of lung congestion, oedema and air trapping (due to airway compression by distended blood vessels and airway mucosal oedema: seen in large left-to-right shunts such as VSD). In infants, the JVP is a difficult sign to elicit. The liver enlarges rapidly as the right atrial pressure increases, and oedema is often non-pitting, and located in the eyelids and the dorsum of the hands and feet.<sup>39</sup>

### INVESTIGATIONS

After a detailed history and clinical examination, investigations include:

- *chest X-ray*: for heart size, shape, position and lung vascularity
- *electrocardiogram (ECG)* and, if necessary, Holter monitoring

**Table 101.8** Common causes of heart failure from infancy to adolescence

#### Heart failure presenting at birth

Birth asphyxia  
Sepsis  
Severe anaemia  
Obstructive left-sided lesions presenting after closure of the ductus arteriosus (e.g. coarctation, aortic stenosis, interrupted aortic arch, hypoplastic left heart syndrome)  
Aortopulmonary window, truncus arteriosus  
Systemic AV fistula (e.g. liver, brain, kidney)  
Congenital cardiomyopathy  
Arrhythmia: congenital SVT or heart block  
Persistent pulmonary hypertension of the newborn

#### Heart failure presenting in the first 8 weeks of life

Large left-to-right shunts (e.g. VSD, PDA, total anomalous pulmonary venous drainage) cause heart failure as pulmonary vascular resistance and the haematocrit decrease  
Infiltrative cardiomyopathy  
Anomalous origin of the left coronary artery from the pulmonary artery  
Hypothyroidism

#### Heart failure presenting later in childhood

Congenital heart disease  
Subaortic stenosis  
VSD with or without aortic regurgitation  
Systemic AV valve regurgitation  
Pulmonary atresia and VSD with large aortopulmonary collaterals  
Congenital heart disease post operation  
Fontan procedure  
Obstructed prosthetic valve  
Post ventriculotomy (e.g. Fallot's tetralogy)  
Coronary artery injury  
Imperfect myocardial preservation during bypass  
Valve regurgitation after aortic or pulmonary valvotomy  
Large Blalock-Taussig shunt  
Cardiomyopathy  
Infective, infiltrative, neuromuscular disease  
Asphyxia (e.g. near-drowning, smoke inhalation)  
Ischaemia (e.g. Kawasaki disease)  
Toxic: acute (e.g. eucalyptus oil, carbamazepine, verapamil, flecainide)  
Toxic: chronic (e.g. anthracycline)  
Metabolic (e.g. LCAD deficiency)  
Heart transplant rejection  
Valvular (e.g. post-rheumatic, infective endocarditis, trauma)  
Arrhythmia (e.g. SVT, complete heart block)  
Severe polycythaemia or anaemia (haematocrit > 70% or < 15%)  
Cor pulmonale (e.g. bronchopulmonary dysplasia, severe scoliosis)  
Acute hypertension (e.g. glomerulonephritis, haemolytic-uraemic syndrome)

AV, arteriovenous; LCAD, long-chain acyl-CoA dehydrogenase; PDA, patent ductus arteriosus; SVT, supraventricular tachycardia; VSD, ventricular septal defect.

- *echocardiography* (usually transthoracic; less often transoesophageal): for structural abnormality; valve stenosis, regurgitation and structure; chamber size and filling; wall thickness; pericardial fluid and estimates of ventricular systolic and diastolic function; left-to-right and right-to-left shunts, and pulmonary artery pressure
- *cardiac catheterisation* when indicated to quantify shunts, measure pressures and elucidate anatomy.

Plus other investigations as indicated:

- CT angiography to demonstrate 3-dimensional extra-cardiac structures
- MR angiography
- blood gases; chromosomal analyses; viral culture of stool, blood and throat swabs; urine screen for amino- and ketoacids, and myocardial biopsy.

#### MANAGEMENT<sup>40,41</sup>

The development of heart failure in infancy is an emergency requiring urgent hospitalisation. Management priorities include the following:

- *Correct precipitating factors* (e.g. fever, infection, anaemia or hypertension).
- *Diagnose and correct the underlying cause* (e.g. correct an aortic coarctation; repair or replace a regurgitant valve; treat an arrhythmia or infection; correct anaemia).
- *Support the systemic and pulmonary circulations* and reduce systemic and pulmonary venous congestion:
  - Give oxygen by mask or nasal prongs.
  - Give diuretics such as furosemide and spironolactone to reduce ventricular preload and venous congestion. Spironolactone has been shown to reduce mortality in adults with cardiac failure by inhibiting ventricular remodelling and improving diastolic compliance. Addition of a sulphonamide diuretic such as metolazone or hydrochlorothiazide has been shown to produce a diuresis in children with oliguria resistant to furosemide after cardiac surgery.<sup>42</sup> Restriction of fluid and salt intake, head elevation and venodilator drugs such as nitroglycerin (GTN) 1–10 µg/kg per min may be required. Preload reduction may depress the cardiac output in acute correctable lesions which obstruct ventricular inflow (e.g. cardiac tamponade).
  - Reduce left ventricular afterload by infusion of milrinone (0.25–0.75 µg/kg per min) or sodium nitroprusside (0.5–5.0 µg/kg per min). Angiotensin-converting enzyme (ACE) inhibitors may be added carefully when the child's heart is capable of increasing its output to sustain an adequate blood pressure. ACE inhibitors reduce mortality in early and late heart failure by improving ventricular performance and inhibiting myocardial remodelling. Vasodilators must be used cautiously in obstructive left-sided lesions to avoid myocardial ischaemia

(due to reduced aortic diastolic pressure in the presence of ventricular wall hypertrophy. Vasodilators exacerbate volume loading in VSD or aortopulmonary shunts.

- Reduce right ventricular afterload in intubated children with nitric oxide (NO) (0.5–10.0 ppm). In non-ventilated children, and to permit weaning of nitric oxide, sildenafil (0.3 mg/kg 6-hourly enterally) or infusion of prostacyclin (PGI<sub>2</sub> 5–15 ng/kg per min) may be used.<sup>29,43</sup>
- Increase contractility acutely with i.v. infusion of dobutamine (2–10 µg/kg per min) or adrenaline (0.02–0.5 µg/kg per min). β-adrenergic agonists increase oxygen consumption, myocardial work and ventricular diastolic stiffness, and may provoke tachyarrhythmias. They should therefore be used in the lowest effective dose.
- Levosimendan infusion (12.5 µg/kg over 10 minutes, then 0.2 µg/kg per min for 24 hours) has been shown to improve haemodynamics and 31-day survival compared with dobutamine in adults with severe heart failure, even when combined with β-blockers.<sup>44</sup> It offers improvement in contractility without increasing myocardial oxygen consumption or downregulating β-receptors.
- Consider careful use of β-blockers when diastolic dysfunction is prominent and when the child's circulation is sufficiently stable for β-agonists to be withdrawn. If the child tolerates infusion of a short-acting drug such as esmolol (50 µg/kg per min gradually increased to 200 µg/kg per min), a longer-acting agent such as carvedilol may be substituted.<sup>45</sup>
- *Mechanical ventilation* improves myocardial performance by improving gas exchange and reducing acidemia, work of breathing and left ventricular afterload.<sup>46</sup> When pulmonary hypertension is the main cause of heart failure, intubation and mechanical ventilation can improve RV output by improving gas exchange and allowing NO to be given, but a short inspiratory time and low positive end-expiratory pressure (PEEP; 4–5 cmH<sub>2</sub>O) are used to avoid further raising pulmonary vascular resistance.
- *Sedation and muscle relaxants* reduce metabolic rate and the cardiac output needed to meet metabolic demands. In a child with severe heart failure, commencing an inotrope such as dobutamine 10 µg/kg per min via peripheral cannula if necessary, 30 minutes before intubation reduces the risk of severe hypotension during intubation.
- *Ventricular assist devices (VAD)* can maintain life for weeks to months in very severe but reversible cardiac failure pending ventricular recovery or heart transplantation. When severe respiratory failure complicates severe heart failure, ECMO may be needed. Aortic balloon counterpulsation is less feasible and much less often helpful in small children than in adults.

## CONGENITAL HEART DISEASE

Children critically ill with congenital heart disease (CHD) often require urgent resuscitation before a definitive structural diagnosis is made. The appropriate management then depends on the mode of presentation. A paediatric cardiologist should be consulted immediately about all such children. Management of acute postoperative deterioration depends on the underlying condition, nature of surgery and cause of deterioration.

Congenital heart disease in children may present in the following ways.

### SHOCK IN THE FIRST FEW DAYS OF LIFE<sup>47</sup>

The commonest CHD causes are obstructive lesions of the left heart, including coarctation of the aorta with or without VSD, aortic stenosis and hypoplastic left heart syndrome (HLHS). Differential diagnosis includes cardiomyopathy, systemic arteriovenous malformation (AVM), septicaemia, inborn error of metabolism, anaemia, congenital heart block and supraventricular tachycardia (SVT).

In left-sided obstructive lesions, shock develops as the ductus arteriosus closes. All pulses (especially the femoral pulses in the case of coarctation) are decreased or absent. Tachycardia, tachypnoea, oliguria, cool mottled extremities, metabolic acidosis, hepatomegaly, cardiomegaly and pulmonary oedema are often present. Murmurs are often absent.

Emergency management<sup>48</sup> consists of prostaglandin E<sub>1</sub> infusion (start at 10 ng/kg per min and increase to 25 if necessary) to provide aortic blood flow from the pulmonary artery by opening the ductus arteriosus, dopamine infusion, NaHCO<sub>3</sub> 1 mmol/kg i.v. over 1 hour to correct metabolic acidosis, and mechanical ventilation (to reduce work of breathing, maintain normocarbica and prevent apnoea due to the PGE<sub>1</sub>). Hypocarbica and a high *F*iO<sub>2</sub> should be avoided as they reduce pulmonary vascular resistance and divert blood flow to the lungs, thereby reducing systemic blood flow. Normoglycaemia and normocalcaemia should be maintained.

### ACYANOTIC HEART FAILURE

#### IN THE FIRST WEEK OF LIFE<sup>47</sup>

Coarctation, aortic stenosis, cardiomyopathy (including obstructive cardiomyopathy in an infant of a diabetic mother) and endocardial fibroelastosis, anaemia, septicaemia, overtransfusion and systemic AVM can present as heart failure. Signs include poor feeding, tachycardia, tachypnoea, sweating, hepatomegaly, cardiomegaly, gallop rhythm, alar flaring, wheezing and expiratory grunt. Femoral pulses may be absent in coarctation and bruits are audible in skull, liver or kidneys in AVM. An aortic flow murmur may be present in anaemia or AVM.

Emergency management includes oxygen, diuretics and fluid restriction (to 50% of maintenance requirements; see Chapter 99). In severe failure, mechanical ventilation

and inotropic drug infusion (see above) are started, and the child is transferred to a paediatric cardiac centre. When femoral pulses are absent or if aortic stenosis is suspected, i.v. infusion of PGE<sub>1</sub> (5–25 ng/kg per min) is started.

#### AFTER 2–8 WEEKS OF AGE

Systolic murmurs and signs of heart failure appear in infants with left-to-right shunts (such as VSD, patent ductus arteriosus (PDA), aortopulmonary window and AV septal defect) due to the physiological decreases in haemoglobin concentration and pulmonary vascular resistance at this time.

Emergency management includes diuretics and oxygen given via nasal prongs. Transfusion (to haemoglobin 13–14 g/dl) may reduce left-to-right shunt. If these measures fail to control heart failure, surgery is often needed, preceded if necessary by mechanical ventilation and inotropic drug infusion (see above).

### CYANOSIS

*P*aO<sub>2</sub> greater than 150 mmHg (20 kPa) breathing 100% oxygen almost completely rules out cyanotic CHD. Most cyanotic CHDs have a *P*aO<sub>2</sub> less than 60 mmHg (8 kPa). A chest X-ray should be obtained urgently. Cyanosis due to CHD occurs when:

- pulmonary blood flow is reduced (e.g. pulmonary atresia)
- pulmonary and systemic circulations are not in series but are separate (e.g. transposition of the great arteries)
- saturated and unsaturated blood mix in the heart (e.g. anomalous pulmonary venous drainage)

#### CYANOSIS WITH PULMONARY OLIGAEMIA ON CHEST X-RAY

This is usually caused by stenosis at, below or above the pulmonary valve, or by tetralogy of Fallot. Deep cyanosis is present, often without murmurs or with a pulmonary ejection murmur. Tachypnoea may be present. Chest X-ray shows paucity of lung vessels and concavity in the pulmonary artery segment of the left heart border.

#### Emergency management<sup>47,49</sup>

**In the newborn** PGE<sub>1</sub> infusion (5–25 ng/kg per min) is used to open the ductus arteriosus and increase pulmonary blood flow. *F*iO<sub>2</sub> of 0.5 gives a small increase in oxygen delivery, and NaHCO<sub>3</sub> is used to correct a metabolic acidosis. Gentle assisted ventilation is needed if PGE<sub>1</sub> causes apnoea. The lungs are very compliant and airway pressures above 12–15 cmH<sub>2</sub>O further reduce lung blood flow. The haemoglobin concentration should be kept at 120–150 g/l by transfusion if necessary. The child needs urgent echocardiographic diagnosis and most need a Blalock–Taussig shunt.

**Beyond 1 month of age** If the *P*aO<sub>2</sub> is less than 30 mmHg (4.0 kPa), or if cyanotic spells occur in a child with tetralogy of Fallot despite plasma volume expansion

and oral  $\beta$ -blockers, an urgent Blalock–Taussig shunt is needed. Urgent treatment of Fallot spells consist of high  $F_{iO_2}$ , knee–chest (older child) or legs raised (infant) position, 0.9% saline infusion 20 ml/kg and i.v. morphine 0.1 mg/kg. If these measures fail, then esmolol (0.5 mg/kg i.v. then infusion of 50–200  $\mu$ g/kg per min) may be needed to reduce subpulmonary obstruction in Fallot’s tetralogy. Inotropic drugs and vasodilators should be avoided.

#### CYANOSIS WITH PULMONARY PLETHORA OR OEDEMA IN THE NEWBORN<sup>47</sup>

The commonest cardiac causes are transposition of the great arteries (TGA), single ventricle, HLHS, truncus arteriosus and total anomalous pulmonary venous drainage (TAPVD). Signs include tachypnoea, tachycardia, cardiomegaly and hepatomegaly. A murmur may be present. Differential diagnosis includes lung disease such as hyaline membrane disease and neonatal pneumonia, group B streptococcal sepsis and persistent pulmonary hypertension of the newborn.

#### Emergency management

Acidaemia should be corrected and  $F_{iO_2}$  should be high. If heart failure is present, mechanical ventilation and dobutamine infusion are used. PGE<sub>1</sub> infusion (5–25 ng/kg per min) is used in all cases except when a small heart accompanies cyanosis and pulmonary oedema. These signs suggest TAPVD with obstruction of the pulmonary veins, in which case PGE<sub>1</sub> will exacerbate the pulmonary oedema. Assessment at a paediatric cardiac centre is needed urgently. A child with TGA needs balloon atrial septostomy and the other lesions need urgent surgery.

### ARRHYTHMIAS IN CHILDREN<sup>50</sup>

#### SINUS BRADYCARDIA (SEE TABLE 101.3: 2ND–98TH CENTILE OF NORMAL HEART RATE FOR AGE)

Predisposing conditions include normal sleep, hypoxaemia, acidosis, hypotension, high intracranial pressure, cervical spinal cord injury, tracheal suction and drugs such as  $\beta$ -blockers, amiodarone and digoxin.

#### MANAGEMENT

No treatment is needed for asymptomatic bradycardia unless it is extreme. Correct any reversible cause. If the sinoatrial node is damaged, atropine (20  $\mu$ g/kg) or isoprenaline infusion (0.1–0.5  $\mu$ g/kg per min) or temporary transoesophageal or (in an older child) transvenous pacing may be used.

#### BRADYCARDIA–TACHYCARDIA (SICK SINUS) SYNDROME<sup>51</sup>

The usual form is severe sinus bradycardia with junctional escape rhythm. It can cause syncope and even sudden death. Predisposing conditions include:

- congenital atrial anomalies (e.g. Ebstein’s anomaly and AV septal defects)
- extensive atrial surgery (e.g. Fontan and Senning operations)
- viral myocarditis
- congenital sinus node dysfunction

#### MANAGEMENT

Atrial pacing then treat tachyarrhythmias on their merits.

#### ATRIOVENTRICULAR BLOCK<sup>52</sup> (TABLE 101.9)

Often asymptomatic, but may present with fatigue, syncope or cardiac failure.

#### MANAGEMENT

- *Acquired complete heart block* should be paced, regardless of symptoms, as escape rhythms are unreliable.
- *Symptomatic second or third degree AV block* requires i.v. atropine, isoprenaline infusion (0.1–0.5  $\mu$ g/kg per min) and, if necessary, external cardiac massage until pacing is established. Temporary transoesophageal or (in an older child) transvenous pacing may precede insertion of a permanent pacemaker.
- *Congenital in infants*: temporary, then permanent pacing if the heart rate is < 55 beats/min, regardless of symptoms.
- *Congenital in an older child*: temporary, then permanent pacing if the heart rate is < 50 beats/min or if symptomatic, or if there are ventricular escape beats or ventricular dysfunction.

#### SUPRAVENTRICULAR TACHYCARDIA (SVT)

##### RE-ENTRANT SVT

In younger children, an accessory AV pathway is usually present, which may conduct antegrade (pre-excitation, e.g. Wolff–Parkinson–White (WPW)) or retrograde (no pre-excitation; normal QRS). These AV re-entrant tachycardias may be episodic (e.g. precipitated by an extrasystole or a junctional escape beat) or may be permanent. The latter may be associated with heart failure in infants.

In older children and adolescents, a re-entrant pathway may exist in the peri-AV node area, and is sometimes

Table 101.9 Causes of atrioventricular block

Normal variant in newborn, adolescents, athletes
Structural heart abnormalities (atrioventricular septal defects or left atrial isomerism)
Post cardiac surgery (e.g. repair of ventricular septal defect or Fallot’s tetralogy, Konno procedure)
Maternal antibodies
Cardiomyopathies, myocarditis (including rheumatic) and muscular dystrophies
Drugs (e.g. carbamazepine overdose)

associated with congenital heart lesions such as Ebstein's anomaly, tricuspid atresia and AV canal defects, as well as post cardiac surgery, myocarditis, drugs, sepsis, acidosis and catecholamine administration.

### Management

#### Infants

- *If shocked:*
  - Give O<sub>2</sub> by mask
  - Sedation: i.v. midazolam (0.05–0.1 mg/kg i.v.)
  - Synchronised DC cardioversion 1 joule/kg
- *If stable:*
  - Vagal stimulation: induce gag reflex or apply ice water to the whole face for ~30 seconds. Do not use eyeball pressure.
  - Overdrive atrial pacing via transoesophageal or epicardial leads
  - Adenosine by rapid i.v. bolus 0.05 mg/kg (max 3 mg) increasing by 0.05 mg/kg (max 3 mg) every 2 minutes to a maximum of 0.25 mg/kg (max 12 mg)
  - Synchronised DC cardioversion 1 joule/kg. Record ECG during reversion to sinus rhythm, as pre-excitation may only be revealed at that time
  - Consider amiodarone or (provided WPW is absent) digoxin
  - Avoid verapamil which causes shock and cardiac arrest in infants

#### Older children

- As above.
- Verapamil (0.1 mg/kg i.v. over 30 minutes) or atenolol (0.05 mg/kg i.v. every 5 minutes until response, maximum of 2.5 mg or four doses, then 0.1 mg/kg every 12–24 hours) may also be used.

### JUNCTIONAL ECTOPIC TACHYCARDIA (JET)<sup>50,52</sup>

Atrioventricular dissociation and ventricular rate 160–290 beats/min with narrow QRS complexes are seen on ECG. JET usually follows cardiac surgery, especially when myocardial function is poor and when surgery involves the AV node or its blood supply (e.g. Fontan operation or repair of VSD or AV septal defect). Postoperative JET can be fatal, but is usually self-limiting after 12–72 hours.

### Management

- Reduce  $\beta$ -adrenergic stimulation: use low-dose nor-adrenaline or vasopressin to maintain blood pressure. Avoid the use of pancuronium as a muscle relaxant.
- Induce hypothermia to 34–35 °C for 2–3 days with 12-hourly brief normothermia to allow assessment.
- Amiodarone infusion: 25  $\mu$ g/kg per min for 4 hours, then 5–5  $\mu$ g/kg per min (max 1.2 g/24 hours).
- Consider procainamide (400  $\mu$ g/kg per min for 25 minutes, then 20–80  $\mu$ g/kg per min) or propafenone (2 mg/kg over 2 hours i.v., then 4  $\mu$ g/kg per min): beware of hypotension.

JET is usually resistant to vagal manoeuvres, adenosine and overdrive pacing.

### VENTRICULAR ECTOPIC BEATS AND VENTRICULAR TACHYCARDIA

Ventricular tachycardia (VT)<sup>51</sup> is uncommon in childhood, but may present as syncope, poor feeding (in infants) or heart failure. The rate is 120–300 beats/min. The QRS axis is different from that of the underlying sinus rhythm. QRS duration is usually (but not always) prolonged (> 0.08 seconds). Supraventricular tachycardia with aberrant conduction is rare in children: more than 90% of wide-complex tachycardias in children are VT. Fusion or capture beats, AV dissociation and new bundle branch block also favour the diagnosis of VT.

Predisposing conditions include congenital heart lesions and their surgery (e.g. aortic and subaortic stenosis, with hypertrophy of the left ventricular wall), myocardial ischaemia, mitral valve prolapse, myocarditis, cardiomyopathy, the hereditary long QT syndromes, blunt chest trauma, hypokalaemia or hypomagnesaemia and drug toxicity (including digoxin, cocaine, phenothiazines and tricyclic antidepressants).

### MANAGEMENT<sup>50</sup>

Synchronised DC cardioversion should be used for any child with haemodynamic compromise due to VT.

Occasionally, i.v. lidocaine (1 mg/kg) or procainamide (see above) are used to convert VT to sinus rhythm when the cardiac output is adequate. These drugs or amiodarone (see above) are also used to prevent reversion to VT after DC cardioversion. In these circumstances, serum K<sup>+</sup> should be kept above 4.5 mmol/l, and serum Mg<sup>++</sup> above 1.0 mmol/l.

# Neurological emergencies in children

Anthony J Slater

Neurological emergencies are the most common life-threatening emergencies in children. In developed societies after the first year of life, the leading cause of death in childhood is injury, particularly traumatic brain injury. There is a range of conditions affecting the brain, spinal cord and peripheral nervous system that require prompt recognition, resuscitation and definitive management. The pathophysiology, clinical features, treatment and outcome of these acute neurological emergencies are influenced by several important differences between adults and children. These differences include response to injury, developmental maturity and capacity for growth and recovery.

## **PATHOPHYSIOLOGY OF BRAIN INJURIES IN CHILDREN**

Brain injuries are usually caused by a primary event (e.g. trauma, ischaemia, infection or metabolic disturbance) and are frequently accompanied by secondary injuries including oedema, altered cerebrovascular autoregulation, tissue hypoxia or other cytotoxic events. It is unlikely that therapy administered after the event will influence the outcome of the primary injury. However, appropriate resuscitation and treatment and the avoidance of iatrogenic complications may prevent or reduce the impact of secondary injuries.

Features of brain injury particular to the paediatric patient are described below.

### **DIFFUSE CEREBRAL SWELLING**

Diffuse brain swelling in the absence of oedema is a frequent early finding in paediatric brain injury, and is due to generalised cerebral vasodilatation. It often resolves in 1–2 days if there is no other significant brain injury. With more severe primary traumatic injury, diffuse cerebral swelling may be accompanied by areas of contusion, multifocal petechial haemorrhage and vasogenic oedema that progress over several days.

### **CEREBRAL BLOOD FLOW AND METABOLISM**

The cerebral perfusion pressure (CPP) represents the difference between mean arterial pressure (MAP) and intracranial pressure (ICP).

$$\text{CPP} = \text{MAP} - \text{ICP}$$

If autoregulation is disturbed as part of the illness, CPP becomes the major determinant of cerebral blood flow, particularly in areas with more severe damage. The ideal CPP in childhood is not known. The normal range of MAP varies with age from 40 mmHg in a term neonate to 90 mmHg in an adult. The target CPP is usually adjusted with age, taking into consideration the normal blood pressure for age. For example, for an adolescent patient, therapy may be directed at maintaining a CPP of 70 mmHg, while for a child aged 5 years, the aim may be to maintain a CPP of 50 mmHg.

In conditions where vasogenic oedema occurs, arterial hypertension may increase vascular shift of fluid and worsen brain swelling. However, treatment aimed at lowering arterial pressure (e.g. with vasodilators) may interfere with homeostatic mechanisms and should be used cautiously.

The brain comprises up to 12% of body weight in infancy compared with 2–3% in adulthood. Cerebral oxygen and glucose consumption is therefore proportionately greater in childhood while glycogen stores are readily depleted. As hypoglycaemia occurs commonly in severe illnesses such as sepsis, blood glucose should be monitored regularly.

### **HYPOVOLAEMIA**

Children have small blood volumes and commonly develop hypovolaemia from scalp bleeding or intracranial haemorrhage. For example, hypovolaemia will develop in a 5-kg infant (blood volume 400 ml) following blood loss of only 100 ml. Hypovolaemia should be treated aggressively with fluid boluses of 20 ml/kg to ensure adequate cerebral perfusion.

### **RELATIVE GROWTH**

The child's short stature and proportionately large head confer a number of risks. The toddler's head is at the level of the front of a motor vehicle and isolated head injury is subsequently common following pedestrian injury in this age group. The neck muscles are relatively weak in infancy and they support a large head. This renders the brain prone to deceleration injury in motor vehicle crashes and in cases of domestic violence. Injury inflicted by shaking an infant by the shoulders snaps the head to and fro, leading to compression of brain tissue and rupture of delicate bridging veins.

### BONE DEVELOPMENT

The skull bones in the first year of life are thin with open sutures and open fontanelles. Beyond 2 years, the skull sutures close and the cranial vault thickens. In young children there tends to be less bony protection from high impact trauma, while the non-rigid skull may expand to partially decompress expanding lesions.<sup>1</sup>

### UNDIAGNOSED COMA

An ordered approach to diagnosis and treatment is required for a child with depressed conscious state of unknown origin. This approach must consider common life-threatening and rare treatable diseases (Table 102.1).

### INITIAL MANAGEMENT

Management should always begin with rapid assessment of the adequacy of airway, ventilation and circulation. If inadequacies are detected, interventions aimed at correcting them should occur immediately. Once venous access is obtained, blood should be drawn for routine tests including immediate measurement of blood glucose. If hypoglycaemia is demonstrated 2 ml/kg of 25% glucose or 5 ml/kg of 10% glucose should be given intravenously as the neurological sequelae of unrecognised hypoglycaemia can be profound.

Concurrent with the initial assessment and resuscitation, relevant details of the present and past history should be obtained. A detailed neurological and general physical examination should be performed. It is important to document accurately the conscious state so that changes over time, particularly deterioration, can be easily recognised. The Glasgow Coma Scale (GCS) is appropriate for this

purpose. The responses of children change with development and therefore the GCS requires modification for paediatric use (Table 102.2). After completing the clinical assessment, the likely diagnosis is often apparent and appropriate investigation and treatment can commence. Multiple factors may compound to produce coma. For example, a child with severe gastroenteritis may have hyperthermia, hyponatraemic dehydration, metabolic acidosis and hypovolaemic shock.

### CONTROLLED VENTILATION

Indications for ventilating a comatose child are:

- upper-airway obstruction or loss of airway reflexes
- apnoea, respiratory failure
- rapidly worsening coma
- signs of progressive elevation of ICP (i.e. bradycardia, hypertension, abnormal pupillary light reflexes and localising signs)

Once ventilation is initiated the stomach should be drained with a gastric tube and blood pressure checked every 5 minutes. Raised ICP should be considered in any case of rapidly progressive coma. Intracranial hypertension should be managed with moderate hyperventilation and intravenous mannitol (0.25 g/kg). Hypertonic saline given as 0.5 ml/kg of 20% solution (3.4 mmol/ml) can also rapidly reduce ICP.<sup>2</sup> Once stability is achieved, adequate sedation and analgesia is required. Muscle relaxants may be necessary to facilitate ventilation and prevent straining; however, their use precludes further neurological assessment and therefore, if long-acting muscle relaxants are continued, ICP monitoring is advisable. Hyperventilation is a short-term manoeuvre and following the early resuscitation phase, gradual return to a low-normal  $P_{aCO_2}$  should be the aim. This is best achieved with end tidal  $CO_2$  and ICP monitoring. Particular attention should be paid to restoring intravascular volume and maintaining an adequate CPP.

