#### **Notice**

Medical knowledge is constantly changing. Standard safety precautions must be followed, but as new research and clinical experience broaden our knowledge, changes in treatment and drug therapy may become necessary or appropriate. Readers are advised to check the most current product information provided by the manufacturer of each drug to be administered to verify the recommended dose, the method and duration of administration, and contraindications. It is the responsibility of the practitioner, relying on experience and knowledge of the patient, to determine dosages and the best treatment for each individual patient. Neither the Publisher nor the authors assume any liability for any injury and/or damage to persons or property arising from this publication.

# Contents

Contributors	xiii
Preface	xvii
Acknowledgements	xix

## Part One – Organisational Aspects

1	<b>Design and organisation of intensive care units</b> 3 <i>Felicity Hawker</i>
2	<b>Outreach</b> 11 <i>David R Goldhill and John R Welch</i>
3	<b>Severity of illness and likely outcome from critical illness</b> 17 <i>Mark Palazzo</i>
4	<b>Transport of the critically ill</b> 31 <i>Evan Everest and Blair Munford</i>
5	<b>Physiotherapy in intensive care</b> 43 <i>Fiona H Moffat and Mandy O Jones</i>
6	<b>Critical care nursing</b> 53 <i>John R Welch and Chris Theaker</i>
7	<b>Ethics in intensive care</b> 61 <i>Raymond F Raper and Malcolm McD Fisher</i>
8	<b>Common problems after ICU</b> 67 <i>Carl S Waldmann</i>
9	<b>Clinical information systems</b> 75 <i>David Fraenkel</i>
10	<b>Clinical trials in critical care</b> 83 <i>Simon Finfer and Anthony Delaney</i>

## Part Two – Shock

11	<b>Shock – an overview</b> 97 <i>Angela McLuckie</i>
12	<b>Haemodynamic monitoring</b> 105 <i>David J Sturgess and Thomas John Morgan</i>
13	<b>Multiple organ dysfunction syndrome</b> 123 <i>Patricia Figgis and David Bihari</i>
14	<b>Monitoring oxygenation</b> 133 <i>Thomas John Morgan and Balasubramanian Venkatesh</i>

- 15 **Lactic acidosis** 145  
*D J (Jamie) Cooper and Alistair D Nichol*

### Part Three – Acute Coronary Care

- 16 **Acute cardiac syndromes, investigations and interventions** 155  
*Brad Power*
- 17 **Adult cardiopulmonary resuscitation** 179  
*Peter T Morley*
- 18 **Management of cardiac arrhythmias** 189  
*Andrew Holt*
- 19 **Cardiac pacing and implantable cardioverter/defibrillators** 245  
*Karl D Donovan and Bernard E F Hockings*
- 20 **Acute heart failure** 259  
*David Treacher*
- 21 **Valvular and congenital heart disease** 275  
*John E Sanderson*
- 22 **Intensive care after cardiac surgery** 285  
*Raymond F Raper*
- 23 **Echocardiography in intensive care** 295  
*Karl D Donovan and Frances B Colreavy*

### Part Four – Respiratory Failure

- 24 **Oxygen therapy** 315  
*Adrian T J Wagstaff*
- 25 **Airway management and acute upper-airway obstruction** 327  
*Gavin M Joynt*
- 26 **Acute respiratory failure in chronic obstructive pulmonary disease** 343  
*Matthew T Naughton and David V Tuxen*
- 27 **Mechanical ventilation** 355  
*Andrew D Bersten*
- 28 **Humidification and inhalation therapy** 367  
*Andrew D Bersten*
- 29 **The acute respiratory distress syndrome (ARDS)** 375  
*Andrew D Bersten*
- 30 **Pulmonary embolism** 387  
*Andrew R Davies and David V Pilcher*
- 31 **Acute severe asthma** 399  
*David V Tuxen and Matthew T Naughton*
- 32 **Pneumonia** 415  
*Charles D Gomersall*
- 33 **Non-invasive ventilation** 429  
*Graeme Duke and Andrew D Bersten*

34 Respiratory monitoring 439  
*Andrew D Bersten*

35 Imaging the chest 451  
*Simon P G Padley*

#### Part Five – Gastrointestinal Emergencies

36 Acute gastrointestinal bleeding 471  
*Joseph J Y Sung*

37 Severe acute pancreatitis 479  
*Duncan L A Wyncoll*

38 Acute liver failure 487  
*Elizabeth Sizer and Julia Wendon*

39 Abdominal surgical catastrophes 499  
*Stephen J Streat*

#### Part Six – Acute Renal Failure

40 Acute renal failure 509  
*Rinaldo Bellomo*

41 Renal replacement therapy 515  
*Rinaldo Bellomo*

#### Part Seven – Neurological Disorders

42 Disorders of consciousness 525  
*Balasubramanian Venkatesh*

43 Status epilepticus 541  
*Helen Ingrid Opdam*

44 Acute cerebrovascular complications 551  
*Bernard Riley*

45 Cerebral protection 563  
*Victoria Heaviside and Michelle Hayes*

46 Brain death 575  
*Marcus Peck and Martin Smith*

47 Meningitis and encephalomyelitis 583  
*Angus M Kennedy*

48 Tetanus 593  
*Jeffrey Lipman*

49 Neuromuscular disorders in intensive care 599  
*George A Skowronski*

#### Part Eight – Endocrine Disorders

50 Diabetic emergencies 613  
*Richard T Keays*

- 51 **Diabetes insipidus and other polyuric syndromes** 621  
*Craig Carr*
- 52 **Thyroid emergencies** 637  
*Jonathan Handy*
- 53 **Adrenocortical insufficiency in critical illness** 647  
*Balasubramanian Venkatesh and Jeremy Cohen*
- 54 **Acute calcium disorders** 653  
*Balasubramanian Venkatesh*

#### Part Nine – Obstetric Emergencies

- 55 **Pre-eclampsia and eclampsia** 665  
*Warwick D Ngan Kee and Tony Gin*
- 56 **General obstetric emergencies in the ICU** 673  
*Tony Gin and Warwick D Ngan Kee*
- 57 **Severe pre-existing disease in pregnancy** 681  
*Steve M Yentis*

#### Part Ten – Infections and Immune Disorders

- 58 **Anaphylaxis** 689  
*Malcolm McD Fisher*
- 59 **Host defence mechanisms and immunodeficiency disorders** 693  
*Steve Wesselingh and Martyn A H French*
- 60 **HIV and the acquired immunodeficiency syndrome** 701  
*Steve Wesselingh and Martyn A H French*
- 61 **Severe sepsis** 709  
*A Raffaele de Gaudio*
- 62 **Nosocomial infection** 719  
*Neil Soni*
- 63 **Severe soft-tissue infections** 731  
*Hugo Sax and Didier Pittet*
- 64 **Principles of antibiotic use** 739  
*Jeffrey Lipman*
- 65 **Tropical diseases** 745  
*Ramachandran Sivakumar and Michael E Pelly*

#### Part Eleven – Severe and Multiple Trauma

- 66 **Severe and multiple trauma** 757  
*James A Judson*
- 67 **Severe head injury** 765  
*John A Myburgh*

- 68 Maxillofacial and upper-airway injuries 783  
*Cyrus Edibam*
- 69 Chest injuries 791  
*Ubbo F Wiersema*
- 70 Spinal injuries 803  
*Geoff A Gutteridge*
- 71 Abdominal and pelvic injuries 815  
*Colin McArthur*

#### Part Twelve – Environmental Injuries

- 72 Near drowning 825  
*Cyrus Edibam*
- 73 Burns 829  
*David P Mackie*
- 74 Thermal disorders 837  
*Anwar Hussein*
- 75 Electrical safety and injuries 851  
*Lester A H Critchley*
- 76 Envenomation 857  
*James Tibballs*
- 77 Blast injury and gunshot wounds: pathophysiology and principles of management 867  
*Stephen Brett*
- 78 Biochemical terrorism 877  
*Munita Grover and Michael E Pelly*

#### Part Thirteen – Pharmacological Considerations

- 79 Pharmacokinetics, pharmacodynamics and drug monitoring in critical illness 887  
*Richard N Upton, John A Myburgh and Raymond G Morris*
- 80 Management of acute poisoning 903  
*Duncan L A Wyncoll*
- 81 Sedation, analgesia and muscle relaxation in the intensive care unit 913  
*Peter V van Heerden*
- 82 Inotropes and vasopressors 921  
*John A Myburgh*
- 83 Vasodilators and antihypertensives 935  
*John A Myburgh*

#### Part Fourteen – Metabolic Homeostasis

- 84 Acid–base balance and disorders 949  
*Thomas John Morgan*
- 85 Fluid and electrolyte therapy 963  
*Anthony Delaney and Simon Finfer*

- 86 Metabolic response to injury and infection 975  
*Ian K S Tan*
- 87 Enteral and parenteral nutrition 981  
*Richard Leonard*

#### Part Fifteen – Haematological Management

- 88 Blood transfusion 995  
*James P Isbister*
- 89 Colloids and blood products 1011  
*Michael Mythen*
- 90 Therapeutic plasma exchange and intravenous immunoglobulin immunomodulatory therapy 1017  
*James P Isbister*
- 91 Haemostatic failure 1025  
*James P Isbister*
- 92 Haematological malignancies 1041  
*James P Isbister*

#### Part Sixteen – Transplants

- 93 Organ donation 1051  
*Stephen J Streat*
- 94 Liver transplantation 1061  
*Elizabeth Sizer and Julia Wendon*
- 95 Heart and lung transplantation 1073  
*Cliff J Morgan*

#### Part Seventeen – Paediatric Intensive Care

- 96 The critically ill child 1085  
*Alan W Duncan*
- 97 Upper respiratory tract obstruction in children 1093  
*Alan W Duncan*
- 98 Acute respiratory failure in children 1101  
*Alan W Duncan*
- 99 Paediatric fluid and electrolyte therapy 1117  
*Frank A Shann*
- 100 Sedation and analgesia in children 1125  
*Geoff Knight*
- 101 Shock and cardiac disease in children 1133  
*Robert D Henning*
- 102 Neurological emergencies in children 1147  
*Anthony J Slater*

- 103 Paediatric trauma 1161  
*Neil T Matthews*
- 104 Equipment for paediatric intensive care 1169  
*James Tibballs*
- 105 Paediatric poisoning 1179  
*James Tibballs*
- 106 Paediatric cardiopulmonary resuscitation 1189  
*James Tibballs*
- Appendices 1197
- Index 1225

# Preface to the sixth edition

In the five years since the last edition there have been significant advances in most areas of intensive care medicine as the specialty has continued to evolve. This has included continued insights into both normal biology and disease, translation of this knowledge to the bedside, and results from large clinical trials directly relevant to clinical practice. Concurrently, health care professionals, patients and their relatives have unparalleled access to new knowledge through the internet. The original manual sought to provide useful and usable information at the bedside by distilling the immense amount of available information into a relevant and practical format. The burgeoning information highway that is the web does present a real challenge to a new edition of *Oh's Intensive Care Manual* but it also mandates this edition, which seeks to make that information more readily usable at the bedside. Well-known and well-respected clinicians have once again produced an edition that presents a current framework with the most up-to-date contextual references which

we hope will be an important and practical contribution to the practice of intensive care medicine.

Many chapters have been extensively updated, and a number of new authors have faced the difficulty of summarising their field and choosing the key new references. While trying to prevent the manual from becoming any larger, we also felt the increasing importance and contribution of large clinical trials required a specific chapter. However, given the vast area of knowledge covered by the manual, there will be times when the reader wants further detail. The sixth edition will have been a success if it provides a clear framework for additional detail, and if it cites most of the key references. Indeed, this has been the successful format of previous editions that has made them so useful. More importantly, the sixth edition will have been worthwhile if it continues to make a positive contribution to the care of the critically ill.

ADB  
NS

## ACKNOWLEDGEMENTS

Since the fifth edition we have received a lot of feedback from readers. We are thankful for constructive comments received from medical students, residents, trainees, colleagues, nurses and other health professionals. Hopefully some of the issues have been addressed. Without the great efforts of the authors, their colleagues and mentors and publishers there would not be a sixth edition. We also thank our wives and children (Libby, Eleanor, David and Ben; Alison, Kate and Ben) for their unfailing and generous support.

# Design and organisation of intensive care units

Felicity Hawker

An intensive care unit (ICU) is a specially staffed and equipped area of a hospital dedicated to the management of patients with life-threatening illnesses, injuries or complications. ICUs developed from the postoperative recovery rooms and respiratory units of the 1920s, 1930s and 1940s when it became clear that concentrating the sickest patients in one area was beneficial. Intermittent positive-pressure ventilation (IPPV) was pioneered in the treatment of respiratory failure in the 1948–1949 poliomyelitis epidemic and particularly in the 1952 Copenhagen poliomyelitis epidemic when IPPV was delivered using an endotracheal tube and a manual bag.<sup>1</sup> Subsequently mechanical ventilators were developed and became increasingly used for the treatment of thoracic surgery, general surgery, tetanus and ‘crushed chests’.

The 1970s saw a heightened interest in intensive care medicine, with research into the pathophysiological processes, treatment regimens and outcomes of the critically ill and the founding of specialty journals, training programmes and qualifications dedicated to intensive care. Modern intensive care or critical care medicine is not limited to postoperative care or mechanical ventilation. It is a separate specialty and, although some period of training in an ICU is valuable to all specialties, it can no longer be regarded as ‘part of’ anaesthesia, medicine, surgery or any other discipline.

As outlined below, the ICU is not just a ward but a department with dedicated medical, nursing and allied health staff: it operates with defined policies and procedures and has its own quality improvement, continuing education and research programmes. Through its care of critically ill patients in the ICU and its outreach activities (see Chapter 2), the intensive care department provides an integrated service to the hospital, without which many programmes (e.g. cardiac surgery, trauma, transplantation) could not function.

## CLASSIFICATION AND ROLE DELINEATION OF AN ICU

The delineation of roles of hospitals in a region or area is necessary to rationalise services and optimise the use of

resources. Each ICU should similarly have its role in the region defined and should support the defined duties of its hospital. In general, small hospitals require ICUs that provide basic intensive care. Critically ill patients who need complex management and sophisticated investigative back-up should be managed in an ICU located in a large tertiary referral hospital. Three levels of adult ICUs are classified as follows by the Joint Faculty of Intensive Care Medicine (Australia and New Zealand).<sup>2</sup> The European Society of Intensive Care Medicine has a similar classification.<sup>3</sup> The American College of Critical Care Medicine also has a similar classification but uses a reversed-numbering system.<sup>4</sup> It should be noted that full-time directors and directors with qualifications in intensive care medicine are less common in the USA,<sup>5</sup> as are the requirement for a dedicated doctor for the ICU around the clock and referral to the attending ICU specialist for management.<sup>6</sup>

1. *Level I adult ICU*: a level I adult ICU has a role in small district hospitals. It provides resuscitation and short-term cardiorespiratory support of critically ill patients and monitors and prevents complications in ‘at-risk’ medical and surgical patients. It is capable of providing mechanical ventilatory support and simple invasive cardiovascular monitoring for a limited period. The medical director should be an intensive care specialist. Referral and transport policies are required.
2. *Level II adult ICU*: a level II adult ICU is located in larger general hospitals. It provides a high standard of general intensive care, including multisystem life support, in accordance with the role of its hospital (e.g. regional centre for acute medicine, general surgery, trauma). It has a medical officer on site and access to pharmacy, pathology and radiological facilities at all times, but may not have all forms of complex therapy and investigations (e.g. interventional radiology, cardiac surgical service). The medical director and at least one other consultant are intensive care specialists. Patients admitted are referred to the attending intensive care specialists for management. Referral and transport policies are required.

**Table 1.1** UK classification of critical care beds**Level 0**

Patients whose needs can be met through normal ward care in an acute hospital

**Level I**

Patients at risk of their condition deteriorating, or those recently relocated from higher levels of care whose needs can be met on an acute ward with additional advice and support from the critical care team

**Level II**

Patients requiring more detailed observation or intervention, including support for a single failing organ system or postoperative care, and those stepping down from higher levels of care

**Level III**

Patients requiring advanced respiratory support alone or basic respiratory support together with support of at least two organ systems. This level includes all complex patients requiring support for multiorgan failure (<http://www.ics.ac.uk/icmprof/downloads/icsstandards-levelsofca.pdf>)

3. *Level III adult ICU*: a level III adult ICU is located in a major tertiary referral hospital. It should provide all aspects of intensive care required by its referral role for indefinite periods. The unit is staffed by specialist intensivists with trainees, critical care nurses, allied health professionals and clerical and scientific staff. Complex investigations and imaging and support by specialists of all disciplines required by the referral role of the hospital are available at all times. All patients admitted to the unit must be referred to the attending intensive care specialist for management.

The classification of types of ICU must not be confused with the description of critical care beds throughout a hospital, as with the UK classification of critical care beds (Table 1.1).

### TYPE AND SIZE OF AN ICU<sup>2</sup>

Within each of these classifications, an ICU may not be able to provide intensive care for all subspecialties, or may need to be more oriented towards a particular area of expertise (e.g. neurosurgery, cardiac surgery, burns or trauma). An institution may organise its intensive care beds into multiple units, under separate management by single-discipline specialists, for example, medical ICU, surgical ICU and burns ICU. Although this may be functional in some hospitals, Australasian experience has favoured the development of general multidisciplinary ICUs. Thus, with the exception of dialysis units, coronary care units (CCUs) and neonatal ICUs, critically ill patients are admitted to the hospital's multidisciplinary

ICU and are managed by intensive care specialists (or paediatric intensivists in paediatric hospitals).

There are good economic and operational arguments for a multidisciplinary ICU as against separate, single-discipline ICUs. Duplication of equipment and services is avoided. Critically ill patients develop the same pathophysiological processes no matter whether they are classified as medical or surgical and they require the same approaches to support of vital organs. Doctors without intensive care training lack the experience and expertise to deal with the complexities of multiorgan failure.

The number of ICU beds in a hospital usually ranges from 1 to 4 per 100 total hospital beds. This depends on the role and type of ICU. Multidisciplinary ICUs require more beds than single-specialty ICUs, especially if high-dependency beds are integrated into the unit. ICUs with fewer than four beds are considered not to be cost-effective and are too small to provide adequate clinical experience for skills maintenance for medical and nursing staff. On the other hand, the emerging trend of ICUs having 26<sup>7</sup> or more beds creates major management problems. Although the evidence is scant, there is a suggestion that efficiency deteriorates once the number of critically ill patients per medical team exceeds 12.<sup>8</sup> Consequently two or more medical teams may need to work together in these 'mega-units'.

### HIGH-DEPENDENCY UNIT (HDU)<sup>9,10</sup>

An HDU is a specially staffed and equipped area of a hospital that provides a level of care intermediate between intensive care and general ward care. Although HDUs may be located in or near specialty wards, increasingly they are located within or immediately adjacent to an ICU complex and are often staffed by the ICU personnel.

The HDU provides invasive monitoring and support for patients with or at risk of developing acute (or acute on chronic) single-organ failure, particularly where the predicted risk of clinical deterioration is high or unknown. It may act as a 'step-up' or 'step-down' unit between the level of care delivered on a general ward and intensive care, but does not normally accept patients requiring mechanical ventilation. Several older studies have shown benefits to outcome associated with the introduction of HDUs,<sup>9</sup> whereas a more recent study has questioned these findings.<sup>11</sup>

### PAEDIATRIC ICU (PICU)<sup>2</sup>

A PICU is a separate area in the hospital capable of providing complex, multisystem life support for indefinite periods to infants and children less than 16 years of age. It is a tertiary referral centre for children needing intensive care and has extensive back-up laboratory

and clinical services to support this tertiary role. Consultants in a PICU are paediatric intensive care specialists with expertise different from their adult intensive care colleagues. All patients admitted to the PICU are referred to the attending PICU specialists for management.

### DESIGN OF AN ICU<sup>1,3,12</sup>

The ICU should be sited in close proximity to relevant acute areas, that is, operating rooms, emergency department, CCU, labour ward and acute wards, and to investigational departments (e.g. radiology department, cardiac catheterisation laboratory). Safe transport of critically ill patients to and from the ICU should be facilitated by sufficient numbers of lifts and these, with doors and corridors, should be spacious enough to allow easy passage of beds and equipment – vital points often ignored by ‘planning experts’.

There should be a single entry and exit point, attended by the unit receptionist. Through traffic of goods or people to other hospital areas must never be allowed. An ICU should have areas and rooms for public reception, patient management and support services. The whole unit should be 2.5–3 times the area of the specific patient care areas.

### PATIENT AREAS

Each patient bed area in an adult ICU requires a minimum floor space of 20 m<sup>2</sup> (215 ft<sup>2</sup>), with single rooms being larger (at least 25 m<sup>2</sup>), to accommodate patient, staff and equipment without overcrowding. The ratio of single-room beds to open-ward beds will depend on the role and type of the ICU, but with a recommended range of between 1:6 and 1:2. They should be equipped with an anteroom of 2.5 m<sup>2</sup>. Single rooms are essential for isolation and, less importantly, privacy for conscious long-stay patients. The emergence of resistant bacterial strains in ICUs around the world has increased the need for isolation facilities in recent years. A non-splash hand wash basin with elbow- or foot-operated taps should be close to each bed and a hand disinfection facility at each bed.

Bedside service outlets should conform to local standards and requirements (including electrical safety and emergency supply, such as to the Australian Standard, Cardiac Protected Status AS3003).

Utilities per bed space as recommended for a level III ICU are:

- 4 oxygen
- 3 air
- 3 suction
- 16–20 power outlets

- a bedside light
- a telephone and data outlets

Adequate and appropriate lighting for clinical observation must be available. How the services are supplied (e.g. from floor column, wall-mounted, or ceiling-pendant) depends on individual preferences. There should be room to place or attach additional portable monitoring equipment and, as much as possible, equipment should be kept off the floor. Space for charts, syringes, sampling tubes, pillows, suction catheters and patient personal belongings should be available, often in a moveable bedside trolley.

All central staff and patient areas must have large clear windows. Lack of natural light and windowless ICUs give rise to patient disorientation and increased stress to all. Efforts should be made to reduce sound transmission and therefore noise levels, e.g. walls and ceilings should be constructed of materials with high sound-absorbing capability. Suitable and safe air quality should be maintained at all times. Air conditioning and heating should be provided with an emphasis on patient comfort.

Since critical care nursing is at the bedside, staffing of a central nurse station is less important than in a CCU. Nevertheless, the central station and other work areas should have adequate space for staff to work in comfort and situated so that patients can be seen. This central station usually houses a central monitor, satellite pharmacy and drug preparation area, satellite storage of sterile and non-sterile items, telephones, computers with internet connections, patient records, reference books and policy and procedure manuals. A dedicated computer for the picture archive and communication system (PACS) or a multidisplay X-ray viewer should be located within the patient care area.

### STORAGE AND SUPPORTING SERVICES AREAS

Storage areas should take up a total floor space of about 25–30% of all the patient and central station areas. They should have separate access remote from the patient area for deliveries and be no farther than 30 m from the patient area. Frequently used items (e.g. intravenous fluids and giving sets, sheets and dressing trays) should be located closer to patients than infrequently used or non-patient items. There should be an area for storing emergency and transport equipment within the patient area with easy access to all beds.

Floor areas for supporting services should make up about 20–25% of the patient and central station areas. Utility rooms must be clean and separate, each with its own access. Disposal of soiled linen and waste must be catered for, including contaminated items from infectious patients, using one-way traffic schemes. Facilities for estimating blood gases, glucose, electrolytes, haemoglobin, lactate and sometimes clotting status are usually sufficient

for the unit's laboratory. There should be a pneumatic tube or other system to transfer specimens to pathology. A good communication network of phones/intercoms is vital to locate and inform staff quickly. Adequate arrangements for offices, doctor-on-call rooms, staff lounge (with food/drinks facilities), wash rooms, education (seminar room) and a waiting room (see below) complete the unit.

### RELATIVES AREA

Apart from a waiting room, levels II and III ICUs should have a separate room to interview and comfort distressed relatives. There should be facilities for tea/coffee making and a water dispenser and toilets should be located close by. Television and/or music should be provided.

### STAFFING<sup>2-5</sup>

The level of staffing depends on the type of hospital and a tertiary hospital ICU requires a large team. Whatever the size of the team, it is crucial that there is free communication and collaboration among team members and a true multidisciplinary approach. Knaus *et al.* in a classic study<sup>13</sup> first showed a relationship between the degree of coordination in an ICU and the effectiveness of its care. Other studies have shown relationships between collaboration and teamwork and better outcomes for patients and staff.<sup>14,15</sup> Inadequate communication is the most frequent root cause of sentinel events.<sup>16</sup>

### MEDICAL STAFF<sup>17</sup>

An intensive care department should have a medical director who is qualified in intensive care medicine and who coordinates the clinical, administrative and educational activities of the department. The duties of the director should involve patient care, supervision of trainees/other junior doctors, the drafting of diagnostic and therapeutic protocols, responsibility for the quality, safety and appropriateness of care provided and education, training and research. It is recommended that the director be full-time in the department.

The director should be supported by a group of other specialists trained in intensive care medicine who provide patient care and contribute to non-clinical activities. In an ICU of level II or III there must be at least one specialist exclusively rostered to the unit at all times. Specialists should have a significant or full-time commitment to the ICU ahead of clinical commitments elsewhere. There should be sufficient numbers to allow reasonable working hours, protected non-clinical time and leave of all types. The recent increase in ICU outreach activities (medical emergency team calls, outpatient review: see Chapter 2) has increased the workload of intensive care specialists as well as junior staff in many

hospitals, resulting in the need to increase the size of the medical team.

There should also be at least one junior doctor with an appropriate level of experience rostered exclusively to level II and III units at all times. Junior medical staff in the ICU may be intensive care trainees, but should ideally also include trainees of other acute disciplines (e.g. anaesthesia, medicine and surgery). It is imperative that junior doctors are adequately supervised, with specialists being readily available at all times.

This physician staffing model has been used in Australia and New Zealand for many years, but has not been common in the USA. A systematic review<sup>18</sup> has shown that when there has been mandatory intensivist consultation (or closed ICU – see below) compared with no or elective intensivist consultation or open ICU, both ICU and hospital survival were improved and there was a reduced length of stay in ICU and in hospital.

### NURSING STAFF

Critical care nursing is covered in Chapter 6. The bedside nurse conducts the majority of patient assessment, evaluation and care in an ICU. In ICUs supporting tertiary hospitals 1:1 nursing is required for all ventilated patients, whereas one nurse per two patients is appropriate for HDU patients. Some complex patients with multiple supports may require more than one nurse. When leave of all kinds is factored in, long-term 24-hour cover of a single bed requires a staff complement of six nurses. Nurse shortages have been shown to be associated with increased patient mortality and nurse burnout and adversely affect outcome and job satisfaction in the ICU.<sup>19,20</sup>

There should be a nurse manager who is appointed with authority and responsibility for the appropriateness of nursing care and who has extensive experience in intensive care nursing as well as managerial experience. In tertiary units the nurse manager should participate in teaching, continuing education and research. Ideally, all nurses working in an ICU should have training and certification in critical care nursing.

### ALLIED HEALTH

Major ICUs must have 24-hour access to pathology and radiological services. Access to physiotherapists, dieticians, social workers and other therapists should also be available. A dedicated ward clinical pharmacist is invaluable and participation of a pharmacist on ward rounds has been associated with a reduction in adverse drug events.<sup>21</sup> Respiratory therapists are allied health personnel trained in and responsible for the equipment and clinical aspects of respiratory therapy, a concept well established in North America, but not the UK, continental Europe and Australasia. Technical support staff,<sup>22</sup> either as members of the ICU staff, or seconded from biomedical departments, are necessary to service, repair and develop equipment.

## OTHER STAFF

Provision should be made for adequate secretarial support.<sup>23</sup> Transport and 'lifting' orderly teams will reduce physical stress and possible injuries to nurses and doctors. If no mechanical system is available to transport specimens to the laboratories (e.g. air-pressurised chutes), sufficient and reliable couriers must be provided to do this day and night. The cleaning personnel should be familiar with the ICU environment and infection control protocols. There should also be a point of contact for local interpreters, chaplains, priests or officials of all religions, when there is need for their services.

## CLINICAL ACTIVITIES

### OPERATIONAL POLICIES<sup>2</sup>

Clear-cut administrative policies are vital to the functioning of an ICU. An *open* ICU has unlimited access to multiple doctors who are free to admit and manage their patients. A *closed* ICU has admission, discharge and referral policies under the control of intensivists. Improved cost benefits are likely with a closed ICU and patient outcomes are better, especially if the intensivists have full clinical responsibilities.<sup>18,24</sup> Consequently ICUs today, especially levels II and III, should be *closed* under the charge of a medical specialist director. All patients admitted to the ICU are referred to the director and his/her specialist staff for management, although it is important for the ICU team to communicate regularly with the parent unit and to make referrals to specialised services when appropriate.

There must be clearly defined policies for admission, discharge, management and referral of patients. Lines of responsibilities must be delineated for all staff members and their job descriptions defined. The director must have final overall authority for all staff and their actions, although in other respects each group may be responsible to respective hospital heads, for example, director of nursing.

Policies for the care of patients should be formulated and standardised. They should be unambiguous, periodically reviewed and familiarised by all staff. Examples include infection control and isolation policies, policies for intra- and interfacility transport, end-of-life policies (e.g. do not resuscitate (DNR) procedure) and sedation and restraint protocols. It should be noted, however, that when protocols involve complex issues (such as weaning from mechanical ventilation) they may be less efficient than the judgement of experienced clinicians.<sup>25</sup> Clinical management protocols, e.g. for feeding and bowel care, can be laminated and placed in a folder at each bed or loaded on to the intranet.

## EQUIPMENT

The type and quantity of equipment will vary with the type, size and function of the ICU and must be appropriate to the workload of the unit. There must be a regular

programme in place for checking its safety. Protocols and in-service training for medical and nursing staff must be available for the use of all equipment, including steps to be taken in the event of malfunction. There should also be a system in place for regular maintenance and service. The intensive care budget should include provision to replace old or obsolete equipment at appropriate times. A system of stock control should be in place to ensure consumables are always in adequate supply. The ICU director should have a major role in the purchase of new equipment to ensure it is appropriate for the activities of the unit.

## PATIENT CARE

ICU patient management should be multidisciplinary, with medical, nursing and other staff working together to provide the best care for each patient. The critical care nurse is the primary carer at the bedside and monitors, manages and supports the critically ill patient (see Chapter 6). The medical team consists of one or more registrars, residents or fellows who direct medical care with an intensive care specialist. The patient should be assessed by a formal ward round of the multidisciplinary team twice daily, usually at a time when the junior medical staff are handing over from one shift to the next. The nurse coordinating the floor and in larger units allied health staff such as pharmacists and dieticians also take part. Each patient should be assessed clinically (examination, observations and pathology, radiological and other investigation results), the medication chart reviewed, progress determined and a management plan developed for the immediate and longer term. The ward round is also an opportunity to assess compliance with checklists such as Fast Hug.<sup>26</sup> Clearly, unstable patients will require much more frequent assessment and intervention.

It is crucial that all observations, examination findings, investigations, medical orders, management plans (including treatment limitations) and important communications with other medical teams and patients' families are clearly documented in the appropriate chart or part of the medical record either electronically or in writing.

Wherever possible clinical management should be evidence-based and derived through consensus of the members of the ICU team, accepting, however, that evidence-based medicine has limitations when applied to intensive care medicine.<sup>27</sup>

## CARE OF FAMILIES<sup>28</sup>

ICU care includes sensitive handling of relatives. It is important that there are early and repeated discussions with patients' families to reduce family stress and improve consistency in communication. Ideally one senior doctor should be identified as the ICU representative to liaise with a particular family. Discussions should be interactive and honest and an attempt made

to predict the likely course, especially with respect to outcome, potential complications and the duration of intensive care management required. The time, date and discussion of each interview should be recorded. Cultural factors should be acknowledged and spiritual support available, especially before, during and after a death. Open visiting hours allow families maximum contact with their loved one and promote an atmosphere of openness and transparency.

Education and debriefing may be necessary for staff, especially in relation to difficult and/or unexpected deaths and grieving families.

## OUTREACH

ICU outreach activities are described in Chapter 2.

## NON-CLINICAL ACTIVITIES<sup>2</sup>

Non-clinical activities are very important in the ICU, as they enhance the safety, quality and currency of patient care. The Joint Faculty of Intensive Care Medicine recommends that full-time intensive care specialists should have as protected non-clinical time three half-day sessions per week.<sup>29</sup> Nursing and allied health staff should also seek protected time for these activities.

## QUALITY IMPROVEMENT<sup>30,31</sup>

It is essential that senior medical and nursing staff promote a culture of quality improvement (QI) within the ICU, whatever its size and role. All ICUs should have demonstrable and documented formal audit and review of its processes and outcomes in a regular multidisciplinary forum. Staff who collect and process the data should have dedicated QI time.

Quality indicators can be considered under three headings:

1. *Structure*. Structural indicators assess whether the ICU functions according to its operational guidelines and conforms to the policies of training and specialist bodies (e.g. clinical work load and case mix, staffing establishment and levels of supervision).
2. *Clinical process*. Clinical process indicators assess the way care is delivered. Examples include whether deep-vein thrombosis prophylaxis is given, time to administration of antibiotics and glycaemic control.
3. *Outcome*. Examples of outcome measures include survival rate, quality of life of survivors and patient satisfaction.

The QI process involves *identification* of the indicator to be improved (e.g. high ventilator-associated pneumonia (VAP) rate), *development* of a method to improve it (e.g. checklist such as Fast Hug<sup>26</sup>), *implementation* of the method to improve it (e.g. requirement to tick off

the checklist on the morning ward round), re-evaluation of the indicator (e.g. VAP rate) to ensure the intervention has improved the outcome and finally to *ensure sustainability* (e.g. print checklist on ICU chart).

Activities that assess processes include clinical audit (including morbidity and mortality meetings and delayed transfer out of ICU), compliance with protocols, guidelines and checklists and critical incident reporting.

Activities that assess outcomes are calculating risk-adjusted mortality using a scoring system such as the Acute Physiology and Chronic Health Evaluation II (APACHE II) and calculation of standardised mortality ratios (see Chapter 3), measurement of rates of adverse events such as central venous catheter-associated blood stream infection rate or serious adverse drug event rate and surveys (e.g. patient or relative satisfaction, bad backs from lifting in ICU nurses).

Risk management is a closely related field. In the ICU, risks can be identified from critical incident reports, morbidity and mortality reviews and complaints from staff, patients or family members. Using similar methodology to the QI process risks must be identified, assessed and analysed, managed and re-evaluated. A major patient safety incident should result in a root cause analysis.<sup>32</sup>

## EDUCATION

All ICUs should have a documented orientation programme for new staff. There should be educational programmes for medical staff and a formal nursing education programme. Educational activities for intensive care trainees include lectures, tutorials, bedside teaching and trial examinations (written, clinical and viva). Apart from clinical reviews, meetings to review journals and new developments should be held regularly. Nurses are usually required to undergo annual assessment for advanced life support and sometimes other assessments (e.g. medication safety). Increasingly, simulation centres are used to teach and assess skills and teamwork in crisis scenarios.<sup>33</sup> A number of ICUs are also involved in undergraduate medical teaching. All staff should also participate in continuing education activities outside the hospital (e.g. local, national or international meetings).

## RESEARCH

Level III ICUs should have an active research programme, preferably with dedicated research staff, but all units should attempt to undertake some research projects whether they be unit-based or contributions to multicentre trials.

## THE FUTURE

In the USA critical care medicine is thought to account for 1–2% of the gross domestic product<sup>34</sup> and has become increasingly used and prominent in the delivery of health care. Although the total number of hospitals, hospital

beds and inpatient days has decreased, there has been shown to be a large increase in the number of intensive care beds and bed days.<sup>35</sup> There is every reason to expect that other developed countries will follow this trend. As ICUs become larger and ICU staff become larger still (because of outreach activities: see Chapter 2) it is crucial that the basic principles outlined in this chapter are followed and that standards of ICU design, staffing and clinical and non-clinical activities are maintained.

# Outreach

David R Goldhill and John R Welch

## CRITICAL CARE OUTREACH

A key innovation in critical care has been the development of dedicated outreach and medical emergency/rapid response services aiming 'to ensure equity of care for all critically ill patients irrespective of their location'.<sup>1</sup>

Outreach is multidisciplinary 'collaboration and partnership between critical care and other departments to ensure a continuum of care for patients and to enhance the skills and understanding of all staff in the delivery of critical care'.<sup>2</sup> Outreach services primarily focus on patients with potential or actual critical illness on general wards. They are not a substitute for insufficient critical care beds, poor ward facilities or inadequate staffing.

## BACKGROUND

Many patients who require critical care are on a ward for part of their hospital admission. Comparison of outcomes of patients admitted to a critical care unit from the emergency department, operating theatre/recovery area and wards shows that the highest number of deaths is found in patients admitted from wards.<sup>3</sup> The longer patients are in hospital before admission to critical care, the higher their mortality.<sup>4</sup> Reports from many countries show that hospital patients frequently suffer adverse events and that these events can cause major morbidity or death.<sup>5</sup> Sub-optimal treatment is common before admission to critical care and is associated with worse outcomes.<sup>6</sup> Crucially, the baseline characteristics of patients who receive sub-optimal care are not significantly different from those who are well managed. Differences in mortality are attributable to differences in the quality of care rather than differences between patients themselves. Many factors are implicated, including lack of knowledge and failure to appreciate clinical urgency and to seek advice, compounded by poor organisation, breakdown in communication and inadequate supervision.

About one-quarter of all 'critical care deaths' occur *after* patients have been discharged back to wards from critical care. Patients discharged inappropriately early have

an increased mortality.<sup>7,8</sup> There are also deaths among surgical patients who have returned to the ward following surgery without ever being admitted to critical care.

Nonetheless, these at-risk patients are in hospital, so they are accessible. If such patients can be identified early, prompt intervention may improve outcomes.

Even in well-resourced health care systems, critical care beds are a small proportion of all acute beds and have high rates of occupancy. Hospital lengths of stay have fallen and hospital admission criteria have been made more stringent in recent years. The result is that many ward patients have serious medical problems, although only the most unstable gain admission to a critical care unit. Therefore, many at-risk patients are cared for in inappropriate areas by staff unpractised in managing critical illness.

Changes in nursing education have reduced nurses' training time in acute and critical care areas, while such key tasks as measuring respiratory rate and blood pressure are delegated to untrained staff who may not understand the significance of abnormal values. Many hospitals use temporary staff who may not provide the stability and commitment essential for effective working. Medical education is also problematic. Recently qualified doctors are often unable to recognise or treat life-threatening problems and, because training is shorter and more specialised, consultants may also be less experienced in managing critical illness.

With shorter hospital stays and sicker patients, the system of care must be able to respond rapidly to changes in a patient's condition. For some patients, even daily medical review may not be enough.

## OUTREACH SYSTEMS

Medical emergency teams (METs) were first introduced in Australia in 1990. METs expanded the role of the hospital cardiac arrest team to include the pre-arrest period, with call-out criteria generally based upon markedly deranged physiological values.<sup>9</sup> In the UK, critical care outreach (CCO) services became relatively widespread following negative publicity about shortages of critical care facilities and the national review of critical care

services in 2000.<sup>10</sup> This led to some additional funding for critical care beds and outreach services. Other countries have also recognised the needs of critically ill patients outside designated critical care areas and have introduced their own systems to address these problems.

There are now many models and a variety of terms for outreach services.<sup>11,12</sup> Some organisations have enthusiastically embraced the concept whereas others have reservations. METs are usually physician-led, while CCO teams and rapid response teams (RRTs) are typically nurse-led but may include physiotherapists and other allied health professionals as well as doctors. Most teams respond to defined triggers, although some, particularly CCO services, also work proactively with known at-risk patients such as intensive care unit (ICU) discharges.

These systems have the following features in common:

- a mechanism for identifying ward patients who are, or have the potential to become, critically ill
- a trigger designed to initiate a response when certain criteria are fulfilled
- a prompt response from personnel with the required skills, experience and resources

The aim is to prevent unnecessary critical care admissions, to ensure timely transfer to critical care when needed, to facilitate safe discharge from critical care back to the ward, to share critical care skills and to improve standards of care throughout the hospital. There may also be a role in outpatient support for patients and their families after hospital discharge (Table 2.1).

**Table 2.1** Functions of critical care outreach

- Identification of at-risk patients
- Support for ward staff caring for at-risk patients and those recovering from critical illness
- Referral protocols for obtaining timely, effective critical care treatments
- Immediate availability of expert critical care and resuscitation skills when required
- Facilitation of timely transfer to a critical care facility when needed
- Education for ward staff in recognition of fundamental signs of deterioration, and in understanding how to obtain appropriate help promptly
- Outpatient support to patients and their families following discharge from hospital
- Development of systems of coordinated, collaborative, continuous care of critically ill and recovering patients across the hospital and also in the community
- Audit and improvement of basic standards of acute and critical care – and of the outreach team itself – to minimise risk and optimise treatment of the critically ill throughout the hospital

Together, these elements comprise a system to deliver safe, quality care by proactive management of risk and timely treatment of critical illness

## RECOGNISING CRITICAL ILLNESS

Critically ill patients are identified by review of the history, by examination and investigations. Higher risks are associated with extremes of age, with significant comorbidities or with serious presenting conditions. Outcome is often related to and can be predicted by abnormal physiology. Many studies show patients have abnormal physiology for hours and sometimes days before critical events such as cardiopulmonary arrest.<sup>13–18</sup> However, measuring and recording of vital signs on general wards are often inadequate.<sup>19</sup>

A physiologically based system for identifying critical illness should have certain attributes (Table 2.2).

For early recognition of hospital patients to be effective:

- Abnormal physiological values or biochemistry or other patient factors should enable identification
- There must be enough time to identify the patients – and to obtain expert assistance
- Early intervention should be beneficial

## ABNORMAL PHYSIOLOGY AND ADVERSE OUTCOME

There is an association between abnormal physiology and adverse outcome. Critical care severity scoring systems such as Acute Physiology, Age and Chronic Health Evaluation II (APACHE II)<sup>20</sup> are based on this relationship. Patients who suffer cardiopulmonary arrest or who die in hospital generally have abnormal physiological values recorded in the preceding period, as do patients requiring transfer to the critical care unit.

It therefore follows that vital signs can predict many adverse events. These principles have been incorporated into a number of early-warning scoring (EWS) systems. The systems incorporate different combinations of physiological parameters, a range of approaches to scoring and various trigger thresholds. Examples of the variables included in a few of the scoring systems are given in Table 2.3.

In the UK these methods are often called track and trigger warning systems. They can be broadly summarised as single-parameter systems, multiple-parameter systems, aggregate weighted scoring systems or combinations (Table 2.4).<sup>1</sup>

In Australia, MET call-out criteria are usually based upon markedly deranged physiological values, although ward staff concern is also a trigger (Table 2.5).<sup>21</sup>

**Table 2.2** Ideal attributes of an early-warning (track and trigger) scoring system

Timely	Measurable
Reliable	Reproducible
Inexpensive	Non-invasive
Repeatable	Safe
Accurate	Independent of disease state

**Table 2.3** Variables used by different scoring systems to trigger referrals to a critical care service

Variable	Critical care service

**Table 2.4** Classification of track and trigger warning systems

<b>Single-parameter systems</b>
<b>Tracking</b>
Periodic observation of selected basic signs
<b>Trigger</b>
One or more extreme observational values
<b>Multiple-parameter systems</b>
<b>Tracking</b>
Periodic observation of selected basic vital signs
<b>Trigger</b>
Two or more extreme observational values
<b>Aggregate weighted scoring systems</b>
<b>Tracking</b>
Periodic observation of selected basic vital signs and the assignment of weighted scores to physiological values with calculation of a total score
<b>Trigger</b>
Achieving a previously agreed trigger threshold with the total score
<b>Combination systems</b>
Elements of single- or multiple-parameter systems in combination with aggregate weighted scoring

(Definitions taken from Department of Health/Modernisation Agency. *Critical Care Outreach 2003 – Progress in Developing Services: National Outreach Report*. London: Department of Health, 2003.)

**Table 2.5** Medical emergency team call-out criteria

Airway	Respiratory distress Threatened airway
Breathing	Respiratory rate < 6 or > 30 breaths/min SpO <sub>2</sub> < 90% on oxygen Difficulty speaking
Circulation	Systolic blood pressure < 90 mmHg despite treatment Heart rate > 130 beats/min
Neurology	Unexplained decrease in consciousness Agitation or delirium Repeated or prolonged seizures
Other	Concern about patient Uncontrolled pain Failure to respond to treatment Unable to obtain prompt help

(Call-out criteria from Buist MD, Moore GE, Bernard SA *et al.* Effects of a medical emergency team on reduction of incidence of and mortality from unexpected cardiac arrests in hospital: preliminary study. *Br Med J* 2002; **324**: 387–90.)

**Table 2.6** Early-warning score (EWS)

Variable	Score						
	3	2	1	0	1	2	3
Heart rate (beats/min)		≤ 40	41–50	51–100	101–110	111–130	≥ 130
Systolic blood pressure (mmHg)	< 70	71–80	81–100	101–199			≥ 200
Respiratory rate (breaths/min)		< 8		9–14	15–20	21–29	≥ 30
Temperature (°C)			≤ 35	35.1–36.5	36.6–37.4		≥ 37.5
Central nervous system				A	V	P	U

This EWS is the one originally published by Morgan RJM, Williams F, Wright MM. An early warning score for detecting developing critical illness. *Clin Intens Care* 1997; **8**: 100.

A, alert; V, responds to voice; P, responds to pain; U, unresponsive.

The use of physiological values in the form of a multiple-parameter EWS to identify at-risk ward patients was first described by Morgan *et al.*<sup>22</sup> There are different formats but they follow a similar theme, awarding points for varying degrees of derangement of different physiological functions (Table 2.6). The higher the total score, the more the patient is ‘at risk’.

To date, EWSs have been devised using clinical acumen and common sense. They have yet to be scientifically validated as predictors of preventable adverse outcomes. Crucially, the calculated score depends on the definition of normal physiological values and how much relative importance is attributed to the derangements of each measured parameter.

Physiologically based EWS systems are now widely used to identify at-risk patients. There is little concrete evidence about the most important parameters and the exact values that identify critical illness. It is possible that a combination of factors and analysis of changes over time may be the best way of identifying such patients.

## MEASURING OUTCOME

The concept of outreach is based upon the premise that early detection and treatment of critical illness should improve patient outcomes. The quality of an outreach service may be evaluated against these and other measures, including indicators of effective processes (Table 2.7).

Outreach systems have certainly highlighted shortcomings in the care of ward patients and contributed to a change in attitude and more attention to at-risk patients. They have been instrumental in improving ward monitoring and charting and in disseminating critical care skills. There is much anecdotal evidence of benefit to individual patients. There is published evidence that outreach services improve the recognition of at-risk patients on wards and can reduce length of stay, cardiac arrest rates, unplanned admissions to critical care and morbidity and mortality of such patients.<sup>21,23–26</sup> However, there are

**Table 2.7** Possible outcome and process measures

- Numbers of staff trained to recognize critical illness and respond appropriately
- Completeness of physiological values recording and other documentation
- Response times to triggers
- Appropriateness and timeliness of interventions
- Cardiopulmonary arrests, unexpected deaths and adverse events
- The interface with critical care departments, e.g. timeliness of patient transfer to critical care
- Numbers of admissions to critical care (and readmissions)
- Critical care and hospital mortality
- Critical care and hospital lengths of stay
- Patient and staff satisfaction

as many reports that do not show significant effects. In fact there are as yet few good-quality studies, with just two randomised controlled trials.<sup>26,27</sup>

Positive studies include a UK randomised trial of phased introduction of a 24-hour outreach service to 16 wards in a general acute hospital.<sup>26,28</sup> The outreach team routinely followed up patients discharged from critical care to the wards and saw referrals generated by ward staff concern or use of an aggregate weighted scoring system. There was a statistically significant reduction in hospital mortality in wards where the service was operational. In contrast, a large prospective randomised trial of METs in Australia did not find improvements in cardiac arrests, unplanned admissions to critical care or unexpected deaths.<sup>27</sup> The study did reveal many shortcomings in the identification and care of critically ill patients. One possible conclusion is that for outreach to work there must be a whole-systems approach to early identification of at-risk patients and to obtaining an appropriate, timely and effective response.

It can be argued that outreach should not be necessary in a properly run and funded first-world health care

system. Time will tell if outreach services are simply a stopgap solution to compensate for hospital system failings. Nonetheless, there is no doubt that there are significant numbers of patients on hospital wards with potential or actual critical illness whose care should and could be improved. Outreach systems are one method of addressing these issues.

### SETTING UP AN OUTREACH SERVICE

Patients with potential or actual critical care illness may be found in almost every area of the acute hospital, so systems to identify and treat at-risk patients promptly and improve quality across an institution need to be planned at an organisational level. Involvement of managerial and clinical staff at all levels, particularly from the general wards, is essential. It is particularly important that there is agreement and clarity about how the outreach team interacts with the parent/primary medical team. The Institute for Healthcare Improvement has useful information on setting up a rapid response team.<sup>29</sup>

### KEY STEPS IN PLANNING AN OUTREACH SERVICE

- Appoint senior clinical and managerial leads to develop the service.
- Institute organisational needs analysis, audit and evaluation, asking:
  - Which patients are at risk of critical illness and where are they located?
  - Where do cardiopulmonary arrests and unexpected deaths occur?
  - What is the source of unplanned admissions to ICU?
  - What is the pattern of adverse events where actual harm can be attributed to the process of care?
  - What are the other relevant clinical governance/risk management issues, e.g. complaints, or morbidity and mortality data?
- A point prevalence study can give snapshot views of the location of patients with physiological derangement.
- Review of unplanned ICU admissions can identify systems failings, including quality of patient management and appropriateness and timeliness of intensive care admission. Practice can be assessed against specific, measurable standards set locally or nationally/internationally.
- Such analyses should also highlight staff education and training needs.

Other factors to consider include:

- The patient case mix
- Existing skills of general ward staff
- Proposed hours of service
- Size of hospital – and likely demand
- Existing services such as pain teams, nutrition teams, tracheostomy specialist practitioners, respiratory specialists, renal specialists, night teams

- Training facilities for nursing, medical and other clinical staff
- Outreach service location and equipment needs, including information technology facilities
- Funding

### THE OUTREACH TEAM

The composition and skills of the outreach team should be designed to meet the specific needs identified by individual organisations. At a minimum, a team should be capable of assessment, diagnosis, initiation of resuscitation and rapid triage of the patient to a higher level of care with authority to act. Such clinical skills as airway management techniques, venepuncture and cannulation are essential and so are skills in education and training, research and audit. A multiprofessional team is likely to be required in order for this range of skills to be available and also for the team to be able to communicate readily with the whole range of staff in the hospital.

A pragmatic, staged implementation could include:

1. Establishing an education programme in fundamental care of the critically ill for general ward staff so that all staff can recognise basic signs of deterioration and understand the necessity and means of obtaining timely help. Staff should update their skills annually
2. Introducing a physiological track and trigger warning system and defined referral/response protocols
3. Developing clinical bedside support – incrementally if necessary – increasing the number of clinical areas covered by the team and the hours of work. This might include follow-up of patients discharged from critical care and responding to patients identified through the track and trigger system or by referral from ward staff
4. It is essential that robust data are collected on the work of the service and that this information is used for audit and evaluation – and for feedback to ward managers and clinical staff. Successes should be highlighted and areas for improvement in practice identified. Data may include:
  - Numbers of referrals and patient follow-ups
  - Date and time of episode
  - Patient details, e.g. age, sex, date of hospital admission, location, emergency/elective admission, medical/surgical, resuscitation status
  - Trigger event, e.g. EWS, cardiac arrest call
  - Key problems identified
  - Interventions performed
  - Patient outcomes

# Severity of illness and likely outcome from critical illness

Mark Palazzo

At present scoring systems are not sufficiently accurate to make outcome predictions for individual patients.

Clinical assessment of severity of illness is an essential component of medical practice. It influences the need and speed for supportive and specific therapy. Initial acuity may also indicate likely prognosis when other factors such as comorbidity and organisational aspects of critical care delivery are considered. It is intuitive to consider whether patterns and severity of physiological disturbance can predict patient outcome from an episode of critical illness.

Perhaps the earliest reference to grading illness was in an Egyptian papyrus which classified head injury by severity.<sup>1</sup> More recently it has been the constellation of physiological disturbances for specific conditions which popularised an approach which linked physiological disturbance to outcome in the critically ill. Examples include the Ranson score for acute pancreatitis,<sup>2</sup> the Pugh modification of Child–Turcotte classification for patients undergoing portosystemic shunt surgery and now widely used for classification of end-stage liver disease,<sup>3</sup> Parsonnet scores for cardiac surgery<sup>4</sup> and the Glasgow Coma Score (GCS) for acute head injury.<sup>5</sup> The earliest attempts to quantify severity of illness in a general critically ill population was by Cullen *et al.*<sup>6</sup> who devised a therapeutic intervention score as a surrogate for illness. This was followed in 1981 with the introduction of the Acute Physiology, Age and Chronic Health Evaluation (APACHE) scoring system by Knaus *et al.*<sup>7</sup> Since then numerous scoring systems have been designed and tested in populations across the world.

The potential advantages of quantifying critical illness include:

- providing a common language for discussion
- provision of risk-adjusted expected mortality rates facilitating acuity comparisons for clinical trials
- estimates of prognosis
- providing a method by which critical care practice and processes can be examined

The least controversial use for scoring systems has been as a method for comparing patient groups in clinical trials. While this seems to have been widely accepted

by the critical care community, there has been less enthusiasm to accept the same systems as comparators for between-unit and even between-country performances, unless of course your performance is good. Most clinicians agree that scoring systems have limited value for individual patient decision pathways, although recently an APACHE II score above 25 under appropriate circumstances has been included in the guidelines for the administration of recombinant human activated protein C for severe sepsis and septic shock. Much of the sceptical views among clinicians are based on studies which show poor prognostic performance from many of the models proposed.<sup>8–14</sup> The fundamental problem for these scores and prognostic models is poor calibration for the cohort of patients studied, often in countries with different health service infrastructures, to where the models were first developed. Other calibration issues arise either because there is poor adherence to the rules for scoring methodology by users, or patient outcomes improve following introduction of new techniques and treatments or models failed to include important prognostic variables. For example it has become clearer that prognosis is as much affected by local organisation, patient pathways, location prior to admission and preadmission state as it is by acute physiological disturbances.<sup>15,16</sup>

Score systems would be better calibrated if developed from a narrow number of countries with similar health services. However this limits their international usefulness for clinical studies. The latter can be improved by score systems developed from a wider international cohort; however when used for an individual country it can be expected to calibrate poorly. Simplified Acute Physiology Score 3 (SAPS 3: developed across the globe) has provided customisation formulae so that the risk-adjusted expected mortality can be related to the geographical location of the unit.<sup>16</sup>

Inevitably, as advances occur, risk-adjusted mortality predictions become outdated with some old models overestimating expected mortality<sup>14,17</sup> and others underestimating observed mortality.<sup>18</sup> The designers of the scoring systems have recognised the changing baselines

**Table 3.1** Revision dates for the most common internationally recognized risk adjusted models for mortality prediction

Severity of illness model	Year	Timing of score	Cohort size	ICU units	ICU countries
SAPS	1984	First 24 hours	679	8	France
SAPS 2	1993	First 24 hours	13 152	137	Europe/USA
SAPS 3	2005	Admission	16 784	303	Europe, Australia, South and Central America
MPM I	1987	Admission	1997	1	USA
MPM II <sub>0</sub>	1993	Admission	19 124		USA/Europe
APACHE I	1981	First 24 hours	805	2	USA
APACHE II	1985	First 24 hours	5815	13	USA
APACHE III	1991	First 24 hours	17 440	40	USA
APACHE IV	2006	First 24 hours	110 558	104	USA

ICU, intensive care unit; SAPS, Simplified Acute Physiology Score; MPM, Mortality Probability Model; APACHE, Acute Physiology, Age and Chronic Health Evaluation.

and review the models every few years, Table 3.1 outlines some characteristics of the upgraded systems.

#### FACTORS INDICATING RISK AND SEVERITY OF ILLNESS THAT MIGHT HELP PREDICT LIKELY OUTCOME

- Degree of physiological disturbance
- Primary pathological process causing the physiological disturbance
- Patient's physiological reserve specific, comorbid states and age
- Source of admission and mode of presentation
- Organ support prior to admission
- Unit organisation and processes

#### PHYSIOLOGICAL DISTURBANCE

An insult which potentially interferes with normal organ function is usually followed by increasing compensatory activity in order to retain vital organ activity. Most compensatory mechanisms are mediated through the endocrine and autonomic nervous system directed to maintain effective circulating volume, oxygenation and acid-base homeostasis to ensure normal mitochondrial function and vital organ function. Therefore hyperventilation, tachycardia, vasoconstriction and consequent oliguria – all signs of compensation – are hallmarks of early untreated critical illness. Once overwhelmed, the compensatory mechanisms lead to signs of decompensation such as hypotension, progressive coma, icterus and metabolic acidosis.

Most organs have limited ways in which they manifest their dysfunction in response to a systemic illness, for example the brain responds by becoming confused,

developing seizures or progressive coma, while respiratory function is limited to hyperventilation, hypoventilation, wheezing or coughing with commensurate changes in blood gases. Therefore it is not surprising that most systemic pathophysiological processes result in common acute physiological disturbances. Consequently severity of illness can be assessed from a limited number of vital sign and biochemical observations. However it is not so clear what the magnitude of a response should be for a given insult. Therefore severity of illness for most conditions has been traditionally measured by the magnitude of physiological response rather than size of insult. The physiological response is further confounded by:

- Natural variability between patients
- Variable physiological reserve between patients
- Non-linear organ dysfunction in response to an insult, for example both the liver and kidney only manifest biochemical abnormality when a significant proportion of organ mass is malfunctioning
- Poor understanding of relative equivalence of degrees of malfunction between organs, e.g. what degree of jaundice is equivalent to a tachycardia 130 beats/min as an objective measure of severity of illness?
- Impact of organ support on physiological measurements, e.g. inotropes

Some scoring systems such as Mortality Probability Model (MPM II<sub>0</sub>) and SAPS 3 estimate severity of illness on or near admission to intensive care in order to avoid the confounding effect of supportive therapy.

#### PRIMARY PATHOLOGICAL PROCESS

The primary pathology leading to intensive care admission has a significant influence on prognosis. Therefore,

for a given degree of acute physiological disturbance, the most serious primary pathologies or underlying conditions are likely to have the worst predicted outcomes. For example, similar degrees of respiratory decompensation in an asthmatic and a patient with haematological malignancy are likely to lead to different outcomes. Furthermore the potential reversibility of a primary pathological process, whether spontaneous or through specific treatment, also greatly influences outcome, e.g. patients with diabetic ketoacidosis can be extremely unwell but insulin and volume therapy can rapidly reverse the physiological disturbance.

Both APACHE and the most recent SAPS systems include diagnostic categories with different weightings which improve the precision of estimated risk of hospital death calculations.

#### PHYSIOLOGICAL RESERVE, AGE AND COMORBIDITY

Physiological reserve is a surrogate term which broadly combines age and health status prior to critical illness. Age may be associated with diminishing physiological capacity but not in a predictable fashion.

- Chronological age alone is not a very strong influence on outcome.
- Biological age is a vague term usually used to imply physiological reserve below that expected for a patient's chronological age. Biological age greater than chronological age is common in patients who smoke heavily, abuse alcohol or who have insidious systemic diseases such as diabetes and hypertension; these patients typically have reduced reserve of one or more organs.

Chronic health states such as immunosuppression, cirrhosis, cancer and haematological malignancies all result in significant diminution of physiological reserve and may have an overwhelming influence on outcome. These conditions are commonly included in any assessment of critical illness.

#### SOURCE OF ADMISSION AND MODE OF PRESENTATION

Patients arriving in intensive care either come as an emergency or for a variety of reasons come following elective surgery. There are a very small number of patients who come to intensive care for elective medical reasons. By its very nature emergency admission implies that patients are likely to be unstable and that the acute physiological disturbances are in the process of being managed. Most scoring systems quantifying risk of death include an adjustment for emergency admission. It has become widely recognised that the source of admission also

influences the likely outcome. This might in part be because it increases the likelihood of patients having resistant organisms, such as those admitted from a health care environment.

#### ORGAN SUPPORT PRIOR TO ADMISSION

Many patients may arrive in ICU already ventilated, and receiving inotropes. Assessment of severity of illness at this stage when some physiological abnormalities have been corrected would make a physiologically based assessment underscore. Therefore either the assessment has to be adjusted to a time when no organ support was provided or some allowance has to be made for the support in the assessment. The approach to this has been varied; for example, SAPS 3 makes an adjustment for patients on inotropes, whereas MPM II allows measurements for the hour on either side of admission to be included.

#### UNIT ORGANISATION AND PROCESSES

Soon after the introduction of APACHE II it was recognised that units with effective teams, nursing and medical leadership, good communications and run by dedicated intensive care specialists potentially had better outcomes than those without such characteristics.<sup>19–21</sup>

#### OTHER FACTORS

Some factors have not been included in risk-adjusted models for prediction of mortality; these include socio-economic and genetic variables. However SAPS 3 has included a customisation adjustment to calibrate their model for patients in different parts of the world, possibly taking account of local factors and health care systems.

#### RISK-ADJUSTED EXPECTED OUTCOME AND ITS MEASUREMENT

Physiological disturbance, physiological reserve, pathological process and mode of presentation can be related to expected outcome by statistical methods. Common outcome measures for clinical trials are ICU mortality, or mortality at 28 days; however most models used for risk-adjusted mortality prediction are based on hospital mortality. Patient morbidity might also be considered nearly as important an endpoint as mortality, since many patients survive with serious functional impairment.<sup>22,23</sup> For socioeconomic reasons there would be a strong argument to consider 1-year survival and time to return to normal function or work as endpoints.<sup>24,25</sup> These latter measures however have been more closely related to chronic health status.