Table 102.1 Causes of coma in children

Structural	Metabolic
Trauma	Post-ictal state
Accidental	Infection
Inflicted	Meningitis
Hydrocephalus	Encephalitis
Haemorrhage	Drugs and toxins
AVM	Hypoxia–ischaemia
Aneurysms	Circulatory shock
Tumour	Biochemical
Tumour	Hypoglycaemia
Cerebral abscess	Electrolyte disorders
	Sodium/water
	Calcium
	Acid–base disturbance
	Hyperthermia
	Hepatic failure
	Haemolytic–uraemic syndrome
	Inborn errors of metabolism
	Reye's syndrome

### CRANIAL COMPUTED TOMOGRAPHY (CT)

A CT scan is required in comatose children with localising signs and in those in whom the diagnosis is not clear. A CT should also be performed if the conscious state is abnormal and there is a history of trauma. Even if the general condition does not warrant controlled ventilation, a CT is often best performed under general anaesthesia. Unwanted movement will cause poor-quality images and sedation alone may place the child at risk of hypoventilation or aspiration.

### LUMBAR PUNCTURE

Lumbar puncture (LP) should be performed when there is reasonable suspicion of meningitis or encephalitis. The risks and contraindications to LP are discussed under bacterial meningitis.

**Table 102.2** Glasgow Coma Scale for children

Glasgow Coma Scale (4–15 years)		Child's Glasgow Coma Scale (< 4 years)	
Response	Score	Response	Score
Eye opening		Eye opening	
Spontaneously	4	Spontaneously	4
To verbal stimuli	3	To verbal stimuli	3
To pain	2	To pain	2
No response to pain	1	No response to pain	1
Best motor response		Best motor response	
Obeys verbal command	6	Spontaneous or obeys verbal command	6
Localises to pain	5	Localises to pain or withdraws to touch	5
Withdraws from pain	4	Withdraws from pain	4
Abnormal flexion to pain (decorticate)	3	Abnormal flexion to pain (decorticate)	3
Abnormal extension to pain (decerebrate)	2	Abnormal extension to pain (decerebrate)	2
No response to pain	1	No response to pain	1
Best verbal response		Best verbal response	
Orientated and converses	5	Alert, babbles, coos, words to usual ability	5
Disorientated and converses	4	Less than usual words, spontaneous irritable cry	4
Inappropriate words	3	Cries only to pain	3
Incomprehensible sounds	2	Moans to pain	2
No response to pain	1	No response to pain	1

### ADDITIONAL INVESTIGATIONS

Additional investigations include arterial blood gas analysis, serum electrolytes, glucose, urea and creatinine, liver function tests, serum ammonia, serum and CSF lactate and pyruvate, and urine analysis. Appropriate screening of blood and urine will exclude common poisons and drug intoxications.

### SPECIFIC TREATMENT

The clinical signs and results of investigations generally guide treatment. If hypoglycaemia occurs, after initial correction, care should be taken to ensure that it does not recur by the administration of appropriate glucose containing i.v. fluid and regular blood glucose monitoring. Herpes simplex encephalitis can present in many ways and is not excluded by the absence of CSF pleocytosis. Aciclovir therapy should therefore be considered in any patient in whom herpes cannot be confidently excluded.

### STATUS EPILEPTICUS

Convulsive status epilepticus (CSE) is usually defined as a continuous convulsion lasting 30 minutes or longer or repeated convulsions lasting 30 minutes or longer without recovery of consciousness between convulsions.<sup>3</sup> The common causes of CSE in children are:

- prolonged febrile convulsion
- epilepsy associated with first presentation, anticonvulsant withdrawal or intercurrent illness, often with fever
- central nervous system infection (i.e. meningitis or encephalitis)

- metabolic disturbance (e.g. hypoglycaemia, hyponatraemia, hypocalcaemia)
- trauma, including inflicted injury

### PATHOPHYSIOLOGY

Many physiological changes occur during prolonged seizures. There is an initial phase of compensation lasting less than 30 minutes. Following a period of transition there is a phase of decompensation commencing between 30 and 60 minutes and evolving over hours. Physiological changes during the compensated phase include tachycardia, hypertension, increased catecholamine release and increased cardiac output. Changes within the brain include increased cerebral blood flow and increased cerebral utilisation of glucose and oxygen. After 30–60 minutes the mechanisms for homeostatic compensation fail. During the decompensated phase there may be falling blood pressure and cardiac output, hypoglycaemia, hypoxia, acidosis, electrolyte disturbance and rhabdomyolysis. The cerebral physiology is characterised by failing autoregulation and reduced cerebral blood flow and oxygen and glucose utilisation. Over hours a deficit in brain energy develops and this is associated with the development of brain damage.<sup>4</sup>

### EXCITATORY AMINO ACIDS AND BRAIN INJURY

Mesial temporal sclerosis is the most common acquired brain lesion following CSE. There is evidence that the accumulation of a number of excitatory and inhibitory amino acids have a role in the pathophysiology of neuronal injury. In particular, glutamate accumulation and

stimulation of NMDA receptors (*N*-methyl-D-aspartate) leads to an influx of intracellular calcium, which triggers a number of cytotoxic events and ultimately cell death.<sup>5</sup>

### MANAGEMENT

The initial management is as for other neurological emergencies with attention to airway and oxygenation. Most seizures in childhood cease spontaneously in a short time, but if they persist for 5 minutes or continue after presentation to an emergency department, they should be stopped to avoid metabolic and ischaemic neuronal damage. Hypoglycaemia should be excluded or detected early. If intravenous access cannot be obtained rapidly, drugs can be administered intramuscularly, intranasally, rectally or via the intraosseous (i.o.) route. If benzodiazepines are administered within 20 minutes of a seizure commencing, the rate of seizure control is higher than if they are administered after 30 minutes.<sup>6</sup> This justifies early prehospital administration of benzodiazepines to children with active seizures at the time of ambulance arrival.<sup>7</sup> Specific drug treatment includes the following.

#### BENZODIAZEPINES

Diazepam, midazolam and lorazepam are the most useful agents.

Diazepam is given initially as 0.2 mg/kg i.v./i.o., and repeated up to 0.5 mg/kg. If venous access cannot be secured, it can be given per rectum. The recommended rectal dose is higher than the intravenous dose (0.5 mg/kg p.r.). Excessive sedation and respiratory depression occur with larger doses and must be dealt with effectively.

Lorazepam (0.05–0.1 mg/kg i.v.) may have advantages over diazepam as it is as effective, has a longer half-life, and causes less respiratory depression.<sup>8,9</sup>

Midazolam and clonazepam are also effective. When i.v. access is not available, intramuscular or intranasal administration of midazolam is an alternative to rectal diazepam.<sup>10–12</sup> In children presenting to an emergency department still convulsing, 0.2 mg/kg i.m. of midazolam has been reported to control 83% of seizures within 5 minutes of administration and 93% of seizures within 10 minutes.<sup>13</sup> Midazolam has also been used by constant i.v. infusion (1–8 µg/kg per min) to control refractory CSE in children.<sup>14–16</sup>

#### PHENYTOIN

Phenytoin should be commenced if benzodiazepines are not effective. It is given as 20 mg/kg i.v. over 30 minutes, which is followed by a maintenance dose (4 mg/kg 8-hourly past the neonatal period). It causes minimal sedation or respiratory depression, but is not suitable in neonates and in patients who are already on maintenance doses. As it is given slowly, phenytoin will not have rapid effects and if generalised CSE persists, consideration should be given to the use of thiopental (see below). Fosphenytoin, a prodrug of phenytoin, can be administered i.m. or i.v., but has a less irritant effect when given

i.v.<sup>17</sup> Its place in the management of CSE in children is not yet clear.<sup>18</sup>

#### PHENOBARBITAL

When phenytoin is contraindicated, phenobarbital (20 mg/kg i.v. over 30 minutes) should be given. Respiratory depression and hypotension occur, particularly after benzodiazepines. Further doses can be safely administered to the ventilated child who has ongoing seizures.

#### THIOPENTAL

If seizures are prolonged and are not controlled by benzodiazepines, thiopental 2–5 mg/kg slowly i.v., then 1–5 mg/kg per hour by continuous infusion into a central vein can be given. Appropriately skilled staff and suitable equipment are necessary as thiopental necessitates endotracheal intubation and mechanical ventilation, and possibly inotropic drugs to counter its myocardial depressant effects. Blood concentrations need to be monitored during prolonged use. Whenever muscle relaxants are used they should be short acting to ensure ongoing seizure activity is not masked. Seizures are only controlled by anaesthetic doses of thiopental.

#### PARALDEHYDE

In many centres rectal paraldehyde (0.4 ml/kg mixed with an equal quantity of olive oil) is frequently used in the management of CSE.<sup>18</sup> One advantage of paraldehyde is that, like diazepam, it can be administered rectally if i.v. access is difficult to obtain.

#### OTHER MANAGEMENT

The patient must be protected from self-injury during seizures. Severe respiratory and metabolic acidosis are common and are best managed by rapid control of the seizure and maintenance of adequate ventilation and oxygenation. Once seizures are controlled, the cause should be sought. A detailed history is invaluable. A CT scan should reveal structural lesions. An LP should be deferred if the child is unconscious after a seizure. However, if the conscious state improves and there are no signs of raised ICP (see below), an LP will confirm or exclude meningitis. When the diagnosis remains unclear, viral encephalitis (e.g. herpes, enterovirus), metabolic encephalopathy, poisoning and inflicted injury should be considered.

#### OUTCOME

The outcome of CSE is dependent on the aetiology. Neurologically normal children in whom CSE is precipitated by fever are considered to have a good prognosis with mortality reported between 0 and 2%.<sup>19</sup> The incidence of neurological deficits or cognitive impairment in this group is also very low.<sup>5</sup> In acute symptomatic CSE (where CSE is a symptom of an acute neurological process such as infection or trauma), mortality is 12–16% and the incidence of new neurological dysfunction is more than 20%.<sup>19</sup> In this setting, however, it is very difficult to tease

out the extent to which prolonged seizures contribute to neurological sequelae.

## BACTERIAL MENINGITIS

### PATHOPHYSIOLOGY

Bacterial meningitis (BM) usually occurs following haematogenous spread of organisms carried in the nasopharynx. In childhood the common bacteria causing BM are *Streptococcus pneumoniae*, *Neisseria meningitidis* and *Haemophilus influenzae* type b (Hib). Group B *Streptococcus*, *Escherichia coli* and *Listeria monocytogenes* are the most common causative organisms of neonatal BM. Occasionally, meningitis occurs as a complication of other pathology such as base of skull fracture, chronic middle ear infection or infection of a congenital dermoid sinus.

In the early stages of the disease cerebral hyperaemia occurs. This can be followed by cerebral ischaemia, which may occur by several different mechanisms. Local vasculitis of vessels transverse the subarachnoid space can progress to arterial thrombosis and focal infarction. Other vascular abnormalities including vasospasm and sagittal sinus thrombosis can also occur. Cerebral oedema is relatively common in meningitis and is caused by a combination of vasogenic, cytotoxic and hydrostatic factors. If cerebral oedema is severe, raised ICP and impaired cerebral perfusion can occur, leading to global cerebral ischaemia.

### CLINICAL FEATURES

In children the typical features of BM are fever, headache, photophobia, neck stiffness and vomiting. The history may extend over several days; however, in fulminant cases the time from first symptom to coma and death may only be a few hours. Neonates and young infants do not present with the typical localised symptoms and signs. Instead, they present with generalised signs of illness including lethargy, poor feeding and pallor. Generalised or focal convulsions or apnoea may be present at presentation. Tuberculous meningitis usually presents with a more insidious onset of symptoms and may be associated with focal neurological signs.

Complications occur commonly in BM. During the early phase, meningitis may be associated with septic shock and disseminated intravascular coagulation (DIC). Fluid and electrolyte abnormalities are relatively common, particularly hyponatraemia and hypoglycaemia. Focal and generalised convulsions are relatively common and may progress to status epilepticus. During the recovery phase subdural effusions or hydrocephalus may occur.

### INVESTIGATIONS

Lumbar puncture for CSF microscopy, culture and bacterial antigen testing is required for definitive diagnosis of BM and to guide antibiotic therapy. While an LP can be

performed safely in the majority of children with BM, LP may precipitate brainstem herniation if raised ICP is present.<sup>20</sup> Identifying children at risk of this complication is difficult, so it is generally recommended that empiric antibiotic therapy be commenced and LP deferred if any of the following clinical features are present:

- depressed conscious state
- decorticate or decerebrate posturing
- focal neurological signs
- other signs of raised ICP

A normal CT scan does not exclude the possibility of elevated ICP.<sup>20</sup> Therefore, the decision to defer an LP should be based on clinical rather than radiological signs. In addition to signs of increased ICP, other indications for deferring the LP include cardiorespiratory instability and severe coagulopathy.

If LP is deferred, alternative methods of establishing a bacterial diagnosis include blood culture and bacterial antigen testing in urine and polymerase chain reaction (PCR) testing of blood.<sup>21,22</sup>

## MANAGEMENT

### RESUSCITATION

Severely ill patients require rapid resuscitation. Comatose patients require intubation and ventilation to prevent airway obstruction and hypoventilation. Hypovolaemia should be treated rapidly with boluses of fluid. Patients with septic shock will also require inotropic support.

### CEREBRAL RESUSCITATION

General principles of supporting brain injury apply to BM. These include optimising cerebral oxygen delivery, controlling intracranial pressure and preventing cerebral metabolic stress. The role of ICP monitoring is controversial. There is some anecdotal evidence to support the use of ICP monitoring in a small number of selected cases. Unfortunately, there are no large studies that assess the benefit or harm of ICP monitoring and ICP targeted therapy in BM.

### ANTIBIOTIC THERAPY

Empiric broad-spectrum antibiotics should be selected based on likely pathogens and local resistance patterns. A common protocol for BM is to use ampicillin plus cefotaxime for the first month of life and to use a third-generation cephalosporin (cefotaxime or ceftriaxone) after the first month.<sup>23</sup> In regions where penicillin and cephalosporin-resistant *Pneumococcus* occurs, vancomycin should be added to the initial empiric antibiotics until the causative organism is identified and the antibiotic sensitivities are known. When cephalosporin-resistant pneumococci are found to be the causative organism in meningitis, both a third-generation cephalosporin and vancomycin should be continued as vancomycin penetrates into CSF poorly and therefore should not be used as a single antibiotic. The addition of rifampicin should be considered.<sup>24</sup>

**ADJUVANT THERAPY**

Although a number of adjuvant therapies have been investigated experimentally, the only one that is commonly used clinically is dexamethasone. If dexamethasone is used it should ideally be given before the first dose of antibiotics and continued for 48 hours (0.4 mg/kg 12-hourly).<sup>25</sup> There is evidence that dexamethasone reduces the incidence of neurological sequelae and sensorineural deafness; however, the beneficial effects are greatest in Hib meningitis.<sup>26,27</sup> Now that immunisation has changed the epidemiology and antibiotic-resistant pneumococcal strains are more common, it is possible that the relationship between risk and benefit of dexamethasone therapy has changed. However, current recommendations support the use of dexamethasone for children more than 6 weeks of age with bacterial meningitis.<sup>24,28</sup>

**FLUID THERAPY**

Although there is consensus that hypovolaemia should be treated rapidly and aggressively, fluid therapy after the initial resuscitation is controversial. It is important to consider both the tonicity of i.v. fluids as well as the rate of fluid administration. Although dextrose saline solutions with low sodium content (0.18–0.3% saline) are isotonic with plasma when first administered, as the dextrose crosses the blood–brain barrier or is metabolised, the net effect is that the cerebral circulation is exposed to hypotonic fluids, which potentially exacerbates cerebral oedema. Therefore, the i.v. fluid used in BM should be 0.45% or 0.9% saline in 5% dextrose.<sup>29,30</sup>

Restriction of maintenance fluids in BM has been commonly practised. Hyponatraemia is common and if it is assumed that this is secondary to the syndrome of inappropriate antidiuretic hormone secretion (SIADH) then fluid restriction is logical. Recent evidence, however, suggests that ADH is appropriately elevated in response to hypovolaemia<sup>31</sup> and that hyponatraemic patients with BM tend to be more dehydrated than normonatraemic patients.<sup>32</sup> Compared to fluid restriction, fluid therapy aimed at providing maintenance plus the fluid deficit has been reported to result in a more rapid correction of sodium and ADH.<sup>31,33</sup>

Although these studies suggest fluid restriction may not benefit all children with BM, it is important that fluid is restricted in patients with BM and true SIADH, as maintenance fluid therapy in these patients will cause the serum sodium to fall further. This complication is potentially life threatening, with the progressive fall in sodium precipitating seizures and worsening cerebral oedema. Therefore, serum sodium should be monitored closely during the first 24–48 hours of therapy in all patients with BM.

**CHEMOPROPHYLAXIS FOR CONTACTS**

Prophylaxis is required for every household member in cases of meningococcal infection and in cases of Hib infection when there is another child in the household under 5 years who is unimmunised. Rifampicin (10 mg/kg to a maximum of 600 mg b.d.) for 2 days in meningococcal

disease or 4 days in Hib disease is appropriate. Neonates require 10 mg/kg per day. Pregnant women can be effectively managed with a single intramuscular dose of ceftriaxone (250 mg). Ciprofloxacin (15 mg/kg to a maximum of 750 mg) is also effective and has the advantage of single dose therapy.<sup>34</sup>

**OUTCOME**

Bacterial meningitis is associated with significant mortality and morbidity. Overall mortality for BM in childhood is 5–10%; however, in children requiring mechanical ventilation a mortality rate of 30% has been reported, with major neurosequelae occurring in 33% of survivors.<sup>35</sup>

**PREVENTION**

Immunisation has significantly reduced the incidence of Hib meningitis in developed countries,<sup>36,37</sup> while initial trials of heptavalent pneumococcal vaccine have shown a reduction in invasive pneumococcal infection in children.<sup>38</sup> Meningococcal serogroup C conjugate vaccines have reduced the incidence of severe meningococcal disease in infants in the UK and Australia.<sup>39,40</sup>

**ENCEPHALITIS**

Common causes of encephalitis include enteroviruses, mycoplasma, cytomegalovirus, herpes, Epstein–Barr and respiratory viruses (adenovirus and parainfluenzae). The most significant causes worldwide are the insect-transmitted arbovirus encephalitides including Australian, Japanese B and St Louis. These can cause profound coma and are associated with significant incidence of residual neurological deficit.

Presenting symptoms of encephalitis include seizures, focal neurological deficits in the setting of an acute febrile illness, confusion and coma. Meningeal irritation may not be obvious. CSF analysis may show a pleocytosis and in the early phase this can consist predominantly of neutrophils. As mentioned, herpes is the most important diagnosis to make, because it is treatable. Electroencephalography (EEG), CT and magnetic resonance imaging (MRI) are helpful in making the diagnosis. MRI is more sensitive than CT for detecting signs of encephalitis, particularly during the early stages of the illness. PCR on CSF may also aid rapid diagnosis.<sup>41,42</sup> Aciclovir used early improves outcome and should be commenced when the diagnosis is suspected.

The enteroviruses are important causes of encephalitis in children. In addition, they cause other acute neurological illnesses including acute flaccid paralysis due to transverse myelitis and Guillain–Barré syndrome.<sup>43</sup> Pleconaril is a promising new antiviral agent that appears to have clinical benefit in enteroviral infections, including CNS disease.<sup>44</sup> Outcome of viral encephalitis is worse in infancy than in older age groups.<sup>45</sup>

### NON-TRAUMATIC INTRACRANIAL HAEMORRHAGE

Non-traumatic intracranial haemorrhage (ICH) is uncommon in children. Arteriovenous malformations (AVM) are a more common cause of haemorrhage in children than aneurysms<sup>46</sup> (Table 102.3). The presenting features are similar to those seen in adults, and include sudden severe headache, altered conscious state and seizures. Diagnosis can usually be made by CT scan. Raised ICP, if present, is managed in the usual manner. A mass lesion or acute obstructive hydrocephalus requires neurosurgical assessment.

Following diagnosis of ICH further investigations may be required to clarify the underlying cause. These include coagulation profile and platelet count. Angiographic images can be obtained with CT, MRA (magnetic resonance angiography) or digital subtraction. In some cases definitive cerebral angiography may be required to define the underlying vascular malformation or tumour. Definitive surgery or endovascular treatment of an AVM can be planned once the underlying lesion has been defined. A period of close observation is required as children may be at greater risk of rebleeding from an AVM than adults.<sup>47</sup> The efficacy of therapies (e.g. calcium channel blockers) used to prevent vasospasm in adults has not been studied in children with aneurysmal haemorrhage. Sequelae of ICH include hemiparesis, aphasia, seizures and hydrocephalus.

### HYPoxic–ISCHAEMIC ENCEPHALOPATHY

#### AETIOLOGY

The most common causes of hypoxic–ischaemic encephalopathy outside the neonatal period are:

- near-miss sudden infant death syndrome
- immersion

**Table 102.3** Aetiology of spontaneous intracranial haemorrhage in children

Vascular malformations
Arteriovenous malformation
Capillary telangiectasia
Cavernous malformation
Venous malformation
Aneurysm
‘Berry’

Posttraumatic
Coagulopathy
Thrombocytopenia
Haemophilia
Anticoagulant therapy
Tumours
Gliomas
Hypertension

- accidents, including drug ingestion and strangulation
- inflicted injury

#### PATHOLOGY

The brain depends on an uninterrupted supply of oxygen and glucose to produce, via aerobic glycolysis, sufficient high-energy adenosine triphosphate (ATP) to maintain neuronal membrane and synthetic function. Under anoxic conditions anaerobic glycolysis occurs which produces lactic acid but less ATP (by 18 times). As there are virtually no stores of ATP, rapid neuronal failure ensues. If ischaemia accompanies hypoxia, there is associated failure of both substrate delivery and metabolic waste removal, which amplifies the cellular insult. Ischaemia produces coma in less than 10 seconds and cerebral damage in as little as 2 minutes.

Following restoration of cerebral blood flow there is a period of relative hyperaemia followed by relative hypoperfusion. Animal studies suggest that the blood flow during this phase of postischaemic hypoperfusion is determined by the metabolic needs of the brain.<sup>48</sup> Cytotoxic cerebral oedema may subsequently develop, but significant elevation of ICP is unusual unless ischaemia and damage are profound.

#### MANAGEMENT

The principles of therapy are similar to those for other brain injuries. It is mandatory to provide rapid cardiopulmonary resuscitation (CPR) and prevent secondary insults. In cases of out-of-hospital cardiac arrest, full resuscitation must be attempted while the history is sought. Postresuscitation care is important for optimising outcome. Comatose patients with hyper- or hypotonia and a Glasgow Coma Scale score (GCS) < 8 are probably best managed by mechanical ventilation, sedation and paralysis for at least 1–2 days although benefits are not proven. Ventilation should be targeted at normocapnia, and hyperventilation avoided due to the risk of further cerebral ischaemia.<sup>49</sup> Haemodynamic disturbance may develop because of primary cardiac dysfunction or hypovolaemia secondary to fluid loss from capillary leak syndrome. Circulating volume should be restored and inotropic agents considered to improve the state of the circulation. The dose and choice of vasoactive agent should be individualised based on haemodynamic monitoring.

Following cardiac arrest children are usually hypothermic. Fever commonly develops during the subsequent hours and is associated with worse outcome.<sup>50</sup> Fever should therefore be anticipated and prevented. Further to preventing fever, there is evidence that therapeutic hypothermia of 32–34°C improves outcome. There are two trials in adults following cardiac arrest<sup>51,52</sup> and two trials in newborns following birth asphyxia<sup>53,54</sup> demonstrating improved neurological outcome if hypothermia is used for between 12 and 72 hours. Although there are no

paediatric trials, therapeutic hypothermia should be considered as a treatment option in children who are comatose following hypoxic–ischaemic events. Hyperglycaemia has been associated with a worse prognosis and, although it may simply be a marker of injury severity, active treatment has been advocated. The role of ICP measurement is limited as intracranial hypertension usually only occurs in the setting of severe injury and poor outcome.<sup>55</sup>

## PROGNOSIS

The major determinants of recovery are:

- ischaemic time
- cerebral metabolic rate
- quality of resuscitation.

In immersion injuries in young children, full recovery may be possible despite prolonged ischaemia if sufficient rapid cerebral cooling has occurred. In these cases the onset of ischaemia may be delayed by bradycardia with preferential cerebral flow (the ‘diving reflex’). In general, survival from out-of-hospital cardiac arrest is unlikely, even with expert CPR, if asystole is present on arrival at hospital.<sup>56</sup> The rare exception is the hypothermic child who presents following immersion; prolonged CPR may be justified in selected cases when profound hypothermia was induced rapidly. If cardiac output is present on arrival at hospital, with either flexion or extension to pain, recovery is likely. Normothermic patients, who present apnoeic, flaccid and unresponsive to pain, are likely to die or have serious neurological deficits. This group is also prone to further deterioration several days after the insult, with progression of cerebral oedema.<sup>55</sup> Coma persisting for more than 24 hours is a predictor of poor prognosis and minimal long-term improvement is likely in this group.<sup>57</sup> Residual neurological deficits present at the end of the first week are less likely to improve following ischaemic injury than following traumatic brain injury.

A number of ancillary tests have been investigated as predictors of neurological outcome. Somatosensory-evoked potentials (SEPs) performed at the bedside are the most useful aid to prediction. One report of 109 children with severe brain injury concluded that, with appropriate patient selection, the positive predictive value for poor outcome of bilaterally absent SEPs is 100% (95% CI, 92–100%).<sup>58</sup>

## GUILLAIN–BARRÉ SYNDROME

### CLINICAL FEATURES

Guillain–Barré syndrome (GBS) is the most common cause of acute motor paralysis in children. Although most patients develop typical ascending, symmetrical areflexic weakness, GBS may present insidiously with apparent lethargy or loss of motor milestones in the young child.

There may also be rapid progression and admission criteria to the intensive care unit (ICU) include respiratory failure, bulbar palsy, severe autonomic disturbance or rapidly progressive weakness. Sensory loss is usually minimal and transient. Pain in the back and legs, possibly neurogenic in origin, is common and may be the presenting feature.<sup>59</sup> This pain may be severe and is often difficult to control. Papilloedema and encephalopathy occasionally occur.<sup>60</sup> The complications of deep venous thrombosis and thromboembolism are not common problems in young children but may occur in adolescents.

## INVESTIGATIONS

An LP should be done ideally before treatment with intravenous immunoglobulin (IVIG) is commenced. CSF typically shows a white cell count  $< 10 \times 10^6$ , while CSF protein is usually raised but may be normal during the first week of illness. Nerve conduction studies may be normal if performed early. Neurophysiological criteria have been used to classify GBS subtypes according to either demyelinating or axonal and whether or not both sensory and motor nerves are involved.<sup>61</sup> Anti-ganglioside antibodies are raised in some but not all patients.<sup>62</sup>

If there is uncertainty about the clinical diagnosis, brain and spinal cord imaging, as well as screening for infection, should be considered.

## MANAGEMENT

Adequate respiratory care is the basis of minimising morbidity and mortality in GBS. Up to one-third of patients require ventilatory support and, ideally, mechanical ventilation should be undertaken electively. Early indications are increased work of breathing, fatigue, poor cough and progressive bulbar palsy. Hypercarbia is a late sign and should be avoided. In children that are old enough to cooperate, forced vital capacity (FVC) should be monitored during the progressive phase of the illness. Mechanical ventilation should be considered if FVC falls below 15–20 ml/kg. Careful frequent clinical assessment is necessary. Once mechanically ventilated, many patients require some degree of hyperventilation to prevent ‘air hunger’. Although nasotracheal intubation is satisfactory initially, a tracheostomy should be performed if recovery is delayed. This will improve comfort and allow speech via pressure-generated ventilation and an air leak around the tracheostomy tube. Successful weaning is unlikely unless vital capacity exceeds 12 ml/kg and maximum negative inspiratory force is at least 20 cmH<sub>2</sub>O (2 kPa).

Autonomic dysfunction is an important cause of morbidity and mortality in children with GBS. Airway manipulation or induction of anaesthesia, particularly in the presence of hypoxia, may provoke serious cardiac arrhythmias. Fluctuating blood pressure, urinary retention and gut dysfunction also occur.

Plasma exchange (PE) and IVIG are effective therapies. The indications for either are rapid progression and

respiratory insufficiency or weakness to the point of being unable to walk unassisted. The strongest evidence for these therapies is from adult trials.<sup>63–65</sup> Although large trials adequately powered to separately test the efficacy of PE and IVIG in children have not been performed, a number of small retrospective studies have described local experiences with these immune therapies in children with mixed results.<sup>66–70</sup> As IVIG has significant potential technical advantages over PE, IVIG is generally the first-line therapy in children. Indications for IVIG are based on the degree of functional impairment and time from onset of symptoms. The indications are not influenced by the clinical or neurophysiological subtype or the results of antibody screening. There is no evidence to support sequential treatment using both PE and IVIG.<sup>71</sup>

Pain is a common feature of GBS and may have a neuropathic basis. Paracetamol and non-steroidal anti-inflammatory drugs are useful, while drugs to treat neuropathic pain (including gabapentin, carbamazepine and amitriptyline) may also be beneficial.