Hospital mortality is the most common outcome measure because it is frequent enough to act as a discriminator and is easy to define and document.

## PRINCIPLES OF SCORING SYSTEM DESIGN

### CHOICE OF INDEPENDENT PHYSIOLOGICAL VARIABLES AND THEIR TIMING

The designers of the original APACHE and SAPS systems chose variables which they felt would represent measures of acute illness. The chosen variables were based on expert opinion weighted equally on an arbitrary increasing linear scale, with the highest value given to the worst physiological value deviating from normal.<sup>26,27</sup> Pre-morbid conditions, age, emergency status and diagnostic details were also included in these early models and from these parameters a score and risk of hospital death probability could be calculated. Later upgrades to these systems, SAPS 2, APACHE III and the MPM,<sup>28</sup> used logistic regression analysis to determine the variables which should be included to explain the observed hospital mortality. Variables were no longer given equal importance but different weightings and a logistic regression equation were used to calculate a probability of hospital death. The more recent upgrades, APACHE IV and SAPS 3, have continued to use logistic regression techniques to identify variables that have an impact on hospital outcome.

The extent of physiological disturbance changes during critical illness. Scoring systems therefore needed to predetermine when the disturbance best reflected the severity of illness which additionally facilitated discrimination between likely survivors and non-survivors. Most systems are based on the worst physiological derangement for each parameter within the first 24 hours of ICU admission. However some systems, such as MPM II<sub>0</sub>, are based on values obtained 1 hour either side of admission; this is designed to avoid the bias that treatment might introduce on acute physiology values.<sup>29</sup>

### DEVELOPING A SCORING METHODOLOGY AND ITS VALIDATION

All the scoring systems have been based on a large database of critically ill patients, usually derived from at least one country and from several ICUs (Table 3.2). Typically, in the more recent upgrades of the common scoring systems, part of the database is used to develop a logistic regression equation with a dichotomous outcome – survival or death, while the rest of the database is used to test out the performance of the derived equation. The equation includes those variables which are statistically related to outcome. Each of these variables is given a weight within the equation. The regression equation can be tested, either against patients in the developmental dataset using special statistical techniques such as

**Table 3.2** Ability of scores to discriminate correctly between survivors and non-survivors when tested on similar casemixes. A value of 1 represents perfect prediction

Score	Area under ROC curve
APACHE II	0.85
APACHE III	0.90
SAPS 2	0.86
MPM II <sub>0</sub>	0.82
MPM II <sub>24</sub>	0.84
SAPS 3	0.84
APACHE IV	0.88

ROC, receiver operating characteristic; APACHE, Acute Physiology, Age and Chronic Health Evaluation; SAPS, Simplified Acute Physiology Score; MPM, Mortality Probability Model.

‘jack-knifing’ and ‘boot-strapping’ or against a new set of patients – the validation dataset – who were in the original database but not in the developmental dataset. The aim of validation is to demonstrate that the derived model from the database can be used not only to measure severity of illness but also to provide hospital outcome predictions.

Once a satisfactory equation has been developed it can be used to calculate a probability of death for an individual patient. Similarly an overall probability of death can be calculated for a group of patients; however, this methodology can not indicate which of the patients in the cohort is going to die. These models are not powerful enough to provide sufficiently accurate discrimination.

In a perfect model the aim would be that:

- Overall predicted and observed outcomes should be the same.
- Individual patients observed to die or survive have been predicted.

The performance of a mortality prediction model used on a cohort of patients other than the developmental set is usually judged by two functions: first, its ability to predict which patients will survive and which will die (discrimination) and second, how well a model correctly predicts the overall observed mortality (calibration). The appendix shows some commonly calculated measures for a scoring system.

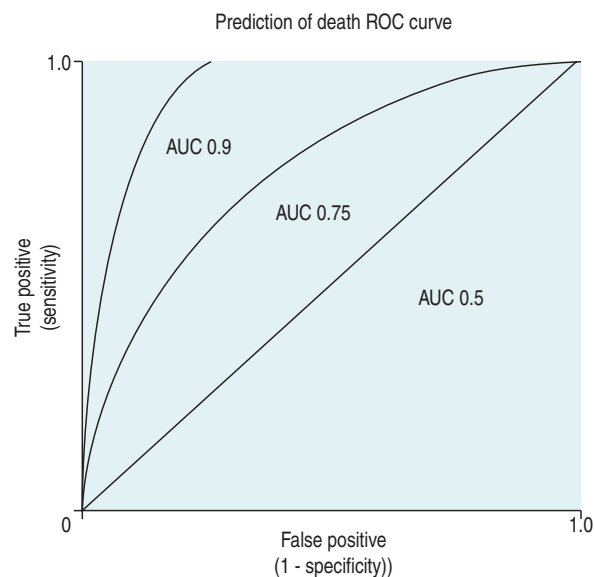

### DISCRIMINATION

The discriminating power of a model can be determined by defining a series of threshold probabilities of death such as 50, 70, 80% above which a patient is expected to die if their calculated risk of death exceeds these threshold values and then comparing the expected number of deaths with what was observed in those patients at the various probability cut-off points. For example, the APACHE II system revealed a misclassification rate (patients predicted to die who survived and

those predicted to survive who died) of 14.4, 15.2, 16.7 and 18.5% at 50, 70, 80 and 90% cut off points above which all patients with such predicted risks were expected to die. These figures indicate that the model predicted survivors and non-survivors best i.e., discriminated likely survivors from non-survivors when it was assumed that any patient with a risk of death greater than 50% would be a non-survivor.

A conventional approach to displaying discriminating ability is to plot sensitivity, true positive predictions on the  $y$ -axis against false-positive predictions ( $1 - \text{specificity}$ ) on the  $x$ -axis for several predicted mortality cut-off points, and producing a receiver operator characteristic curve (ROC) (Figure 3.1).

The ROC area under the curve (AUC) summarises the paired true-positive and false-positive rates at different cut-off points (Figure 3.1) and provides a curve which defines the overall discriminating ability of the model. A perfect model would show no false positives and would therefore follow the  $y$ -axis and has an area of 1, a model which is non-discriminating would have an AUC 0.5,

**Figure 3.1** A receiver operator curve (ROC) plots true-positive against false-positive rates for a series of cut-off points for risk of death. For example, a risk of death cut-off point of 10% would predict that all patients with a risk greater than 10% will die and all those below will survive. This would be compared with the observed rates in those patients. The prediction would be expected to be frequently wrong and would reflect itself in the calculation of true-positive and false-positive rates. These calculations would represent one point on the ROC curve. The exercise is repeated at different cut-off points, such as 15, 20, 25, 30, from which a curve can be constructed. The resulting area under the curve (AUC) reflects the ability of the model to predict survival correctly. This is a measure of discriminatory power. The best models have values greater than 0.85.

whereas models which are considered good would have AUC greater than 0.8. The AUC can therefore be used for comparing discriminating ability of severity of illness predictor models.

### CALIBRATION

A model with good calibration is one that for a given cohort predicts a similar percentage mortality as that observed. (Hosmer–Lemeshow goodness-of-fit C statistic compares the model with the patient group.)<sup>30</sup>

Observations with many models have revealed that, unless the casemix of the test patients is similar to that used to develop the model, the models may underperform due to poor calibration. This is particularly true when the testing is done for patients in different countries.<sup>12,16,31,32</sup>

## COMMONLY USED SCORING SYSTEMS

### GLASGOW COMA SCORE

Introduced in 1974 to quantify level of consciousness after the first 6 hours of head injury, it individually scores best eye opening, verbal and motor responsiveness, provides an overall scale between 3 (profound coma) and 15 (normal alert state). The Glasgow Coma Score (GCS) has been included in a number of general severity-of-illness scoring systems.

Its main characteristics are:

- Consistency between expert and non-expert observers and has been adopted worldwide.<sup>33,34</sup>
- Consistency has allowed head-injury management protocols to be based on the initial scale at presentation; decision-making is based on GCS trends.
- When combined with age it provides some assessment of prognosis.

The standard form of GCS is inapplicable to infants and children below the age of 5 years and has been modified to recognise that the expected normal verbal and motor responses must be related to the patient's age.<sup>35</sup>

### THERAPEUTIC INTERVENTION SCORING SYSTEM (TISS)

Introduced in 1974 with the aims of estimating severity of illness, the burden of work for ICU staff and nursing resource allocation,<sup>6</sup> it requires the daily collection of 76 listed items, primarily interventions or treatments, although a cut-down version has been suggested – TISS 28.<sup>36,37</sup>

Its main characteristics are:

- good indicator of nursing and medical work
- poor measure of severity of illness
- successfully used as a method of accountancy through allocation of average costs per point

### ACUTE PHYSIOLOGY AGE AND CHRONIC HEALTH EVALUATION (APACHE) SYSTEMS I–IV

In 1981 Knaus and colleagues described APACHE, a physiologically based classification system for measuring severity of illness in groups of critically ill patients. They suggested it could be used to control for casemix, compare outcomes, evaluate new therapies and study the utilisation of ICUs. APACHE II, a simplified version, was introduced in 1985<sup>27</sup> and, although superseded by APACHE III in 1991,<sup>38</sup> APACHE II has remained the most widely studied and extensive used severity-of-illness scoring system. APACHE IV was introduced in 2006 and, like APACHE, remains a proprietary system. Consequently, worldwide it is predominantly APACHE II rather than the later versions which is continued to be used for reporting severity of illness.

APACHE II was developed and validated on 5030 non-coronary artery bypass or burns patients admitted to ICUs in the USA.

It is the sum of three components:

1. an acute physiology score (APS)
2. a chronic health score based on defined premorbid states
3. a score based on the patient's age

The 12 variables of the APS and their relative weights were decided by expert opinion. These variables are collected in the first 24 hours after admission to intensive care and should represent the worst physiological values. The APACHE II score can be included in a logistic regression equation with a coefficient for one of 50 diagnostic categories representing the reason for admission and a factor for emergency surgery to provide a risk of death probability for an individual.

APACHE II functions best when the ICU patient cohort is similar to the original database used for its development and as expected, is less well calibrated when used for cohorts with limited diagnostic categories or in countries not represented in the developmental database. It has been noted that as critical care management and organisation improve, this older scoring system has tended to overestimate mortality predictions. Modifying old scoring systems does not readily correct the calibration problems, hence the need to develop upgraded systems from completely new databases.

#### MODIFICATIONS OF APACHE II

Bion *et al.*<sup>39</sup> and Chang *et al.*<sup>40</sup> separately were the first to explore the possibility of using APACHE II in a dynamic scoring system. The former used a modified APACHE II in the Sickness Score System, in which the day 1 score was compared with day 4 and risk of mortality was predicted. Chang *et al.*, on the other hand, used the product of daily APACHE II scores with a modified Organ Failure Score and calculated thresholds above which individual patient mortality could be predicted.<sup>40</sup>

#### APACHE III

APACHE III, based on a larger reference database, was introduced in 1991 and was designed:

- to improve prognostic estimates by re-evaluating the selection and weighting of physiological variables
- to examine how outcome is related to patient selection for ICU admission and its timing
- to clarify the distinction between using the APACHE scoring system to stratify by risk of mortality within particular patient groups and using it to make individual estimates of mortality

#### Characteristics of the new system

- The database is threefold larger (17 440 patients) from 40 US hospitals equally divided between developmental and validation groups.
- Exclusions included admission for less than 4 hours, age less than 16 years, burn injuries or patients admitted with chest pain.
- Coronary artery bypass patients were a separate group.
- Seventeen physiological variables and their weights were chosen through statistical analysis. There were 78 diagnostic categories.
- Treatment location immediately prior to ICU admission was included.
- A revised version of the GCS was used.
- Only those comorbidities which seem to affect the patient's immune status were taken into consideration
- Chronic disease and age contributed 15% to total mortality risk, the rest being acute physiology.

APACHE III represents an advance over APACHE II with improved discriminatory power (ROC 0.9 versus 0.85) and better calibration.<sup>38</sup>

Castella *et al.*<sup>41</sup> reported that, whereas APACHE II proved better calibrated results than SAPS and MPM I in a mixed-patient cohort of 14 745 from European and American ICUs, it failed to be as discriminating or as well calibrated as APACHE III.

APACHE III not only aimed to provide a calculated risk of death based on the worst first-day values but also if calculated on subsequent days gave an updated risk of death calculation. The coefficients for the regression equations are not in the public domain, and this has made independent assessment of the predictive aspect of the scoring system more difficult.

#### APACHE IV

It was the failure of customisation techniques with APACHE III to account for observations in subgroup analysis that indicated that a new model might be needed. Further the authors of APACHE IV revealed that when APACHE III in its modified form was applied to patients collected between 2002 and 2003, measures of calibration were poor.<sup>17</sup>

In 2006 there was consequently a further upgrade to the APACHE system based on a new database of 104

US ICUs in 45 hospitals. The selected hospitals had the APACHE III computerised data collection and analysis system already installed. The database, drawn from 131 618 admissions, analysed 110 558 patients, 60% of whom were randomly selected to make up the developmental dataset. The analysed patients excluded patients admitted for less than 4 hours, patients with burns, those < 16 years old and those who had received organ transplants other than kidney or liver. In addition patients in hospital for more than a year or who had no APS on the first day were excluded. Only first admissions were counted and those admitted from another ICU were excluded. The statistical and modelling techniques included cubic regression splines which allow a non-linear relationship between variable and outcome. This technique was applied to age, acute physiology and prior length of stay.

#### Variables included in APACHE IV

- Age
- Retained variables and weights of APACHE III and worst value collected on day 1
- Chronic health status
- 116 diagnostic categories for reason for admission
- Hospital length of stay and location prior to admission
- Emergency surgery status
- Ability to determine GCS
- Mechanical ventilation
- $PaO_2/FiO_2$  ratio
- Thrombolytic therapy for acute myocardial infarction

A different series of variables was used to develop a model for coronary artery bypass graft patients.

The AUC ROC (see Table 3.2) derived from the model used on a validation dataset was 0.88, indicating very good discrimination.

The APACHE IV mortality prediction model (Table 3.3) is in the public domain and can be found at [www.criticaloutcomes.cerner.com](http://www.criticaloutcomes.cerner.com).

The APACHE IV system has not been tested outside the USA and therefore may not be appropriately calibrated. Indeed, this may also be the case within the USA, given the selected units used for the database.<sup>42</sup>

**Table 3.3** The relative contribution of predictor variables (%) for hospital mortality in APACHE IV

Acute physiology	65.5
Diagnosis	16.5
Age	9.4
Chronic health	5.0
Admission source and previous length of stay	2.9
Mechanical ventilation	0.6

APACHE, Acute Physiology, Age and Chronic Health Evaluation.

#### SIMPLIFIED ACUTE PHYSIOLOGY SCORE (SAPS 1–3)

The SAPS was originally based on data derived from French ICUs, based almost entirely on acute physiological variables.<sup>26</sup> The 14 physiological variables chosen were based on expert opinion and the points ascribed to deviation of these variables from normal were arbitrary. Initially the score was not related to an equation for predicting probability of death, although later this was possible. Unlike APACHE II, this system did not include a diagnostic category or chronic health status as part of the estimate of severity of illness.

In 1993 SAPS 2 was introduced and this was based on European and North American patients<sup>43</sup> The database contained 13 152 patients divided 65% and 35% between developmental and validation samples. Patients under 18 years, burns patients, coronary care and post cardiac surgery patients were excluded.

The weightings given to physiological derangements were derived from logistic regression analysis. This included 12 physiological variables and specific chronic health conditions such as the presence of acquired immunodeficiency syndrome (AIDS), haematological malignancies, cirrhosis and metastasis. Like SAPS, there was no requirement for inclusion of diagnostic groups to calculate probability of hospital mortality. The probability for hospital death could be readily calculated from a logistic regression equation based on APS and chronic health weightings. In the validation sample the area under the ROC curve was 0.86. It had equivalent calibration and discrimination to the APACHE III and MPM II systems. It is the most commonly used scoring system in Europe.

#### SAPS 3

SAPS 3 was introduced in 2005<sup>15,16</sup> and developed from a database of 16 784 patients from 303 ICUs from around the world, including South and Central America. The model used multilevel logistic regression equations based on 20 variables.

The variables were separated by the authors into those which were related to the period prior to admission, those concerning the admission itself and the acute physiological derangement (Table 3.4). These variables allow calculation of a SAPS 3 score which can be used to derive a risk of death from a logistic regression equation. Discrimination was good, with ROC AUC 0.848; however, the calibration varied depending on the geographical area tested. The best fits for the general SAPS 3 risk adjustment model were for northern European patients whereas the worst was for Central and South America, reflecting the number of patients used in the developmental dataset to derive the overall model. However the model can be customised with alternative equations to improve calibration for different regions of the world, and the authors suggest that customisation in future may allow within-country models.

Table 3.4 Factors considered in SAPS 3

Patient characteristics before admission	Circumstances surrounding admission	Acute physiological changes within 1 hour before and after admission
Age	Planned or unplanned	GCS
Comorbidities	Reason for admission (diagnostic group)	Bilirubin
Length of stay before ICU admission	Medical or surgical	Temperature
Hospital location before admission	Anatomical site of surgery	Creatinine
Vasoactive agents before admission	Acute infection at time of surgery	Leukocytes
		pH
		Systolic blood pressure
		Oxygenation and mechanical ventilation

SAPS, Simplified Acute Physiology Score; GCS, Glasgow Coma Score; ICU, intensive care unit.

The authors found that 50% of the explanatory power of the model for predicting hospital mortality was from patient characteristics prior to admission while circumstances surrounding admission and acute physiology parameters accounted for 22.5 and 27.5% respectively. Thus far experience with this model remains limited.

#### MORTALITY PREDICTION MODELS (MPM I AND II)

Introduced in 1985 to provide an evidence-based approach to constructing a scoring system,<sup>44</sup> the data were derived from a single US institution and included observations at the time of admission to ICU and within the first 24 hours. MPM I<sub>0</sub> was based on the absence or presence of some physiological and diagnostic features at the time of admission while a further prediction model, MPM I<sub>24</sub>, was based on variables reflecting the effects of treatment at the end of the first ICU day. Unlike APACHE and SAPS systems, it does not calculate a score but computes the hospital risk of death from the presence or absence of factors in a logistic regression equation.

MPM II is based on the same dataset as SAPS 2.<sup>28</sup> The system is a series of four models which provide an outcome prediction estimate for ICU patients at admission and at 24, 48 and 72 hours. In common with the early APACHE and SAPS systems the models excluded burns, coronary care and cardiac surgery patients. The models were derived by using logistic regression techniques to choose and weight the variables, with the additional criterion that variables had to be 'clinically plausible'.

MPM II<sub>0</sub> and MPMII<sub>24</sub> have similar discriminatory power to SAPS 2, with ROC and AUC of 0.82 and 0.84 respectively.

In a comparison between MPM II, SAPS 2 and APACHE III and the earlier versions of these systems, all the newer systems performed better than their respective older versions. However no system stood out as being superior to the others.<sup>41</sup>

#### POSSUM

In 1991 Copeland *et al.* introduced a scoring system in the UK as a tool for adjusting for the risk of mortality and morbidity.<sup>45</sup> Physiological and Operative Severity Score for the enumeration of Mortality and Morbidity (POSSUM) includes 12 acute physiological parameters divided into four grades measured at the time of surgery and variables related to the severity of surgery (Table 3.5).

The POSSUM system was originally designed to predict risk of death by 30 days based on a logistic regression formula. However in 1996 Whiteley *et al.* noted that the POSSUM system overpredicted risk of death, particularly in those with very low risk (10%), by sixfold.<sup>46</sup> Whiteley

Table 3.5 Factors assessed for POSSUM risk of death

Acute physiological variables at time of surgery	Variables related to operative severity
Age	Presence of malignancy
Cardiac signs and chest X-ray findings	Operative magnitude, e.g. minor, intermediate, major, major +
Respiratory signs and chest X-ray findings	Number of operations within 30 days
Systolic blood pressure	Blood loss per operation
Pulse rate	Peritoneal contamination
Glasgow Coma Score	Timing of operation, e.g. elective, emergency < 2 hours or < 24 hours
Urea	
Sodium	
Potassium	
Haemoglobin	
White cell count	
Electrocardiogram	

POSSUM, Physiological and Operative Severity Score for the enumeration of Mortality and Morbidity.

*et al.* proposed that the POSSUM system was modified using the same parameters but a different logistic regression equation predicting risk of hospital mortality. This modification was named the Portsmouth-POSSUM (P-POSSUM) based on where it was developed. The P-POSSUM equation is more commonly used.

There have since been more modifications of the POSSUM logistic regression equation to obtain better calibration for other forms of surgery, e.g. vascular surgery (V-POSSUM), and Colon cancer resection (Cr-POSSUM).

POSSUM cannot be used for patients who do not have surgery and because the equation includes operative detail it cannot be used as a tool to make decisions as to whether surgery is undertaken. However it has become a very useful audit tool for surgeons who needed a risk adjustment tool for comparing their relative performances.

### ORGAN FAILURE SCORES

These are simple prognostic values relating the number of failed organs and their duration to probability of mortality. The organ system failures (OSF) were defined for five organs in an all-or-nothing manner and the number of failures summed.<sup>47</sup> The outstanding observations were that:

- Single OSF lasting more than 1 day produced a hospital mortality rate of 40%.
- Two OSFs for more than 1 day (medical and surgical) increased rates to 60%.
- With three or more OSFs lasting more than 3 days, the mortality rate was 98%.
- Advanced chronologic age increased both the probability of developing OSF and the probability of death once OSF occurred.

Scores to take account of grades of dysfunction and supportive therapy have been proposed, including the multiple organ dysfunction score (MODS), which was based on specific descriptors in six organ systems (respiratory, renal, neurological, haematological, cardiovascular and hepatic). Progressive organ dysfunction was measured on a scale of 0–4; the intervals were statistically determined for each organ based on associated mortality. The summed score (maximum 24) on the first-day score was correlated with mortality in a graduated fashion.<sup>48</sup>

ICU mortality was approximately:

- 25% at 9–12 points
- 50% at 13–16 points
- 75% at 17–20 points
- 100% at levels of > 20 points

Good discrimination was seen, with areas under the ROC curve of 0.936 in the development set and 0.928 in the validation set.

### SEQUENTIAL ORGAN FAILURE ASSESSMENT (SOFA)

This score was originally associated with sepsis. It takes into account six organs (brain, cardiovascular, coagulation, renal, hepatic, respiratory) and scores organ function from zero (normal) to 4 (extremely abnormal). Experts defined the parameter intervals.<sup>49</sup>

It was intended to provide the simplest daily description of organ dysfunction for use in clinical trials. It has the merit of including supportive therapy and, although increasing scores can be shown to be associated with increasing mortality, it was not designed for estimation of outcome probability. This simple method has become a popular method by which to track and describe patient changes in morbidity.

Logistic Organ, Dysfunction System (LODS) is an organ failure score that could be used for hospital outcome prediction.<sup>50</sup> Based on the patient cohort used to derive the SAPS 2 and MPM II systems, logistic regression was used on first-day data to propose an organ failure score. The LOD system identified 1–3 levels of organ dysfunction for six organ systems and between 1 and 5 LOD points were assigned to the levels of severity. The resulting LOD scores ranged from 0 to 22 points. Calibration and discrimination were good. LODS demonstrated that neurological, cardiovascular and renal dysfunction carried the most weight for predictive purposes followed by pulmonary and haematologic dysfunction, with hepatic dysfunction carrying the least weight. Unlike SOFA, the system takes into account the relative severity between organs and the degree of severity within an organ system by attributing different weights.

### SCORES FOR INJURY AND TRAUMA

This is a relatively homogeneous group for assessment of severity of illness. There are two principal methods:

1. Injury Severity Score (ISS) scores the extent of anatomical injury.<sup>51</sup> Based on the Abbreviated Injury Scale (AIS), which assigns a code and a value from 1 (minor) to 6 (un survivable) to six body regions, and incorporates a modification for blunt and penetrating injury,<sup>52</sup> ISS is calculated from the sum of the squares of the highest AIS score in each of the three most severely injured body regions. (The square of values transformation results in a relatively linear relationship with mortality and other measures of severity.) The highest score is 5 (6 is fatal) in each body region and consequently the highest ISS is 75 (3×25).
2. Major trauma is defined as an ISS greater than 16 and this is associated with a greater than 10% risk of mortality. The ISS is a purely anatomical system that ignores physiological derangements or chronic health status.
3. Trauma Score (TS) is a physiologically based triage tool for use in the field, based on systolic blood pressure, capillary refill, respiratory rate and chest expansion and GCS. It could be used with anatomical and age data.<sup>53</sup>

The Revised Trauma Score (RTS)<sup>54</sup> is based on disturbances in three variables: (1) GCS; (2) systolic blood pressure; and (3) respiratory rate. Each is coded between 1 and 4. The physiological disturbance was further modified by use of a coefficient to indicate a relative weighting for that organ.

The ISS and RTS individually had flaws as indicators of outcome, but they were successfully combined by Boyd *et al.* to provide the Trauma Injury Severity Score (TRISS) methodology for outcome prediction. TRISS also included the presence of penetrating injury and age in its methodology.<sup>51,54,55</sup>

It uses coefficients derived from the data of 30 000 injured patients, from which it calculates an estimated probability of survival for individual trauma victims. It also provides a comparative measure of quality of care by trauma centres, using expected and observed outcomes.

A Severity Characterisation of Trauma (ASCOT) was introduced to rectify perceived problems with TRISS.<sup>56</sup> There are more details on injuries in the same body region, more age subdivisions and the use of emergency room acute physiology details rather than field values. ASCOT predicts survival better than TRISS, particularly for blunt injury. Reluctance to use ASCOT derives from increased complexity for only a modest gain in predictive value.

#### APPLICATION OF SCORING SYSTEMS

Standardised mortality ratio (SMR) is the comparison of predicted with observed mortality rates. This is used as surrogate evidence for good quality of care and a value of 1 is considered normal, above 1 worse than normal, below 1 better than normal but:

- standard deviations for SMR were not defined, therefore whether a unit significantly deviates from normal is unquantifiable
- SMR should be considered in the context of casemix and calibration<sup>32</sup>
- ideally samples should be very large and of a similar casemix as the original development database

The introduction of scoring systems has brought some standardisation and a new language that allows clinicians to describe the physiological disturbance of their casemix relatively accurately.

Such descriptions have led to numerous potential uses, including:

- stratification of patients for clinical trials
- comparison of predicted and observed outcomes
- relating resource allocation to severity of illness at presentation
- predicting length of stay for a cohort<sup>57</sup>

Decision-making for an individual patient based on the predictions of scoring systems is widely considered an

inappropriate use because such systems are unable to discriminate patient outcome with certainty. The logistic regression equations only provide a probability for a dichotomous event, such as death or survival, and therefore they have no potential use as a guide to further treatment or limitation orders for an individual. When APACHE II was tested against an identical casemix to that from which it was derived and used as a predictor of outcome for individuals it at best had a misclassification rate of 15%.<sup>27</sup> The performance of these systems may be worse with different casemixes.<sup>58–60</sup>

Attempts to correct for this have included recalibrating the APACHE II system<sup>61</sup> and the use of neural networks. Neural networks use ongoing patient data input to modify predictor equations continually. This approach theoretically gets closer and closer to predicting outcome for a specific casemix but it never reaches certainty.

While scoring systems might facilitate recognition of hopelessly ill patients it is likely that patient management decisions will remain based on clinical judgement for the foreseeable future.

There are good reasons for not using severity score predictions to guide management but they can be used as a valid benchmark method for stratifying comparable patient groups for clinical studies. This stratification is best based on estimates of risk of death.

Unfortunately, unless there is a strict protocol for the collection of data across critical care units comparison of performance based on scoring systems can be very misleading particularly if further confounded by casemix differences which alter calibration. Clinical trials can control the quality of their data more easily than is achieved on a day-to-day basis in individual ICUs. Consequently comparison of risk of death and outcome between two patient groups might be more robust.

In order for between-ICU comparison to be representative of efficacy of care, some fundamental assumptions must be made:

- All pre ICU care is identical between hospitals and has no differential impact on ICU or hospital outcome.
- Patients in the different hospitals are drawn from the same population (casemix).
- The samples are large enough to obey the mathematical principles of logistic regression calculations.
- Data acquisition is both flawless with respect to the rules of the scoring system and consistent between units.

Although SMR may be misleading for between-unit comparisons as a measure of performance, it may remain a useful tool for within-ICU comparisons where it is assumed many of the confounding factors are the same. In such circumstances changes in ICU process or improvements prior to ICU admission while casemix remains the same may be revealed through improvements in SMR.

In the context of patient management scoring systems can be used as guidelines. A simple example is the use of a

GCS cut-off value below or equal to 8 for elective intubation and ventilation of a patient before transfer from the scene of injury. This has contributed to a reduction in secondary brain injury.

More controversial is the recent protocol for administration of recombinant human activated protein C, which suggests that it is only administered to patients with APACHE II scores > 25.<sup>62</sup>

**APPENDIX**

Calculations of sensitivity and specificity for a prediction model for mortality

	Observed deaths	Observed survivors	Total
Predicted deaths	450	100	550
Predicted survivors	40	410	450
Total	490	510	1000

Sensitivity: the proportion of observed deaths that are predicted correctly (i.e. true positive).

Sensitivity =  $450/490 = 0.92$ .

Specificity: the proportion of survivors that are predicted to survive (i.e. true negative).

Specificity =  $410/510 = 0.80$ .

1 – specificity is proportion of survivors that were predicted to be dead (i.e. false positive).

Positive predictive value: observed deaths as a percentage of predicted deaths =  $450/550 = 0.82$ .

Negative predictive value: observed survivors as a percentage of those predicted to survive =  $410/450 = 0.91$ .

Misclassification rate is the proportion of patients wrongly predicted:  $(100 + 40)/1000 = 14\%$ .

Correct classification rate is the proportion of patients correctly predicted =  $450 + 410/1000 = 86\%$ .

False-positive rate =  $100\% - \text{positive predictive value} = 18\%$ .

False-negative value =  $100\% - \text{negative predictive value} = 9\%$ .

Prevalence of death:  $490/1000 = 49\%$ .

# Transport of the critically ill

Evan Everest and Blair Munford

All intensive care units (ICUs) are required to move critically ill patients for investigations or procedures that cannot be performed in the ICU. These patients have reduced or absent physiological reserves and even short trips can result in significant adverse events.<sup>1,2</sup> These events can be reduced by the use of trained personnel.<sup>3,4</sup>

In addition, ICU personnel are frequently involved in the stabilisation and transfer of critically ill patients into an ICU,<sup>5</sup> and some units may be involved in the transport of patients from the site of a prehospital incident, or between hospitals.<sup>6,7</sup> The interhospital transfer could be due to the increasing sophistication of critical care facilities in tertiary hospitals compared with district or rural hospitals, different subspecialty capabilities, local bed shortages<sup>3</sup> or, in certain health systems, for insurance or financial reasons. In some cases, the complexity of these interhospital transfers can be further complicated by the need for rapid transport, or the distances involved. All patient movement is associated with an increase in mortality or morbidity, but with an integrated approach using high-level clinical personnel who have the correct equipment and undertake sufficient planning, adverse events can be reduced.<sup>3,4,6-8</sup> Regular ambulances or untrained hospital staff should not be expected to manage ICU patients. Compared with specialist transport teams, standard ambulances with junior doctor escorts are associated with more cases of hypotension, acidosis and death.<sup>9</sup>

The hospital of the future has been described as the critical care hub of a dispersed network of facilities linked by information systems and critical care transport services.<sup>10</sup> Critical care transport should be part of a regional intensive care network and adhere to promulgated minimum standards for transport of the critically ill.<sup>11,12</sup>

## INTERHOSPITAL TRANSPORT

The general principles of patient transport regarding equipment, patient monitoring and checking after movement are identical, whether intrahospital or interhospital. In interhospital transport the same problems are encountered but compounded by distance and the vehicular environment.

Patients are generally moved from the ICU for two reasons:

- diagnostic imaging that cannot be performed in the ICU, and
- for procedures, traditionally in the operating theatre, but increasingly for radiologically guided procedures including vascular embolisation, angioplasty, percutaneous drainage and stent insertion.

Moving an ICU patient is a high-risk procedure but with sufficient planning and preparation there should be little or no compromise to the patient's condition. Unfortunately, this is not always achieved, as there are often a number of distractions that will divert staff from monitoring the patient, or disconnection of infusions or ventilation. In up to 70% of ICU patient transports, adverse events occur, in which:

- one-third are equipment-related<sup>13</sup>
- acute deterioration of  $PaO_2/FiO_2$  ratio is common
- ventilator-associated pneumonia is significantly increased<sup>14,15</sup>

However management is changed in 40–50% of patients, thus justifying the risk. Sufficient notification will allow the assembly of equipment, monitoring and sufficient staff who are trained and familiar with the equipment and the patient. The more complex the patient, the more capable the team required. In unstable patients the minimum team should consist of a suitably trained doctor (e.g. one capable of reintubating a ventilated patient and able to manage any changes occurring in the patient's condition), the patient's nurse and two assistants to move the bed and help to lift the patient. For more stable, less complicated patients the patient's nurse and assistants may be sufficient.

## COMPUTED TOMOGRAPHY SCANNING

The most common diagnostic investigation necessitating transport is computed tomography (CT). On most occasions very little planning and preparation is required for what is almost a routine procedure. The exceptions are patients with head injuries, the administration of nasogastric contrast and the increased aspiration risk in patients with decreased gastric motility. Repeated CT scanning of

head-injury patients is common. In those patients with decreased cerebral compliance, movement and changes in body position or  $P_{aCO_2}$  can result in marked changes in intracranial pressure (ICP). Prior to transport,  $E_{tCO_2}$  should be measured on the transport monitor while the patient remains connected to the ICU ventilator. ICP changes caused by ventilator-induced variations in  $P_{aCO_2}$  when switching to the transport ventilator can be reduced by adjusting the minute volume to maintain a stable  $E_{tCO_2}$ . Adequate sedation will also decrease movement-induced rises in ICP. Ideally, the ICP should be measured on the transport monitor but this is often not possible. Whether a staff member remains in the scanner room or views the patient and monitor from outside depends on patient stability. Radiation exposure is small and is not considered a risk, and depends on where personnel stand in relation to the scanner's 'doughnut', from where the radiation is emitted.

### MAGNETIC RESONANCE IMAGING SCANNING

The hazards to a patient in magnetic resonance imaging (MRI) are greater due to limitations in the proximity of infusion pumps, ventilators and monitors to the magnet, and at times on catheters and pacemakers inserted in the patient. The need for the MRI should be balanced against the information likely to be gained. The three main problems with transport equipment are:

1. metal objects becoming projectiles when in close proximity to the magnet
2. equipment interfering with the MRI
3. the MRI causing failures in transport equipment

MRI units vary in policy, from prohibiting any equipment in the room to having minimal equipment that is placed as far away from the magnet as possible. The ability of ventilators and infusion pumps to function in the MRI scan room must have been tested prior to any patient being scanned, as some modern transport ventilators have failed in the MRI. Ideally, the equipment should be left outside the room with extensions added to the infusion and ventilator tubing, but this increases the risk of disconnection. There is one reported case of the external part of a pulmonary artery catheter burning through during an MRI scan,<sup>16</sup> probably caused by the development of radiofrequency eddy currents. Thermodilution pulmonary artery catheters are probably safe, but although patients with internal defibrillators and permanent pacemakers have been scanned with no consequence, deaths have been reported. Prior discussion with individual MRI units on how ICU patients can be scanned is required.

### INTERHOSPITAL TRANSPORT

#### ORGANISATIONAL ASPECTS

Provision of critical care transport services needs to be a part of regional ICU services. The staffing of critical care transport teams will depend on the workload, with

around 300 per year being the threshold for a specific transport roster, depending on transport duration and regulations affecting duty times. Other factors include regional demographics, resources and geography. A team from within that unit, or from another ICU, or an emergency department, or a stand-alone transport service may provide transport of patients to a particular ICU. The merits of each system have been summarised.<sup>17</sup> Whatever arrangement is chosen, staff should not be conscripts but selected from those interested in critical care transport, and should be appropriately trained. Use of junior inexperienced staff is associated with increases in preventable mortality and morbidity.<sup>18,19</sup> Rostering of teams needs to be appropriate for the workload and take into account the potential for significant overtime hours when urgent requests occur near shift changeovers. If personnel are also allocated to other clinical duties, they need to be readily relieved when required. Equipment should be pre-checked and the team should have a practised routine to enable prompt departure.

A coordination centre should be used in systems involving multiple requests and transport teams.

#### PERSONNEL

The aim of the transport team is at least to maintain but preferably to enhance the level of care. This requires transport teams to have diagnostic and procedural skills to provide the full complement of care for the full range of patients transported. Ideally, the personnel caring for the patient in transit should be equivalent to the 'front-line' clinical team at the destination, implying a physician-based team, although transport of well-stabilised patients by non-physician teams has been reported.<sup>20</sup>

The transport team should be a minimum of two people. For multiple patients a formula of  $n + 1$  personnel for  $n$  critical patients has been suggested.<sup>21</sup> Multidisciplinary teams of physicians, nurse and/or ambulance officers offer advantages of a wider range of skills and training than a team from any single profession. In certain circumstances, other specialised staff may need to be taken, for example a surgeon or obstetrician.<sup>6</sup> It is preferable and safer to add a specialist to the standard team because of the latter's familiarity with the practicalities of the transport environment. Other desirable attributes in staff include: good teamwork and communication skills; adaptability; reasonable body habitus and physical condition; and no significant visual or auditory impairment or susceptibility to motion sickness. Travel sickness medications such as hyoscine (scopolamine) are of limited value, needing to be taken up to 4 hours pretransport and possibly causing significant side-effects.<sup>22</sup>

Training should encompass:

- principles and practicalities of clinical care in transport
- vehicle familiarisation
- relevant communication, safety and emergency procedures

Staff should have:

- appropriate personal protective equipment
- light-weight fireproof overalls or other clothing
- uniforms for prehospital responses, which should be of high visibility and bear identification

### PATIENT SELECTION

The best utilisation of a critical care transport system is when it is activated for appropriate patients, which will depend on the levels of care available within the ambulance services. The need for critical care transport may be identified by:

- a diagnosis with the potential to deteriorate
- the requirement for physiological monitoring and acute interventions
- the continuation of treatment already instituted during transport

Both receiving hospitals and ambulance services need to be alert to possible cases where critical care transport is indicated, but not identified by the referring team. A mechanism that is highly sensitive and specific at identifying patients unsuitable for standard ambulance transport is required. Triage mechanisms and tables to aid in patient selection have been described.<sup>23,24</sup>

### COMMUNICATIONS

A systematic approach is necessary to ensure a smooth response when the need for transport of a critically ill patient is identified. A single toll-free telephone number with conference call capability is the ideal. Facsimile and teleradiology capabilities may also be of value. The one call for assistance should result in the provision of clinical advice if required, the dispatch of a transport team, and finding a bed in an appropriate hospital. Concise, simple clinical advice appropriate for the capabilities of the referring hospital by either the receiving hospital or the transport service is paramount. No matter how fast the transport team's response, without some interim care the patient with major airway, breathing or circulatory compromise will not survive.<sup>6,7</sup> Ongoing advice, including stabilisation and preparation of the patient for transport, may be required prior to the arrival of the transport team. The provision to referring hospitals of a checklist for patient management and preparation for transport may assist.

The transport team should communicate with the receiving hospital, especially where changes in the patient's condition change the time of arrival, posttransport management or destination within the hospital or to another centre. Cellular telephones have revolutionised communication in transit, but their use may not be possible in all circumstances. Radio communication between ground and air ambulances and relevant hospitals is a preferred back-up.

### EQUIPMENT

#### GENERAL CONSIDERATIONS

Minimum standards for supplies, equipment and monitoring for critical care transport have been developed.<sup>10,17</sup> Equipment selection is a compromise between providing for every conceivable scenario and being mobile. The aim should be to have a core set of equipment plus optional items for specific scenarios plus some back-up redundancy for vital supplies and equipment such as oxygen, airway devices and basic circulatory monitoring. A suggested equipment schedule is given in Table 4.1. Meticulous checking of equipment after each use and on a regular basis is essential.

**Table 4.1** Suggested equipment schedule for interhospital critical care transport

#### Respiratory equipment

##### Intubation kit

- Endotracheal tubes and connectors – adult and paediatric sizes
- Introducers, bougies, Magill forceps
- Laryngoscopes, blades, spare globes and batteries
- Ancillaries: cuff syringe and manometer, clip forceps, 'gooseneck' tubing, heat moisture exchanger/filter(s), securing ties, lubricant

##### Alternative airways:

- Simple: Guedel and nasopharyngeal
- Supraglottic: laryngeal masks and/or Combitube
- Infraglottic: cricothyrotomy kit and tubes
- Oxygen masks (including high-FiO<sub>2</sub> type), tubing, nebulisers

##### Suction equipment:

- Main suction system – usually vehicle-mounted
- Spare (portable) suction – hand, O<sub>2</sub> or battery-powered
- Suction tubing, handles, catheters and spare reservoir
- Self-inflating hand ventilator, with masks and positive end-expiratory pressure (PEEP) valve
- Portable ventilator with disconnect and overpressure alarms
- Ventilator circuit and spares
- Spirometer and cuff manometer
- Capnometer/capnograph.

##### Pleural drainage equipment:

- Intercostal catheters and cannulae
- Surgical insertion kit and sutures (see below)
- Heimlich-type valves and drainage bags
- Main oxygen system (usually vehicle-mounted) of adequate capacity with flowmeters and standard wall outlets
- Portable/reserve oxygen system with flowmeter and standard outlet

#### Circulatory equipment

- Defibrillator/monitor/external pacemaker, with leads, electrodes and pads
- Intravenous fluid administration equipment:
  - Range of fluids: isotonic crystalloid, dextrose, colloids
  - High-flow and metered-flow giving sets
  - Intravenous cannulae in range of sizes: peripheral and central/long lines

*Continued*

**Table 4.1** Suggested equipment schedule for interhospital critical care transport—*Continued*

Intravenous extension sets, three-way taps and needle-free injection system
Syringes, needles and drawing-up cannulae
Skin preparation wipes, intravenous dressings and BandAids
Pressure infusion bags (for arterial line also)
<b>Blood pressure-monitoring equipment:</b>
Arterial cannulae with arterial tubing and transducers
Invasive and non-invasive (automated) blood pressure monitors
Aneroid (non-mercury) sphygmomanometer and range of cuffs (preferably also compatible with non-invasive arterial blood pressure)
Pulse oximeter, with finger and multisite probes
Syringe/infusion pumps (minimum 2) and appropriate tubing
<b>Miscellaneous equipment</b>
Urinary catheters and drainage/measurement bag
Gastric tubes and drainage bag
Minor surgical kit (for intercostal catheter, central venous lines, cricothyrotomy, etc.):
Sterile instruments: scalpels, scissors, forceps, needle holders
Suture material and needles
Antiseptics, skin preparation packs and dressings
Sterile gloves (various sizes); drapes $\pm$ gowns
Cervical collars, spinal immobilisation kit, splints
Pneumatic antishock garment (military antishock trousers (MAST) suit)
Thermometer (non-mercury) and/or temperature probe/monitor
Reflective (space) blanket and thermal insulation drapes
Bandages, tapes, heavy-duty scissors (shears)
Gloves and eye protection
Sharps and contaminated waste receptacles
Pen and folder for paperwork
Torch $\pm$ head light
Drug/additive labels and marker pen
Nasal decongestant (for barotitis prophylaxis)
<b>Pharmacological agents</b>
<b>Central nervous system drugs:</b>
Narcotics $\pm$ non-narcotic analgesics
Anxiolytics/sedatives
Major tranquilisers
Anticonvulsants
Intravenous hypnotics/anaesthetic agents
Antiemetics
Local anaesthetics
<b>Cardiovascular drugs:</b>
Antiarrhythmics
Anticholinergics
Inotropes/vasoconstrictors
Nitrates
$\alpha$ - and $\beta$ -blockers; other hypotensives
<b>Electrolytes and renal agents:</b>
Sodium bicarbonate
Calcium (chloride)
Magnesium
Antibiotics
Oxytocics
Potassium

Loop diuretics
Osmotic diuretics
<b>Endocrine and metabolic agents:</b>
Glucose (concentrate) $\pm$ glucagon
Insulin
Steroids
<b>Other agents:</b>
Neuromuscular blockers: depolarising and non-depolarising
Anticholinesterases (neuromuscular block reversal)
Narcotic and benzodiazepine antagonists
Bronchodilators
Antihistamines
H <sub>2</sub> -blockers/proton pump inhibitors
Anticoagulants
Thrombolytics
Vitamin K
Tocolytics
Diluents (saline and sterile water)
<b>Additional/optional equipment</b>
Transvenous temporary pacing kit and pacemaker
Blood (usually O negative) and/or blood products
Additional infusion pumps and associated intravenous sets
Obstetrics kit
Additional paediatric equipment (depending on capability of basic kit)
Antivenene (polyvalent or specific)
Specific drugs or antagonists

Transport monitors, infusion pumps and ventilators must work outside the transport vehicle. This requires equipment to be battery-powered and readily portable. Although newer monitors and other devices have rechargeable batteries with improved endurance, problems can still occur. The equipment-checking process includes different charging regimes. Nickel cadmium (NiCad) batteries need to be fully discharged before recharging to decrease memory effect, which reduces endurance, whereas sealed lead-acid or lithium batteries perform best when continually charged between uses.<sup>25</sup>

Internal batteries should not be relied upon unless transport duration is less than half the estimated battery life. For longer trips, a supplementary power source from either an external battery pack or the transport vehicle should be available to reduce battery use or even charge the batteries. An external supply combined with a wiring harness to run and recharge internal batteries on all devices is preferable. Spare batteries are not ideal, as many devices are not amenable to rapid 'on-the-job' battery swaps without interruption of monitoring and therapy.

Portability can be addressed in two ways. Equipment can be vehicle-mounted but readily detachable to accompany the patient, either as individual devices or more conveniently as a modular unit.<sup>26</sup> Alternatively, a mobile intensive care module can be incorporated into the stretcher, either in the base<sup>27</sup> or as a 'stretcher bridge'

straddling the patient.<sup>28</sup> Such designs are now widely used and allow the patient and equipment to be assembled into one unit at the referral point; this reduces loading and unloading time, ventilator and other device disconnections, and the risk of leaving equipment behind. Minor disadvantages include the increase in weight (25–30 kg), with corresponding reduction in maximum patient weight, and slight top-heaviness of the stretcher/patient combination.

### MONITORING

Clinical observation by experienced personnel remains the mainstay of monitoring,<sup>10</sup> but some clinical assessments such as auscultation are impossible during transit. Hence monitoring by appropriate equipment should be at the same level or a higher level than what the patient receives in the stationary setting. Referring institutions should not allow patients to be transported by teams with inferior monitoring capability. Compact transport monitors offering electrocardiogram (ECG), *SpO<sub>2</sub>*, non-invasive and multichannel invasive pressures, capnography and temperature monitoring have largely superseded older techniques, such as systolic pressure estimation by palpation and mean arterial pressure monitoring via an aneroid interface and gauge. These older techniques can still be used for back-up, as can defibrillators for ECG, while small hand-held pulse oximeters and *EtCO<sub>2</sub>* detector are also available. Non-invasive blood pressure and pulse oximetry devices are susceptible to artefact<sup>29,30</sup> and the use of invasive arterial monitoring or shielding pulse oximetry probes may be required. Mercury-containing devices are unsuitable, especially in aircraft. For longer transports, or patients with major biochemical or respiratory disturbances, compact biochemical and blood gas analysers may be valuable.<sup>31</sup>

### VENTILATION AND RESPIRATORY SUPPORT

A mechanical ventilator should be used on all ventilated patients during transport. Manual ventilation occupies one team member fully and cannot reliably deliver constant tidal volumes and stable *EtCO<sub>2</sub>*.<sup>32</sup> Transport ventilators are a compromise between portability and features.

The characteristics of an ideal transport ventilator are outlined in Table 4.2. No currently available transport ventilator meets all of these, and different models are optimised for different scenarios, so selection of a transport ventilator should take into account likely clinical and operational requirements. Back-up manual ventilation equipment must be available. In some cases of severe respiratory disease, a standard ICU ventilator may be needed. This may require medical air and AC power, although newer hybrid ICU/transport ventilators can provide enhanced ventilation capability without supply of these.<sup>33</sup> Similar requirements will apply to transport of patients on extracorporeal membrane oxygenation.

The provision of continuous positive airways pressure (CPAP) in transport remains problematic. ‘Clapperboard’-type systems are economical on gas consumption, but being gravity-driven perform poorly during movement. Conventional CPAP systems have extremely high gas

**Table 4.2** Features of an ideal transport ventilator

- Small, light, robust and cheap
- Not dependent on external power source
- Easy to use and clean, with foolproof assembly
- Economical on gas consumption
- Suitable for patients from neonates to large adults
- *FiO<sub>2</sub>* continuously variable from ambient air to 100% oxygen
- Able to deliver positive end-expiratory pressure, continuous positive airways pressure, synchronised intermittent mandatory ventilation and pressure support
- Variable inspiratory-to-expiratory ratios
- Flow or pressure generator modes
- Integrated monitoring and alarm functions with audio and visual signals
- Altitude compensated

consumption, rendering them impractical except for short road transports. Electronically triggered CPAP is a feature of some newer transport ventilators; however, though they have been successfully used on occasions, poor performance with mask CPAP has been reported,<sup>34</sup> and some patients may need to be converted to synchronised intermittent mandatory ventilation or intermittent positive-pressure ventilation (IPPV) for transport.

Maintenance of humidification of inspired gases is important during transport. In most cases, heat and moisture exchangers should provide adequate protection for intubated patients.<sup>35</sup> In special circumstances, for example, in neonates and cystic fibrosis patients, it may be necessary to use active humidification.

A suction system and preferably a reserve are needed during all phases of transport. These may be Venturi systems, electrical-powered pumps or manual aspirators. Oxygen Venturi systems are lighter than electrical systems and outperform manual aspirators, but have high oxygen consumption, > 40 l/min.<sup>36</sup>

### INFUSIONS

Critically ill patients often have multiple drug infusions which need to be continued during transport. A reduction in pumps may be obtained by combining sedation infusions or by suspending some infusions for transport and giving them as intermittent boluses.

During the referral process it is important to ascertain the number of infusions running to ensure sufficient pumps are taken. Modern light-weight syringe drivers are preferable for most infusions but a volumetric pump is superior if an infusion of large volumes of fluid is required. Older ‘drop-counting’-type infusion pumps are susceptible to disruption by movement and ambient pressure change and should not be used. Infusion pressure bags should also be available to maintain intravenous flow rates, as only minimal elevation of fluid bags is possible in most transport vehicles.

### MISCELLANEOUS EQUIPMENT

Transcutaneous pacing is adequate in an emergency, or during very short transports, but in other circumstances elective

transvenous pacing should be instituted. Equipment to institute or maintain other specialised therapy en route should be carried if required. In some situations, such as with an intra-aortic balloon pump, the equipment may be bulky and can influence the selection of the transport vehicle.<sup>37</sup>

Heimlich or similar one-way flap valves for pleural drainage are essential, as underwater seal drainage systems are not suitable for transport, owing to the likelihood of tipping and/or syphoning. Equipment to maintain nasogastric, urinary and wound drainage is also required.

### MODE OF TRANSPORT

Three types of transport vehicle are commonly employed: road, aeroplane (fixed-wing), and helicopter (rotary-wing). Basic requirements for critical care transport vehicles are listed in Table 4.3. Ideally, dedicated vehicles for all transport modes should be used, but the workload may not justify this and often vehicles that can be readily converted for mobile ICU use are seconded as required. The mode of transport depends on distances involved between referring and receiving hospitals and transport team locations; it also depends on the urgency of the case, which is often influenced by the clinical capability of the referring centre. Guidelines for vehicle utilisation should be developed but should have some flexibility for special circumstances, e.g. workload, traffic congestion, weather. Features and limitations of different modes of transport are summarised in Table 4.4.

### ROAD TRANSPORT

The ground ambulance remains the most commonly used critical care vehicle. With patients for whom time is not critical and level of care in transit is more important than

**Table 4.3** Essential features of transport vehicles

- Readily available
- Adequate operational safety
- Capable of carrying at least one stretcher and mobile intensive care equipment set
- Safe seating for full medical team, including at head and side of patient
- Adequate space and patient access for observation and procedures
- Equipped with adequate supply of oxygen/other gases for duration of transport
- Fitted with medical power supply of appropriate voltage and current capacity
- Appropriate speed, coupled with comfortable ride, without undue exposure to accelerations in any axis
- Acceptable noise and vibration levels
- Adequate cabin lighting, ventilation and climate control
- Fitted with overhead intravenous hooks, and sharps/biohazard waste receptacles
- Straightforward embarkation and disembarkation of patient and team
- Fitted with appropriate radios and mobile telephone

speed, road transport over considerable distances is feasible and may be safer in some patient groups.<sup>38</sup>

### FIXED-WING TRANSPORT

Conventional aircraft are the most suitable for long-range transport. Their faster speed is offset by the secondary ambulance transport at both ends. Advantages over helicopters include pressurised cabins (in most models), decreased cabin noise compared with helicopters and the ability to fly in icing conditions.

### ROTARY-WING TRANSPORT

Helicopters remain the most controversial, high-profile and expensive vehicles which require significant internal adaptations by clinical teams to enable them to perform patient care. Smaller helicopters are relatively or totally unsuitable as air ambulances. Appropriate helicopters are versatile vehicles, with the ability to perform transport both inside and beyond their 50–30-km optimum range ‘doughnut’. Maximum value is obtained with a high workload, ensuring efficient clinical team utilisation, and between hospitals with on-site helipads to avoid secondary transport.

### SAFETY AND TRAINING

Transport by any mode involves risk to staff and patients, and also imposes limitations on the delivery of care. In the aeromedical environment unfamiliar personnel perform clinical tasks poorly,<sup>39</sup> so teams must be appropriately trained and equipped to function effectively and safely in each mode of transport. They need to be familiar with use of the various transport vehicles’ oxygen, suction, medical power, communications systems, and other equipment and stores. A senior member of their own professional group should train and accompany new personnel for several missions. Other specialist staff added to a team should receive a thorough safety brief and work under the direction of regular transport team members. Aeromedical crew training should encompass safety equipment, crash response, emergency egress and survival. Safety should be a foremost consideration in any transport. Activities that compromise road and air safety such as hazardous driving or flying below safe minima are not acceptable, and clinical teams must avoid attempting to coerce drivers or pilots to take risks. This has been recognised as a contributor to air ambulance accidents.<sup>40</sup>

### ALTITUDE AND TRANSPORT PHYSIOLOGY

All transport modes result in increased noise, vibration, turbulence and accelerations in various or all axes (see Table 4.4). Personnel need to be aware of altitude-related complications that can occur with air transport. Increasing altitude results in decreasing oxygen partial pressure in accordance with Dalton’s law; while gas volumes increase or where volume change is restricted, relative increases in pressure occur in accordance with Boyle’s law (Table 4.5). Good introductory<sup>41,42</sup> and more detailed<sup>43,44</sup> aviation physiology texts are available.

Table 4.4 Properties of transport vehicles

	Road	Helicopter	Fixed wing
Launch time	3–5 min	5–10 min (more if IFR)	30–60 min
Speed	10–120 km/h dependent on roads and traffic	120–150 knots (220–290 km/h), straight line	140–180 knots (piston) 230–270 knots (turboprop) 375–460 knots (jet)
Secondary transport	Not applicable	Sometimes	Inevitable
Effective range	0–100 km (longer if required)	50–300 km (longer or shorter in special cases)	200–2000 km
Noise	Low, except at high speed	Moderate to high (headsets required)	Low to moderate (cruise). Higher on take-off/landing
Vibrations	Variable with speed and road surface	Moderate in most phases (varies with rotor type)	Low in cruise, moderate or high on take-off/landing
Accelerations	Variable and sometimes unpredictable in all axes	Minimal and usually vertical only	Significant (fore/aft) on take-off and landing
Special features	Base vehicles readily available	Versatility; point-to-point capability	Cabin pressurisation and all-weather capability (most)
Acquisition cost	Lowest	High (US\$ 1–4.5 million new) depending on capabilities	Moderate (piston) to very high (jet)
Operating costs (per km)	Intermediate	Intermediate to high	Low to intermediate

IFR, international flight rules.

### OXYGENATION AND HYPOXIA

Critical patients who are already dependent on an increased  $F_{iO_2}$  will be compromised by reduction in atmospheric pressure. Further oxygen supplementation will be required to maintain arterial  $P_{aO_2}$ . Only in special or unexpected circumstances, for example, alpine helicopter operations or cabin decompression, would hypoxia be expected to affect the medical crew; however, they should be aware of the risk and be alert to symptoms. The manifestations of hypoxia are well described elsewhere.<sup>37–40</sup>

### GAS EXPANSION

Expansion of trapped gases can manifest in: (1) physiological air spaces; (2) pathological air spaces; and (3) air-containing equipment.

The first category includes the middle ear, nasal sinuses and the gastrointestinal tract. These manifestations can affect crew as well as patients; consequently staff with upper respiratory tract infections or gastrointestinal disturbances should not fly.

The second category includes pneumothoraces, emphysematous lung cysts or bullae, intraocular or intracranial air from open injuries, bowel obstruction or rupture and gas emboli. Such patients should be transported at the lowest possible cabin or ambient altitude, with close monitoring and extreme care, especially on the ascent phase. The effect of trapped gas expansion can be

reduced with denitrogenation by breathing 100%  $O_2$  before and during flight.

Air-containing equipment includes: endotracheal and tracheostomy tube cuffs; Sengstaken–Blakemore tubes; pulmonary artery catheter balloons; air splints, pneumatic antishock garments (military antishock trousers (MAST) suit); and pleural, gastric and some wound drainage bags. Endotracheal cuff pressures need to be adjusted during flight, or filled with water. Increases in tidal volume in pneumatically controlled ventilators can occur with altitude, necessitating setting changes.<sup>45</sup>

### CABIN PRESSURISATION

Most fixed-wing air ambulances have pressurised cabins, which decreases hypoxia and gas expansion. The pressurisation creates a cabin pressure equivalent to flying at a lower altitude, hence the term ‘cabin altitude’. The maximum pressure differential that can be generated depends on the aircraft model. Most turboprop air ambulances can provide around 350 mmHg (46.7 kPa) differential, or cabin altitude of 1000 m (3000 ft) while flying at 6500 m (20 000 ft). Once maximum differential has been achieved, lower cabin altitude can only be provided by lower flight, which may be relatively or absolutely contraindicated – for example, a slower more turbulent flight or beneath lowest safe altitude, respectively. The medical team should not request a lower cabin altitude than what

Table 4.5 Changes with altitude

Altitude (ft)	Pressure (mmHg)	Alveolar $P_{O_2}$		Gas space expansion	Standard temperature ( $^{\circ}C$ )	Notes
		(on air)	(100% $O_2$ )			
Sea level	760	103	663	–	15	15 $^{\circ}C$ is 'reference' average temperature – actual obviously varies
1000 (304.8 m)	733	98	636	13.6%	13	Minimum altitude above ground level for helicopter transports
2000 (609.6 m)	706	94	609	18%	11	Likely altitude for most (VFR) helicopter flights over sea-level terrain
3000 (914.4 m)	681	89	584	112%	9	Likely range of cabin altitude for standard flights in most turboprop air ambulance craft (e.g. Raytheon–Beech King Air series)
4000 (1219.2 m)	656	85	559	116%	7	
7000 (2133.6 m)	586	73	489	129%	1	Standard cabin altitude for airliners and most jet air ambulances (e.g. Lear 35)
10 000 (3048 m)	523	61	426	145%	25	Likely ceiling of helicopter operations and hypoxic threshold in normal individuals
15 000 (4572 m)	429	45	332	177	214.5	Threshold for hypoxic decompensation in non-acclimatised individuals
20 000 (6096 m)	349	34	252	1117	224.5	Likely upper range of cruise altitude for turboprop aircraft. Decompression at these altitudes causes rapid loss of consciousness and death without $O_2$
25 000 (7620 m)	282	30	185	1170	234	
40 000 (12 192 m)	141	10	61	1439	256	Cruise ceiling for airliners and jets. Limit for survivable decompression, even with 100% $O_2$ for flight crew

VFR, visual flight rules.

is required, with the final decision resting with the pilot. Failure of cabin pressurisation is rare, but if sudden can have dramatic consequences, and teams should be aware of procedures to follow.

#### OTHER CONSIDERATIONS

Temperature falls by  $2^{\circ}C$  for every 300 m (1000 ft) altitude increase. Water partial pressure also falls and is not corrected by cabin pressurisation. Respiratory and other exposed mucosa can become dehydrated and could eventually lead to systemic hypovolaemia. All intubated patients should have at least passive humidification. On prolonged journeys, staff may also be affected. Staff rostered for air transport should refrain from compressed-gas diving for at least 24 hours prior to the shift.<sup>46</sup>

#### PATIENT PREPARATION FOR TRANSPORT

The preparation phase for transport will depend on the patient's diagnosis and condition. If possible, the patient should be stable; efforts, which may include surgery, should be undertaken to obtain stability. The exception

would be a patient requiring time-critical intervention at the receiving hospital. These transports are riskier, but are likely to be less futile than attempting to stabilise an inevitably deteriorating patient. Prior to any transport all patients must have a secure airway, either self-maintained or intubated and ventilated, and intravenous access. Any external bleeding should be controlled. Urgent investigations (e.g. X-rays, arterial blood gases) should be obtained where indicated, and possible in the time available. The patient should be secured on the stretcher and connected to ventilators and monitoring commensurate to the degree of stability and time constraints. Infusions should be rationalised and sedation may need to be increased during the trip.

Intercostal drains, if present or placed, should be connected to Heimlich-type valves. If parenteral nutrition is discontinued, an appropriate dextrose infusion should be substituted, with interval blood glucose estimation.