The problems of long-term ventilation in a conscious patient, compounded by emotional immaturity, speech failure, fear of procedures and family disruption, make the management of a child with GBS and their family particularly challenging. A sensitive team approach is essential.

## PROGNOSIS

The prognosis in acute GBS may be better for children than adults. Full recovery is likely if the time from maximal deficit to onset of recovery is less than 18 days. Complete recovery, despite a longer plateau phase, has been reported, however.<sup>72</sup> Good recovery can occur in patients who have required ventilation and the need for ventilation may not be a poor prognostic factor in children.<sup>66</sup> Those presenting with a subacute course are at risk of relapses and permanent motor deficits.

## METABOLIC ENCEPHALOPATHY

Approximately 0.1% of babies have an inborn error of metabolism. Acute encephalopathy is one of the many ways neurometabolic diseases present in childhood.<sup>73,74</sup> In general, acute presentations occur in the neonatal period and early infancy. Symptoms are often vague and include lethargy, poor feeding and vomiting. Older infants and children more commonly present with a chronic encephalopathy, with features that may include seizures, long-tract signs, visual impairment and loss of milestones.

## APPROACH TO DIAGNOSIS

A careful history and examination may elicit clues to a possible metabolic problem. Family history and history of drug exposure are extremely important. Valproate, in

**Table 102.4** Biochemical markers of metabolic disorders

Biochemical marker	Disorder
Hypoglycaemia	Organic acidurias Methylmalonic/propionic acidemia Reye's syndrome Fat oxidation defects MCAD
Ketoacidosis	Diabetes mellitus Organic acidurias
Lactic acidosis	Mitochondrial encephalomyopathies Respiratory chain disorders Pyruvate carboxylase deficiency
Hyperammonaemia (2–3 × normal)	Reye's syndrome Urea cycle defects Fat oxidation defects MCAD Organic acidurias

MCAD, medium-chain acyl CoA dehydrogenase.

particular, has been associated with a Reye-like illness. The following readily available investigations are useful to allow a broad categorisation and direct further detailed investigations: blood gas analysis, blood sugar, serum ammonia, serum lactate, urine metabolic screen and urine ketones. While lactic acidosis and hypoglycaemia can occur in a number of disease states, including sepsis, persisting abnormalities require further investigation. This is best done in collaboration with a metabolic disease specialist or a clinical biochemist.

Lactic acidosis can be further assessed with measurement of lactate:pyruvate ratio and urine biochemical analysis may provide further diagnostic information (Table 102.4).

## ASSESSMENT

Metabolic coma can be staged using Lovejoy's classification for Reye's syndrome (Table 102.5).<sup>75</sup>

## MANAGEMENT

Initial management is largely supportive. Metabolic derangements such as acidosis and hypoglycaemia should be corrected. Acute intracranial hypertension should be managed with mechanical ventilation while the role of ICP monitoring is controversial. Hyperammonaemia should be managed with limited protein intake initially. In certain circumstances increasing ammonia metabolism using agents such as arginine and sodium benzoate is helpful. In some settings providing calories intravenously in the form of glucose and fat may help limit the extent of catabolism and thereby help to curtail the metabolic crisis. Dialysis is used to control severe hyperammonaemia

Table 102.5 Staging in metabolic encephalopathy

Stage	Coma	Pain response	Reflexes
1	Lethargy	Normal	Normal
2	Combative	Variable	Pupils sluggish
3	Coma	Decorticate	Pupils sluggish
4	Coma	Decerebrate	Pupils sluggish, abnormal oculocephalic
5	Coma	Flaccid	No pupil response, absent oculocephalic

Adapted from NIH, modification of Lovejoy.<sup>75</sup>

and acidosis. Continuous venovenous haemodiafiltration is considered more effective than peritoneal dialysis.<sup>76</sup>

### REYE'S SYNDROME AND REYE-LIKE ILLNESS

Reye's syndrome is a rare disorder, occurring almost exclusively in children. It is characterised by an acute encephalopathy with brain swelling and fatty degeneration of viscera, especially the liver. Typically the patient presents with intractable vomiting followed by progressive encephalopathy. There is an association with aspirin use and a preceding varicella infection. Diagnosis can be made when a compatible history accompanies hyperammonaemia and elevation of serum hepatocellular enzymes to at least twice normal, but with a normal bilirubin concentration. Hypoglycaemia occurs in patients under 2 years. Management consists of correction of hypoglycaemia, neurological monitoring and management of raised ICP.

A wide range of conditions has been described that closely mimic typical Reye's syndrome. Ten percent of cases originally described as being Reye's syndrome were subsequently found to be due to an inherited metabolic disorder.<sup>77</sup> A careful approach is mandatory to ensure detection of inherited disorders.

The introduction of neonatal screening programmes using tandem mass spectrometry will see many inherited metabolic diseases diagnosed in the neonatal period, often prior to the onset of symptoms. This technology is particularly useful for detecting fatty acid oxidation defects (e.g. medium-chain acyl CoA dehydrogenase deficiency, or MCAD) and disorders of amino acid metabolism (e.g. methylmalonic acidaemia).<sup>78</sup>

### SPINAL INJURY

#### INCIDENCE

Paediatric spinal trauma is relatively rare, comprising < 5% of all spinal injuries. Approximately 5% of children with severe head trauma will have a cervical spine injury. However, a high proportion of children who die following motor vehicle trauma, particularly those who suffer

immediate cardiorespiratory arrest, or who die before arrival at hospital, have disruption of the spinal cord above C3, particularly at the cervicomedullary junction.<sup>79,80</sup>

#### AETIOLOGY

The commonest causes of paediatric spinal trauma are motor vehicle crashes, either as a pedestrian or passenger, falls and diving injuries. Sports-related injuries are uncommon.

#### PATHOPHYSIOLOGY

The patterns of spinal injury in children differ from those seen in adults in many ways. Spinal cord injury without radiographic abnormality (SCIWORA) occurs almost exclusively in children (20–60% of spinal cord injuries). It is associated with a high incidence of complete neurological deficit. Spinal injury in the first decade occurs most commonly in the first two cervical segments, with atlanto-axial rotatory subluxation, bony or ligamentous injuries, or SCIWORA and severe cord injury. Although not as common as upper cervical injuries, lower cervical injuries below C4 do occur in young children,<sup>81</sup> while injury may occur at more than one level. Atlanto-axial rotatory subluxation is rarely associated with neurological deficit and ligamentous injury is more likely than high cervical fractures to be associated with permanent neurological deficit.<sup>82</sup> As the bony spine matures, the pattern of injury becomes more adult-like with lower cervical and thoracic injuries seen in the second decade.<sup>83,84</sup>

#### CLINICAL FEATURES

The immediate effects of spinal cord damage are similar at any age. Frequently an associated head injury can render clinical assessment extremely difficult; confirmation of cord injury is sometimes delayed. Clues to the diagnosis in the unconscious patient include:

- flaccidity, immobility and areflexia below the level of the lesion
- hypoventilation with paradoxical chest movement; this occurs if intercostal muscles are paralysed and the phrenic nerves are intact (in the absence of airway obstruction)

- apnoea with rhythmic flaring of the alae nasi (Duncan's sign), seen when the lesion is above C3
- hypotension with inappropriate bradycardia and cutaneous vasodilatation below the level of injury, due to absent spinal sympathetic outflow
- priapism, which occurs frequently

There may be visible or palpable evidence of trauma to the spine and surrounding soft tissues, including retropharyngeal or retrolaryngeal haematomas. Spinal shock is common with temporary complete loss of function. As this resolves after 3–5 days, reflexes progressively return, usually starting with bulbocavernosus and anal reflexes. Incomplete lesions, including the Brown–Sequard cord hemisection, and anterior and central cord syndromes may become apparent at this stage.

### INVESTIGATIONS

Resuscitation, including emergency intubation, should not be delayed to perform X-rays. The entire spinal column should, however, be X-rayed subsequently to demonstrate the presence of subluxation, fractures or dislocations. MRI is useful in both the acute setting and in assessment at later stages, and is now accepted as the standard for identifying haemorrhage, contusion or compression of the cord. CT produces better definition of bony injuries, and may also show cord involvement by haematomas, bone fragments and foreign bodies. SCIWORA was defined in an era before MRI was routinely available. In the majority of children with SCIWORA, MRI will also be normal; however, if intramedullary lesions are demonstrated with MRI, permanent neurological deficits are more likely.<sup>85,86</sup> Somatosensory-evoked potentials may be useful to evaluate the integrity of the spinal cord, particularly in the comatose patient.

### MANAGEMENT

Achieving control of airway, ventilation and circulation is always of first priority. If tracheal intubation is indicated, and if stability of the neck is unknown, skilled assistance is necessary to immobilise the head and neck and prevent flexion or extension. Because of the sympathectomised state in high cord injuries, a relatively low blood pressure can be expected even after hypovolaemia is corrected. Significant hypotension becomes more likely the higher the lesion and the younger the patient. Haemodynamic support with a vasoconstrictor such as noradrenaline (norepinephrine) is useful if hypotension is problematic following restoration of intravascular volume. As up to 20% of patients will have multiple trauma, many will require major surgical procedures, during which the spinal cord must remain protected. If muscle relaxants are required 2–3 days following the injury, suxamethonium, which may cause fatal hyperkalaemia, should be avoided.

The use of steroids is controversial and there are no studies specific to children. Two randomised controlled

trials in adults demonstrated that high-dose methylprednisolone administered within 8 hours of the injury (30 mg/kg initially followed by 5.4 mg/kg per hour for the following 24–48 hours) improved outcome.<sup>87,88</sup> These studies have significant limitations and the results have not been universally accepted.<sup>89–91</sup>

As with brain injuries, preventing secondary injury is vital. Adequate perfusion of the cord should be ensured, as autoregulation of blood flow is lost after trauma. Immobilisation can be maintained by skull tongs with axial traction or external bracing. Operative intervention is controversial with little evidence of neurological improvement from decompressive surgery. Laminectomy and decompression in children with complete cord injuries carry significant mortality.

The incidence of venous thromboembolism after spinal injury in adolescents approaches that in adults and therefore patients in this age group should receive standard prophylaxis. Venous thromboembolism is rare in prepubertal children (approximately 1%), and the risk–benefit ratio of routine prophylaxis in this age group is unknown.<sup>92</sup> There should be early consultation with a specialised spinal injuries unit. Optimal rehabilitation requires a team of orthopaedic and neurosurgeons, rehabilitation specialists, nurses, physiotherapists, occupational therapists, psychiatrists, social workers and schoolteachers.

### PROGNOSIS

The prognosis of all spinal injuries in children may be better than in adults. In one series of 113 children with spinal column injuries, 55 (48%) had no neurological deficit, and 38 (34%) had an incomplete deficit. Of these, 23 (20%) made a complete recovery and 11 (10%) improved.<sup>79</sup> The remaining 20 (18%) children had a complete cord injury and, of these, 4 improved and 3 died. In a smaller series, 44% had neurological deficits, SCIWORA was seen in 21% and 11% of injuries were immediate, complete and permanent. Of the 18 children with SCIWORA, 4 had a permanent, complete deficit.<sup>82</sup>

# Paediatric trauma

Neil T Matthews

The management of paediatric trauma is different from adults. Paediatric patients presenting with trauma have mechanisms of injury, clinical symptoms and examination findings which differ from adults, and differ across the range of their ages. Trauma is by far the leading cause of death in children over 1 year old, and the third leading cause less than 1 year after congenital abnormalities and sudden infant death syndrome.<sup>1</sup> Causes of trauma and patterns of injury are determined by age-related behaviour, with falls and assaults more common in younger children, and motor vehicle accidents more common in older children. Injury patterns differ, with impact forces dissipated over a smaller target, severe organ damage resulting without bony fracture because bones are not ossified, and greater potential for hypothermia. In general, blunt trauma with multiorgan injury is most likely.

As with adults, there are three peak mortality periods after injury:

- *minutes* at the scene, from airway obstruction, bleeding and fatal primary brain injury
- *hours* during resuscitation and transport from airway obstruction, aspiration, haemorrhage and the head injury
- *days to weeks* later from head injury or complications

The mainstay of early management is optimising the ABC of resuscitation as outlined in other chapters. Importantly, vascular access can be difficult, and expertise in intraosseous needle insertion is essential.<sup>2</sup>

## PREVENTION STRATEGIES

Paediatric trauma requires resources and separate systems to successfully reduce mortality and morbidity.<sup>3</sup> New emphasis has seen the development of prevention strategies (Table 103.1), including:

- injury surveillance, prevention research, legislation and public safety campaigns
- education programmes directed at care-givers
- nationally coordinated approaches to trauma care

## HEAD INJURY

Significant head injury occurs in 75% of children admitted with blunt trauma,<sup>5</sup> and 70% of these result in death. Causes of injury are determined by behaviour patterns, which change with age and are commonly due to falls and assaults in infants, and motor vehicle accidents (including bicycle-related injuries) in older children.

## ASSESSMENT

The Glasgow Coma Scale (GCS) requires different interpretation in children, because scores tend to be more subjective and prone to misinterpretation. When using the original GCS described for adults, children under 5 years are unable to score normally for verbal and motor responses. Normal aggregate scores for age are:

- 9 at 6 months
- 11 at 12 months
- 13–14 at 5 years.

This has led to attempts to modify the scale by either changing the scoring assessment signs, or by reducing the total score (i.e. eliminating some response categories).<sup>6</sup> The latter does not allow for comparison of outcome data.

An example of a commonly used scale modified for infants is shown in Table 103.2. However, difficulties remain as regards the accuracy and reproducibility of GCS for infants. Clinical assessment must prioritise the signs and symptoms of cerebral oedema or raised intracranial pressure (ICP) (Table 103.3).

## MANAGEMENT

The aims of therapy are to minimise secondary effects on the primary brain injury by maintaining adequate cerebral blood flow and oxygen supply, and preventing secondary ischaemic injury and herniation from raised ICP.

Table 103.1 Prevention strategies<sup>4</sup>

Paediatric injuries	Preventative strategies
MVA – occupant	Child car seat Seatbelt restraints Car design Airbags
MVA – pedestrian	Safety programmes in schools
Bicycle	Helmet Separate sidewalks
Playground	Equipment structural design Soft surfaces
Drowning	Surround pool fencing
Burns	Smoke detectors Water tap regulators Flammable fabric legislation
Poisoning	Preventative packaging
Violence	Hand gun legislation Crisis resolution counselling

- Deterioration in level of consciousness and the appearance of signs of herniation must be rapidly recognised.
- Airway, oxygenation and respiration should be optimised and intubation performed when the airway is compromised.
- Controlled ventilation with muscle relaxation and sedation should be instituted in the presence of hypoventilation, seizures and signs of raised ICP (see Table 103.3).
- Hypotension significantly increases mortality in children and the systemic circulation must be maintained.

Table 103.3 Signs of raised intracranial pressure

Depressed level of consciousness
Changes in respiratory pattern, blood pressure and pulse rate
Increased head circumference (less than 18 months of age)
Full or bulging fontanelle
Motor weakness
Cranial nerve palsies
Decorticate or decerebrate posturing
Vomiting
Headache
Papilloedema (late)

- Management of blood pressure is difficult because the exact ranges of cerebral autoregulation are unknown in children.<sup>7</sup> Hypotension is most likely from blood loss (especially from scalp lacerations) and not brain injury. Fluid management needs to balance the need for volume resuscitation with the attempt to avoid hypovolaemia.
- Hypotonic and glucose-containing solutions should be avoided because of the association with poor outcomes.<sup>8</sup>
- Studies on the effectiveness of induced hypothermia in paediatric trauma are ongoing.
- Hyperthermia should be avoided with a servo-controlled cooling blanket and adjustment of humidifier temperature because each 1°C temperature rise increases cerebral metabolic rate by 5%.<sup>9</sup>
- Cerebral venous return should be optimised by neutral head positioning. Cerebral perfusion pressure may be best with the bed flat.<sup>10</sup>
- Treatment of seizures with phenytoin (20 mg/kg i.v.) provides less central nervous system depression than barbiturates or benzodiazepines. Monitoring for seizures to guard against resulting increases in cerebral blood flow and oxygen consumption is difficult in the

Table 103.2 Glasgow Coma Scale modified for infants

paralysed patient. Systems for continuous electroencephalogram monitoring are complex to interpret at the bedside and provide limited information. Post-traumatic seizures are more common under 2 years of age,<sup>11</sup> but their long-term incidence is not reduced by acute prophylaxis.<sup>12</sup>

- Continuous measurement of jugular venous oxygen saturation ( $SjO_2$ ) via fiberoptic reflection oximetry can identify global cerebral hypoperfusion and ischaemia.<sup>13</sup> However, its use in children is subject to technical difficulties, mainly related to catheter position. Its use is not clinically routine in paediatrics.

### DIAGNOSTIC INVESTIGATIONS

Supportive investigations can be performed while emergency assessment and therapy proceed. These include pH and acid–base, serum glucose, osmolality, electrolytes, calcium, magnesium and phosphate, complete blood profile and blood crossmatch.

X-rays of skull and cervical spine (anteroposterior, lateral and C1–C2 views), chest and pelvis are needed. Ultrasound of the skull, where the fontanelle is open, measures ventricular size, and can detect intracranial haemorrhage. It is useful for repeated assessment in the unstable patient.

A cranial computed tomography (CT) scan in stable patients excludes surgically treatable lesions, assesses the size of cerebrospinal fluid (CSF) spaces, including the basal cisterns, detects herniation and shift, and shows the presence of hyperaemia, oedema, intracerebral haematomas, contusions and fractures. A normal CT scan does not exclude raised ICP. Intracranial blood collections are less common than in adults.<sup>5</sup> The following are poor prognostic signs:

- subdural haemorrhage (as an indication of severe trauma and damage to underlying brain tissue)
- ablated basal cisterns and midline shift
- lack of or reversal of grey/white differentiation

### CEREBRAL PERFUSION PRESSURE

Maintenance of cerebral perfusion pressure (CPP) in children is important and has significant implications, but the minimal required CPP in children has not been determined. CPP depends on the difference between mean systemic blood pressure and ICP and these values vary with age. In particular, blood pressure assumes great importance in the younger age group, where physiological systolic pressures are lower:

- 85 mmHg (11.3 kPa) at 6 months
- 95 mmHg (12.6 kPa) at 2 years
- 100 mmHg (13.3 kPa) at 7 years<sup>14</sup>

Normal ICP is also lower,<sup>15</sup> being normally less than 5 mmHg (0.67 kPa) at 2 years and less than 10 mmHg (1.3 kPa) at 5 years. Thus, in younger age groups, relative

hypotension has a more profound effect on CPP and outcome,<sup>16</sup> and hypotension may be the main cause of cerebral ischaemia. For adolescents, therapy should aim to sustain CPP at 60–70 mmHg (8.0–9.3 kPa), while maintaining normal blood volume and adequate blood pressure (with pressor agents if required). A CPP less than 40 mmHg (5.3 kPa) reduces the likelihood of intact survival. Younger patients should have therapeutic targets adjusted to age-related realistic end-points.

### INTRACRANIAL PRESSURE

Mechanisms of raised ICP in childhood trauma are listed in Table 103.4. If ICP remains persistently raised and uncompensated, cerebral ischaemia and herniation result. This herniation can be cingulate, uncal (temporal lobe), cerebellar tonsillar, upward cerebellar (posterior fossa hypertension) or transcalvarian (through vault defects). Signs of herniation are as for raised ICP (Table 103.3).

### MEASUREMENT OF INTRACRANIAL PRESSURE

Measurement of ICP is indicated when intracranial hypertension is likely or potential (e.g. GCS 8 or less), or where signs are hidden by muscle relaxation. Technically, measurement in children can be more difficult. Subdural catheters and intracranial transducers require careful placement in children. Ventricular catheters allow removal of CSF, but are difficult to insert when ventricles are small, and readings are difficult to interpret when ventricles collapse. Strain-gauge technology will allow easier and more meaningful measurement of ICP (including intracerebral pressure).

### REDUCTION OF RAISED INTRACRANIAL PRESSURE

Several mechanisms allow physiological compensation for raised ICP in children (Table 103.5). In the child under

**Table 103.4** Mechanisms of raised intracranial pressure

Increased intracranial blood volume
Intracranial bleeding (epidural, subdural, subarachnoid, intracerebral)
Cerebral hyperaemia (in the first 1–2 days post injury <sup>17</sup> )
Increased cerebral blood flow (increased $PaCO_2$ , decreased $PaO_2$ , and convulsions)
Cerebral oedema (after day 2 <sup>18</sup> )
Hydrocephalus from intraventricular blood

**Table 103.5** Physiological compensatory mechanisms for raised intracranial pressure in children

Displacement of CSF to distensible spinal subarachnoid space
Compression of intracranial venous system
Increased CSF reabsorption
Reduced CSF production
Stretching of dura, unfused skull bones and skin (less than 18 months of age)

18 months of age, a gradual increase in intracranial volume is achieved by an increase in head circumference. Measurement of the circumference is important, because compensation can delay recognition of clinical signs and diagnosis in emerging intracranial pathology. The important factor in the rate of change in compliance and ICP is the elasticity of the dura, which is dependent on the rate of change in intracranial volume.

Hyperventilation is effective in lowering raised ICP. However, excessive hyperventilation may cause cerebral ischaemia, and  $P_{aCO_2}$  should be maintained between 35 and 40 mmHg (4.7–5.3 kPa). Weaning from hyperventilation should be slow, to minimise rebound rises in ICP.<sup>19</sup> Fluid restriction is helpful, provided circulating blood volume is maintained.

Mannitol (0.25–0.50 g/kg i.v. slowly) reduces raised ICP by increasing the osmotic gradient across the intact blood–brain barrier and reducing cerebral oedema. Its effects may also be due to reduced blood viscosity and induced cerebral vasoconstriction. Serum osmolality should be monitored to avoid hyperosmolar states.

Furosemide (1 mg/kg) reduces cerebral water and CSF production, but excessive diuresis from mannitol or furosemide may compromise the circulation. The use of hypertonic saline in children (3%) reduces ICP and appears to be more beneficial in resuscitation. CSF drainage is possible if a ventricular drain is in situ. Controlled hypothermia reduces raised ICP in patients with refractory intracranial hypertension, but improvement in outcomes is uncertain. Surgical decompression or removal of cerebral contusion in the face of intractably raised ICP in head trauma is advocated,<sup>5</sup> with improved results in unremitting focal oedema.

### SPINAL CORD INJURY

Spinal cord injury is rare in children. Anatomical differences in children under 8 years render their spines more mobile and subject to stress with flexible ligaments and joint capsules, less muscular support, and horizontal facet joints. In addition, the relatively large head mass increases momentum, with the fulcrum of mobility at C2–C3 as opposed to C4–C5 in the adult. Thus paediatric cervical spine injuries tend to be above C4. The use of seat belts has led to an increase in lumbar spinal cord injury in children.<sup>20</sup>

### ASSESSMENT

Clinical assessment can be difficult, as can the interpretation of radiological investigations because of normal variation and age-dependent ossification changes. Spinal cord injury without obvious radiological abnormality (SCI-WORA) occurs in 10–20% of all paediatric spinal cord injuries.<sup>21</sup> Sensory-evoked potentials can be a valuable adjunct to diagnosis. Spinal cord injury can only be dismissed after imaging assessments (which may include magnetic resonance imaging in the non-acute setting) and careful and repeated examination of the lucid patient.

### MANAGEMENT

From the time of injury, the spine should be assumed to be unstable until proved otherwise. Immobilisation, which at times is difficult, is necessary from the time of injury in the presence of:

- signs or symptoms suggesting neurological spinal deficit
- a history of loss of consciousness
- altered mental status
- history of a high-speed accident or significant fall (including diving)
- significant head or chest trauma

Immobilisation should continue until appropriate assessment can be made, looking for abnormal peripheral neurological signs and spinal distraction pain in the presence of normal imaging.

It is often difficult to decide whether the spinal-injured child is initially best cared for in a paediatric ICU or a specialised spinal unit. This decision will be ultimately determined on the age of the child and the stability of the spine. Certainly, infants should not be managed in adult spinal units, whereas for older children, expertise in spinal care may be more important. However, once spinal column stability and surgical fixation have been achieved, children are best managed in paediatric facilities for ongoing management and rehabilitation.<sup>22</sup> Ongoing care is complex, and requires a multidisciplinary approach. Attention to pressure areas, bladder and bowel care and training, nutrition and prevention of contractures is essential. Symptoms of hypercalcaemia (e.g. vomiting, anorexia, nausea and malaise) can be distressing and difficult to control. Depression is common in adolescents. With high spinal cord injury, chin-operated battery-powered wheelchairs, portable ventilators and computer-activated environment control devices allow for relative independence and a functional lifestyle.

### THORACIC TRAUMA

Despite a low incidence in children, thoracic trauma is usually associated with multiorgan injury and high mortality.<sup>23</sup> The mechanism of injury is almost entirely related to motor vehicle accidents, with penetrating trauma being uncommon. The child's small size and more elastic chest wall allow transmission of more kinetic energy to intrathoracic structures, with a high incidence of pulmonary contusions without rib fractures or flail chest.

As for adults, life-threatening injuries which require immediate intervention are upper-airway obstruction, tension pneumothorax, open pneumothorax, flail chest, pericardial tamponade and massive haemothorax (see Chapter 69). Potentially life-threatening injuries are airway rupture, pulmonary contusion, ruptured aorta, diaphragmatic rupture, oesophageal perforation and myocardial contusion. Contrast CT scan and angiography

are the methods of choice in diagnosing aortic rupture in children.

### ABDOMINAL TRAUMA

Abdominal trauma is usually associated with blunt injury<sup>24</sup> and recognition may be difficult in the presence of multisystem injury. Mortality is relatively high and missed abdominal trauma is the leading cause of preventable morbidity and mortality.<sup>25</sup> The abdominal wall and thoracic cage of children provide less protection to intra-abdominal organs. Also, the liver and spleen are relatively large and more exposed below the rib cage. Forces need not be excessive to cause rupture of internal organs. Absence of bruising does not exclude injury while bruising means severe injury is likely. Lap seat belt injuries are an important cause of abdominal injury in restrained children.

Improvements in radiological imaging techniques have allowed blunt abdominal trauma to be managed conservatively in children.<sup>26</sup> This approach requires appropriate monitoring and supervision in a paediatric intensive care setting, with an awareness of the need for urgent intervention, i.e. laparotomy (Table 103.6).

- Ultrasonography is an important screening tool for detecting free fluid<sup>27</sup> and confirming intra-abdominal bleeding.
- CT scan assessment with intraluminal and i.v. contrast is indicated with clinical suspicion of abdominal injury or when physical examination is unreliable. It allows for examination of solid organs and renal tract, and detection of intraperitoneal blood and free air.
- Diagnostic peritoneal lavage is less important, and is only indicated when the source of continued bleeding is undetermined, when an urgent procedure is required for a non-abdominal injury or when a prolonged observation period is anticipated and ultrasonography or CT scan is not available.

### NON-ACCIDENTAL INJURY

Non-accidental injuries to children are seen in younger age groups, and include physical assault, sexual and emotional abuse and neglect (especially inadequate supervision

**Table 103.6** Indications for laparotomy in paediatric abdominal trauma<sup>28</sup>

Profound hypovolaemia
Persistent haemorrhage
Haemodynamic instability after replacement 40 ml/kg
Penetrating injury
Gastrointestinal perforation
Signs of peritonism
Pancreatic injury

and deprivation of nutrition and medical care). Injuries resulting from intentional assault can be difficult to diagnose, unless a high index of awareness is maintained.

With regard to the history, suspicion should be raised when:

- the cause of the injury cannot be explained
- there is discrepancy between the volunteered history and the sustained injury, especially when the child's stage of development is taken into account
- there is a history of repeated injuries
- it is alleged that the injury is self-sustained; or
- there is a delay in seeking care

Physical examination should be thorough, to establish a pattern of injury.<sup>29</sup> Multiple bruises in differing stages of development can be separately estimated for age. Patterns for burns are typical for forced immersion in hot water (with sparing of the groin area) and from cigarettes. Suspicion should be raised where cerebral trauma is associated with retinal haemorrhages, subdural haematomas or fractures. Findings of retinal haemorrhages on ophthalmological examination increases suspicion for inflicted injury but do not confirm the diagnosis.<sup>30</sup> The most common intracranial pathology is subdural and subarachnoid haemorrhage, which account for the higher morbidity and mortality. A whole-body X-ray series and bone scan will detect fractures in differing stages of healing from multiple assaults.

Whenever non-accidental injury is suspected or diagnosed, a multidisciplinary approach is required by a specialised child protection unit to deal with medical and legal issues, and with the counselling. Urgent intervention may be necessary where the safety of other siblings is threatened.

### TRANSPORT

The outcome of trauma in remote locations is optimal when advice, prehospital stabilisation and transport are provided by teams based in tertiary paediatric ICUs.<sup>31</sup> Secondary insults occur more frequently when paediatric-trained personnel are not used for transport.<sup>32</sup> A referral and retrieval infrastructure which links a tertiary centre to outlying areas within the region is necessary. Local health care providers must have sufficient skills to stabilise any critically ill child adequately. The transport team must offer a level of care during the stabilisation and transport phases that is equivalent to that of the receiving paediatric ICU.

It is important for regional hospitals not used to routinely caring for paediatric trauma patients to recognise and acknowledge their individual abilities and limitations. A relationship with a tertiary PICU is essential to allow appropriate and timely communication regarding advice on clinical care, prehospital stabilisation and safe transport for individual patients.

### BRAIN DEATH

Determination of brain death in children has different implications.<sup>33</sup> Isoelectric EEGs have been reported in neonates with partially preserved clinical brain function, and cerebral death can occur without marked increase in ICP, allowing partial cerebral blood flow in the presence of brain death criteria and electrocerebral silence. In addition, partial brain recovery has been demonstrated after prolonged periods of clinical unresponsiveness. So for determination of brain death, consideration needs to be given to longer observation periods, more frequent use of confirmatory tests, and an emphasis on the history and clinical findings.

The American Academy of Pediatrics has set longer observation times which include the requirement for two separate EEGs or one EEG and a cerebral radionuclide angiogram. These longer observation times depend on the child's age, namely:

- over 1 year of age – 12 hours' observation
- ages 1 month to 12 months – 24 hours' observation
- ages 7 days to 2 months – 48 hours' observation
- under 7 days of age – no recommendation

The Australian and New Zealand Intensive Care Society recommendations on brain death and organ donation only make reference to the under 2 months age group when 'determination of brain death may be more difficult and different time periods may be required'.<sup>34</sup> Importantly, there is a lack of evidence for any required observation periods, so that cerebral blood flow imaging may be required in the neonate and infant. The most important factors when determining brain death are in knowing the cause of coma, and being certain of its irreversibility. Time must be allowed for relatives to come to terms with the diagnosis, and there is a responsibility to discuss organ donation. Having relatives watch the physical examination for brain death testing is helpful.

### ORGAN DONATION

During the process of brain death determination and consideration of organ donation, there are significant emotional implications for both the care-givers and the relatives:

- There is a critical time when the hopelessness of the child's outcome becomes apparent and consideration is about to be given for the declaration of brain death.
- The treatment plan previously focused on cerebral resuscitation, and intensive care staff reach a pivotal decision point when treatment is deemed unsuccessful.
- If organ donation is to be considered, then some therapies must be withdrawn to allow for an assessment of cerebral function.

This moment can be a very stressful time for the professional care-givers involved, because they need to shift

from a cerebral resuscitation paradigm to withdrawal of support to allow for declaration of brain death, and then institute protocols aimed at organ resuscitation for possible organ donation.

Parents and relatives have to deal with:

- their child being taken from them unexpectedly
- the death being surrounded by tragic circumstances
- intensive medical therapy and critical decisions concerning interventions
- discussions on withdrawal of support
- confronting the issue that their child who outwardly looks no different is clinically dead; and
- subliminal conflicts of blame and guilt which can lead to conflict within family relationships

Success in asking for paediatric organs from parents is associated with:

- knowing the certainty of death
- a willingness to do good for others
- previous discussion of organ donation within the family unit; and
- a knowledge of the patient's wishes before death

Factors inhibiting a willingness to donate by parents include:

- an uncertainty in the parents understanding the diagnosis
- insufficient information and counselling from health professionals; and
- a fear of mutilation

### WITHDRAWAL OF SUPPORT

The emotion surrounding a child's impending death can be overwhelming for both relatives and intensive care staff. Children are involved in sudden and catastrophic events that at times seem unreasonable and unfair. For parents, the grieving process begins before or during the intensive care admission, and intensive care staff are intimately involved in helping parents and relatives through this process. The death of any child is a tragedy, and communication between staff is important to ensure appropriate emotional support. Intensive care staff need to understand that withdrawal of therapy can be appropriate. Ensuring the process has dignity and helping relatives through their grieving process are important facets of the intensive care commitment.<sup>35</sup>

# Equipment for paediatric intensive care

James Tibballs

This chapter discusses equipment and its performance required in paediatric and neonatal intensive care. How to use equipment is not discussed. Examples of equipment are given, but exhaustive lists are not intended. Only essential equipment is considered.

Not discussed includes equipment for aerosol therapy, anaesthesia, bronchoscopy, cardiovascular monitoring, cardiac output measurement, echocardiography, ultrasonography, electroencephalographic monitoring, extracorporeal membrane oxygenation, ventricular assistance, home mechanical ventilation, hyperbaric treatment, negative pressure ventilation, nitric oxide therapy, phrenic nerve pacing, mechanical devices for treatment of shock, suction devices and tracheostomy–cricothyrotomy.

All equipment should be purchased, used and maintained in accordance with recognised local standards and manufacturers' instructions. Medical and nursing staff should read the manuals accompanying all items of equipment and receive instruction on safe use.

Numerous items including laryngoscopes, resuscitation bags and ventilator circuits are available as disposable items in response to a market demand for infection safety and reduction of sterilisation costs. The user should subject such items to measures of quality control.

## AIRWAY MANAGEMENT

### ENDOTRACHEAL TUBES

#### TUBE TYPES

Polyvinyl chloride or silastic tubes are suitable for long-term intubation. There is little difference in the safety of uncuffed and cuffed tubes provided correct sizes are used and cuff pressures are regulated. The cuff should be inflated with the minimum volume of air necessary to maintain a seal, and checked every 4–8 hours. Recording of pressure in the cuff is desirable. Nonetheless, cuffs reduce effective tube diameter, which would otherwise be available for gas flow. High-volume low-pressure cuffed tubes may be used after puberty when the cricoid region of the trachea has enlarged and is no longer a narrow region at special risk. In circumstances of poor lung compliance, high airway resistance or foreseeable

difficulties changing a tube (e.g. as in facial burns), it may be preferable to use a cuffed tube from the outset.

The curve of the tube should be of the Magill type – curved but neither preformed nor of variable diameter. Preformed tubes (e.g. Rae and Childs) make suction difficult and automatically stipulate length in relation to diameter and circumference. Tubes of non-uniform diameter (e.g. Cole and Oxford) may damage the vocal cords, and do not prevent endobronchial intubation.

- Radio-opacity is necessary for correct positioning.
- All tubes should have length markings and a Murphy eye, i.e. a side aperture at the distal end, allowing gas to flow if the tip abuts against the tracheal wall.

#### TUBE SIZE

A selection of sizes, one larger and one smaller than the anticipated size, should be available at intubation. Tube sizes according to body weight and age are given in Table 104.1 and 104.2. A rough guide for internal diameter size in the child is  $\text{age (in years)}/4 + 4 \text{ mm}$ .

Correct selection of size is necessary to avoid pressure-induced ischaemia/ulceration of tracheal mucosa and to limit aspiration around the tube. The correct size should allow not only a small leak on application of moderate inflation pressure (25 cmH<sub>2</sub>O, 2.5 kPa) but also enable adequate pulmonary inflation and expiration. When lung compliance is poor, it is permissible to use a cuffless tube without a leak or a cuffed tube to achieve lung inflation.

#### PLACEMENT

Oral or nasal tubes may be used. Orally placed tubes are preferred in acute resuscitation and when only a short duration of intubation is required, e.g. for anaesthesia during insertion of a central venous cannula. Nasal placement of tubes is preferred in the setting where spontaneous or mechanical ventilation is required for prolonged periods.

Nasal tubes are more comfortable and manageable for the awake patient and are more easily secured to the face, but pose risks, which include sinus infection and necrosis of the alae nasi. Oral tubes are difficult to fix, uncomfortable and are easily occluded by biting by conscious/semiconscious patients.

**Table 104.1** Orotracheal and nasotracheal tube lengths for premature neonates

Birth weight (g)	Gestation (weeks)	Oral depth (cm)	Nasal depth (cm)
750	24–25	5–5.5	6.5
1000	27	5.5	7
1500	30–31	6	8
1750	31–32	6.5	8.5
2000	33	7	9
2250	34–35	7–7.5	9.5
2500	35–36	7.5	9.5–10
2750	36–37	8	10.5
3000	37–38	8–8.5	10.5
3500	40	9	11–11.5

ETT sizes: BW <1 kg, 2.5 mm; 1–3.5 kg, 3.0 mm; >3.5 kg, 3.5 mm.

**Table 104.2** Endotracheal tube sizes (internal diameter) and orotracheal and nasotracheal depths for infants and children

Body weight/age	Size (mm)	Oral depth (cm)	Nasal depth (cm)
Newly-born 3.5 kg	3.0	9	11–11.5
1–6 months	3.5	9.5–11	12–13
6–12 months	4.0	11.5–12	13–14
2–3 years	4.5	13–13	15–16
4–5 years	5.0	14–14	17–18
6–7 years	5.5	15–15.5	19
8–9 years	6.0	16–16	20
10–11 years	6.5	17–17	21
12–13 years	7.0	18–18	22
14–16 years	7.5	19	23

### TUBE LENGTH (DEPTH)

The endotracheal tube tip should be located in the mid-trachea so that the risks of accidental extubation and endobronchial intubation are minimised. Correct positioning of the tube should always be checked by auscultation in the axillae, by chest X-ray immediately after intubation and daily thereafter.<sup>1</sup> At intubation, visualisation of the depth of the tube passed through the cords should be a guide only, since the tube advances when the head is released from extension as the laryngoscope is removed.<sup>2</sup>

The lengths (depths) at which orotracheal and nasotracheal tubes can be chosen initially on the basis of weight or gestation in premature neonates are given in Table 104.1, and on the basis of age for infants and children in Table 104.2. The lengths are at the lips for oral tubes and at the exit from the nose for nasal tubes. For oral tubes, a guide to correct depth for 2 years and over is given by the formula: (age in years/2 + 12 cm), while for nasal tubes the formula is: (age in years/2 + 15 cm). The depth of insertion of any tube should be documented or marked on the tube.

### LARYNGOSCOPES

The adult curved Macintosh blade is suitable for all paediatric patients except neonates and infants, in whom a straight blade is needed to displace the relatively large epiglottis anteriorly from the laryngeal inlet. A straight flat blade, e.g. Miller (size 0 or 1) or Seward blade, or a straight blade with a medial flange (Magill, Robertshaw, Oxford or Wisconsin) is equally suitable for this purpose. The latter blades displace the tongue medially and give a better view of the larynx, but leave less room for instrumentation with a sucker, introducer or forceps.

### SUCTION CATHETERS

Sizes 5, 6, 8, 10 and 12 FG should be available. The suction catheter should be large enough to remove secretions but not too large to occlude the endotracheal/tracheostomy tube lumen (Table 104.3). Many suitable types are available – differing in number and location of suction ports (end and side ports are needed) and whether the tip is angled or straight. Angled tips facilitate entry into the left main bronchus. Satin-finish types with smooth port edges are needed. Single use suction catheters may be reused up to 24 hours without adding to the risk of pneumonia.<sup>3</sup> Closed suction systems permit suction without disconnection from ventilator as may be indicated during nitric oxide therapy, severe lung disease or frequent suction.

**Table 104.3** Recommended suction catheters

Internal diameter (mm) of ETT or tracheostomy	Recommended suction catheter (FG)
2.5	5
3.0	6
3.5–5.5	8
6.0–6.5	10
7.0 and larger	12

ETT, endotracheal tube.

### OROPHARYNGEAL AIRWAYS

A range of Guedel airways (sizes 000, 00, 0, 1, 2 and 3) constructed of polyvinyl chloride with a metal insert should be available: an airway that is too small may be occluded by the surface of the tongue or displace the tongue backwards to obstruct the airway; an airway that is too large may enter the oesophagus. The correct size, when placed alongside the cheek, extends from the centre of the lips to the angle of the mandible. Nasopharyngeal airways are available for the older child, but any size can be constructed from an endotracheal tube. A guide to length is from the tip of the nose to the tragus of the ear.

### LARYNGEAL MASK AIRWAYS

Sizes are available to suit body weight (kg) of newborns, infants and children:

● size 1	< 5 kg
● size 1½	5–10 kg
● size 2	10–20 kg
● size 2½	20–30 kg
● size 3	30–50 kg
● size 4	50–70 kg
● size 5	70–100 kg
● size 6	> 100 kg

They have complementary roles in paediatric intensive care practice which are as airways under anaesthesia, a limited role during cardiopulmonary resuscitation (CPR) and as emergency relief of upper-airway obstruction.

## MECHANICAL VENTILATION

### RESUSCITATOR 'BAGGING' CIRCUITS

Manual pulmonary inflation is often necessary via a mask or endotracheal/tracheostomy tube. Two types of device are available: flow-inflated and self-inflated bags.

#### FLOW-INFLATED BAGS

These are exemplified by Jackson-Rees modified Ayre's T-piece. Gas flow must exceed 220 ml/kg per min for children and 3 l/min for infants to prevent rebreathing during manual ventilation. It is possible to control precisely the concentration of inspired oxygen, which is an advantage, especially for the premature neonate at risk of oxygen-induced retrolental fibroplasia. However, considerable experience is necessary to provide adequate ventilation without barotrauma in the intubated infant. The circuit has neither a valve nor any pressure-relief device. A pressure gauge should be incorporated in the circuit to help prevent barotrauma.

#### SELF-INFLATED BAGS

These bags are designed to give positive-pressure ventilation attached to either a mask or endotracheal/tracheostomy tube. Rebreathing is prevented by one-way duck-bill valves, spring disk/ball valves or diaphragm/leaf valves.

The Laerdal bag series (infant, child, adult) typify these devices. A pressure-relief valve (infant and child size) opens at 35 cmH<sub>2</sub>O (3.5 kPa). A pressure monitor can be incorporated in the circuit. Supplemental oxygen is added to the ventilation bag, with or without attachment of a reservoir bag, whose movement may serve as a visual monitor of tidal volume during spontaneous ventilation when intubated. However, the valve may offer too much resistance for spontaneous ventilation and they should not be used to provide supplemental oxygen to a spontaneously breathing patient via a mask placed loosely over the face.

With Laerdal and Partner bags, negligible amounts of oxygen (0.1–0.3 l/min) issue from the patient valve when 5–15 l/min of oxygen is introduced into bags unconnected to patients.<sup>4</sup> The valve is unlikely to open unless the mask is sealed well on the face. The delivered oxygen concentration is dependent on the flow rate of oxygen, use of the reservoir bag, and the state of the pressure relief valve (whether open or closed).

- With use of the reservoir bag and oxygen flow greater than the minute ventilation, 100% oxygen is delivered.
- Without the reservoir bag the delivered gas is only 50% oxygen, despite oxygen flow rate at twice minute ventilation.
- At an oxygen flow rate of 10 l/min to the infant resuscitator bag, the delivered gas is 85–100% oxygen without the use of the reservoir bag.

Other self-inflated bags include the Combibag, Ambu, AirViva and Hudson RCI.

### MASKS

Masks should facilitate an airtight seal on the face with minimal dead space.

- For neonates, Rendell-Baker Soucek masks (sizes 0 and 1) or Bennett masks (sizes 1 and 2) are suitable.
- For infants and small children, the larger Rendell-Baker Soucek masks (sizes 2 and 3) or small masks with inflatable rims, such as CIG (sizes 2 and 3) or MIE (sizes 0 and 1), are suitable.
- For older children, masks with inflatable rims are preferred.

Masks with rims created by infolding of the body are more difficult to use.

## MECHANICAL VENTILATORS

### CONVENTIONAL VENTILATORS

Some ventilators are designed specifically for neonates and infants. A few adult ventilators are also satisfactory. In addition to general requirements of ventilators, the paediatric ventilator should have:

- low circuit volume, compliance and resistance
- minimal dead space within the ventilator and circuit

- rapid response time for gas flow during spontaneous respiratory effort
- a lightweight circuit
- inspiratory time adjustment independent of the inspiratory/expiratory ratio
- capability for a ventilation rate up to 60 breaths/min (excluding capability for high-frequency ventilation)
- variable gas flow at least up to 2–3 l/kg per min
- electronic display of inspiratory pressure wave
- accurate measurement of low tidal volume

A generic classification of ventilators, their operational characteristics and their modes of ventilation has been proposed.<sup>5</sup> It is described here briefly to enable functional description and comparison of some ventilators.

Ventilators may be operationally classified as pressure, volume, flow or time controllers. These are the independent or control variables. Since only one variable can be controlled at a given time, i.e. predetermined, the remaining features of the waveform are dependent variables. If pressure, volume or flow is not predetermined, the ventilator is presumed to be a time controller in which only the timing of the inspiratory and expiratory phases is controlled.

- *Pressure controller*: the pressure waveform does not change when resistance or compliance changes, but volume waveform will.
- *Volume and flow controllers*: the volume waveform does not change when resistance and compliance change but the pressure waveform changes. In a volume controller the volume is measured and used in control whereas it is not in a flow controller. In a flow controller it is flow that is used.
- *Time controller*: both pressure and volume waveforms change when resistance and compliance change.

These concepts allow understanding of any mode of ventilation and interpretation of bedside pulmonary mechanics, i.e. resistance, compliance, time constants, etc. The manner of controlling the independent variable may be an open-loop system, in which no feedback occurs during inspiration to achieve the target goal, or a closed-loop or feedback or servo-controlled system in which the independent variable is modified according to progress during inspiration.

During inspiration, dual control may be used and may be altered from one independent variable to another. For example, in the VAPS mode (volume assured pressure support mode) of the Bird VIP Gold ventilator, control is switched from pressure to flow control if a preset tidal volume has not been achieved. In another example using the Pmax feature of the Dräger Evita 4, if in flow control a pressure limit has been reached, control is passed to pressure while the tidal volume is monitored and the inspiratory time increased until the preset tidal volume has been achieved.

#### PHASE VARIABLES

The manner of initiation of inspiration (triggering), sustaining inspiration (limit variables), initiation of expiration

(cycling) and sustaining expiration are the phase variables. Initiation of inspiration, or triggering, may be dictated by machine or patient. Usual triggers are the elapse of time or generation of pressure or flow by the patient. Flow triggering during spontaneous ventilation is more energy efficient and better tolerated than other variables, particularly when the flow sensor is located at the endotracheal tube. Mandatory breaths are all those triggered by a preset frequency or minimum minute ventilation, or terminated by a preset frequency or tidal volume. Spontaneous breaths are those initiated by the patient and terminated by lung mechanics or ventilatory drive. The quantification of the inspiratory phase is by time, pressure or volume. Initiation of expiration (termination of inspiration) or cycling is achieved by elapse of time, pressure, volume or flow. Expiration is usually sustained by pressure alone.

Modes of ventilation may be described on the following generic basis. It is derived from the controller variables. It should not be assumed that a manufacturer's mode terminology accurately defines its functional attributes or is intuitively obvious. Terminology is not necessarily interchangeable between different manufacturers. Although some new modes are genuine inventions, another purpose appears to be differentiation of product from competition. The capabilities of any ventilator can be defined by the following:

- The controller variable (pressure, volume, dual)
- The pattern of mandatory breaths versus spontaneous breaths
  - CMV is continuous mandatory ventilation (conventional IPPV)
  - SIMV is synchronised intermittent mandatory ventilation
  - CSV is continuous spontaneous ventilation.
- The phase variable for mandatory breaths, especially trigger and cycle variables
- Whether spontaneous breaths are assisted

If conditional variables exist, these act to change the pattern of ventilation – for example, to give a sigh breath based on elapse of time, or switching from patient-triggered breaths to machine-triggered breaths in the SIMV mode or mandatory minute ventilation modes.

Volume/flow-control modes are suitable for conditions in which lung compliance and resistance are variable. In these circumstances, the peak inspiratory pressure attained is a valuable observation. However, when a pressure limit is imposed, such information is lost. A mode consisting of flow control, time triggering, pressure limitation and time cycling is commonly used because of the relative ease of operation. However, relatively small leaks may severely compromise tidal volume, mean airway pressure and oxygenation. Large leaks may also delay attainment of preset pressure until late in the inspiratory cycle. Thus, it is helpful to display the volume and pressure waveforms. Some ventilators do, however, provide leak compensation (e.g. Bird VIP Gold). Gas flow should be set above 2 l/kg per min to achieve the preset pressure

early in the inspiratory period. This flow rate is also suitable for peak inspiratory flow rate during spontaneous respiratory effort with intermittent mandatory ventilation.

Pressure in the circuit should be monitored in close proximity to the endotracheal tube. Changes in endotracheal tube resistance from encrustation or kinking have a major adverse effect on tidal volume.<sup>6</sup>

Neonates and infants have small tidal volumes (5–50 ml), and are therefore prone to alveolar hypoventilation when variable air leaks occur around the endotracheal tube and from the ventilator–humidifier circuit. Moreover, the internal compliance and compressible volume of the circuit may exceed the tidal volume. Small tidal volumes are difficult to set and maintain when the lung compliance and resistance are abnormal.<sup>7</sup>

Most neonatal intensive care units (ICUs) use pressure-control modes which in hyaline membrane disease achieves adequate oxygenation with minimal barotrauma.<sup>8</sup> The pressure-control mode is more appropriate than the volume-control mode for neonates and infants 0.5–5.0 kg body weight. Ventilators, which are pressure controllers, deliver a variable flow dependent on lung and airway characteristics.

Improvements in ventilatory management of newborns are observed with a new generation of ventilators, which utilise changes in airway pressure, airway gas flow or abdominal movement to trigger inspiration, and which have ultrashort trigger delays.<sup>9</sup> Previously, ventilators were unable to cope with the very short inspiratory times (mean 0.31, SD 0.06 seconds) of newborns with respiratory distress syndrome.<sup>10</sup> Patient-triggered ventilation (PTV) permits synchronous ventilation with better gas exchange, prevents the patient fighting the ventilator and reduces the need for neuromuscular paralysis.<sup>11,12</sup> Some ventilators suitable for paediatric use are the Bear Cub 2001, Bear Cub 750vs, Bird T Bird, Bird VIP Gold, Drager Babylog 8000 (plus), Drager Evita 4, Evita XL, Infant star 950, Sechrist IV-100B, Sechrist IV-200 SAVI, Siemens Servo 900C, Siemens Servo 300, Siemens Servo-*i*, Viasy Aeva, and SLE 5000.

### HIGH-FREQUENCY VENTILATORS

These provide ventilation at at least four times normal rate and may be classified into five types:<sup>5</sup>

- high-frequency positive-pressure ventilation (HF-PPV)
- high-frequency jet ventilation (HFJV)
- high-frequency flow interruption (HFFI)
- high-frequency oscillation (HFO)
- high-frequency percussive ventilation (HFPV)

High-frequency oscillatory ventilation (HFO) at 15 Hz has been shown to achieve better gas exchange with less barotrauma than conventional mechanical ventilation in infants with respiratory distress.<sup>13,14</sup> Examples of high-frequency oscillators are the Sensor Medics and 3100A and 3100B (adult) and the Humming series models, of

which the latest is Atom Humming V. The latter also offers a synchronised intermittent mandatory ventilation mode. An example of a high-frequency jet ventilator is the Bunnell Life Pulse jet ventilator which is used in conjunction with a conventional ventilator to provide positive end-expiratory pressure (PEEP) and humidified gas for spontaneous ventilation. An example of a high-frequency positive-pressure ventilator is the Nellcor Puritan-Bennett Infant Star 950, which operates as a flow interrupter.

### TRANSPORT VENTILATORS

Although ‘hand-bagging’ may be used during transport from the field to hospital, between hospitals and within hospitals, it is highly desirable to utilise a purpose-designed transport ventilator to ensure consistent ventilation and cardiorespiratory stability. Ventilation by machine also enables personnel to attend to other tasks. Whether pneumatic or electronically powered, it must be compact, light, rugged, easy to operate and yet provide a standard and mode of ventilation required by a wide variety of patient illnesses and equivalent to that required by any patient in the ICU. Electrically powered ventilators should have both mains and battery power.

The ventilator should be capable of providing SIMV with time or flow cycling and flow or pressure-triggering, non-invasive ventilation, continuous positive airway pressure (CPAP) and PEEP, and provide 21–100% oxygen. Controls for rate, inspiratory time, flow, tidal volume and pressure should be independent. It should be unaffected by altitude and be operable in an MRI environment. It should incorporate alarms for low and high pressure, apnoea and disconnection. All these aims are difficult if not impossible to fulfil. Examples of ventilators are Drager Oxylog 2000, Pulmonic Systems LTV1000 and Newport HTSO.

### NON-INVASIVE VENTILATION (NIV)

The application of ventilation ‘BiPAP’ (bilevel positive airways pressure) or CPAP by means other than intubation (NIV) has become an essential part of paediatric intensive care practice. Although a proprietary name (Respironics), ‘BiPAP’ has become synonymous with non-invasive ventilation. It is distinct from BIPAP (biphasic positive airway pressure), a mode available in some conventional ventilators in which spontaneous ventilation is permitted during all phases of mechanical ventilation. CPAP or BiPAP may be given by an interface of a nasal, oronasal (full face) mask with harnesses with or without a chin strap (head-gear). Other interface devices such as mini-masks, nasal pillows, nasal cushions, mouthpiece/lipseal and helmets are less common in paediatrics.

CPAP is commonly used to relieve upper-airway obstruction or improve oxygenation in lung disease. BiPAP is commonly used to provide ventilation in chronic hypoventilatory states such as congenital central hypoventilation syndrome, neuromuscular diseases, pretransplantation cystic fibrosis and in acute conditions such as

asthma, pneumonia and pulmonary oedema. Both CPAP and BiPAP are used before resorting to invasive ventilation and after extubation. Although stand-alone, BiPAP machines are primarily intended for use in adult patients with obstructive sleep apnoea and are not generally intended for use as life support. Consequently, many machines are not licensed to provide ventilation via endotracheal tube or tracheostomy but this capability is a distinct advantage and may be provided as an optional mode in mechanical ventilators.

The defining characteristics of BiPAP are the automatic breath-by-breath compensation for air leaks and the ability to trigger and cycle by flow or time in synchronisation with patient effort. The devices can be set to provide a spontaneous (assisted) mode, timed (mandatory) mode or a combined mode. When the inspiratory positive airway pressure (IPAP) is set the same as the expiratory positive airway pressure (EPAP), CPAP is provided. Examples of CPAP machines are Tranquility (Healthdyne) and CPAP S6 series (Resmed). Examples of BiPAP machines are the BiPAP S/T, S/T-D, S/T-D 30, Harmony and Synchrony series (Respironics), the KnightStar 335 (Nellcor-Puritan-Bennett) but not suitable for children < 30 kg, and the Sullivan VPAP II and VPAP II ST (Resmed).

## OXYGEN THERAPY AND MONITORING

### OXYGEN CATHETERS

Sizes 6, 8 and 10 FG should be available and placed in the same nostril as the nasogastric tube, to limit airway resistance. Size 6 FG is suitable for neonates, 8 FG for infants and small children and 10 FG for older children. It should be appreciated that oxygen catheters placed in the nasopharynx provide a small amount of PEEP, and indeed may be used for that purpose.<sup>15</sup> Nasal cannulae (two-pronged) are not recommended. Excessive flow may cause gastric distension. Flow rate for infants should be regulated by a low-flow meter, graduated 0–2.5 l/min.

### OXYGEN MASKS

Masks may not be well tolerated by the infant or small child; oxygen catheters are preferable.

### HEAD BOXES AND INCUBATORS

A clear perspex head box is the best way of administering a high concentration of oxygen to the unintubated neonate and infant. Precise oxygen therapy is possible but rebreathing, heat loss and desiccation are potential problems. To avoid rebreathing, a large flow rate (10–12 l/min) of fresh gas with predetermined oxygen content should be introduced. The practice of introducing a low flow rate of 100% oxygen into a head box (to gain a lesser concentration) may cause rebreathing and hypercarbia. If

100% oxygen is the only compressed gas available, lesser concentrations of oxygen may be attained without rebreathing by using a flow of 100% oxygen and a Venturi device. The relatively large capacity of an incubator precludes the attainment of a high concentration of oxygen, but limited oxygen therapy, up to 60%, can be achieved.