Appropriate documentation, including a referral letter, results of investigations and hospital and ambulance observations, needs to accompany the patient. The team should ensure that any relevant legal requirements have

**Table 4.6** Suggested predeparture checklists

<b>A. Before leaving hospital</b>	
Patient identity and next of kin	Recorded
Consent for transport	Obtained and documented
Paperwork and X-rays	Collected
Drugs for transport	Present and sufficient
Emergency drugs/equipment	Available
Medical equipment	Collected and repacked
Monitors, ventilator and infusions	Connected and on
Tubes, lines, drains and catheters	Secured
Altitude request (if applicable)	Passed to pilot
Receiving unit	Contacted and updated
<b>B. In-vehicle and predeparture</b>	
Stretcher and patient restraints	Secured and checked
Oxygen supply	On and sufficient
Monitors, ventilator and infusions	Working and secure
Emergency drugs/equipment	Stowed and accessible
Other medical packs	Stowed
Intravenous fluids	Hung and running
Intravenous injection port	Accessible
Medical power	On and connected
Communications	Checked as applicable
Seatbelts	On and checked
Staff/patient headsets	On/checked (if applicable)

been complied with and, where possible, consent for transport obtained.<sup>47</sup> The final step prior to transport should be a series of checks, as listed in Table 4.6.

### PATIENT CARE DURING TRANSPORT

If the patient is adequately prepared this phase should be uneventful. Special vigilance should be employed in the initial stages of movement, as this is the most likely time for either physiological decompensation or technical problems such as disconnections to occur. Once in the transport vehicle, a further set of checks is advisable (see Table 4.6). Therapy, monitoring and documentation should continue during transport. Transported patients are vulnerable to hypothermia, especially if intubated and/or paralysed and/or receiving multiple infusions.<sup>2,48</sup> Active heating in transit may be possible using the vehicle heating, while passive heat conservation should be practised during loading and unloading. Transport crews should be restrained during transport. If a critical event occurs necessitating the crew leaving their seats, the driver or pilot should be informed.

Death in transport should be a rare occurrence.<sup>6,7</sup> If it does occur, distance and the expectations and location of relatives should be taken into account in making the decision whether or not to continue transport to the destination. Carriage of relatives remains a controversial issue. For conscious patients, especially children, the presence of family members may have a beneficial effect. For

unconscious patients it is less clear and needs to be balanced against space constraints in the mobile ICU vehicle, and the potential reaction of relatives in case of a critical event. Transport services should have policies in place both for carriage of relatives and for death in transit.

### QUALITY ASSURANCE IN EDUCATION AND RESEARCH

Critical care transport is a recent development where accepted standards and guidelines are still evolving.<sup>49</sup> This means there is still considerable likelihood of problems, errors and critical incidents, with corresponding scope for research and quality improvement. This requires good clinical and operational data collection and patient outcomes. The process should be sensitive to the existence of system errors as well as individual patient, equipment or staff incidents. Preliminary results from the use of a critical incident monitoring system have been reported.<sup>13</sup> Users of the service must be informed of recommendations and system changes resulting from this process. Innovation and research by staff involved in this area should be encouraged.

### SPECIAL TRANSPORT SITUATIONS

#### PERINATAL TRANSPORT

This encompasses both in utero and extrauterine transport of the neonate. Specialised neonatal teams normally perform neonatal transport.<sup>50</sup> Alternatively, part or all of the regular transport team may accompany specialist neonatal personnel. Neonatal transport stretchers are bulky and heavy, and require a vehicular power output of up to 250 W for the incubator and active humidifier as well as monitors, ventilator and infusion pumps. They also require a supply of medical air to allow precise regulation of  $F_{iO_2}$ .<sup>51</sup> Transport of the pregnant patient carries the risk of precipitating labour, and in rare cases, delivery in transit.<sup>52</sup> This is suboptimal, especially where the baby is premature or otherwise at risk. Where labour cannot be suppressed, consideration should be given to delivery at the referring hospital, with subsequent neonatal and maternal transport.

#### TRANSPORT OF DIVING-INJURY PATIENTS

Patients with decompression sickness or arterial gas embolus require expeditious transport to a recompression facility. This must be balanced against the risk of even small decreases in ambient pressure; even a 10-m (30-ft) increase in altitude can exacerbate pathogenesis.<sup>42</sup> Divers with other problems such as marine animal envenomation or other medical conditions will still have increased total body nitrogen stores and can be at risk of developing evolved gas disorders during air transport. The use of transportable hyperbaric chambers has been reported<sup>53</sup> but their use severely compromises speed of response, and therapy possible in transit. Transport at or very near sea-level cabin pressure on 100% oxygen is the usual procedure.

### INTERNATIONAL AND LONG-DISTANCE TRANSPORTS

International transport of critically ill patients is becoming increasingly common. There are often complex medical, social and economic factors for returning patients to their own medical system. These must be balanced against the immigration, visa and logistic requirements, and medical problems of ultralong-distance transport.<sup>54</sup> A physician-based team is less likely to have problems relating to drug carriage and status compared with a paramedical team. Logistic problems include carriage of sufficient supplies, and clinical staff to work shifts for prolonged transports. Pressure may be exerted to utilise cheaper regular passenger transport services instead of much more expensive air ambulances. Most international airlines will accept a stable seated patient, but there is considerable variation among airlines willing to carry stretcher patients and associated equipment. Such transports require considerable planning to arrange stretcher fitment and sufficient supplies of oxygen and electric power. A separate oxygen system for critical care transports is required as the aircraft's emergency oxygen system is not permitted for patient care and the oxygen systems for in-flight use by passengers with medical conditions can only deliver up to 4 l/min.<sup>50</sup> Airline engineering clearance of medical equipment is often required. Aircraft power needs to be negotiated or sufficient batteries carried. An air ambulance may be indicated for cases that are urgent, infective or require low cabin altitude, whereas stable post myocardial patients can be safely transported in commercial aircraft with appropriate escorts.<sup>55</sup>

### CRITICAL CARE SCENE RESPONSES

Critical care teams offer a wide range of measures to complement standard prehospital providers, especially for major trauma, including: sedative/relaxant-assisted intubation; cricothyrotomy; tube thoracostomy; intravenous cutdown or central line insertion; and blood administration, as well as triage to an appropriate hospital.<sup>56</sup> These teams are only useful for trapped patients in the urban setting,<sup>57</sup> but combined with helicopter transport can improve outcomes in rural patients with blunt trauma.<sup>56,58,59</sup> In these situations the team should include an experienced prehospital provider. With appropriate activation the team may reach the patient at the scene or supplement management at the local hospital.

Critical care teams may also be of value in disaster situations.<sup>60</sup> Disaster medicine involves a change in emphasis to performing a small number of basic life-saving procedures on a large number of patients. Personnel with transport/prehospital experience are likely to be better trained and equipped to work at disaster scenes than traditional hospital disaster teams.<sup>61</sup> The order of priority remains the same as traditional critical care transport: triage, treatment and then transport.

# Physiotherapy in intensive care

Fiona H Moffat and Mandy O Jones

Historically, physiotherapy in the intensive care unit (ICU) was confined to the treatment of respiratory problems performed routinely on all patients. Evidence-based practice has demonstrated that there is no longer a place for routine physiotherapy treatment in ICU.<sup>1</sup> Physiotherapeutic intervention is based on clinical reasoning following the identification of physiotherapy-amenable problems, which are elucidated from a thorough systematic assessment.

There is still some debate about the precise role of the physiotherapist within ICU, which may vary,<sup>2</sup> but the main features include:

- optimisation of cardiopulmonary function
- assistance in the weaning process utilising ventilatory support and oxygen therapy
- instigation of an early rehabilitation/mobilisation programme to assist in preventing the consequences of enforced immobility
- advice on positioning to protect joints and to minimise potential muscle, soft-tissue shortening and nerve damage
- optimisation of body position to effect muscle tone in the brain-injured patient
- optimisation of voluntary movement to promote functional independence and improve exercise tolerance
- management of presenting musculoskeletal pathology
- advice and education of family and carers
- liaison with medical and nursing staff on the continuation and monitoring of ongoing physiotherapy devised care plans

## CARDIOPULMONARY PHYSIOTHERAPY

### TREATMENT MODALITIES TO OPTIMISE CARDIOPULMONARY FUNCTION

Patients who are critically ill may present with impaired cardiopulmonary physiology secondary to both the underlying pathology and the therapeutic interventions employed to treat them. In their approach to any

individual patient, physiotherapists may use specific treatment techniques targeted at improving ventilation/perfusion ( $V/Q$ ) disturbances, increasing lung volumes, reducing the work of breathing and removing pulmonary secretions. Physiotherapy treatment modalities may differ depending on the presence of an endotracheal tube, although patient participation with treatment is encouraged and promoted at the earliest point during intubation. Each intervention is rarely used in isolation, but as part of an effective treatment plan. Some physiotherapeutic techniques may have short-lived beneficial effects on pulmonary function, and some have no clear evidence to validate their effectiveness (Table 5.1).

#### MANUAL HYPERINFLATION

In this technique a self-inflating circuit is used to deliver a volume of gas 50% greater than tidal volume ( $V_T$ ) via an endotracheal or tracheostomy tube. An augmented  $V_T$  may recruit atelectatic lung secondary to reduced airflow resistance and enhanced interdependence via the collateral channels of ventilation.<sup>3</sup> Bronchial secretions may be mobilised by the increased expiratory flow rate and/or stimulation of a cough.<sup>4</sup> However, ventilator hyperinflation, the delivery of an augmented  $V_T$  via the ventilator, has been shown to be as effective in the removal of secretions and maintenance of static lung compliance as conventional manual hyperinflation (MHI).<sup>5</sup> This may also avoid cardiopulmonary instability associated with ventilator disconnection and loss of positive end-expiratory pressure (PEEP). In an emergency situation an Ambu-bag and facemask can be used to perform MHI in the self-ventilating patient. However, an alternative technique such as intermittent positive-pressure breathing (IPPB) should be considered when an augmented  $V_T$  is required during a therapeutic intervention (Table 5.2).

#### RECRUITMENT MANOEUVRES

Recruitment manoeuvres may be employed to reverse hypoxaemia in patients with acute lung injury (ALI)/acute respiratory distress syndrome (ARDS). A recruitment manoeuvre involves a transient increase in transpulmonary

**Table 5.1** Treatment modalities to optimise cardiopulmonary function

Invasively ventilated patients	Non-invasive/self-ventilating patients
Manual hyperinflation (MHI)	Active cycle of breathing technique (ACBT)
Suction	Manual techniques
Manual techniques	Positioning
Positioning	Intermittent positive-pressure breathing (IPPB)
Mobilization/rehabilitation	Continuous positive airways pressure (CPAP)
	Non-invasive ventilation (NIV)
	Nasopharyngeal/oral suction
	Positive expiratory pressure (PEP) mask, flutter valve
	Mobilization/rehabilitation

**Table 5.2** Potential advantages and complications of manual hyperinflation**Potential advantages**

Reversal of acute lobar atelectasis<sup>3</sup>  
 Alveolar recruitment via channels of collateral ventilation<sup>3</sup>  
 Improvement in arterial oxygenation  
 Mobilisation of secretions and contents of aspiration<sup>5</sup>  
 Improved static lung compliance<sup>5</sup>  
 Effectiveness may be increased when combined with appropriate positioning and manual techniques<sup>1</sup>

**Potential complications**

Absolute contraindications include undrained pneumothorax and unexplained haemoptysis  
 Cardiovascular and haemodynamic instability<sup>6</sup>  
 Loss of PEEP, inducing hypoxia and potential lung damage. This can be minimised by incorporating a PEEP valve into the circuit of a 'PEEP-dependent' patient  
 Risk of volutrauma, barotrauma and pneumothorax,<sup>7</sup> which can be reduced by including a manometer in the circuit  
 Risk of increased intracranial pressure  
 Increased patient stress and anxiety

PEEP, positive end-expiratory pressure.

pressure in an attempt to reinflate and maintain atelectatic lung units.<sup>8</sup> No standard approach exists; however, common options include: the application of incremental levels of continuous positive airways pressure (CPAP) with no tidal excursion; incremental increases in PEEP with additional  $V_T$ ; and the application of intermittent larger 'sigh' breaths. In randomised studies, although recruitment manoeuvres may transiently improve oxygenation, there is as yet no proven outcome benefit.<sup>9</sup>

**SUCTION**

Suction is used to clear secretions from central airways when a cough reflex is impaired or absent. A suction

**Table 5.3** Potential advantages and complications of suction**Potential advantages**

Stimulation of a cough when reflex is impaired by mechanical stimulation of the larynx, trachea or large bronchi  
 Removal of secretions from central airways when cough is ineffective or absent

**Potential complications**

Tracheal suction is an invasive procedure and should only be undertaken when there is a clear indication  
 Absolute contraindications to suctioning are unexplained haemoptysis, severe coagulopathies, severe bronchospasm, laryngeal stridor, base-of-skull fracture and a compromised cardiovascular system  
 Hypoxaemia can be induced secondary to suctioning. This can be limited by pre- and postoxygenation  
 Cardiac arrhythmias may be more common in the presence of hypoxia  
 Tracheal stimulation may produce increased sympathetic nervous system activity or a vasovagal reflex producing cardiac arrhythmias and hypotension

catheter is passed via an endotracheal or tracheostomy tube or via a nasal/oral airway to the carina, and this may stimulate a cough in a non-paralysed patient (Table 5.3). The catheter is pulled back 1 cm before suction is applied on withdrawal. The suction catheter diameter should not be greater than 50% of the diameter of the airway through which it is inserted as large negative pressure can be generated intrathoracically without air entrainment. The use of suction following effective MHI optimises removal of secretions.<sup>10</sup> Instillation of normal saline prior to suctioning remains controversial; however, it may stimulate a cough, maximising secretion mobilisation and clearance.

**MANUAL TECHNIQUES****CHEST SHAKING AND VIBRATIONS**

Shaking and vibrations are oscillatory movements of large and small amplitude performed during expiration, and are thought to increase expiratory flow rate, aiding mucociliary clearance.<sup>11</sup> These techniques are believed to be more effective when performed at high lung volumes.

**CHEST WALL COMPRESSION**

Compression of the chest wall can be used to augment an expiratory manoeuvre such as a 'huff' (see section on active cycle of breathing technique (ACBT), below) or a cough by providing tactile stimulation, or wound support.

**CHEST CLAPPING/PERCUSSION**

Chest clapping is a rhythmical percussion applied over specific areas of the chest. It may mobilise secretions secondary to the transmission of mechanical oscillations through the chest wall. However, there is little evidence to support this claim.

### NEUROPHYSIOLOGICAL FACILITATION (NPF) OF RESPIRATION

NPF of respiration is a set of techniques designed for the treatment of the neurologically impaired adult. Manual externally applied stimuli to the thorax, abdomen and mouth can be used to stimulate increased  $V_T$ , a cough reflex, augmented contraction of the abdominal muscles or an increased conscious level.<sup>12,13</sup>

### POSITIONING

A simple change of position can have a profound effect on cardiopulmonary physiology<sup>14,15</sup> (Table 5.4). As such, positioning is commonly utilised to achieve several different goals: drainage of secretions using gravity-assisted positioning (GAP), reduction of the work of breathing/breathlessness or to optimise  $V/Q$  matching.

### GRAVITY-ASSISTED POSITIONING

GAP facilitates the removal of excess bronchial secretions by positioning a specific bronchopulmonary segment perpendicular to gravity (Table 5.5). This technique is not used in isolation but in conjunction with augmented  $V_T$ , via the ventilator, MHI or ACBT in a spontaneously breathing patient. An individual position exists for each bronchopulmonary segment based on the anatomy of the bronchial tree;<sup>16</sup> however, these may need modification in the ICU setting.

### REDUCTION OF THE WORK OF BREATHING

A reduction in the work of breathing/breathlessness can be achieved by putting a patient in a position that optimises the

**Table 5.4** Potential advantages and complications of mobilisation<sup>14</sup>

Potential advantages	
Positioning supine to upright	Mobilisation
↑ Lung volumes	↑ Ventilation
↑ Lung compliance	↑ $V/Q$ matching
↓ Airway closure	↑ Recruitment of lung units
↑ $Pa_{O_2}$	↑ Surfactant production/distribution
↓ Work of breathing	↑ Mobilisation of secretions
↑ Mobilisation of secretions	↑ Cardiopulmonary fitness and exercise capacity
Potential complications	
Cardiovascular/neurological/haematological instability	
Increased oxygen/ventilatory requirement	

(Adapted from Dean E: The effects of positioning and mobilization on oxygen transport. In: Pryor JA, Webber BA (eds) *Physiotherapy for Respiratory and Cardiac Problems*, 2nd edn. Edinburgh: Churchill Livingstone; 1998: 125.)

**Table 5.5** Potential advantages and complications of gravity-assisted positioning (GAP)

#### Potential advantages

Maximises removal of excess bronchial secretions when combined with active cycle of breathing technique  
Allows accurate treatment of specific bronchopulmonary segments  
Self-treatment can be included in a home programme on discharge

#### Potential complications

Positions need modification when used in the presence of cardiovascular/neurological instability, haemoptysis or gastric reflux

length–tension relationship of the diaphragm, promotes relaxation of the shoulder girdle and upper chest and facilitates the use of breathing control.<sup>17</sup> This approach to positioning is particularly effective when used in conjunction with non-invasive ventilation (NIV). Adequately supported high side-lying is a useful position to promote relaxation of the breathless patient. In addition, it can discourage the overuse of accessory muscles of respiration, which may reduce energy expenditure. Some patients prefer forward lean-sitting with their arms placed in front of them on a high table. In this position the length–tension relationship of the diaphragm is optimised secondary to forward displacement of the abdominal contents.

### VENTILATION/PERFUSION

Appropriate positioning of a patient can maximise  $V/Q$ .<sup>18</sup> In the self-ventilating adult,  $V/Q$  matching increases from non-dependent to dependent areas of lung.<sup>19</sup> However, in adults receiving positive-pressure ventilation lung mechanics are altered, producing  $V/Q$  inequality. In this situation non-dependent areas of lung are preferentially ventilated while dependent regions are optimally perfused; as such, a regular change of position is recommended.

In an extreme form prone positioning has been used to improve refractory hypoxaemia in patients with ALI/ARDS. The mechanisms behind these improvements are complex, but likely centre around a combination of a redistribution of some pulmonary perfusion together with a more homogeneous distribution of ventilation, leading to improved  $V/Q$  matching. Although prone positioning improves oxygenation in 70% of patients with ALI/ARDS, its role in improving outcome remains controversial.<sup>20</sup>

### ACTIVE CYCLE OF BREATHING TECHNIQUE

The ACBT is a cycle of breathing exercises used to remove excess bronchial secretions (Table 5.6). The cycle can be adapted for each patient according to existing

**Table 5.6** Potential advantages and complications of active cycle of breathing technique (ACBT)

Potential advantages
Mobilises and clears excess bronchial secretions <sup>21,22</sup>
Improves lung function <sup>23</sup>
Minimises the work of breathing
Individual components of the cycle can be utilised/emphasised to target specific problems
Can be used in combination with other manual techniques, gravity-assisted positioning, V/Q matching, positioning to reduce breathlessness and during activities such as walking
Self-treatment can be included in a home programme
Potential complications
Without adequate periods of breathing control, bronchospasm and desaturation can occur
Poor technique can lead to ineffective treatment and unnecessary energy expenditure

underlying pathology and presenting clinical signs. It consists of:

- breathing control × 4–6 breaths
  - normal tidal breathing using the lower chest
  - minimising the use of accessory muscles of respiration
  - promoting relaxation
- lowering thoracic expansion × 4–6 breaths
  - with/without an inspiratory hold
- forced expiration technique
  - expiration with an open glottis ('huff'), combined with breathing control

Although mainly used in the self-ventilating patient, alert, cooperative, ventilated patients can participate with this technique. The ACBT can be delivered via MHI in sedated and ventilated patients requiring mobilisation of secretions and airway clearance.

## MECHANICAL ADJUNCTS

### INTERMITTENT POSITIVE-PRESSURE BREATHING

IPPB is a patient-triggered, pressure-cycled mechanical device mainly used in self-ventilating patients to increase ventilation, mobilise bronchial secretions and re-expand lung tissue by augmenting  $V_T$ <sup>24</sup> (Table 5.7). Positive airway pressure is maintained throughout inspiration. Expiration is passive. IPPB requires constant adjustment of pressure and flow rates and careful patient monitoring to maintain effectiveness and cooperation. Effectiveness is increased when used in conjunction with positioning, ACBT and manual techniques<sup>24</sup> (Table 5.8).

### CONTINUOUS POSITIVE AIRWAYS PRESSURE

CPAP maintains a positive airway pressure throughout inspiration and expiration. It is used in both intubated and self-ventilating patients to increase/normalise

**Table 5.7** Site and action of intermittent positive-pressure breathing (IPPB), continuous positive airways pressure (CPAP) and non-invasive ventilation (NIV)

	IPPB	CPAP	NIV
Lung volume affected	↑ $V_T$	↑ FRC	↑ $V_T$ and FRC
Action	Assists removal of excess bronchial secretions	Reverses atelectasis	Ventilatory support

FRC, functional residual capacity.

**Table 5.8** Potential advantages and complications of intermittent positive-pressure breathing (IPPB), continuous positive airways pressure (CPAP) and non-invasive ventilation (NIV)

Potential advantages
Improves lung volumes
Improves gaseous exchange
Decreases the work of breathing
IPPB and NIV can mobilise excess bronchial secretions by improving $V_T$
IPPB and NIV can improve lung and chest wall compliance
CPAP reduces left ventricular afterload by reducing the transmural pressure gradient
Patients can be mobilised while on CPAP and some modes of NIV. Alteration of ventilator settings might be indicated to maximise patient potential/exercise tolerance during treatment
Settings can be adjusted to augment physiotherapy intervention, e.g. increased inspiratory positive airway pressure to assist removal of secretions
Potential complications
Absolute contraindications include severe bronchospasm, undrained pneumothorax, pneumomediastinum, unexplained haemoptysis and facial fractures. Use with care in pre-existing bullous lung disease
Haemodynamic/neurological instability
Risk of decreased urine output with CPAP and NIV
Risk of carbon dioxide retention with CPAP
Risk of aspiration

IPAP, Inspiratory positive airway pressure.

functional residual capacity (FRC) via recruitment of atelectatic lung. Clinically increased FRC is associated with improved lung compliance, improved oxygenation and a reduced work of breathing.<sup>24</sup> Effectiveness is increased when used in conjunction with appropriate positioning. The self-ventilating patient must be able to generate an adequate  $V_T$  as this volume is not augmented with CPAP (see Table 5.7).

### NON-INVASIVE VENTILATION

In recent years there has been an expansion in the role of NIV in the ICU. This includes the prevention of invasive ventilation in patients with chronic obstructive pulmonary disease,<sup>25</sup> pulmonary oedema and immunocompromise; early weaning from mechanical ventilation; and potentially the prevention of reintubation in those who suffer extubation failure. In addition,  $V_T$  may be augmented during physiotherapy treatment to remove secretions, or when mobilising the patient (see Table 5.7). Improved oxygenation may be achieved using NIV when the patient is positioning to optimise  $V/Q$  (see Table 5.8).

### TREATMENT ADJUNCTS AND TECHNIQUES

Positive expiratory pressure mask and flutter devices are specialised mucociliary clearance devices used by some patients with chronic lung disease. These devices are rarely introduced in the ICU setting.

## CRITICAL CARE REHABILITATION

The effects of deconditioning on the cardiovascular (Table 5.9), respiratory (Table 5.10) and neuromusculoskeletal system (Table 5.11) are well documented.<sup>26–28</sup> This phenomenon occurs as a result of restricted physical activity, and reduces the ability to perform work. The effects of deconditioning can occur with even relatively short periods of immobility, and are significantly influenced by age, premorbid condition, nature of the

**Table 5.9** Deconditioning and the cardiovascular system<sup>26,28,30</sup>

#### Cardiovascular system

↓ Stroke volume – ventricular remodelling and reduced preload (see ↓ Plasma volume)  
 ↑ Heart rate (resting and exercising): ↓ vagal tone, ↑ sympathetic catecholamine secretion and ↑ cardiac  $\beta$ -receptor activity  
 ↓ Cardiac output and systemic oxygen delivery  
 ↓  $V_{O_{2max}}$ : magnitude highly correlated to duration, static exercise effective in preventing some decrease. Related to changes centrally (cardiac output) and peripherally (oxygen delivery and utilisation)  
 ↓ Plasma volume: secondary to fluid shift and altered renin–angiotensin–aldosterone activity. Contributes to ↓ orthostatic tolerance  
 Orthostatic intolerance develops more rapidly in the elderly or those with cardiovascular pathology. Often slow to resolve  
 Increased blood viscosity and vascular stasis: predisposition to thromboembolism  
 Altered cardiovascular reflexes: proposed attenuated baroreflex-mediated sympathoexcitation and enhanced cardiopulmonary receptor-mediated sympathoinhibition. Contributes to orthostatic intolerance  
 Altered arterial/venous vascular function

**Table 5.10** Deconditioning and the respiratory system<sup>31–33</sup>

#### Respiratory system

Adverse effects on:  
 Functional residual capacity  
 Compliance (lung and chest wall)  
 Resistance  
 Closing volume  
 Respiratory muscle function – impaired strength and endurance, reduced performance of ventilatory pump, ↑ days of mechanical ventilation, complex weaning issues  
 Concept of ventilator-induced diaphragmatic dysfunction proposed (atrophy, fibre remodelling, oxidative stress and structural injury). Time-dependent reduction in force-generating capacity, secondary to disuse and passive shortening  
 Respiratory muscle weakness may be limited by judicious choice of ventilation mode. Role of inspiratory muscle training unclear

illness/injury and pharmacological factors. The consequences of deconditioning are significant in terms of patient outcome, length of hospital stay, duration of rehabilitation and subsequent ability to function independently in the community.<sup>29</sup> The psychological impact of deconditioning should not be underestimated. Inability to function at a ‘normal’ level of activity may result in depression and reduced self-efficacy.

An increasing volume of research suggests that the deleterious consequences of immobility may be in part attenuated by selected rehabilitation interventions.<sup>38,39</sup> The physiotherapist possessing expertise in rehabilitation and exercise physiology should direct the multiprofessional team in evaluating individual patients, devising a therapeutic strategy and referring to other specialties (e.g. speech and language therapy, occupational therapy) as required. Considerations must include:

- current physiological reserve
- extent of physiological impairment (associated with deconditioning and coexisting pathology, e.g. sepsis, multiorgan failure, neurological insult, inotrope dependence)
- nutritional status
- premorbid physiological reserve
- premorbid functional ability
- extent of patient participation
- external limitations (e.g. surgical instructions, traction, sedation, paralyzing agents)
- risk assessment for moving and handling
- selection of appropriate/validated outcome measures

Traditionally, exercise rehabilitation has progressed linearly from activity in bed, then sitting, and finally to standing/walking. The model demonstrated in Figure 5.1 represents a three-stage functional rehabilitation programme. It is supported by evidence that suggests that a multimodal training regime is required to maintain/restore both

**Table 5.11** Deconditioning and the neuromusculoskeletal system<sup>26,34–37</sup>**Neuromusculoskeletal system**

Muscle atrophy – protein degradation (loss of contractile protein, increased non-contractile tissue, e.g. collagen) and cytokine activity. Reduction in strength, especially lower-limb antigravity muscles (i.e. those involved with transferring and ambulation). Inactivity amplifies the catabolic response of skeletal muscle to cortisol, therefore there is more marked atrophy following trauma or illness. Particularly significant in patient groups with low relative muscle mass, e.g. the elderly. Nutritional countermeasures should be considered and carefully titrated to meet demands best

↓ Muscle endurance (cf. Table 5.10) – reduced muscle blood flow/red cell volume/capillarisation/oxidative enzymes and biochemical changes. Generally longer to rehabilitate compared to reduction in muscle strength

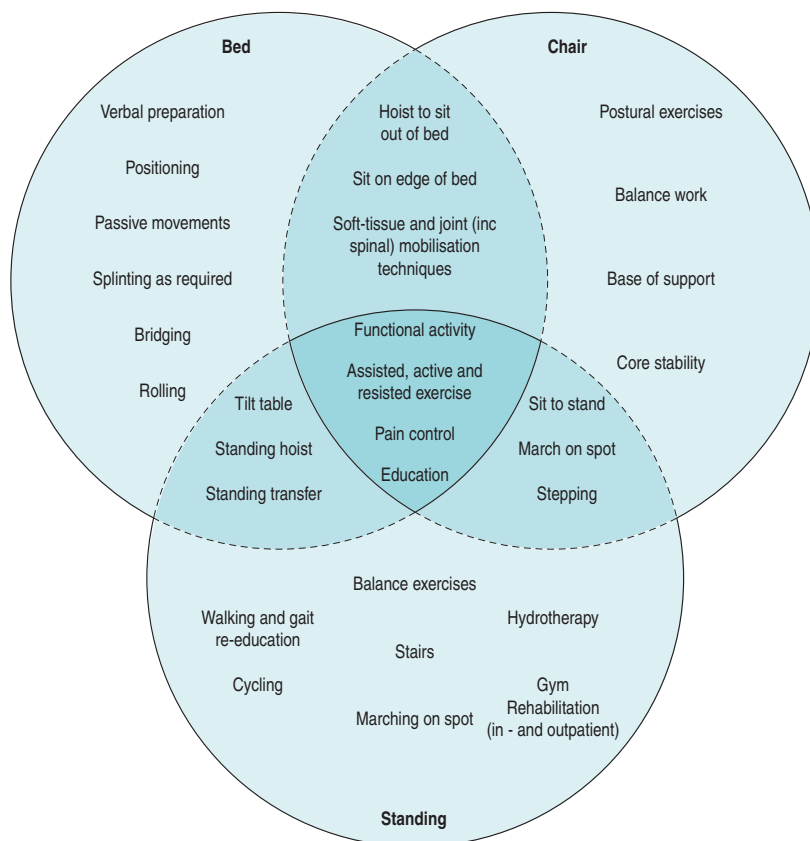

Muscle shortening or changes in peri-/intra-articular connective tissue (including chest wall and thoracic spine) → contractures, ↓ joint range of motion, pain. Positioning and stretching maintain range and delay invasion of non-contractile protein

Decreased bone mineral density (particularly trabecular bone) – may be attenuated by standing or resistance exercise. Rate of recovery tends to lag behind that of muscle strength. Increased risk of fracture on remobilisation, especially in elderly

Microvascular and biochemical changes in peripheral nerves impair neuromuscular function. Adversely affects maximal voluntary contraction, and balance/proprioceptive activity

Critical illness neuropathy and myopathy frequently develop in patients hospitalised in an ICU for > 1 week. Risk factors include sepsis, SIRS and severe MOF. Associated with higher mortality rate, prolonged ventilation and rehabilitation, disability and reduced quality of life

ICU, intensive care unit; SIRS, systemic inflammatory response syndrome; MOF, multiorgan failure.

**Figure 5.1** Schemata representing three-stage functional rehabilitation programme.<sup>41</sup>

physiological and psychological performance after a period of immobility and illness.<sup>39</sup> The use of interlinking circles is intended to reflect the non-linear pattern of exercise progression more commonly utilised in patients with critical illness, e.g. patients may be able to stand using a tilt-table before they are able to tolerate sitting out of bed. The central shaded area represents the core components that should be addressed at every stage in the patient’s recovery. The areas bordered by the broken lines represent the progression or regression from one stage to the next. During all stages, the patient’s cardiopulmonary response must be closely monitored, and exercise titrated accordingly. Modifications (e.g. temporarily increasing the Fio<sub>2</sub> and/or level of ventilatory assistance) during exercise and in the early postexercise period may be necessary. Such modifications are commonly required as increasing physical activity invariably coincides with weaning from ventilatory support – both significant challenges to the physiological reserve.

The wealth of evidence regarding deconditioning should play a central role in planning treatment, both preventive and rehabilitative. For example, those muscle groups known to be most adversely affected by disuse should be the first to be targeted with a gradual, progressive regime. During the remobilisation period, the multi-professional team must be particularly mindful of those elements with delayed recovery, e.g. orthostatic tolerance and bone mass (predisposition to falls and fractures) and muscle endurance (diminished exercise tolerance).

It has been suggested that, in order to improve long-term outcomes for survivors of ICU (e.g. late mortality, ongoing morbidity, neurocognitive defects, functional disability, quality of life, economic burden), critical illness and its management should be viewed on a continuum and not merely the time spent in a critical care facility.<sup>29</sup> Consequently, rehabilitation must also reflect this change in focus, continuing into the community, outpatient or follow-up clinic setting.<sup>40</sup>

In recent years the concept of ‘prehabilitation’ has been introduced. Some have argued the case for exercise training prior to planned ICU admissions in order to ameliorate functional capacity. It is proposed that this would enable an individual to withstand better the stressor of inactivity and decrease the duration of dependency post critical care discharge.<sup>26</sup>

**PATIENT PROBLEMS AFTER ICU DISCHARGE**

A prolonged stay in ICU can be debilitating mentally and physically and can affect recovery after discharge (Table 5.12). In order to optimise a fast and effective recovery, a patient’s care plan should be multidisciplinary in origin with ongoing appropriate rehabilitation following discharge from the ICU and indeed hospital.

**PHYSIOTHERAPY ROLE EXPANSION**

The nature of the critical care environment offers diverse opportunities for role expansion. The lead physiotherapist for the service must possess specialist cardiopulmonary and rehabilitative skills, as well as an expert knowledge of exercise physiology in health and disease. Furthermore, as a member of a dynamic multiprofessional team, it may be appropriate to extend diagnostic or clinical skills beyond the remit of conventional physiotherapy, e.g. developing weaning strategies, advanced tracheostomy management, bronchoscopy, prescription, arterial blood gas sampling and managing NIV services.

As an educator, the clinician must ensure that all professionals who provide physiotherapy input are competent in their assessment, clinical reasoning and skill execution. A commitment to audit and research is essential in order to ensure evidence-based service provision, clinical governance and best possible patient outcome.

**PHYSIOTHERAPY AND CRITICAL CARE OUTREACH TEAMS**

The development of specialist physiotherapist posts within critical care outreach teams (CCOTs) constitutes a prime example of role expansion. Following the publication of *Comprehensive Critical Care*<sup>42</sup> CCOT services were developed to meet the actual or potential needs of patients through critical care provision ‘without walls’:

- Avert critical care admission where possible
- Facilitate timely critical care admission when appropriate

**Table 5.12** Psychological, cardiopulmonary and functional problems often encountered after discharge from the intensive care unit

Psychological	Cardiopulmonary	Functional
Depression	Compromised cardiopulmonary system	Back pain
Fear	Difficulty clearing retained secretions (trache tube, mini-trach in situ)	Shoulder pain
Anxiety	Decreased lung volumes	Muscle atrophy/decreased strength
Confusion	Oxygen dependence	Inability to carry out activities of daily living independently
Disorientation		Limited mobility
Flashbacks		Poor exercise tolerance
Lack of motivation		Poor gait pattern
Functional dependence		

- Empower all health care staff by disseminating ward-based critical care skills
- Optimise patient management and make best use of critical care resources via effective clinical decision-making

The introduction of CCOT has been associated with a varied approach to team configuration; however it has been suggested that those following a multiprofessional model are most likely to affect clinical and organisational improvements.<sup>43</sup> Consequently, many teams have elected to employ a designated specialist physiotherapist who can bring physiotherapeutic expertise to the service whilst also developing generic outreach practitioner skills (e.g. advanced tracheostomy management, cannulation, venopuncture, prescription via patient group directions, arterial blood gas sampling, drug administration, advanced life support, management of central/peripheral lines, 12-lead electrocardiogram interpretation, ordering/interpreting blood results and chest X-rays).

### SUMMARY

The physiotherapist has an important and varied role within the ICU/high-dependency unit setting working as part of the multidisciplinary team to optimise cardiopulmonary function and functional ability. The physiotherapist is often uniquely placed to follow and treat a patient from the acute stages at ICU admission, through the rehabilitation process to subsequent discharge from hospital and, if necessary, treatment can be continued in the outpatient setting.

There is no longer a place for routine physiotherapy treatment. Regular systematic assessment will identify physiotherapy-amenable problems that contribute to a multidisciplinary care plan. Implementation of any physiotherapy treatment should always utilise continuous analytical reassessment.

# Critical care nursing

John R Welch and Chris Theaker

## NATURE AND FUNCTION OF CRITICAL CARE NURSING

Nurses are the one round-the-clock constant for critically ill patients and their families, acting as the ‘glue’ that holds the critical care service together. Nurses ensure safety and provide continuity and fine-tuning, coordinating and communicating all the elements of treatment and care needed by the patient.

Skilled critical care nurses provide:

- continuous, close monitoring of the patient and attached apparatus
- dynamic analysis and synthesis of complex data
- anticipation of complications
- decision-making, execution and evaluation of interventions to minimise adverse effects
- enhancement of the speed and quality of recovery
- emotional support of the patient and family, including support through the process of death<sup>1</sup>

Nursing in critical care is influenced by both the essential nature of nursing and the specific characteristics of the field. Fundamental concerns for all nurses are said to take in:

- the concept of holism
- an appreciation of the whole range of influences on all areas of life
- the pursuit of health rather than treatment of illness<sup>2</sup>

There is inevitably an emphasis on technology in the intensive care unit (ICU), and nurses must be technically competent. However, treatments should be administered with an understanding of the essential human elements of care. ICU patients report that such care is often missing: one described his experience as ‘rooted in the minute analysis of charts and the balancing of chemicals, not so much in the warmth of human contact’.<sup>3</sup>

Patients are not usually able to control what happens to them during the first phases of critical illness, but seek to reassert their autonomy as they begin to recover, e.g. when weaning from ventilation or with the transition to lower levels of care. Critical care nurses can enable patients to

have a say in the management of these processes while still ensuring safe progression through different stages of treatment. Studies highlight the value of connecting with patients both psychologically and physically,<sup>4</sup> and that patient-centred care and emotional support can be lost when the nursing resource is reduced.<sup>5</sup> Fundamental care (e.g. personal cleansing, protection of tissue integrity, prevention of infection) is also generally undertaken or supervised by nurses. Other important functions (e.g. chest physiotherapy, mobilisation, delivery of nutrition) may be managed by other specialists, but it is nurses who integrate these treatments into a complete package of care.

## A SYSTEMATIC APPROACH TO CARE

Nursing the critically ill patient is highly complex. It is vital to structure the patient review in order to clarify and prioritise patient needs, so that the whole range of patient function – and dysfunction – is addressed. In acute situations, assessment in turn of the fundamental A–B–C–D–E aspects of physiology is a useful method:

- Airway:** establishment and maintenance of airway patency (usually with the use of artificial devices), removal of pulmonary secretions, etc.
- Breathing:** adequacy of oxygenation and ventilation, optimising patient position, etc.
- Circulation:** circulatory volume and pressures; perfusion of brain, heart, lungs, kidneys, gut and other organs; control of bleeding, haematology, etc.
- Disability:** consciousness/reduced consciousness, and the factors that affect it; systemic and localised neurology.
- Exposure:** hands-on, head to toe, front and back examination, and everything else (!); wounds and drains; electrolytes and biochemistry, renal function.

Appropriate treatment strategies can be prioritised using this schema, which has the additional benefit that it will be familiar to colleagues trained in advanced life support and similar systems.

Further detail may then be gained from review of:

- F. *fluid* and electrolyte balance, fluid input, urine output
- G. *gastrointestinal* tract function: nutritional needs; elimination
- H. *history* and *holistic* overview of the patient
  - I. *infection* and infection control; microbiology
  - L. *lines* – utility and risks
- M. *medications*
- N. *nursing* and interdisciplinary teamwork: ensuring resources are sufficient for the patient's severity of illness and the physical demands of care
- P. *psychology* – pain and comfort, rest and sleep; managing the dying process
- R. *relatives* – communication of the plan of care and prognosis in the short, medium and longer term (after Hillman *et al.*<sup>6</sup>)

More sophisticated models can be used to frame a wider impression of the patient and to reflect a particular philosophy or approach to nursing. For example, the Roy model<sup>7</sup> expresses a view of nursing as a vehicle for enabling adaptive adjustments to any dysfunction. The model prompts analysis of both immediate and other contributing influences in a systematic consideration of oxygenation, nutrition, elimination, activity and rest, protective mechanisms, sensory function, fluid, electrolyte and acid–base balance, neurological and endocrine function, as well as the patient's self-concept, role-mastery and psychosocial interdependence.<sup>7</sup> Such an approach has a commendable breadth of vision, but may be too complex for the novice. Articulation of patient problems may be aided by the use of validated nursing diagnoses, as developed in North America. This system provides definitions and recommended nursing responses for many problems, and specifies appropriate outcome measures. What is most important is that any system used gives unambiguous definitions of patient problems and a clear statement of specific, measurable therapeutic goals.

#### NURSING AND PATIENT SAFETY

Inadequate nurse staffing is linked to increases in adverse events, patient morbidity and mortality. Significant numbers of patients suffer serious harm caused by errors in clinical practice, but nurses prevent many more incidents by intercepting and mitigating errors made by other professionals.<sup>8</sup> Direct observation and patient care remain key to patient safety:<sup>9</sup> it has been calculated that at least seven nurses need to be employed for each patient if a nursing presence is required continually 24 hours a day.<sup>1</sup> No particular system of critical care nursing has been shown to be definitively superior to others,<sup>9</sup> but ensuring appropriate nursing numbers, skills and experience to meet patient need is a gold standard of care<sup>10</sup> (see Staffing the critical care unit, below).

#### EVOLVING ROLES OF CRITICAL CARE NURSES

Critical care nurses' range of practice has evolved rapidly with progress in technology and with changes in the working of interdisciplinary team colleagues. The benefits of developing new skills must be balanced against ensuring the maintenance of fundamental patient care.<sup>11</sup> There remains a large variation in the array of tasks undertaken by nurses in critical care, with invasive procedures and drug prescriptions still usually performed by doctors. However, from 2006 qualified nurse (and pharmacist) prescribers in the UK have been enabled – in theory at least – to prescribe licensed medicines for the whole range of medical conditions. Nurse prescribing is not as yet a widespread phenomenon in critical care, but may become a routine part of practice in the future.

Critical care nurses also have a large and developing role in decision-making regarding the ongoing adjustment, titration and troubleshooting of such key treatments as ventilation, fluid and inotrope administration, and renal replacement therapy. The use of less invasive techniques (e.g. transoesophageal Doppler ultrasonography for cardiac output estimation) means that it is possible for nurses to institute relatively sophisticated monitoring and administer appropriate therapies for restoration of homeostasis. There is evidence that nurses can achieve good outcomes in these areas, especially with the use of clinical guidelines and protocols; for example, by reducing the time to wean respiratory support.<sup>12</sup> This indicates that further development of protocols, guidelines, care pathways and the like can be used to enhance the nursing contribution to critical care.

#### NEW NURSING ROLES IN CRITICAL CARE

Medical and nursing staffing in the ICU is an ongoing problem in many countries. This has led to the development of various new ways of working to deliver both fundamental and more sophisticated modes of care.<sup>13</sup> New nursing roles include those that essentially substitute for medical roles, as well as those that retain a nursing focus and aim to fill gaps in health care with nursing practice rather than medical care. For example, the UK has designated a relatively small number of nurse consultant posts in all areas of health care, with the largest proportion in critical care, particularly in outreach roles. These are advanced practitioners focusing primarily on clinical practice but also required to demonstrate professional leadership and consultancy, development of appropriate education and training, macrolevel practice and service development, research and evaluation.<sup>14</sup>

Other sorts of non-nursing staff are increasingly being used to deliver what has been seen as basic nursing care (e.g. oral and ocular care, recording of vital signs), in order to support trained nurses and enable them to concentrate

on more advanced practices.<sup>15</sup> Nursing shortages may make such developments inevitable in some areas, but it is imperative that nurses continue to ensure best outcomes for patients with proper arrangements for training, support and working systems.

### CRITICAL CARE NURSING BEYOND THE ICU: CRITICAL CARE OUTREACH

Around the world, general wards are required to manage an increasing throughput of patients who are, on average, older than before, with more complex, chronic diseases, and more acute and critical illness. Review of admissions to ICU from general wards shows that many patients experience substandard care before transfer.<sup>16</sup> Various factors are implicated, including lack of knowledge and failure to appreciate clinical urgency and to seek advice, compounded by poor organisation, breakdown in communication and inadequate supervision.

These issues are problems for the whole interdisciplinary team, but the nursing contribution is significant. It is nurses who record or supervise the recording of vital signs, suggesting that there is often poor understanding of the seriousness of such indicators, or failures to communicate effectively with medical staff, or difficulty in ensuring that appropriate treatment is prescribed and administered. Nurse-led outreach teams can support ward staff caring for at-risk and deteriorating patients, and facilitate transfer to intensive care when appropriate<sup>17</sup> (see Chapter 2). They can also support the care of patients on wards after discharge from ICU, and after discharge from the hospital (see Chapter 8). Potential problems with these approaches include a loss of specialist critical care staff from the ICU, and being sure that outreach teams have the necessary skills to manage high-risk patients in less well-equipped areas, particularly when there are limitations placed on nurses prescribing and administering treatments.

### NURSING IN THE INTERDISCIPLINARY TEAM

Effective critical care is based on interdisciplinary teamwork, with:

- 'clear individual roles
- members who share knowledge, skills, best practice and learning
- systems that enable shared clinical governance, individual and team accountability, risk analysis and management'.<sup>18</sup>

### QUALITY OF CARE

Robust systems of audit are the foundation of quality care. Various measures have been suggested as indicators

of the effectiveness of nursing structures, processes and outcomes, e.g. pressure ulcer prevalence, nosocomial infection rates and patient satisfaction. Although nurses should take responsibility for the care that they deliver, there are few, if any, nursing activities that can be considered entirely separately from other variables that influence patient outcomes. Furthermore, there are few, if any, medical interventions that are unaffected by nursing care. Rather, quality care depends on a collective interdisciplinary commitment to continuous improvement.<sup>19</sup> This interdependence of different critical care personnel was illustrated in a multicentre investigation where interaction and communication between team members were more significant predictors of patient mortality than the therapies used or the status of the institution.<sup>20</sup>

### CRITICAL CARE NURSING MANAGEMENT

The critical care nurse manager role is crucial to the performance of the service. The responsibilities and challenges of the nurse manager vary across different national systems and hospitals, but the most important concern for the manager is probably the problem of attracting and retaining a flexible, developing and consistently effective nursing team that works well with other health care professionals to meet patient needs within a limited budget.

### STAFFING THE CRITICAL CARE UNIT<sup>1</sup>

The starting point for calculations of staffing requirements is an understanding of patient needs – and the knowledge and skills that will be required to meet those needs – with an awareness that there will be unpredictable variations over time.

- Patient need has many components, including:
  - the severity and complexity of the acute illness and chronic disease
  - other physical characteristics, e.g. mobility, body weight, skin integrity, continence
  - consciousness and cognition (alert, oriented, cooperative or confused, agitated, at risk of self-harm)
  - mood and emotionality (e.g. anxiety, depression, motivation)
  - the frequency and complexity of observation/monitoring and intervention required
  - the needs of relatives
- The staff resource includes members of the clinical team and a whole range of ancillary staff, and support services. Collectively, these personnel must be adequate to meet patient needs. This requires evaluation of:
  - nursing numbers and skill-mix
  - interdisciplinary team skill-mix, and consideration of variations in the continuous availability of team members (e.g. doctors, respiratory/physiotherapists, equipment technicians)

- The context of care is also significant:
  - The physical environment, e.g. the ease with which patients can be observed, whether in groups or in separate rooms
  - Workload variations – peaks, troughs and overall activity in the department, e.g. admissions, discharges, transfers

### OTHER RESPONSIBILITIES

The manager is also typically responsible for:

- the coordinated operational management of the area
- the quality of nursing care
- management of nursing pay and non-pay budget
- personnel management

There are dynamic political, social and economic forces bearing on the organisational objectives and resources of the hospital and the ICU. The nurse manager needs to have an understanding of these factors and how they influence the practical delivery of patient care and the maintenance of a healthy environment for individual and team development. The manager must be able to communicate the key issues to the whole team in the form of an agreed strategy and a clear, regularly updated operational plan for the department. This should enable a shared understanding of exactly what needs to be done in practice, and where each team member fits into the plan. Externally, the manager represents the service and ensures that other disciplines and the organisation are informed about critical care issues.

Teams perform most effectively when individuals believe that they are working toward some common and worthwhile goals. A key role of the manager is to provide such coherence not just within the unit but also by integrating the views of all users of the service, including patients and their families, into the departmental plan. The principles of shared governance can be usefully applied in this perspective, whereby staff collectively review and learn from existing practices in order to develop and improve patient care within the unit. This has to be in the context of:

- the strategic agendas of the unit and the hospital
- the development of the service
- financial issues, budgets and budgetary restraints
- an appreciation of day-to-day working issues

Not surprisingly, the complexity and range of requirements may be too much for one person, so that different individuals are employed to take responsibility for particular aspects of management.

### STRESS MANAGEMENT AND MOTIVATION

The ICU can be extremely stressful, demanding considerable cognitive, affective and psychomotor effort. Supervisory arrangements and feedback mechanisms should be in place to alleviate such demands, and enable prompt

recognition of staff who are having difficulties at work. Regular individual performance reviews and formulation of development plans provide positive assurance and encouragement and can identify individuals' personal requirements, such as educational needs. They also provide an opportunity to identify poor practice that can then be rectified in a constructive manner. Study of human resource practices in acute hospitals has found a strong association between the quantity and quality of staff appraisal and patient mortality.<sup>21</sup> Organisations that emphasise training and team-working also have better outcomes.<sup>21</sup> Developing nurses' critical thinking and decision-making skills is important for effective working. The nurse manager should provide a system that facilitates such training.

Occupational psychology suggests that providing staff at all levels with opportunities to feel that they can influence and perhaps change the working environment tends to decrease stress and increase motivation. Flexibility to work in different ways at different times, while still meeting the overall demands of the department, is important. It is the manager's job to balance and meet the needs of staff, patients and the organisation. One method is to give staff choice regarding rostering, so that a nurse may opt to work with particular patients for a period in order to practise particular skills, and to promote continuity and coordination of care. This can have real benefits for patients and their families too.

### NURSE EDUCATION

Critical care nurses generally enjoy well-established educational programmes, although there is variability in the content and quality of such training. Nurses usually wish to gain formal academic credentials, and there is a role for study of relevant philosophy, nursing theory and research methods. However, there is a fundamental requirement for learning that focuses on clinical practice issues and problem-solving that benefits patients.<sup>22</sup> It is also clear that there should be more widespread deployment of critical care nursing skills. These imperatives drive a need to produce unambiguous statements about the standards necessary for proper nursing assessment and nursing management of critically ill patients.

Summarised examples of competencies for critical care nurses might include the following:<sup>23</sup>

- Safe, effective, appropriate nursing management of patient requiring invasive ventilation, using:
  - a range of suitable ventilatory modes
  - pulmonary recruitment manoeuvres (e.g. prone positioning)
  - strategies for weaning
  - consideration of patient comfort (sedation, etc.)
- Safe, effective, appropriate nursing management of patient suffering from cardiovascular instability, including:
  - acute coronary syndromes
  - cardiac dysrhythmias

**Table 6.1** Assessment of critical care nurses' performance

Rating	Definition	Observed behaviour	Prompts
Novice	Limited skill and/or knowledge, inconsistent practice, variable interpersonal skill. Limited understanding of wider context, inflexible rule-governed behaviour	Lacks coordination and confidence. Potential for omissions or inaccuracies. Unable to demonstrate accurate and safe performance despite repeated attempts	Requires frequent directive prompts, supervision and advice
Advanced beginner	Some skill and knowledge, generally consistent practice and interpersonal skill; variable ethical thought. Some appreciation of situational influences	Coordinated and confident in fundamental tasks. Easily distracted or unable to integrate other aspects of patient care	Requires occasional directive prompts and some supervision
Competent	Consistent safe, accurate and effective practice, interpersonal skill and ethical thought. Conscious and deliberate planning with consideration of immediate context	Skillful, confident and coordinated patient-focused practice, with evident integration of other aspects of care. Prioritisation of workload	Self-directing without supervision
Proficient	Consistent safe, accurate and effective practice, higher-level interpersonal skill and ethical reasoning. Conscious and deliberate planning with consideration of longer-term goals. Adapts care in response to changing situations	Skilled and accomplished practice, proactive and flexible approach to care. Problem-solving and decision-making through reflection. Role model	Capable of supporting and demonstrating skills to others

(After Benner P. *From Novice to Expert: Excellence and Power in Clinical Nursing Practice*. Menlo Park: Addison-Wesley; 1984.)

- haemodynamic instability secondary to other factors
- circulatory failure
- periarrest situations
- cardiopulmonary arrest
- Safe and effective management of prerenal failure, intrinsic renal failure and postrenal failure, with appropriate nursing care, including:
  - fluid and drug therapies
  - urinary drainage devices
  - renal replacement techniques (in the appropriate setting)

These statements outline the types of competencies that might be required by nurses, and can be used to structure in-depth descriptors of the skills, applied knowledge and attitudes needed to achieve specific patient outcomes. Clear detailing of specific skills is essential, but there also needs to be consideration of how individual actions are integrated into holistic care, and the role of independent clinical judgement. Appraisal of performance requires suitable assessors to observe and question the nurse in practice, but this places great demands on hard-pressed clinical areas. It may be that increasingly sophisticated simulators can be used to test performance away from the practice setting.

Various frameworks to identify different levels of performance have been developed, e.g. based on Benner's hierarchy<sup>4</sup> (Table 6.1). These can be used to mark progression to particular standards in core skills.

### CRITICAL CARE NURSING RESEARCH

Critical care services treat small numbers of patients at high cost. Critical care has great physical and psychological

impact, but often uses somewhat untested methods. Patient outcomes are influenced by different organisational approaches, staff characteristics, varied working practices and treatment methods, as well as differences between patients themselves. Therefore, a range of quantitative and qualitative investigative procedures is needed to gain a comprehensive understanding of the issues and to develop best practice. The approach chosen depends on the nature of the research question, and also the objectives of the researcher and the resources available.

### REVIEWING RESEARCH

The methods used to appraise research depend partly on the type of work under review. The following questions may be used to structure a critique:

- Justification for the research: are the background and rationale of the study clearly established?
- Scientific content: is there a specific question/hypothesis?
- Originality: is it a new idea, or re-examining an old problem differently or better?
- Methodology and study design: are the methods appropriate and are they likely to produce an answer to the question? For example:
  - comparisons of different treatments generally require quantitative measurements of particular end-points, e.g. the dose of a drug needed to achieve a target physiological variable, or the time taken to wean from ventilation
  - understanding how an individual thinks or feels usually involves analysis of qualitative material, e.g. data from interviews with patients and families to obtain their views of the service<sup>24</sup>

- Is the research method described in a way that can be readily understood, and replicated?
- Are the relevant results shown? Are data given that provide details of the individuals under investigation (e.g. demographics) and details of how representative these might be of a larger population?
- Is the analysis appropriate and is the power of the study adequate? (This is usually determined by the numbers involved and the size of the difference being examined.)
- Interpretation and discussion: are the conclusions and comments reasonable in the light of the results? Do the conclusions follow from the analysis?
- Are any references to background literature reasonably comprehensive and appropriate?
- What can be taken from the study, that is, what value does the study have in terms of supporting or developing clinical practice?
- What is the overall impression of the work? Is it credible? Is the presentation clear and informative?
- If evaluating a paper, has the work undergone proper peer review?

## UNDERTAKING A RESEARCH PROJECT

### STAGE 1: IDENTIFY AND CLARIFY THE TOPIC TO BE EXAMINED

Research in clinical settings is most valued when it is relevant to practice. The researcher is more likely to gain support for investigation of high-risk and high-cost processes. Current political priorities in health care may also be significant. Many everyday methods and treatments warrant examination too, particularly when there are significant variations in practice. The researcher should determine how the topic of interest might be described in a measurable way, and formulate the investigation as a question, with some consideration of how answers can be obtained.

### STAGE 2: GATHER RELEVANT BACKGROUND INFORMATION

It is important to collect information that enables an understanding of the issues under investigation, and helps justify performing the study. Hospital libraries are useful, not least because there may be staff who can give advice about the project. Indexes for journals and books are in print and computer-based formats, with databases and texts also available through the internet. A good starting point is Google Scholar (<http://scholar.google.com/>). This uses a broad approach to locating articles in searches across many disciplines and sources. More specific medical/nursing websites include:

- PubMed, a service from the US National Library of Medicine (<http://www.nlm.nih.gov/>), with access to the MEDLINE (Medical Literature, Analysis, and Retrieval System Online) biomedical database
- the Cumulative Index to Nursing and Allied Health (CINAHL) at <http://www.cinahl.com>

- the Cochrane Collaboration of systematic reviews of health care interventions (<http://www.cochrane.org>)
- EMBASE (<http://www.embase.com/>) is particularly good for pharmacological information

The most important piece of advice when conducting a search is not to enter the first word that comes to mind into the database or search engine, but to start by formulating a question and then break it down into its component parts. Training in searching databases is recommended.

The researcher must also evaluate the quality of the information gathered. Different types of research are traditionally considered to have different weights, e.g. results obtained from randomised controlled trials are considered to be high-grade evidence, whereas observational studies are deemed less useful.<sup>25</sup> This hierarchy is not always applicable and may devalue some sorts of valuable work, but it does emphasise the need to examine critically the credibility of research.

### STAGE 3: DESIGN A METHOD THAT:

- will provide data that will answer the question
- is adequate to answer the question (e.g. studies that use statistics require consideration of the numbers of data items needed to demonstrate differences between different groups or categories)
- is feasible to do in practice
- is ethical

### STAGE 4: COLLECT THE DATA

This is usually relatively simple provided that the data items to be collected are clearly defined at the planning stage of the study. A common pitfall is to collect vast amounts of unnecessary data and lose the focus of the original question. Data should be collected in a manageable format, often using some type of database.

### STAGE 5: ORGANISE THE DATA

By this stage, a large amount of material may have been gathered from primary and secondary sources. It is important that:

- a system of categorisation and analysis is used that meets the objectives of the investigation
- the analysis addresses the original question
- appropriate statistical methods are used (specialist expertise or advice may be required)

### STAGE 6: PRESENT AND EXPLAIN THE DATA

Presentation can take many forms, but it is always necessary to set out the question asked, to describe the research method so that it is clear what was done, to illustrate the results and their analysis and to present the key findings and conclusions. The conclusions should follow from the analysis, without inappropriate extrapolations. Any applications to clinical practice should be highlighted. The report must be presented succinctly and in a constructive manner, but with any shortcomings or

**Table 6.2** Issues for consideration in the review of research proposals

Particular to the patient/research subject	Particular to study design/integrity
<ul style="list-style-type: none"> <li>• The possibility of risk of harm</li> <li>• The degree of inconvenience to the patient/research subject (or associated persons, e.g. patients' relatives)</li> <li>• The duration of the study period (for the patient/subject)</li> <li>• Whether the individual patient or research subject may obtain a direct or indirect benefit from participating</li> <li>• The characteristics of the population to be studied</li> <li>• Inclusion and exclusion criteria, and the rationale for inclusion and exclusion</li> <li>• Whether any of the patients/research subjects are enrolled into other research projects that could influence the new study</li> </ul>	<ul style="list-style-type: none"> <li>• The credentials of the researchers</li> <li>• Whether the researchers are subject to any conflicts of interest</li> <li>• The benefits of the research balanced against its detriments</li> <li>• What is needed to fund and resource the study</li> <li>• Whether there is an effective mechanism for managing adverse events</li> <li>• Whether there is an effective mechanism for terminating the study</li> <li>• The frequency of occurrence of the phenomenon to be studied</li> <li>• The duration of the study</li> <li>• The feasibility of recruiting sufficient patients or research subjects to meet statistical power requirements</li> <li>• Where, when and how patients or research subjects are to be recruited, and who will be doing the recruiting</li> <li>• How long the patient or research subject will be given to decide whether or not to take part</li> <li>• What happens if the patient agrees to take part but subsequently wishes to withdraw</li> <li>• How data will be collected, scrutinised, stored – and subsequently disposed of – in order to protect patient confidentiality</li> <li>• Whether the research is analysing an established procedure or a novel method</li> </ul>

problems in the study discussed. The goal is that the reader can understand the methodology and how the results were interpreted, while acknowledging any limitations of the work.

The main point of research is to share what has been learnt: the researcher should think about how the work may be made available to as large an audience as is possible or appropriate.

### STAGE 7: EVALUATE THE PROJECT

The final phase is reflective. Conducting research is a process that can always be improved. Constructive feedback from colleagues is an effective way of determining the value of a study. The researcher should review what has been learnt from the process as well as from the results of the study, and consider how the work might be further developed in the future.

## RESEARCH ETHICS

The practitioner must always consider the ethical issues associated with conducting research: in many countries it is a criminal offence to undertake medical research without ethical approval. The researcher generally needs to submit a detailed application document for approval to an ethics committee. There are local differences in the process of obtaining ethical approval for research on humans, but most systems incorporate the principles of the Declaration of Helsinki (see the World Medical

Association website at <http://www.wma.net/e/policy/b3.htm>).

One important area is the question of how informed consent will be obtained from patients. Even if patients are awake it does not necessarily mean that they have the capacity to provide informed consent. Some countries adopt the practice of obtaining consent from a patient's next of kin in an effort to circumvent this issue, but this is in fact obtaining 'assent' rather than 'consent'. In the European Union, this approach is only legal when the research is a clinical trial for medicinal products.

An ethics committee is usually made up of professional and lay members attached to hospitals or universities. The committee looks beyond the stated necessity and significance of the proposed research to evaluate a range of matters particular to the patients who may be involved, and to aspects of the study design. Some of these issues are summarised in Table 6.2.

# Ethics in intensive care

Raymond F Raper and Malcolm McD Fisher

## DEFINITION

Ethics is the study of how one ought to behave. In contrast, the law defines how one must behave to avoid punishment. Ethics is concerned with differentiating right from wrong behaviour. For most people, a sense of ethics is innate. Medical ethics particularly relates to the relationships between health care practitioners and patients and is not limited to doctors even if it is particularly applicable to doctors. Ethical conflict almost always involves a clash of values and appropriate resolution depends on recognition of the conflicting interests and values.