### OXYGEN ANALYSERS

These are essential to regulate oxygen therapy via incubator or head box. The devices utilise either a polarographic electrode or galvanic cell (microfuel cell) as oxygen sensor. The polarographic types require a source of power (battery or mains), are more expensive to buy but cheaper to run, and have a faster response time.<sup>13,16</sup> An incorporated alarm is recommended. The sensing electrode should be placed close to the patient's head.

An oxygen analyser capable of monitoring deliberate hypoxic gas mixtures (e.g. OX60+, Parker Healthcare Pty Ltd) is required if nitrogen is to be used – for example, to increase pulmonary vascular resistance in management of post-Norwood repair of hypoplastic left heart syndrome.

### TRANSCUTANEOUS GAS ANALYSERS

Transcutaneous gas tensions in paediatric patients equate well with arterial gas tensions. However,  $P_{aO_2}$  is underestimated by  $P_{tcO_2}$  during mild hyperoxaemia in neonates.<sup>17</sup> Transcutaneous gas values are dependent on both arterial gas tensions and on blood flow. During normovolaemia with adequate flow,  $P_{tcO_2}$  reflects  $P_{aO_2}$  and  $P_{tcCO_2}$  reflects  $P_{aCO_2}$ . However, during circulatory failure, a reduction in  $P_{tcO_2}$  reflects a reduction in flow, provided  $P_{aO_2}$  is normal.<sup>18</sup> Likewise, during circulatory failure,  $P_{tcCO_2}$  exceeds  $P_{aCO_2}$  and is flow dependent.<sup>19</sup> Typical transcutaneous dual function single electrodes are Hewlett Packard Virida  $tcO_2/tcCO_2$ , Sensormedics FasTrac  $SO_2/CO_2$  monitor.

Continuous pulse oximetry ( $SpO_2$ ) has evolved to be an integral part of monitoring in neonatal and paediatric intensive care. Transcutaneous pulse oximetry is more convenient than transcutaneous partial pressure measurement. Each patient should have a pulse oximeter. The value of pulse oximetry is detection of hypoxaemia, not hyperoxaemia. They cannot be used accurately to titrate oxygen therapy, which requires blood or transcutaneous partial pressure measurement. The accuracy of pulse oximetry at low  $SO_2$  (< 75%) is poor.<sup>20</sup> Numerous devices are available.

### BLOOD GAS ANALYSERS

In many neonatal and paediatric conditions, frequent blood gas analysis is essential for optimal management. A blood gas analyser utilising small volumes (< 0.2 ml) is essential. The instrument should be located within or near the ICU, so that tests can be performed and the results known without delay. Hand-held bedside devices are available, e.g. i-Stat.

### APNOEA MONITORS

Infant apnoea is often due to upper-airway obstruction, seizures or gastro-oesophageal reflux,<sup>21</sup> although it may be idiopathic and is commonly associated with prematurity. Short apnoeic spells (< 15 seconds) are normal during sleep and feeding. Significant apnoea is associated with bradycardia, cyanosis and hypotonia. The detection and treatment of apnoea in intensive care are dependent on cardiovascular monitoring and constant nursing observation. In the home or ward, where observation is less than that available in the ICU, apnoea may be detected by the use of a pressure sensor in a pad or mattress under the infant, or by impedance pneumography, in which diaphragmatic movement causes a change in resistance between two electrodes on the skin. Apnoea of central origin is detected early by these devices but obstructive apnoea, resulting in paradoxical respiratory effort, is detected late. Some devices incorporate electrocardiogram monitoring and rely upon bradycardia as evidence of hypoxaemia, which is a useful but late sign in obstructive apnoea, when both hypoxaemia and movement of the diaphragm are present. False-positive alarms are not uncommon.

## THERMOREGULATION

### RADIANT HEATERS AND INCUBATORS

Adequate temperature regulation is essential in neonates and infants to avoid cold stress and to maintain a thermoneutral environment.<sup>22</sup> Numerous heaters and incubators are available with special features for transport, resuscitation, intensive care and regular ward nursing. Open-type radiant heaters (e.g. Drager Babytherm 8000 OC, Air Shields Vickers IICS-90, Datex Ohmeda Infant Warmers series) are more suitable for use in intensive care. The ideal radiant heater should incorporate:

- servo-controlled overhead heating device with alarm for overheating
- open tilt bed of adequate area
- clear perspex removable/hinged sides
- adequate illumination
- adjustable height
- facility for X-ray examinations
- facility for phototherapy

Additional features may include facilities for bottled oxygen and air, positive pressure, resuscitation and suction equipment.

Incubators are less suitable for use in intensive care because of limited access, but are better for transportation. Heating is via a conductive mattress. Double-walled infant incubators (e.g. Air-Shields Isolette C2000) reduce heat loss, attain preset temperature rapidly, do not produce excessive air currents or sound levels, and do not permit carbon dioxide accumulation.<sup>23</sup> Oxygen therapy and mechanical ventilation are possible with both types of unit, but are technically easier with all open-cot radiant heaters.

### CONVECTION AND CONDUCTION THERMOREGULATORS

Mattresses with circulating fluid and air-inflated blankets are essential for maintaining preset body temperatures as might be required for therapeutic hypothermia (after cardiac arrest or head injury) or restoration of normothermia after hypothermic or hyperthermic injuries.

### HUMIDIFIERS

Adequate humidification of ventilator circuits is of utmost importance in the paediatric patient. Unless adequately humidified, the relatively narrow endotracheal and tracheostomy tubes are prone to encrustation and blockage. Insensible water and heat loss are also prevented with adequate humidification. High-flow heated humidifiers provide near 100% humidification (44 mg H<sub>2</sub>O/l gas, 47 mmHg) at body temperature and are preferred. They are easily adapted for use into ventilator circuits, face and tracheostomy masks, T-piece circuits and oxygen head boxes. When used in ventilator circuits, it is important to realise that they contribute to internal compliance and a compressible volume, which produce errors in both volume-preset and pressure-preset ventilators. Ideally, the compliance should not exceed 1.0 ml/cmH<sub>2</sub>O for infants less than 10 kg body weight.<sup>24</sup>

Several methods exist to maintain the water level including an airlock system, parallel-fill system, float-system and a pinch-clamp system.<sup>5</sup> Systems that automatically maintain a constant level are preferred for the aforementioned reasons. Incorporation of servo-control is also important. A thermistor probe incorporated into the proximal inspiratory circuit and heating of the inspiratory limb ensure that gas is delivered to the patient at body temperature. However, because some heat loss may occur along the inspiratory limb and much more along the expiratory limb (which is not heated), significant condensation (rain-out) occurs. A water trap must be incorporated to gather 'rain-out' and the circuit, particularly the expiratory limb, positioned in a dependent manner to prevent aspiration by the patient. Such water, although potentially contaminated by airway bacteria, does not pose nosocomial infection risk and may be allowed to drain into the humidifier where high temperature inhibits bacterial growth. Circuits may be changed infrequently. Examples of servo-controlled heated humidifiers are Puritan-Bennett Cascade II and Fisher and Paykel MR600, 700, 720, 850 series.

Condenser-type humidifiers or 'artificial noses' have a role in intensive care. They are passive humidifiers capturing exhaled water vapour and heat, permitting their reuse on inhalation (heat and moisture exchangers, HME). Numerous devices exist, some incorporating filters and/or hygroscopic materials leading to subclassifications of heat and moisture exchanging filter (HMEF), hygroscopic heat and moisture exchanger (HHME) and hygroscopic heat and moisture exchanging filter (HHMEF). They are

often added to tracheostomy or endotracheal tubes of spontaneously breathing patients or inserted into the inspiratory limb of a ventilator circuit for short periods, e.g. for transport. They cannot replace full humidification. HMEs provide approximately one-quarter to one-third relative humidity whereas HHME/HHMEFs provide approximately one-half to three-quarters relative humidity.<sup>5</sup> Problems with these devices include deterioration of performance with time, resistance and dead space. The appropriate size for the patient (adult, paediatric, neonatal) must be used. They are not suitable for use if the patient is hypothermic, has thick or bloody secretions or requires frequent changes. They should never be used in conjunction with heated water humidifiers because of potential circuit blockage. They should not be moistened and the addition of oxygen, although sanctioned by some manufacturers, will compromise performance.

Unheated humidifiers of the passover, bubble, bubble diffuser and jet types are inefficient and have limited applicability in the intensive care setting. Other types of humidifiers such as jet nebulisers and ultrasonic nebulisers have little role in intensive care.

## MISCELLANEOUS EQUIPMENT

### INFUSION DEVICES

Numerous electromechanical devices have been developed to overcome the deficiencies of gravity-fed i.v. infusion sets. They enable constant and accurate infusion of predetermined volumes. These devices have wide clinical application and are used to control the administration of potent drugs, hormones and parenteral nutrition. Performance and application are variable.<sup>25,26</sup>

### VOLUMETRIC PUMPS

These regulate flow rate by delivering a premeasured bolus under pressure. In some the delivery is not smooth. They utilise disposable closed cassettes. The risk of air pumping is minimal and alarms indicate infusion failure. High (up to 999 ml/hour) and low flow rates (1 ml/hour) are possible. Examples are IVAC Neo-mate 565, Alaris Medical Systems Gemini PC-1, PC-2, Abbott Life-care 5000 'Plum' Pump, and B/Braun Infusomat fm.

### SYRINGE PUMPS AND DRIVERS

These are suitable for infusion of potent drugs in concentrated form at very low rates (down to 0.1 ml/hour). They are mains electricity and/or battery powered. The latter are suitable for use during transport and miniaturised models are suitable for ambulant use. These devices are suitable for i.v., intra-arterial, intramuscular, subcutaneous infusion or enterogastric feeding, being particularly suitable for use in neonates and infants. They are not suited to infusion of large volumes and offer no safeguard against extravasation

unless an overpressure alarm is incorporated. Generally, the pumps utilise specified syringes unless recalibrated. Some syringe brands do not run smoothly. At low flows (< 1 ml/hour) infusion line compliance contributes to irregular drug delivery associated with vertical displacement of the pump.<sup>27</sup>

Examples of syringe infusion pumps are B/Braun Perfusor, Graseby 3100, IVAC Alaris P3000, P6000, and Alaris asena GH.

## INDIRECT MEASUREMENT OF BLOOD PRESSURE

Measurement of blood pressure in the critically ill neonate and infant is important in cardiovascular monitoring. Continuous direct intra-arterial measurement is preferred in cardiovascular instability, but adequate monitoring can be achieved with Doppler ultrasonography (e.g. Roche Arteriosonde) or with microprocessor analysis of oscillometric signals (e.g. Critikon Dinamap, Nippon-Colin, Ohio NIMP, Narco Scientific and Vita-Stat, Kenz BPM). The latter devices provide time-automated analysis of systolic, diastolic and mean blood pressure, as well as heart rate at specified intervals. Some portable monitoring devices provide additional data, such as invasive pressure measurement, electrocardiogram, heart rate, pulse oximetry, capnography, respiratory rate and temperature (e.g. Nellcor Propaq, Datascope Passport, Schiller Argus TM-7, S & W Diascope, BCI 6100).

Continuous non-invasive measurement of blood pressure may be measured with the Ohmeda Finapres non-invasive blood pressure monitor. Blood pressure measured with these non-invasive devices correlates well with simultaneous measurement by direct intra-arterial measurement in neonates,<sup>28</sup> infants and children.<sup>29</sup> Generally, systolic pressure is underestimated by only 2–4 mmHg (0.3–0.5 kPa), while the diastolic pressure is overestimated by a similar amount. Venostasis and radial nerve compression are occasional complications.<sup>30</sup>

## NASOGASTRIC TUBES

These are mandatory in all intubated and/or ventilated patients as aids to prevent aspiration, and are a useful means of providing nutrition and medication. A range of sizes should be available: 5–6 FG for neonates; 8 FG for infants; 10 FG for small children and 12 FG for larger children.

## PLASMAPHERESIS/HAEMOFILTRATION

Generally, the techniques described in dialytic therapy are applicable to infants and children. Although separate veins – or an artery and a vein – may be cannulated, it is common to perform these procedures via a double lumen catheter inserted into a large vein (femoral, jugular, subclavian), i.e. to perform continuous venovenous haemo/diafiltration (CVVH, CVVHD), plasmfiltration or haemoperfusion. In infants (0–1 year), this requires a 6.5 FR catheter to achieve blood flow of 25–40 ml/

min, small children (1–8 years) an 8.5 FR catheter to achieve 30–60 ml/min and in large children (> 8 years) an 11 FR catheter to achieve 50–100 ml/min via a blood pump (e.g. Gambro MPM 10, Kimal ultra or Infomed HF400). Typically, the filtration rate is approximately one-third of the blood flow while the size of the molecules appearing in the filtrate is determined by filter size. To remove molecules up to 30 000 Daltons, Gambro FH 22, 55, 66, 77 or 88 is used. To remove molecules up to 3 million Daltons, Gambro PF1000 or PF2000 is used.

## DEFIBRILLATION

DC shock machines should be able to give shocks as low as 1 or 2 joules with gradations up to adult doses, with a preference for a biphasic waveform.

# Paediatric poisoning

James Tibballs

## EPIDEMIOLOGY

The peak incidence of poisoning in childhood is among 1–4 year olds. It usually occurs in the home when the child ingests a single prescribed or over-the-counter medication or a household product. Approximately 3500 young children are admitted to hospital each year in Australia.<sup>1</sup> This mode of poisoning is called ‘accidental’ – erroneously because it is usually the result of inadequate supervision or improper storage of poisons. The mortality is very low and if hospitalisation is required, it is usually brief (1–3 days). In this circumstance, care must be taken to ensure that whatever treatment is applied, it does not impose additional risk.

Occasionally, poisoning in childhood is either truly accidental as in ingestion of a decanted chemical, or is part of a syndrome of child abuse (Munchausen syndrome by proxy), or is iatrogenic as when a parent mistakes medications at home or when medical or nursing staff make errors in drug administration in hospital. Medication errors occur in approximately 5% of paediatric inpatient medication.<sup>2</sup> Self-poisoning in older children is usually with the intention to manipulate their psychosocial environment or to commit suicide, or is the result of substance abuse. All circumstances of poisoning require remedial action.

## DIAGNOSIS

Commonly, the diagnosis of poisoning in paediatric practice is self-evident and supported by a history detailed by parents or guardians. Although a single poison is usually involved, the possibility of several or multiple poisons should be considered. Occasionally the diagnosis is unknown on presentation. Any child who presents with unexplained obtundation, fitting, hypoventilation, hypotension or has a metabolic derangement should have the diagnosis excluded.

A knowledge of important poisons is indispensable. A number of poisons or classes of poison are potentially fatal to a small child if taken as a single tablet or a teaspoonful. These include opiates (methadone, buprenorphine, lomotil), camphor, quinine derivatives, cyclic antidepressants, clonidine,<sup>3</sup> sulphonylureas, salicylates and calcium channel blockers.<sup>3</sup>

## OPTIONS FOR TREATMENT

The treatment should be determined by the poison, severity of poisoning as judged by the observed and expected effects of the poison, by the amount ingested, by the interval between ingestion and presentation and by the existence or otherwise of an antidote.

The range of treatment options is to: discharge home, observe for a short duration in the emergency department or ward, provide intensive nursing care or to treat medically. The task is to match the intensity of treatment to the severity of the poisoning, thereby avoiding under- and overtreatment.

## PRINCIPLES OF MANAGEMENT

The four basic principles in management of poisoning are:

- support vital functions
- confirm the diagnosis
- remove the poison from the body
- administer an antidote. Few poisons have antidotes (Table 105.1).

Individual poisons may require specific measures. Consult toxicology texts<sup>4–6</sup> for details.

The vast majority of poisoning in childhood is by ingestion. The correct choice of a gastrointestinal decontamination technique is crucial to uncomplicated recovery. The choices are induced emesis, gastric lavage, activated charcoal, whole-bowel irrigation or a combination of these techniques. The efficacy, indications, contraindications and disadvantages and complications of these techniques are discussed below. A general plan of management is presented in Figure 105.1.

A crucial point in management is initial recognition that the patient is in a state of either ‘full-consciousness’ or ‘less-than-full consciousness’. Traditionally, management has been dependent on a judgement of whether the gag reflex is present or absent, but in practice this is rarely tested. Since aspiration pneumonitis is a common feature of poisoning management, particularly among (but not confined to) CNS obtunded patients, it is prudent to regard all obtunded patients as having incompetent pharyngeal reflexes.

Table 105.1 Antidotes to some serious poisons

Poison	Antidotes	Comments
Amfetamines	Esmolol i.v. 500 µg/kg over 1 min, then 25–200 µg/kg per min Labetalol i.v. 0.15–0.3 mg/kg or phentolamine i.v. 0.05–0.1 mg/kg every 10 minutes	Treatment for tachyarrhythmia Treatment for hypertension
Benzodiazepines	Flumazenil i.v. 3–10 µg/kg, repeat 1 minute, then 3–10 µg/kg per hour	Specific receptor antagonist. Beware convulsions
β-Blockers	Glucagon i.v. 7 µg/kg, then 2–7 µg/kg per min Isoprenaline i.v. 0.05–3 µg/kg per min Noradrenaline i.v. 0.05–1 µg/kg per min	Stimulates non-catecholamine cAMP (preferred antidote) Beware β <sub>2</sub> hypotension Antagonises at receptors
Calcium channel blocker	Calcium chloride i.v. 10%, 0.2 ml/kg	Antagonises at receptors
Carbon monoxide	Oxygen 100%	Decreases carboxyhaemoglobin. May need hyperbaric oxygen
Cyanide	Dicobalt edetate i.v. 4–7.5 mg/kg Hydroxocobalamin (vitamin B <sub>12</sub> ) i.v. 70 mg/kg Amyl nitrite 0.2 ml perles by inhalation until sodium nitrite 3% i.v. 0.13–0.33 ml/kg over 4 min, then sodium thiosulphate 25% i.v. 1.65 ml/kg (max 50 ml) at 3–5 minutes	Give 50 ml 50% glucose after dose Beware anaphylaxis, hypertension Beware hypotension. Nitrites form methaemoglobin–cyanide complex. Beware excess methaemoglobin >20%. Thiosulphate forms non-toxic thiocyanate from methaemoglobin–cyanide
Digoxin	Magnesium sulphate i.v. 25–50 mg/kg (0.1–0.2 mmol/kg) Digoxin Fab i.v.: acute – 10 vials per 25 tablets (0.25 mg each), 10 vials per 5 mg elixir; steady state: vials, serum digoxin(ng/ml) × BW(kg)/100	Antagonises digoxin at sarcolemma Binds digoxin
Ergotamine	Sodium nitroprusside infusion 0.5–5.0 µg/kg per min Heparin i.v. 100 units/kg then 10–30 units/kg per hour	Treats vasoconstriction. Monitor BP continuously Monitor partial thromboplastin time
Lead	Dimercaprol (BAL) i.m. 75 mg/m <sup>2</sup> 4-hourly, six doses, then i.v. CaNa <sub>2</sub> edetate (EDTA) 1500 mg/m <sup>2</sup> over 5 days if blood level >3.38 µmol/l If asymptomatic and blood level 2.65–3.3 µmol/l, infuse CaNa <sub>2</sub> EDTA 1000 mg/m <sup>2</sup> per day 5 days or oral succimer 350 mg/m <sup>2</sup> 8-hourly 5 days, then 12-hourly 14 days	Chelating agents
Heparin	Protamine 1 mg/100 units heparin	Direct neutralisation
Iron	Desferrioxamine 15 mg/kg per hour 12–24 hours if serum iron >90 µmol/l (500 µg/dl) or >63 µmol/l (350 µg/dl) and symptomatic	Give slowly, beware anaphylaxis
Methanol, ethylene glycol, glycol ethers	Ethanol i.v. loading dose 10 ml/kg 10% diluted in glucose 5%, then 0.15 ml/kg per hour to maintain blood level 0.1% (100 mg/dl) Fomepizole (4-methylpyrazole) 15 mg/kg over 30 minutes, then 10 mg/kg 12-hourly, four doses. (Not available in Australia)	Competes with poison for alcohol dehydrogenase Inhibits alcohol dehydrogenase
Methaemoglobinaemia	Methylene blue i.v. 1–2 mg/kg over several minutes	Reduces methaemoglobin to haemoglobin
Opiates	Naloxone i.v. 0.01–0.1 mg/kg, then 0.01 mg/kg per hour as needed	Direct receptor antagonist

Continued

Table 105.1 Antidotes to some serious poisons—Continued

Poison	Antidotes	Comments
Organophosphates and carbamates	Atropine i.v. 20–50 µg/kg every 15 minutes until secretions dry Pralidoxime i.v. 25 mg/kg over 15–30 minutes then 10–20 mg/kg per hour for 18 hours or more. Not for carbamates	Blocks muscarinic effects Reactivates cholinesterase
Paracetamol	<i>N</i> -acetylcysteine i.v. 150 mg/kg in dextrose 5% over 60 minutes then 10 mg/kg per hour for 20–72 hours OR oral 140 mg/kg then 17 doses of 70 mg/kg 4-hourly (total 1330 mg/kg over 68 hours)	Restores glutathione inhibiting metabolites. Give if serum paracetamol exceeds 1500 µmol/l at 2 hours, 1000 at 4 hours, 500 at 8 hours, 200 at 12 hours, 80 at 16 hours, 40 at 20 hours. Beware anaphylaxis
Phenothiazine dystonia	Benzatropine i.v or i.m. 0.01–0.03 mg/kg	Blocks dopamine reuptake
Potassium	Calcium chloride 10% i.v. 0.2 ml/kg Sodium bicarbonate i.v. 1 mmol/kg  Glucose i.v. 0.5 g/kg plus insulin i.v. 0.05 units/kg  Salbutamol aerosol 0.25 mg/kg Resonium oral or rectal 0.5–1 g/kg	Antagonises cardiac effects Decreases serum potassium (slight effect). Beware hypocalcaemia Decreases serum potassium (rapid marked effect). Monitor serum glucose Decreases serum potassium (rapid marked effect) Absorbs potassium (slow effect)
Sulphonyl ureas	Glucose Octreotide 1–2 µg/kg 8-hourly	Inhibits insulin release
Tricyclic antidepressants	Sodium bicarbonate i.v. 1 mmol/kg to maintain blood pH >7.45	Reduces cardiotoxicity

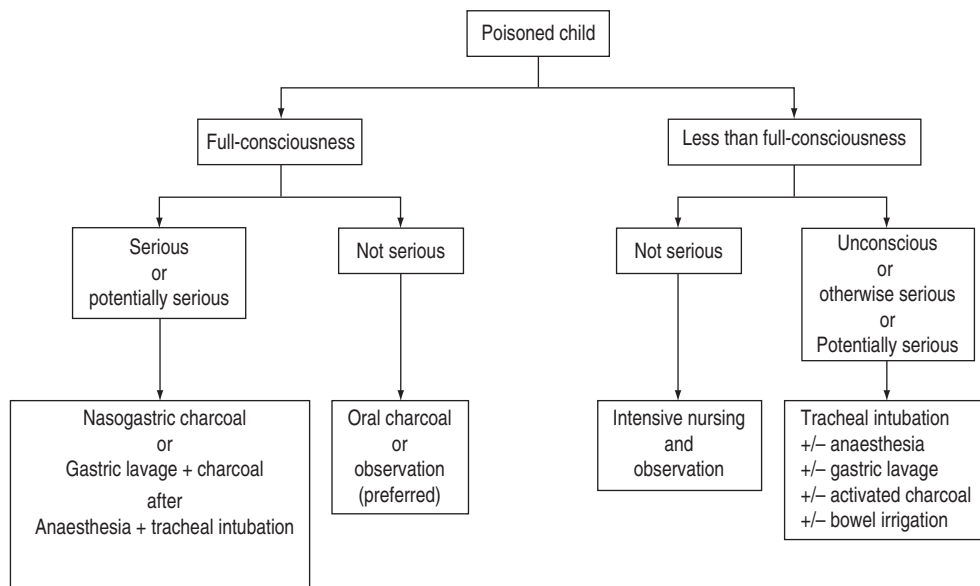

Figure 105.1 General management of the poisoned child.

The decision to attempt removal of a poison should always be made with due reference to two facts:

- The vast majority of childhood poisonings recover with merely supportive care or no treatment at all
- Aspiration pneumonitis is more serious than most poisonings

Occasionally, removal from the circulation by charcoal haemoperfusion, plasmfiltration or haemofiltration is indicated.

### INDUCED EMESIS

Induced emesis is quickly disappearing from hospital practice and should not be performed routinely in this setting.<sup>7</sup> It does not improve outcome and may reduce effectiveness of the alternative treatments of activated charcoal, oral antidotes and whole-bowel irrigation.

Specific contraindications include actual or impending loss of full consciousness or ingestion of corrosives or hydrocarbons.<sup>7</sup>

Syrup of Ipecacuanha has superseded other more injurious substances as emetic agents. It contains alkaloids, mainly emetine and cephaeline, which induce emesis by stimulation of the chemoreceptor trigger zone of the medulla and by irritation of the gastric mucosa.

The efficacy of ipecacuanha (ipecac) is limited and decreases with time from ingestion. Although it causes vomiting in a high percentage (93–100%) of children within 25 minutes, the percentage of stomach contents ejected is small (28%) even when administered immediately after ingestion.<sup>8</sup> Moreover, solids are retained in the stomach or may even be propelled into the duodenum.<sup>9</sup>

In experimental drug ingestions, approximately 50–83% of ingested experimental drug is removed if ipecac is given after 5 minutes,<sup>10</sup> but falling to 2–44% if given at 30 or 60 minutes.<sup>11–15</sup> In paediatric paracetamol poisoning, the 4-hour postingestion serum level was approximately 50% of controls if ipecac-induced vomiting occurred within 60 minutes of ingestion, but no benefit was derived if emesis occurred beyond 90 minutes after ingestion.<sup>16</sup> Similarly, serum levels of paracetamol were reduced approximately 50% if ipecac was administered at home, inducing emesis at a mean of 26 minutes after ingestion, compared with ipecac administered at a medical facility at a mean of 83 minutes.<sup>17</sup>

In adults, ipecac is even less useful and has to be given immediately to have quantifiable effects.<sup>18</sup>

Induced emesis appears superior to gastric lavage but inferior to activated charcoal. In children poisoned with salicylate, emesis retrieved twice as much compared with gastric lavage.<sup>19</sup> In adult volunteers ipecac-induced vomiting, occurring at an average of 19 minutes after ingestion, removed 54% of a tracer compared with 30% with gastric lavage performed at the equivalent times after ingestion.<sup>20–22</sup>

The use of ipecac has potential complications:

- time-related lack of efficacy
- protracted vomiting (17%)
- diarrhoea (13%)
- lethargy (12%)<sup>23</sup>

More serious, but rare complications include:

- gastric, oesophageal or brain haemorrhage
- pneumomediastinum
- aspiration pneumonitis may occur, even in the fully conscious
- delayed onset of vomiting which is a threat if loss of consciousness subsequently occurs
- abuse in bulimia which may cause cardiotoxicity as well as the sequelae associated with repetitive vomiting

Critics claim that induced emesis merely creates work, delays discharge from the emergency department,<sup>24</sup> increases complications<sup>24</sup> and does not benefit the patient who presents more than 1 hour after ingestion.<sup>25</sup> Importantly, ipecac did not alter the clinical outcome of patients who presented awake and alert to the emergency department.<sup>26</sup>

Induced emesis has been largely abandoned by emergency departments but its use in the home is safe and is associated with fewer paediatric emergency department attendances.<sup>27</sup> Its use at home is still recommended by authoritative paediatric health organisations in the USA<sup>28</sup> and by approximately half of poison centre staff.<sup>29</sup> Although ipecac was recommended inappropriately in 20% of cases to poisons information centres, it caused little morbidity.<sup>30</sup>

### CONCLUSION

In hospital, it has no practical role. Even when a child presents very early after significant poisoning, oral or nasogastric charcoal is preferred. Whenever induced emesis is used the child must be fully conscious on administration and expected to be fully conscious when vomiting occurs.

### GASTRIC LAVAGE

Its place in the management of the poisoned victim has also been curtailed. It is an invasive technique with questionable efficacy. Moreover, it is potentially harmful and should be reserved for the child who presents soon after life-threatening poisoning such as ingestion of iron or colchicine.