## ETHICAL FRAMEWORK

Medical ethics are usually discussed in the context of principles. These principles inform ethical behaviour and can be summarised as:

1. *Autonomy*: the principle of individual self-determination in respect of medical care.
2. *Beneficence*: the principle of ‘doing good’, an obligation always to act in the best interests of patients with respect to saving lives, curing illness and alleviating pain and suffering.
3. *Non-maleficence*: the principle of doing no harm.
4. *Fidelity*: faithfulness to duties and obligations, a principle underlying confidentiality, telling the truth, keeping up with medical knowledge (i.e. continuing professional development) and not neglecting patient care.
5. *Social justice*: the principle of equitable access of all citizens to medical care according to medical need.
6. *Utility*: the principle of doing most good for the most number of people; that is, achieving maximum benefits for society without wasting health resources.

Utility is a consequentialist concept, where the right or wrong of an action is determined by the outcome rather than by an a priori principle. The ‘correct’ action may thus vary with the particular circumstances. This is sometimes seen as an entirely different framework from the rights or principles-based system. The utility principle is more applicable to systems development in medical

practice and may create conflict with individual patient responsibility. It is important that intensivists participate in the public debate that determines how much of society’s goods are to be allocated to medicine and how much of the health budget is to be allocated to intensive care without, at the same time, surrendering responsibility for the interests of individual patients. Moving between these public and private spheres of functioning can be challenging but is essential to good medical practice.

Ethical conflict is most often encountered where there is a clash of values. Rationing, for instance, involves a clash between the values of individual rights and collective rights. Euthanasia usually involves a clash between the values of sanctity of life and autonomy. Resolution of ethical conflict depends on recognition of the values that are in dispute and of the principles that are operative. Absolutist terms such as ‘futility’ tend to mask the values-in-clash and are thus unhelpful in resolution of ethical conflict. Consideration of the various interests involved is also helpful in foregrounding the real issues behind an ethical conflict.

## ICU ETHICAL PROBLEMS

### END-OF-LIFE MANAGEMENT

During its relatively brief history, intensive care has seen a dramatic increase in both capacity and capability. Practice has become codified and at least partly standardised and intensive care is more generally accessible. Greater emphasis on individual rights has seen an increased demand for medical resources in general and this has flowed on to intensive care. The great challenge for intensive care lies in the reality that prolonged life support is often quite easily achieved without there being either inevitable recovery or intractable demise. Of the sickest patients in the intensive care unit (ICU), only a proportion ultimately recovers and can be returned to a reasonable quality of life. Even this would not be a problem if it were possible to predict survival with any degree of certainty and a great deal of effort has been expended in an attempt to achieve this. Unfortunately, this has met with only limited success and consideration of the appropriateness of ongoing intensive

care is necessarily conducted against a background of prognostic uncertainty.<sup>1</sup>

In consequence of this, death in ICU usually involves some limitation or withholding of life-sustaining treatment.<sup>2,3</sup> This has now been well documented in many studies from around the world and the driving factors are now reasonably well understood.<sup>2-9</sup> The ethical principles underpinning this practice are those described above. Intensive care is inevitably burdensome and requires a commensurate benefit to conform to beneficence and non-maleficence. While life itself has a value, this is considerably offset if it is brief, painful and non-interactive. As death becomes increasingly imminent, its deferment at any cost becomes less appropriate. Considerations of justice should rarely intrude at the bedside. However, prolongation of life by artificial means in a patient with little or no chance of survival may challenge the rights of survivable patients to limited intensive care resources.<sup>10</sup> Where resources are publicly owned, offering to one patient treatment that cannot be made available to all patients in similar circumstances is fundamentally unethical. The collective has the ethical right to regulate access to even beneficial therapy provided it does so in a non-discriminatory fashion. The intensive care specialist does not have a right unilaterally to apply or withhold resources against the will of the collective. Unfortunately, the will of the collective is rarely known.

End-of-life management in the intensive care setting has been subjected to a considerable research endeavour over the past several years.<sup>2,4,11-13</sup> Insights that can be gleaned from published studies include:

- Patients not infrequently die in some discomfort in ICU receiving unwanted therapy.
- Considerable dissatisfaction has been reported by both patients and families with management at the end of life.
- Patient wishes with respect to end-of-life treatment are commonly unknown.
- Patients and families may be quite ignorant of the nature and prognosis of end-of-life initiatives such as cardiopulmonary resuscitation.<sup>14</sup>
- Active interventions including obligatory, outside consultations have not been particularly effective in improving the quality of end-of-life management.
- There is a good deal of practice variability across countries and communities with respect to attitudes to death, dying and the withholding and withdrawing of active treatment.<sup>2,8</sup>
- The reported variability in practice relates to attitudes of doctors and nurses, decision-making processes and to actual practices once a treatment-limiting decision has been made.
- Although some form of treatment limitation is common, withdrawal of treatment is not practised and is even illegal in some communities while active foreshortening and active euthanasia are reported in others.

- There remains some confusion concerning the distinction between active foreshortening of life and administration of drugs that both relieve unwanted symptoms and shorten the dying process. The nature and doses of agents used actively to shorten life are not necessarily different from those used to relieve symptoms without the intention of accelerating death and the time to death may also not be affected.<sup>2</sup>
- Most patients and families report a preference for some form of collaboration in end-of-life decision-making.<sup>15-17</sup>

### PRACTICAL CONSIDERATIONS

- Decisions to limit treatment in ICU depend on a careful consideration of the burdens and benefits of treatment.
- Prognostication in ICU practice is imperfect so that decision-making is based on probability rather than certainty.
- Decision-making is usually an evolving process, commonly involving several discussions of therapeutic possibilities, quality of life and patient preferences.<sup>9,11</sup>
- Competent patients should always be involved in discussions and inclusion of family members should be encouraged and fostered.
- Given the common desire for collaborative decision-making, seeking patient preferences and consensus in a proposed management plan is more appropriate than either surrendering decision-making responsibility to patients or surrogates or systematically excluding patients and/or carers.
- The important role of nurses and allied health practitioners in the management of critically ill patients warrants respect by inclusion in discussions. Failure to do so has resulted in nurses inappropriately taking unilateral, surreptitious action justified as patient advocacy. Legal action for unlawful termination of life has also resulted.

### ADVANCE DIRECTIVES AND POWER OF ATTORNEY

Patients may formally signal their preferences for end-of-life care in a written document or may nominate a surrogate decision-maker in the event of future incompetence. The legal standing of such documents is highly variable. Nevertheless, as expressions of self-determination they have considerable ethical validity and warrant respect. Unfortunately, advance directives are often insufficiently specific and it is not always possible to be sure that decisions included in such documents were fully informed and rational. Given the frequent reticence of patients to consider end-of-life matters,<sup>14</sup> advance directives are unlikely to become widely pervasive.

### EUTHANASIA

This term is strictly applicable only to situations of active termination of life with the knowledge of and usually at the request of a patient suffering a terminal and/or

debilitating, incurable illness. Physician-assisted suicide is a variation of this practice. This is a subject of considerable debate and is now legal in a small number of jurisdictions though likely practised surreptitiously in many more. Ethicists, largely on consequentialist grounds, maintain no distinction between this and the terminal withdrawal or withholding of treatment<sup>18</sup> (sometimes inappropriately termed ‘passive euthanasia’). For intensive care practice, however, the distinction seems obvious and essential. The distinction is most often argued on the basis of intent. Although there may well be a difference in intent between active euthanasia and withdrawal of treatment, relief of pain and suffering may be at the heart of both activities. Even if this is the case, active euthanasia is certainly a disproportionate means to the end. Treatment limitation is arguably an essential component of intensive care practice while euthanasia is not and there is usually a clear and obvious difference in the acts themselves. While it may be true that in some instances there is no moral distinction between euthanasia and withdrawal of treatment, this does not mean that there is never such a distinction.

#### TREATMENT WITHDRAWAL

- Once a decision has been made to withdraw or withhold treatment, the decision, the participants, the rationale and the details of the treatment limitation should be clearly documented in the patient records. Surreptitious treatment limitation is difficult to justify and potentially hazardous.
- There is no moral hierarchy of treatments but ventilator withdrawal is more obviously terminal than, say, withdrawal of renal replacement therapy or antibiotics.
- Although treatment may sometimes be withdrawn or withheld in ICU, care must never be withdrawn. An alternative, palliative management plan focusing on symptom relief and patient dignity should be instituted and documented.
- From a practical perspective, progressive treatment withdrawal enables progressive management of any resultant discomfort. It also helps foster an appreciation that death is a consequence of disease or organ system failure rather than of the withdrawal of treatment.
- Symptom relief with especially sedatives and narcotics may sometimes appear to hasten death. This is often justified on the ‘double effect’ principle, as the acceleration of death, though foreseen, was not intended. More importantly, however, this should be seen simply as a trade-off of two aims where the relief of unwanted symptoms assumes a higher priority than avoidance of the foreshortening of life. Certainly, it is difficult to justify unnecessary pain and suffering at the end of life on ethical grounds. Finally clinical experience suggests that, rather than shortening life, narcotics and sedatives commonly prolong the dying process by reducing cardiovascular stress.

#### CONSENT

Informed consent lies at the heart of the doctor–patient relationship and has both ethical and legal implications. Consent relates both to treatment (especially to invasive procedures) and to participation in research. General principles relating to consent can be listed:

- Patient consent is a fundamental tenet of medical practice. Routine or minor procedures may be included in the general consent to treatment.
- Consent may be waived in an emergency for treatment that is immediately necessary to save life or avoid significant physical deterioration. This applies whether or not the patient is technically competent.
- Valid consent is dependent on the provision of adequate information, including benefits and risks, and must be voluntary and free from coercion.
- Written consent provides evidence of the consent process, but consent itself need not be in writing, unless specifically required by a local authority.
- Competent patients are entitled to refuse consent to treatment even when doing so may result in harm or death.
- Surrogate consent for more elective procedures relies for ethical justification on the principle of autonomy. Patients’ interests must be paramount. Legal requirements relating to surrogate consent are highly variable and ‘surrogate’ is often formally defined and limited by local statute.
- Autonomy also provides the ethical justification for advance directives, the legal status of which is also highly variable.
- An enduring power of attorney generally applies to financial affairs rather than to consent to treatment. Again, the ethical basis relates to self-determination.
- Competent minors may or may not have a legal right to consent but age does not affect ethical considerations independently of insight and understanding. Even incompetent minors have some entitlement to confidentiality and all are entitled to protection from harm, even if that harm devolves from parental or guardian decisions based on well-meaning conviction or prejudice.
- Consent is especially required to involve a patient in research, where the importance of full disclosure is even greater. Medical research imposes some particular ethical issues, to be discussed below.
- Consent is also required for teaching purposes, such as video recording and photographing patients and teaching practical procedures.
- There may be a legal requirement for consent for testing for diseases such as human immunodeficiency virus (HIV)/acquired immunodeficiency syndrome (AIDS) and hepatitis. These diseases are not especially unique from an ethical perspective, however, and patients’ rights to privacy are not absolute.

Because intensive care patients are often unable to provide formal consent and because critical illness itself may negate the preconditions for consent, this issue is commonly neglected. Consent to ‘routine’ or everyday procedures in critically ill patients is often presumed or rather subsumed under the general consent to treatment. Near-universal consent is possible, however.<sup>19</sup> The precise role for consent in the intensive care context has not been fully defined but deviations from the general requirement for consent require some justification. The legal requirement for consent varies with different interpretations and jurisdictions. If taken to extreme, such as enabling surrogate refusal for ‘routine’ procedures such as central venous access, consent-related autonomy may become incompatible with the beneficence and non-maleficence principles and may largely become untenable.

### RATIONING AND SOCIETAL ROLE

Intensive care is, by nature, expensive. This creates a tension and a potential ethical conflict for intensive care practitioners. It is essential to find a balance between responsibilities to individual patients and to those of the collective. In theory, this is achieved by removing all rationing decisions from the bedside. Established norms rather than temporal availability or personal influence should determine access to ICU. Treatment is withheld or withdrawn not because there is a ‘more deserving’ patient at the door but because it would always be withheld or withdrawn under the particular clinical circumstances. Wide variations in access to medical care for similar patients across a single society cannot be ethically justified. More challenging is the definition of society. If a sufficiently broad perspective is adopted, most intensive care is difficult to justify. The ethically responsible intensive care practitioner will both advocate for individual patients and participate in the mostly unstructured social debate that determines what proportion of community resources is expended on medicine and on intensive care in particular.

### PROFESSIONALISM

Medical practitioners occupy a unique and, usually, a privileged position in society. With this come a number of responsibilities. These are generally well covered in codes of conduct issued from time to time by professional societies and institutions of learning. The oldest and perhaps best known is the hippocratic oath. Professional, ethical responsibilities may be sorely tested where the well-being of the practitioner is at risk from medical practice, as with infectious disease epidemics and acts of terrorism. Resolution of this potential conflict has not been satisfactorily determined to date.

Among the ethical responsibilities of medical practitioners are:

- Maintenance of appropriate professional relationships with patients
- Appropriate documentation of medical interactions
- Participation in quality and safety initiatives and practices
- Respect for patient and staff confidentiality
- Respect for the tenets of the law

### INDUSTRY AND CONFLICT OF INTEREST

Relationships among doctors and the medical technology and pharmaceutical companies are complex.<sup>20</sup> Doctors and industry are somewhat interdependent. Medical advances do not occur in a vacuum and the invention, assessment, development and marketing of new drugs and technologies necessitate close relationships among doctors and industry. While doctors are entitled to fair consideration for their skills and effort, the relationships must be overt and openly scrutinised if conflicts of interests are not to occur. The nature of the rewards offered by companies for medical involvement in product development is diverse but includes both direct and indirect payments. The economic justification for all these payments depends on their effects on subsequent product marketing. The propriety of travel and related support is questionable unless it is directly and attributable related to openly contracted services. Involvement of companies with vested interests in pseudoeducational initiatives and even guideline development may be little more than covert marketing.<sup>21</sup> Some open labelled research initiatives with large, practitioner reward programmes are similarly worrisome. Initiatives designed to limit these conflicts of interest include open disclosure of all financial relationships and voluntary and involuntary codes of conduct on both sides of the relationship. Financial inducements can be easily concealed, however, and specific financial relationships can be obscured by their volume and pervasiveness. Although this potential for ethical conflict exists in many other commercial relationships, the nature of medicine and the associated expenditure of, often, public funds dictate that this is not an entirely private consideration.

### RESEARCH

Critically ill patients can rarely consent themselves to participation in research projects and yet they are able to benefit from the results of earlier studies with similarly problematic consent issues. Locating surrogate decision-makers within a timeframe appropriate for some types of research can also be impossible. This has been recognised and enacted in a consent waiver for even randomised clinical trials. The potential ethical conflict in this situation lies in the use of a patient as an instrument to achieve another’s end without express consent. There is a potential ‘slippery slope’ in valuing the rights of the collective over those of the individual and yet the individual can be seen to have an interest in the resolution of some of

- Maintenance of professional standards by continuing education and professional development

these important clinical questions. The conduct of such research must be carefully scrutinised by outside agents and careful consideration must be given to the balance between risk and benefit. A potentially greater benefit might help justify a potentially greater risk even if the benefit might not be directly applicable to the subject. Studies of, for example, disease mechanisms involving little or no potential direct patient benefit would need to involve no material risk. In general, the principles of consent detailed above are applicable. When a waiver is applied, patients and/or surrogates should be afforded an opportunity to withdraw from study at the earliest opportunity.

### RESOLVING ETHICAL CONFLICT

Ethical conflict most commonly arises where there is a clash of values or interests. Resolution is often difficult because of entrenched positions and convictions. The innate sense of right and wrong lends itself to strong convictions in a way not seen in other human activities. The fundamental basis of resolution is discussion, enabling exposure of the values or interests that are in conflict. This may require a third party or mediator. Absolutist convictions such as 'sanctity of life' and absolutist terminology such as 'futility' impede conflict resolution and have to be unravelled.

There are several useful guidelines informing practice, particularly in relation to end-of-life decision-making. Individual practitioners should be aware of these and adapt them to local circumstances. Institution-based guidelines that conform to more overarching documents are probably most useful. Most learned colleges and professional societies now promulgate such practice guidelines in various forms.

Ethics committees have an important role in establishing frameworks for ethical practice. There is some evidence that formal ethics consultations improve end-of-life management but the principles utilised are those of open discussion and full disclosure that should inform normal bedside communication. Committees should normally have no individual decision-making role.

Recourse to legal processes may be essential but should be infrequent as the legal system does not cope well with the complexity of medical decision-making and is generally slow and ponderous. Practice should conform to legal norms, however, so long as these are not unethical.

# Common problems after ICU

Carl S Waldmann

Until recently, an intensive care unit (ICU) stay was deemed successful if a patient survived to go to the ward. No consideration was taken of the patient dying on the ward or soon after leaving hospital or indeed if the patient went home with an appalling quality of life.

Mortality figures for patients leaving our own ICU recently are shown in Figure 8.1.

A Kings Fund report<sup>1</sup> in 1989 concluded that it was necessary to look at the morbidity following critical illness as well as mortality: 'There is more to life than measuring death'.

Publications such as that of the Audit Commission (*Critical to Success*)<sup>2</sup> and that of the National Expert Group<sup>3</sup> (*Comprehensive Critical Care*) have supported the development of follow-up for patients following a stay in intensive care. In 2007, the National Institute for Clinical Excellence (NICE) began to take an interest in the rehabilitation of critically ill patients and it is hoped will make recommendations to facilitate the introduction of follow-up programmes in all hospitals looking after critically ill patients.

In Reading, a follow-up programme has been ongoing since 1993. Until recently the rehabilitation of patients after a critical illness has fallen between too many stools. Following multiorgan dysfunction, it is difficult to categorise a patient to an individual specialty such as cardiac, respiratory or the stroke rehabilitation teams. Family doctors often have difficulty taking on the complexity of these patients, with the result that they are denied vital advice and assistance and lack an advocate with 'teeth' to ensure timely help.

## SETTING UP A FOLLOW-UP SERVICE

Funding such a follow-up programme has posed local problems in many trusts. The service in Reading was initially approved and funded by local then regional audit committees.

The service is staffed by a follow-up sister who spends most of her time in this role helped by a staff nurse and an ICU consultant for the clinics held as a formal out-patient clinic 2/3 times monthly.

Patients who were in ICU for more than 4 days are seen in clinic at 2 months, 6 months and 1 year after discharge and, occasionally, we see patients who have been in ICU for a shorter time period and we also see referrals from other hospitals where follow-up isn't happening. It is important to identify clerical and IT support, and to achieve good collaboration with other hospital departments and general practitioners (GPs) to ensure patients do not make unnecessary journeys to the hospital, by trying to coordinate their visits and ensuring that transport is organised where necessary. Very often, patients will voluntarily come from long distances if they had initially been admitted from other geographical locations – out-of-area transfers.

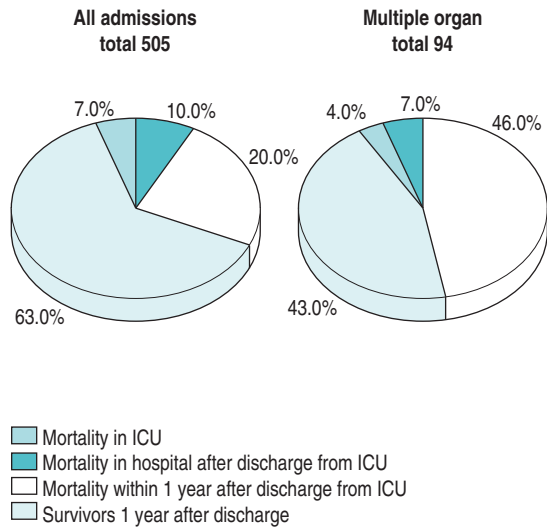

The logistics of running the service include arranging specific tests that may be required for the visit, such as pulmonary function tests, swabs for methicillin-resistant *Staphylococcus aureus* (MRSA), blood/urine for creatinine clearance. There may be special tests such as magnetic resonance imaging (MRI)<sup>4</sup> for patients who had a tracheostomy during their stay in ICU.

The service in Reading costs £30 000 annually which, in the context of the bigger picture (£4.5 million budget for our ICU), is a small price to pay (Figure 8.2). An unexpected bonus is that the clinic is often seen by the patients as a convenient place to make donations to the ICU.

## SPECIFIC PROBLEMS POST-ICU

The range of problems seen after intensive care is vast and ranges from nightmares and sleep disturbance through to ill-fitting clothes. Many of the problems are very specific to the individual but there are also recurrent themes. Flashbacks are common, as are taste loss, poor appetite, nail and hair disorders and sexual dysfunction.

There are several quality-of-life tools used in follow-up studies (Table 8.1). Objective measurements may be inappropriate because they look at aspects such as return to work: often, patients in their 50s may not return to work after a traumatic episode, including ICU, and subjective measures would be more applicable, such as Perceived Quality Of Life (PQOL).

**Figure 8.1** Mortality rates for leaving the intensive care unit (ICU).

**Figure 8.3** Assessment of long-term sequelae.

## TRACHEOSTOMY

Since percutaneous techniques performed by intensivists started to replace surgical tracheostomy in 1991, we have seen an increasing number of patients tracheostomised earlier in their ICU stay.

The long-term sequelae have been assessed by lung function tests, nasoendoscopy and MRI screening (Figure 8.3). There are minor cosmetic problems, such as

**Figure 8.4** Tethering.

tethering (Figure 8.4). Tethering is easily dealt with in ear, nose and throat outpatients under local anaesthetic.

More difficult to manage is tracheal stenosis, defined as a 15% reduction in tracheal diameter. However, there have only been two cases to date. These were seen in the first series of 30 cases.<sup>4</sup>

## MOBILITY

Even in the absence of trauma, patients can expect to need 9 months to 1 year to regain full mobility. This is usually due to a mixture of joint pain, stiffness and muscle weakness. In one study,<sup>10</sup> the duration of ICU stay was associated with mobility problems probably associated with loss of muscle mass. If questioned, patients will often

**Figure 8.5** Climbing and descending stairs.

report climbing stairs on all fours and descending on their bottoms (Figure 8.5). Muscle wasting can present as a severe localised problem.

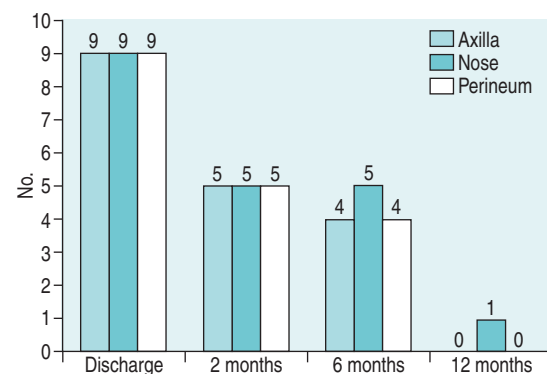

This may be associated with critical illness polyneuropathy (CIP),<sup>11</sup> which not only prolongs ventilatory weaning but frequently both complicates and delays rehabilitation. Muscle relaxants have been implicated in the development of CIP<sup>12</sup> but have not been shown to be statistically significant in terms of delayed weaning of intermittent positive-pressure ventilation and duration of stay in ICU.<sup>13</sup>

Until now, there have been no specific rehabilitation programmes for patients recovering from critical illness, although rehabilitation programmes for heart attack, stroke and respiratory disease are well established. A three-centre study has shown that a self-help physiotherapy guided rehabilitation exercise programme will speed up physical recovery after intensive care.<sup>14</sup>

It is important for a member of the team to try and spend time with patients at their homes to assess their special needs and liaise with the GPs, district nurses, community physiotherapists and occupational therapists.

## SKIN

Patients complain of a variety of non-specific disorders, including hair loss and nail ridging. Severe pruritus used to be common and not amenable to treatment and was traced back to the use of high-molecular-weight starch solutions in ICU. Described in 2000,<sup>15</sup> in 85 cardiac surgical patients, pruritus was absent in the 26 patients who did not receive starch, but there was a 22% incidence in the 59 patients who did receive starch. This is now supposedly less of a problem with the newer starches.

**Figure 8.6** Colonisation with methicillin-resistant *Staphylococcus aureus* (MRSA).

Colonisation with MRSA often persists for up to 9 months or longer (Figure 8.6). It is common to hear that patients are being treated as ‘lepers’ by their own family.

## SEXUAL DYSFUNCTION

Any patients who estimate their sex-life activity to be less active than before ICU admission are deemed to have sexual dysfunction.

In a group of 57 patients,<sup>16</sup> there was a 39% incidence of sexual dysfunction, although in 4 patients, sex life had improved. Sexual dysfunction improves with time, from a frequency of about 26% at 2 months post-ICU down to 16% at 1 year.<sup>17</sup> Sexual dysfunction is often thought to be a psychological problem but, interestingly, following

severe burns, it has been reported that there is no correlation between the incidence of posttraumatic stress syndrome and sexual dysfunction.<sup>18</sup> Nevertheless, withdrawing sexual intimacy because of fear of failure can damage relationships. Often sexual dysfunction may go untreated because people are too embarrassed to mention the problem when they have recovered from a life-threatening illness.

Sexual dysfunction affects both men and women. In men it usually manifests itself as impotence or inability to maintain an erection sufficient for satisfactory sexual activity. For management guidelines for erectile dysfunction, see Ralph and McNicholas.<sup>19</sup>

In investigating sexual dysfunction, it is important to eliminate causes such as the use of drugs e.g. L-dopa and H<sub>2</sub>-blockers and certain types of surgery (aortic aneurysm) or trauma/radiotherapy to the pelvic region. The patients may be diabetic.

Treatments available include intracavernous or transurethral alprostadil or oral Viagra. Patients with cardiovascular dysfunction have to be carefully assessed before being given Viagra. Non-pharmacological therapies include the use of vacuum devices and inflatable penile prostheses.

In females, sexual dysfunction may occur due to surgery or trauma to the pelvis. More commonly, there is a reduction in desire. Various lubricating gels can be used. As yet, the role of Viagra for women has to be determined. In 127 patients asked to fill in a questionnaire while attending the clinic, the incidence of sexual dysfunction was 45%.<sup>20</sup> There was no link with gender but there was a close association with posttraumatic stress disorder (PTSD).

### OTHER PHYSICAL PROBLEMS

A variety of other problems have been seen during follow-up:

- Visual acuity – particularly in patients who have been profoundly hypotensive, visual problems may occur. Occasionally ischaemic changes may be seen on fundoscopy (Figure 8.7a), which may be amenable to laser therapy (Figure 8.7b).
- Facial scarring, where the tape securing the endotracheal tube has been too tight. This scarring can be the whole thickness of the cheek.
- Unnecessary medication. Frequently medication started in ICU as a temporary measure may have been continued (e.g. amiodarone started for sepsis-related arrhythmias).

### PSYCHOLOGICAL PROBLEMS

Most patients admitted to ICU have no warning of their admission (emergency admission) and these are the patients who are very much at risk of psychological sequelae post-ICU.

The majority of patients do not have a structured memory of their ICU stay. Those who do may have upsetting memories which may be relatively innocuous,

Figure 8.7 (a, b) Ischaemic changes in fundoscopy.

such as being thirsty and hearing a can of Coke being opened, or of a far more profound nature.

The story of ‘torture’ experiences is not unusual when you talk to an ex-ICU patient. The psychological impact of the experience may be formidable and may be resented by the patient. The memory of hearing that a patient is about to be ‘bagged’ was interpreted as being put into a body bag rather than a physiotherapy manoeuvre and the use of a tape measure was interpreted as being measured for a coffin and not as part of the cardiac output measurements. Previous studies demonstrate a high incidence of anxiety, depression and posttraumatic stress.<sup>21</sup> It is common for patients to have memories of being trapped, of being unable to move easily, of being unable to see what is happening and of feeling intensely vulnerable. The anxiety of impending death is also reported.

Below is a typical nightmare of one of our patients:

*I was in a tunnel knee-deep in mud. It was pitch black, but I could see light at the end. I felt a cold chill on my neck as if someone was breathing down my neck. I thought it was the grim reaper, I knew I had to get to the light.*

There may be several reasons for these experiences (Table 8.2). There is a common belief that, when on ICU, it is better that a patient does not remember anything. However, it is increasingly realised that false memories or delusions during an ICU stay can have a

**Table 8.2** Psychological problems

Illness
Sedation technique
Withdrawal
No communication aids
Lack of clear night/day
Continuous noise of alarms
Sleep disturbance – lack of rapid-eye-movement sleep

significant impact on psychological recovery after ICU<sup>22</sup> and factual memories of ICU may reduce anxiety.<sup>23</sup>

It now seems likely that delusional memories of ICU and nightmares are associated with PTSD.

PTSD is a normal reaction to severe stress and is similar to a grief reaction to bereavement. It occurs in about 1% of the population and increases to 10% in victims of road traffic accidents and 65% in prisoners of war. About 15% of patients have the typical disorder post-ICU. In those with adult respiratory distress syndrome, the incidence increases to 27.5%.

PTSD is the development of characteristic symptoms after being subjected to a traumatic event. PTSD can be triggered by any memory or mention of something to do with the traumatic event and is characterised by intrusive recollections, avoidance behaviour and hyperarousal symptoms.<sup>24</sup>

Chronic fatigue syndrome (CFS), previously known as myalgic encephalitis (ME), is thought to describe the condition of many patients post-ICU who have had a period of prolonged inactivity. CFS is diagnosed by the presence of fatigue at 6 months post-ICU with impairment of daily living, social and leisure pursuits and with no medically significant cause of the fatigue. There is no doubt that a graded exercise programme is of benefit to aid physical recovery in such ICU patients.<sup>14</sup> Drugs such as fluoxetine (Prozac) do not seem to benefit such patients, even though there is a great temptation to use antidepressants in these patients.<sup>25</sup>

Various strategies to deal with the psychological sequelae of ICU stay have been tried.

#### DURING ICU STAY

- There is no doubt that continuous intravenous sedation has been identified as an independent predictor of a longer duration of mechanical ventilation, ICU stay and total hospital stay.<sup>26</sup> Kreiss *et al.*<sup>27</sup> demonstrated that, in 128 adults, ICU stay was reduced from an average of 7.3 to 4.9 days by the daily interruption of the sedative regime. This regime may have had an impact by reducing PTSD as the patients are more likely to have some recollection of their ICU stay, thus helping them to understand the reasons for the need for their prolonged rehabilitation period. Concerns have been raised as to the type of sedative agent used in ICU. It is well known that etomidate may cause an excess in mortality in trauma patients in ICU<sup>28</sup> and

propofol may do the same in head-injured patients at doses greater than 5 mg/kg per h.<sup>29</sup> The decision to use benzodiazepines such as midazolam increasingly may be associated with dependence. This has been studied; 21 out of 148 ICU patients were discharged home on oral benzodiazepine, of whom 10 were still taking them at 6 months post-discharge having not been on them pre-ICU.<sup>30</sup> Lorazepam has been promoted as the benzodiazepine of choice for sedation in ICU<sup>31</sup> and is preferred by a task force in the USA for adult patients in ICU.<sup>32</sup>

- Encouraging the use of communication aids, involving speech therapists particularly in patients with tracheostomies<sup>33</sup> and training more nurses to lip-read can be invaluable.
- When building or modifying ICUs, remember that windows and 24-hour clocks visible to patients may help re-establish circadian rhythms and the use of curtains to ensure patient dignity should not be forgotten. There has been some interest in appropriate colours that should be used in ICU décor, avoiding colours that cause alarm in the animal kingdom, such as red, yellow and black.
- Use of aromatherapy and massage whilst patients receive their ICU does seem to reduce stress levels and encourages contact between the patient and relatives, reducing the feeling of isolation.<sup>34</sup>

#### POST-ICU DISCHARGE

Visiting patients on the ward post ICU discharge and giving them an information booklet helps to prepare them better for the long rehabilitation process ahead.

As well as three ICU follow-up clinic appointments in the year after their discharge, patients with PTSD are encouraged to visit the ICU and, with the help of a diary, reconstruct the lost period of time in the patient's life. We are considering the use of photos of patients whilst they are on ICU to help them understand how ill they actually were.

#### CONCLUSION

It is important to assess patient satisfaction or dissatisfaction with their follow-up. This may be audited by questionnaire during their third visit to the follow-up clinic at 1 year post ICU discharge.<sup>35</sup>

The findings have been reassuring. The response rate was 87 out of 88 patients and all but one of the 87 patients found benefit from the clinic, particularly because questions could be answered (often their GP could not help). Other findings are as follows:

- 28% benefited from referral to other specialists
- 26% had PTSD counseling
- 25% felt they derived some benefit from returning to the ICU and having a diary written for them
- 48% felt they were helping the staff of the ICU

The comments were very useful, e.g.:

- 'You helped me retrace the time lost whilst under sedation'
- 'It was frightening leaving ICU to go back to the ward. My wife slept next to me in the ward on a mattress on the floor'

There is no end to the surprises and unexpected problems that arise in patients after intensive care. It is not unusual to see patients who were initially deemed inappropriate for surgery and ICU who have done well and who on questioning have an excellent quality of life. It is only by the ICU specialists undertaking to follow up patients that we can assess the appropriateness of our decision-making and treatments.

In the UK follow-up clinics were recommended by the Audit Commission in 1999 (*Critical to Success*)<sup>2</sup> and in the *Comprehensive Critical Care* document in 2000<sup>3</sup>, yet only a small number of hospitals have been able to fund such a service. Griffiths *et al.*<sup>36</sup> demonstrated that clinics are not widely established and show marked heterogeneity. Of those established, only two-thirds are funded and most do not have a prenegotiated access to other outpatient services. It is hoped that NICE will support their growth and that the National Outreach Forum will support the idea that follow-up will be one of the quality indicators of a hospital's resolve to set up a comprehensive service for patients who have been critically ill. Meanwhile there is an exponential increase in literature related to outcome following critical illness as health economists and intensivists try and make some sense out of the cost-effectiveness of intensive care.<sup>37-40</sup> Further studies are under way. The DiPEX study seeks to obtain a variety of patient and relative experiences of critical care ([www.dipex.org](http://www.dipex.org)). I-CANUK is a website that is being set up to provide a forum and voice for those involved in patient care following intensive care discharge and to support research into potential therapies following critical illness. The results of the PrACTICaL (Pragmatic Randomised Controlled Trial of Intensive Care Follow-up clinics in improving longer-term outcomes trial from critical illness) should be available by the end of 2008.

# Clinical information systems

David Fraenkel

Clinical record-keeping requires an integrated system to manage the information, including its acquisition during clinical care, and archiving and availability for future clinical, business and research uses.

The term 'clinical information systems' (CIS) refers to computerised systems for managing the clinical record, often within specialised areas of a hospital, such as intensive care, emergency medicine, operating theatres or cardiology. CIS for intensive care units (ICUs) have been developing since the late 1980s; however, their implementation has been limited by cost, functionality and clinician acceptance.<sup>1-8</sup>

The electronic medical record (EMR) and electronic health care records (EHR) embrace respective hospital and community-wide electronic systems for managing patient records which may be integrated with the more specialised CIS. Over the next decade we can expect to see EHR implementation throughout the health systems of the more developed nations. The driving incentive is community concern for safety and quality in health care and the EHR is the single most powerful measure to produce a safer, more effective and efficient health care system.<sup>8-12</sup>

In the UK the National Health Service (NHS) has embarked on an ambitious National Programme for Information Technology (NPFIT) featuring a national summary care record (SCR) or 'spine' to hold limited essential information on each consenting patient. Additional features include picture archiving and communication systems (PACS), more detailed data held on integrated local computer systems, electronic prescribing and computerised physician order entry (CPOE).<sup>13,14</sup>

The US government has placed a high priority on electronic health records, although progress will be uneven due to the fragmented nature of its health system. The Veterans Health Administration (VHA) has a system-wide EHR (VistA) that is closely integrated with its quality monitoring and enhancement programme and is delivering tangible results.<sup>15-17</sup> Similarly, the Partners HealthCare System at the Brigham and Women's Hospital and Massachusetts General Hospital has demonstrated real improvements in health care with cost and quality benefit outcomes.<sup>18-21</sup>

The coordination of effort in Europe will be similarly challenging, although the need is recognised by the

European Commission. In Australia, the HealthConnect strategy is largely focused on broadband connections for primary health care providers and establishing data dictionaries and standards with limited strategies or funding for actual implementation of EHRs.<sup>22</sup>

## FUNCTIONS AND ADVANTAGES OF CIS

CIS seek to deliver several key benefits (Table 9.1).<sup>23</sup> These include the automation of repetitive manual tasks, improved accuracy through reductions in human error, attributable records simultaneously available from multiple points of care and integration with other bedside equipment and information systems. The built-in error checking and knowledge-based systems should also provide a safer and higher-quality clinical process. The CIS electronically capture the data and make this information potentially available to a multitude of systems. This obviates the need for repetitive manual data entry or transcription, while making the data accessible for a range of purposes which may include clinical, business and research reporting.

The ICU is already a technology-rich environment, where bedside devices process and provide data elements in electronic format. Similarly, many clinical measurements are available on monitors, ventilators and pumps. Traditionally, these electronically derived values are transcribed on to observation charts and paper-based clinical records, as are repetitive clinical observations and arithmetic calculations which are often performed manually or with the aid of a calculator. The voluminous observation charts present a challenge for both storage and access, and transcription errors and arithmetic errors are prolific in these paper systems.

The CIS automates the process of electronic data collection from monitors, ventilators, infusion pumps, dialysis/filtration equipment, cardiac assist devices and other bedside devices and provides a real-time spreadsheet with arithmetic accuracy. Incorporation of clinical documentation and progress notes provides a legible and attributable record of events.

The patient record can then be accessed from geographically distant workstations in the ICU, the hospital,

**Table 9.1** Clinical information systems (CIS) benefits

1. Recording of bedside observations
  - (a) Automation of physiological data collection
  - (b) Reduction in transcription and arithmetic errors
  - (c) Downloading from bedside therapeutic devices (e.g. pumps, ventilators)
2. Clinical documentation
  - (a) Legible and attributable clinical record
  - (b) Structures and cues encourage comprehensive documentation
  - (c) Electronic record of drug prescription and administration
  - (d) Attributable record simultaneously available from multiple points of care
3. Access to additional clinical information at the bedside
  - (a) Pathology results
  - (b) Digitised medical imaging and reports
  - (c) Digital clinical photographs
  - (d) Other hospital systems (e.g. admission/discharge/transfer (ADT), CIS)
4. Bedside decision support systems
  - (a) Passive
    - (i) Improved and accessible clinical record
    - (ii) Online clinical policies and procedures
    - (iii) Online knowledge bases
    - (iv) Online literature searches
  - (b) Active
    - (i) Investigative and therapeutic management algorithms
    - (ii) Clinical pathways
    - (iii) Drug allergy and interaction alerts
    - (iv) Drug dosing and monitoring support
    - (v) Antibiotic selection and prescribing
    - (vi) Ventilation and haemodynamic management systems
5. Medicolegal archiving
  - (a) Audit trail for all changes during episode of care
  - (b) No ability to change once archived
  - (c) Secure long-term storage and ensured availability
6. Clinical database
  - (a) Long-term accessible storage of relevant clinical data
  - (b) Industry-standard database format
  - (c) Efficient and flexible query and reporting solutions
  - (d) Scheduled and ad hoc reports
  - (e) Clinical, research and management requirements

and even from other more remote sites. As long as the system is running, the record is easy to locate and always available.

A major contribution of CIS to clinical safety and quality is through the provision of an electronic prescribing and administration record for drugs and fluids. Errors in prescription and administration are a leading cause of adverse events with associated morbidity.<sup>18,24</sup> CIS provide both legibility and varying levels of decision support which may include defining usual dosages and administration routes, suggesting dose modification in the setting of

organ failures, or preventing prescribing in cases of known allergy or likely drug interaction.<sup>25</sup>

## ARCHITECTURE AND COMPONENTS OF CIS

### BASIC CIS ARCHITECTURE

All CIS share certain basic components consisting of workstations, a network and central servers (Figure 9.1). The user interface is presented at the workstation, which is usually at each bedside but may also be in nearby central and administrative areas, such as the nurses' station, or more distant in the offices of clinical or administrative staff. Workstations commonly consist of relatively standard personal computer (PC) hardware being desk-, pendant or trolley-mounted, but may include laptops or personal digital assistants (PDAs) with wireless systems where technical challenges related to speed and reliability of data transmission can be overcome.

Most CIS allow other applications, such as PACS, word processing or e-mail, to be run on the same PC, but this is potentially a rich source of system conflicts and requires careful administration.

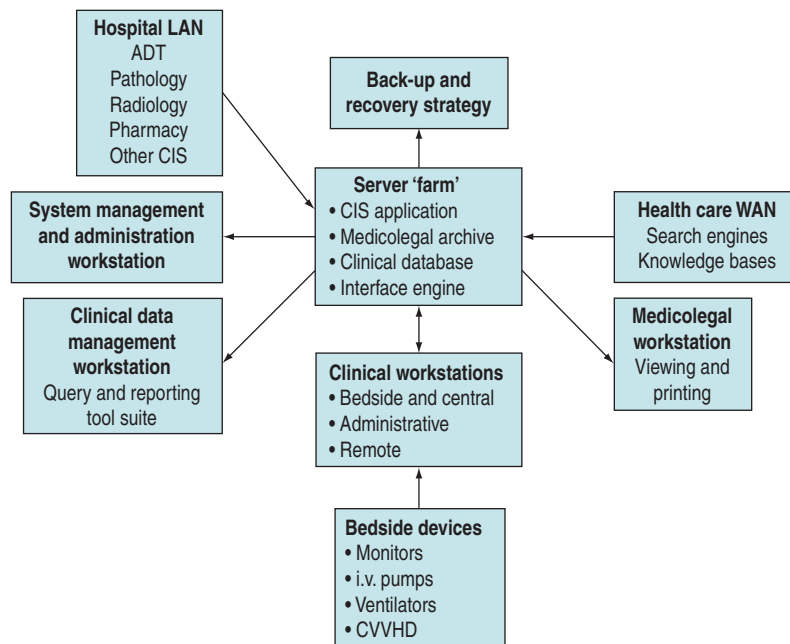

Workstations are linked to each other and a centralised set of servers through a network of communication cables. Hubs, switches and routers control network traffic. A dedicated network, either actual or virtual, enhances system performance but it is important to ensure built-in redundancy in network loops and power sources to minimise potential interruptions from physical disruption or component failure.

The configuration of computer servers varies widely but it is common to have 'paired' or 'mirrored' servers, which duplicate their partner's function. This provides protection from hardware failure, minimising system down time, and provides some degree of data protection. Servers have a finite capacity to process data from multiple workstations and other peripheral connections, and so larger systems may require multiple server pairs.

CIS usually require a separate workstation or server to manage the interfaces with other systems. These include hospital demographics (ADT systems for admission/discharge/transfer), pathology laboratory, pharmacy, radiology and hospital finance. Interfacing requires a software platform known as an interface engine. Additional software identifies the relevant data and directs and processes these data to the correct field in the appropriate format. Due to the huge variety of current and legacy systems, this process almost always requires custom-written code and programming, representing one of the major risks and expenses of systems integration.<sup>13</sup>

Bedside monitoring systems usually include a central station or server that can be linked with the CIS servers to transfer their downloaded information back to the bedside. Transferring data from other bedside devices is usually achieved by a cable connection from the device to a bedside concentrator in the patient bay. The connection requires an electronic decoder, specific to the

**Figure 9.1** Clinical information systems architecture. LAN, local area network; WAN, wide area network; ADT, admission/discharge/transfer; CVHD, continuous venovenous haemodialysis.

manufacturer and model of the device. The concentrator must then communicate with the central servers via a subsidiary server that provides the software translator to complete the interface. A selection of established interfaces to commonly utilised equipment exists but often additional customised interfaces must be written.

### MEDICOLEGAL STORAGE

Electronic data capture does not necessarily result in long-term electronic data storage. Many CIS sites have continued to require the printing-out of all reports from the patient episode to store in the paper-based hospital medical record. Modern servers have extensive storage capacity but this can be rapidly consumed by the equally enormous amount of data being collected from every patient. Some server pairs can only hold 2–3 months of data before data begin to be purged or overwritten. Although hard-disk memory is ever-increasing and more affordable, additional strategies such as more efficient databases or offline storage formats may be needed. When the choice of storage solution is made, it is equally important to be aware that the format of data storage is determined by the anticipated use of the data and to ensure that future software upgrades do not render the stored data unreadable.

Data archiving for medicolegal purposes requires that the clinical information be readily accessible and preferably presented in exactly the same format as it was recorded and reviewed by the clinicians during the episode of patient care. Any changes to the clinical record during the patient episode must be clearly displayed

and attributable – this is known as an audit trail or change history. An audit trail is a standard feature of most CIS and actually offers improved accountability over paper-based systems. It may be desirable to make it impossible to alter the record after the patient episode, which requires specialised storage formats or strict access restrictions to the data archive.

Once the record is stored, by whatever method, it must be protected from accidental loss. This usually requires a carefully engineered and documented management plan with regular scheduled back-ups, off-site storage of duplicates and robust recovery strategies. When these requirements are fulfilled, the electronic medicolegal archive can readily exceed the performance of a paper-based record through its assured availability and authenticity.

### CLINICAL DATABASE STORAGE

A major objective of CIS is to provide a comprehensive clinical database which will accumulate data in real time that can be stored and queried for a wide range of reports for a variety of purposes. The relevant data need to be held in an accessible and readily searchable database that will allow a variety of sophisticated reports to be prepared on both a scheduled and ad hoc basis. These requirements are quite different from those of medicolegal storage and usually require a separate form of data storage, commonly known as a clinical database, data repository, data warehouse or data management solution.

It may be desirable to adopt a significantly different database structure from the core CIS database

which may have been designed with prospective user configurability in mind, rather than allowing easy location of data fields in a structure designed for rapidly processing queries. The design of the clinical database is a compromise between saving effectively the large amount of data collected while maintaining speed and ease of use in running queries. Even when the vendor has utilised an industry-standard database application, such as Oracle or SQL, in the core CIS application, designing and running queries may still present a challenging specialist task because of the complexity of the table structure or the huge amount of aggregated data.

The clinical data management solutions currently offered are quite diverse. One solution simply provides an industry-standard data transfer protocol (e.g. 'ODBC driver') as a means of accessing the data. The local circumstances of each hospital then dictate customised queries or secondary database designs for local use. Alternatively, an industry-standard query tool is used to generate reports from the core CIS database, but the number of queries that can be designed and preconfigured in this fashion is often limited, particularly as the user configurations of the CIS vary widely. There is inevitably a compromise between standardisation and flexibility. Data fields must be standardised in the configuration of the CIS to allow standard queries to be performed. Some CIS solutions offer a proprietary subsidiary database containing selected clinical data with a wider range of reports preconfigured into the query tool.

#### EVALUATION AND IMPLEMENTATION OF CIS

Clinicians frequently underestimate the managerial requirements, human resource demands and opportunity costs of CIS implementation.<sup>11</sup> The process should be viewed as a major project requiring advanced planning and management skills (Table 9.2). The project team must be multidisciplinary, consult widely and consider workplace flows and processes, or else a suboptimal result is guaranteed, as has been demonstrated in the literature.<sup>26,27</sup> The CIS will impact on medical, nursing, allied health, managerial and technical staff within the ICU, together with those from other clinical disciplines. Involvement of hospital information management and medical records staff is strongly recommended. Extensive documentation and continued scheduled reviews are required throughout the process.

Business case development to secure funding is less problematic than previously and assisted by the quality benefits of CIS implementation.<sup>11,21</sup> The most basic system can be expected to cost in the order of AUD \$25 000–50 000 per bed, while more advanced systems may be two to three times that cost. Annual recurrent costs are significant and usually exceed 20% of the capital cost of the system.

The CIS industry is subject to the same vagaries as other parts of the IT industry, including high turnover of personnel and frequent inability to deliver on promised functionality and timelines. CIS selection is best conducted

**Table 9.2** Clinical information systems (CIS) implementation

1. Professional project management
  - (a) Structured multidisciplinary team
    - (i) Sponsor, director, manager, representatives
    - (ii) Medical, nursing, allied health, managerial
  - (b) Comprehensive documentation
  - (c) Consultative approach
    - (i) Medical records department
    - (ii) IT/IM department
    - (iii) Hospital and business managers
2. Project framework
  - (a) Needs analysis
  - (b) Definition of scope
  - (c) Management of expectation and scope creep
3. Tender evaluation (see Table 9.3)
4. Implementation process
  - (a) Implementation plan and schedule
  - (b) Training
  - (c) Installation
  - (d) Schedule of payments
  - (e) Quality monitoring of process
5. Postimplementation review
  - (a) Actual outcomes of plan
  - (b) Unresolved issues
  - (c) Process improvement
6. System management plan
  - (a) Identification of system components
  - (b) Departmental and individual roles and responsibilities
  - (c) Identification of vendor responsibilities
  - (d) Back-up schedules and recovery plans
7. Support contracts
  - (a) Scope and level of support
  - (b) Pricing
8. Future issues
  - (a) Ongoing management of 'special projects'
  - (b) Continued development and innovation
  - (c) System upgrades
  - (d) Scheduled hardware replacement
  - (e) System obsolescence and replacement

as a formal tender process, and the evaluation of submissions is a complex task (Table 9.3). Availability and expense of on-site support during and following implementation are also critical factors.

Implementation planning should be detailed and requires a full-time project officer on site. A standard implementation needs 4–6 months prior to the 'go live' date with hospital-wide consultation, issue management and carefully scheduled staff training. It is desirable to have as many as possible of the interfaces and bedside devices linked to the CIS at the implementation date. This will maximise perceived benefits early and thereby encourage acceptance of the system. It should be implemented through the whole ICU as partial implementations are rarely successful.

Post-implementation review is essential to progress outstanding issues, which are usually prolific, and help establish

**Table 9.3** Clinical information systems (CIS) evaluation

1. Vendor characteristics
  - (a) Monitoring of software experience
  - (b) Niche specialty products, cf. health care-wide
  - (c) Development base by specialty and geography
2. Preliminary evaluation
  - (a) Evaluate tender documents
  - (b) Product demonstration
  - (c) Prepared and impromptu scenario testing of product
  - (d) Ensure all required components identified, e.g. database, interfaces, etc.
  - (e) Comparative levels of best fit for needs and specifications
3. Site visits to installed customer base
  - (a) Reference sites and 'sites like us'
  - (b) Demonstrations with vendor
  - (c) Candid visits without vendor
  - (d) Observe functionality
  - (e) Examine interfaces
  - (f) Explore support issues
4. Interfaces
  - (a) Identify requirements
  - (b) Assess vendor capabilities
  - (c) Inspect working interfaces
  - (d) Customisation scope and cost
5. Technical issues
  - (a) Industry-standard hardware and software
  - (b) Local acceptability
  - (c) Integration with existing systems
  - (d) Upgrade paths
  - (e) Network specifications
  - (f) Network costs and management
6. Support issues
  - (a) Location and availability
  - (b) Product support specialists
  - (c) Technical engineers
  - (d) Level of risk-sharing
  - (e) Whole-of-life costing

the arrangements for the support and continued development of the system. A system management plan identifies the responsibility centres for management of the CIS components and clarifies requirements and expectations. A permanent on-site system management position is required for system maintenance, progressing outstanding issues and managing future upgrades and developments.

#### BENEFITS OF CIS: THE STATE OF THE ART

Basic CIS requirements are fulfilled by the majority of systems currently available:

- Charting, including tabulation of bedside observations and measurements such as fluid balance. The flow sheets are usually more than adequately flexible and configurable to meet local requirements.
- Bedside device interfaces. New devices may not have the necessary decoders and software. The expense of developing new interfaces can be considerable when calculated on a per-bed basis.
- Clinical progress notes. These are adequate but the free text may not be 'searchable', and structured text may be only marginally better.
- Keyboard skills are increasingly widespread but may still be an issue with some clinicians.
- Drug and fluid prescription and administration are good but not always incorporated in some systems, necessitating a separate system.

Decision support systems have previously been disappointing but their further development offers substantial benefits.<sup>25,28</sup> A legible and available record of previous and ongoing care does offer an improved level of decision support, albeit one that the general community would already expect and see as mandatory. Passive decision support with access to knowledge-based systems through CIS and hospital intranets, as well as resources such as pharmacopoeia, literature search engines and online texts and journals, is widely available. It is intuitive that these resources would improve the quality of clinical outcomes; but there is little evidence to support this.

Active decision support has not been generally available, including the flagging of drug allergies and interactions and the integration of relevant information, such as baseline renal function, recent urine output, last measured creatinine and required dose of aminoglycoside. Decision support systems to recommend antimicrobial prescribing, ventilatory therapy or haemodynamic measurement have been developed in dedicated centres of excellence, but are also not generally available nor necessarily able to be migrated successfully across boundaries of international practice. The provision of prompts has been shown to be effective for routine prophylaxis and care processes, supported by clinical pathways and guidelines.<sup>19,29</sup> Increasing emphasis on decision support from safety and quality initiatives may be expected to accelerate developments.

CPOE is exemplified in electronic prescribing, but its benefits extend to other areas such as pathology and radiology orders and results viewing. There is good evidence that a reduction in ordering occurs through reduced duplication and timeliness and access to results.<sup>25,28</sup> The availability of CPOE (computerised physician order entry) varies with the level of systems integration and compatibility with other legacy and proprietary computer systems. Standardised communications protocols (e.g. HL-7) are helpful but only provide similarities of electronic language. High-level interfaces require continued maintenance and development and therefore expenditure. Other solutions include seamless and simultaneous operation in multiple systems (Clinical Context Object Workgroup) or placing all data in a single repository for access by multiple applications.<sup>13</sup>

Clinical databases remain a significant challenge, whether at a local departmental, hospital, regional or national level.

Although many products are purported to include data management and query solutions, those that are available 'off the shelf' may be quite rudimentary and their development may require additional expenditure and a major commitment from the clinical staff. Part of the problem is the need for clinicians to define prospectively what is expected of the system. This requires exhaustive definition of the questions that the system should be able to answer and therefore also specification of the detailed nature of the data and queries that will be required.

Accurate analysis of diagnoses and procedures requires that key information is entered correctly and consistently and that reliable and high-quality data capture is achieved. Data entry should be 'once-only', simple and robust, and should be easily performed as the clinical scenario unfolds. There is very limited agreement and standardisation between clinicians with respect to mandatory data fields, diagnostic criteria and classifications. Standardised reports are therefore difficult to develop in different clinical environments, let alone regions or countries. The eventual adoption of common international standards and classifications (e.g. SNOMED for diagnoses, National Library of Medicines for pharmaceuticals) would greatly facilitate solution design and querying. Other issues, including the speed of data access in huge data repositories, the development of unique patient/episode identifiers and privacy considerations, are still significant.

#### FUTURE DEVELOPMENTS

Over the next decade the EHR will provide the most significant and comprehensive improvement in the delivery of health care in developed nations. Central clinical repositories will probably initially hold sentinel data for consenting patients such as identifiers, past and present diagnoses, medications and allergies. More detailed data will be held in peripheral repositories where the challenge is ensuring appropriate accessibility and/or systems integration. The use of CIS with active decision support and computerised order entry will be an integral part of delivering and monitoring improved patient care. Despite requiring huge levels of investment, these developments are happening now and should include clinical involvement and leadership to realise and maximise their benefits.

# Clinical trials in critical care

Simon Finfer and Anthony Delaney

*Evidence based medicine is the conscientious, explicit, and judicious use of current best evidence in making decisions about the care of individual patients. The practice of evidence based medicine means integrating individual clinical expertise with the best available external clinical evidence from systematic research.<sup>1</sup>*

The most reliable evidence, and thus the best evidence for guiding clinical practice in critical care, will generally come from adequately powered and properly conducted randomised clinical trials (RCTs). It is commonly the case, however, that there are no individual RCTs that adequately address a particular question, and so clinicians may have to assess the ability of other studies such as cohort studies, case-control studies and systematic reviews to supplement their clinical expertise. It is important that clinicians are familiar with the underlying principles and potential sources of bias in each of these study designs, so that they can incorporate evidence from reliable trials into their clinical practice and treat with appropriate caution those studies whose design makes it possible that they will produce unreliable results.

## RANDOMISED CLINICAL TRIALS

The result of any clinical trial may be due to three factors:

1. a true treatment effect;
2. the effects of bias or confounding; or
3. the play of chance.

RCTs, when properly designed, conducted and analysed, offer the optimal conditions to minimise bias and confounding, and to define the role that chance may have played in the results. As such, they represent the best study design to delineate true treatment effects under most circumstances. However, it is imperative that RCTs are designed, conducted, analysed and reported correctly. Studies that have not adhered to the principles outlined below still may produce results that do not reflect a true estimate of treatment effects.

## THE QUESTION TO BE ADDRESSED

Every trial should seek to answer a focused clinical question that can be clearly articulated at the outset. For

example, ‘we sought to assess the influence of different volume replacement fluids on outcomes of intensive care patients’ is better expressed as the focused clinical question ‘we sought to address the hypothesis that when 4 percent albumin is compared with 0.9 percent sodium chloride (normal saline) for intravascular-fluid resuscitation in adult patients in the ICU, there is no difference in the rate of death from any cause at 28 days’.<sup>2</sup> The focused clinical question defines the interventions to be compared, the population of patients to be studied and the primary outcome to be considered. This approach can be formalised using the PICO system. PICO stands for patient, intervention, comparison and outcome. In the example above:

- Patient – adult intensive care unit (ICU) patient
- Intervention – albumin
- Comparison – saline
- Outcome – 28-day all-cause mortality

The question that a trial is designed to address will vary somewhat depending on the stage of development of the proposed treatment. After development and testing in animal models, the testing of pharmaceutical agents in humans is generally conducted in three phases. Sometimes a fourth phase is added:

1. Phase I trial – testing in healthy volunteers
2. Phase II trial – first testing in population of patients with disease to be modified. Usually small trials focused on establishing safety and evidence of efficacy using surrogate outcome measures. Phase II trials provide an estimate of treatment effect and baseline outcomes which can be used to calculate the sample size for phase III trials
3. Phase III – large-scale trial in patients that is powered to determine the effect of the treatment on the primary outcome of interest.
4. Phase IV – postmarketing open label trials to confirm efficacy and safety profile once the agent is introduced into routine clinical practice

Trials may be designed to answer two quite different questions about the same treatment and the design will be quite different depending on the questions to be answered. An *efficacy trial* seeks to determine whether a treatment will work under optimal conditions whereas

an *effectiveness trial* seeks to determine the effects of the intervention when applied in normal clinical practice. For a detailed comparison of the features of efficacy and effectiveness trials, please see Hebert *et al.*<sup>3</sup>

### POPULATION AND SAMPLE SIZE

The population to be studied will be defined by the study question. Efficacy trials may have a very narrowly defined population, with strict eligibility criteria and many exclusion criteria, whereas effectiveness trials are likely to have more broad inclusion criteria and few exclusion criteria. In any case the population included in the study should be well described. This will allow readers to assess the scientific merit of the study. It also allows clinicians to judge whether the results of the study could apply to their patients, to assess the generalisability of the results. Trials that look only at a very narrowly defined population may also face difficulties in recruiting sufficient participants to reach a definitive conclusion.

How large do trials need to be to reach a definitive conclusion? In a parallel-group trial the number of patients required to answer a question depends on four factors:

1. The percentage of patients expected to have the outcome in the control group – the control group outcome rate
2. The expected change (usually reduction) that may result from the treatment being tested – the treatment effect
3. The level of probability to be accepted to indicate that the difference did not occur by chance, i.e. the probability level at which a treatment effect will be deemed to be real – significance level or  $\alpha$  (alpha)
4. The desired percentage chance of detecting a clinically important treatment effect if one truly exists (power)

It is clear that many published trials addressing issues of importance in intensive care medicine are too small to detect clinically important treatment effects;<sup>4</sup> fortunately

this is now changing.<sup>2,5</sup> This has almost certainly given rise to a significant number of false-negative results (type II errors). Type II errors result in potentially beneficial treatments being discarded. In order to avoid these errors, clinical trials have to include a surprisingly large numbers of participants. Examples of sample size calculations based on different baseline incidences, different treatment effects and different power are given in Table 10.1.

### RANDOMISATION AND ALLOCATION CONCEALMENT

Two components of the randomisation procedure are critically important. The first is the generation of a truly random allocation sequence; modern computer programs make this relatively straightforward. The second is the concealment of this allocation sequence from the investigators, so that the investigators and participants are unaware of the treatment allocation (group) prior to each participant entering the study.

There are a number of benefits of using a random process to determine treatment allocation. Firstly, it eliminates the possibility of bias in treatment assignment (selection bias). In order for this to be ensured, both a truly random sequence of allocation must be produced and this sequence must not be known to the investigators prior to each participant entering the trial. Secondly, it reduces the chance that the trial results are affected by confounding. It is important that, prior to the intervention in a RCT being delivered, both groups have an equal chance of developing the outcome of interest. A clinical characteristic (such as advanced age, gender or disease severity, as measured by Acute Physiology, Age and Chronic Health Evaluation (APACHE) or Sequential Organ Failure Assessment (SOFA) scores) that is associated with the outcome is known as a confounding factor. Randomisation of a sufficient number

**Table 10.1** Examples of sample size calculations

Control group outcome rate (%)	Treatment group outcome rate (%)	ARR	Power ( $\beta$ )	Total sample size
50	30	20	80	206
50	30	20	90	268
30	15	15	90	348
30	20	10	90	824
30	25	5	90	3428
15	10	5	90	1914
15	12	3	90	5582
10	8	2	80	6626
10	8	2	90	8802

ARR, absolute risk reduction.

All calculations performed with STATA 8.2, assuming a two-sided  $\alpha = 0.05$ .

of participants ensures that both known and unknown confounding factors (for example, genetic polymorphisms) are evenly distributed between the two treatment groups. The play of chance may result in uneven distribution of known confounding factors between the groups and this is particularly likely in trials with fewer than 200 participants.<sup>6</sup> The third benefit of randomisation is that it allows the use of probability theory to quantify the role that chance could have played when differences are found between groups.<sup>7</sup> Finally, randomisation with allocation concealment facilitates blinding, another important component in the minimisation of bias in clinical trials.<sup>8</sup>

The generation of the allocation sequence must be truly random. There are a number of approaches to generating a truly random allocation sequence, most commonly using a computer-generated sequence of random numbers. More complicated processes where randomisation is performed in blocks or is stratified to ensure that patients from each hospital in a multicentre trial or those with certain baseline characteristics are equally distributed between treatment groups can also be used. Allocation methods based upon predictable sequences, such as those based on medical record numbers or days of the week do not constitute true randomisation and should be avoided. These methods allow researchers to predict to which group participants will be allocated prior to them entering the trial; this introduces the possibility of selection bias.

Whatever method is used to produce a random allocation sequence, it is important that allocation concealment is maintained. Methods to ensure the concealment of allocation may be as simple as using sealed opaque envelopes,<sup>9</sup> or as complex as the centralised automated telephone-based or web-based systems commonly used in large multicentre trials. Appropriate attention to this aspect of a clinical trial is essential as trials with poor allocation concealment produce estimates of treatment effects that may be exaggerated by up to 40%.<sup>10</sup>

## THE INTERVENTIONS

The intervention being evaluated in any clinical trial should be described in sufficient detail that clinicians could implement the therapy if they so desired, or researchers could replicate the study to confirm the results. This may be a simple task if the intervention is a single drug given once at the beginning of an illness, or may be complex if the intervention being tested is the introduction of a process of care, such as the introduction of a medical emergency team.<sup>11</sup> There are two additional areas with regard to the interventions delivered in clinical trials that require some thought by those conducting the trial and by clinicians evaluating the results, namely blinding and the control of concomitant interventions.

### BLINDING

Blinding, also known as masking, is the practice of keeping trial participants (and, in the case of critically

ill patients, their relatives or other legal surrogate decision-makers), care-givers, data collectors, those adjudicating outcomes and sometimes those analysing the data and writing the study reports unaware of which treatment is being given to individual participants. Blinding serves to reduce bias by preventing clinicians from consciously or unconsciously treating patients differently on the basis of their treatment assignment within the trial. It prevents data collectors from introducing bias when recording parameters that require a subjective assessment, for example pain scores and sedation scores or the Glasgow Coma Score. Although many ICU trials cannot be blinded, for example, trials of intensive insulin therapy cannot blind treating staff who are responsible for monitoring blood glucose and adjusting insulin infusion rates, the successful blinding of the Saline versus Albumin Fluid Evaluation (SAFE) trial demonstrated the possibility of blinding even large complex trials if investigators are sufficiently committed and innovative.<sup>2</sup> Blinded outcome assessment is also necessary when the chosen outcome measure requires a subjective judgement. In such cases the outcome measure is said to be subject to the potential for ascertainment bias. For example, a blinded outcome assessment committee should adjudicate the diagnosis of ventilator-associated pneumonia (VAP) and blinded assessors should be used when assessing functional neurological recovery using the extended Glasgow Outcome Scale; both the diagnosis of VAP and assessment of the Glasgow Outcome Scale require a degree of subjective assessment and are therefore said to be prone to ascertainment bias.

It has been traditional to describe trials as single-blinded, double-blinded or even triple-blinded. However these terms can be interpreted by clinicians to mean different things, and the terminology may be confusing.<sup>12</sup> We recommend that reports of RCTs include a description of who was blinded and how this was achieved, rather than a simple statement that the trial was 'single-blind' or 'double-blind'.<sup>13</sup> Blinding is an important safeguard against bias in RCTs, and although not thought to be as essential as maintenance of allocation concealment, empirical studies have shown that unblinded studies may produce results that are biased by as much as 17%.<sup>10</sup>

### CONCOMITANT TREATMENTS

Concomitant treatments are all treatments that are administered to patients during the course of a trial other than the study treatment. With the exception of the study treatment, patients assigned to the different treatment groups should be treated equally. When one group is treated in a way that is dependent on the treatment assignment, but not directly related to the treatment, there is the possibility that this third factor will influence the outcome. An example might be a trial of pulmonary artery catheters (PACs), compared to management without a PAC. If the group assigned to receive management based on the data from a PAC received an additional daily

chest X-ray to confirm the position of the PAC, they could conceivably have other important complications noted earlier, such as pneumonia, pulmonary oedema or pneumothoraces, and this may affect outcome in a fashion unrelated to the data available from the PAC. Maintaining balance in concomitant treatments is facilitated by blinding. When trials cannot be blinded, use of concomitant treatments that may alter outcome should be recorded and reported, so that the potential impact of different concomitant treatments can be assessed.

### OUTCOME MEASUREMENT

All clinical trials should be designed to detect a difference in a single outcome. In general there are two types of outcome: clinically meaningful outcomes and surrogate outcomes.

A *clinically meaningful outcome* is a measure of how patients feel, function or survive.<sup>14</sup> Clinically meaningful outcomes are the most credible end-points for clinical trials that seek to change clinical practice. Phase III trials should always use clinically meaningful outcomes as the primary outcome. Examples of clinically meaningful outcomes include mortality and measures of health-related quality of life. In contrast, a *surrogate outcome* is a substitute for a clinically meaningful outcome; a reasonable surrogate outcome would be expected to predict clinical benefits based upon epidemiologic, therapeutic, pathophysiologic or other scientific evidence.<sup>14</sup> Examples of surrogate end-points would include cytokine levels in sepsis trials, changes in oxygenation in ventilation trials or blood pressure and urine output in a fluid resuscitation trial.

Unless a surrogate outcome has been validated, it is unwise to rely on changes in surrogate outcomes to guide clinical practice. For example, it seemed intuitively sensible that after myocardial infarction the suppression of ventricular premature beats (a surrogate outcome) which were known to be linked to mortality (the clinically meaningful outcome) would be beneficial. Unfortunately the Cardiac Arrhythmia Suppression Trial (CAST) trial found increased mortality in participants assigned to receive antiarrhythmic therapy.<sup>15</sup> The process for determining whether a surrogate outcome is a reliable indicator of clinically meaningful outcomes has been described.<sup>16</sup>

### ANALYSIS

Even when trials are well designed and conducted, inappropriate statistical analyses may result in uncertain or erroneous conclusions. A detailed discussion of the statistical analysis of large-scale trials is well beyond the scope of this chapter but certain guiding principles can be articulated:

- All trials should adhere to a predetermined statistical analysis plan; otherwise the temptation to perform multiple analyses and only report those that support

the preconceived ideas of the investigators may prove irresistible. A predetermined analysis plan protects the investigators from such temptation and allows readers to give appropriate weighting to the results.

- The convention of accepting a  $P$ -value of  $<0.05$  to indicate statistical significance is based on assessment of a single outcome. Assessing multiple outcomes increases the likelihood of finding a  $P$ -value of  $<0.05$  purely due to the play of chance. Each trial should have a single predefined primary outcome measure. If more than one primary outcome measure is used then the  $P$ -value used to indicate statistical significance should be reduced. The simplest method is to perform a Bonferroni correction which divides 0.05 by the number of outcomes examined to determine the new level of statistical significance. Thus, for two outcomes the  $P$ -value must be below 0.025, and for three it must be below 0.017. The  $P$ -value may also have to be further reduced if the trial employs interim analyses.

Clinicians should pay close attention to the analysis to make certain that a true intention-to-treat analysis is presented, and that any subgroup analysis is viewed with an appropriate amount of caution.

### INTENTION-TO-TREAT ANALYSIS

Trials should be analysed using the intention-to-treat principle. This means that all participants are analysed in the group to which they were randomised regardless of whether they received all or any of the treatment to which they were assigned. To some readers the intention-to-treat principle may appear intuitively incorrect; it is reasonable to ask why patients who did not receive the intended treatment should be included in the analysis. Use of intention-to-treat analysis prevents bias arising from the selective exclusion of patients – attrition bias. In an appropriately sized trial, loss of patients at random should occur equally in both groups and inclusion of those patients will not alter the result. If loss of patients is occurring as a non-random event (for example, because of protocol violations or intolerance of the treatment in one arm of the trial) then the trial result will be different if the lost patients are excluded. Consider a trial of a 5-day course of  $N^G$ -monomethyl  $L$ -arginine ( $L$ -NMMA) for the treatment of patients with septic shock. In the trial a number of patients who receive  $L$ -NMMA die in the first 24–48 hours and are excluded from the analysis as they have received only a little of the study treatment. A trial report based on the remaining patients who completed the treatment protocol (per-protocol analysis) will not give a true estimate of the effect of using  $L$ -NMMA in clinical practice. Although this is an extreme example, once patients are included in a trial their outcome should always be accounted for in the study report.

### SUBGROUP ANALYSIS

Particular difficulties arise from the selection, analysis and reporting of subgroups. Subgroups should be predefined and kept to the minimum number possible. When many subgroups are examined, the likelihood of finding a subgroup where the treatment effect is different from that seen in the overall population increases. A well-known example of this was the analysis of the treatment effect of aspirin in patients with myocardial infarction in the large second International Study of Infarct Survival (ISIS-2) trial. Overall the trial indicated that aspirin reduced the relative risk of death at 1 month by 23%. To illustrate the unreliability of subgroup analyses, the participants were divided into subgroups according to their astrological birth signs; the analysis showed that patients born under Libra or Gemini did not benefit from treatment with aspirin.<sup>17</sup> Although it is easy to identify this as a chance subgroup finding, this may be much harder when the choice of the subgroup appears rational and a theoretical explanation for the findings can be advanced. For example, in the Gruppo Italiano per lo Studio della Streptochinasi nell'infarto miocardico (GISSI) trial, subgroup analysis suggested that fibrinolytic therapy did not reduce mortality in patients who had suffered a previous myocardial infarct.<sup>18</sup> Although this finding appears biologically plausible, subsequent trials have shown quite clearly that fibrinolytic therapy is just as effective in patients with prior infarction as in those without.<sup>19</sup>

Separation of patients into subgroups should be on the basis of characteristics that are apparent at the time of randomisation. Selection of subgroups using features identified after randomisation risks introducing bias as the patients have already been subjected to the different study treatments and the subgroup analysis will therefore not be comparing like with like.

### TESTS OF INTERACTION VERSUS WITHIN-SUBGROUP COMPARISONS

Even when subgroups are selected appropriately many readers will be tempted to draw inappropriate conclusions from the results. As the trial will have been designed and powered to examine the effect of the treatment on the primary outcome in the whole study population, the best assessment of the treatment effect in any subgroup will be the effect seen in the trial as a whole. When analysing a subgroup result, the investigators should seek to answer the following question: is the treatment effect in the subgroup different from the treatment effect seen in the remaining participants? This is a test of interaction or of heterogeneity. Often the investigators err and perform within-subgroup comparisons which instead answer the question: what was the effect of treatment A versus treatment B in this subgroup? Within-subgroup comparisons are more likely to lead to unreliable results.

For example, the SAFE study identified patients with severe sepsis at baseline as an a priori subgroup. In the

overall population studied the relative risk of death for those assigned albumin versus those assigned saline was 0.99 (95% confidence interval (CI) 0.91–1.09). In those with severe sepsis at baseline, the relative risk was 0.87 (95% CI 0.74–1.02,  $P = 0.09$ ); the mortality rate for patients assigned albumin was 30.7% (185 deaths in 603 patients) versus 35.3% (217 deaths in 615 patients) for patients assigned saline. Despite this result, the most likely estimate for the treatment effect in the subgroup is the effect seen in the trial as a whole, namely a relative risk (RR) of 0.99. The investigators reported the test of common RR (a test of heterogeneity) which asked whether the RR in the subgroup of patients with severe sepsis (RR 0.87, 95% CI 0.74–1.02) was different from that in those without severe sepsis (RR 1.05, 95% CI 0.94–1.17); the  $P$ -value for this comparison was 0.06. This means that the probability that the difference in RR (0.87 versus 1.05) arose by chance is 0.06; a  $P$ -value of this order suggests that it would be reasonable to conduct an appropriately powered trial of albumin versus saline in patients with severe sepsis.

### REPORTING

The reporting of RCTs has been greatly improved by the work of the Consolidated Standards of Reporting Trials (CONSORT) group.<sup>13,20</sup> The CONSORT statement provides a framework and checklist (Table 10.2) which can be followed by investigators and authors to provide a standardised high-quality report.<sup>20</sup> An increasing number of journals require authors to follow the CONSORT recommendations when reporting the results of an RCT. The group also recommends the publication of a structured diagram which documents the flow of patients through four stages of the trial: enrolment, allocation, follow-up and analysis (Figure 10.1). It is likely that the use of the CONSORT statement to guide the reporting of RCTs does lead to improvements, at least in the quality of reporting of RCTs.<sup>21</sup>

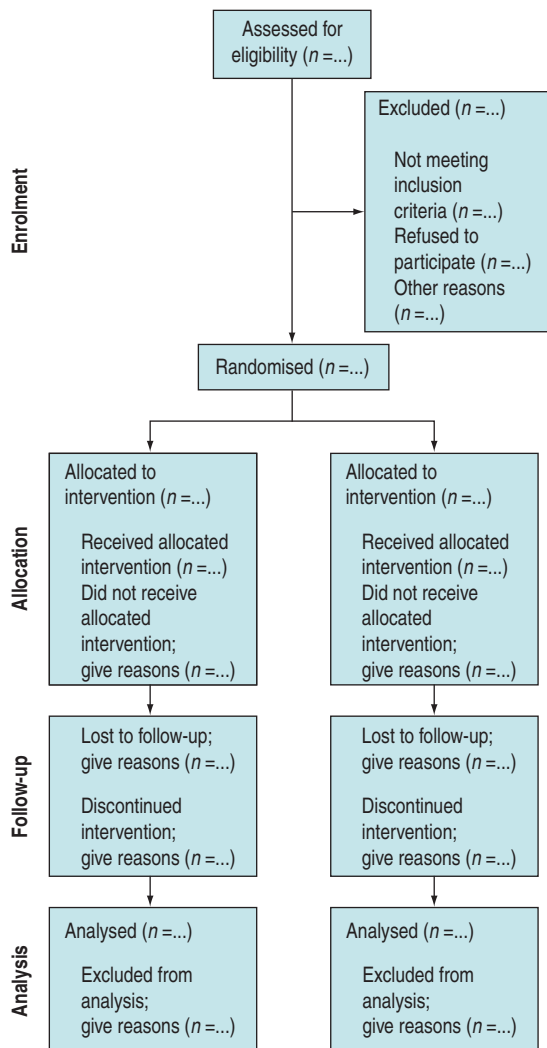

Trials may report results using a number of values that, taken together, will give readers a full understanding of the trial results. These may include a  $P$ -value, CI and number needed to treat (or harm).

- Probabilities – the  $P$ -value represents the probability that a difference has arisen by chance. In very large trials, small and clinically insignificant differences may give rise to  $P$ -values of less than 0.05. Conversely, a moderately sized trial may report a clinically important difference with a  $P$ -value that is close to or greater than 0.05.  $P$ -value should not be viewed in isolation but assessed in combination with other measures such as CI and the number needed to treat (or harm).
- CI give an indication of the precision of the result. Whenever a trial reports a difference it is reporting a difference found in a finite sample of the population of interest. If the same trial is repeated it is highly likely a slightly or very different result will be reported. If the

Table 10.2 The CONSORT checklist

	Item number	Descriptor	Reported on page number
<b>Title and abstract</b>	1	How participants were allocated to interventions (e.g. 'random allocation', 'randomised', or 'randomly assigned')	
<b>Introduction</b>			
Background	2	Scientific background and explanation of rationale	
<b>Methods</b>			
Participants	3	Eligibility criteria for participants and the settings and locations where the data were collected	
Interventions	4	Precise details of the interventions intended for each group and how and when they were actually administered	
Objectives	5	Specific objectives and hypotheses	
Outcomes	6	Clearly defined primary and secondary outcome measures and, when applicable, any methods used to enhance the quality of measurements (e.g. multiple observations, training of assessors, etc.)	
Sample size	7	How sample size was determined and, when applicable, explanation of any interim analyses and stopping rules	
<b>Randomisation</b>			
Sequence generation	8	Method used to generate the random allocation sequence, including details of any restriction (e.g. blocking, stratification)	
Allocation concealment	9	Method used to implement the random allocation sequence (e.g. numbered containers or central telephone), clarifying whether the sequence was concealed until interventions were assigned	
Implementation	10	Who generated the allocation sequence, who enrolled participants, and who assigned participants to their groups	
Blinding (masking)	11	Whether or not participants, those administering the interventions, and those assessing the outcomes were aware of group assignment. If not, how the success of masking was assessed	
Statistical methods	12	Statistical methods used to compare groups for primary outcome(s); methods for additional analyses, such as subgroup analyses and adjusted analyses	
<b>Results</b>			
Participant flow	13	Flow of participants through each stage (a diagram is strongly recommended). Specifically, for each group, report the numbers of participants randomly assigned, receiving intended treatment, completing the study protocol, and analysed for the primary outcome. Describe protocol deviations from study as planned, together with reasons	
Recruitment	14	Dates defining the periods of recruitment and follow-up	
Baseline data	15	Baseline demographic and clinical characteristics of each group	
Numbers analysed	16	Number of participants (denominator) in each group included in each analysis and whether the analysis was by 'intention to treat'. State the results in absolute numbers when feasible (e.g. 10/20, not 50%)	
Outcomes and estimation	17	For each primary and secondary outcome, a summary of results for each group, and the estimated effect size and its precision (e.g. 95% CI)	
Ancillary analyses	18	Address multiplicity by reporting any other analyses performed, including subgroup analyses and adjusted analyses, indicating those prespecified and those exploratory	
Adverse events	19	All important adverse events or side-effects in each intervention group	
<b>Discussion</b>			
Interpretation	20	Interpretation of the results, taking into account study hypotheses, sources of potential bias or imprecision and the dangers associated with multiplicity of analyses and outcomes	
Generalisability	21	Generalisability (external validity) of the trial findings	
Overall evidence	22	General interpretation of the results in the context of current evidence	

(Reproduced from Moher D, Schulz KF, Altman DG. The CONSORT statement: revised recommendations for improving the quality of reports of parallel-group randomised trials. *Lancet* 2001; **357**: 1191–4.)

**Figure 10.1** Flow diagram of the progress through the phases of a randomised trial. (Reproduced from Moher D, Schulz KF, Altman DG. The CONSORT statement: revised recommendations for improving the quality of reports of parallel-group randomised trials. *Lancet* 2001; 357: 1191–4.)

trial is reporting relatively small number of patients with the outcome of interest (small number of events) then the difference between the results may be large; if the trial reports a large number of events then it is likely the two results will be quite close to each other. CIs give a range of values within which it is likely the ‘true’ result lies – they give an indication of the precision of the result. The most commonly quoted are the 95% CIs; these are the limits within which we would expect 95% of study results to lie if the study was repeated an infinite number of times. They are often interpreted to mean that we can be 95% confident that the ‘true’ result lies within these limits.

- Number needed to treat (or harm) – a useful concept for clinicians is the number needed to treat (or harm). This is the reciprocal of the absolute difference in outcomes arising from two treatments. For example, in the ISIS-2 trial, patients randomised to intravenous streptokinase had an absolute reduction in mortality of 2.8%. Thus the number needed to treat to prevent one death is  $100/2.8$  or 35.7 patients. As the trial was very large with a large number of events (17187 participants and 1820 deaths), this relatively small absolute reduction in mortality (2.8%) yielded a *P*-value of less than 0.000 001. The same calculation can be performed to calculate the number needed to harm. For example, in the Corticosteroid Randomisation After Significant Head injury (CRASH) trial, patients with traumatic brain injury treated with high-dose steroids had a 3.4% increase in the absolute risk of death. The number needed to harm is calculated as  $100/3.4$ , or one extra death for every 29.4 patients treated with high-dose corticosteroids. Again, as this was a large trial (10 008 participants and 1945 deaths), the *P*-value is small ( $P = 0.00001$ ).

## ETHICAL ISSUES SPECIFIC TO CLINICAL TRIALS IN CRITICAL CARE

The ethical principles guiding the conduct of research in human subjects are outlined in the *International Ethical Guidelines for Biomedical Research Involving Human Subjects*.<sup>22</sup> In addition country-specific guidelines are provided by various national bodies. The ethical principles of integrity, respect for persons, beneficence and justice should be considered whenever research is conducted and an appropriately convened human research ethics committee or equivalent should assess all research to ensure adherence to these principles. As the potential participants in critical care research are particularly vulnerable due to the nature of their clinical conditions and the limitations to communication that exist, special consideration needs to be given to a number of areas, including informed consent.

### INFORMED CONSENT

That all mentally competent participants in clinical research should give informed consent prior to entering a study is an important ethical principle. This is rarely possible for people suffering critical illness, where the disease process (e.g. traumatic brain injury, encephalitis, severe hypoxaemia) or the required treatment (e.g. intubation, use of sedative medications) may make it impossible to obtain informed consent. Even awake, alert patients may not be able to give fully informed consent when they are facing stressful and potentially life-threatening situations.<sup>23</sup> This applies equally to surrogate decision-makers. However, the treatment of critically ill patients can only be improved through the conduct of research and in many jurisdictions this has been recognised by making special provisions for consent in

emergency research, including research in the critically ill. In some circumstances, it may be ethical to allow a waiver of consent for research involving treatments that must be given in a time-dependent fashion (e.g. in the setting of cardiac arrest). A waiver of consent may well improve recruitment into clinical trials; it is unclear if this approach is universally acceptable. Another approach has been to allow delayed consent, where patients are included in the study and consent from the patient or the relevant surrogate decision-maker is sought as soon as practical. Neither approach is without problems.<sup>24</sup>

### CRITICAL APPRAISAL

Clinicians reading reports of RCTs should use a structured framework to assess the methodological quality of the trial and the adequacy of the trial report. They should also address the magnitude and precision of reported treatment effects and ask themselves whether the results of the trial can be applied to their own clinical practice. There are a number of resources available to assist clinicians in this task, notably the *Users' Guides to Evidence-Based Practice*, originally published in the *Journal of the American Medical Association*, and the *Critical Appraisal Skills* programme from Oxford, UK, both of which are freely available on the internet.<sup>25,26</sup> These resources provide a structured framework which allows any reader to perform a systematic critical appraisal of almost any piece of medical literature. A checklist is provided for the appraisal of RCTs (Table 10.3).

### OBSERVATIONAL STUDIES

Although RCTs are the optimal study design for deciding whether or not a treatment 'works', not all research questions can be addressed with this type of study. When the disease is rare, the outcome is rare or the treatment may be associated with harm, other study designs may be more appropriate. In these circumstances a cohort study or case-control study may be used to explore potential associations between exposure to a treatment and the occurrence of outcomes.

### DESCRIPTIVE STUDIES

Case reports, case series and cross-sectional studies are all examples of descriptive studies. These types of studies may be important in the initial identification of new diseases such as human immunodeficiency virus (HIV)/acquired immunodeficiency syndrome (AIDS)<sup>27-30</sup> and severe acute respiratory syndrome (SARS).<sup>31</sup> The purpose of these studies will be to describe the 'who, when, where, what and why' of the condition, and so further the understanding of the epidemiology of the disease. It is important that clear and standardised definitions of cases are utilised, so that the information gathered can be used by clinicians and

**Table 10.3** Critical appraisal checklist for randomised controlled trials

#### I. Are the results of the study valid?

##### Primary guides

1. Was the assignment of patients to treatments randomised?
2. Were all patients who entered the trial properly accounted for and attributed at its conclusion?
3. Was follow-up complete?
4. Were patients analysed in the groups to which they were randomised?

##### Secondary guides

1. Were patients, health workers and study personnel 'blind' to treatment?
2. Were the groups similar at the start of the trial?
3. Aside from the experimental intervention, were the groups treated equally?

#### II. What were the results?

1. How large was the treatment effect?
2. How precise was the estimate of the treatment effect?

#### III. Will the results help me in caring for my patients?

1. Can the results be applied to my patient care?
2. Were all clinically important outcomes considered?
3. Are the likely treatment benefits worth the potential harms and costs?

(Reproduced from Centre for Health Evidence. *Users' guides to evidence-based practice*, 2007. Available online at: <http://www.cche.net/usersguides/main.asp>.)

researchers to identify similar cases. While there are some famous examples where data from simple observational studies have been used to solve particular problems,<sup>32</sup> in general only very limited inferences can be drawn from descriptive data. In particular, it is dangerous to draw conclusions about 'cause and effect' using data from descriptive studies alone.<sup>33</sup>

### ANALYTICAL OBSERVATIONAL STUDIES

There are two main types of analytical observational studies: case-control studies and cohort studies.

*Case-control studies* are performed by identifying patients with a particular condition (the 'cases'), and a group of people who do not have the condition (the 'controls'). The researchers then look back in time to ascertain the exposure of the members of each group to the variables of interest.<sup>34</sup> A case-control design may be appropriate when the disease has a long latency period and is rare. *Cohort studies* are performed by identifying a group of people who have been exposed to a certain risk factor and a group of people who are similar in most respects apart from their exposure to the risk factor. Both groups are then followed to ascertain whether they develop the outcome of interest. Cohort studies may be the appropriate design to determine the effects of a rare exposure, and have the advantage of being able to detect multiple outcomes that are associated with the same exposure.<sup>35</sup>

Both types of observational study are prone to bias. In particular, although it is possible to correct for known confounding factors using multivariate statistical techniques, it is not possible to control for unknown or unmeasured confounding factors. There are a number of other biases that may distort the results of observational studies; these include selection bias, information bias and differential loss to follow-up.<sup>35,36</sup> Critical appraisal guides for observational studies are available to help readers assess the validity of these studies.<sup>37</sup> These limitations and inherent biases mean that observational studies may not always provide reliable evidence to guide clinical practice, although it has been argued that this is not always the case.<sup>38,39</sup>

#### SYSTEMATIC REVIEWS AND META-ANALYSIS

Systematic reviews have been proposed as a solution to the problem of the ever expanding medical literature.<sup>40</sup> A systematic review utilises specific methods to identify and critically appraise all the RCTs that address a particular clinical question, and, if appropriate, statistically combine the results of the primary RCTs in order to arrive at an overall estimate of the effect of the treatment. By systematically assembling all RCTs that address one specific topic, a methodologically sound systematic review can provide a valuable overview for the busy clinician. Systematic reviews play an important role in providing an objective appraisal of all available evidence and may reduce the possibility that treatments with moderate effects will be discarded due to false-negative results from small or underpowered studies.<sup>41</sup> The use of meta-analysis could have resulted in the earlier introduction of life-saving therapies such as thrombolysis.<sup>42</sup> By using systematic methods, meta-analyses can provide more accurate and unbiased overviews, drawing conclusions that are often at odds with those of 'experts' and narrative reviews.<sup>43,44</sup>

In spite of these advantages and benefits there are still problems with interpretation of meta-analyses. Like all clinical trials, they need to be performed with attention to methodological detail. There are guidelines for performing and reporting systematic reviews.<sup>45,46</sup> It is clear that in the critical care literature these guidelines are not always followed.<sup>47</sup> Clinicians should critically appraise the reports of all systematic reviews and meta-analyses regardless of the source of the review, using an appropriate guide.<sup>48,49</sup> Problems with interpretation can arise when the results of a meta-analysis are at odds with the results of large RCTs which address the same issue;<sup>50,51</sup> this is not uncommon and clinicians will have to compare the methodological quality of meta-analysis and the RCTs included in the meta-analysis to the validity of the large RCT in order to decide which provides the most reliable evidence.<sup>2,52</sup>

# Shock – an overview

Angela McLuckie

## DEFINITION

Shock is a clinical state, with characteristic symptoms and signs, which occurs when an imbalance between oxygen supply and demand results in the development of tissue hypoxia. Although changes in systemic perfusion are always present in shock, oxygen delivery to the tissues is not invariably reduced, and indeed may be increased in shock due to severe sepsis.<sup>1</sup>

## CLASSIFICATION

Physiologically, tissue hypoxia may be considered as hypoxic (low  $P_{aO_2}$ ), anaemic (low haemoglobin level or increased levels of carboxy- or met-haemoglobin), stagnant (low cardiac output) or histotoxic (e.g. cyanide poisoning). Clinically, it is more common to subdivide shock into cardiogenic, obstructive, hypovolaemic or septic. Infrequently it may be neurogenic or anaphylactic in origin (Table 11.1).

Most often, cardiogenic shock is the result of myocardial disease, e.g. infarction, myocarditis. However, valvular abnormalities, e.g. mitral regurgitation due to papillary muscle rupture, and mechanical problems, e.g. ischaemic ventriculoseptal defect, may also be implicated. The term ‘obstructive shock’ is applied to situations where pump failure is due to extrinsic cardiac obstruction rather than primary myocardial pathology, with the two most common causes being pulmonary embolus and cardiac tamponade.

Hypovolaemic shock is usually the result of uncontrolled haemorrhage, but may be due to excessive fluid loss from the gastrointestinal and urinary tracts, and even the skin in severe burns. Any type of infection – bacterial, fungal or viral – can be complicated by the development of shock. The clinical findings, perhaps with the exception of the cutaneous manifestations of meningococcal disease, are not specific to the type of organism involved, and it is not generally possible to determine the nature of the infecting organism from clinical examination alone.<sup>2</sup>

In practice, there is often considerable overlap between the different types of shock and it is not unusual, for example, to find both hypovolaemia and myocardial dysfunction in patients with predominantly septic shock. Even in cardiogenic shock, some improvement in cardiac

function may be achieved with a careful volume challenge if the patient has been overaggressively diuresed.

## PATHOPHYSIOLOGY

Oxygen delivery to the tissues ( $DO_2$ ) is reduced in hypovolaemic, obstructive and cardiogenic shock. Several factors contribute to this, including low cardiac output, anaemia and hypoxaemia. In hypovolaemic shock, the diminished cardiac output is secondary to a reduction in myocardial preload. In obstructive shock venous return to the left ventricle is also reduced, whilst in cardiogenic shock impaired contractility predominates.

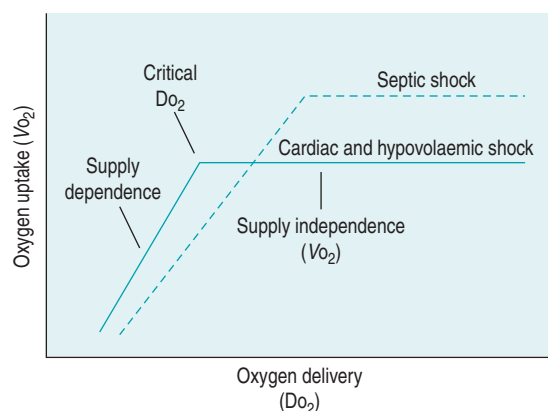

During the initial stages of hypovolaemic and cardiogenic shock, as oxygen delivery begins to fall, the tissues are able to maintain their oxygen uptake ( $VO_2$ ) at a normal level (170 ml/min per  $m^2$ ) by extracting more oxygen from each unit of blood (supply-independent  $VO_2$ ). However, once oxygen delivery falls below a critical value of 330 ml/min per  $m^2$ , this compensatory mechanism is insufficient and oxygen uptake begins to decline (supply-dependent  $VO_2$ ). This phase is associated with the accumulation of an ‘oxygen debt’, and its severity may be gauged by the degree to which blood lactate is elevated (Figure 11.1).

In septic shock, microbial components or their toxins are recognised by soluble cell-bound receptors, e.g. the lipopolysaccharide of Gram-negative bacteria binds to CD14 and Toll-like receptor 4 (TLR4), whilst the peptidoglycan of Gram-positive bacteria binds to TLR2. This process stimulates the release of proinflammatory (tumour necrosis factor- $\alpha$  (TNF- $\alpha$ ), interleukin-1 (IL-1), IL-6) and anti-inflammatory (IL-10, IL-1ra, TNF receptors) cytokines, generation of complement, activation of coagulation and platelet aggregation. There is also increased synthesis of arachidonic acid metabolites, reactive oxygen species and nitric oxide.<sup>3</sup> The combined effect of these changes is to produce vasodilatation, increased cardiac output despite impaired contractility and reduced intravascular volume secondary to increased capillary permeability.

$DO_2$  in septic shock is supranormal, mainly as a result of the elevated cardiac output.  $VO_2$  is also raised, due to an increase in tissue metabolic activity. At levels of  $DO_2$  above the normal critical threshold, although  $VO_2$  is increased, it appears to be inadequate and a lactic acidosis

Table 11.1 Classification of shock

Physiological	Clinical
Hypoxic	Cardiogenic
Anaemic	Obstructive
Stagnant	Hypovolaemic
Histotoxic	Septic
	Neurogenic
	Anaphylactic

**Figure 11.1** Relationship between oxygen uptake ( $V_{O_2}$ ) and oxygen delivery ( $D_{O_2}$ ) in cardiogenic, hypovolaemic and septic shock.

develops. Supply dependency is thus observed over a wider range of oxygen delivery values than usual. This may be explained by abnormalities in perfusion at a microcirculatory level, resulting in locally reduced  $D_{O_2}$  despite a supranormal global value. Alternatively, sepsis-induced mitochondrial dysfunction may prevent oxygen utilisation at a cellular level.

In all forms of shock, anaerobic cellular metabolism leads to depletion of adenosine triphosphate and failure of the cell membrane sodium–potassium pump. Cell swelling occurs due to the influx of sodium and water. Anaerobic metabolism also leads to a worsening lactic acidosis. Mitochondrial calcium loss further impairs the efficiency of oxidation and phosphorylation, and may interfere with other organ-specific functions such as myocardial contractility.

If untreated, or suboptimally treated, shock will eventually progress via multiple-organ dysfunction to frank failure.

### CLINICAL PRESENTATION

The clinical picture observed with the different types of shock can be divided into two categories, depending upon whether cardiac index is reduced (hypodynamic shock) or increased (hyperdynamic shock).

Hypovolaemic, obstructive and cardiogenic shock are usually associated with a low cardiac index; however blood pressure may be normal due to compensatory sympathetic and neurohormonal responses. Classically, the patient is confused, pale, tachycardic, tachypnoeic, poorly perfused and oliguric. The combination of extreme respiratory difficulty and inspiratory crepitations on auscultation of the chest should alert the physician to the possibility of pulmonary oedema due to left ventricular failure, which occurs frequently in cardiogenic shock. Clinically, estimation of central venous pressure (CVP) may help to differentiate between hypovolaemic and cardiogenic shock, since it is invariably low in the former and often raised in the latter. However, in obstructive shock the CVP is also raised.

In contrast septic shock is usually hyperdynamic, unless the patient is also significantly hypovolaemic. By definition, the patient must have a proven source of infection, be hypotensive (or requiring vasopressors to maintain a systolic blood pressure of 90 mmHg), exhibit two or more signs of systemic inflammation (tachycardia, tachypnoea, hypo-/hyperthermia, leukocytosis/leukopenia) and have dysfunction of at least one end-organ.<sup>4</sup> As with other forms of shock, the patient is often confused, tachycardic, tachypnoeic and oliguric. However, in contrast to hypovolaemic, obstructive and cardiogenic shock, peripheral pulses are bounding and the extremities are warm to touch. In meningococcal septicaemia a characteristic purpuric rash may be visible.

### INVESTIGATIONS

#### LABORATORY, RADIOLOGICAL AND NON-INVASIVE CARDIAC INVESTIGATIONS

Investigations should be tailored to the history and clinical findings. In most cases, a few simple blood tests (full blood count, clotting, electrolytes, urea and creatinine, arterial blood gas, lactate, troponin and blood cultures), in conjunction with an electrocardiogram and chest X-ray, will be sufficient to confirm the nature of the shock.

In cardiogenic and obstructive shock echocardiography is invaluable, since it provides an objective measure of ventricular function, can identify and quantify abnormalities of regional wall motion and valvular function, and excludes cardiac tamponade or massive pulmonary embolus. Where the history and preliminary findings raise the suspicion of pulmonary embolus, alternative confirmatory tests include spiral computed tomography (CT), which is readily available in most hospitals, and pulmonary angiography.<sup>5</sup>

Hypovolaemic shock, due to concealed haemorrhage, may require further invasive and radiological investigations such as diagnostic peritoneal lavage, abdominal ultrasound, or CT scanning. When hypovolaemia is due to excessive gastrointestinal or renal losses, electrolyte disturbances can be severe, and urea and creatinine are often

markedly elevated. Haemoconcentration may also be noted. Further investigations will depend upon the likely pathology, but may include supine and erect abdominal X-rays in bowel obstruction, abdominal ultrasound in acute cholecystitis and serum amylase and abdominal CT scan in pancreatitis.

Septic shock can lead to a rise or fall in the white cell count, the latter being associated with a particularly poor prognosis. Best practice dictates that blood and other relevant cultures are taken prior to initiating antibiotic therapy wherever possible, and in certain cases measurement of C-reactive protein and procalcitonin may be of value.<sup>6,7</sup> Disseminated intravascular coagulation, diagnosed by the combination of prolonged clotting, thrombocytopenia and reduced fibrinogen, is often present. When measured, antithrombin III, protein C and protein S levels are commonly low.

Blood lactate is elevated in all forms of shock, and indicates the presence of tissue hypoxia. The degree to which it is elevated corresponds to the severity of the shock, and it is frequently used as a guide to the effectiveness of therapeutic interventions.<sup>8</sup> Furthermore, lactate, base excess or a combination of the two can be used to predict outcome in patients admitted to the intensive care unit (ICU).<sup>9</sup>

### INVASIVE HAEMODYNAMIC MEASUREMENTS

Whilst the therapeutic efficacy of the pulmonary artery catheter (PAC) remains controversial,<sup>10</sup> the measurements obtained from it are undoubtedly extremely useful in differentiating between the four major types of shock (Table 11.2).

Pulmonary artery catheterisation is rarely required to aid in the diagnosis of uncomplicated hypovolaemic shock. The clinical picture and presence of a low CVP are usually sufficient. However, the additional information obtained from a PAC may be invaluable in differentiating cardiogenic shock due to acute myocardial infarction (pulmonary artery occlusion pressure (PAOP) elevated, CVP normal or elevated, pulmonary artery pressure (PAP) normal), from pulmonary embolus (PAOP normal, CVP and PAP elevated) and cardiac tamponade (PAOP and CVP identical and elevated). It may also be helpful in cases of septic shock that are not clinically hyperdynamic, particularly in relation to optimising fluid, inotrope and

vasopressor therapy. Alternatively, optimisation of cardiac preload and index in all forms of shock may be guided by measurement of stroke volume variation and cardiac index using lithium dilution (LiDCO) or intrathoracic blood volume index, extravascular lung water, stroke volume variation and cardiac index by transpulmonary thermodynamic dilution (PiCCO).<sup>11–13</sup>

## PRINCIPLES OF MANAGEMENT

Management may be considered in terms of general measures that are applicable to all shocked patients, and specific measures that are appropriate in shock of a particular aetiology. Irrespective of the type of shock, it should be treated as a medical emergency. Resuscitation and investigation must therefore proceed in parallel and not in series.

### GENERAL MEASURES

#### OXYGEN THERAPY AND MECHANICAL VENTILATION

All shocked patients should be given high-flow oxygen via a facemask, with the aim of improving arterial oxygen saturation and oxygen delivery to the tissues. Tachypnoea is common, and work of breathing is greatly increased, particularly in those cases with either cardiogenic or non-cardiogenic pulmonary oedema. Mechanical ventilation has much to commend it in this situation, since it will reduce oxygen consumption by the respiratory muscles at a time when their oxygen supply is compromised. Intubation at an early stage will also facilitate the insertion of invasive haemodynamic monitoring devices, which are invariably required to monitor and deliver fluid and inotropic therapy, but may be difficult to insert safely in a confused, agitated patient.

#### FLUID THERAPY

Optimising cardiac preload and restoring circulating volume are fundamental aspects of correcting tissue hypoxia in patients with shock. In cases of hypovolaemic and septic shock several litres of fluid are usually needed to achieve this, but occasionally even some patients with cardiogenic shock may benefit from a judicious volume challenge. In patients with severe sepsis, aggressive volume replacement within 6 hours of presentation in conjunction

**Table 11.2** Values obtained from the pulmonary artery catheter in the four major types of shock

	Septic shock	Cardiogenic shock	Hypovolaemic shock	Obstructive shock
Cardiac index	↑	↓	↓	↓
Pulmonary artery occlusion pressure (PAOP)	Normal or ↓	↑	↓	Normal or ↑
Central venous pressure (CVP)	Normal or ↓	Normal or ↑	↓	↑
Systemic vascular resistance (SVR)	↓	↑	↑	↑
Oxygen delivery ( $Do_2$ )	↑	↓	↓	↓

with targeting a central venous oxygen saturation  $> 70\%$  ( $S_{cv}O_2 > 70$ ) and haemoglobin level  $> 10$  g/dl can reduce hospital mortality by up to 16%.<sup>14</sup>

CVP is often used as a surrogate for myocardial preload in uncomplicated hypovolaemic shock. However, in patients with ischaemic heart disease PAOP is usually preferred. Intrathoracic blood volume, an alternative measure of cardiac preload, offers theoretical advantages over both CVP and PAOP, particularly in mechanically ventilated patients, and is obtained using either double (COLD) or single (PiCCO) indicator dilution.<sup>12,13</sup> More recently, stroke volume variation (SVV) with respiration has been shown to be the best predictor of volume responsiveness, and has the advantage of being relatively easy to obtain through analysis of the arterial waveform trace.<sup>15</sup> When SVV is 9.5% or greater a 100 ml volume load will increase stroke volume by at least 5%.<sup>16</sup> It is less useful in patients with atrial fibrillation or frequent ventricular ectopics, where wide fluctuations in baseline stroke volume are present.

Logically, the fluid used to correct any deficit should reflect the type of fluid lost, and patients who have significant bleeding will clearly require blood. In intensive care patients without acute coronary syndromes, it appears safe to aim for a haemoglobin level of 7–9 g/dl once the acute resuscitation phase has passed. Indeed, targeting this level is associated with a lower mortality than 10–12 g/dl.<sup>17</sup> At present, the use of blood substitutes such as diasprin cross-linked haemoglobin is not recommended in haemorrhagic shock, as they are linked to a higher death rate.<sup>18</sup>

Given that blood is usually supplied in the form of red cell concentrates, the clinician must decide whether to combine it with a crystalloid, human albumin or a synthetic colloid in order to restore circulating volume. The same dilemma, over whether to use a crystalloid or a colloid during resuscitation, also arises in patients with septic shock. One property in favour of colloids is that they restore circulating volume more efficiently than crystalloids, since approximately 1.5 times as much crystalloid must be infused to achieve the same haemodynamic end-point.<sup>19</sup> It is therefore common to begin resuscitation with a colloid to restore intravascular volume, and to continue with crystalloid to correct interstitial and intracellular losses. A recent, large placebo-controlled trial of normal saline versus 4% albumin for resuscitation in ICU may challenge this practice, however, since no differences in mortality or morbidity could be demonstrated between the groups, and crystalloids are undoubtedly much cheaper to use.<sup>19</sup>

In addition, several papers have raised concerns regarding the safety of colloids. A systematic review of randomised studies comparing the use of crystalloids and colloids in the resuscitation of critically ill patients concluded that the use of colloid was associated with a 4% increase in mortality.<sup>20</sup> The specific issue of renal failure was highlighted in a randomised controlled study comparing the use of the synthetic colloid hydroxyethyl starch (MMW-HES 200 kDa, 0.6–0.66 substitution) with 3%

gelatine in patients with sepsis and septic shock. In this study the incidence of renal failure was significantly higher in the HES group.<sup>21</sup> The use of high-molecular-weight hydroxyethylstarch (HMW-HES 450 kDa, 0.5 substitution) has also been associated with abnormal clotting and increased bleeding.<sup>22</sup>

A number of recent publications have focused on the use of hypertonic crystalloids, such as 7.5% sodium chloride alone or in conjunction with dextran 70, for initial resuscitation. While most of the large studies have failed to show a clear survival benefit in the general trauma population, hypertonic solutions may be useful in certain subgroups, such as those with severe head injuries, in whom the administration of large volumes of isotonic crystalloid may worsen cerebral oedema.<sup>23,24</sup> Most studies also show that the use of hypertonic solutions is associated with a reduction in fluid and blood transfusion requirements.<sup>25</sup>

### INOTROPIC SUPPORT

Inotropic support is rarely required in hypovolaemic shock, except when it is severe and surgical control of bleeding is delayed. In most instances, fluid replacement alone is sufficient to restore cardiac output and blood pressure. Although fluid therapy is also important in patients with septic shock, it is rarely helpful in those with cardiogenic shock, and in both septic and cardiogenic shock vasoactive drugs are often required to improve tissue perfusion and reverse tissue hypoxia.

In cardiogenic shock cardiac output and blood pressure are characteristically low, and systemic vascular resistance increased. Ideally an inodilator, e.g. dobutamine or milrinone, should be selected, provided that blood pressure is not unduly compromised. When hypotension is a prominent feature, the use of an inoconstrictor, e.g. epinephrine or dopamine, or a pure constrictor in combination with an inodilator, e.g. norepinephrine and dobutamine, is often preferred. A number of adverse side-effects are to be expected with epinephrine, including hyperglycaemia, hypokalaemia and hyperlactataemia.<sup>26,27</sup> Consequently, use of epinephrine should be taken into account when interpreting blood lactate measurements. Levosimendan, a new inotropic agent that exerts its effect by binding to troponin C and increasing myocyte sensitivity to calcium, is being used increasingly in the setting of acute heart failure.<sup>28</sup> It has the advantage of not increasing myocardial oxygen consumption when compared to dobutamine, and is particularly useful in cases where an element of load-induced right ventricular failure exists since it also reduces pulmonary artery resistance.<sup>29,30</sup>

Septic shock classically results in a high cardiac output and low blood pressure due to excessive peripheral vasodilatation. This so-called peripheral circulatory failure is mediated via increased production of nitric oxide due to stimulation of inducible nitric oxide synthase in vascular smooth muscle and endothelium. Once cardiac preload is optimised, use of a pure vasoconstrictor, e.g. norepinephrine,

is recommended. If cardiac output is reduced, it is often helpful to combine norepinephrine with dobutamine or milrinone. Theoretically, the inoconstrictor dopamine could also be used in this situation, if it were not for a number of problematic side effects. These include adverse effects on pituitary function (reduced prolactin, growth hormone and TRH), T-cell function, gut mucosal perfusion and renal medullary oxygen consumption.<sup>31,32</sup>

#### DIURETICS

The use of 'low-dose' or 'renal-dose' dopamine, to prevent renal failure in shocked patients, does not reduce the number of patients who subsequently require renal replacement therapy, and, given the concern about possible adverse effects of dopamine, should be abandoned.<sup>33,34</sup> If a natriuresis is desired, this can usually be achieved with furosemide, given by intermittent bolus (10–80 mg) or continuous infusion (3–10 mg/h). Care should be taken to ensure that the patient is adequately volume-resuscitated before a diuretic is given, so that hypovolaemia is not exacerbated by an inappropriate diuresis.

### SPECIFIC MEASURES

#### HYPOVOLEMIC SHOCK

Surgical, radiological or endoscopic intervention may be required in haemorrhagic shock, and should be undertaken in a timely fashion. In most situations fluid resuscitation precedes definitive intervention, but in some trauma patients outcome may be improved if fluid resuscitation is delayed until bleeding is controlled.<sup>35</sup> Hypovolaemic shock due to other intrabdominal pathologies, e.g. perforation/obstruction, may also warrant surgery. In these cases, measures taken to improve the condition of the patient preoperatively, such as correcting hypovolaemia, hypoxia and anaemia, and increasing oxygen  $DO_2$ , can reduce perioperative mortality substantially.<sup>36,37</sup>

#### SEPTIC SHOCK

##### Source control

Infected fluid collections should be drained, either radiologically or surgically. Surgical intervention may also be required for other sources of sepsis, for example bowel perforation.

##### Antibiotics

It is vital to select an appropriate antibiotic(s) and to ensure that the dosing regimen is optimal. This latter task is often the more difficult, especially when re-dosing depends upon monitoring of drug levels. Any delay in obtaining a level can expose the patient to a significant period of suboptimal antibiotic therapy. In order to reduce this problem, antibiotics whose efficacy does not depend upon peak levels, e.g. vancomycin, may be given by continuous infusion (0.5–2 g/day, depending on renal function) with a random level taken once daily.<sup>38</sup> In the absence of culture results, initial antibiotic therapy is designed to cover a broad range of likely pathogens.

However, once culture results are available, antibiotic cover should be narrowed and directed at the identified organism(s).

##### Steroids

Large doses of steroid (30–120 mg/kg of methylprednisolone) given within 24 hours of the onset of shock result in haemodynamic improvement but not lower mortality, a finding that may be explained by the increased incidence of secondary infection associated with their use.<sup>39,40</sup> More recently, administration of lower doses of steroid (300 mg/day hydrocortisone), particularly to those patients with a 'flat' Short Synacthen Test (SST), became common practice following a study demonstrating a beneficial effect on both haemodynamics and mortality.<sup>41</sup> However, the merits of this practice are now being re-evaluated following publication of a large randomized, double-blind, placebo controlled trial (CORTICUS) that failed to demonstrate a mortality benefit from steroids (300 mg hydrocortisone/day), irrespective of the SST result. Worryingly even low doses of steroid appear to be associated with more episodes of superinfection, including new sepsis and septic shock.<sup>42</sup> At present it would seem prudent to reserve steroid therapy for patients who are poorly responsive to adequate fluid therapy and vasopressor support, and to limit the dose to < 300 mg of hydrocortisone/day.

##### L-NMMA

The results of phase I and II trials of  $N^G$ -monomethyl-L-arginine hydrochloride (L-NMMA), a non-selective nitric oxide synthase inhibitor, in septic shock appeared promising. When infused at a maximum rate of 20 mg/kg per h for 8 hours, there was a 60–80% reduction in the amount of norepinephrine required to maintain a mean arterial pressure of 70 mmHg or greater.<sup>43</sup> Unfortunately, the subsequent phase III study demonstrated an increased mortality in the L-NMMA group. This was largely due to L-NMMA-induced increases in both systemic and pulmonary vascular resistances that resulted in cardiac failure.<sup>44</sup> Further investigations in this area are likely to focus on the development of a selective inducible nitric oxide synthase inhibitor.

##### Vasopressin

Vasopressin secretion from the posterior pituitary is an important homeostatic mechanism for restoring blood pressure in various forms of shock. In septic shock vasopressin levels may be inappropriately low, due to either impaired secretion or depletion.<sup>45,46</sup> In cases of septic shock with refractory hypotension despite high doses of catecholamines, the addition of an intravenous infusion of vasopressin (0.04 U/min) can increase mean arterial pressure, systemic vascular resistance and urine output.<sup>47</sup> A recent large, double-blind trial (VASST) comparing vasopressin (0.01–0.03 U/min) and norepinephrine (5–15 µg/min), in addition to open-label vasopressors in patients with septic shock requiring more than 5 µg norepinephrine, failed to show a difference in

28 day mortality. Reassuringly, given previous concerns regarding the potential of vasopressin to cause tissue ischaemia, there was no significant difference in the incidence of serious adverse events between the two groups.<sup>48</sup>

#### Activated protein C

Activated protein C is an endogenous protein capable of promoting fibrinolysis and inhibiting thrombosis and inflammation. In sepsis, the conversion of protein C from an inactive to active form, which is stimulated by thrombin bound to thrombomodulin, is impaired due to downregulation of thrombomodulin by inflammatory cytokines. In patients with severe sepsis, infusing activated protein C (24 µg/kg per h) for up to 96 hours reduces absolute risk of death by 6%.<sup>49</sup> Hospital survival is increased from 65.1% to 70.3%.<sup>50</sup> Administering the drug in this fashion does however result in an increased risk of serious bleeding, and its effect on mortality has not been studied in patients who are at increased risk of bleeding, including those who have had recent surgery or trauma.

It is of no benefit in patients with a low risk of death, such as those with single-organ failure or an Acute Physiology, Age and Chronic Health Evaluation (APACHE) score less than 25. Indeed, it is contraindicated in this group of patients, since its use is associated with an increased incidence of serious bleeding complications.<sup>51</sup>

#### High-volume haemofiltration

Haemofiltration is frequently used to manage severe metabolic acidosis, as well as renal failure itself, in patients with septic shock. Numerous studies have demonstrated that haemodynamic status often improves following commencement of haemofiltration, and it is postulated that this is due to cytokine removal in the ultrafiltrate and by adsorption on to the filter.<sup>52,53</sup> In patients with sepsis, there is some evidence to suggest that using a higher 'dose' of haemofiltration, e.g. 45 ml/kg per h, may improve outcome.<sup>54</sup> However, a rigorous, randomised, controlled study of high-volume haemofiltration in septic patients has not been undertaken to date.

### CARDIOGENIC SHOCK

#### PERCUTANEOUS CORONARY INTERVENTION (PCI), THROMBOLYSIS, CORONARY ARTERY BYPASS GRAFTING

For the treatment of myocardial infarction with ST-segment elevation, PCI is superior to thrombolysis in terms of short-term mortality, non-fatal reinfarction, stroke and a composite of all three.<sup>55</sup> This benefit is maintained, even when patients have to be transferred to a specialist centre to undergo PCI, provided that the transfer takes 2 hours or less.<sup>56</sup> Coronary artery bypass grafting may be undertaken in a small number of patients who are not suitable for PCI. Thrombolysis alone does not reduce the mortality of cardiogenic shock complicating acute myocardial infarction (55% at 30 days).<sup>57</sup>

#### INTRA-AORTIC BALLOON PUMP

The intra-aortic balloon pump provides a useful bridge to surgery in cases of cardiogenic shock due to papillary muscle rupture and ischaemic ventricular septal defect. Its use as a supportive therapy, in conjunction with other aggressive invasive treatments, in the wider population of patients with acute myocardial infarction is also associated with a reduction in 1-year mortality.<sup>58</sup>

### OBSTRUCTIVE SHOCK

#### PULMONARY EMBOLUS

Even patients without hypotension or shock may benefit from thrombolysis, if they have evidence of pulmonary hypertension or right ventricular dysfunction. Those who receive heparin alone are more likely to require an escalation in their therapy (catecholamine infusion, secondary thrombolysis, intubation, cardiopulmonary resuscitation or embolectomy).<sup>59</sup>

#### CARDIAC TAMPONADE

Surgical or percutaneous drainage of pericardial fluid should be undertaken immediately for pericardial tamponade. Whenever possible percutaneous drainage should be guided by echocardiography.

### OUTCOME

Outcome in shock depends upon a multitude of factors, including aetiology, severity of illness at presentation, response to therapy and comorbidity. In general terms, the mortality associated with hypovolemic shock is considerably lower than that for either cardiogenic or septic shock, provided that the source of bleeding can be controlled. Even in good centres, where patients receive aggressive therapy, mortality from septic shock is approximately 30–50%, and often higher for cardiogenic shock.<sup>60</sup>

# Haemodynamic monitoring

David J Sturgess and Thomas John Morgan

Haemodynamics is the study of blood flow. Haemodynamic monitoring therefore refers to the monitoring of blood flow through the cardiovascular system. In the intensive care unit (ICU), haemodynamic monitoring is used to detect cardiovascular insufficiency, differentiate contributing factors and guide therapy.

There has been debate over the risks and benefits of invasive haemodynamic monitoring in critically ill patients. Because there are scant data to show that invasive monitoring leads to improved survival, there has been a steady trend toward less invasive monitoring in the ICU. Regular clinical assessment remains an important component of haemodynamic monitoring, and any acquired physiological data must be interpreted in the clinical context. Importantly, monitoring must be combined with effective therapy in order to demonstrate an impact on outcome.<sup>1</sup>

As an aid to understanding haemodynamics, several circulatory models have been proposed, each with limitations. The standard model consists of a non-pulsatile pump and a hydraulic circuit with discrete sites of flow resistance. Heart rate and stroke volume determine cardiac output. The concepts of preload, contractility and afterload (Frank–Starling mechanism) are incorporated as determinants of stroke volume. In practice, quantification of these parameters is difficult, both clinically and in the laboratory. The model itself is simplistic, and does not allow for the pulsatile interaction of the cardiac pump with the elastance of the arterial tree. More complex models based on electrical circuits have been devised, but are still unable to quantify afterload and contractility precisely.

At the bedside the clinician must work with inexact surrogates of preload, contractility and afterload, measured or derived from arterial blood pressure (systemic or pulmonary), volume or pressure indices of cardiac filling, cardiac output and various markers of tissue well-being. In this chapter we focus on all these measurements except for those of tissue well-being, which are discussed elsewhere.

## ARTERIAL BLOOD PRESSURE

The systemic pulse wave propagates from the aortic valve at 6–10 m/s. During its passage into the peripheral vasculature there is a progressive increase in systolic (SBP)

and reduction in diastolic blood pressures (DBP), as standing and reflected waves become incorporated into the waveform, a process known as distal pulse amplification. Consequently, systemic arterial pressure measurements vary according to the site of measurement.

Mean arterial pressure (MAP) is arguably a more relevant index to monitor than either SBP or DBP for three reasons:

1. MAP is least dependent on measurement site or technique (invasive versus non-invasive).
2. MAP is least altered by measurement damping.
3. MAP determines tissue blood flow via autoregulation (apart from the left ventricle, which autoregulates from DBP).

In the absence of sophisticated waveform analysis, arterial pressure is poorly correlated with cardiac output. Hence clinical estimation of cardiac output from arterial pressure and heart rate is unreliable until extreme hypotension occurs.<sup>2</sup>

## NON-INVASIVE ARTERIAL BLOOD PRESSURE (NIBP) MEASUREMENT

In ICU, most standard NIBP instruments are automated intermittent oscillometric devices. Finger plethysmography and arterial tonometry can monitor both arterial pressure and waveforms continuously, but there are concerns regarding their accuracy.

Oscillometric NIBP is often used to check the reliability of invasive measurements, or can be used alone when beat-to-beat monitoring is not required. Contraindications to NIBP are relative, and influence the site of cuff placement. For instance, it is preferable to avoid extremities with severe peripheral vascular disease, venous cannulation, arteriovenous fistula or previous lymph node clearance (for example, radical mastectomy).

To make an oscillometric blood pressure measurement, a pneumatic cuff is inflated around a limb until all oscillations in cuff pressure are extinguished. The occluding pressure is then lowered stepwise, so that oscillations reappear over a discrete interval. Proprietary algorithms compute MAP, SBP and DBP from the alterations in oscillatory amplitude during deflation.

Oscillometry overestimates low pressures and underestimates high pressures, but for the normotensive range the 95% confidence limits are  $\pm 15$  mmHg (2 kPa). Dysrhythmias increase the error. Cuff width should be 40% of the mid-circumference of the limb. Narrower cuffs overestimate and wider cuffs underestimate blood pressures.

Complications are unusual. Repeated cuff inflations can cause skin ulceration, oedema and bruising, more so when the consciousness is impaired by illness and sedation. Ulnar nerve injury is also possible, especially with low cuff placement.

### INVASIVE BLOOD PRESSURE MEASUREMENT<sup>3</sup>

Invasive blood pressure measurement is desirable in the presence of haemodynamic instability, end-organ disease requiring beat-to-beat blood pressure monitoring, during therapeutic manipulation of the cardiovascular system or if non-invasive methods fail. Cannulation of a systemic artery allows continuous monitoring of the arterial pressure waveform, heart rate and blood pressure, and also facilitates frequent arterial blood gas analysis. Relative contraindications include coagulopathy and vascular abnormality or disease.

The radial artery is the most common site for cannulation. Nothing larger than a 20-gauge cannula is advisable, and either a modified Seldinger technique or direct cannulation can be used. Once inserted, the cannula is usually infused with normal or heparinised saline at 3 ml/h, with a snap flush rate of 30–60 ml/h. Although it appears not to prolong patency, the use of heparinised saline (2–4 units/ml) might improve accuracy.<sup>4</sup> It should be avoided if heparin-induced thrombocytopenia syndrome is suspected.

The axillary, brachial, femoral, posterior tibial and dorsalis pedis arteries can all be used without apparently raising the complication profile (Table 12.1). In severe circulatory compromise, gaining peripheral arterial access may be difficult and time-consuming. Rapid femoral cannulation by the Seldinger percutaneous technique usually remains feasible, with the added advantage that femoral arterial monitoring more accurately reflects aortic pressure in low-output states.

Cannulae are usually removed or resited between days 5 and 7, or earlier if a complication is suspected. Distal perfusion should be checked at least 8-hourly, and the cannula removed if there is persistent blanching, coolness with sluggish capillary refill, loss of pulses or evidence of raised muscle compartment pressures. Complications associated with arterial cannulation are presented in Table 12.1.

### PHYSICAL PROPERTIES OF CLINICAL PRESSURE MEASUREMENT SYSTEMS<sup>5,6</sup>

In the standard set-up, the arterial cannula is connected to a linearly responsive pressure transducer via fluid-filled non-compliant tubing < 1 m in length. Modern disposable transducers are precalibrated using electrical signals,

and are not normally calibrated further against known pressures. The system is zeroed to the level of the phlebostatic axis, normally the mid-axillary line at the fourth intercostal space. Subsequent lowering of the transducer relative to this axis will cause pressure overestimation, while raising it will cause underestimation.

The *natural resonant frequency* of the system should ideally exceed 30 Hz (> 10 harmonics) for heart rates up to 180 beats/min (3 Hz) to prevent distortion of the biological signal by sine-wave system oscillations. *Damping* refers to any property of an oscillatory system that reduces the amplitude of oscillations. Factors that increase oscillation in the system, such as increased tubing length, diameter or compliance, cause underdamping. Overdamping tends to smooth the waveform, causing underestimation of SBP and overestimation of DBP, while MAP tends to be preserved. Contributing factors include clots, air bubbles and loose connections. Damping can be assessed clinically by the fast-flush test (Table 12.2).<sup>7</sup>

Upstream resistance or turbulence can result in a flow-dependent pressure reduction at the cannula site that differs from damping in that the MAP, SBP and DBP are all reduced. This is described as *attenuation* and is often observed in 'positional' arterial lines.