It involves passage of a large bore oro- or nasogastric tube into the stomach and the repeated instillation of fluid, usually water but some authorities advocate normal or half-normal saline. The oral route is preferred because of less potential for traumatic injury but an oropharyngeal airway may be needed to prevent tube occlusion by choking. A smaller tube may be used if the poison is a

liquid. Traditionally, the child should be placed in the left lateral position to limit stomach emptying but volume of intragastric contents rather than body position determines gastric emptying.<sup>31</sup>

Experimental studies with therapeutic substances in volunteers, or with liquid medicines or substances instilled into the stomachs of overdose victims, reported that gastric lavage retrieved 90% at 5 minutes,<sup>32</sup> 45% at 10 minutes<sup>21</sup> and 30% at 19 minutes<sup>20</sup> and reduced absorption or bioavailability by 20–32% at 1 hour after ingestion.<sup>11,33</sup> When gastric lavage was performed 5 minutes after ingestion of tablet drugs, it failed to prevent absorption, presumably because the tablets had not disintegrated.<sup>34</sup> In true overdose situations, gastric lavage within 4 hours of admission reduced serum paracetamol levels by 39%.<sup>35</sup>

Efficacy of gastric lavage, even with large bore tubes, is poor because tablets are not removed and lavage encourages propulsion into the duodenum.<sup>8</sup> In symptomatic patients, gastric lavage alone compared with gastric lavage and activated charcoal increased pneumonic aspiration and did not alter the duration of intubation or the stay in the emergency department or the intensive care unit (ICU),<sup>36</sup> and was not beneficial unless performed within 1 hour of ingestion.<sup>26</sup> A prospective randomised trial of gastric lavage in acute overdose,<sup>37</sup> although criticised on methodological grounds,<sup>37,38</sup> suggested that it made no difference to outcome of obtunded patients when preceding activated charcoal.

### CONTRAINDICATIONS

- Less-than-full consciousness patient (unless already intubated) because of the risk of aspiration pneumonitis – which is not negligible even during full consciousness<sup>36</sup>
- After ingestion of corrosives because of the risk of perforation
- After ingestion of hydrocarbons or petrochemicals because of the risk of pneumonitis

### COMPLICATIONS

- Aspiration pneumonitis
- Water intoxication
- Minor trauma to oropharynx (gastro-oesophageal perforation occurs rarely)
- Intrabronchial instillation of lavage fluid

As expected, infants and children never cooperate fully for gastric lavage, thus increasing risks of complications and the degree of psychological trauma.

If lavage is indicated, i.e. for life-threatening poisoning, rapid sequence induction of anaesthesia with intubation is advised. The largest possible lubricated tube of diameter similar to an appropriate sized endotracheal tube should be used and correct placement in the stomach confirmed. Small volumes (1–2 ml/kg) of

warm tap water may be used to lavage until clear. However, most water should be retrieved to avoid hyponatraemia.

### ACTIVATED CHARCOAL

Charcoal is a substance which adsorbs many drugs and is regarded as a ‘universal antidote’. It is advocated as the sole treatment in most poisonings although it is overused for minor poisonings. For many poisons no data exist regarding efficacy.

Treatment of charcoal with chemicals and heat increases its surface area to approximately 950 m<sup>2</sup>/g in so-called low surface area activated charcoal and to 2000 m<sup>2</sup>/g in superactivated charcoal. The latter adsorbs paracetamol better<sup>38</sup> and is more palatable.<sup>39,40</sup> Activated charcoal is not pleasant to drink and was associated with vomiting in 20% of poisoned children.<sup>41</sup>

It is superior to induced emesis and gastric lavage in treatment of symptomatic poisoned patients.<sup>22,26,36</sup> Its efficacy diminishes with time after ingestion. Activated charcoal reduces absorption of ingested experimental drugs in volunteers by 85–100% when administered 5 minutes after ingestion,<sup>10,34,42</sup> by 40–75% at 30 minutes<sup>9</sup> and by 30–50% at 60 minutes.<sup>14,42</sup> At a mean time of 98 minutes (SD 44) or more than 2 hours after poisoning, it was not effective at all.<sup>43,44</sup>

Studies have suggested that charcoal alone is as effective as when combined with either emesis or with lavage.<sup>37,38</sup> Furthermore, combined methods have a higher incidence of aspiration, 8.5% versus none.<sup>34</sup> Activated charcoal failed to show a benefit in asymptomatic poisoned patients.

Repeated doses of activated charcoal enhance elimination of some drugs by increasing adsorption and by achieving postabsorption elimination by interrupting enterohepatic circulation and by removing drug from the gastrointestinal mucosa (‘gastrointestinal dialysis’). Although there are multiple reports in experimental and clinical practice (Table 105.2), there is no hard evidence to show that this therapy reduces mortality or morbidity. Only in life-threatening poisoning by carbamazepine, dapsone, phenobarbital, quinine or theophylline should multiple-dose activated charcoal be considered.<sup>45</sup>

A suitable single dose is 1–2 g/kg. A multiple-dose regimen for children is 1–2 g/kg stat followed by 0.25–0.5 g/kg 4–6-hourly. An alternative is 0.25–0.5 g/kg hourly for 12–24 hours.<sup>46</sup>

### CONTRAINDICATIONS

- If ileus is present
- A less-than-fully conscious patient unless already intubated
- Substances not adsorbed – for example, strong corrosive acids and alkalis, cyanide, metals (iron, lithium, mercury, lead), alcohols, glycols, petroleum distillates (not all) and essential oils<sup>4–6</sup>

Table 105.2 Elimination and lack of elimination of drugs by multiple dose activated charcoal<sup>45</sup>

Elimination increased in experimental and clinical studies	Elimination increased in volunteer studies	Elimination not increased in experimental or clinical studies
Carbamazepine	Amitriptyline	Astemizole
Dapsone	Dextropropoxyphene	Chlorpropamide
Phenobarbital	Digitoxin	Doxepin
Quinine	Digoxin	Imipramine
Theophylline	Disopyramide	Meprobamate
	Nadolol	Methotrexate
	Phenylbutazone	Phenytoin
	Phenytoin	Sodium valproate
	Piroxicam	Tobramycin
	Sotalol	Vancomycin

See text for details.

### COMPLICATIONS

Aspiration of charcoal causes severe and often fatal pneumonitis, bronchiolitis obliterans and adult respiratory distress syndrome. Intratracheal instillation of activated charcoal causes a significant increase in lung microvascular permeability and arterial blood gas derangements.<sup>47</sup>

Constipation is common after charcoal but bowel obstruction is fortunately rare. The addition of a laxative (e.g. sorbitol or magnesium sulphate) is not recommended because although transit time through the gut is decreased, efficacy of the charcoal is reduced and life-threatening fluid and electrolyte imbalance may occur.<sup>48</sup>

### WHOLE-BOWEL IRRIGATION

Irrigation of the bowel with an iso-osmolar solution of polyethylene glycol and electrolytes is effective in reducing absorption of experimental drug by 24–67% at 1 hour after ingestion<sup>49,50</sup> and up to 73% at 4 hours after ingestion.<sup>51</sup> However, it has not been shown conclusively to improve the outcome of poisoned patients. The technique has limited applications to sustained-release or enteric-coated drugs and remains a theoretical option for ingestions of iron, lead, zinc (substances not adsorbed by activated charcoal), packets of illicit drugs<sup>52</sup> and for lithium.<sup>53</sup> Whole-bowel irrigation may be useful in delayed presentations when poisons have progressed beyond the stomach.

Irrigation solutions are adsorbed by activated charcoal and cause desorption of drug – necessitating prior administration of charcoal if a combined technique is used.<sup>54</sup> However, whole-bowel irrigation did not add to the benefits of activated charcoal in an experimental model of sustained-release theophylline poisoning.<sup>55</sup>

A suitable regimen is approximately 30 ml/kg per hour for 4–8 hours until rectal effluent is clear. A regimen of 25 ml/kg per hour has been used safely for 5 days (total 44.3 litres),<sup>56</sup> but a total of 3 litres performed as well as 8 litres in a simulated poisoning.<sup>57</sup>

### CONTRAINDICATIONS

Risk of aspiration during:

- less-than-full consciousness
- bowel obstruction or ileus

### PLAN OF MANAGEMENT

A general plan of management is suggested in Figure 105.1, but each case of poisoning mandates a specific plan of management according to circumstances. The primary determinant is the state of consciousness which relates to the risk of aspiration. Apart from that, the timing of presentation in relation to the severity of poisoning and the existence or otherwise of an effective antidote dictate if removal should be attempted, and by what means.

### POISONING BY SPECIFIC SUBSTANCES

Like adults, children are poisoned regularly by therapeutic prescription or over-the-counter therapeutic drugs and substances. The poisons probably reflect their availability in the home. In a survey, the most common agents responsible for hospital admission were benzodiazepines, anticonvulsants, anti-parkinsonism drugs, paracetamol, major tranquillisers, antidepressants and cardiovascular drugs.<sup>58</sup> The inquisitive nature of young children, however, may lead to poisoning by substances not normally regarded as dangerous – a few of these and others which have notably different management from similar poisoning in adults are considered here, briefly.

### BUTTON OR DISC BATTERIES

Ingestion may cause electrolytic injury and potentially corrosive, toxic or pressure injury. There are many types of batteries that contain a variety of substances: the most important are lithium, mercury and potassium hydroxide.

Impaction in the oesophagus is the most significant situation; this can result in oesophageal perforation and tracheo-oesophageal fistula or aorto-oesophageal fistula. An impacted battery must be removed endoscopically as soon as possible. Lithium batteries are large and impact readily and they have higher voltages than other types. Electrolysis commences as soon as the battery surfaces are immersed in oesophageal fluid. The consequence is local and surrounding tissue destruction, including the trachea.<sup>59</sup> Strong alkali is produced at the cathode and strong acid is produced at the anode. Mercury batteries are more likely to fragment<sup>60</sup> but mercury poisoning is very uncommon.

Sufficient follow-up is necessary to exclude oesophageal and tracheal damage and to ensure that a battery in the stomach or distal bowel is eliminated.

### PETROLEUM DISTILLATES

Numerous by-products of petroleum distillation are utilised in industrial and domestic purposes. Ingestion of these hydrocarbons may cause CNS toxicity (comprising obtundation and convulsion), gastrointestinal irritation, occasional hepatorenal toxicity, and pneumonitis.

Pneumonitis is the most significant and it may occur during ingestion or subsequent vomiting. Although variable, these substances have low surface tensions which enable their rapid dispersment throughout contiguous mucosal surfaces which include the respiratory tree. Prime examples are petrol, kerosene, lighter fluid, lamp oil and mineral spirits. Any child who ingests a distillate must be assessed for pneumonitis and this should include clinical examination, a chest X-ray and at least a non-invasive measurement of oxygenation such as pulse oximetry. Although most children who ingest petroleum distillates do not develop pneumonitis, the onset of this complication may be within 30 minutes<sup>61</sup> and progress rapidly to severe lung disease. An adequate period of observation (6 hours) is necessary to exclude this complication. There is a poor correlation between the amount ingested and the severity of pulmonary toxicity.

Deliberate inhalation of volatile hydrocarbons such as petrol or aerosolised paint has the additional toxicity on myocardial tissue, including fatal tachydysrhythmia, possibly due to sensitisation to endogenous catecholamines. The deliberate inhalation of paint fumes, usually via a plastic bag, is called 'chroming'.

### ESSENTIAL OILS

The oils from certain plants contain mixtures of terpenes, alcohols, aldehydes, ketones and esters, which are used domestically for various purposes. The well-known oils are eucalyptus, turpentine, citronella, cloves, melaleuca, peppermint, wintergreen and lavender. In general, small amounts cause depression of conscious state, irritation of gastrointestinal tract, liver dysfunction and pneumonitis if inhaled. Each has different toxicity. For example, as

little as 5 ml of eucalyptus oil<sup>62</sup> or 15 ml of turpentine may cause depression of conscious state.

Emesis should not be induced and gastric lavage performed only if airway protection is required.

### LEAD

Children are more susceptible to lead poisoning after ingestion than are adults, possibly because of better absorption.

Acute poisoning usually occurs after ingestion of a lead salt or metallic foreign body or a lead-containing product, such as paint or traditional remedy or cosmetic. Acute poisoning by a salt may cause life-supporting cardiovascular collapse, and encephalopathy.

Chronic poisoning can occur with ingestion of lead-contaminated water, or by inhalation of leaded petrol fumes or contaminated house dust. Chronic poisoning causes multiorgan dysfunction including neuromuscular dysfunction and encephalopathy.

Treatment consists of gastric decontamination in the case of recent ingestion of lead salts. The use of chelating agents may be indicated. In the case of ingestion of a lead foreign body, serial X-rays should be taken to ensure elimination, otherwise surgical removal is indicated. In the case of multiple embedded gunshot pellets and in all cases of chronic poisoning, serum lead levels should be measured to guide chelation therapy (see Table 105.1).

### PARACETAMOL

This is the most common drug ingested by children in an accidental, iatrogenic or deliberate overdose situation. Overdose has the potential for hepatic failure and, less commonly, renal failure. The onset of toxicity is delayed – up to several days. Consequently, the need for acute gastric decontamination is uncommon, but would be justifiable for acute large dose presentations. The toxicity in part is caused by the hepatic metabolite of the drug (*N*-acetyl-*p*-benzoquinoneimine) which accumulates when endogenous glutathione, which normally facilitates conversion of *N*-acetyl-*p*-benzoquinoneimine to non-toxic substances, becomes exhausted. Adequate supply of glutathione is ensured by administration of the antidote, *N*-acetylcysteine, a glutathione precursor which can be administered intravenously or orally (see Table 105.1).

The time of presentation after ingestion, as well as the dose, determines the management. If presentation is within 1 hour of ingestion, effective gastric removal or administration of activated charcoal may be all that is required pending a serum paracetamol level. In contrast, if presentation is several hours after ingestion, administration of the antidote, according to serum paracetamol level, takes precedence and although it may be administered orally or intravenously, the intravenous route is preferred.<sup>63</sup> Near-simultaneous administration of activated charcoal may be of some benefit but it may also cause vomiting or desorption, thus decreasing the effectiveness

of the antidote. If presentation is many hours after the poisoning, activated charcoal would not be indicated, so the antidote could be administered orally if necessary according to serum paracetamol levels. In all cases, evidence of liver dysfunction mandates administration of the antidote.

The threshold single toxic dose of paracetamol indicating *N*-acetylcysteine administration is generally regarded as 150 mg/kg, although it has been suggested that a single dose less than 200 mg/kg in children less than 6 years of age may be safely managed at home.<sup>64</sup> However, in situations of repeated sub-150 mg/kg doses hepatotoxicity has a high mortality among children<sup>65</sup> and in adults.<sup>66</sup> Unfortunately, toxic overdosing by chronic administration is not uncommon even in paediatric institutions.<sup>67</sup>

No sufficient data exist on which to firmly base a decision to administer *N*-acetylcysteine to children. Time-related serum levels of paracetamol should be measured and reference made to a guideline to administer the antidote (see Table 105.1) as derived from single toxic dose adult data.<sup>68</sup> The serum paracetamol level indicating antidote has been predicted as > 225 mg/l (1500 µmol/l) at 2 hours after ingestion of a single overdose of elixir in children 1–5 years of age.<sup>43</sup> If serum levels of paracetamol cannot be obtained and > 150 mg/kg has been ingested as a single dose or liver dysfunction is present after chronic poisoning, the antidote should be given.

Adverse reactions to *N*-acetylcysteine (approximately 8%) respond to an antihistamine<sup>69</sup> and its temporary cessation.

## IRON

Small quantities of elemental iron (> 20 mg/kg) are toxic to children. This dose may be reached by ingestion of few iron tablets. The initial effects are gastrointestinal, which may include gastric erosion, followed sometimes by an interval before cardiovascular failure occurs at 6–24 hours and then followed by multiorgan failure (including encephalopathy) and hepatic and renal failure up to some 48 hours after ingestion. In addition to general supportive measures, specific management should include abdominal X-ray to determine if unabsorbed tablets are present, in which case gastric lavage or whole-bowel irrigation may be useful. Activated charcoal is useless. Chelation therapy with desferrioxamine (see Table 105.1) should be guided by serum iron level and clinical status.

## CAUSTIC SUBSTANCES

In a study of 743 children,<sup>70</sup> the incidence of oesophageal burns caused by ingestion of automatic machine dish-washing detergents was 59%, caustic soda 55% and drain cleaners 55%. All are strongly alkaline and are corrosive. Dishwasher detergents are presented as liquids, powders or tablet blocks and are commonly accessed in an open dishwasher.<sup>71</sup> Pharyngeal and oesophageal irritation,

burns or corrosion may occur. There may be simultaneous ocular and dermal toxicity. Any child presenting with a history of ingestion of a caustic substance, irrespective of clinical signs, should be considered for oesophagoscopy and follow-up since the correlation between symptoms and signs and oesophageal burns is poor<sup>70</sup> and significant oesophageal damage may occur in the absence of more proximal injury.<sup>72</sup>

# Paediatric cardiopulmonary resuscitation

James Tibballs

This chapter concerns basic and advanced cardiopulmonary resuscitation (CPR) for infants and children (Figure 106.1). The essentials of resuscitation of the 'newly-born' (at birth) infant are also provided (Figure 106.2). The recommendations are based on guidelines published by several authoritative resuscitation organisations<sup>1–3</sup> which are in turn derived from an extensive evaluation of the science of resuscitation conducted by the International Liaison Committee on Resuscitation.<sup>4</sup>

This chapter is intended primarily for use by medical and nursing personnel in hospital (health carers). To add ability to knowledge, it is advisable to undertake a specialised paediatric cardiopulmonary resuscitation course, such as the Advanced Paediatric Life Support (APLS) or Paediatric Advanced Life Support (PALS) courses. This chapter should be regarded as an addendum to Chapters 17 (Adult cardiopulmonary resuscitation), 96 (The critically ill child) and 104 (Equipment for paediatric intensive care).

Distinctions within the term paediatric are based on combinations of physiology, physical size and age. Some aspects of CPR are different for the 'newly-born', infant, small (younger) child and large (older) child. 'Newly-born' refers to the infant at birth or within several hours of birth. 'Infant' refers to an infant outside the 'newly-born' period up to the age of 12 months. Other terms, such as newborn or neonate, do not enable that distinction. 'Small/young child' refers to a child of preschool and early primary school from the age of 1–8 years. 'Large/older child' refers to a child of late primary school from the age of 9 up to 14 years. Children older than 14 years may be treated as adults but they do not have the same propensity for ventricular fibrillation as do adults.

## EPIDEMIOLOGY

The causes of cardiopulmonary arrest (CPA) in infants and children are many but include any cause of hypoxaemia or hypotension or both. Common causes are trauma (motor vehicle accidents, near-drowning, falls, burns, gunshot), drug overdose and poisoning, respiratory illness (asthma, upper-airway obstruction, parenchymal diseases), postoperative (especially cardiac), septicaemia and sudden infant death syndrome. As many as 10% of newly-born infants

require some form of resuscitation for varied conditions of which birth asphyxia is the most common.

## BASIC LIFE SUPPORT

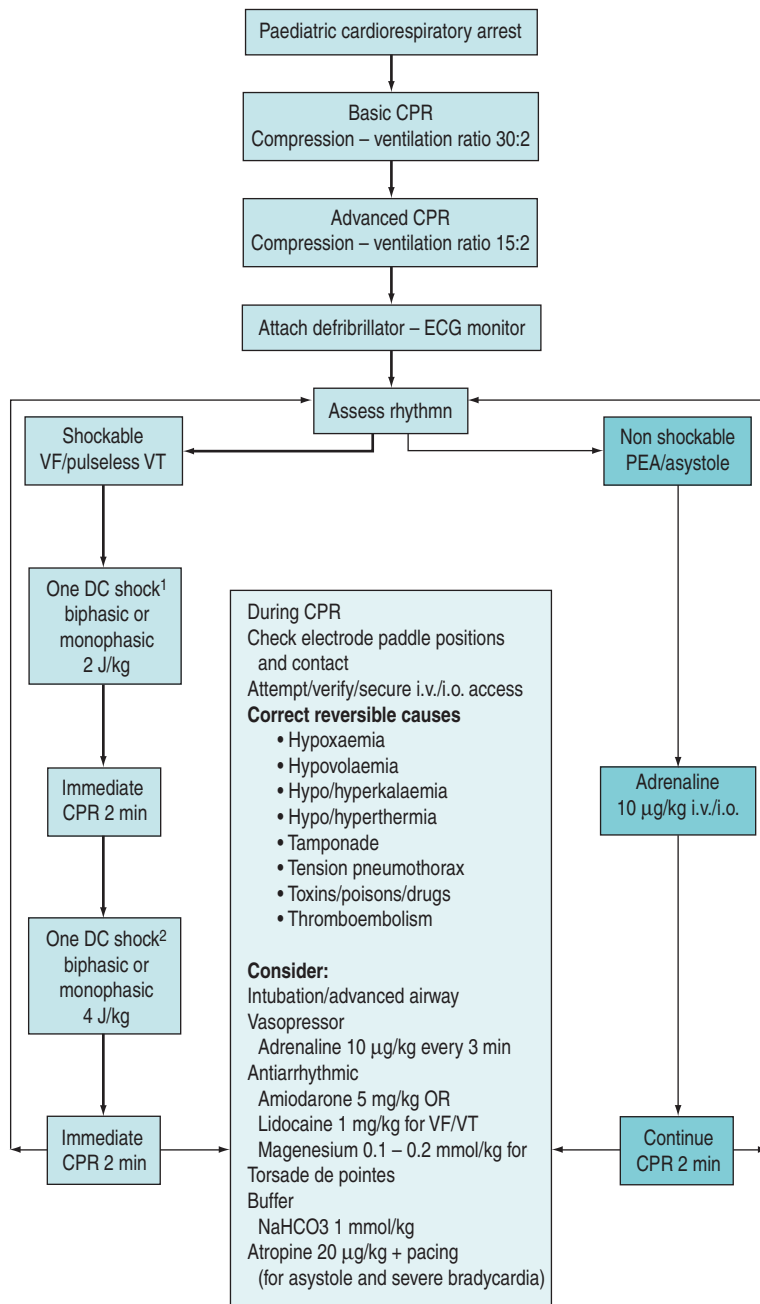

### ASSESSMENT OF AIRWAY AND BREATHING

On determining that the patient is not responsive to tactile and auditory stimulation, not breathing normally and not moving, airway opening manoeuvres and assessment of breathing should be performed. Assessment of the patient's airway and breathing can be performed effectively in either the supine or lateral position.

Obvious causes of airway obstruction in the pharynx should be removed. Fluids such as vomitus or blood should be aspirated with a Yankauer sucker. Solid or semi-solid objects, such as food particles or foreign objects, should be removed with an instrument, e.g. Magill's forceps. Since the most common cause of airway obstruction in an obtunded state is the tongue, first-aid manoeuvres to elevate it should be performed. The manoeuvres are backward head tilt, chin lift and jaw thrust. Head tilt and chin lift are often combined. If neck injury is present or suspected, neither the head tilt nor the chin lift manoeuvre should be used. Following establishment of an airway, the presence or absence of adequate breathing is assessed by inspection of movement of the chest and abdomen, and by listening and feeling for escape of exhaled air from the mouth and nose (look, listen and feel). If adequate breathing is occurring the patient should be placed on the side in a coma position.

### RESCUE BREATHING (EXPIRED AIR RESUSCITATION)

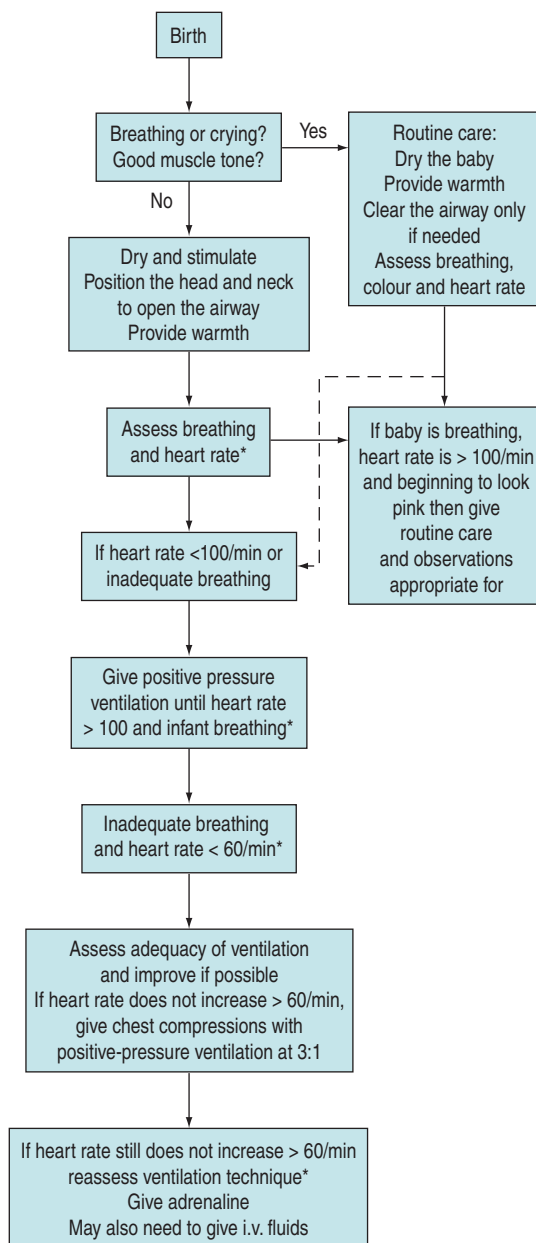

If inadequate breathing is present, rescue breathing (expired air resuscitation) or bag-valve-mask ventilation should be commenced immediately. There is no evidence to dictate the number of initial breaths. However, at least two breaths are recommended by all resuscitation organisations, with some stating up to five. While maintaining the airway, slow breaths over 1–1.5 seconds should be given with enough air to achieve adequate chest inflation. In children of all sizes, a mouth-to-mouth technique is possible by pinching the nostrils closed. In newly-born

**Figure 106.1** Paediatric resuscitation. PEA, pulseless electrical activity; VF, ventricular fibrillation; VT, ventricular tachycardia. (Reproduced with permission from the Australian Resuscitation Council, Melbourne.)

<sup>1</sup> For witnessed arrest, give up to three stacked shocks (2, 4, 4 J/kg) at first defibrillation attempt.

<sup>2</sup> If further shocks are needed these should be single shocks 4 J/kg.

\*Endotracheal intubation may be considered at several stages

**Figure 106.2** Newly-born infant resuscitation. (Reproduced with permission from the Australian Resuscitation Council, Melbourne.)

and infants, a mouth-to-mouth-and-nose technique is recommended, but if the rescuer has a small mouth, a mouth-to-nose technique is an alternative. Lack of chest rise may signify obstruction of the airway requiring repositioning of the head and neck.

### ASSESSMENT OF SIGNS OF LIFE OR CIRCULATION

If ‘signs of life’ or ‘signs of circulation’ are absent (unresponsiveness, inadequate breathing, lack of movement) or a pulse cannot be detected within 10 seconds or is inadequate (<60 beats/min) external cardiac compression (ECC) should be commenced. Although the pulse check has been discarded in guidelines for lay-person CPR, because of their inability to reliably check the pulse, it has been retained in guidelines for health care personnel. Palpation of any major pulse (carotid, brachial, femoral) is appropriate.

### EXTERNAL CARDIAC COMPRESSION (ECC)

Different techniques are used for infants and children of different sizes but in all patients the depth of compression is one-third the depth of their chest. For newly-born infants and infants, two techniques are in common use. In the ‘two-finger technique’, the middle and forefinger are used. This technique is taught to lay-persons and is also the preferred technique by a single health care rescuer. With the ‘two-thumb technique’, the hands encircle the thorax, approaching the chest from either above or below, and the thumbs are placed either opposite, alongside or atop one another. With this technique, the rescuer must take care to avoid restriction of the patient’s chest during inflation. With premature newly-borns and small infants, the rescuer’s encircling fingers may reach and stabilise the vertebral column, without limiting chest inflation. With both techniques, the sternum is compressed above the xiphoid or about one finger breadth below the inter nipple line.

Either a single hand or both hands may be used for infants and children as determined by the relationship between the size of the patient’s chest and the hands of the rescuer. For young children, ECC can be performed with the heel of one hand. For older children, a bimanual technique as per adults may be used. In all ages, the ‘centre of the chest’ – which corresponds to the lower sternum – is compressed. Approximately 50% of each cycle should be compression.

### RATES OF COMPRESSION AND RATIO OF COMPRESSION TO VENTILATION

In hospitals where there are usually two (or more) rescuers, the ratio of compressions to ventilation for infants and children should be 15:2. After every 15 compressions, a pause should allow delivery of two ventilations whenever expired air resuscitation or any type of mask ventilation is given. ECC can be given during the second exhalation. The aim should be to achieve about five cycles per minute, i.e. about 75 compressions and 10 breaths. If circulation returns, but respiration remains inadequate, the number of ventilations should be higher but care should be taken to avoid hypercarbia which results in cerebral ischaemia. A health care rescuer, when alone, may use the lay-person ratio of 30:2, aiming to achieve about five cycles in 2 minutes, i.e. about 75 compressions and 5 breaths per minute.

For infants and children, compressions should be delivered at a rate of 100/min, i.e. one compression every 0.6 seconds or approximately two per second. This does not mean that 100 actual compressions are given each minute. When ventilation is interposed between compressions, the actual compressions delivered will be less than 100 each minute.