### ADDITIONAL INFORMATION FROM THE ARTERIAL WAVEFORM

Measurement systems used in ICU do not precisely quantify the rate of arterial pressure rise and fall. Nevertheless, the wide pulse pressure of aortic regurgitation and the slowed upstroke of severe aortic stenosis may be detected. Pulsus paradoxus can readily be quantified in the spontaneously breathing patient. Systolic time intervals can provide an indication of ventricular contractility.

The systemic arterial pressure waveform can also assist in the prediction of fluid responsiveness (see Functional haemodynamic monitoring, below).

### Estimation of stroke volume and cardiac output<sup>8</sup>

Estimation of stroke volume by analysis of the arterial pressure waveform, in particular various properties of the pulse pressure (pressure above diastolic) component, has been studied for many years. Pulse contour analysis calculates stroke volume from the area under the systolic portion of the arterial pressure waveform. After individual calibration, these monitors can determine stroke volume beat-to-beat. Cardiac output, derived by multiplying stroke volume by heart rate, appears to offer reliable continuous cardiac output monitoring, even during haemodynamic instability.<sup>9</sup> However, accuracy in the presence of arrhythmia has not been validated.

Transpulmonary indicator dilution (discussed below) is the usual method of calibration. Pulse contour devices that use thermodilution or lithium ion calibration are commercially available.<sup>10</sup> Comparisons with pulmonary artery catheter (PAC) cardiac output measurements have shown good agreement, with mean bias values  $\leq 0.1$  l/min and precision (SD of bias) of the order of 0.6 l/min.

**Table 12.1** Complications of arterial cannulation, with suggested preventive and treatment options<sup>61</sup>

Complication	Prevention	Treatment
Vascular thrombosis (ranges from 7 to 30% following radial artery cannulation). Risk factors for digital ischaemia include: shock, sepsis, embolus of air or clot, hyperlipoproteinaemia, vasculitis, female sex, prothrombotic states, accidental intra-arterial injection of drugs	Risks reduced by smaller catheter, larger artery, decreased duration of cannulation, avoiding traumatic insertion and multiple attempts. Allen's test (including modifications such as Doppler, plethysmography and digital blood pressure) is probably unhelpful	Remove cannula. Arterial thrombosis is usually self-limiting. Severe ischaemic damage estimated at < 0.01%. Anticoagulation and/or vascular surgery/intervention may be necessary
Distal embolisation	Diligent catheter care and observation	As for thrombosis
Proximal embolisation of clot or air (can result in stroke)	Diligent catheter care and observation. Exclude air from pressurised system. Avoid axillary, subclavian or carotid access	Tailored to sequelae
Vascular spasm	Smaller catheter, larger artery. Avoid traumatic insertion and multiple attempts	Remove cannula. Resite if necessary
Skin necrosis at catheter site	Diligent catheter care and observation	Surgical debridement and skin grafting may be necessary
Line disconnection and bleeding/exsanguination	Minimise connections. Diligent catheter care and observation	Control bleeding. Transfusion may be necessary
Accidental drug injection	Clearly label arterial line near ports	Leave cannula in situ to facilitate treatment if required. Depends on drug injected. May require papaverine or procaine, analgesia, sympathetic block of limb and anticoagulation
Infection – local or systemic	Diligent catheter care and observation	Remove cannula and send tip for culture. Resite if necessary. Immobilise and elevate affected upper limb. Start empiric antibiotics if sepsis or septic shock is present
Damage to nearby structures such as nerves, directly or due to haematoma (e.g. compartment syndrome or carpal tunnel syndrome). Arteriovenous fistula. Femoral approach can be associated with bowel damage	Careful insertion technique. Seek assistance from experienced operator	Tailored to sequelae. Haematomas can develop into pseudoaneurysms requiring surgery

**Table 12.2** Fast-flush test to assess dynamic response (damping) of the blood pressure-monitoring system

Make a paper record of transducer output  
 Snap the valve of the continuous flush system. This produces a square wave on the output trace  
 Repeat the process at least twice  
 Resonant frequency is the distance between successive peaks divided by the paper speed in millimetres per second  
 Damping is satisfactory (critical damping) if each snap test has two to three oscillation waves, with each wave one-third or less the size of the preceding wave

Disadvantages of such techniques can include:

- calibration against another method, such as thermodilution
- recalibration every few hours is advisable to allow for changes in systemic vascular resistance. This is especially important if there is haemodynamic instability or during the administration of vasoactive drugs
- alterations in abdominal pressure or changes in body position, particularly in the obese, can alter aortic compliance, necessitating recalibration
- dependence on arterial site. Clinical validation studies usually document femoral cannulation
- aortic aneurysms and significant aortic regurgitation are both difficult to model and invalidate the technique

Recently developed proprietary algorithms continuously measure stroke volume and cardiac output without requiring calibration against another method.<sup>11</sup> Additional clinical validation is awaited.

### CENTRAL VENOUS CATHETERISATION (CVC)

CVC is indicated for monitoring of central venous pressure (CVP) and administration of certain drugs and parenteral

nutrition. Modified catheters are also available which continuously monitor central venous oxygen saturation ( $S_{cv}O_2$ ). Contraindications to CVC are relative and reflect potential complications of the procedure (Table 12.3). These should be considered in selecting the site for catheter insertion. Particular attention should be paid to the coagulation profile and factors which affect coagulation such as thrombolysis and activated protein C therapy.

Traditionally, puncture of the central vein is performed by passing a needle along the anticipated line of the vein

**Table 12.3** Complications of central venous catheterisation, with preventive and treatment options<sup>62</sup>

Complication	Prevention	Treatment
Intravascular loss of guidewire	Ensure guidewire is always secured. Avoid retracting guidewire into insertion needle. Seek assistance from experienced operator	Interventional radiology or surgery may be required for retrieval
Air embolism	Proper patient positioning, including Trendelenburg (head-down tilt) for jugular or subclavian insertion. Consider alternative insertion sites. Ensure connections are tight	Left lateral Trendelenburg position. Administer 100% oxygen and ventilatory support. If catheter in place, tighten all connections and attempt to aspirate air. Basic/advanced life support if necessary
Dysrhythmias and conduction defects such as right bundle branch block	Continuous electrocardiographic monitoring during insertion. Correct placement of catheter tip	Withdraw or remove guidewire or catheter
Damage to nearby structures: Pneumothorax/haemothorax/chylothorax/hydrothorax, particularly with approaches to subclavian vein. Nerve injury such as phrenic, recurrent laryngeal, Horner's syndrome. Arterial puncture – including injury to carotid, subclavian, aorta or pulmonary artery. Haematoma, pseudoaneurysm, arteriovenous fistula can result. Stroke may result from carotid artery injury. Tracheal injury. Femoral approach can be associated with bowel damage	Identify risk factors such as previous surgery, skeletal deformity or scarring at site of insertion. Seek assistance from experienced operator. Select insertion site depending on impact of potential complications. Consider ultrasound guidance. Scheduled, routine replacement of catheter increases risk of mechanical complications	Tailored to sequelae
Line disconnection and bleeding	Minimise connections. Proper catheter care and observation	Control bleeding. Transfusion may be necessary
Infection – local or systemic (including endocarditis)	Aseptic insertion technique. Lower risk with subclavian compared to internal jugular or femoral insertion. Antimicrobial-impregnated catheters. Disinfect catheter hubs. Routine scheduled resiting appears not to reduce systemic infection rates. Remove catheter when no longer required	Remove catheter; resite if necessary. Culture blood and catheter tip. Start empiric antibiotics if sepsis or septic shock is present
Superior vena caval erosion can result in haemothorax or cardiac tamponade	Remove catheter when no longer required	Early detection and surgical intervention
Thrombosis	Remove catheter when no longer required. Subclavian insertion lower risk than internal jugular or femoral	Anticoagulation, vascular or endovascular intervention may be required

with reference to surface anatomical landmarks (landmark method). Catheterisation is usually achieved via the subclavian, internal jugular or external jugular veins into the superior vena cava.<sup>12</sup> The median cubital and basilic veins are used less commonly. Access to the subclavian vein is usually via the infraclavicular approach, but the supraclavicular approach is safe and reliable in experienced hands.

The use of ultrasound has been advocated to optimise the success rate of CVC insertion and minimise complications.<sup>13</sup> Two-dimensional imaging can be used to localise the vein and define anatomy prior to placement of a CVC by standard landmark techniques. Ultrasound can also provide real-time, two-dimensional guidance during CVC insertion. Alternatively, audio-guided Doppler ultrasound can aid localisation of the vein and differentiate it from its companion artery during CVC insertion.

In 2002, the UK National Institute for Clinical Excellence issued guidelines recommending the use of ultrasound for elective catheterisation of the internal jugular vein, and consideration of ultrasound guidance in most clinical situations.<sup>14</sup> These recommendations for ultrasound-guided internal jugular catheterisation are supported by meta-analysis.<sup>15</sup> However, there are limited data supporting its use for subclavian and femoral veins.

The right tracheobronchial angle and carina are common radiological markers of insertion depth. In an attempt to reduce further the incidence of venous erosion (which is rare but potentially catastrophic), some practitioners place the catheter tip lower in superior vena cava or even in the upper right atrium, ensuring that the catheter is parallel to the long axis of the vein so that the tip does not abut the vein or heart wall end-on.<sup>16</sup>

Femoral venous catheterisation with radiological positioning of the tip close to the right atrium produces pressure measurements in good agreement with the subclavian CVP.<sup>17</sup>

## CENTRAL VENOUS PRESSURE

Jugular venous pressure, CVP and right atrial pressure (RAP) are often used interchangeably. However, in situations associated with increased central venous resistance,

such as central vein sclerosis, these pressures may not be the same.

The normal CVP in the spontaneously breathing supine patient is 0–5 mmHg, while 10 mmHg is generally accepted as the upper limit during mechanical ventilation. In health there is a good correlation between CVP and pulmonary artery occlusion pressures (PAOP), but this is lost in many types of critical illness such as pulmonary hypertension, pulmonary embolism, right ventricular infarction, left ventricular hypertrophy and myocardial ischaemia. The relationship between CVP and right ventricular end-diastolic volume (RVEDV: preload) is altered in critical illness by changes in right ventricular diastolic compliance and juxtacardiac pressures.<sup>18</sup>

Except at extreme values, static measures of CVP do not differentiate patients likely to respond to fluid therapy from non-responders. However, dynamic changes in CVP either in response to volume loading or related to respiration can assist in evaluating volume status.<sup>19</sup> For instance, a steep increase in CVP following volume challenge suggests the heart is functioning on the plateau portion of the Frank–Starling curve. Severe hypotension with a low or normal CVP is unlikely to be due to acute pulmonary embolism, cardiac tamponade or tension pneumothorax.

Although fluid manometry is sufficient to measure the CVP, the frequency response is low and waveform analysis impossible (Table 12.4). Therefore, an electrical transducer system is normally used.

In a trend toward less invasive monitoring, peripheral venous pressure and non-invasive estimates of CVP have demonstrated potential as alternatives to direct CVP measurement.<sup>20,21</sup>

### $S_{cvO_2}$

A recent prospective randomised study of patients with severe sepsis and septic shock demonstrated a survival advantage with the use of this monitoring technique and an emergency department treatment protocol (early goal-directed therapy).<sup>22</sup>  $S_{cvO_2}$  has been proposed as a marker of tissue hypoxia (see Chapter 14). It is mentioned here as an example of the scant data relating haemodynamic monitoring to improved survival.

**Table 12.4** Analysis of central venous pressure waveform

Condition	Pressure changes	Waveform changes
Tricuspid regurgitation	Increased RA pressure	Prominent v-wave, x descent obliterated, y descent steep
Right ventricular infarction	RA and RV pressure elevated. RAP does not fall and may rise in inspiration	Prominent x and y descents
Constrictive pericarditis	RA, RV diastolic, PA diastolic and occlusion pressures elevated and equalised. RAP may rise in inspiration	Prominent x and y descents
Pericardial tamponade	RA, RV diastolic, PA diastolic and occlusion pressures elevated and equalised. RAP usually falls in inspiration	y descent damped or absent

RA, right atrial; RV, right ventricular; RAP, right atrial pressure; PA, pulmonary artery.

### PULMONARY ARTERY CATHETER

Right-heart catheterisation using a flow-directed balloon-tipped catheter was introduced by Swan and Ganz in 1970.<sup>23</sup> The ability to monitor sophisticated haemodynamic and gas exchange variables at the bedside appealed to clinicians, and the PAC was rapidly accepted into routine critical care.

In 1996 a non-randomised cohort study of PAC use in American teaching hospitals appeared to show that, in any of nine major disease categories, PAC in the first 24 hours increased 30-day mortality (odds ratio 1.24, 95% confidence interval (CI) 1.03–1.49), mean length of stay and mean cost per hospital stay.<sup>24</sup> A simultaneous editorial called for a moratorium on PAC use, and for a prospective multicentre trial.<sup>25</sup>

A subsequent Cochrane database systematic review of PAC monitoring in adult ICU patients incorporated data from two recent multicentre trials and 10 other studies.<sup>26</sup> The pooled mortality odds ratio for studies of general ICU patients was 1.05 (95% CI 0.87–1.26) and for studies of high-risk surgery patients was 0.99 (95% CI 0.73–1.24). PAC monitoring had no impact on ICU or hospital length of stay (where reported). A recent multicentre trial incorporating protocolised haemodynamic management of patients with acute lung injury compared PAC-guided with CVC-guided therapy.<sup>27</sup> There were no significant differences in 60-day mortality or organ function between groups. Overall, these data suggest that PAC monitoring in critically ill patients is not associated with increased mortality or with survival benefit.

On the other hand, recent data suggest a differential association between PAC use and mortality dependent upon severity of illness. Logistic regression analyses of data from a tertiary-care university teaching hospital<sup>28</sup> and from the National Trauma Data Bank (American College of Surgeons)<sup>29</sup> suggest that PAC use may be associated with survival benefit in the most severely ill/injured patients.

Overall, the PAC still finds application as a haemodynamic monitoring tool in the ICU and the operating room. However, its role is under increasing scrutiny, and continues to decline in favour of less invasive alternatives. It could be argued that future PAC use should be guided by studies to determine optimal management protocols and appropriate patient groups.<sup>26</sup>

Traditional indications for PAC monitoring have been to:

- characterise haemodynamic perturbation (e.g. distributive, cardiogenic, obstructive and hypovolaemic shock or combinations)
- differentiate cardiogenic from non-cardiogenic pulmonary oedema
- guide use of vasoactive drugs, fluids (including renal replacement therapy) and diuretics, especially when haemodynamic disturbances are coupled with increased lung water, right ventricular or left ventricular dysfunction, pulmonary hypertension and organ dysfunction

Contraindications for insertion reflect those for CVC. If known in advance, atypical cardiac or vascular anatomy, either congenital or secondary to trauma or surgery, should also be considered. Less invasive monitoring might provide the data that are sought. Also, PAC monitoring does not exclude simultaneous recourse to other monitoring techniques.

### CATHETER INSERTION<sup>30</sup>

A 7.5–9 F 15-cm introducer sheath is first inserted by the Seldinger technique. The subclavian and internal jugular veins are most commonly used. Access is feasible with the 110-cm catheter via the median cubital, basilic and femoral veins. The external jugular veins can also be used, although difficulty may be encountered passing the introducer both into the vein and then subsequently below the clavicle into the subclavian vein.

Balloon volume is 1.5 ml. The balloon should be tested prior to insertion into the sheath. Deflation should always occur passively to minimise the risk of balloon damage. Before passage through the heart the balloon should be inflated to assist flow guidance and protect against myocardial injury and dysrhythmias. Inflation should not be forced, and should not alter the waveform prior to wedging. The right atrium is reached at 15–20 cm from the internal jugular vein, 10–15 cm from the subclavian vein, 30–40 cm from the femoral vein and 40 and 50 cm respectively from the right and left basilic veins. The right ventricle and pulmonary artery (PA) are then entered at additional 10-cm intervals, with a further 10 cm to PA occlusion.<sup>31</sup> Waveforms seen as the catheter floats to the wedged position are shown in Figure 12.1.

### MEASURED VARIABLES

The PAC remains unique in its ability to measure right ventricular and pulmonary arterial pressures directly at the bedside. In acute respiratory distress syndrome (ARDS), where pulmonary hypertension and increased right ventricular afterload are linked to excess mortality,<sup>32</sup> a PAC can assist in the titration of afterload-reducing therapies such as inhaled prostacyclin or nitric oxide.

In this context echocardiography might be considered as a less invasive alternative, since it provides a qualitative assessment of right ventricular loading<sup>33</sup> and can estimate PA pressures via Doppler techniques.<sup>34</sup> However, these are largely confined to intermittent ‘snapshot’ assessments, and can be challenging in mechanically ventilated patients.

Normal pressures are given in Table 12.5.

### PULMONARY ARTERY OCCLUSION PRESSURE

Measurements of PAOP should be performed by slow injection of air into the balloon while watching the PA waveform. Overwedging can lead to falsely high occlusion pressures or pulmonary arterial rupture. Less than 1.5 ml air may be required. Deflation after PAOP measurement should re-establish the normal pulmonary

**Figure 12.1** Pressure tracings and electrocardiogram (ECG) trace obtained on insertion of a pulmonary artery catheter. The snap flush test confirms an appropriate frequency response and degree of damping. RA, right atrial trace; RV, right ventricular trace (note simultaneous premature ventricular contractions during RV passage of the catheter); PA, pulmonary artery trace (note dichotic notch and elevated diastolic pressure); PW, pulmonary wedge trace (note respiratory variation). In: Tobin MJ (ed.) *Principles and Practice of Intensive Care Monitoring*. New York: McGraw Hill; 1998: 822.)

**Table 12.5** Measured and derived variables from pulmonary artery catheter

Site	mmHg	kPa
Right atrium: mean	-1-7	0.13-0.93
Right ventricle: systolic	15-25	2.0-3.3
Right ventricle: diastolic	0-8	0-1.1
Pulmonary artery: systolic	15-25	2.0-3.3
Pulmonary artery: diastolic	8-15	1.1-2.0
Pulmonary artery: mean	10-20	1.3-2.6
Pulmonary artery occlusion pressure	6-15	0.8-2.0

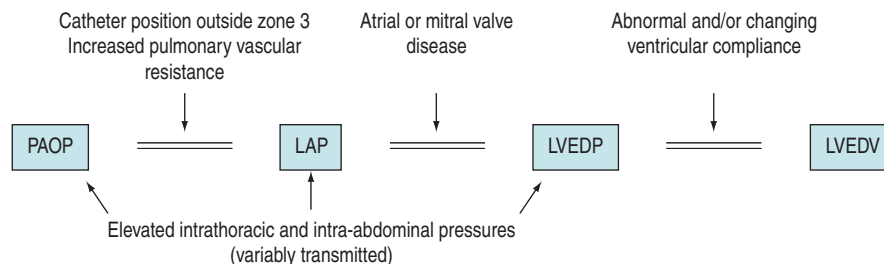

arterial waveform. If not, distal migration has occurred and the catheter should be withdrawn until the waveform is re-established.

PAOP should be measured during end-expiration and ideally in end-diastole, using the electrocardiogram (ECG) P-wave as a marker. PAOP has been termed the

back-pressure to pulmonary blood flow,<sup>35</sup> and is also a key determinant of pulmonary capillary pressure (see below) and hence extravascular lung water. When the catheter wedges in a branch of the PA it creates a static column of blood which equilibrates with downstream pressure at the site where it rejoins the flowing pulmonary venous system (the j point). Here the blood is very near the left atrium. PAOP therefore closely approximates left atrial pressure (LAP), which approximates left ventricular end-diastolic pressure (LVEDP). The validity of PAOP as a surrogate of preload depends on a number of assumptions (Figure 12.2). These assumptions are often incorrect in critically ill patients and the use of PAOP to reflect preload has been questioned.<sup>36</sup>

### Zone 3 or not?<sup>37</sup>

The catheter tip usually floats to a level at or below the left atrium. To maintain a column of fluid between the

**Figure 12.2** Factors affecting the accuracy of pulmonary artery occlusion pressure (PAOP) as a measure of preload in critically ill patients. Clinically, left ventricular end-diastolic volume (LVEDV) is usually accepted as a surrogate of preload. LAP, left atrial pressure; LVEDP, left ventricular end-diastolic pressure.

pressure transducer and the LAP, the tip should be in West's zone 3 (alveolar pressure < pulmonary venous pressure). Factors which increase the likelihood of wedging in zones 1 and 2 include high intrathoracic pressures when there is normal or increased lung compliance (e.g. obstructive pulmonary disease and high intrinsic positive end-expiratory pressure (PEEP)) and low cardiac output states. Here, rotating the relevant lung down maximises the likelihood of zone 3 positioning.

At the bedside, tests which suggest appropriate zone 3 catheter tip positioning include:

- tip of the catheter at or below the left atrium on lateral supine chest radiograph
- clearly delineated atrial waveforms
- respiratory variation of PAOP is  $\leq 50\%$  static airway pressure (peak – plateau)
- PAOP alters by < 50% of PEEP alterations

#### Waveform analysis

As with CVP, analysis of the PAOP waveform may give some indication of cardiac pathology. Constrictive pericarditis and pericardial tamponade show the same abnormalities (but less clearly) as in the CVP trace. Mitral regurgitation may cause a large v-wave, which may be confused with the PA waveform. The two can be distinguished by examining the timing of the waves relative to the T-wave of the ECG. The peak of the PA systolic wave occurs before and the v-wave occurs after the T-wave. Large v-waves may also be associated with mitral stenosis, congestive heart failure or ventricular septal defect.

#### Potential substitutes for PAOP

Measurement of PAOP requires wedging, which is associated with a number of risks (Table 12.6). The normal PA diastolic pressure (PADP) to PAOP gradient is < 5 mmHg, so that PADP may normally be used as a close approximation for PAOP. However, tachycardia (> 120 beats/min) and conditions that increase pulmonary vascular resistance (such as ARDS, chronic obstructive pulmonary disease and pulmonary embolism) variably increase this gradient, invalidating direct substitution of PADP for PAOP. The relationship between PADP and PAOP tends to be stable over hours. Once this is determined, PADP can be used to track PAOP in the short term without repeated wedge manoeuvres.

Echocardiographic (non-invasive) estimation of PAOP has recently been described in critically ill patients.<sup>38</sup>

#### PULMONARY CAPILLARY HYDROSTATIC PRESSURE ( $P_{cap}$ )<sup>39</sup>

$P_{cap}$  tends to force fluid out of the pulmonary capillaries into the interstitium, and when elevated can contribute to the development of pulmonary oedema. In critical illness such as ARDS and sepsis, variability in the distribution of the precapillary and postcapillary resistance alters the relationship between  $P_{cap}$  and PAOP. Because of this, a normal PAOP may substantially underestimate the tendency for fluid leakage from the pulmonary capillaries.

Although it can be challenging, measurement of  $P_{cap}$  can be performed at the bedside by analysis of a pressure transient after an acute PA occlusion (Figure 12.3).

#### MIXED VENOUS OXYGEN TENSION AND SATURATION

See Chapter 14.

#### BOLUS THERMODILUTION CARDIAC OUTPUT

A bolus injection into the right atrium of cold injectate (usually 5% dextrose) transiently decreases blood temperature in the PA (monitored by a thermistor proximal to the balloon). The mean decrease in temperature (calculated by integrating temperature over time) is inversely proportional to the cardiac output, which can be determined by a modification of the Stewart–Hamilton equation:

$$Q = \frac{V \times (Tb - Ti)K1 \times K2}{Tb(t)dt}$$

where  $Q$  = cardiac output;  $V$  = volume injected;  $Tb$  = blood temperature;  $Ti$  = injectate temperature;  $K1$  and  $K2$  = corrections for specific heat and density of injectate and for blood and dead space volumes; and  $Tb(t)dt$  = change in blood temperature as a function of time.

This is an indicator dilution method, using temperature change instead of indocyanine green dye, radioisotopes or chemicals such as sodium thiocyanate and hypertonic saline. Advantages are:

- The indicator is non-toxic.
- It does not recirculate. Repeat measurements are limited only by volume constraints and the time to regain temperature stability between injections.
- The method shows good agreement with the Fick and indocyanine green methods. However, there is considerable variability. A clinically significant change in cardiac output cannot be diagnosed with certainty unless there is a difference of approximately 15% between the mean of three cardiac output determinations and the previous mean.<sup>40</sup>

Too much or too little injectate will respectively underestimate and overestimate cardiac output. Cold injectate (preferably 0–4°C, but up to 12°C is usually accepted) improves the signal-to-noise ratio, but causes a brief decrease in heart rate, reducing cardiac output while it is being measured. Room temperature injectate introduces a small decrement in bias and precision, but has acceptable accuracy. However, the accuracy using room temperature injectate is further degraded at extremes of cardiac index, high ambient temperatures (and thus injectate temperature) or in patient hypothermia.<sup>29</sup>

Respiration causes fluctuations in cardiac output and PA temperature. Reproducibility is improved by taking measurements in expiration, though this may not reflect cardiac output throughout the respiratory cycle. Timing can be difficult and in practice an average of three evenly spaced measurements is taken. Causes of inaccurate measurements are listed in Table 12.7.

**Table 12.6** Complications encountered with the pulmonary artery catheter (PAC) with proposed measures for prevention and treatment<sup>63</sup>

Complications	Prevention	Treatment
<b>During insertion</b>		
Damage to adjacent structures	As for central venous cannulation	As for central venous cannulation
Perforation of pulmonary artery	Ensure balloon inflated throughout insertion. Continuously monitor pulmonary artery waveform. Avoid distal PAC tip position	As for pulmonary artery rupture below
Air embolism	Raise venous pressure prior to insertion. Always occlude open ends during insertion. Use sheaths with pneumatic valve. Periodically check and tighten all connections. Remove air from fluid bag and tubing. Dress site with occlusive dressing after removal	Left lateral Trendelenburg position. Administer 100% oxygen and ventilatory support. If PAC in place, tighten all connections and attempt to aspirate air from right atrium or right ventricle. Basic/advanced life support if necessary
Dysrhythmia	Keep balloon inflated during passage from RA to PA. Minimise insertion time	For sustained ventricular tachycardia, remove PAC from right ventricle. For ventricular fibrillation, remove PAC and defibrillate
Right bundle branch block/complete heart block	Avoid PAC insertion in patients with left bundle branch block (LBBB) if possible. Insert PAC with pacing electrodes in patients with LBBB	Use pacing equipment as required
Catheter knotting/kinking	Minimise insertion time. Do not advance catheter against resistance. Check for waveform change from RA to RV or RV to PA after advancing 15 cm; if not, withdraw catheter	Check chest X-ray. Pull knot back then remove the sheath and catheter. If no sheath used, a cut-down to vein under local anaesthesia may be required. Exploration by a vascular surgeon is indicated if unsuccessful (5% of occasions)
Valve damage	Ensure balloon is inflated during forward passage through the heart and deflated prior to any retraction	Cardiothoracic consultation
<b>During maintenance</b>		
Dysrhythmia (37%)	Remove PAC when no longer required	See above
Thrombosis	As for central venous cannulation	As for central venous cannulation
Pulmonary artery rupture (0.2%)	Risk factors include pulmonary hypertension, anticoagulation and in situ duration > 3 days. Maintain high level of suspicion. Avoid distal PAC tip position. Minimise wedge procedures. Continuously monitor pulmonary artery waveform – withdraw PAC if spontaneous wedging occurs, inflate with only enough air to change PA to PAOP waveform. Withdraw PAC if PAOP obtained with < 1.25 ml air	Check PAC position on chest X-ray, deflate and pull back. If applicable, stop anticoagulation therapy. Lateral position, affected side down. Selective bronchial intubation. PEEP. Surgical repair
Pulmonary infarction	As for pulmonary artery rupture	Check PAC position on chest X-ray, deflate and pull back. Observe
Infection – including endocarditis	As for central venous cannulation	As for central venous cannulation
Air embolism	High suspicion of balloon rupture. Avoid repeating failed attempts to inflate	See above

RA, right atrial; PA, pulmonary artery; RV, right ventricular; PEEP, positive end-expiratory pressure; PAOP, pulmonary artery occlusion pressure.

**Figure 12.3** Capillary pressure ( $P_{cap}$ ) has been estimated from the pulmonary artery pressure decay following occlusion with balloon inflation. For better visualisation the occlusion trace is superimposed on a non-occluded trace, both recorded during an expiratory hold during mechanical ventilation. An additional trace using 20 data point moving average smoothing of the original trace (collected at 100 Hz) is superimposed on the curves. This further facilitates the visual estimation of the capillary pressure by defining more exactly the point of divergence of the occluded and non-occluded curves. In addition, an exponential curve has been fitted on the curve 0.3–2 s after occlusion. This fitted curve has then been extrapolated to the time of occlusion to provide the capillary pressure. (Reproduced from Takala J. Pulmonary capillary pressure. *Intens Care Med* 2003; **29**: 890–3, Figure 1, with kind permission of Springer Science and Business Media.)

**Table 12.7** Causes of inaccurate bolus thermodilution cardiac output measurements

Catheter malposition
Wedge position
Thermistor impinging on vessel wall
Abnormal respiratory pattern
Intracardiac shunts
Tricuspid regurgitation (common in mechanically ventilated patients)
Cardiac dysrhythmias
Incorrect recording of injectate temperature (minimised by siting thermistor on injection port)
Rapid intravenous infusions, especially if administered via the introducer sheath
Injectate port close to or within introducer sheath
Abnormal haematocrit values (affecting $K_2$ value)
Extremes of cardiac output (room temperature injectate)
Poor technique
Slow injection (> 4 s)
Incorrect injectate volume

### SEMICONTINUOUS THERMODILUTION CARDIAC OUTPUT<sup>41</sup>

This method uses the same principles as bolus thermodilution, but allows semicontinuous measurement by employing a thermal filament wrapped around the right ventricular segment of the catheter. This transmits low-power pulses of heat. ‘On-off’ heat pulses in pseudo-random binary code are delivered in cycles. The downstream thermistor detects the heat pulses, which are then cross-correlated with the input sequence and power (to allow differentiation of thermal signal from noise).

The method shows good experimental agreement with the Fick and bolus thermodilution methods, with bias and precision in the ranges of  $-0.08$  to  $+0.35$  and  $0.5$ – $1.2$  l/min respectively.

Drawbacks of the technique are:

- inaccuracy during thermal disequilibrium,<sup>42</sup> such as rapid infusions of cool fluids or after cardiac bypass
- delay in detecting sudden changes in cardiac output<sup>42</sup>
- magnetic resonance imaging is contraindicated (it can melt the thermal filament)
- electrocautery can interfere with measurements

### DERIVED VARIABLES

A number of variables can be derived from the measurements obtained with a standard PAC (Table 12.8).

### VOLUMETRIC PAC<sup>43</sup>

A recently available PAC incorporating a rapid-response thermistor allows semicontinuous assessment of cardiac output, right ventricular ejection fraction (RVEF) and RVEDV. This algorithm supersedes RVEDV based on bolus thermodilution. The new algorithm uses the slaved electrocardiograph signal and generates a relaxation waveform, which resembles the bolus thermodilution washout decay curve. The waveform is generated by accumulating the temperature change for each on- and each off-segment of the input signal. Calculation of RVEF is based on estimation of the exponential decay time constant ( $t$ ) of this curve and heart rate (HR):

$$\text{RVEF} = 1 - \exp(-60/[t \times \text{HR}])$$

Table 12.8 Derived haemodynamic variables

Parameter	Abbreviation	Formula	Normal range	Units
Mean arterial pressure	MAP	$DBP + 0.33 \times (SBP - DBP)$	70–105	mmHg
Mean pulmonary artery pressure	MPAP	$PADP + 0.33 \times (PASP - PADP)$	9–16	mmHg
Mean right ventricular pressure	MRVP	$CVP + 0.33 \times (PASP - CVP)$		mmHg
LV coronary perfusion pressure	LVCPP	$DBP - PAOP$		mmHg
RV coronary perfusion pressure	RVCP	$MAP - MRVP$		mmHg
Cardiac index	CI	$CO/BSA$	2.8 – 4.2	l/min per m <sup>2</sup>
Stroke volume index	SVI	$CI/HR$	35 – 70	ml/beat per m <sup>2</sup>
Systemic vascular resistance index	SVRI	$(MAP - CVP)/CI \times 79.92$	1760 – 2600	dyn s/cm <sup>5</sup> per m <sup>2</sup>
Pulmonary vascular resistance index	PVRI	$(PAP - PAOP)/CI \times 79.92$	44 – 225	dyn s/cm <sup>5</sup> per m <sup>2</sup>
Left ventricular stroke work index	LVSWI	$SVI \times MAP \times 0.0144$	44 – 68	g m/m <sup>2</sup> per beat
Right ventricular stroke work index	RVSWI	$SVI \times PAP \times 0.0144$	4 – 8	g m/m <sup>2</sup> per beat
Body surface area	BSA	$Weight (kg)^{0.425} \times height (cm)^{0.725} \times 0.007184$		m <sup>2</sup>

DBP, diastolic blood pressure; SBP, systolic blood pressure; PADP, pulmonary artery diastolic pressure; PASP, pulmonary artery systolic pressure; CVP, central venous pressure; LV, left ventricular; PAOP, pulmonary artery occlusion pressure; RV, right ventricular; CO, cardiac output; HR, heart rate.

RVEDV is calculated from cardiac output (CO) and RVEF as follows:

$$RVEDV = (CO/HR)/RVEF$$

The correlation between thermodilution RVEDV and thermodilution cardiac output is not fully explained by mathematical coupling of these variables.<sup>44</sup> Thermodilution techniques appear to overestimate RVEDV and underestimate RVEF.<sup>45</sup> However, right ventricular geometry is complex and there are limited options for bedside volumetric evaluation.

### COMPLICATIONS OF PAC

These are listed in Table 12.6. A catheter may not actually be knotted, despite a chest X-ray appearance to suggest this. If knotting is suspected, other catheters should be removed in reverse order to which they were inserted, and the chest X-ray repeated.

### TRANSPULMONARY INDICATOR DILUTION

With this technique, thermal and other indicators injected into a central vein are detected in a systemic artery. Because the indicators pass through all chambers of the heart as well as the entire pulmonary circulation,

information additional to cardiac output can be gained. In particular, central blood volumes and indices of extravascular lung water can be quantified (Figure 12.4).

### TRANSPULMONARY THERMODILUTION<sup>8,46</sup>

A fiberoptic thermistor is positioned in the femoral artery at the tip of a modified 4F arterial catheter. Cardiac output is measured by administering a central venous bolus of cold injectate, constructing an arterial thermodilution curve and applying the Stewart–Hamilton equation. The axillary artery can also be used, but placing the sensor in more peripheral arteries such as the radial causes overestimation of cardiac output. Curves are longer and flatter than PAC curves due to thermal equilibration with intrathoracic blood and extravascular lung water, but are unaffected by the respiratory phase of injection. Measurements are in good agreement with pulmonary thermodilution and direct Fick methods. There is a positive bias of about 5%, perhaps because of indicator loss, or because transpulmonary measurements are less affected by the transient decrease in heart rate induced by cold thermodilution.

### USE OF A SECOND INDICATOR

Combining thermal dilution with simultaneous dye dilution is the basis of the double-indicator technique. Indocyanine green is used because it is non-toxic and highly

**Figure 12.4** Diagrammatic representation of the mixing chambers of the cardiopulmonary system. CV, central venous; EVLW, extravascular lung water; LAEDV, left atrial end-diastolic volume; LVEDV, left ventricular end-diastolic volume; PBV, pulmonary blood volume; RAEDV, right atrial end-diastolic volume; RVEDV, right ventricular end-diastolic volume; TD, thermodilution. ITTV is the whole volume between the points of injection and detection, including the EVLW. Pulmonary thermal volume (PTV) is the sum of PBV + EVLW. ITBV is the sum of RAEDV + RVEDV + PBV + LAEDV + LVEDV. EVLW = ITTV – ITBV. GEDV is the sum of RAEDV + RVEDV + LAEDV + LVEDV. (Reproduced from Hudson ERGN, Beale RF. Lung water and blood volume measurements in the critically ill. *Curr Opin Crit Care* 2000; **6**: 222–6.)

albumin-bound, remaining confined to the intravascular space on its initial circulation. Rapid-response measurements can now be achieved using an in vivo fiberoptic sensor at the catheter tip.

### Calculations

The equilibration volumes for each indicator between injection and detection points are calculated as the product of the transpulmonary thermodilution cardiac output ( $CO_{TPTD}$ ) and the mean transit time (MTT), where MTT is first determined from a semilogarithmic transformation of the indicator dilution curve. Hence:

$$\begin{aligned} CO_{TPTD} \times MTT_{dye} &= \text{intrathoracic blood volume (ITBV)} \\ CO_{TPTD} \times MTT_{thermal} &= \text{intrathoracic thermal volume (ITTV)} \\ ITTV - ITBV &= \text{extravascular lung water (EVLW)} \end{aligned}$$

Indocyanine green concentrations after complete mixing can then be used to calculate the circulating blood volume and the subsequent concentration decay can serve as a liver function test.

### ITBV

Unlike CVP and PAOP, ITBV is a volumetric preload index. Interpretation is thus independent of alterations in juxtacardiac pressures or myocardial compliance, and should be superior to conventional pressure indices. There is experimental and clinical evidence that this is so.<sup>47</sup>

### EVLW<sup>48</sup>

EVLW is a marker of the severity of illness. Following EVLW as a therapeutic end-point may reduce positive fluid balances and ventilator and ICU days. EVLW also

appears to offer prognostic information in sepsis and acute lung injury.

### EXTENDED APPLICATION OF TRANSPULMONARY THERMODILUTION (SINGLE INDICATOR)<sup>8,46</sup>

This approach retains the advantages of the double indicator method, while being much easier and less expensive, and thermodilution-derived EVLW\* and ITBV\* show good agreement with the double-indicator method. (Note: asterisks differentiate parameters derived from the single-indicator method (EVLW\* and ITBV\*) from the identically named/labelled double-indicator parameters.) However, errors in volume measurement may occur in the presence of large aortic aneurysms, intracardiac shunts, pulmonary embolism or acute changes in chamber size (such as recent pulmonary lobectomy or pneumonectomy).

The pulmonary thermal volume (PTV; Figure 12.4) can be determined from the product of cardiac output and the 'exponential downslope time' (DST) on the semilogarithmic thermodilution curve. This relationship assumes that the majority of temperature decay occurs in the largest mixing chamber (PTV). This allows calculation of the global end-diastolic volume (GEDV), which is said to represent the volume of blood in all chambers of the heart at end-diastole. Hence:

$$ITTV - PTV = GEDV$$

ITBV\* can be derived as a linear function of GEDV:

$$ITBV^* = 1.25 \times GEDV - 28.4 \text{ ml}$$

Like ITBV, GEDV has been shown to be a more reliable measure of cardiac preload than conventional pressure-based surrogates.<sup>49</sup> Interpretation of measurements should account for the lack of differentiation between left and right cardiac volumes. For example, the clinical context and supplemental data may be important in differentiating acute cor pulmonale from left ventricular failure. Both these conditions could result in elevated ITBV/GEDV but require different therapy. Also low ITBV/GEDV does not mandate fluid challenge. For instance, low ITBV/GEDV in the setting of restrictive or constrictive pathology might not represent inadequate intravascular volume. These conditions may be associated with high CVP despite low ITBV/GEDV.

A device is available which employs transpulmonary thermodilution both to measure EVLW\* and the preload indices ITBV\* and GEDV, and to calibrate continuous cardiac output measurements by the pulse contour technique. The method is suitable for small children, in whom PAC is not feasible.

### LITHIUM DILUTION CARDIAC OUTPUT<sup>50</sup>

Lithium can also serve as a transpulmonary indicator. The small doses of lithium required are non-toxic and easily measured with an ion-selective electrode. Following injection, there is no significant first-pass loss from the

circulation. Blood is sampled from an arterial line via a three-way tap. A peristaltic pump limits sampling to 4 ml/min. After passing through the sensor, blood is discarded.

The main advantage over thermodilution is that more peripheral arteries such as the radial can be used without loss of accuracy. Also, injection can be performed peripherally if central venous access is unavailable. The technique shows good agreement with bolus thermodilution (PAC). It is able to measure cardiac output safely and accurately in adult and paediatric populations.

Limitations include:

- It cannot be used in patients receiving lithium therapy (background lithium concentration contributes to overestimation of cardiac output).
- Electrode drift can occur in the presence of high peak doses of muscle relaxants.
- Abnormal shunts can result in erroneous cardiac output measurements (true for all indicator dilution methods).
- Ex vivo analysis requires disposal of sampled blood.

### PULSED-DYE DENSITOMETRY<sup>51</sup>

Pulsed-dye densitometry allows intermittent cardiac output measurement based on transpulmonary dye dilution, with transcutaneous signal detection adapted from pulse oximetry. After central venous injection of indocyanine green, the concentration is estimated in the arterial blood by optical absorbance measurements. Using the Stewart–Hamilton formula, the cardiac output can be calculated from the resultant dye dilution curve.

Poor peripheral circulation, vasoconstriction, interstitial oedema, movement artefact and ambient light influences impair peripheral signal detection. This technique still has significant limitations.

### ULTRASOUND

Two approaches are available to measure stroke volume (and thereby, cardiac output) using sound waves. The first involves the use of echocardiography to measure systolic and diastolic left ventricular volumes. Stroke volume is calculated as the difference between these two volumes. Access to expensive echocardiographic equipment and trained personnel limits the usefulness of this technique for haemodynamic monitoring. The second method uses Doppler techniques to measure stroke volume (Figure 12.5).<sup>52</sup> This approach is less dependent on image quality and shows better agreement with thermodilution.<sup>53</sup> Although ultrasonic measurements tend to be operator-dependent, Doppler measurement of aortic blood flow demonstrates good reproducibility (intraobserver, interobserver and day-to-day variability  $3.2 \pm 2.9\%$ ,  $5.4 \pm 3.4\%$  and  $3.3 \pm 3.1\%$ , respectively).<sup>54</sup>

The Doppler principle states that the frequency of reflected sound is altered by a moving target, such as red blood cells. Continuous and pulsed-wave Doppler are the main techniques employed to measure flow. Physical principles for the two techniques are similar. Pulsed-wave Doppler allows the site (depth) of sampling to be specified; the target sample is usually central laminar flow. With continuous-wave Doppler, a piezoelectric crystal transmits the ultrasound beam while another measures the frequency of

**Figure 12.5** Doppler stroke volume calculation. The cross-sectional area (CSA) of flow is calculated as a circle from echocardiographic measurements or nomogram-based estimations. Velocity–time integral (VTI) is the integral of Doppler velocity with regard to time. Stroke volume (SV) is calculated as the product of CSA and VTI (ml/s in this example). Cardiac output is calculated from the product and SV and heart rate. Peak velocity of flow ( $V_{\text{peak}}$ ) is also indicated.

reflected waves. The velocities of all the red blood cells moving along the path of the ultrasound beam are recorded. As a result, a continuous-wave Doppler recording consists of a full spectral envelope with the outer border corresponding to the fastest-moving blood cells. The flow velocity ( $V$ ) of red cells can be determined from the Doppler shift in the frequency of reflected waves.

$$V = (2F_0 \times \cos \theta)^{-1} \times C \Delta F$$

where  $C$  is the speed of ultrasound in tissue (1540 m/s),  $\Delta F$  is the frequency shift,  $F_0$  is the emitted ultrasound frequency, and  $\theta$  is the angle of incidence. The most accurate results are obtained when the ultrasound beam is parallel to flow ( $\theta = 0^\circ$ ,  $\cos \theta = 1$ ;  $\theta = 180^\circ$ ,  $\cos \theta = -1$ ). However, angles up to  $20^\circ$  still yield acceptable results ( $\theta = 20^\circ$ ,  $\cos \theta = 0.94$ ).

In addition to measuring stroke volume, Doppler assessment of aortic blood flow can provide additional haemodynamic information. For instance, the duration of the aortic velocity signal corrected for heart rate (corrected flow time:  $FT_c$ ) is inversely related to the systemic vascular resistance; hence, it is a marker of left ventricular afterload. A decrease in left ventricular preload can be associated with an increase in afterload (low  $FT_c$ ). Other causes include excessive vasopressor doses, heart failure and hypothermia (all produce a low  $FT_c$ ).<sup>55</sup> The peak velocity of aortic blood flow ( $V_{\text{peak}}$ ) has been proposed as an index of contractility. Also, respiratory variation in  $V_{\text{peak}}$  ( $\Delta V_{\text{peak}}$ ) has been described as a predictor of increased cardiac output in response to fluid challenge.<sup>56</sup>

### OE SOPHAGEAL DOPPLER MONITORING<sup>8,57</sup>

Oesophageal Doppler measures blood flow velocity in the descending aorta with a Doppler probe (usually 4-MHz continuous wave or 5-MHz pulsed wave depending upon device) incorporated in the tip of a flexible probe. The probe is positioned in the oesophagus about 30–40 cm from the teeth. At this point, the aorta runs parallel to the oesophagus and the systolic cross-sectional area varies least. The probe is rotated to obtain a characteristic aortic signal. The aortic cross-sectional area is either determined from nomograms of age, weight and height, or calculated from a measured diameter (M-mode ultrasound). Calibration against other cardiac output methods is also possible.

Oesophageal Doppler appears to offer a useful alternative to thermodilution techniques for monitoring cardiac output and its variation. Moreover, randomised studies using the technique to guide fluid titration have demonstrated benefit in high-risk surgical patients. Lower complication rates and shorter hospital stay have been demonstrated after cardiac and abdominal surgery and after femur fracture fixation.

#### ADVANTAGES

- Only a short period of training is required. Nurses at the bedside can follow volume challenge protocols guided by Doppler indices.

- The probes (6 mm in diameter) are minimally invasive, and can be inserted nasally or orally.
- Contraindications are few. They include severe agitation, pharyngo-oesophageal pathology, aortic balloon counterpulsation, aortic dissection or severe aortic coarctation.<sup>43</sup>
- Insertion is simple, allowing reduced time to data acquisition and treatment.
- Probes are relatively stable once placed. If displaced they can be repositioned quickly, and can be left in place for days in a sedated, ventilated patient.

#### DISADVANTAGES

- Assumptions that descending aortic flow is 70% of total cardiac output and that nomograms accurately determine aortic cross-section can be incorrect. This limits usefulness when there is aortic pathology or compression, or abnormal upper-/lower-body blood flow distributions.
- Flow in the aorta is not always laminar. Conditions such as tachycardia, anaemia and aortic valve disease can cause turbulent aortic blood flow and alter velocity measurements.
- Assumptions that the aorta is cylindrical with a fixed systolic cross-section are not always valid. The cross-sectional area of the aorta is actually dynamic and is dependent on the pulse pressure and aortic compliance. This may be particularly relevant in children, where aortic cross-section fluctuates in systole.
- Finding and maintaining optimal probe positioning is important for consistency in trend measurements.
- The probe may be poorly tolerated in non-sedated patients. Oral insertion is usually reserved for intubated patients receiving sedation. Trends toward minimal sedation and shorter duration of endotracheal intubation might decrease the practicality of this technique in many patients.

### TRANSCUTANEOUS DOPPLER MONITORING

In the past, stroke volume and cardiac output have been measured with varying success by placing Doppler probes externally at the cardiac apex and suprasternal notch. Recently, an external continuous-wave Doppler monitoring device capable of measuring transpulmonary (parasternal) and transaortic (suprasternal) cardiac output has become available. Flow diameters are estimated by a proprietary algorithm based upon the linear association between height and cardiovascular dimensions.<sup>58</sup> This allows measurement of stroke volume without two-dimensional echocardiographic measurements of valve diameters, which can be technically difficult.<sup>52</sup> If diameters are known, this information can be entered into the device.

Like oesophageal Doppler, this method appears to offer a clinically useful alternative to thermodilution techniques for monitoring cardiac output and its variation.<sup>59</sup> The technique can be used in all age groups and can be comfortably performed in non-sedated patients.

**PARTIAL REBREATHING OF CO<sub>2</sub>**<sup>8,10,51</sup>

The Fick principle is an extension of the law of conservation of mass and states that the amount of a substance taken up by an organ (or the whole body) per unit time is the product of the arteriovenous concentration difference by the blood flow to the organ (or body). Historically it has been used to determine cardiac output by analysing oxygen uptake from the lungs (direct Fick method). This method requires PA catheterisation to sample mixed venous blood. Traditionally, it has been considered the 'gold standard', but in most ICU patients the stringent preconditions for accuracy are not met. Further error is introduced by the elevated oxygen consumption of inflamed lungs. Use is therefore mainly confined to cardiac laboratories.

The Fick principle can be applied to indicators other than oxygen. The indirect Fick method employs CO<sub>2</sub> as an alternative. The indirect Fick method can be represented mathematically by the formula:

$$\text{Cardiac output} = V_{\text{CO}_2} / (C_{\text{vCO}_2} - C_{\text{aCO}_2})$$

where  $V_{\text{CO}_2}$  is whole-body CO<sub>2</sub> elimination, and  $C_{\text{aCO}_2}$  and  $C_{\text{vCO}_2}$  are the CO<sub>2</sub> contents of arterial and mixed venous blood respectively.

A partial rebreathing technique can be used to eliminate the need to measure  $C_{\text{vCO}_2}$  directly. The rebreathing values are obtained by introducing an additional 150 ml of dead space into the ventilator circuit (disposable rebreathing loop) and taking measurements once a new equilibrium has been established. Cardiac output can be measured at 3-minute intervals. Assuming that the  $C_{\text{vCO}_2}$  concentration does not change significantly throughout the rebreathing period, the terms associated with  $C_{\text{vCO}_2}$  cancel each other out and are not needed to calculate cardiac output.

The CO<sub>2</sub> concentration and airflow during a breathing cycle are measured by a mainstream infrared and airflow sensor.  $V_{\text{CO}_2}$  is obtained by multiplying airflow by CO<sub>2</sub> concentration.  $C_{\text{aCO}_2}$  is derived from end-tidal CO<sub>2</sub> (etCO<sub>2</sub>) and the slope of the CO<sub>2</sub> dissociation curve ( $S$ ). This is represented mathematically as:

$$\text{Cardiac output} = \Delta V_{\text{CO}_2} / (S \times \Delta \text{etCO}_2)$$

Partial CO<sub>2</sub> rebreathing really measures non-shunted pulmonary capillary blood flow rather than total cardiac output. Therefore a correction for venous admixture is added based on  $\text{FiO}_2$  and  $\text{SaO}_2$  (measured by pulse oximetry).

**PROBLEMS WITH THE PARTIAL REBREATHING OF CO<sub>2</sub> METHOD**

- It is unsuitable for non-intubated patients (who have variable tidal volumes and leakage around facemasks).
- Changes in mechanical ventilator settings that alter dead space or ventilation/perfusion relationships may

result in an artefactual change in cardiac output measurements. The accuracy of the technique also appears to be challenged by spontaneous mechanically assisted ventilation.

- etCO<sub>2</sub> may not accurately reflect change in pulmonary end-capillary and  $P_{\text{aCO}_2}$ , especially in chronic lung disease.
- $V_{\text{CO}_2}$  may not reach steady state in the time available (especially in chronic lung disease).
- The value of  $S$  varies with haemoglobin concentration and  $P_{\text{CO}_2}$ .
- Venous admixture cannot be calculated reliably from  $\text{FiO}_2$  and  $\text{SaO}_2$  when there is significant  $V/Q$  scatter (e.g. in chronic lung disease).
- Overall there is a lack of validation in chronic lung disease.

**THORACIC ELECTRICAL BIOIMPEDANCE**<sup>8,10</sup>

An alternating electrical current (high-frequency, very low magnitude) is passed through the thorax. Current is kept constant and fluctuations in electrical impedance are measured. Six electrodes are usually attached (two in the upper thorax/neck region and four in the lower thorax). These electrodes detect changes in bioimpedance and monitor cardiac electrical signals. The technique is very sensitive to any alteration in position or contact of the electrodes to the patient.

The change in aortic blood flow due to myocardial contraction (stroke volume) is measured from the changes in thoracic bioimpedance through the cardiac cycle. Other factors that contribute to a change in overall thoracic bioimpedance include changes in tissue fluid volume and changes in venous and pulmonary blood volume induced by respiration. Respiratory artefact is eliminated by averaging values over several cardiac cycles using the R-R interval as a synchronising signal.

Measuring whole-body rather than truncal impedance by placing electrodes on wrists and ankles also appears successful.

Inaccuracies can arise from numerous sources. These include motion artefact, electrical interference, dysrhythmias (including frequent premature atrial contractions and atrial fibrillation) and acute change in tissue water content (such as pulmonary oedema, pleural effusions or expansion of interstitial fluid). Despite these limitations, it is clinically appealing due to its non-invasive nature. Recent studies of second-generation technology have shown improved reliability of this technique.

**FUNCTIONAL HAEMODYNAMIC MONITORING**

The recently coined term, *functional haemodynamic monitoring*, implies a therapeutic application, independent of diagnosis.<sup>60</sup> It has been posed in response to the

Table 12.9 Variables described as indices of cardiac preload or fluid responsiveness in critically ill patients

Static	Dynamic
<p><b>Intracardiac pressures</b></p> <p>Central venous pressure (CVP)/right atrial pressure (RAP) Pulmonary artery occlusion pressure (PAOP)</p> <p><b>Cardiovascular volumes</b></p> <p>Thermodilution right ventricular end-diastolic volume (RVEDV) Echocardiographic RVEDV Echocardiographic left ventricular end-diastolic area (LVEDA)/volume (LVEDV) Transpulmonary thermodilution global end-diastolic volume (GEDV) Transpulmonary thermodilution intrathoracic blood volume (ITBV)</p> <p><b>Doppler</b></p> <p>Duration of the aortic velocity signal corrected for heart rate (<math>FT_c</math>)</p>	<p><b>Spontaneous respiratory effort</b></p> <p>Inspiratory decrease in right atrial pressure (<math>\Delta</math>RAP)</p> <p><b>Mandatory mechanical ventilation</b></p> <p>Systolic pressure variation (SPV) Decrease in systolic pressure (<math>\Delta</math>down) Pulse pressure variation (PPV) Pulse contour analysis stroke volume variation (SVV) Respiratory variation in peak aortic blood velocity (<math>\Delta V_{\text{peak}}</math>) Respiratory change in the pre-ejection period (<math>\Delta</math>PEP) Respiratory systolic variation test (RSVT)</p> <p><b>Passive leg raising</b></p> <p>Change in aortic blood flow Change in pulse pressure</p>

Variables have been divided into static and dynamic categories. Static variables are estimates of ventricular preload at a point in time, usually end-expiration. Dynamic variables are characterised by measurement of variation in haemodynamic measurements in response to changes in cardiac loading conditions.<sup>47,49,56,64–69</sup>

observation that, although stated in physiological terms, haemodynamic questions must be practical and concrete in order to address clinical problems. Arguably the most relevant functional haemodynamic question is: ‘Will stroke volume (or consequently cardiac output) increase with volume loading?’ This question can help guide the resuscitation of haemodynamically unstable patients and defines the clinical usefulness of predicting fluid responsiveness. This is an area of increasing research and clinical interest beyond the scope of this chapter. For reference, variables that have been described as indices of preload or predictors of fluid responsiveness in critically ill patients are presented in Table 12.9.

# Multiple organ dysfunction syndrome

Patricia Figgis and David Bihari

The incidence of multiple organ dysfunction syndrome (MODS) is increasing and accounts for up to one-half of deaths in intensive care. Some 50 years ago, multiple organ failure did not exist as a clinical entity. Patients could not be kept alive long enough for the sequential disturbances in the function of distant organs to occur. In the 1960s, acute respiratory failure characterised by bilateral infiltrates on chest radiograph, now termed acute respiratory distress syndrome (ARDS), was described following a variety of non-pulmonary insults. Finally, in 1973, the first description of multiple organ failure appeared in the surgical literature, describing the course of three patients who subsequently died following surgery for ruptured aortic aneurysm.<sup>1</sup>

Critical illness is often associated with a downward spiral through a systemic inflammatory response syndrome (SIRS) towards frank organ failure and death. Since organ failure is not an all-or-nothing phenomenon, and because dysfunction usually precedes and may progress to gross organ failure, the old term 'multiple organ failure' was deemed unsatisfactory. The American College of Chest Physicians/Society of Critical Care Medicine (ACCP/SCCM) consensus conference in 1992 proposed that the term 'dysfunction' identifies a phenomenon in which organ function is not capable of maintaining homeostasis (Table 13.1).<sup>2</sup> However, it should be remembered that it is only a descriptive definition and does not provide any insight into the aetiology or pathogenesis of MODS. In fact, it is not clear whether MODS is a single pathological process with variable clinical expression, or a limited phenotypic expression of a large number of pathological processes. As yet no therapeutic interventions specifically directed at MODS have significantly altered outcome.

## AETIOLOGY

Uncontrolled infection was classically thought to be the main precedent leading to SIRS and subsequently to MODS. In an Australian epidemiological study, infection was not identified in 912 of a total of 1803 SIRS episodes.<sup>4</sup> Therefore it is thought that a substantial proportion of cases of MODS are not initiated by infection. Table 13.2 lists many of the causes of MODS, but is

not exhaustive. It must be noted that any number of these causes may in fact act as a secondary insult precipitating MODS. The common features of non-infective aetiologies of MODS are ischaemia, hypoxia, cytokine release, mechanical injury or any combination of these. Thus MODS may occur after all forms of shock and compartment syndromes. Other important causes include trauma, major surgery, burns, pancreatitis, hepatic failure, pulmonary aspiration syndromes and mechanical ventilation.<sup>5</sup> Less commonly, cardiopulmonary bypass, blood product and cytokine infusions, and some drug reactions have been associated with MODS.<sup>6</sup>

## PATHOPHYSIOLOGY

### INFLAMMATION

The current explanation for the development of SIRS and MODS is local inflammation with activation of the innate immune system and subsequent unbridled systemic inflammation.<sup>7</sup> There is a spectrum of clinical sequelae, ranging from the mildest SIRS that just meets the definition, through organ dysfunction that resolves within a few days, to overwhelming SIRS and MODS. The balance between the inflammatory and regulatory arms of the host response may in part explain these varied responses.

Inflammation involves the activation of circulating immune cells (in particular natural killer (NK), T and B cells and macrophages), the endothelium, and multiple mediator cascades balanced by an anti-inflammatory system. Following injury, proinflammatory mediators are released locally to combat foreign antigens and promote wound healing. Concurrently, anti-inflammatory mediators are released to downregulate this process. If the regulatory mechanisms are unable to contain the response, then inflammatory mediators enter the systemic circulation, additional leukocytes are recruited and activated, and a whole-body response ensues. Homeostasis may be lost and so-called 'immunological dissonance' occurs, when the host's inflammatory or anti-inflammatory response to injury (or both) is excessive or inadequate (Figure 13.1).<sup>8</sup> Thus, MODS is not necessarily due to the primary insult, but more likely to be related to an

**Table 13.1** Definition of systemic inflammatory response syndrome (SIRS) and multiple organ dysfunction syndrome (MODS)<sup>3</sup>

<b>Systemic inflammatory response syndrome</b>
The systemic inflammatory response to a variety of severe clinical insults is manifest by two or more of the following conditions:
Temperature >38°C or <36°C
Heart rate >90 beats/min
Respiratory rate >20 breaths/min or $P_{aCO_2}$ <32 mmHg (or ventilator dependence)
White blood cell count >12 000 cells/mm <sup>3</sup> , <4000 cells/mm <sup>3</sup> or >10% band forms
<b>Multiple organ dysfunction syndrome</b>
The presence of altered function involving at least two or more organ systems in an acutely ill patient such that homeostasis cannot be maintained without intervention

**Table 13.2** Causes of multiple organ dysfunction syndrome (MODS)

<b>Infectious agents</b>	<b>Non-infectious insults</b>	<b>Mechanism</b>
Bacteria	Mechanical ventilation	Ischaemia
Viruses	Aspiration	Hypoxia
Fungi	Surgery	Cytokine release
Protozoa	Burns	
	Reperfusion syndromes	
	Visceral ischaemia	
	Pancreatitis	
	Hepatic failure	
	Cardiopulmonary bypass	
	Massive transfusion	
	Transfusion reactions	
	Hyperthermia	
	Malignancy	

uncontrolled, aggressive systemic response of the host to that primary insult. Without intervention, SIRS may lead to MODS and death.

### MOLECULAR MECHANISMS

In sepsis, activated cell/antigen products interact with a member of the Toll-like receptor family to signal gene expression of inflammatory mediators. Toll-like receptors are evolutionarily-conserved receptors expressed by monocytes and macrophages, which recognise whole subsets of pathogens, and represent the phylogenetically ancient innate immune system. Toll-like receptors

mediate cell signalling through the same intracellular transcription pathways as cytokines themselves, most notably nuclear factor  $\kappa$ B (NF- $\kappa$ B).<sup>10</sup> Non-infective causes of MODS seem to have this final common pathway, resulting in mediator release. For example, in ventilator-associated lung injury, the signalling cascade converting the physical stimulus into mediator release operates via NF- $\kappa$ B, but the upstream events remain unclear.<sup>11</sup> Large numbers of mediators are involved in inflammation, with chemotactic factors attracting, adhesion molecules focusing, and cytotoxic agents assisting this process. They include cytokines, leukotrienes, prostaglandins, platelet factors and the coagulation and complement systems.

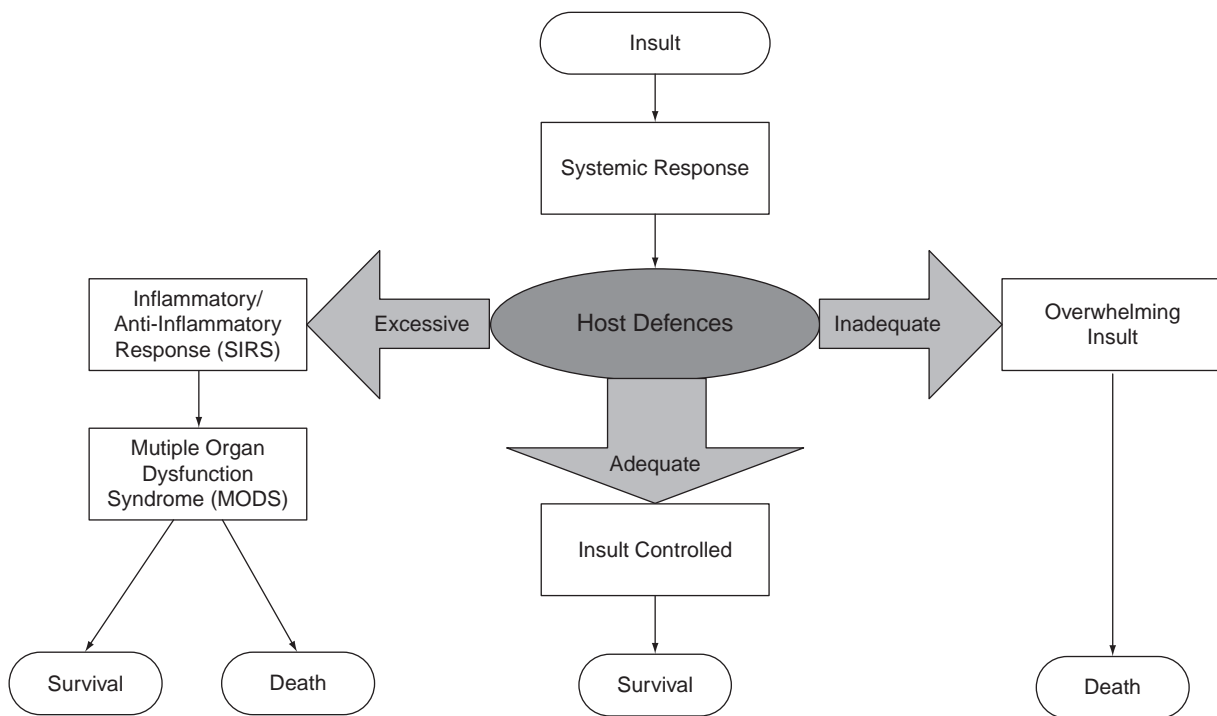

Cytokines are the main mediators of inflammation, with several actions, including directing the cellular response, inducing enzyme production such as inducible nitric oxide synthase (iNOS) and altering adhesion molecules. Their actions are pleiotropic, acting on multiple target cells in different ways depending on timing and local tissue concentration. Several cytokines have been implicated in the development of SIRS and MODS, including tumour necrosis factor (TNF)- $\alpha$ , and interleukins (IL) 1 $\beta$ , 6, and 8. Cytokine and NF- $\kappa$ B concentrations appear to be linked to morbidity and mortality.<sup>12,13</sup> In response to proinflammatory mediators, there is endogenous production of anti-inflammatory cytokines such as IL-4, IL-10 and IL-13.

However, it seems that the prevailing internal milieu is likely to be more important than any absolute levels of one mediator or another. Patients at increased risk of SIRS and MODS, such as the elderly and those with pre-existing illnesses, seem to have abnormal cytokine levels.<sup>14</sup> The ability of a cell to synthesise pro- or anti-inflammatory mediators is influenced by many factors, both genetic and environmental in origin, but also by its previous state of activation. It may be that an initial insult, insufficient to cause MODS, nevertheless pre-primed a susceptible individual such that a subsequent or secondary insult generates a response that overwhelms homeostasis.

If a relative excess or deficiency of mediator expression can upset inflammatory homeostasis, then it is not surprising to find a strong genetic correlation. Families characterised by low TNF- $\alpha$  production have a 10-fold increased risk of fatal outcome in meningococcal disease, whereas high IL-10 production increases the risk 20-fold.<sup>15</sup> TNF- $\alpha$  and IL-10 receptor antagonist polymorphisms are associated with greater susceptibility and worse outcomes to severe sepsis.<sup>16</sup> Unfortunately genetic determinants are likely to be more complicated than simple quantitative expression of one mediator or another.

### TISSUE INJURY

The final common pathway leading to MODS is often tissue hypoxia. Many factors can compromise oxygen

**Figure 13.1** Varied host response to injury. (Adapted from Johnson D, Mayers I. Multiple organ dysfunction syndrome: a narrative review. *Can J Anaesth* 2001; **48**: 502–9, with permission).

delivery to tissues. Among these factors are arterial hypoxaemia due to acute lung injury, and reduced cardiac output from reduced left ventricular preload and/or impaired ventricular performance. Over and above oxygen delivery abnormalities, evidence is rapidly building that microcirculatory and mitochondrial dysfunction with an abnormal distribution of blood flow and defective oxygen utilisation ('tissue dysoxia') is central to the pathogenesis of MODS. Indiscriminate injury by mediators of inflammation leads to deranged endothelial function with altered vascular relaxation and abnormal modulation of coagulation, and mitochondrial and cellular damage. This is compounded by an ongoing initial or subsequent insult. Unchecked, cellular dysfunction leads to loss of ion gradients, leakage of lysosomal enzymes, proteolysis and cell death. If enough tissue injury occurs, organ dysfunction and ultimately failure ensue.

### ENDOTHELIAL DYSFUNCTION

The endothelium is activated by the engagement of antigen, for example lipopolysaccharides from bacterial cell walls, with Toll-like receptors or inflammatory mediators with various receptors. At any stage other environmental factors such as hypoxia, hypoperfusion, increased temperature, acidosis and glycaemic perturbations may also affect endothelial function. The interaction of these

extracellular factors with their receptors activates downstream signalling pathways, influencing transcription factors and altering cellular function and/or gene expression. Cell surface adhesion molecules are upregulated, leading to increased leukocyte rolling, adhesion and transmigration, with cytokine-mediated positive feedback and cellular recruitment enhancing this process.<sup>17,18</sup> Upregulation of iNOS leads to excessive amounts of NO production.

In addition, inappropriate intravascular coagulation is an important cause of tissue injury. Activation and amplification of the tissue factor pathway, and possibly downregulation of anticoagulatory pathways, lead to the generation of thrombin and hence fibrin formation. Coagulation may result in focal areas of ischaemia, and concurrent depletion of counterregulatory networks. The mechanisms that regulate inflammation, coagulation and the various cell types are intimately linked and cannot be thought of as discrete entities. A schematic diagram of the processes involved in endothelial dysfunction is shown in Figure 13.2.

It can therefore be seen that following endothelial cell activation, abnormal blood flow distribution may occur as a result of a combination of:

- NO-mediated extensive vasodilatation and increased endothelial cell permeability

**Figure 13.2** Mechanisms of endothelial dysfunction. The temporal sequence of events is depicted from left to right. E, endothelium; LPS, lipopolysaccharide; TLR, Toll-like receptor; IL, interleukin; TNF, tumour necrosis factor; C5a, complement factor 5a; NF- $\kappa$ B, nuclear factor  $\kappa$ B; TF, tissue factor; NO, nitric oxide; ROS, reactive oxygen species; NADPH, nicotinamide adenine dinucleotide phosphate; iNOS, inducible nitric oxide synthase. (Adapted from Aird WC. The role of the endothelium in severe sepsis and multiple organ dysfunction syndrome. *Blood* 2003; **101**: 3765–77, with permission.)

- functional shunting
- obstruction of flow by microthrombi, platelet or leukocyte aggregates, abnormal red cell deformability, and possibly endothelial cell oedema
- hypoperfusion secondary to reduced cardiac output from various causes such as a reduction in cardiac preload (actual or relative hypovolaemia or a decrease in effective blood volume), myocardial depression (mediated by NO, IL-1 $\beta$  and TNF- $\alpha$ ), and reduced lusitropy (mediated by NO)<sup>19</sup>

Relatively new non-invasive techniques such as orthogonal polarisation (Figure 13.3) have demonstrated these abnormalities in microcirculatory blood flow distribution in septic states compared with normal controls. As a consequence of the derecruitment of capillaries, the increased diffusion distances will in turn contribute to the development of hypoxia.

## APOPTOSIS

Changes in the dynamics and regulation of apoptosis in critical illness contribute to organ dysfunction. Apoptosis is the fundamental physiological process by which cells activate an endogenous programme that leads to controlled death and clearance of cells without evoking an inflammatory response. In contrast, necrosis is uncontrolled cellular death with release of intracellular contents and subsequent inflammation. Alterations in the control of apoptosis are caused by changes in the expression of proapoptotic and antiapoptotic genes. Excessive apoptosis has been particularly implicated in gastrointestinal, liver, kidney and cardiac dysfunction.

Interestingly, the apoptosis of lymphocytes is delayed, which could lead to prolonged injurious function.<sup>20,21</sup>

## MITOCHONDRIAL DYSFUNCTION

Normally more than 85% of oxygen extracted by tissues is used in the mitochondrial respiratory chain to produce adenosine triphosphate (ATP), the main intracellular energy source. It is widely accepted that oxygen consumption, and hence extraction, is reduced in many disease states leading to MODS. This decrease in oxygen consumption may be out of proportion to any reduction in oxygen delivery caused by microcirculatory dysfunction. Abnormal mitochondrial respiration with markedly reduced ATP production has been implicated in some cases.<sup>22</sup> The strong inherited component to the heterogeneity seen in MODS outcome may be influenced by the natural genetic variation in mitochondrial DNA.<sup>23</sup>

Several mutually compatible mechanisms have been postulated to account for this tissue dysoxia (previously confused with ‘cytopathic hypoxia’). There is diminished delivery of pyruvic acid to the tricarboxylic acid (TCA) cycle by inhibition of pyruvate dehydrogenase leading to increased lactate production. NO and reactive oxygen species (ROS) have been demonstrated to inhibit the mitochondrial respiratory chain significantly. ROS can also induce DNA damage, which activates poly (ADP-ribose) polymerase-1 (PARP-1), consuming NAD<sup>+</sup>/NADH for repair as a consequence. Since NADH is the main reducing equivalent in oxidative phosphorylation, energy production is compromised. Animal studies suggest that tissue dysoxia occurs after the disease process is well established, which suggests that early intervention may prevent the evolution of MODS.<sup>24,25</sup>

In addition to energy production, mitochondria are critical for other aspects of cellular function, such as modulating calcium levels and the biosynthesis of haem and sulphur centres. Thus, mitochondrial dysfunction causes cell damage by a combination of reduced energy production, abnormal calcium homeostasis and oxidative stress through release of ROS. Furthermore, mitochondrial damage can contribute to deranged apoptosis by releasing proapoptotic factors into the cytoplasm.

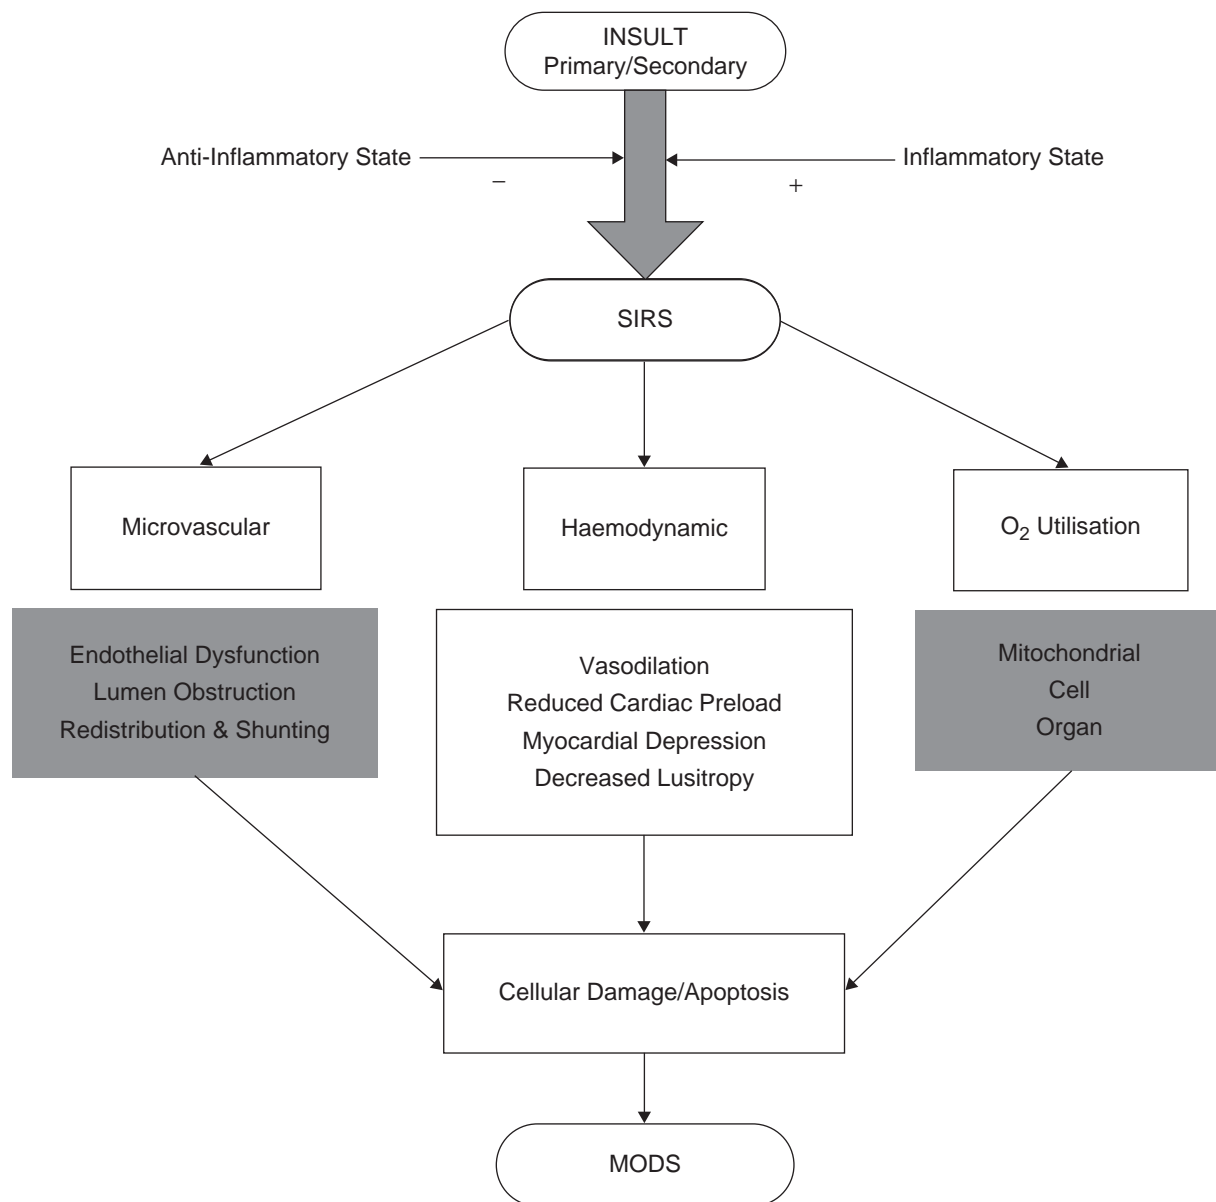

The mechanisms of tissue injury described above are not mutually exclusive, but the result of interactions between multiple predisposing patient factors, a series of physiologic insults and an endogenous response effected via multiple cell types and hundreds of biochemical mediators. Figure 13.4 attempts to simplify and illustrate the pathogenesis and mechanisms of tissue injury.

## CLINICAL FEATURES

As SIRS progresses, an often unpredictable but nonetheless sequential pattern of organ dysfunction ensues. Once two or more organs are involved, the term ‘MODS’ can

**Figure 13.3** Orthogonal polarisation images of the sublingual mucosa in a normal (top) and a septic (bottom) patient. Note, firstly, paucity of smaller blood vessels in the septic sublingual mucosa with increased diffusion distances between blood vessels and, secondly, that the remaining blood vessels are of smaller calibre. (Courtesy of Cytometrics.)

**Figure 13.4** Summary of mechanisms of tissue injury. SIRS, systemic inflammatory response syndrome; MODS, multiple organ dysfunction syndrome. (Adapted from Johnson D, Mayers I. Multiple organ dysfunction syndrome: a narrative review. *Can J Anaesth* 2001; **48**: 502–9, with permission.)

be used. Table 13.3 lists the commoner organ systems affected and their associated clinical features.

Encephalopathy is very common and correlates with mortality in sepsis.<sup>26</sup> As many as 30% of patients have evidence of myocardial dysfunction (reduced ejection fraction) and ARDS complicates 60% of cases of septic shock.<sup>3,27</sup> There is a close relationship between increased

intestinal permeability on intensive care unit (ICU) admission and the subsequent development of MODS.<sup>28</sup> Increased intestinal permeability may lead to the translocation of endotoxin, bacteria and other mediators. It can therefore be seen that many of these physiological changes can also act as secondary insults in the development of MODS.

**Table 13.3** Commonly affected organs, with associated clinical features

Organ system	Associated clinical features	Physiological and biochemical changes
Neurological	Decreased level of consciousness/encephalopathy (confusion, agitation and/or drowsiness)	Abnormal EEG suggestive of metabolic encephalopathy
Cardiovascular	SBP < 90 mmHg or a reduction of > 40 mmHg from baseline Tachycardia > 90 beats/min, dysrhythmia Oedema formation	Reduced systemic vascular resistance Myocardial depression and reduced lusitropy Increased capillary permeability
Respiratory	Tachypnoea > 20 breaths/min Desaturation Central and peripheral cyanosis Requirement for mechanical ventilation	$P_{aCO_2}$ < 32 mmHg Hypoxaemia (reduced $P_{aO_2}/F_{iO_2}$ ratio) Increased work of breathing Increased lung water
Renal	Urinary output < 0.5ml/kg per h despite adequate fluid resuscitation	Increasing urea and creatinine
Gastrointestinal	Abdominal discomfort and distension Large nasogastric aspirates Failure to absorb enteral nutrition Haemorrhage	Increased intestinal permeability Splanchnic ischaemia Ileus Acalculous cholecystitis Pancreatitis Stress ulceration
Hepatic	Jaundice Encephalopathy	Increasing bilirubin Increasing lactate Hyperglycaemia (increased gluconeogenesis, impaired clearance) Hypoglycaemia (failing gluconeogenesis)
Haematological	Haemorrhage, petechial rash Peripheral cyanosis	White blood cell count > 12 000 cells/mm <sup>3</sup> , < 4000 cells/mm <sup>3</sup> or > 10% band forms DIC with coagulopathy and platelets reduced by 50% over 3 days, or < 80 000 cells/mm <sup>3</sup> Anaemia

EEG, electroencephalogram; SBP, systolic blood pressure; DIC, disseminated intravascular coagulation.

## MANAGEMENT

The cornerstones of the management of patients with SIRS and impending MODS are firstly, the prevention of secondary insults such as nosocomial infection; secondly, early identification of dysfunctional organs with regular clinical assessment and appropriate monitoring, and thirdly, the timely treatment of both primary and secondary insults. Good supportive care, including recognition of the requirement and instigation as necessary of fluid resuscitation, vasopressors/inotropes, mechanical ventilation (with lung protective strategies) and renal replacement therapies, reduce mortality from MODS. In addition, infection control, avoiding oversedation, pressure area care, nursing the patient head-up, early enteral nutrition, and stress ulcer and deep-vein thrombosis thromboprophylaxis are all paramount in reducing secondary insults.

A sobering consequence of high-quality clinical trials performed in the ICU over the past decade has been the realisation that making a normal or supranormal physiologic state the therapeutic target in a critically ill

patient whose homeostasis is profoundly disrupted may be detrimental rather than beneficial and that many interventions carry the potential cost of inadvertent harm. The majority of research has been conducted in MODS of septic origin and it is unclear whether the results can be extrapolated to non-sepsis-mediated MODS. Many specific therapies have been investigated over the last two decades and have appeared to be promising. Although some of these so-called 'innovative' therapies have found their way into algorithms such as the 'Surviving Sepsis' guidelines, there remains much controversy regarding their benefits. Thus, at present, there is insufficient evidence to warrant graded recommendations for directed therapeutic interventions in MODS.

## INNOVATIVE THERAPIES

### GLYCAEMIC CONTROL

Hyperglycaemia has been reported to impair the immune system, increase endothelial cell apoptosis and cause

mitochondrial dysfunction.<sup>29</sup> Moreover, insulin promotes endothelial cell survival.<sup>30</sup> Hence it may be that tight glucose control could have a protective effect on the endothelium.

In a single-centre study, an absolute mortality risk reduction of 3.4% from MODS and sepsis has been demonstrated in critically ill surgical intensive care patients treated with intensive insulin therapy (aiming for a blood glucose in the range of 4.1–6.1 mmol/l).<sup>31</sup>

### LOW-DOSE GLUCOCORTICOIDS

There has been renewed interest in the therapeutic role of ‘replacement doses’ of steroids in SIRS and MODS, with some evidence suggesting improved survival in patients with septic shock.<sup>32</sup> Specifically, steroids inhibit NF- $\kappa$ B and the induction of iNOS by cytokines. Hence the mechanisms by which physiological, and perhaps beneficial, doses of corticosteroids are thought to act include:

- anti-inflammatory via a decreased transcription of proinflammatory cytokines and iNOS
- treatment of relative adrenocortical insufficiency
- restoration of catecholamine receptor sensitivity

### MANIPULATION OF THE COAGULATION CASCADE

A 28-day absolute reduction in the risk of death of 6.1% ( $P = 0.005$ ) has been reported with the administration of human recombinant activated protein C (APC) to patients with severe sepsis and evidence of organ dysfunction (PROWESS study group).<sup>33</sup> APC has several potentially beneficial effects:

- potent inhibition of factors Va and VIIIa (and a lesser effect on unactivated forms)
- promotion of fibrinolysis by indirectly inducing plasmin activity, and thus clot lysis
- complex anti-inflammatory effects
- possible inhibition of endothelial cell apoptosis

However, there is a small but significant increased risk of serious bleeding complications. Certain patient groups, notably those with low Acute Physiology and Chronic Health Evaluation (APACHE) II scores (less than 25) and children appear not to benefit from such treatment.<sup>34,35</sup> A confirmatory study in patients with APACHE II scores greater than 25 is planned by the original PROWESS investigators.<sup>33</sup>

Other research into the modulation of the coagulation system has proven disappointing. In contrast to the initial promising preclinical data on antithrombin III, a phase III trial failed to show any benefit, although a recent subgroup analysis of the trial hinted at improved survival in those who also received heparin.<sup>36,37</sup> Furthermore, treatment with recombinant tissue factor pathway inhibitor had no effect on all-cause mortality in patients with severe sepsis and high international normalised ratio (INR).

Moreover, there was an increased risk of bleeding, irrespective of baseline INR.<sup>38</sup>

### NUTRITION

Studies in ARDS and sepsis patients have suggested that  $\omega$ -3 fatty acid administration may reduce the release of proinflammatory mediators with decreased cytokine production, NF- $\kappa$ B inhibition and macrophage-mediated systemic dysfunction.<sup>39,40</sup> Whilst some studies suggest a reduction in the severity of MODS in humans, conclusive clinical data are lacking. This raises the interesting possibility that not only may nutritional factors influence the course of MODS, but an individual may be susceptible to developing the syndrome in the first instance.

### BLOOD PURIFICATION

High-volume haemofiltration (2–6 l/hour) with highly permeable biocompatible membranes has been postulated to remove large quantities of mediators either by filtration or by membrane absorption. While improved cardiovascular parameters have been observed, this may also be due to control of hyperthermia, correction of fluid overload, metabolic acidosis and electrolyte abnormalities.<sup>41</sup>

### IMMUNE MODULATION

Extensive investigation has been undertaken with drugs targeted at manipulating the immune system. Not surprisingly, attempts to block or replace single mediators have failed to improve the outcome of SIRS and MODS. The therapeutic challenge in attempting to modulate the anti-inflammatory and proinflammatory responses is that the numbers of mediators are numerous, they are intimately interrelated and interdependent, their expression varies during the course of a particular illness and between patients, and laboratory measurement may not represent *in vivo* action.

### NITRIC OXIDE INHIBITORS

Indiscriminate NOS inhibition with  $N^G$ -monomethyl-L-arginine hydrochloride (L-NMMA), whilst improving vasomotor tone, also leads to significantly increased myocardial and renal complications and mortality. Selective NOS inhibitors may have a role in the treatment of MODS in the future.<sup>42</sup>

### OUTCOMES

The mortality from MODS is related to the number and duration of organ systems in failure,<sup>43</sup> and remains the leading cause of death in non-coronary ICUs.<sup>44</sup> A simple count of organs affected and the duration of dysfunction will stratify mortality in broad ranges, for example 60–98% depending on age, with three organs affected for

more than 1 week.<sup>45</sup> Although the incidence and overall outcome of MODS did not seem to change very much in the 1980s, an analysis of the APACHE II and III databases suggests that patients with three or more organ systems in failure did indeed have a better outcome in the later APACHE III database.<sup>46</sup> Since the results of research into specific interventions have on the whole been disappointing, any improvement in outcome must be related to better (or earlier) resuscitation and supportive therapies. Survival rates do seem to be improving in this very sick population of patients, but whether MODS can be prevented by any new specific therapy remains to be seen.

MODS may serve as a useful outcome measure of disease severity for risk adjustment and outcome markers in critical care. The advantage of using MODS is that it may be a less biased measure of the original insult and subsequent care provided. One specific instrument designed to assess organ failure is the Sequential Organ Function Assessment (SOFA) score (see Appendix 8). Using the worst values for six commonly measured parameters ( $PaO_2/FiO_2$  ratio, platelet count, bilirubin, blood pressure, Glasgow Coma Score and urine output or creatinine), a score is assigned on admission to intensive care and repeated every 48 hours until discharge. The advantage of the SOFA score is in its ability to describe the epidemiology of critical illness both at the time of admission and during ICU care. There is a positive association between total SOFA score on admission and ICU mortality before 7 days, but not after. Interestingly, ICU mortality after 7 days is associated with high SOFA scores on day 6 after adjusting for admission score. Thus, illness on admission becomes less important, and the course during the ICU stay becomes more relevant, with the presence or development of cardiovascular dysfunction having the strongest independent effect on the probability of death compared with other organ system dysfunctions.<sup>47</sup>

Although mortality is an important outcome measure in ICU, permanent restrictions in daily activities as measured by quality of life (QOL) scores are often also relevant to both the individual and society. MODS has been shown in a prospective observational study using the QOL score RAND-36 to have a statistically significant negative effect on vitality and emotional role limitations. Some 47.2% of all patients were unable to return to work and/or experienced severe limitations in their daily activities and 3.8% were unable to live at home 1 year after hospital discharge.<sup>48</sup> Similarly diminished QOL scores have been found in post cardiac surgery and acute lung injury patients.<sup>49,50</sup> However, patients with acute renal dysfunction appear to have a less marked deterioration in their QOL.

# Monitoring oxygenation

Thomas John Morgan and Balasubramanian Venkatesh

## THE ROLES OF OXYGEN IN AEROBIC ORGANISMS

Oxygen has several vital physiological roles:

1. *Bioenergetics*. Aerobic mitochondrial respiration accounts for 90% of oxygen consumption, generating adenosine triphosphate (ATP) by oxidative phosphorylation. Mitochondrial electron transfer oxidase systems provide the fundamental machinery, in particular the cytochrome oxidase of complex IV. Oxygen acts as terminal electron acceptor, combining with two protons to produce water.<sup>1</sup>
2. *Biosynthetics*. Oxygen transferase systems incorporate oxygen into substrates, such as prostanoids, catecholamines and some neurotransmitters.
3. *Biodegradation and detoxification reactions*. These mixed-function oxidase reactions require oxygen and a co-substrate (e.g. NADPH). The cytochrome P-450 hydroxylases are examples.
4. *Generation of reactive oxygen species*. These are essential antimicrobial defences deployed by neutrophils and macrophages.<sup>2</sup>

## TISSUE HYPOXIA

As tissue  $P_{O_2}$  falls, the biosynthetic and biodegradation systems are the first to succumb. Cell signalling by reactive oxygen species, released at mitochondrial complex III, activates hypoxia-inducible factor-1, a transcription factor upregulating genes important in hypoxic cell survival.<sup>3</sup> Oxidative phosphorylation starts to fail at an intracellular  $P_{O_2}$  of 0.1–1 mmHg, equivalent to an extracellular  $P_{O_2}$  of around 5 mmHg. At this point oxygen-limited cytochrome turnover causes progressive ATP depletion, a process which has been termed ‘dysoxia’.<sup>4</sup> Stopgap production continues by anaerobic glycolysis, but without correction of dysoxia there is progressive lactic acidosis and eventual cell death by apoptosis and necrosis. On reoxygenation, further release of reactive oxygen species causes oxidant stress, often overshadowing the hypoxic insult.<sup>2</sup>

## CATEGORIES OF HYPOXIA

Classically, hypoxia has been categorised under three headings:<sup>1</sup>

1. stagnant hypoxia, where the primary abnormality is reduced tissue blood flow
2. hypoxaemic hypoxia, where the primary abnormality is a low arterial oxygen tension
3. anaemic hypoxia, where the primary abnormality is a low haemoglobin concentration

However in critical illness, tissue oxygenation can be disordered with a normal or even high tissue  $P_{O_2}$ :

1. cytopathic hypoxia, defined as abnormal cellular oxygen utilisation despite adequate oxygen delivery<sup>5</sup>
2. oxygen toxicity, defined as abnormal cell function due to high oxygen tensions<sup>6</sup>

## THE OXYGEN CASCADE

In unicellular organisms, oxygen reaches the mitochondria across a short diffusion path with a steep partial pressure gradient. In multicellular animals the much longer diffusion path traverses a series of small partial pressure reductions known as the oxygen cascade. As a result, oxygen arrives at intracellular organelles at tensions above the anaerobic threshold.

Important steps in the oxygen cascade include:

1. inspired gas
2. alveolar gas
3. arterial blood
4. microcirculation
5. interstitium
6. mitochondria and other intracellular organelles

The cascade can be jeopardised at any step, with downstream oxygen deprivation of mitochondria and other intracellular organelles. In this chapter we will consider how oxygenation can be monitored at strategic points along the cascade.

### INSPIRED GAS

Monitoring the fraction of inspired oxygen ( $F_{iO_2}$ ) is necessary to prevent both hypoxaemia and the adverse effects of excess oxygen. The inspired oxygen tension ( $P_{iO_2}$ ) of humidified gas is determined by the  $F_{iO_2}$ , the barometric pressure (BP) and the saturated vapour pressure of water (47 mmHg).

$$P_{iO_2} = F_{iO_2} \times (BP - 47) \quad \text{Equation 14.1}$$

Gas supply pressures are monitored continuously. Ventilators incorporate input pressure alarms and oxygen analysers within the inspiratory module to identify oxygen source failure. Direct measurement of circuit oxygen concentration can be performed.

### TRANSFER OF INSPIRED GAS TO ALVEOLI

Communication between oxygen delivery system and pulmonary alveoli is open if:

1. There are no signs of upper-airway obstruction (Chapter 25).
2. Expired tidal and minute volumes and airway pressures for the ventilated patient are within correctly set alarm limits (Chapter 27).
3. There is an appropriate end-tidal  $CO_2$  waveform (Chapter 34).

### ALVEOLAR GAS

In a patient receiving 100% oxygen, alveolar  $P_{O_2}$  in individual lung units can range from < 40 mmHg to > 600 mmHg. Consequently, end-tidal  $P_{O_2}$  monitoring is of no value.

### DISTRIBUTION OF ALVEOLAR VENTILATION

Clinicians routinely track chest movement, auscultate air entry and examine plain chest radiographs. Although computed tomography scanning can reveal occult overdistension,<sup>7</sup> it has logistical disadvantages and is a significant radiation hazard. Electrical impedance tomography is under development as an alternative, and shows promise.<sup>8</sup> Simple and non-invasive, it tracks lung volume changes in real time, with potential to optimise alveolar ventilation distribution while limiting overdistension.<sup>9</sup>

### MATCHING OF VENTILATION AND PERFUSION

For efficient gas exchange, the majority of lung units must have well-matched alveolar ventilation and perfusion ( $V/Q$  ratios close to 1). Even in health there is a spread to lower and higher  $V/Q$  ratios, all clustered around unity. When lungs are diseased,  $V/Q$  scatter is much greater, with variable representation across the full spectrum from zero to infinity. Such complexity resists simple bedside quantification. The best method is the multiple inert gas technique (MIGET). MIGET generates a lung model with 50

compartments spanning the full range of  $V/Q$  ratios, by measuring the retention and elimination of six inert gases of varying solubility.<sup>10,11</sup> Because MIGET is impractical at the bedside, simpler non-invasive modelling of shunt and  $V/Q$  mismatch is under evaluation, using  $F_{iO_2}$  as a forcing function while tracking haemoglobin oxygen saturation.<sup>12</sup> Predictive capacity<sup>13</sup> and ease of application<sup>14</sup> are encouraging.

### THE IDEAL ALVEOLUS AND THE THREE-COMPARTMENT LUNG MODEL

Meanwhile the simplest model of all, a three-compartment model devised in the mid 20th century, is still in use. No manipulations such as  $F_{iO_2}$  switching or inert gas infusions are needed. However, the trade-off is that the model is overly simplistic, with poor predictive capacity in many respiratory disorders. The three compartments are:

1. the ideal compartment, consisting of alveoli with perfectly matched perfusion and ventilation ( $V/Q=1$ )
2. the venous admixture or shunt compartment, containing perfused non-ventilated alveoli ( $V/Q=0$ )
3. the alveolar dead space compartment, made up of ventilated non-perfused alveoli. ( $V/Q=\infty$ )

The alveolar  $P_{O_2}$  in the ideal compartment ( $PA_{O_2}$ ) is calculated from the alveolar gas:

$$PA_{O_2} = P_{iO_2} - (1 - F_{iO_2} \times (1 - R)) \times Pa_{CO_2}/R \quad \text{Equation 14.2}$$

where  $R$  is the respiratory exchange ratio, either measured by indirect calorimetry or assumed to be 0.8.  $P_{iO_2}$  is calculated as in Equation 14.1.  $Pa_{CO_2}$  is arterial  $PCO_2$ .

Most clinicians use the following approximation:

$$PA_{O_2} = P_{iO_2} - Pa_{CO_2}/0.8$$

It is important to remember that  $PA_{O_2}$  is not a physiological reality. It is an artificial construct. Other parameters based on the three-compartment lung model, such as the A-a gradient and venous admixture (see below) must be regarded in the same light.

### TRANSFER FROM ALVEOLI TO ARTERIAL BLOOD (PULMONARY OXYGEN TRANSFER)

The MIGET technique has identified  $V/Q$  mismatch and intrapulmonary right-to-left shunt as the two main causes of reduced pulmonary oxygen transfer in critical illness.<sup>15</sup> Intrapulmonary shunt predominates in the acute respiratory distress syndrome (ARDS), in lobar pneumonia and after cardiopulmonary bypass, whereas  $V/Q$  mismatch without shunt is more prominent in chronic lung disease.<sup>16</sup>

### BEDSIDE INDICES OF PULMONARY OXYGEN TRANSFER

These are either tension-based or content-based.

**TENSION-BASED INDICES****A-a gradient**

The A-a gradient is calculated as  $PAO_2 - PaO_2$ , where  $PAO_2$  is the 'ideal' compartment alveolar  $PO_2$  determined from the alveolar gas equation (Equation 14.2). Hypoxaemia can then be classified under two headings:

**Normal A-a gradient**

1. Alveolar hypoventilation (elevated  $PACO_2$ )
2. Low  $PIO_2$  ( $FI_{O_2} < 0.21$ , or barometric pressure  $< 760$  mmHg)

**Raised A-a gradient**

1. diffusion defect (rare)
2.  $V/Q$  mismatch
3. right-to-left shunt (intrapulmonary or cardiac)
4. increased oxygen extraction ( $CaO_2 - CvO_2$ )

Although the A-a gradient forms part of the Acute Physiology, Age and Chronic Health Evaluation (APACHE 2) score, several drawbacks reduce its clinical usefulness. They include:

1. Normal values which vary with  $FI_{O_2}$  and age. The normal A-a gradient breathing air is 7 mmHg in young

adults and 14 mmHg in the elderly. On 100% oxygen, these values become 31 and 56 mmHg respectively.

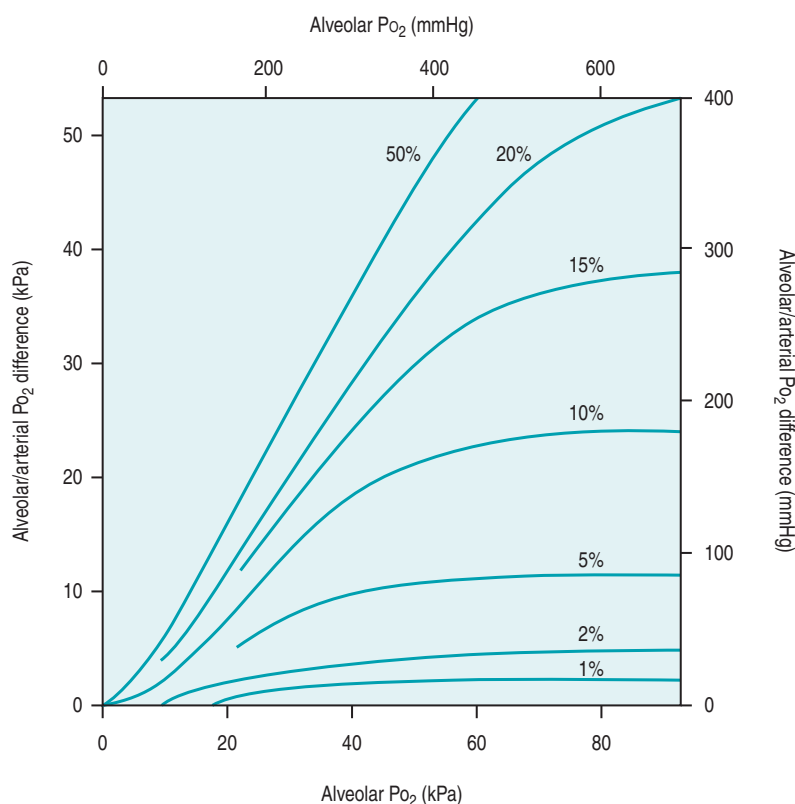

2. An exaggerated  $FI_{O_2}$  dependence in intrapulmonary shunt<sup>17</sup> (Figure 14.1) and even more so in  $V/Q$  mismatch (Figure 14.2).

 **$PaO_2/FiO_2$  ratio**

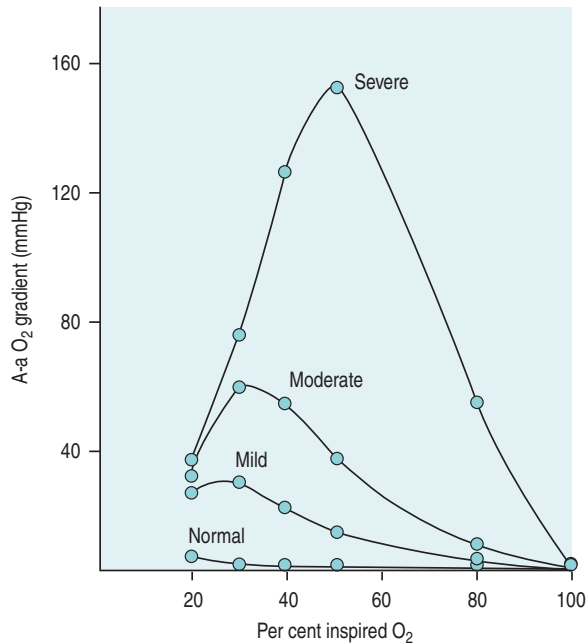

The  $PaO_2/FiO_2$  ratio is used to define acute lung injury and ARDS,<sup>18</sup> and is an input variable in the Simplified Acute Physiology Score (SAPS II)<sup>19</sup> and lung injury scoring systems.<sup>20</sup> At sea level its normal value is  $\geq 500$  mmHg. In acute lung injury,  $PaO_2/FiO_2 < 300$  mmHg, whilst in ARDS the ratio is  $< 200$  mmHg.

Its only advantage is simplicity. There are several major disadvantages:

1. Barometric pressure alters the normal  $PaO_2/FiO_2$  ratio. A ratio of 380 mmHg is unremarkable at 1600 metres elevation for a young adult breathing air, but not at sea level.
2. Unlike the A-a gradient, the  $PaO_2/FiO_2$  ratio cannot distinguish hypoxaemia due to alveolar hypoventilation from other causes.
3. The ratio is markedly  $FI_{O_2}$ -dependent, both in right-to-left shunt (the predominant ARDS abnormality)

**Figure 14.1** Effect of varying  $FI_{O_2}$  ( $PAO_2$ ) on A-a gradient with different degrees of intrapulmonary shunt. (Reproduced from Nunn JF. Oxygen. In: Nunn JF (ed.) *Applied Respiratory Physiology*, 4th edn. Oxford, UK: Butterworth-Heinemann; 1993: 264, with permission.)

**Figure 14.2** Effect of varying  $F_{iO_2}$  on A-a gradient with mild, moderate and severe  $V/Q$  mismatch. No allowance is made for absorption atelectasis or alterations in hypoxic pulmonary vasoconstriction. (Reproduced from D'Alonzo GE, Dantzker DR. Respiratory failure, mechanisms of abnormal gas exchange, and oxygen delivery. *Med Clin North Am* 1983; **67**: 557–71, with permission.)

and in lungs with a wide  $V/Q$  scatter (chronic obstructive pulmonary disease).<sup>17,21</sup>

- The ratio is also highly dependent on  $C_{aO_2} - C_{vO_2}$ ,<sup>17</sup> which tends to fluctuate markedly in sepsis.

### CONTENT-BASED INDICES

#### Venous admixture ( $Q_s/Q_T$ )

Venous admixture, another construct based on the three-compartment lung model (see above), represents the proportion of mixed venous blood flowing through the shunt ( $V/Q=0$ ) compartment. It is determined according to the formula:

$$\frac{Q_s}{Q_T} = \frac{C_{t'O_2} - C_{aO_2}}{C_{t'O_2} - C_{vO_2}} \quad \text{Equation 14.3}$$

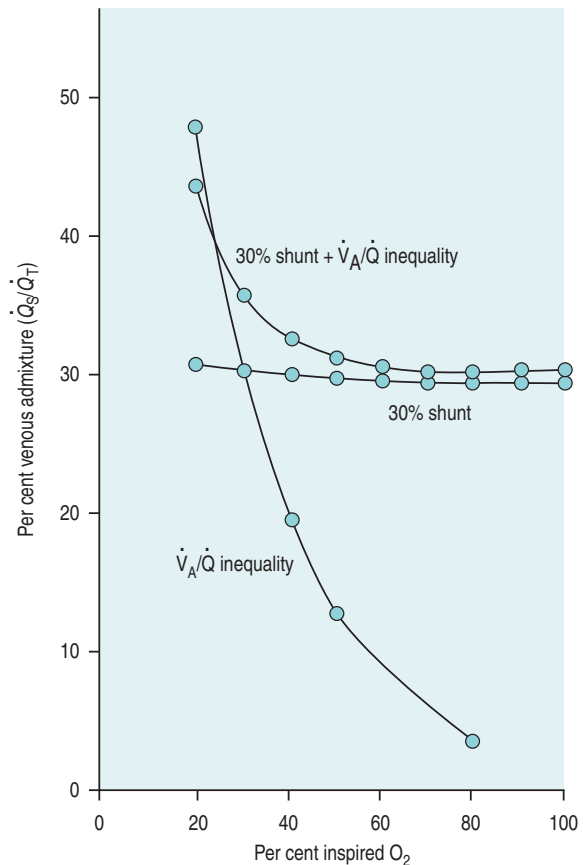

$C_{t'O_2}$ ,  $C_{aO_2}$  and  $C_{vO_2}$  are the oxygen contents of pulmonary end-capillary, arterial and mixed venous blood respectively.  $C_{aO_2}$  and  $C_{vO_2}$  are calculated using data from arterial and mixed venous blood gas analysis and CO oximetry (see Table 14.4, below).  $C_{t'O_2}$  is derived differently, since pulmonary end-capillary blood cannot be sampled.  $P_{CO_2}^1$  is assumed to equal  $P_{AO_2}$  as derived from the alveolar gas equation (Equation 14.2).  $S_{CO_2}^1$  (normally close to 1) can then be computed from an algorithm for the HbO<sub>2</sub> dissociation curve.<sup>22</sup>

#### Advantages of venous admixture

- unaffected by barometric pressure
- unaffected by alveolar hypoventilation
- provided intrapulmonary right-to-left shunt is the dominant pathology (e.g. ARDS), venous admixture is stable across the entire  $F_{iO_2}$  range, despite variations in  $C_{aO_2} - C_{vO_2}$ .<sup>23</sup>

#### Disadvantages of venous admixture

- Sampling mixed venous blood requires a pulmonary arterial (PA) catheter.
- In  $V/Q$  mismatch without right-to-left shunt, venous admixture varies markedly with  $F_{iO_2}$  and virtually disappears at  $F_{iO_2} > 0.5$  (Figure 14.3). Venous admixture is thus of little use in conditions where the dominant gas exchange abnormality is not intrapulmonary right-to-left shunt, such as chronic obstructive pulmonary disease.

**Figure 14.3** Effect of varying  $F_{iO_2}$  on venous admixture in various combinations of  $V/Q$  mismatch and shunt. No allowance has been made for absorption atelectasis or alterations in hypoxic pulmonary vasoconstriction. (Reproduced from D'Alonzo GE, Dantzker DR. Respiratory failure, mechanisms of abnormal gas exchange, and oxygen delivery. *Med Clin North Am* 1983; **67**: 557–71, with permission.)

When determined at  $FiO_2 = 1$ , venous admixture is an accurate measure of right-to-left shunt. However, exposure to 100% oxygen causes absorption atelectasis of unstable low  $V/Q$  units and increases intrapulmonary shunt.

#### Estimated shunt fraction

If a fixed  $CaO_2 - CvO_2$  can be assigned, no PA catheter is necessary. However, in critical illness  $CaO_2 - CvO_2$  can range from 1.3 to 7.4 ml/dl. The inaccuracy from assigning a fixed value is such that even the direction of change of estimated shunt can be wrong.<sup>23</sup>

#### Non-invasive estimates of V/Q mismatch and shunt

Simpler lung models using varying  $FiO_2$  as a forcing function are under evaluation, as discussed above.<sup>12-14</sup>

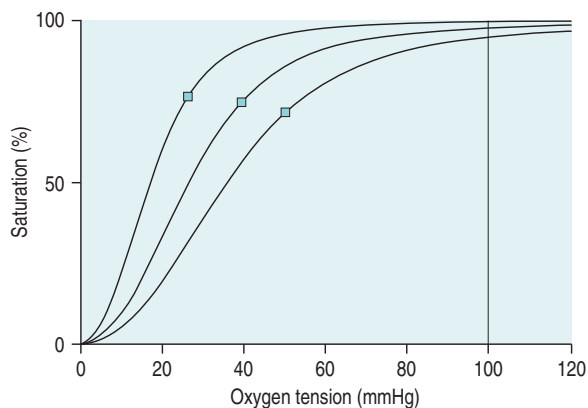

### ARTERIAL BLOOD

Indices of arterial oxygenation are  $PaO_2$  and  $SaO_2$ . They are linked by the  $HbO_2$  dissociation curve (Figure 14.4).

Clinically significant hypoxaemia is defined as  $PaO_2 < 60$  mmHg or  $SaO_2 < 0.9$ . These values normally lie near the descending portion of the  $HbO_2$  dissociation curve, so that a further drop in  $PaO_2$  leads to a marked fall in  $SaO_2$  and thus  $CaO_2$ .

### BLOOD GAS ANALYSIS AND CO-OXIMETRY

Arterial blood is collected in a purpose-designed syringe containing lyophilised heparin to a final concentration of 20–50 U/mL.  $PaO_2$  measurements are made by a Clark electrode, and  $SaO_2$  by CO-oximetry. The Clark electrode works on polarographic principles, and CO-oximeters compute the concentrations of each of the four main

**Figure 14.4** Three  $HbO_2$  dissociation curves: normal ( $P_{50} = 26.7$  mmHg), left-shifted ( $P_{50} = 17$  mmHg) and right-shifted ( $P_{50} = 36$  mmHg). The vertical line represents the normal oxygen loading tension ( $P_{O_2} = 100$  mmHg). The filled squares represent an oxygen extraction of 5 ml/dl blood, assuming a haemoglobin concentration of 150 g/l. (Reproduced from Morgan TJ. The  $HbO_2$  dissociation curve in critical illness. *Crit Care Resusc* 1999; 1: 93–100, with permission.)

haemoglobin species ( $HbO_2$ , Hb, COHb, MetHb) from light absorbances of haemolysed blood over several wavelengths.  $SaO_2$  is functional saturation, determined from concentrations of  $HbO_2$  and Hb (see Table 14.4, below). Interference to CO-oximetry arises from substances with competing absorbance spectra, such as bilirubin, HbF, lipid emulsions and intravenous dyes. Newer multi-wavelength techniques reduce or eliminate this interference.  $SaO_2$  should always be measured rather than calculated.

#### ERRORS (TABLE 14.1)

##### Temperature correction

All measurements are made at 37°C. Temperature-corrected values can be calculated if the core temperature of the patient is entered into the device software. Most clinicians interpret blood gas data at 37°C, except when evaluating the A-a gradient.

### CONTINUOUS INTRA-ARTERIAL BLOOD GAS MONITORING (TABLE 14.2)<sup>24</sup>

Multiparameter fiberoptic sensors can be placed in the arterial stream. Fiberoptic sensors are called 'optodes', and those measuring  $P_{O_2}$  normally operate by fluorescence quenching. They require calibration with precision gases or solutions before use. Typical sensors are 0.5 mm in diameter, and can be inserted through 20-G arterial cannulae. The 90% in vitro response time to a change in  $P_{O_2}$  is 78 seconds.  $P_{O_2}$  drift in vivo is 0.03 mmHg/hour. Recalibration in vivo can be performed against conventional blood gas analysis. Accuracy on in vitro and animal testing is good.

Clinical trials evaluating the accuracy of these monitoring systems have revealed varying degrees of bias and imprecision. Trials demonstrating an improved outcome when therapeutic decisions are based on data from these devices are lacking. These factors, combined with the costs of these devices, have limited their bedside application.

Some problems encountered with intra-arterial sensors, particularly artefact due to flow and position, have prompted the development of extracorporeal monitors placed in line but ex vivo. These devices do not provide continuous real-time data. When a measurement is desired, a sample is drawn into the externally located cassette, and then returned. Results are available in 2 minutes. In preterm neonates this method has allowed significant reductions in red cell transfusions.<sup>25</sup>

### TRANSCUTANEOUS $P_{O_2}$ AND $P_{CO_2}$ MONITORING

Continuous non-invasive assessment of blood gas tensions is possible with transcutaneous  $P_{O_2}$  and  $P_{CO_2}$  monitoring. Available systems incorporate  $P_{O_2}$  and  $P_{CO_2}$  electrodes with integral thermistors and servo-controlled heaters.  $P_{O_2}$  measurement utilises the principle of the Clark electrode, while the  $P_{CO_2}$  device is a pH-sensitive glass electrode. To achieve good correlation with arterial values, the skin is warmed to a temperature of 42–44°C.

Table 14.1 Preanalytic and analytic errors in  $P_{O_2}$  measurement

Preanalytic	Analytic
Oxygen diffusing into or out of air bubbles, according to the tension gradient	Interanalyser variability. There is 7–8% measurement variation on the same sample
Contamination with flush solution. Discard volume should be 2–3 times the internal volume of cannula and tubing	Inadequate anticoagulation, allowing protein deposition on the electrodes
Pseudohypoxaemia. Oxygen consumption in vitro from extreme leukocytosis	Non-linearity at high $P_{O_2}$ (> 150 mmHg)
Artifactual $P_{aO_2}$ elevations. With polypropylene syringes stored on ice, the semipermeable plastic allows oxygen ingress, facilitated by the cold-induced increase in oxygen solubility	Maintenance of electrode temperature within narrow limits ( $37 \pm 0.1^\circ\text{C}$ ) is critical. $P_{O_2}$ changes by 7% for every degree Celsius temperature change Interference by nitrous oxide and halothane is minimal, provided the polarizing voltage of the electrode does not exceed 600 mV Quality control materials such as aqueous, perfluorocarbon and bovine haemoglobin solutions are used for convenience, but tonometry is the primary reference method Arterial blood gas tensions fluctuate breath to breath Intermittent analysis is a snapshot

Table 14.2 Continuous intra-arterial  $P_{aO_2}$  monitoring – advantages and disadvantages

Advantages	Disadvantages
Eliminates preanalytic errors of intermittent blood gas analysis	The 'wall' effect – a sudden decrease in measured $P_{aO_2}$ due to contact with the arterial wall, with averaging of arterial and wall oxygen tensions. The problem is reduced in larger arteries such as the femoral artery
More sensitive than pulse oximetry to changes in arterial oxygenation when $P_{aO_2} > 70$ mmHg (the flat part of the $HbO_2$ dissociation curve).	The 'flush' effect. Unless the sensor is inserted a sufficient distance beyond the cannula tip, measured $P_{aO_2}$ can be altered by contamination with the continuous flush solution
Free from the sources of error of pulse oximetry (see Table 14.3)	Damping of the arterial waveform
Near real-time $P_{aO_2}$ allows prompt tracking of responses to changed ventilator settings	Large footprint of the free-standing monitor
Reduced exposure of personnel to potentially infected blood	
Reduced blood loss for diagnostic purposes	

Transcutaneous monitors generate reliable  $P_{CO_2}$  values in adequately perfused patients, but  $P_{O_2}$  measurements are more for trend analysis. Skin warming necessitates frequent site changes to prevent burns, and there is a need for regular recalibration. Monitoring in haemodynamically unstable patients is not recommended. The monitors have a role in the prevention of neonatal hyperoxia, a problem not reliably detected by pulse oximetry.<sup>26</sup>

#### PULSE OXIMETRY<sup>27,28</sup>

Pulse oximetry determines  $S_{pO_2}$  from the absorbance of light at wavelengths 660 nm (red) and 940 nm (infrared) by tissue capillary beds such as fingers, earlobes and the

nasal septum. Two light-emitting diodes cycle on and off at multiples of the mains frequency. A single photodiode detects the transmitted light, and a third interval allows correction for background ambient light. The emergent signal is pulsatile due to arterial volume fluctuations. Subtraction of the background signal (tissue, capillary blood and venous blood) isolates the arterial component.

For both wavelengths, absorbance ( $A$ ) is determined as follows:

$$A = \log_{10}(I_0/I)$$

where  $I_0$  = incident light intensity, and  $I$  = emergent light intensity. For a given chromophore,  $A$  is proportional to

its concentration (Beer's law) and to the path length (Lambert's law). From the pulsatile (AC) and background (DC) absorbance signals at both wavelengths, a ratio ( $R$ ) is derived:

$$R = (AC_{660}/DC_{660})/(AC_{940}/DC_{940})$$

$SpO_2$  is then computed from  $R$ , using software 'look-up' tables of empirically derived relationships between  $R$ -values and either  $SpO_2$  or fractional saturation (FHbO<sub>2</sub>) measured in the arterial blood of volunteers breathing hypoxic gas mixtures.

$SpO_2$  is usually displayed as a percentage. Only two wavelengths are used, forcing the assumption that HbO<sub>2</sub> and Hb are the only haemoglobin species in the light path. This is always incorrect, but the error is trivial with normal dyshaemoglobin concentrations. Some manufacturers calibrate  $R$  against FHbO<sub>2</sub> rather than  $SpO_2$  (functional saturation). Because volunteers generating the data have normal dyshaemoglobin concentrations, differences between the two calibrations are small.

#### SPEED OF RESPONSE

$SpO_2$  is averaged over 3–6 seconds, and updated every 0.5–1 second. With forehead probes a sudden reduction in  $FiO_2$  produces a response within 10–15 seconds, whereas with finger probes and peripheral vasoconstriction the delay can exceed 1 minute.

#### ACCURACY

In the 90–97% saturation range,  $SpO_2$  has a mean absolute bias of < 1%, and a precision (standard deviation of bias)

of < 3%. At  $SpO_2 < 80\%$  there is significant imprecision and a tendency towards negative bias. This is because very low  $SpO_2$  values are unsafe in volunteers, necessitating extrapolation from  $SpO_2/R$  relationships at higher saturations.

#### ERROR

Causes of error are set out in Table 14.3. A falsely high  $SpO_2$  is of greatest concern.

Unlike CO-oximetry, pulse oximetry is not subject to interference from bilirubin, lipid emulsions and HbF.

#### Dyshaemoglobins and pulse oximetry

Pulse oximeters cannot distinguish COHb from HbO<sub>2</sub>. When [COHb] is elevated,  $SpO_2$  tends to overestimate  $SpO_2$ .  $SpO_2$  can thus provide false reassurance when hypoxaemia is combined with a high [COHb], for example after an inhalational burn injury.

MetHb has more complex effects, since it absorbs both wavelengths. At normal saturations, increased [MetHb] causes underestimation of  $SpO_2$ , but at very low oxygen tensions overestimation is possible. At [MetHb] ≥ 35%, the  $R$ -value becomes unity, which translates to  $SpO_2 = 85\%$ .

#### IMPORTANCE OF PULSE OXIMETRY

Pulse oximeters generate accurate real-time information without calibration, within moments of sensor placement. Their use is mandatory in patient transport, and in high-acuity areas such as operating rooms, recovery rooms and intensive care units. They are also useful screening tools. On the down side, pulse oximeters are the most common source of false alarms in intensive care. They are also

**Table 14.3** Causes of error in  $SpO_2$  readings

Factor	Comment
Carboxyhaemoglobin	Measured as HbO <sub>2</sub> – $SpO_2$ may be falsely high – see text
Methaemoglobin	Absorbs both wavelengths – see text
Low saturations	Progressive inaccuracy below 70–80%, usually falsely low $SpO_2$
Prominent venous signal	Dependent limb, tricuspid regurgitation (venous pulsations) – falsely low $SpO_2$
Non-pulsatile flow	Cardiopulmonary bypass – poor signal
Vasoconstriction, limb ischaemia, shock states	Low pulsatile signal
Motion artefact	Tremor, voluntary movement – falsely low $SpO_2$
Ambient light	Strong sunlight, fluorescent and xenon lamps, flickering light – falsely low $SpO_2$
Anaemia	No effect
Dyes	Methylene blue, indocyanine green, indigo carmine – falsely low $SpO_2$
Black skin pigmentation	Variable precision and bias. May require separate calibration
Nail polish	Especially blue. Falsely low $SpO_2$ . Acrylic nails do not interfere
Optical shunting	Due to inadequate probe contact – falsely low $SpO_2$
Radiofrequency interference	Reported with magnetic resonance imaging scanners – falsely high $SpO_2$

insensitive to changes in arterial oxygenation at higher  $P_{aO_2}$  values (> 70–100 mmHg).

### MONITORING HAEMOGLOBIN–OXYGEN AFFINITY

Haemoglobin–oxygen affinity is the relationship between the oxygen tension of blood and its oxygen content, described by the sigmoid-shaped  $HbO_2$  dissociation curve (see Figure 14.4). The P50 is the oxygen tension at  $S_{O_2} = 0.5$ . The normal value in humans is 26.7 mmHg. Factors which decrease haemoglobin–oxygen affinity increase the P50. They include acidaemia (the Bohr effect), hypercapnia, high levels of erythrocytic 2,3-diphosphoglycerate (2,3-DPG) and fever, whereas P50 is decreased (increased affinity) by alkalaemia, hypocapnia, low 2,3-DPG levels, hypothermia, COHb, MetHb and FHb.

In the intensive care unit, it is possible to calculate accurate P50 values from a single measurement of blood gases and  $S_{aO_2}$  up to  $S_{aO_2} = 0.97$ .<sup>29</sup> However the impact of haemoglobin–oxygen affinity on tissue oxygenation in critical illness appears to be small,<sup>30</sup> making routine monitoring unnecessary.

### OXYGEN DYNAMICS

Common indices of oxygen dynamics are set out in Table 14.4.

**Table 14.4** Oxygen dynamics – measured and derived indices

Parameter	Abbreviation	Formula	Normal range	Units
Functional haemoglobin concentration	$[Hb_{\text{func}}]$	$[HbO_2] + [Hb]$	12.0–18.0	g/dl
Arterial oxygen tension	$P_{aO_2}$	Measured	$95 \pm 5$	mmHg
Mixed venous oxygen tension	$P_{vO_2}$	Measured	$40 \pm 5$	mmHg
Functional saturation	$S_{O_2}$	$[HbO_2]/([HbO_2] + [Hb])$		
Fractional saturation	$FHbO_2$	$[HbO_2]/([HbO_2] + [Hb] + [COHb] + [MetHb])$		
Arterial functional saturation	$S_{aO_2}$		$0.97 \pm 0.02$	
Mixed venous functional saturation	$S_{vO_2}$		$0.75 \pm 0.05$	
Blood oxygen content	$CO_2$	$1.39 \times [Hb_{\text{func}}] \times S_{O_2} + 0.0031 \times P_{O_2}$		ml/dl
Arterial oxygen content	$Ca_{O_2}$		16–22	ml/dl
Mixed venous oxygen content	$Cv_{O_2}$		12–17	ml/dl
Cardiac index	CI	$CO/BSA$	2.5–4.2	l/min/m <sup>2</sup>
Oxygen delivery index	$Do_2I$	$CI \times Ca_{O_2} \times 10$	460–650	ml/min per m <sup>2</sup>
Oxygen consumption index	$Vo_2I$	$CI \times (Ca_{O_2} - Cv_{O_2}) \times 10$	96–170	ml/min per m <sup>2</sup>
Oxygen extraction ratio	$O_2ER$	$(Ca_{O_2} - Cv_{O_2})/Ca_{O_2}$ or $Vo_2/Do_2$	0.23–0.32	

$HbO_2$ , oxyhaemoglobin; Hb, reduced haemoglobin; COHb, carboxyhaemoglobin; MetHb, methaemoglobin; BSA, body surface area.