If the airway has been secured, e.g. by intubation, strict coordination of compression and ventilation is not crucial: ventilation can be given against resistance imposed by chest compression. In this case about 100 compressions/minute will be achieved but ventilation should be limited to about 10–12 per minute and wherever possible guided by arterial blood gas analysis.

For newly-born infants the total number of recommended 'events' per minute is 120, with the aim of achieving 90 compressions and 30 inflations each minute, i.e. in a ratio of 3:1.

### ADVANCED LIFE SUPPORT

As soon as practicable, mechanical ventilation with added oxygen should be commenced with either a bag-valve-mask or via endotracheal intubation. Although intubation is preferred (see below), valuable time should not be wasted in numerous unsuccessful attempts. Initial effective bag-valve-mask ventilation is a necessary prerequisite for successful paediatric CPR. Bags of appropriate sizes should be available for infants, small children and large children. A bag of ~500 ml volume should be available for newly-born infants. Insertion of an oropharyngeal (Guedel) airway may be necessary to facilitate bag-valve-mask ventilation. Access to the circulation and display of the electrocardiograph should also be achieved as soon as possible. Thereafter treatment should be guided by the cardiac rhythm. Underlying causes of CPA should be sought and treated.

### AIRWAY MANAGEMENT

If attending personnel are skilled, the trachea should be intubated as soon as practicable. This establishes and maintains an airway, facilitates mechanical ventilation with 100% oxygen, minimises the risk of pulmonary aspiration, enables suctioning of the trachea and provides a route for the administration of selected drugs. If difficulty is experienced at initial intubation, oxygenation should be established with bag-valve-mask ventilation before a reattempt at intubation. Initial intubation should be via the oral route, not via the nasal route.

Intubation via the oral route:

- is invariably quicker than via the nasal route
- is less likely to cause trauma and haemorrhage
- enables the endotracheal tube to be more easily exchanged if the first choice is inappropriate

On the other hand, a tube placed nasally:

- can be better affixed to the face and so is less likely to enter a bronchus or be subject to inadvertent extubation
- is preferred for transport and long-term management

A nasogastric tube should be inserted after intubation to relieve possible gaseous distension of the stomach sustained during bag-valve-mask ventilation.

Correct placement of the endotracheal tube in the trachea must be confirmed. In the hurried conditions of emergency intubation at cardiopulmonary arrest, it is not difficult to mistakenly intubate the oesophagus or to intubate a bronchus. There is no substitute for:

- visualising the passage of the tip of the endotracheal tube through the vocal cords at intubation
- confirmation of bilateral pulmonary air entry by auscultation in the axillae
- continuous observation of rise and fall of the chest on ventilation

It is recommended that correct placement of the endotracheal tube be confirmed by capnography or colorimetric CO<sub>2</sub> detection after initial placement with the realisation that CO<sub>2</sub> excretion can only occur with effective pulmonary blood flow. This implies that CO<sub>2</sub> detection cannot be expected unless spontaneous cardiac output returns or unless external cardiac compression is effective. Oxygenation should be confirmed with use of a pulse oximeter or measurement of arterial gas tension.

#### Tube size

- 2.5 mm tube is used for a premature newborn <1 kg
- 3.0 mm for infants 1–3.5 kg
- 3.5 mm for infants >3.5 kg and up to age 6 months
- 4 mm for infants 7 months to 1 year
- For children over 1 year, the size is approximately determined by the formula: size (mm) = age (years)/4 + 4.

Tubes larger and smaller should be available. The correct size should allow a small leak on application of moderate pressure but also enable adequate pulmonary inflation.

The tube is inserted a specific depth to avoid accidental extubation or endobronchial intubation. Assessment of the depth of insertion at laryngoscopy is not reliable because this is performed with the neck extended. When the laryngoscope is removed the head assumes a position of neutrality or flexion and the tube depth increases.

The appropriate depth of insertion measured from the centre of the lips for an oral tube is:

- 9.5 cm for a term newborn
- 11.5 cm for a 6-month-old infant
- 12 cm for a 1 year old

An alternative formula for oral tube depth of insertion is: depth (cm) = size (mm) × 3. After 1 year the depth is given by the formula: depth (cm) = age (years)/2 + 12.

The appropriate depth of insertion for a nasal tube in this age group is: depth (cm) = age (years)/2 + 15. On a chest X-ray taken with the head in neutral position, the tip of the tube should be at the interclavicular line.

A laryngeal mask airway (LMA) may be used to establish an airway in the setting of CPA. However, its role in provision of mechanical ventilation remains uncertain. Like bag-valve-mask ventilation, it does not protect the airway from aspiration. Although insertion of an LMA is easier to learn than endotracheal intubation, training should not replace mastery of bag-valve-mask ventilation. An LMA is not suitable for long-term use or during transport when endotracheal intubation is preferred.

### ELECTROCARDIOGRAPH

The electrocardiograph (ECG) should be displayed with either leads or paddles. Drug therapy or immediate direct current (DC) shock is administered according to the existing rhythm.

### ACCESS TO THE CIRCULATION

According to the skills of the personnel, access to the circulation via a peripheral or central vein should be attempted immediately. Any site is acceptable. Visible or palpable peripheral veins are to be found on the dorsum of the hand, wrist, forearm, cubital fossa, chest wall, foot and ankle. In infants, scalp veins are accessible and the umbilical vein can be used up to about 1 week after birth. The external jugulars are usually distended at CPR but cannulation may be impeded by performance of intubation. Cannulation of femoral, subclavian or internal jugulars are options but difficult or hazardous in this situation. Surgical cutdown onto a long saphenous, saphenofemoral junction or basilic is a valuable skill sometimes required in traumatic exsanguination. Any pre-existing functioning line can be used provided it does not contain any drug or electrolyte precipitating the CPA.

### INTRAOSSEOUS INJECTION

If intravenous (i.v.) access cannot be achieved rapidly, say within 60 seconds, intraosseous (i.o.) access should be obtained. This route has been used for patients of all ages and provides rapid, safe and reliable access to the circulation. It serves as an adequate route for any parenteral drug and fluid administration.

A metal needle with a trocar (e.g. disposable intraosseous needle; Cook, Illinois, USA) is preferable although a short lumbar puncture type of needle with an inner trocar may suffice. Although many sites have been used for bone marrow injection, the easiest to identify is the anteromedial surface of the upper or lower tibia, especially in children less than 6 years. The site of the former

is a few centimetres below the anterior tuberosity and the latter a few centimetres above the medial malleolus. The handle of the device needle is held in the palm of the hand while the fingers grip the shaft about a centimetre from the tip. It is inserted perpendicular to the bone surface and a rotary action is used to traverse the cortex. Sudden loss of resistance signifies entry to bone marrow. Correct positioning of the needle is confirmed by aspiration of bone marrow (which may be used for biochemical and haematological purposes) but that is not always possible. Bone injection guns (Wais Med Ltd), which fire a needle a preset distance according to the size of the patient, enable easy i.o. injection for infants, children and adults.

Volume expanders need to be given by syringe to achieve rapid restoration of circulating volume and rapid access of drugs to the central circulation. This is best achieved using a 10-ml syringe with a three-way tap in the i.v. tubing so that the i.o. needle does not become dislodged inadvertently.

Care should be exercised to avoid complications, particularly cutaneous extravasation, compartment syndrome of the leg and osteomyelitis. Contraindications include local trauma and infection.

### ENDOTRACHEAL ADMINISTRATION OF DRUGS

Lipid-soluble drugs – adrenaline (epinephrine), atropine, lidocaine and naloxone – may be administered via the endotracheal tube if neither i.v. nor i.o. access is possible. Although the optimal doses of these drugs by this route are not known, work in animal models suggests doses should be 10 times the i.v. doses. The drugs should be diluted in normal saline up to 2 ml for infants, 5 ml for small children and 10 ml for large children. It is acceptable and simplest to squirt the drugs from the syringe (after removing the needle) directly into the endotracheal tube and disperse them throughout the respiratory tree with bagging.

Neither sodium bicarbonate nor calcium salts should be administered via the tracheal route because they injure the airways.

### DC SHOCK

Defibrillators should have paediatric paddles of cross-sectional area 12–20 cm<sup>2</sup> for use in children <10 kg body weight. For others, adult-sized paddles (50–80 cm<sup>2</sup>) are satisfactory provided the paddles do not contact each other. Selectable energy levels should enable delivery of doses 0.5–4 J/kg. The closest level to the dose should be selected. One paddle is placed over the mid-axilla opposite the xiphoid or nipple, the other to the right of the upper sternum below the clavicle. Conductive gel (confined to the area beneath the paddles) or gel pads and firm pressure are needed to deliver optimum energy to the heart without causing skin burns. The doses for monophasic and biphasic shock are the same.

In the treatment of refractory arrhythmias, equipment failure should be excluded. An anteroposterior position of the paddles (one over the cardiac apex, one over the left scapula) may be efficacious in refractory arrhythmia. Dextrocardia may be present with congenital heart disease and the position of the paddles should be altered accordingly.

Monophasic and biphasic automated external defibrillators (AEDs) with attenuated energy doses (approximately 50 J or less) may be used for children 1–8 years of age (approximately 10–25 kg). Adult energy doses of 150–200 J may be used in children older than 8 years of age or 25 kg body weight. AEDs are not recommended for use in infants since they cannot reliably distinguish ventricular fibrillation from tachycardia and hence pose a risk of harmful DC shock.

Rescuers should be cognisant of the risk of inadvertent shock to themselves and colleagues during operation of defibrillators. They should ensure that they have no physical contact with the patient directly or indirectly at the time of electrical discharge. Paddles should be charged only when already placed on the chest of the patient. If the need to give DC shock abates while the paddles are charged, they should be disarmed before replacing them in their cradles.

#### TREATMENT OF SPECIFIC ARRHYTHMIAS

The following discussion of specific arrhythmias assumes that mechanical ventilation with oxygen and external cardiac compression has been commenced. The treatment of pulseless arrhythmias is summarised in Figure 106.1.

Reversible causes of arrhythmias should be sought and treated during resuscitation. For example:

- hypoxaemia or hypotension causing bradycardia may respond to ventilation
- calcium channel blockade toxicity may be treated with calcium i.v. or i.o. (chloride 10% 0.2 ml/kg, gluconate 10% 0.7 ml/kg)
- hyperkalaemia may be antagonised with a calcium salt then the level lowered with insulin (0.05 U/kg) + dextrose (0.5 g/kg), salbutamol, sodium bicarbonate, hyperventilation or combinations

All drugs should be flushed into the circulation with a small bolus of isotonic fluid. To prevent their inactivation, drugs should not be mixed in the syringe or in infusion lines.

#### ASYSTOLE AND BRADYCARDIA

Asystole and hypotensive bradycardia (<60 beats/min) should be treated with adrenaline 10 µg/kg i.v. or i.o. If these routes are not available, adrenaline 100 µg/kg should be administered via endotracheal tube (ETT).

Unresponsive asystole should be treated with similar doses of adrenaline (10 µg/kg i.v., i.o.; 100 µg/kg ETT) every 3–5 minutes. Higher doses, up to 200 µg/kg i.v. or i.o., may be indicated in special circumstances

(e.g. β-blocker toxicity) but should not be used routinely as they have not altered outcome and predispose to complications (postarrest myocardial dysfunction, hypertension, tachycardia). In newly-born infants, the initial bolus dose is 100–300 µg/kg.

Recurrent bradycardia or asystole may require an infusion of adrenaline at 0.05–3 µg/kg per min: doses <0.3 µg/kg per min are predominantly β-adrenergic; doses >0.3 µg/kg per min are predominantly α-adrenergic. Infuse into a secure large vein. If sinus rhythm cannot be restored, sodium bicarbonate 1 mmol/kg i.v. or i.o. may be helpful but do not allow mixing with adrenaline since catecholamines are inactivated in alkaline solution.

Sinus bradycardia, sinus arrest with slow junctional or idioventricular rhythm, and atrioventricular block are the most common preterminal arrhythmias in paediatric practice. Untreated, bradycardia progresses to asystole.

Bradycardia caused by vagal stimulation should be managed with cessation of the stimulus and/or atropine 20 µg/kg i.v. or i.o. (minimum dose 100 µg) but persistent vagal-mediated bradycardia should be treated with adrenaline 10 µg/kg i.v. or i.o.

If facilities are available, bradycardia may be treated with pacing (oesophageal, transcutaneous, transvenous, epicardial) if sinus node dysfunction or heart block exists, but it is not helpful in asystole.

#### VENTRICULAR FIBRILLATION AND PULSELESS VENTRICULAR TACHYCARDIA

The initial dose for ventricular fibrillation (VF) or pulseless ventricular tachycardia (VT) is a single unsynchronised shock at 2 J/kg followed by immediate resumption of ECC. If VF or VT persists, subsequent single shocks of 4 J/kg are given, each separated by 2 minutes of ECC.

The witnessed (monitored) onset of VF or pulseless VT should be treated with unsynchronised DC shock initially at 2 J/kg, progressing to 4 J/kg in a stack (salvo) of three shocks. Rescuers should maintain the paddles on the chest and be prepared to deliver a series of three shocks in quick succession, pausing only to verify the rhythm. A precordial thump may be given before DC shock but its efficacy has not been proven.

Failure to revert to sinus rhythm should be treated with adrenaline 10 µg/kg i.v. or i.o. or 100 µg/kg ETT and another shock at 4 J/kg after an interval of ECC. Persistent (refractory) or recurrent VF or VT may also be treated with antiarrhythmics (amiodarone, lidocaine, magnesium) interspersed with single DC shocks. Irrespective of other drug therapy, adrenaline should be administered every 3–5 minutes. The dose of lidocaine is 1 mg/kg i.v. or i.o. bolus followed by an infusion if successful at 20–50 µg/kg per min. The dose of amiodarone is 5 mg/kg i.v. or i.o. as a bolus which may be repeated to maximum of 15 mg/kg. Magnesium, 25–50 mg/kg (0.1–0.2 mmol/kg) is indicated for polymorphic VT (torsade de pointes). The alternative to

adrenaline as a vasopressor, vasopressin, has not been adequately investigated for use during CPR for children.

### **PULSATILE VENTRICULAR TACHYCARDIA**

Haemodynamically stable VT may be treated with an antiarrhythmic agent such as amiodarone (5 mg/kg i.v. over 20–60 minutes) or procainamide (15 mg/kg i.v. over 30–60 minutes). Both drugs prolong QT interval and should not be given together. If torsade de pointes is present, magnesium (25–50 mg/kg, 0.1–0.2 mmol/kg i.v.) may be used. If cardioversion is needed, it should be synchronised at 0.5–2 J/kg under sedation/anaesthesia.

### **ELECTROMECHANICAL DISSOCIATION AND PULSELESS ELECTRICAL ACTIVITY**

A normal ECG complex without pulse or circulation is called electromechanical dissociation (EMD). If untreated, the ECG initially deteriorates to an abnormal but still recognisable state when it is called pulseless electrical activity (PEA). Both conditions should be treated as for asystole and their causes ascertained and treated.

### **SUPRAVENTRICULAR TACHYCARDIA**

Supraventricular tachycardia (SVT) is the most common spontaneous arrhythmia in childhood and infancy. It may cause life-threatening hypotension. It is usually re-entrant with a rate of 220–300/min in infants, less in children. The QRS complex is usually narrow (<0.08 seconds) making it difficult sometimes to discern from sinus tachycardia (ST). However, whereas ST is a part of other features of illness, SVT is a singular entity, and whereas the rate in ST is variable with activity or stimulation, it is uniform in SVT. In both rhythms, a P wave may be discernible. SVT with aberrant conduction (wide QRS) may resemble VT.

If haemodynamically stable (adequate perfusion and blood pressure), initial treatment of SVT should be vagal stimulation. For infants and young children, application to the face of a plastic bag filled with iced-water is often effective. Older children may be treated with carotid sinus massage or perform a Valsalva (e.g. blowing through a narrow straw). If unsuccessful, give adenosine 100 µg/kg i.v. by rapid bolus (maximum dose 6 mg), doubling once to 200 µg/kg. If unsuccessful, give synchronised DC shock (cardioversion) commencing with 0.5 J/kg, progressing if unsuccessful to 2 J/kg under sedation/anaesthesia. If SVT is accompanied by haemodynamic instability (i.e. hypotension), proceed to cardioversion (synchronised 0.5–2 J/kg) immediately although vagal stimulation or adenosine (i.v. or i.o.) may be used provided they do not delay cardioversion. Verapamil should not be used to treat SVT in infants and should be avoided in children because it induces hypotension and cardiac depression.

## **POST RESUSCITATION CARE**

Supportive therapy should be provided until there is recovery of function of vital organs. This may require provision of oxygen therapy, mechanical ventilation, inotropic/vasopressor infusion, renal support, parenteral nutrition and other therapy for several days or longer. Recovery of infants and children is usually slow because cardiorespiratory arrest is often secondary to prolonged global ischaemia or hypoxaemia which implies that other organs sustain damage before cardiorespiratory arrest.

Particular care should be taken to ensure adequate cerebral perfusion with well-oxygenated blood. Hyperventilation is not useful for this purpose. Therapeutic hypothermia post resuscitation (33–36 °C) up to 3 days may improve neurological outcome. Inadvertently hypothermic patients, provided temperature is above 33 °C, should not be actively warmed but hyperthermia should be aggressively treated. During deliberate hypothermia shivering should be prevented with sedation and/or neuromuscular blockade, seizures should be actively sought and treated with anticonvulsant and the cause of the CPA should be investigated and treated appropriately, e.g. sepsis or drug overdose.

Complications of CPR should be sought, especially if secondary deterioration occurs. A chest X-ray should be obtained to check the position of the endotracheal tube, to exclude pneumothorax, lung collapse, contusion or aspiration, and to check the cardiac silhouette although an echocardiographic examination is preferable to specifically check contractility and to exclude a pericardial effusion. Measurement of haemoglobin, pH, gas tensions, electrolytes and glucose is important.

### **CESSATION OF CARDIOPULMONARY RESUSCITATION**

Long-term outcome from paediatric CPR is poor, but better if arrest is respiratory alone or if CPA occurs in hospital. The decision to cease CPR should be based on a number of factors including the duration of resuscitation, response to treatment, pre-arrest status of the patient, remediable factors, likely outcome if ultimately successful, opinions of personnel familiar with the patient and, whenever appropriate, the wishes of the parents. In general, unless hypothermia or drug toxicity exists, survival to normality is most unlikely if there has been a failure to respond to full competent CPR after 30 minutes and several doses of adrenaline. In the newly-born infant, discontinuation of treatment is appropriate if CPR does not establish a spontaneous circulation within 10–15 minutes. Family members should be kept informed, allowed to be present or asked if they want to be present during resuscitation.

### **POST RESUSCITATION STAFF MANAGEMENT**

Unfortunately, CPA occurring in hospital is often unexpected – for example, when a moribund patient arrives

unannounced in the emergency department, a patient's condition deteriorates rapidly on the ward or when a mishap occurs under anaesthesia. These situations test the readiness, training, abilities and skills of individuals and the organisation of the institution. It is prudent to monitor performance with a view to improvement and not ignore the psychological impact which such events have on individuals. Sensitive debriefing sessions should be encouraged.

## Normal biochemical values

### I BLOOD CHEMISTRY

S = serum

P = plasma

HWB = heparin whole blood

		0.5–1.4 g/l
$\alpha_1$ -Acid glycoprotein (S)		Supine – 140–530 pmol/l
Aldosterone (S)		Erect – 220–970 pmol/l
Ammonia (P) to lab without delay		4–50 $\mu$ mol/l
Amylase (S or P)		70–300 U/l
$\alpha_1$ -Antitrypsin (S or P)		2.1–4.0 g/l
Aspartate aminotransferase (AST) (P)		6–42 U/l
Bicarbonate (P)		22–32 mmol/l
Bilirubin (total) (S or P)		3–17 $\mu$ mol/l
Bilirubin (direct) (S or P)		2–9 $\mu$ mol/l
Caeruloplasmin (S or P)		0.20–0.60 g/l
Calcium (S or P)		2.25–2.65 mmol/l
Carotene (S or P)		1.0–4.8 $\mu$ mol/l
Chloride (S or P)		98–108 mmol/l
Cholesterol (S or P)		3.1–6.5 mmol/l
Copper (S or P)		11–23 $\mu$ mol/l
Cortisol (S or P)	8–9 am	300–800 nmol/l
	4–5 pm	100–600 nmol/l
Creatinine (P)		50–120 $\mu$ mol/l
Creatinine clearance		> F1.3 ml/s
Creatinine kinase (P)		20–130 U/l
Creatinine kinase isoenzymes		Qualitative
Digoxin (S)	toxic	> 2 $\mu$ g/l
Effective thyroxine ratio (ETR) (S)		0.90–1.09
FSH (S) Male		3–19 U/l
Female Follicular		5–20 U/l
Mid-cycle		15–30 U/l
Luteal		5–15 U/l
Postmenopausal		50–100 U/l
Glucose (fasting) (fluoride) (P)		3.9–6.2 mmol/l
$\gamma$ -Glutamyl-transferase ( $\gamma$ -GT) (P)	F	7–30 U/l
	M	10–50 U/l
Growth hormone (fasting, resting) (S)	M	< 6 mU/l
	F	< 16 mU/l
	Child	< 10 mU/l
Insulin (fasting) (S)		3–28 mU/l
Iron (S or P) (1) Iron	M	14–31 $\mu$ mol/l
8–10 am	F	11–29 $\mu$ mol/l
(2) Iron binding capacity	M	41–70 $\mu$ mol/l
	F	37–77 $\mu$ mol/l

*Continued*

Lactate (special collection)		0.3–1.3 mmol/l
LDH (S or P)		< 80 U
Lead (HWB)		< 2 µmol/l
Lithium (S) not plasma		0.8–1.2 mmol/l (therapeutic range)
Magnesium (S or P)		0.7–1.1 mmol/l
Oestriol (pregnancy) (S)		Depends on gestation
Osmolality (S or P)		275–295 mosm/kg
Phosphatase		
A. Prostatic (S or P)		0–4 U/l
(stabilise plasma with 5 mg/ml of NaHSO <sub>4</sub> or freeze)		
B. Alkaline (S or P)		100–350 U/l
Phosphate (inorganic) (P)		0.8–1.4 mmol/l
Porphyryns (red cell) (HWB)		< 1.2 µmol/l
Potassium (P)		3.4–5.0 mmol/l
Prolactin (S) (resting)		25 µg/l
Proteins		
A. (1) Total (S)		63–78 g/l
(2) Albumin (S)		35–45 g/l
B. Electrophoresis (S) not plasma:		
Albumin		35–45 g/l
α <sub>1</sub> -Globulin		2–4 g/l
α <sub>2</sub> -Globulin		5–9 g/l
β-Globulin		6–10 g/l
γ-Globulin		8–16 g/l
Pyruvate (special collection)		30–80 µmol/l
Renin (special tubes – keep blood cold)		
100–180 mmol Na intake:		
Supine (6 hours)		< 0.58 ng/s/l
Upright (4 hours)		0.28–1.25 ng/s/l
Sodium (P)		134–146 mmol/l
Thyroxine (S)		60–150 nmol/l
Transferrin (S or P)		2.1–3.5 g/l
Triglyceride (fasting) (P)		1.80 mmol/l
Tri-iodothyronine (S)		1.3–2.9 nmol/l
TSH (S)		1–11 mU/l
Urea (P)		3.0–8.0 mmol/l
Uric acid (P)	M	0.18–0.48 mmol/l
	F	0.12–0.42 mmol/l
Zinc (P)		12–20 µmol/l

## II URINE

AA = 20 ml 50% acetate  
d = 24-hour collection  
Sp = spot urine

Aldosterone (d, AA)		14–55 nmol/d
ALA (delta amino laevulinic acid) (Sp or d, AA)	Sp:	< 50 µmol/l
	d:	10–50 µmol/d

*Continued*

Amylase (Sp or d, NO ACID)	Sp:	< 900 U/l
	d:	100–1000 U/d
Calcium (d, AA)		< 7.5 mmol/d
Catecholamines and derivatives (d, 20 ml 50% HCl):		
1. HMMA (VMA) Hydroxymethoxymandelic acid		< 35 µmol/d
2. Metadrenaline		< 5.6 µmol/d
3. Catecholamine		< 1.6 µmol/d
Copper (d, AA)		< 1.6 µmol/d
Coproporphyrin (collect 24-hour urine into 8 g sodium carbonate)		< 245 nmol/d
Creatinine (d, AA)		10–20 mmol/d
5-Hydroxyindole-acetic acid (5-HIAA) (d, AA)		5–37 µmol/d
Hydroxyproline (d, AA)		< 0.35 mmol/d (gelatin-free diet)
Indican (d, AA)		0.04–0.36 mmol/d
Lead (d, AA)		0.4 µmol/d
Magnesium (d, AA)		2.0–6.6 mmol/d
Melanin (fresh Sp)		Qualitative
Oestriol (in pregnancy) (d, AA)		50–160 µmol/d at 36 weeks' gestation
Osmolality (Sp)		300–1300 mosm/kg
Oxalate (d, AA)		< 300 µmol/d
Phosphorus (d, AA)		10–42 mmol/d
Porphobilinogen (fresh Sp)		Qualitative
Potassium (d or Sp, AA)		25–100 mmol/d
Protein (d or Sp, AA)		0.02–0.06 g/d
Sodium (d or Sp, AA)		40–210 mmol/d
Steroids (d, AA):		
1. 17-Oxosteroids	M	28–80 µmol/d
	F	14–60 µmol/d
2. 17-Hydroxy corticosteroids	M	14–70 µmol/d
	F	7–50 µmol/d
Urea (d or Sp, AA)		170–500 mmol/d
Uric acid (d, 8 g sodium carbonate)		< 3.6 mmol/d (purine-free diet)
Urobilinogen (fresh Sp)		Qualitative
Uroporphyrin (collect as for Coproporphyrin)		< 50 nmol/d
Xylose absorption:		
Xylose excretion in 5 hours		> 27 mmol
Plasma value at 2 hours		1.7–3.4 mmol/l

**III FAECES**

Fat (3-day collection)	< 5 g/l
Porphyryns (single stool)	
Coproporphyrins	< 30 nmol/g dry wt
Protoporphyrins	< 135 nmol/g dry wt

**IV CSF**

Protein	0.15–0.45 g/l
Glucose	2.7–4.2 mmol/l
IgG	< 0.05 g/l
IgG:Total protein ratio	5–14%

## Respiratory physiology symbols and normal values

### SYMBOLS

Primary	Secondary symbols for gas phase
C Concentration of gas in blood	A Alveolar
F Fractional concentration in dry gas	B Barometric
F Frequency of respiration (breaths/min)	D Dead space
P Pressure or partial pressure	E Expired
Q Volume of blood	I Inspired
$\dot{Q}$ Volume of blood per unit time	L Lung
R Respiratory exchange ratio	T Tidal
S Saturation of haemoglobin with O <sub>2</sub>	
$\dot{V}$ Volume of gas per unit time	
	<i>Secondary symbols for blood phase</i>
	a arterial
	c capillary
	c̄ end-capillary
	i ideal
	v venous
	$\bar{v}$ mixed venous
	– above any symbol denotes a mean value
	· above any symbol denotes a value per unit time

### NORMAL VALUES

#### 1. Blood

##### (a) Arterial

pH	: 7.36–7.44	(H <sup>+</sup> = 44–36 nmol/l)
P <sub>aO<sub>2</sub></sub>	: 85–100 mmHg	(11.3–13.3 kPa)
P <sub>aCO<sub>2</sub></sub>	: 36–44 mmHg	(4.8–5.9 kPa)
O <sub>2</sub> content	: 20–21 vols%	(8.9–9.4 nmol/l)
CO <sub>2</sub> content	: 48–50 vols%	(21.6–22.5 nmol/l)

##### (b) Venous

pH	: 7.34–7.42	(H <sup>+</sup> = 38–46 nmol/l)
P <sub>vO<sub>2</sub></sub>	: 37–42 mmHg	(5–5.6 kPa)
P <sub>vCO<sub>2</sub></sub>	: 42–50 mmHg	(5.6–6.7 kPa)
O <sub>2</sub> content	: 15–16 vols%	(6.7–7.2 mmol/l)
CO <sub>2</sub> content	: 52–54 vols%	(23.3–24.2 mmol/l)

## 2. Gases

(a) *Inspired air*

O <sub>2</sub>	:	20.93%	
P <sub>I</sub> O <sub>2</sub>	:	149 mmHg	(19.9 kPa)
N <sub>2</sub>	:	79.04%	
P <sub>I</sub> N <sub>2</sub>	:	563 mmHg	(75 kPa)
CO <sub>2</sub>	:	0.03%	

(b) *Expired air*

O <sub>2</sub>	:	16–17%	
P <sub>E</sub> O <sub>2</sub>	:	113–121 mmHg	(15–16 kPa)
N <sub>2</sub>	:	80%	
P <sub>E</sub> N <sub>2</sub>	:	579 mmHg	(77 kPa)
CO <sub>2</sub>	:	3–4%	
P <sub>E</sub> CO <sub>2</sub>	:	21–28 mmHg	(2.8–3.7 kPa)

## 3. Ventilation:perfusion

(a) *Alveolar–arterial oxygen gradient:*

5–20 mmHg	(0.7–2.7 kPa)	breathing air
25–65 mmHg	(3.3–8.6 kPa)	breathing 100% oxygen

(b) *Venous admixture (Q<sub>S</sub>:Q<sub>T</sub>): 5% of cardiac output*(c) *Right to left physiological shunt: 3% of cardiac output*(d) *Anatomical dead space: 2 ml/kg body weight*(e) *Dead space: tidal volume ratio V<sub>D</sub>:V<sub>T</sub>): 0.25–0.4 or  $33 + \frac{\text{Age}}{3}$  per cent*

## 4. Lung volumes

Approximate values in adults are listed. Values are less in smaller subjects and in females.

Tidal volume	:	400 ml or 6 ml/kg
Inspiratory capacity	:	3.6 litres
Inspiratory reserve volume	:	3.1 litres
Expiratory reserve volume	:	1.2 litres
Functional residual capacity	:	2.4 litres
Residual volume	:	1.2 litres
Total lung capacity	:	6.0 litres
Vital capacity	:	4.8 litres

or 2.5 l/sq m body surface or 2.5 l/m height in males

2.0 l/sq m body surface or 2.0 l/m height in females

or 65–75 ml/kg

## 5. Lung mechanics

(a) <i>Peak expiratory flow rate</i>	:	450–700 l/min (males)	
	:	300–500 l/min (females)	
(b) <i>Forced expiratory volume in 1 sec (FEV<sub>1</sub>)</i>	:	70–83% of vital capacity	
(c) <i>Compliance</i> (approximate values)	:		
(i) Lung compliance (CL)			
		<i>Static</i>	<i>Dynamic</i>
conscious (erect)	:	200 ml/cmH <sub>2</sub> O	180 ml/cmH <sub>2</sub> O
paralysed anaesthetised (supine)	:	160 ml/cmH <sub>2</sub> O	80 ml/cmH <sub>2</sub> O
(ii) Chest wall compliance (CCW)	:	200 ml/cmH <sub>2</sub> O	
(iii) Total compliance (CT):			
conscious (erect)	:	150 ml/cmH <sub>2</sub> O	100 ml/cmH <sub>2</sub> O
*paralysed anaesthetised (supine)	:	74 ml/cmH <sub>2</sub> O	56 ml/cmH <sub>2</sub> O
(d) <i>Airways resistance</i>	:		
conscious	:	0.6–3.2 cmH <sub>2</sub> O/l per second	
sedated, partially paralysed and ventilated (includes resistance of endotracheal tube and catheter mount):			
5–10 H <sub>2</sub> O/l per second			

- (e) *Work of breathing*: 0.3–0.5 kg m/min  
or oxygen consumption of 0.5–1 ml/l ventilation

\*Compliance values would be lower for the sedated, partially paralysed, ventilated patient in the intensive care unit, i.e. effective dynamic compliance = 40–50 ml/cmH<sub>2</sub>O

**6. Cardiovascular** – pressures in kPa are given within brackets

(a) Cardiac index	:	2.5–3.6 l/min per m <sup>2</sup>
(b) Stroke volume	:	42–52 ml/m <sup>2</sup>
(c) Ejection fraction	:	0.55–0.75
(d) End diastolic volume	:	75 ± 15 ml/m <sup>2</sup>
(e) End systolic volume	:	25 ± 8 ml/m <sup>2</sup>
(f) Left ventricular stroke work index	:	30–110 g-m/m <sup>2</sup>
(g) Left ventricular minute work index	:	1.8–6.6 kg-m/min per m <sup>2</sup>
(h) Oxygen consumption index	:	110–150 ml/l
(i) Right atrial pressure	:	1–7 mmHg (0.13–0.93)
(j) Right ventricular systolic pressure	:	15–25 mmHg (2.0–3.3)
(k) Right ventricular diastolic pressure	:	0–8 (0–1)
(l) Pulmonary artery systolic pressure	:	15–25 mmHg (2.0–3.3)
(m) Pulmonary artery diastolic pressure	:	8–15 mmHg (1–2)
(n) Pulmonary artery mean pressure	:	10–20 mmHg (1.3–2.7)
(o) Pulmonary capillary wedge pressure	:	6–15 mmHg (0.8–2.0)
(p) Systemic vascular resistance	:	770–1500 dyne-s/cm <sup>5</sup>
	:	77–150 kPa-s/l
(q) Pulmonary vascular resistance	:	20–120 dyne-s/cm <sup>5</sup>
	:	2–12 kPa-s/l

# Appendix 4

## Physiological equations

### RESPIRATORY EQUATIONS

- (a) *Oxygen consumption* (250 ml/min)

Oxygen consumption = amount of oxygen in inspired gas minus amount in expired gas

i.e.  $\dot{V}O_2 = (\dot{V}I \times FIO_2) - (\dot{V}E \times FE_{O_2})$

- (b) *Carbon dioxide production* (200 ml/min)

Volume CO<sub>2</sub> eliminated in expired gas = expired gas volume × CO<sub>2</sub> concentration in mixed expired gas

i.e.  $\dot{V}CO_2 = \dot{V} \times FE_{CO_2}$

As expired volume is made up of alveolar and dead space gas,

$$\dot{V}CO_2 = (\dot{V}A \times FA_{CO_2}) + (\dot{V}D \times FICO_2)$$

As  $FICO_2$  is negligible, especially if there is no rebreathing,

$$\dot{V}CO_2 = \dot{V}A \times FA_{CO_2}$$

or  $FA_{CO_2} = \frac{\dot{V}CO_2}{\dot{V}A}$

or  $PA_{CO_2} \text{ (mmHg)} = \frac{\dot{V}CO_2 \text{ (ml/min STPD)}}{\dot{V}A \text{ (l/min BTPS)}} \times 0.863$

or  $PA_{CO_2} \text{ (kPa)} = \frac{\dot{V}CO_2 \text{ (mmol/min)}}{\dot{V}A \text{ (l/min BTPS)}} \times 2.561$

STPD: Standard temperature (0°C) and pressure (760 mmHg or 101.35 kPa) dry gas

BTPS: Body temperature and ambient pressure, saturated with water vapour

- (c) *Physiological dead space*

Bohr's equation,  $\frac{V_D}{V_T} = \frac{PA_{CO_2} - P\bar{E}CO_2}{PA_{CO_2}}$

or  $\frac{V_D}{V_T} = \frac{Pa_{CO_2} - P\bar{E}CO_2}{Pa_{CO_2}}$

- (d) *Alveolar oxygenation*

$$PA_{O_2} = PIO_2 - \frac{Pa_{CO_2}}{R} \text{ where R is the respiratory quotient (normally 0.8)}$$

$$PA_{O_2} = PIO_2 - Pa_{CO_2} \frac{PIO_2 - P\bar{E}O_2}{P\bar{E}CO_2}$$

$$\text{or } PAO_2 = PIO_2 - PACO_2 \left( FIO_2 + \frac{1 - FIO_2}{R} \right)$$

when  $FIO_2 = 1.0$  (patient breathing 100% oxygen),  
then  $PAO_2 = (PB - \text{saturated water vapour pressure}) - PACO_2$   
 $= (PB - 47) - PACO_2$

(e) *Venous admixture*

$$\begin{aligned} \frac{\dot{Q}_S}{\dot{Q}_T} &= \frac{C\dot{c}O_2 - CaO_2}{C\dot{c}O_2 - C\bar{v}O_2} \\ &= \frac{(PAO_2 - PaO_2) \times 0.0031}{CaO_2 + (PAO_2 - PaO_2) \times 0.0031 - C\bar{v}O_2} \\ &= \frac{(PAO_2 - PaO_2) \times 0.0031}{(PAO_2 - PaO_2) \times 0.0031 + 5} \text{ (simplified)} \\ &= C\dot{c}O_2 - C\bar{v}O_2 \end{aligned}$$

(f) *Fractional inspired oxygen concentration*

$$FiO_2 = \frac{O_2 \text{ flow in l/min} + (\text{Airflow in l/min} \times 0.21)}{\text{Total } O_2 + \text{Airflow in l/min}}$$

(g) *Henderson-Hasselbalch equation*

$$\begin{aligned} \text{pH} &= \text{pKA} + \log \frac{(\text{HCO}_3^-)}{(\text{CO}_2)} \\ \text{pH} &= 6.1 + \log \frac{(\text{HCO}_3^- \text{ in mmol/l})}{(\text{PCO}_2 \text{ in mmHg}) \times 0.03} \\ [\text{H}^+] \text{ nmol/l} &= 24 \times \frac{(\text{PCO}_2 \text{ in mmHg})}{(\text{HCO}_3^- \text{ in mmol/l})} \\ [\text{H}^+] \text{ nmol/l} &= 180 \times \frac{(\text{PCO}_2 \text{ in kPa})}{(\text{HCO}_3^- \text{ in mmol/l})} \end{aligned}$$

## CARDIOVASCULAR EQUATIONS

(a) *Mean blood pressure* (BP = DBP + 1/3 (SBP - DBP))

(b) *Rate pressure product* (RPP) = P × SBP

(c) *Body surface area* (BSA) in m<sup>2</sup> = (Ht)<sup>0.725</sup> × (Wt)<sup>0.425</sup> × 71.84 × 10<sup>-4</sup>

(d) \**Cardiac Index* (CI) =  $\frac{CO}{BSA}$  = ml/min per m<sup>2</sup>

(e) *Stroke volume* (SV) =  $\frac{CO}{P}$  = ml/beat

(f) \**Stroke volume index* (SVI) =  $\frac{SV}{BSA}$  = ml/beat per m<sup>2</sup>

(g) \**Left ventricular stroke work index* (LVSWI) = (BP - PCWP) (SVI) (0.0136) = g-m/m<sup>2</sup> per beat

(h) *Systemic vascular resistance* (SVR) =  $\frac{BP - RAP}{CO}$  resistance units

(Multiply × 79.9 to convert to absolute resistance units, dynes sec cm<sup>-5</sup>)

(i) *Pulmonary vascular resistance* (PVR) =  $\frac{PAP - PCWP}{CO}$  resistance units

(Multiply × 79.9 to convert to absolute resistance units, dynes sec cm<sup>-5</sup>)

(j) *Left ventricular pre-ejection period* (PEP) = QS<sub>2</sub> - LVET m sec

(k) *Other systolic time index ratios* may easily be calculated:

$$\frac{1}{\text{PEP}^2} \text{ and } \frac{\text{PEP}}{\text{LVET}}$$

\*For interpatient comparisons and reference standards, the 'index' term, output normalised to body surface, may be used when

SBP	= systolic blood pressure in mmHg
DBP	= diastolic blood pressure in mmHg
P	= heart rate in beats/min
Ht	= height in cm
Wt	= weight in kg
CO	= cardiac output in ml/min
PCWP	= pulmonary capillary wedge pressure in mmHg
RAP	= right atrial pressure in mmHg
PAP	= mean pulmonary artery pressure in mmHg
LVET	= left ventricular ejection time in m sec
QS <sub>2</sub>	= total electromechanical systole in m sec

## RENAL EQUATIONS

(a) *Standard creatinine clearance* (ml/min/1.73 m<sup>2</sup>)

$$= \frac{\text{urine creatinine}(\text{mmol/l})}{\text{serum creatinine}(\text{mmol/l})} \times \text{urine volume (ml/min)} \times \frac{1.73}{\text{body surface area}(\text{m}^2)}$$

(b) *Per cent filtered Na<sup>+</sup> excreted*

$$= \frac{\text{urine Na}^+(\text{mmol/l})}{\text{serum Na}^+(\text{mmol/l})} \times \frac{\text{serum creatinine}(\text{mmol/l})}{\text{urine creatinine}(\text{mmol/l})} \times 100$$

(c) *Free water clearance* (ml/min)

$$= \text{urine vol (ml/min)} - \frac{\text{urine osmolality}(\text{mosm/kg})}{\text{plasma osmolality}(\text{mosm/kg})} \times \text{urine vol (ml/min)}$$

(d) *Additional calculated parameters:*

(i)  $\frac{\text{urine}}{\text{plasma}}$  osmolality ratio

(ii)  $\frac{\text{urine}}{\text{serum}}$  creatinine ratio

(iii)  $\frac{\text{blood urea}}{\text{serum creatinine}}$  ratio

(iv)  $\frac{\text{urine}}{\text{plasma}}$  urea ratio

(v) urinary Na<sup>+</sup> and K<sup>+</sup> excretion (mmol)

(vi)  $\frac{\text{urinary Na}^+}{\text{urinary K}^+}$  ratio

# Appendix 5

## Plasma drug concentrations and American nomenclature

### PLASMA DRUG LEVELS

Drug	Normal or therapeutic concentration mg/l	Toxic concentration mg/l	Lethal or potentially lethal concentration mg/l
Acetazolamide	10–15	–	–
Acetohexamide	21–56	–	–
Acetone	–	200–300	550
Aluminium	0.13	–	–
Aminophylline (Theophylline)	10–20	20	–
Amitriptyline	50–200 µg/l	400 µg/l	10–20
Ammonia	500–1700	–	–
Amphetamine	20–30 µg/l	–	2
Arsenic	0.0–20 µg/l	1.0	15
Barbiturates			
Short-acting	1	7	10
Intermediate-acting	1–5	10–30	30

## Confirmation of intubation

This is a frequently performed procedure in anaesthesia, in the ICU and in a wide range of emergency situations with very variable availability of sophisticated equipment. It is also the cause of significant morbidity and mortality.

This is a simple check list which can be modified depending on the equipment available.

### **Always:**

- Visualise the passage of the tip of the endotracheal tube through the vocal cords at intubation, where possible (most reliable but not perfect).
- Observe. Continuous observation of rise and fall of the chest on ventilation.
- Auscultate. Confirm air entry by auscultation in the axillae and also listen over the stomach. The axillae will confirm bilateral air entry (and indicate endobronchial intubation if air entry is unilateral). Auscultation over the stomach will allow differential breath sounds between axillae and stomach and may indicate oesophageal tube placement if the stomach sounds are louder.
- Observe the patient's colour – they should remain pink.

### **Equipment should be available that will also assist.**

- Capnography. CO<sub>2</sub> in the exhaled air is a reliable indicator of correct tube placement. Capnography should always be available for anaesthesia and certainly for transfer of critically ill patients. Ideally, it should be easily available in any ICU.
- Oximetry helps confirm oxygenation.

Of these, visualisation and capnography are most reliable for intubation but all have a part to play and anyone intubating a patient must have a checklist to confirm correct placement.

'If in doubt, take it out.' Sometimes some of the four basic signs are unconvincing but if there is any doubt the tube should be replaced or mouth to mouth/mask ventilation should be used.

# Appendix 7

## Parameters monitored and measured by the PiCCO monitor

New non-invasive monitors have introduced some new 'measurements' into clinical practice.

Parameter normal value	Symbol
Pulse contour cardiac output/index CI 3.0–5.0 l/min per m <sup>2</sup> Pulse contour cardiac output is calibrated by means of a simple transcardiopulmonary thermodilution measurement	PCCO/PCCI
Global end diastolic volume/index 680–800 ml/m <sup>2</sup> (indexed) The total end-diastolic volume of all four chambers of the heart	GEDV/I
Intrathoracic blood volume/index 850–1000 ml/m <sup>2</sup> (indexed) The global end-diastolic volume plus the pulmonary blood volume	ITBV/I
Extravascular lung water/index 3.0–7.0 ml/kg (indexed) Quantifies lung status in terms of pulmonary permeability	EVLW/I
Cardiac function index 4.5–6.5 l/min (indexed) CO/GEDV = preload independent variable of heart function	CFI
Stroke volume/index 40–60 ml/m <sup>2</sup>	SV/I
Stroke volume variation <10% Percentage difference of biggest to smallest stroke volumes over the last 30 seconds	SVV
Left ventricular contractility 1200–2000 mmHg/sec Maximum velocity of blood pressure curve corresponds to maximum power or contractility of the left heart	dP/dtmax
Systemic vascular resistance/index 1200–2000 dyn/s/cm <sup>-5</sup> per m <sup>2</sup> (indexed)	SVR/SVRI

### EVLW

There are two mechanisms by which the EVLW may be raised – increased intravascular filtration pressure (left heart failure, volume overload), and increased pulmonary vascular permeability as in endotoxic shock and sepsis.

There is a direct relationship between the mortality of intensive care patients with acute respiratory distress syndrome and high extravascular lung water.

### SVV

Large variations in stroke volume are an indication of reduced intravascular volume (also atrial fibrillation, heart valve disease).

# Appendix 8

Paediatric risk of mortality (PRISM) score. Mortality risk assessment.

Parameter	Age limit	Ranges	Points
Systolic blood pressure (mmHg)	Infants	130–160	2
		55–65	2
		>160	6
		40–54	6
		<40	7
	Children	150–200	2
		65–75	2
		>200	6
		50–64	6
		<50	7
Diastolic blood pressure (mmHg)	All ages	>110	6
Heart rate (beats/min)	Infants	>160	4
		<90	4
	Children	>150	4
		<80	4
Respiratory rate (breaths/min)	Infants	61–90	1
		>90	5
		Apnoea	5
	Children	51–70	1
		>70	5
		Apnoea	5
$P_{aO_2}/F_{iO_2}$	All ages	200–300	2
$P_{aCO_2}$ in torr (mmHg)	All ages	<200	3
		51–65	1
Glasgow coma score	All ages	>65	5
		<8	6
Pupillary reactions	All ages	Unequal or dilated	4
		Fixed and dilated	10
PT/PTT	All ages	1.5 times control	2
Total bilirubin mg/dl	>1 month	>3.5	6
Potassium in mEq/l	All ages	3.0–3.5	1
		6.5–7.5	1
		<3.0	5
		>7.5	5
Calcium in mg/dl	All ages	7.0–8.0	2
		12.0–15.0	2
		<7.0	6
		>15.0	6
Glucose in mg/dl	All ages	40–60	4
		250–400	4
		<40	8
		>400	8
Bicarbonate in mEq/l	All ages	<16	3
		>32	3

Infants: 0–1 year of age. PRISM score = (systolic blood pressure points) + (diastolic blood pressure points) + (heart rate points) + (respiratory rate points) + (oxygenation points) + (Glasgow coma score points) + (pupillary reaction points) + (coagulation points) + (bilirubin points) + (potassium points) + (calcium points) + (glucose points) + (bicarbonate points).

**Sepsis-related organ failure assessment (SOFA) score.** Easy to calculate, describes the sequence of complications in a critically ill patient rather than predicting outcome.

Organ system	Measure
Respiration	$P_{aO_2}$ to $F_{iO_2}$ ratio
Coagulation	Platelet count
Liver	Serum bilirubin
Cardiovascular	Hypotension
Central nervous system	Glasgow coma score
Renal	Serum creatinine or urine output

Measure	Finding	Points
$P_{aO_2}$ to $F_{iO_2}$ ratio	$\geq 400$ (mmHg)	0
	300–399 (mmHg)	1
	200–299 (mmHg)	2
	100–199 (mmHg)	3
	$<100$ (mmHg)	4
Platelet count	$\geq 1500/\mu\text{l}$	0
	1000–149 999/ $\mu\text{l}$	1
	500–99 999/ $\mu\text{l}$	2
	200–49 999/ $\mu\text{l}$	3
	$<200$ per $\mu\text{l}$	4
Serum bilirubin	$<1.2$ mg/dl	0
	1.2–1.9 mg/dl	1
	2.0–5.9 mg/dl	2
	6.0–11.9 mg/dl	3
	$\geq 12.0$ mg/dl	4
Hypotension	Mean arterial pressure $\geq 70$ (mmHg)	0
	Mean arterial pressure $<70$ then (no pressor agents used) (mmHg)	1
	Dobutamine any dose	2
	Dopamine $\leq 5$ $\mu\text{g}/\text{kg}$ per min	2
	Dopamine $>5$ – $15$ $\mu\text{g}/\text{kg}$ per min	3
	Dopamine $>15$ $\mu\text{g}/\text{kg}$ per min	4
	Adrenaline $\leq 0.1$ $\mu\text{g}/\text{kg}$ per min	3
	Adrenaline $>0.1$ $\mu\text{g}/\text{kg}$ per min	4
	Noradrenaline $\leq 0.1$ $\mu\text{g}/\text{kg}$ per min	3
	Noradrenaline $>0.1$ $\mu\text{g}/\text{kg}$ per min	4
Glasgow coma score	15	0
	13–14	1
	10–12	2
	6–9	3
	3–5	4
Serum creatinine or urine output	Serum creatinine $<1.2$ mg/dl	0
	Serum creatinine 1.2–1.9 mg/dl	1
	Serum creatinine 2.0–3.4 mg/dl	2
	Serum creatinine 3.5–4.9 mg/dl	3
	Urine output 200–499 ml/day	3
	Serum creatinine $>5.0$ mg/dl	4
	Urine output $<200$ ml/day	4

$P_{aO_2}$  is in mmHg and  $F_{iO_2}$  in per cent, from 0.21 to 1.00.

Adrenergic agents as administered for at least 1 hour with doses in  $\mu\text{g}/\text{kg}$  per min.

A score of 0 indicates normal and a score of 4 indicates most abnormal.

Data can be collected and the score calculated daily during the course of the admission.

Interpretation: minimum total score: 0; maximum total score: 24.

The higher the organ score, the greater the organ dysfunction.

The higher the total score, the greater the multiorgan dysfunction.

**Mortality rate by SOFA score.<sup>1</sup>**

Organ system	0	1	2	3	4
Respiratory	20%	27%	32%	46%	64%
Cardiovascular	22%	32%	55%	55%	55%
Coagulation	35%	35%	35%	64%	64%
CNS	32%	34%	50%	53%	53%
Renal	25%	40%	46%	56%	64%

**LOGISTIC ORGAN DYSFUNCTION SYSTEM (LODS)**

Assess patients for severity of critical organ dysfunction. To predict the probability of death for the patient.

Data collection	During the first 24 hours in the ICU
Data point	If not measured then it is assumed to be normal for scoring purposes If several measurements, use the most severe value

LOD score = (neurologic score) + (cardiovascular score) + (renal score) + (pulmonary score) + (haematological score) + (hepatic score).

**Neurologic score.**

Glasgow coma score	Points
14–15	0
9–13	1
6–8	3
< 6	5

Use lowest value. If sedated, estimate the score prior to sedation.

**Cardiovascular score.**

Heart rate (beats/min)		Systolic BP in (mmHg)	Points
30–139	<i>and</i>	90–239	0
≥ 140	<i>or</i>	240–269	1
		70–89	1
		≥270	3
		40–69	3
<30	<i>or</i>	<40	5

The most abnormal value for heart rate or systolic blood pressure either minimum or maximum.

**Renal score.**

Serum urea nitrogen mg/dl		Creatinine mg/dl		Urine output (l/d)	Points
<17	<i>and</i>	< 1.20	AND	0.75–9.99	0
17–27.99	<i>or</i>	1.2–1.59			1
28–55.99	<i>or</i>	≥1.60	OR	≥10	3
				0.5–0.74	3
≥56				<0.5	5

Highest value for urea nitrogen and for creatinine.

If the urine output data are for less than a 24-hour period, adjust that value to 24 hours, assuming the same rate of excretion.

On haemodialysis, use the value of urine output prior to initiating haemodialysis

**Pulmonary score.**

On ventilation or CPAP?	Ratio ( $PaO_2$ in mmHg)/( $FiO_2$ )	Points
No		0
Yes	<i>and</i> $\geq 150$	1
Yes	<i>and</i> $< 150$	3

Respiratory support; use the lowest ratio of  $PaO_2$  to  $FiO_2$ .

**Haematological score.**

White blood cell count $10^9/l$	Platelet count $10^9/l$	Points
2.5–4.9/ $\mu l$	<i>and</i> $\geq 50/\mu l$	0
$\geq 50/\mu l$		1
1–2.4/ $\mu l$	<i>or</i> $< 50/\mu l$	1
$< 1/\mu l$		3

*Note:* Most abnormal value for the white cell count either minimum or maximum.  
Minimum platelet count if several values are available.

**Hepatic score.<sup>2</sup>**

Bilirubin	Prothrombin time	Points
$< 2.0$ mg/dl ( $< 34.2$ $\mu$ mol/l)	<i>and</i> $\leq 3$ seconds above standard ( $\geq 25\%$ of standard)	0
$\geq 2.0$ mg/dl ( $\geq 34.2$ $\mu$ mol/l)	<i>or</i> $> 3$ seconds above standard ( $< 25\%$ of standard)	1

Highest value for bilirubin available. Highest value for prothrombin time in seconds.

**MPM II, MORTALITY PROBABILITY MODELS.<sup>3,4</sup>**

## Excluded

- Age  $< 18$  years
- Burn patients
- Coronary care patients
- Cardiac surgery patients

(The scoring is either present or not present)

## Definitions

Coma or deep stupor at time of ICU admission

- Not due to drug overdosage
- If patient is on paralysing muscle relaxant, awakening from anaesthesia or heavily sedated, use best judgement of the level of consciousness prior to sedation
- *Coma*: no response to any stimulation; no twitching, no movements in extremities, no response to pain or command; Glasgow coma score 3
- *Deep stupor*: decorticate or decerebrate posturing; posturing is spontaneous or in response to stimulation or deep pain; posturing is not in response to commands; Glasgow coma score 4 or 5

Heart rate at ICU admission

Heart rate  $\geq 150$  beats/min within 1 hour before or after ICU admission

Systolic blood pressure at ICU admission

Systolic blood pressure  $\leq 90$  mmHg within 1 hour before or after ICU admission

Chronic renal compromise or insufficiency

Elevation of serum creatinine  $> 2$  mg/dl and documented as chronic in the medical record

If there is the acute diagnosis on chronic renal failure then only record yes for acute renal failure

Cirrhosis

History of heavy alcohol use with portal hypertension and varices

Other causes of liver disease with evidence of portal hypertension and varices

Biopsy confirmation of cirrhosis

**Metastatic malignant neoplasm**

Stage IV carcinomas with distant metastases

Do not include involvement only of regional lymph nodes

Include if metastases are obvious by clinical assessment or confirmed by a pathology report

Do not include if metastases not obvious, or if pathology report is not available at the time of ICU admission

Acute haematological malignancies are included

Chronic leukaemias are not included unless there are findings attributable to the disease or the patient is under active treatment for the leukaemia. Findings include sepsis, anaemia, stroke caused by clumping of white blood cells, tumour lysis syndrome with elevated uric acid following chemotherapy, pulmonary oedema or the lymphangioectatic form of acute respiratory distress syndrome

**Acute renal failure**

Acute tubular necrosis or acute diagnosis on chronic renal failure

Prerenal azotaemia is not included

**Cardiac dysrhythmia**

Cardiac arrhythmia, paroxysmal tachycardia, fibrillation with rapid ventricular response, second- or third-degree heart block

Do not include chronic and stable arrhythmias

**Cerebrovascular incident**

Cerebral embolism, occlusion, cerebrovascular accident, stroke, brainstem infarction, cerebrovascular arteriovenous malformation (acute stroke or cerebrovascular haemorrhage, not chronic arteriovenous malformation)

**Gastrointestinal bleeding**

Haematemesis, melaena

A perforated ulcer does not necessarily indicate GI bleeding; may be identified by obvious 'coffee grounds' in nasogastric tube

A drop of haemoglobin by itself is not sufficient evidence of acute GI bleeding

**Intracranial mass effect**

Intracranial mass (abscess, tumour, haemorrhage, subdural) as identified by CT scan associated with any of the following: (1) midline shift; (2) obliteration or distortion of cerebral ventricles; (3) gross haemorrhage in cerebral ventricles or subarachnoid space; (4) visible mass > 4 cm; or (5) any mass that enhances with contrast media

If the mass effect is known within 1 hour of ICU admission, it can be indicated as yes

CT scanning is not mandated and is only indicated for patients with major neurological insult

**Age in years**

Patient's age at last birthday

**CPR within 24 hours prior to ICU admission**

CPR includes chest compression, defibrillation or cardiac massage

Not affected by the location where the CPR was administered

**Mechanical ventilation**

Patient is using a ventilator at the time of ICU admission or immediately thereafter

**Medical or unscheduled surgery admission**

Do not include elective surgical patients (surgery scheduled at least 24 hours in advance) or preoperative Swan-Ganz catheter insertion in elective surgery patients