### $Do_2/Vo_2$ RELATIONSHIPS

More than 30 years ago an association was reported between hyperdynamic oxygen flow patterns and survival after high-risk non-cardiac surgery.<sup>31</sup> This led to the hypothesis that an induced perioperative hyperdynamic state is protective, subsequently supported by single-unit studies,<sup>32–35</sup> but not by larger multicentre studies.<sup>36,37</sup> Much of any benefit may be due to fluid loading, or even increased care and attention. Typical therapeutic goals have been cardiac index (CI) > 4.5 l/min per m<sup>2</sup>,  $Do_2I$  > 600 ml/min per m<sup>2</sup>,  $Vo_2I$  > 170 ml/min per m<sup>2</sup>. More recently more emphasis has been placed on the  $Do_2I$  target, since supranormal  $Vo_2I$  values are much harder to achieve. It is now also clear that in sepsis, aggressive pursuit of hyperdynamic goals is counterproductive.<sup>38</sup>

### MEASURING $Do_2I$

Although  $Do_2I$  determinations require accurate measurements of CI and  $Ca_{O_2}$ , a PA catheter is not essential (see Chapter 12). Normal ranges can be quoted (Table 14.4), but oxygen demand in critical illness is so variable that isolated  $Do_2I$  measurements are difficult to interpret.

### MEASURING $Vo_2I$

The two methods of measuring  $Vo_2I$  are the reverse Fick method (Table 14.4) and indirect calorimetry.

**Reverse Fick method**

The reverse Fick method requires a PA catheter, and has large random errors, ranging from 17% overestimation to 13% underestimation. Changes cannot be detected reliably unless they exceed 20%. The error is increased by lung inflammation, when up to 20% of  $\dot{V}O_2I$  can arise from the lungs alone.

**Indirect calorimetry**

Indirect calorimetry has better accuracy.  $\dot{V}O_2I$  is determined from the volumes and oxygen concentrations of inspired and expired gas. However, high  $FiO_2$  settings introduce error. Newer devices retain their accuracy up to  $FiO_2 = 0.8$ , with relative errors of  $< 5\%$ .<sup>39</sup>

**MIXED VENOUS BLOOD**

Mixed venous sampling is by gentle aspiration of blood from the distal port of an unwedged PA catheter. This ensures complete admixture of blood from superior and inferior venae cavae and coronary sinus. Mixed venous  $O_2$  and  $CO_2$  tensions and content are flow-weighted averages of the venous effluents of multiple tissues. The integrating process can conceal pockets of hypoxia and hypercapnia.

**MIXED VENOUS  $P_{vO_2}$  ( $P_{vO_2}$ )**

Venous gas tensions reflect postcapillary and tissue gas tensions. At a  $P_{vO_2}$  of 26 mmHg, the average intracellular  $P_{O_2}$  has fallen from 11 to 0.8 mmHg.<sup>40</sup> A  $P_{vO_2}$  below this value is highly suggestive of intracellular hypoxia. However, a normal or high  $P_{vO_2}$  does not exclude regional tissue hypoxia, whether cytopathic hypoxia<sup>5</sup> or hypoxia due to tissue shunting.<sup>41</sup>

**MIXED VENOUS OXYGEN SATURATION ( $S_{vO_2}$ )**

$S_{vO_2}$  is measured either intermittently by CO-oximetry on mixed venous samples or continuously by fiberoptic reflectance oximetry using a modified PA catheter.  $S_{vO_2}$  measurements have a number of potential uses:

1. To calculate  $C_{vO_2}$  (Table 14.4).  $C_{vO_2}$  can then be used to determine  $Q_s/Q_t$ ,  $\dot{V}O_2I$  by the reverse Fick method, the oxygen extraction ratio (Table 14.4) and cardiac output by the Fick method.
2. As an indirect index of tissue hypoxia. A  $S_{vO_2}$  value of 0.5 corresponds to the theoretical critical  $P_{vO_2}$  of 26 mmHg. Values between 0.7 and 0.8 represent a desirable balance between global oxygen supply and demand (Table 14.4), with lactic acidosis appearing between 0.3 and 0.5.<sup>42</sup> Values exceeding 0.8 can be seen in high-flow states such as sepsis, hyperthyroidism and severe liver disease.

$S_{vO_2}$  as a therapeutic target ( $> 0.7$ ) failed to improve survival in a multicentre trial.<sup>43</sup> Only two-thirds of the treatment group achieved the  $S_{vO_2}$  target. Like  $P_{vO_2}$ ,  $S_{vO_2}$  is insensitive to cytopathic hypoxia and tissue shunting. In chronic heart failure, low values can be surprisingly well tolerated.

**CENTRAL VENOUS SATURATION ( $ScvO_2$ )<sup>43–45</sup>**

As with  $S_{vO_2}$ ,  $ScvO_2$  can be measured either continuously using a central venous catheter modified for reflectance oximetry, or by intermittent sampling and CO-oximetry.  $ScvO_2$  is normally 2–3% lower than  $S_{vO_2}$ . However, in shock this difference can be reversed. Trends in  $S_{vO_2}$  and  $ScvO_2$  in response to management usually run in parallel.

In an influential single-centre study of the early hypodynamic phase of severe sepsis and septic shock, resuscitation guided by a  $ScvO_2$  target of  $> 0.7$ , as well as by central venous pressure and mean arterial pressure values, appeared to reduce 28-day and 60-day mortality, and duration of hospitalization.<sup>45</sup> It remains to be seen whether this success can be replicated in larger trials, and if so whether intermittent sampling is of equivalent benefit. Nevertheless,  $ScvO_2$  currently has equal billing with  $S_{vO_2}$  in the management guidelines of the Surviving Sepsis Campaign.<sup>46</sup>

**VENOARTERIAL  $P_{CO_2}$  GRADIENT ( $\Delta P_{CO_2}$ )**

$\Delta P_{CO_2}$  (normally about 6 mmHg) is markedly increased during cardiac arrest and in experimental low-output states, but lacks sensitivity and specificity as a global index of tissue hypoxia. A sudden increase in the respiratory quotient ( $V_{CO_2}/\dot{V}O_2$ ), or in the venoarterial  $CO_2$  tension difference/arteriovenous  $O_2$  content difference<sup>47</sup> may be more reliable markers of the onset of anaerobic metabolism.

**PLASMA LACTATE AND REDOX INDICES**

See Chapter 15.

**REGIONAL OXYGENATION INDICES****REGIONAL  $P_{CO_2}$ <sup>48</sup>**

Regional  $P_{CO_2}$  reflects the balance between arterial blood  $CO_2$  content, tissue blood flow and tissue  $CO_2$  production. The  $CO_2$  gap, which is regional  $P_{CO_2} - Pa_{CO_2}$ , was devised to correct regional  $P_{CO_2}$  for varying arterial  $CO_2$  content. As tissue blood flow falls, reduced  $CO_2$  clearance causes the  $CO_2$  gap to increase. With the onset of anaerobic metabolism, tissue  $CO_2$  production steadily decreases, although worsening regional metabolic acidosis generates some  $CO_2$  by proton titration of tissue and capillary  $HCO_3^-$ . A rising  $CO_2$  gap merely signals falling tissue blood flow. It cannot identify the onset of anaerobic metabolism.

**GASTRIC TONOMOMETRY<sup>49</sup>**

The impetus to develop regional gastric capnometry was the knowledge that splanchnic hypoperfusion occurs early in circulatory shock, tends to persist as ‘covert shock’, and is manifested by intramucosal hypercapnia and

acidosis. A gastric tonometer was therefore developed as a modified nasogastric tube with a silicone balloon 11.4 cm from the tip. Gastric mucosal CO<sub>2</sub> equilibrates with luminal CO<sub>2</sub>, which equilibrates with (and is measured in) fluid filling the balloon. Early on, this fluid was saline. Subsequently air was found to have more rapid equilibration characteristics, and automated cycling of air through an infrared CO<sub>2</sub> analyser was far more efficient than measuring saline P<sub>CO<sub>2</sub></sub> intermittently and applying time-based correction factors.

The original concept involved calculation of intramucosal pH (pH<sub>i</sub>) via the Henderson–Hasselbalch equation, using gastric luminal P<sub>CO<sub>2</sub></sub> and arterial [HCO<sub>3</sub><sup>-</sup>]. Intramucosal acidosis was defined as pH<sub>i</sub> < 7.3, and taken to indicate inadequate splanchnic perfusion. Changing the monitoring end-point from pH<sub>i</sub> to the mucosal–arterial CO<sub>2</sub> gap (normally 8–10 mmHg) removed the most fundamental flaw – the use of arterial [HCO<sub>3</sub><sup>-</sup>] as a surrogate for mucosal [HCO<sub>3</sub><sup>-</sup>]. Automated air tonometry combined with simultaneous end-tidal CO<sub>2</sub> measurement allows the regular calculation of a gastric to end-tidal CO<sub>2</sub> gap, a parameter linked to outcome in high-risk surgery.<sup>50</sup>

Even with these improvements, the technique has not found widespread application, and is unlikely to do so for several reasons:

1. the need for a nasogastric tube
2. signal degradation by luminal contents, including feeds and blood. Feeds must be stopped 2 hours prior to measurements, jeopardising nutritional support
3. inability to identify a clear hypoxic threshold. Empiric recommendations have been to target a CO<sub>2</sub> gap < 25 mmHg
4. a need to suppress gastric acidity to prevent luminal CO<sub>2</sub> generation by HCl titration of duodenal bicarbonate
5. a lack of convincing evidence that tonometry-guided therapy improves outcome<sup>51</sup>

#### SUBLINGUAL CAPNOMETRY<sup>49,50</sup>

Sublingual capnometry measures the interstitial CO<sub>2</sub> tension under the tongue, as its name suggests, using either electrode or optode technologies. Although the tongue vasculature is not part of the splanchnic circulation, it responds similarly to circulatory disturbances. It has the added advantage of accessibility with minimal invasion. Optode sensors in particular provide rapid-response P<sub>CO<sub>2</sub></sub> signals. It is also possible to perform simultaneous inspections of the microcirculation using orthogonal polarisation spectral imaging.

At this stage, all that can be said is that sublingual P<sub>CO<sub>2</sub></sub> seems to correlate with the severity of haemodynamic disturbances and with gastric mucosal P<sub>CO<sub>2</sub></sub>, and that in a limited number of shocked patients the sublingual CO<sub>2</sub> gap was correlated with survival. It remains to be seen whether the technique can be used to guide therapy.

## CEREBROVENOUS OXYGEN SATURATION MONITORING

See Chapter 67.

### DIRECT TISSUE P<sub>O<sub>2</sub></sub> MEASUREMENT

In patients this is largely impractical. Measurements have been recorded primarily in animal models in the brain, subcutaneous tissue, muscle and renal beds under a variety of perfusion insults.<sup>52</sup> Tensions are commonly around 30–45 mmHg, but can range from < 10 mmHg in the renal medulla to > 70 mmHg in subcutaneous tissue.

### OTHER REGIONAL TECHNIQUES

Orthogonal polarisation spectroscopy (OPS) allows real-time in vivo imaging of microcirculatory blood flow.<sup>42</sup> Tissue beds visualised in intensive care have included the sublingual, rectal, oral and ileal (via stoma) microcirculations. OPS can be combined with near-infrared spectroscopy to monitor deeper regional mitochondrial redox status, and with reflectance spectrophotometry for measurement of superficial microcirculatory oxygen saturation. Combinations of this type provide uniquely integrated information on oxygen transport distribution during sepsis and septic shock.

Other techniques showing promise include in vivo magnetic resonance imaging<sup>53</sup> and optical spectroscopy.<sup>54</sup>

# Lactic acidosis

D J (Jamie) Cooper and Alistair D Nichol

Lactic acidosis is defined by convention as the combination of an increased blood lactate concentration ( $> 5$  mmol/l) and acidaemia (arterial blood pH of  $< 7.35$ ).<sup>1,2</sup> However hyperlactaemia occurs whenever the blood lactate concentration is above the normal range ( $< 2$  mmol/l). Lactic acidosis may be masked by coincident metabolic or respiratory alkalosis. Critically ill patients with lactic acidosis usually have a high mortality<sup>3</sup> and blood lactate concentrations  $> 8$  mmol/l predict fatality.<sup>4</sup> A prospective study reported 83% mortality in patients with blood lactate concentrations of 10 mmol/l.<sup>1</sup> In each individual patient, however, prognosis is completely dependent on the underlying condition, with the initial degree of lactic acidosis being a clinically useful indicator of shock severity, and serial assessment allowing evaluation of response to therapy. Recently, blood lactate concentration has been identified as one marker of the degree of shock triggering treatment in septic patients who may benefit from early goal-directed therapy.<sup>5</sup> It is important to remember that, in healthy athletes, severe lactic acidosis during exercise is a normal, self-limited observation.

## PATHOPHYSIOLOGY

There is a continuous cycle of lactate production and metabolism. Lactate is produced at about 0.8 mmol/kg per h, while simultaneous metabolism in liver, kidneys, skeletal muscle, brain and red blood cells ensures that blood lactate concentrations are normally low ( $< 1$  mmol/l). Lactic acidosis occurs when lactate production exceeds metabolic capacity, or when metabolic capacity is decreased by organ dysfunction. The liver has a key role in lactate homeostasis and many patients who develop lactic acidosis have decreased metabolic capacity due to liver disease.<sup>6</sup>

Formation and metabolism of lactate in cells are catalysed by lactate dehydrogenase (LDH):

Lactate formation is in part dependent upon pyruvate concentrations and pyruvate is sourced from glycolysis (85%) and proteolysis (15%). Glucose is derived from absorption, glycogen and gluconeogenesis. Rate of glycolysis is controlled by three unidirectional enzymes and

the activity of one of these enzymes is increased by increasing intracellular pH. Acidosis therefore decreases (and alkalosis increases) glycolysis and pyruvate, and consequently lactate production. In oxygen excess, pyruvate is oxidised and lactate does not accumulate. Anaerobic metabolism however, causes lactate accumulation and an increased lactate/pyruvate ratio. The blood lactate/pyruvate ratio is however a poor indicator of mitochondrial concentrations, and is not of clinical use.

In critically ill patients, lactic acidosis is often due to shock. In cardiogenic and hypovolaemic shock, hypoperfusion and tissue hypoxia increase lactic acid production while decreased hepatic perfusion decreases lactic acid metabolism. In septic shock, lactic acidosis is multifactorial. Contributors include global hypoperfusion, microvascular disruption causing regional hypoperfusion and impaired cellular oxygen utilisation by mitochondria.

## CLASSIFICATION (TYPES A AND B)

The Cohen and Woods classification of lactic acidosis<sup>7</sup> defines two subgroups depending on the presence (type A) or absence (type B) of tissue hypoxia (Table 15.1). Type A lactic acidosis due to tissue hypoxia is common in critically ill patients. Type B (no tissue hypoxia) is much less common. Some patients with type B lactic acidosis have increased lactate generation (some malignancies and toxins impair oxygen utilisation by cells, despite adequate oxygen delivery), and other patients have decreased lactate clearance (liver disease). Patients with liver disease have greater hyperlactaemia during states of increased lactate production than those with normal liver function.<sup>6</sup>

## COMBINED ABNORMALITIES (TYPES A AND B)

In clinical practice, separation of types A and B lactic acidosis is usually not helpful, because many critically ill patients have combined abnormalities. Increased lactate formation from tissue hypoxia and decreased lactate clearance often occur together. In patients with cancer, anaerobic glycolysis may be increased while hepatic lactate metabolism is impaired by tumour replacement. Diabetic patients may present with shock, but in non-insulin-dependent diabetes there may also be a defect in pyruvate

**Table 15.1** Classification of lactic acidosis

Type A	Shock Very severe hypoxaemia Very severe anaemia Carbon monoxide poisoning
Type B1 (underlying disease)	Sepsis Liver failure Thiamine deficiency Malignancy Pheochromocytoma Diabetes
Type B2 (drug or toxin)	Epinephrine Salbutamol Propofol Nucleoside analogue reverse transcriptase inhibitor Ethanol Methanol Paracetamol Nitroprusside Salicylates Ethylene (and propylene) glycol Biguanides Fructose Sorbitol Xylitol Cyanide Isoniazid
Type B3 (rare inborn errors of metabolism)	Glucose-6-phosphatase deficiency Fructose-1,6 diphosphatase deficiency Pyruvate carboxylase deficiency Deficiency of enzymes of oxidative phosphorylation

oxidation, and in diabetic ketoacidosis ketones may also inhibit hepatic lactate uptake. Thiamine and biotin are essential cofactors for pyruvate dehydrogenase activity and for conversion of pyruvate to oxaloacetate. Malnutrition (beri-beri) and inadequate parenteral nutrition have therefore been associated with lactic acidosis due to deficiencies of these cofactors. In these cases, pyruvate accumulation increases lactate production. In alcoholics, ethanol oxidation increases the conversion of pyruvate to lactate and inhibits other pathways of pyruvate metabolism. Phenformin therapy is associated with lactic acidosis for several reasons: phenformin increases glycolysis in peripheral tissues, inhibits pyruvate oxidation, increases splanchnic lactate production and decreases hepatic lactate clearance. Phenformin was therefore used to induce lactic acidosis in older animal models until it was recognised that phenformin is also a potent cardiac depressant. These studies reporting the effects of lactic acidosis on cardiac function were flawed. Both endogenous and infused catecholamines cause hepatic vasoconstriction and impair

hepatic lactate clearance, and epinephrine also increases hepatic glycogenolysis to lactate.<sup>8</sup> Importantly, acidosis also stimulates adrenal catecholamine release, which may mask other cardiac effects of acidosis.

### SEPSIS

There has been much recent debate<sup>9</sup> whether the hyperlactaemia of sepsis results from net increased cellular production<sup>10</sup> or reduced net clearance.<sup>11</sup> However the potential for sepsis to derange lactate metabolism is clear. Both impaired regional microvascular and mitochondrial dysfunction have been implicated in the pathogenesis of lactic acidosis during sepsis. Excess catecholamines may impair hepatic lactate extraction (by reducing regional hepatic blood flow) and increase lactate production (increased glycogenolysis). At the same time lactate clearance is decreased because pyruvate dehydrogenase activity is reduced in both skeletal muscle and liver. Mitochondrial pyruvate oxidation is impaired.

Tissue hypoxia may not be a major mechanism for regional lactate production during sepsis: hyperlactaemia is thought to be linked to the severity of the septic cellular inflammatory response and hypermetabolic state.<sup>9,12</sup> Net lactate production from the hepatosplanchnic bed is uncommon in septic patients<sup>13</sup> and nuclear magnetic resonance spectroscopy suggests that hyperlactaemia may occur without tissue hypoxia.<sup>14</sup>

### LUNG INJURY

The lung is a primary source of lactate production in patients with acute lung injury, with pulmonary release of lactate being directly related to the severity of lung injury,<sup>15,16</sup> supporting the view that the primary contributors are the tissues with the most inflammation or injury. The increased lactate production by the injured lung is not only secondary to anaerobic metabolism in the hypoxic regions of the lung but also may be due to altered glucose metabolism and a direct effect of cytokines on pulmonary cells.<sup>16</sup>

Recent laboratory data suggest that both metabolic and respiratory acidosis protect the lung against injury whereas correction of acidosis compounded the injury.<sup>17,18</sup> The two ventilator trials<sup>19,20</sup> which demonstrated a positive impact on mortality in acute respiratory distress syndrome (ARDS) by limiting tidal volume and airway pressures differed widely on how they regarded the resultant hypercapnic acidosis. While Amato *et al.*<sup>19</sup> allowed elevation of the  $P_{aCO_2}$  (permissive hypercapnia) and resultant acidosis, the ARDSnet group<sup>20</sup> in contrast aggressively corrected the hypercapnic acidosis by increasing the respiratory rate and allowing administration of sodium bicarbonate. There is growing evidence that not only may hypercapnic acidosis be beneficial in lung injury,<sup>17,21</sup> but the ARDSnet interventions aimed at correcting the acidosis may also be deleterious.<sup>18,22</sup> These findings have not only promoted a greater tolerance of acidosis in ARDS but also increased reluctance to buffer the acidosis exogenously towards 'normal' values.

**ASTHMA**

Lactic acidosis also often occurs in patients with acute severe asthma.<sup>23</sup> Fatiguing respiratory muscles have been implicated, but severe lactic acidosis also occurs in sedated, paralysed mechanically ventilated patients who have no endogenous respiratory muscle activity.<sup>24</sup>  $\beta$ -agonists, including salbutamol and epinephrine cause lactic acidosis by increasing gluconeogenesis, glycogenolysis, lipolysis and cyclic adenosine monophosphate (AMP) activity. Clinical experience suggests that infusions of  $\beta$ -agonists are the primary cause of lactic acidosis in patients with asthma because decreasing intravenous salbutamol infusions to less than 10 mcg/min is usually associated with resolution of the acidosis. In asthma, lactic acidosis does not have specific prognostic implications.

**CARDIAC SURGICAL PATIENTS**

Hyperlactaemia during cardiopulmonary bypass is relatively frequent and is associated with an increased post-operative morbidity.<sup>25</sup> Recent work has suggested that this 'on-pump' hyperlactaemia is secondary to inadequate peripheral oxygen delivery ( $DO_2$ ) which creates a condition similar to cardiogenic shock, leading to both direct lactate formation by dysoxic tissues and also to catecholamine release, insulin resistance and hyperglycemia-induced lactate production.

The use of epinephrine after cardiopulmonary bypass precipitates lactic acidosis in some patients.<sup>26</sup> This phenomenon is probably  $\beta$ -agonist-mediated, is associated with increased whole-body blood flow and resolves after substitution of norepinephrine. However there is emerging evidence that the severity of lactic acidosis following cardiac surgery is related to certain genetic polymorphisms in tumour necrosis factor and interleukin-10 genes.<sup>27</sup> Similar to asthma, lactic acidosis associated with the administration of epinephrine in this setting does not have the adverse implications of lactic acidosis associated with shock.

**MESENTERIC ISCHAEMIA**

The diagnosis of mesenteric ischaemia can be challenging to make in the critically ill due to a lack of clinical and diagnostic signs, difficulty transferring unstable patients for diagnostic imaging and concern about the deleterious effects of inappropriately administering contrast agents. Animal models have shown that lactate increases within 1 hour of induced intestinal ischaemia. In addition, elevated lactate at the time of diagnosis of mesenteric ischaemia is a predictor of mortality.<sup>28</sup> However, although plasma lactate is a very sensitive marker (100%) for detecting acute mesenteric ischaemia, the low specificity of this marker (42%) is a particular problem in the critically ill, who frequently have many plausible alternate diagnoses.

D-lactate is the isomer of lactate that is produced by intestinal bacterial and not by humans. Experimental work suggests that ischaemic bowel allows the translocation of D-lactate into the systemic circulation; as D-lactate is not eliminated by the liver, plasma levels may be more specific markers of mesenteric ischaemia.<sup>29</sup>

However, many issues need to be clarified, including the effect of antibiotic therapy on the intestinal bacteria, before D-lactate could be considered as a bedside diagnostic test.<sup>30</sup>

It is necessary to have a high index of suspicion for mesenteric ischaemia in a deteriorating patient with an elevated lactate in the absence of a convincing alternative diagnosis, as identification of mesenteric ischaemia is frequently made first at laparotomy in the critically ill.

**CLINICAL PRESENTATION**

Patients present with clinical signs appropriate to their primary disorder. Their lactic acidosis is usually only evident after laboratory testing. In critically ill patients with shock, however, the severity of lactic acidosis can be a valuable monitor of the efficacy of resuscitation. Repeated measures of arterial blood gases and blood lactate concentrations are required. In hypovolaemic shock, resolving lactic acidosis along with the clinical signs of improving perfusion is one of several indicators of successful resuscitation. Conversely, failure of lactic acidosis to resolve in hypovolaemic shock suggests inadequate resuscitation or another undetected or unresolved clinical problem. In patients with severe lactic acidosis<sup>1</sup> a blood lactate concentration of 5 mmol/l indicated a mortality approaching 80% and survival was best in patients whose hyperlactaemia resolved. In septic shock there are many contributors to lactic acidosis, so the time course of acidosis resolution in this setting is a less reliable indicator of the adequacy of shock resuscitation.

Lactic acidosis may also occur in critically ill patients in the absence of shock. Examples include hypermetabolic states where accelerated aerobic glycolysis may contribute (trauma, burns, sepsis), conditions with increased muscle activity (seizures) and during exogenous lactate administration (lactate buffered haemofiltration fluid). In many of these patients (for example, patients with seizures) very high blood lactate concentrations have no prognostic implications because the acidosis is rapidly cleared.

**CARDIAC DYSFUNCTION – ASSOCIATION, CAUSE OR RESULT OF LACTIC ACIDOSIS**

Cardiac dysfunction is common in shocked patients with lactic acidosis and it has often been assumed that therapies for lactic acidosis would improve cardiac function. However, cardiac dysfunction in these patients is very likely due to other factors, with cytokines (tumour necrosis factor- $\alpha$ , interleukins) being the major cause in septic shock, and with lactic acidosis a consequence or association rather than a cause of cardiac dysfunction. In lactic acidosis, some clinicians recommend normalisation of arterial pH based on two assumptions: (1) that acidosis causes cardiac dysfunction; and (2) that patients are better with 'normal' laboratory values.<sup>31</sup> Both of these assumptions are incorrect in most critically ill patients. First, early

research in isolated muscle, isolated heart preparations, animal models and clinical case reports supported the view that acidosis decreased cardiac function and decreased the haemodynamic response to catecholamines. However later large animal studies in which preload, afterload and heart rate were carefully controlled found only marginal effects of lactic acidosis on contractility.<sup>2,32</sup> Also, laboratory reports of decreased cardiac function during acidosis studied an arterial pH much lower (pH 6.6–6.9) than that usually observed in critically ill patients.<sup>33</sup> Increasing experience with permissive hypercapnia in ARDS and asthma has supported the view that patients with respiratory acidosis have fewer complications and better outcomes when normal values are not targeted. The major haemodynamic effect of acute hypercapnic acidosis in ARDS and asthma was increased cardiac output and vasodilatation, not cardiac depression.<sup>34</sup> Therefore, targeting normal values in lactic acidosis is also unlikely in itself to be beneficial, and may be harmful.

## MANAGEMENT

### GENERAL

In critically ill patients, lactic acidosis is often an indicator of major patient pathology. Therefore the main focus is to identify and treat the cause rapidly. A clinical examination and search for occult sepsis, inadequate resuscitation, localised ischaemia or cardiovascular failure are urgently required. In each case, after diagnosis and initial management, lactic acidosis may then be used as an ongoing monitor of disease progression or resolution. pH correction with sodium bicarbonate has the disadvantage of removing this useful clinical monitor.

### TREAT THE PRIMARY DISORDER

Specific therapies and supports must be directed at each underlying cause. In hypovolaemic and cardiogenic shock, restoration of an adequate global oxygen delivery is required. Vasoconstrictors may worsen tissue perfusion and should only follow adequate intravascular volume and appropriate cardiac supports. In septic shock, antibiotics appropriate to cover all likely sources of infection are a priority, and in patients with possible ischaemic gut, surgery may be required for both diagnosis and therapy. Postsurgical gastrointestinal leaks may sometimes be difficult to diagnose, may not be detectable on computed tomography and require early laparotomy. In status epilepticus, lactic acidosis is a result of muscle activity and rapid use of effective anticonvulsants is indicated. In diabetic ketoacidosis, insulin, appropriate fluid and treatment of precipitants enable resolution of all metabolic abnormalities, including associated lactic acidosis. In thiamine deficiency, highlighted during a nationwide American shortage of multivitamins for patients receiving total parenteral nutrition,<sup>35</sup> high-dose intravenous thiamine

corrected both the vasodilated shock and associated lactic acidosis. In acute severe asthma, lactic acidosis is commonly a result of high-dose intravenous  $\beta$ -agonist therapy, and salbutamol dose reduction usually resolves the problem. In vasodilated patients after cardiopulmonary bypass, lactic acidosis may also be related to  $\beta$ -agonist therapy<sup>26</sup> and resolves after substitution of intravenous epinephrine with norepinephrine. In these cases, lactic acidosis is not related to decreased tissue perfusion and adverse effects upon prognosis have not been noted. Patients with human immunodeficiency virus (HIV) receiving nucleoside analogue reverse transcriptase inhibitor (NRTI) therapy have a high incidence of hyperlactaemia (8.3%) which can progress to a rapidly fatal metabolic lactic acidosis syndrome. These patients with NRTI-induced mitochondrial dysfunction require withdrawal of the therapy (if lactate > 5 mmol/l) and close monitoring.<sup>36</sup> In symptomatic patients an elevated lactate level is associated with mortality.

### HYPERVENTILATION

Hyperventilation is a normal compensatory response to metabolic acidosis in conscious patients. Therefore in mechanically ventilated patients with lactic acidosis, most clinicians will use some hyperventilation to correct acidemia partially. Clearly in patients with pulmonary pathology, hyperventilation may be difficult or inappropriate, and in some patients hyperventilation increases intrathoracic pressure, decreases venous return, decreases cardiac output and exacerbates the cause of lactic acidosis.

### BICARBONATE

Bicarbonate therapy for lactic acidosis is controversial.<sup>2,31,37</sup> Correction of acidosis with bicarbonate might reverse depressed cardiac performance, but there is no evidence in critically ill patients that lactic acidosis depresses cardiac function, and more recent laboratory studies also report minimal depression in large animals.<sup>32,38</sup> Further, not all studies have demonstrated a rise in pH after the administration of bicarbonate.<sup>39</sup> Importantly, two randomised studies of bicarbonate therapy in critically ill patients with lactic acidosis and shock found no improvement in cardiac function or any other beneficial effects of pH correction.<sup>33,40</sup> One reason for these findings is that sodium bicarbonate has adverse effects, including acute hypercapnia and ionised hypocalcaemia,<sup>33</sup> which outweigh potential benefits in patients. Hypercapnia may increase intracellular acidosis ( $\text{CO}_2$  crosses cell membranes rapidly), and hypocalcaemia decreases myocardial contractility.<sup>41</sup> Other side-effects of bicarbonate occur because bicarbonate is a hypertonic solution and include acute intravascular volume overload and cardiac depression. In addition, bicarbonate increases lactate production by increasing the activity of the rate-limiting enzyme phosphofructokinase, shifts the haemoglobin–oxygen dissociation curve, increases oxygen

affinity of haemoglobin and thereby decreases oxygen delivery to tissues. Adverse effects of bicarbonate in patients can be reduced by using slow infusions in preference to rapid boluses, and by correcting side-effects, by increasing minute volume in ventilated patients and by correcting ionised hypocalcaemia.

Mechanical ventilation limits the ability to excrete the CO<sub>2</sub> evolved from bicarbonate administration with the potential to attenuate the resultant increase in pH. In support of this, two prospective randomised controlled trials conducted in mechanically ventilated patients with lactic acidosis demonstrated that bicarbonate administration resulted in minimal improvements in pH.<sup>33,40</sup> Furthermore, in the presence of severely limited ventilation such as a lung protection strategy, bicarbonate may lower arterial pH.<sup>42</sup> The ARDSnet group supported administration of bicarbonate to limit the pH effects of hypercapnia,<sup>20</sup> but emerging experimental work suggests that buffering of hypercapnic acidosis may be detrimental,<sup>18</sup> and may not therefore be advisable during protective ventilator strategies.

Importantly, however, despite decades of debate, bicarbonate has never been shown to be beneficial in any clinical trial and its use in patients with lactic acidosis is not now recommended, regardless of the degree of acidaemia.<sup>2</sup>

There are two subgroups of patients with lactic acidosis in whom bicarbonate may be considered. Patients with pulmonary hypertension and right heart failure (e.g. lung transplant recipients) may have pulmonary vasoconstriction which is exacerbated by acidosis. In these patients, although there are other useful therapies, including inhaled nitric oxide, partial pH correction may improve right heart function. Secondly, patients with significant ischaemic heart disease and lactic acidosis may be at increased risk of major arrhythmias, because severe acidosis lowers the myocardial threshold for arrhythmias. In both of these subgroups, slow bicarbonate infusions to keep the arterial pH above 7.15 can currently be justified.

## ALTERNATIVE THERAPIES

### CARBICARB

Carbicarb is an equimolar combination of sodium carbonate and sodium bicarbonate which generates less carbon dioxide than bicarbonate and may therefore have fewer adverse effects. Carbicarb more consistently increases intracellular pH, has inconsistent effects on haemodynamics, like bicarbonate does not address the underlying cause of lactic acidosis, and is not in clinical usage.

### DICHLOROACETATE

Dichloroacetate (DCA) works by stimulating the phosphate dehydrogenase complex, the rate-limiting enzyme which regulates entry of pyruvate into the tricarboxylic acid cycle. DCA increases arterial pH and decreases lactate concentrations<sup>43</sup> but nevertheless, a large multicentre randomised clinical trial in patients with lactic acidosis

found no benefit for either haemodynamics or patient outcome.<sup>44</sup> This study is really the best evidence currently available to support the view that correction of lactic acidosis in critically ill patients without improving the underlying primary disorder has no overall effect on patient outcome. DCA is not available commercially.

### TRIS/THAM

Tris-hydroxymethyl aminomethane (THAM) is a commercially available weak alkali which is rarely used as a clinical therapy because of concerns about side-effects which include hyperkalaemia, hypoglycaemia, extravasation-related necrosis and neonatal hepatic necrosis. In acute lung injury, THAM has been demonstrated to be an effective buffer in ventilated patients, as it is not associated with an increased CO<sub>2</sub> load and is capable of ameliorating some of the haemodynamic effects of hypercapnia.<sup>42,45</sup> However, it is unclear whether buffering of hypercapnic acidosis in acute lung injury patients is of any benefit.

### DIALYSIS/HAEMOFILTRATION

Peritoneal dialysis has been reported to be effective at removing lactate, but bicarbonate-buffered haemofiltration is ineffective, contributing to less than 3% of lactate clearance.<sup>46</sup> Indeed, haemofiltration was so ineffective that it has been noted that lactate concentrations remain a useful clinical marker of disease progression in patients on bicarbonate-buffered haemofiltration.

However, in lactate-intolerant patients (i.e. those with shock-induced lactic acidosis and/or liver disease), the use of lactate-based dialysis fluid may overload the patient's metabolic capacity for lactate, particularly if high-volume haemofiltration is employed.<sup>47</sup> In these patients bicarbonate-based dialysis should be chosen.

# Acute cardiac syndromes, investigations and interventions

Brad Power

Cardiovascular disease (CVD) accounts for 35–40%<sup>1</sup> of deaths in western industrialised society, with coronary artery disease (CAD) being responsible for about half of these. In patients over age 40, acute myocardial infarction (MI) is the cause of approximately 20% of all deaths. Up to 80–90% of these deaths occur outside hospital. Of patients admitted to hospital, mortality is 8–9%,<sup>1</sup> much higher in at-risk groups. Lowering in-hospital mortality from CAD requires us to identify rapidly patients who are at risk and to implement evidence-based treatment regimens.

## MYOCARDIAL INFARCTION

MI is necrosis of myocardial cells due to ischaemic injury. Diagnosis is usually made on the basis of clinical suspicion, although tests such as electrocardiography (ECG) and biomarkers, echocardiography or autopsy findings are required to confirm the diagnosis.

Acute MI can occur in association with or result from a number of different pathological and epidemiological mechanisms:<sup>2</sup>

- a primary coronary artery event such as plaque erosion and/or rupture, fissuring or dissection
- a problem of oxygen supply demand such as coronary spasm, coronary embolism, vasculitis, drug abuse, arrhythmia, anaemia or hypotension
- sudden cardiac death where death precludes determination of causation
- percutaneous coronary intervention (PCI)
- coronary artery bypass grafting (CABG)

Each mechanism may have a different long-term prognosis despite similar biomarker and ECG changes. Such classifications may be clinically important when interpreting the results of clinical trials.<sup>2</sup>

## ACUTE CORONARY SYNDROMES (ACS)

ACS represent the largest group of patients developing MI. They describe the spectrum of patients who present

with chest discomfort or other symptoms caused by acute myocardial ischaemia (Figure 16.1). ACS can be further divided into acute MI and unstable angina (USA). Both are invariably caused by recent thrombus formation on pre-existing coronary artery plaque leading to impaired myocardial oxygen supply. In this sense they differ from stable angina, which is usually precipitated by increased myocardial oxygen demand with severe background coronary artery narrowing. Both represent medical emergencies and are one of the most frequent causes of hospital and coronary care unit (CCU) admission.

## AETIOLOGY AND RISK FACTORS

Atheroma deposits in the walls of coronary arteries provide the substrate for the development of ACS. Major risk factors for the development of coronary artery atheroma are seen in Figure 16.2. Up to 90% of the adult population possess at least one risk factor for the development of atheroma and CAD.

Cessation of smoking, lowering plasma cholesterol (diet and medications) and adoption of a more active lifestyle can all help prevent the development of CAD. Treatment of hypertensive patients produces a large and early reduction in stroke incidence (35–40%) and mortality, and a significant fall in MI (20–25%).<sup>3</sup> Modification of risk factors is one of the most important means of decreasing the prevalence and mortality from CVD.

## PATHOPHYSIOLOGY

Formation of thrombus upon disrupted, fissured or eroded atheromatous plaque is the usual precipitant of an ACS.<sup>4</sup> Atherosclerotic plaque formation is probably initiated by injury to the vessel wall that may commence even as early as childhood. Highly activated macrophages are attracted to the site of injury and differentiate into tissue macrophages. Macrophages incorporate blood stream lipids into the connective tissue fibres of the plaque, forming a thrombogenic soft lipid core. Plaque development is slow, but is rapidly accelerated in people with risk factors.

**Acute coronary syndrome (ACS).** A spectrum of clinical conditions characterized by acute chest pain or myocardial ischaemia. Pain is of recent origin or is more frequent, severe or prolonged than known angina, is more difficult to control with medication or occurs at rest or with minimal exertion. ACS includes myocardial infarction with ST-segment Elevation (STEMI), myocardial infarction in the absence of ST-Segment Elevation (NSTEMI) and unstable angina. An initial clinical subdivision of ACS is made on the presence or absence of ECG ST-segment Elevation

**STEMI.** Patients presenting with ST-segment Elevation ACS will invariably display initial or subsequent troponin elevation, although the extent of myocardial infarction and complications may be significantly moderated by intervention

**NSTEMI/UA.** Patients who present without ST-segment Elevation, may later (after testing of biomarkers) be determined to have:

- a. NSTEMI. Cardiac biomarkers elevated indicating myocardial infarction
- b. Unstable Angina. No evidence of cardiac biomarker elevation

Figure 16.1 Classification of acute coronary syndromes.

Figure 16.2 Risk factors for the development of atherosclerosis and coronary artery disease (CAD).

‘Vulnerable plaque’ is often rich in lipid and covered by a thin fibrin cap. The cause of plaque rupture or fissuring is unknown but exposes thrombogenic lipid and collagen, which are potent activators of platelets. Development of thrombus upon this eroded plaque results from: (1) platelet adherence and activation; and (2) coagulation pathway activation.

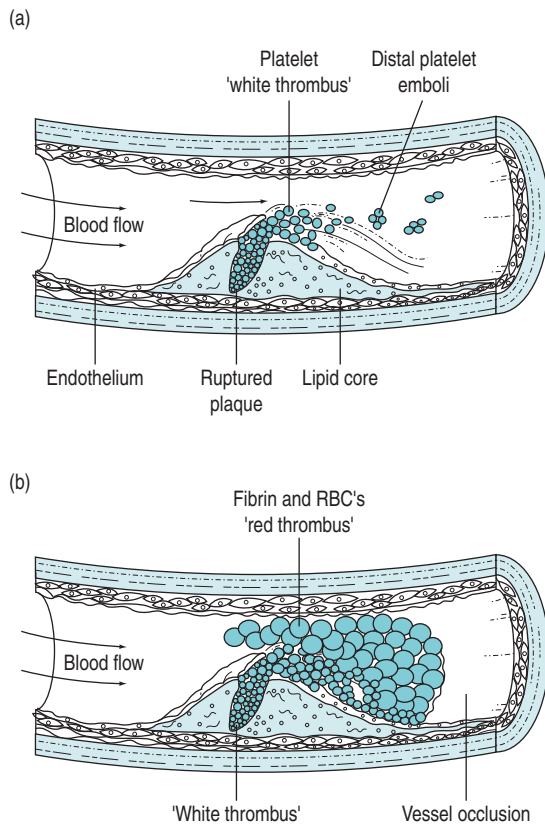

Although many pathways initiate platelet activation, the final common pathway of thrombus formation is via activation of the glycoprotein (GP) IIb/IIIa receptor, the platelet surface membrane receptor for fibrinogen. Activated GP IIb/IIIa receptors cross-link fibrinogen between activated platelets, promoting the formation of platelet thrombi. Platelets aggregate to form ‘white

thrombus’; however this thrombus is seldom totally occluding. Activation of coagulation pathways by exposed lipid and fibrin, as well as by the now activated platelets, leads ultimately to thrombin activation and the laying-down of fibrin clot. Red cells are enmeshed in this so-called ‘red thrombus’ complex, which surrounds the ‘white thrombus’. Sudden artery occlusion by thrombus may thus complicate even only moderate-sized plaque; 70% of ACS patients may have a < 50% stenotic lesion and in only 14% is the underlying stenosis > 70% of the lumen diameter (Figure 16.3).

These processes have immediate relevance to treatment:

- Antiplatelet agents prevent platelet adherence and heaping, which limits and even reverses the development of ‘white thrombus’. These agents may target the adenosine diphosphate receptor (e.g. ticlopidine and clopidogrel) or may inhibit cyclooxygenase (e.g. aspirin). Although aspirin has been the major antiplatelet agent and blocks synthesis of thromboxane A<sub>2</sub>, it fails to block platelet activation by thrombin, adenosine diphosphate and collagen.
- Fibrinolytic agents lyse ‘red thrombus’ but are not active against ‘white thrombus’.
- Antithrombin agents (e.g. heparins) may limit thrombin activation. Current thrombolytic agents lyse fibrin and red cell thrombus, but paradoxically may increase surface thrombin activation.

Totally occluding thrombus causes myocardial necrosis unless there is good collateral flow or the thrombus is rapidly cleared. Occlusion is often accompanied by ST-segment elevation on the ECG. If thrombus is largely ‘white thrombus’, with minimal or non-occlusive red thrombus, ST-segment elevation is far less likely. Non-occlusive thrombus may be asymptomatic, may cause USA or may cause MI, especially if spasm or distal embolisation of thrombus occurs. Although non-occlusive thrombus is less likely to be associated with early or sudden death, it is indicative of unstable plaque

**Figure 16.3** (a) Plaque rupture exposes thrombogenic lipid. 'White thrombus' is formed by adherent activated platelets. Coronary artery narrowing, distal platelet embolisation or arterial spasm can cause ischaemic myocardial pain and possible myocardial necrosis. This lesion is unstable and may lead to thrombin activation. 'White thrombus' is not removed by thrombolytic therapy. (b) Thrombin activation leads to a mesh of fibrin and red blood cells (RBCs) or 'red thrombus'. Arterial occlusion may result and, in arteries without adequate collateral circulation, myocardial necrosis follows. Complete arterial occlusion is suggested by ST-segment elevation on the electrocardiogram. Prompt reperfusion with thrombolytic therapy or with invasive coronary procedures may prevent extensive myocardial necrosis.

and is strongly associated with reinfarction and death in following months.

Ischaemia results in cellular disruption, loss of function, thinning and softening of the affected myocardium, and subsequently fibrosis and ventricular remodelling.

Infarct size determines:

- left ventricular (LV) systolic function impairment
- stroke volume decrease
- ventricular filling pressure rise (leads to pulmonary congestion and hypotension that may impair coronary perfusion pressures and exacerbate the myocardial ischaemia)
- LV diastolic dysfunction

Initially, infarcted muscle is softened, leading to an increase in ventricular compliance, but as fibrosis takes place compliance is decreased. With time, there is often expansion of the infarcted segment and compensatory hypertrophy of unaffected myocardial cells (i.e. ventricular remodelling). This can commence early after infarction, affecting overall ventricular function and prognosis.

### CLINICAL PRESENTATION

The diagnosis of myocardial ischaemia is usually made (suspected) on the basis of clinical history and ECG.<sup>2</sup>

### HISTORY

Patients with myocardial ischaemia can present with chest pain or pressure, syncope, palpitations, dyspnoea or sudden death. Prodromal symptoms of USA occur in the days preceding infarction in 20–60% of patients.

Typically, the pain of acute MI:

- is severe, constant and retrosternal, spreading across the chest
- lasts for more than 20 min and is without a clear precipitant
- may radiate to the throat and jaw, down the ulnar aspect of both arms and to the interscapular area

Sweating, nausea, pallor, dyspnoea and anxiety are common.

The pain of USA may be similar but milder in nature. Features that may suggest it to be ischaemic are:

- waxing and waning characteristics
- reproducibility upon minimal exertion or with emotion
- association with autonomic symptoms

The pain may sometimes be atypical:

- epigastric (leading to possible misdiagnosis)
- confined to the jaw, arms, wrists or interscapular region
- burning or a 'pressure-like' sensation
- sharp or stabbing in nature
- reproduced by chest pressure

These features do not necessarily exclude infarction.<sup>5</sup> Differential diagnosis includes:

- aortic dissection
- pericarditis

Atypical or silent presentations are common: 20–60% of non-fatal infarctions are unrecognised at onset.<sup>4</sup> This presentation is more common in patients who are elderly, diabetic, have hypertension, who smoke or take non-steroidal anti-inflammatory agents.

The assessment of clinical symptoms alone is insufficient for risk stratification and severity of pain does not usually correlate with the extent of infarction.

### PHYSICAL EXAMINATION

Examination of patients with USA is often unremarkable. With more severe infarction and extensive myocardial injury, signs of autonomic activation (pallor, sweating, agitation, clamminess) as well as heart failure and even shock may be apparent. Pericardial friction rubs occur frequently after MI but are usually transient.

LV failure is associated with a higher mortality. Signs include gallop rhythm, tachycardia, tachypnoea and basal crackles. A fourth heart sound is often heard, but a third heart sound usually indicates a large infarction with extensive muscle damage. A systolic murmur may be present and may be transient or persistent. These murmurs can have prognostic significance and usually result from mitral regurgitation, due to either papillary muscle dysfunction or LV dilatation.

Cardiogenic shock, hypotension, oliguria and other features of low cardiac output are associated with particularly poor outcome. Shock may be present without hypotension<sup>6</sup> and may develop many hours after onset of symptoms. Right ventricle (RV) infarction results in hypotension and marked elevation of the jugular venous pressure (also seen with major LV dysfunction, usually in association with marked pulmonary venous congestion).

Conditions with similar presentations that do not benefit from thrombolysis are:

- pericarditis (auscultate for pericardial rub)
- aortic dissection (arterial pulses are compared; review chest X-ray if concerned)

### INVESTIGATIONS

The presence of MI should also be qualified by:<sup>2</sup>

- anatomical location and size
- causation (e.g. ACS, post-CABG, post-PCI, in association with sudden death)
- time from occurrence (acute, early, late)

Technological advances allow accurate detection of very small infarcts (myocardial necrosis < 1.0 g)<sup>7</sup> that would not have been detected in earlier eras.

### ELECTROCARDIOGRAPHY

Acute and complete occlusion of a coronary artery usually leads to serial ECG changes in leads subtending the area of ischaemia, where the:

- number of leads involved broadly reflects the extent of myocardium involved
- height of initial ST-segment elevation is modestly correlated with the degree of ischaemia
- acute resolution of ST-segment elevation correlates well with reperfusion<sup>8</sup>

Identification of classical acute and early changes where ST-segment elevation MI (STEMI) is present identifies patients in whom reperfusion therapy may interrupt, prevent or minimise myocardial necrosis (Figure 16.4). These are:

- *hyperacute* (0–20 min): tall, peaking T-waves and progressive upward curving and elevation of ST-segments
- *acute* (minutes to hours): persisting ST-segment elevation, gradual loss of R-wave in the infarcted area. ST-segments begin to fall and there is progressive inversion of T-waves
- *early* (hours to days): loss of R-wave and development of pathological Q-waves in area of ischaemia. Return of ST-segments to baseline. Persistence of T-wave inversion
- *indeterminate* (days to weeks): pathological Q-waves with persisting T-wave inversion. ST-segments normalise (unless there is aneurysm)
- *old* (weeks to months): persisting deep Q-waves with normalised ST-segments and T-waves

Other causes of acute ST-segment elevation and T-wave changes that should *not* receive thrombolytic therapy are:

- normal variant
- metabolic disturbance, particularly hyperkalaemia
- drug toxicity, pericarditis
- LV hypertrophy
- LV aneurysm
- Wolff–Parkinson–White syndrome and Brugada syndrome
- apical ballooning syndrome (Takotsubo syndrome or ‘broken-heart’ syndrome)

The Takotsubo syndrome is characterised by precordial ST-segment elevation, apical ballooning on echocardiography but normal vessels on angiography. It may follow the onset of recent severe stress and may cause up to 1–2% of STEMI.<sup>9</sup> It has been recognised in critical illness.<sup>10</sup>

Patients with ACS but without significant ST-segment elevation (generically, non-ST-segment elevation ACS

**Figure 16.4** Total acute coronary occlusion leads to serial electrocardiogram changes. The evolution is variable and may be interrupted or altered by successful reperfusion. ST-segment elevation is an early and relatively specific indicator of the need for thrombolysis in patients with acute coronary syndrome.

(NSTEACS), until further subdivided by biomarker studies) may still be at high risk of infarction and death. They likely have active, non-occluding thrombus or, if it is occluding, then some collateral flow is present. ECGs in these patients may be normal or display:

- ST-segment depression
- ST-segment elevation (insufficient to meet thrombolysis criteria)
- T-wave inversion or 'normalisation' of previous inverted T-waves

A normal ECG does not exclude MI. Despite the absence of ST-segment elevation, a small percentage of patients progressively lose R-wave height and develop evidence of Q-waves and a small number progress to cardiogenic shock.

### LOCALISATION OF INFARCTION

The left anterior descending (LAD) coronary artery supplies the anterior two-thirds of the interventricular septum (septal perforators), the anterior and lateral wall of the LV (diagonal branches) and sometimes part of the RV. The left circumflex artery supplies the LV lateral (anterolateral marginal branches) and posterior walls, and occasionally its inferior aspect (posterior LV arteries: 15% of patients) and the posterior septum. The right coronary artery (RCA) supplies the RV wall, and usually the posterior septum and inferior (diaphragmatic) wall of the left ventricle (posterior LV arteries; 85% of people). The RCA is 'dominant' (as opposed to the circumflex) if it gives rise to the posterior descending coronary artery (PDA) (Figure 16.5).

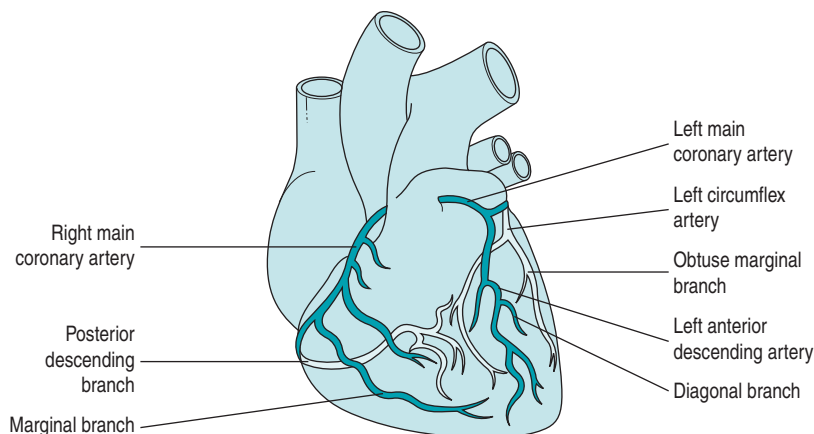

It is usual to use the ECG in initial clinical assessments to localise the area of myocardial ischaemia. The pattern

of lead involvement may thus assist with localisation of the MI (Figure 16.6).<sup>8,11,12</sup> There is a reasonable correlation between the site of infarction as defined by the ECG and the occluded coronary artery and the infarcted region of myocardium (Figure 16.7). However, ECG localisation may differ from angiographic, echocardiographic and autopsy findings, especially where there is collateral circulation or previous CABG. Anterior wall infarctions usually result from occlusion of the LAD; inferior, true posterior and RV infarctions result from occlusion of the RCA or circumflex arteries.

Common ECG patterns of infarction are shown in Figure 16.6. Approximately 40–50% of patients present with anterior infarction and 50% with inferior infarction. Anterior wall infarctions may be extensive or localised (septal, anterior, lateral) whereas inferior infarctions may similarly involve extension to the lateral, posterior or RV myocardium. Of clinical importance:

- 8% of patients with MI will only display ST-elevation in posterior leads V<sub>7</sub>–V<sub>8</sub> (true posterior) or in right precordial leads V<sub>3R</sub>–V<sub>6R</sub> (RV).<sup>4,11</sup>
- True posterior infarction involves 'mirror' changes in leads V<sub>1</sub> and V<sub>2</sub> and is important to diagnose because the amount of threatened myocardium is similar to that of inferior infarction.
- RV infarction is usually concurrent with inferior wall infarction and very rare in isolation. A V<sub>4R</sub> lead (V<sub>4</sub> lead in an equivalent position on the right anterior chest wall) is sensitive and specific for RV infarction.<sup>11,12</sup>

The resting ECG does not have sufficient predictive value to stratify patients with NSTEACS reliably into those with infarction (NSTEMI) and those without (USA).

**Figure 16.5** Coronary artery anatomy. Left anterior descending artery (LAD) supplies anterior two-thirds of the interventricular septum (septal perforators), anterior and lateral wall of the left ventricular (LV: diagonal branches) and sometimes part of the right ventricle (RV). Circumflex (Cx) supplies the LV lateral (anterolateral marginal branches) and posterior walls, and occasionally its inferior aspect (posterior LV arteries: 15% of patients) and the posterior septum. The right coronary artery (RCA) supplies the RV wall, and usually the posterior septum and inferior (diaphragmatic) wall of the LV (posterior LV arteries; 85% of people). The RCA is 'dominant' (as opposed to the circumflex) if it gives rise to the posterior descending coronary artery (PDA) and the posterior left ventricular arteries.

Localization	Leads (predominant)	Anatomy
<b>ANTERIOR WALL</b>		
'Extensive' anterior (anterior-lateral)	V <sub>1</sub> -V <sub>6</sub> , I, aVL	Proximal LAD occlusion
Septal	V <sub>1</sub> -V <sub>3</sub> (V <sub>4</sub> )	Septal perforators of LAD
Anterior (localised or true)	V <sub>4</sub> -V <sub>6</sub> (I, aVL, V <sub>2</sub> )	Diagonal (supplies anterior LV wall). Occasionally marginal branches of Cx
Lateral (apical)	V <sub>5</sub> , V <sub>6</sub> I, aVL	Distal LAD or circumflex
<b>INFERIOR WALL</b>		
Inferior (localized)	II, III, aVF	RCA or posterolateral branch of Cx
Inferior (extended)	II, III, aVF plus	
Infero-lateral	I, aVL, V <sub>5</sub> , V <sub>6</sub>	RCA or dominant Cx
Infero-posterior*	V <sub>1</sub> -V <sub>2</sub>	Posterior descending branch or RCA or posterolateral branch of Cx
Right ventricular	V <sub>1</sub> , V <sub>3R</sub> , V <sub>4R</sub> (additional right chest leads helpful)	Proximal RCA occlusion

**Figure 16.6** Electrocardiogram patterns of myocardial injury. RCA, right coronary artery; LAD, left anterior descending coronary artery; Cx, circumflex coronary artery. \*Initial ST-segment depression and T-wave inversion in V<sub>1</sub>-V<sub>2</sub>, subsequent evolution to tall R-waves in V<sub>1</sub>-V<sub>2</sub> and loss of R-wave in V<sub>6</sub>. The correlation of electrocardiogram localisation with culprit artery (determined at angiography) and echocardiographic or autopsy localisation is variable.

Up to 18% of patients with MI show no changes on the initial ECG and up to 20% of patients with NSTEMI/ACS have normal or minimal CAD.<sup>11,12</sup> Cardiac biomarkers are necessary to confirm myocardial cellular injury and meet diagnostic criteria for MI.

#### CARDIAC BIOCHEMICAL MARKERS

- The increasing sensitivity and specificity of cardiac troponins (cTn) has made them the gold standard for the confirmation of myocardial necrosis. Elevated levels should be taken as evidence of myocardial injury and, in the correct setting, as confirmation of MI.<sup>2,7</sup>
- Troponin measurements have generally replaced creatinine kinase (CK) as the biomarker used to identify the presence of myocardial necrosis.

The typical rise and fall of cardiac markers after infarction are shown in Figure 16.8.

Two (cTnT, cTnI) of the three isoforms of the cTn complex are exclusively expressed in cardiac myocytes (specific). Troponin levels allow early and sensitive detection of myocardial necrosis.

#### TROPONINS

- These are more sensitive indicators than CK and its CK-MB isomer. Up to 20–40% of patients with ACS but normal CK-MB may have elevated cTn levels.

- There is a strong correlation between troponin level, intracoronary thrombus and amount of threatened or ischaemic myocardium.
- Identify patients who will derive benefit from therapies such as low-molecular-weight heparins (LMWHs), glycoprotein inhibitors (GPIs) and early PCI.

The increased sensitivity of troponins compared to CK means that a third of patients previously considered to have USA are now recognised or redefined as having evidence of myocardial necrosis. Troponins also have better specificity than CK, similar to that of its isomer CK-MB. They do not differentiate the cause of the myocardial injury (e.g. ischaemia, myocarditis, trauma), however, and thus clinical context must always be considered.<sup>2</sup> Troponins are more persistent in the serum (up to 7–10 days) and thus may be useful in diagnosis when presentation is delayed. Whilst CK-MB has traditionally been thought to be a better predictor of reinfarction, a rise in troponin of > 20% some 3–6 hours after onset of suspected reinfarction is also significant.<sup>2</sup>

Troponins should be checked in all patients with ACS and aggressive therapies should be targeted at patients with elevated levels.<sup>5</sup>

#### TROPONINS IN CRITICAL ILLNESS

Cardiac-specific troponins are frequently elevated in critical illness, including but not confined to sepsis, pulmonary embolus and renal insufficiency.<sup>13</sup> It is likely that they are

**Figure 16.7** Acute Inferior myocardial infarction (ST-segment elevation in the inferior leads II, III and aVF) with reciprocal ST depression in leads I, aVL, V1 and V2. The addition of right sided (V4R) and posterior leads would help identify the presence of RV and posterior infarction. Reciprocal ST segment depression in leads remote from the site of infarction is a highly sensitive indicator of myocardial infarction. It may be seen in 70% of inferior and 30% of anterior infarctions.

of cardiac origin and are indicative of myocardial injury. Their elevation does correspond with adverse outcomes. Most will not be due to ‘unstable plaque’, however, and the role of standard NSTEMI therapies is uncertain. Clinical context is necessary to decide those likely to have significant underlying CAD that may require acute or subsequent investigation.<sup>2</sup>

Please also see the latest information at the end of the chapter.

## ECHOCARDIOGRAPHY

Two-dimensional transthoracic echocardiography with colour Doppler has good clinical utility as a non-invasive investigation during admission for an ACS. Its primary role is in assessing the degree of regional and global LV dysfunction.

Echocardiography detects regional wall motion abnormalities, which can help confirm or exclude the diagnosis

**Figure 16.8** Serum biochemical marker changes after acute myocardial infarction. The sensitivity and specificity of cardiac troponins makes them useful for the early diagnosis of MI. Their delayed fall may allow diagnosis where presentation is late. CK or CK-MB are useful if re-infarction with secondary biomarker rise is queried.

of MI in the small percentage of cases where diagnosis is uncertain (e.g. left bundle branch block (LBBB) or old infarction with atypical presentations). Regional wall motion abnormality and loss of wall thickening with contraction are often present in these cases if due to ischaemia, while their absence suggests that ischaemia is not acute. It is useful for excluding differential diagnoses (e.g. aortic dissection or pericardial effusions), again in a small percentage of patients.<sup>2</sup>

Echocardiography is subsequently useful to:

- assess infarct size, especially if thrombolysis has interfered with biomarker measurement
- diagnose RV infarction and infarct extension
- assist management by bedside assessment of LV function
- diagnose specific complications, for example, mitral regurgitation, pericardial effusion, mural thrombus and myocardial rupture, including ventricular septal defect

Transoesophageal echocardiography may have an increasing role in the therapy of cardiogenic shock, giving some guide to volume therapy.

Dynamic or graded intravenous (IV) dobutamine stress echocardiography (2–10 days after MI) can assess myocardial viability and distinguish non-viable myocardium from stunned myocardium. Superiority to standard exercise testing has not been proven.

### RADIONUCLIDE STUDIES

Radionuclide angiography has little practical role in the emergency-room diagnosis of ACS. Dynamic or functional radionuclide studies (thallium-201 or technetium-99m-sestamibi myocardial perfusion imaging studies) are useful in postinfarction risk stratification and are able to detect ‘threatened myocardium’. They are useful in the later risk assessment of patients who have presented with USA or NSTEMI and where the clinical significance of lesions noted on angiography is uncertain.

### STRESS TESTING

Stress testing may be useful in risk stratification and diagnosis of stable angina. Following infarction, the following may be of use:

- submaximal stress testing (to a heart rate of 120 beats/min), pre-discharge, upon patients with an uncomplicated course
- maximal symptom-limited stress test 3–6 weeks postinfarction

### CORONARY ANGIOGRAPHY AND LEFT VENTRICULOGRAPHY

Coronary angiography is the gold standard for the diagnosis (and often treatment) of CAD; however the timing and need for this are determined by clinical risk. In the appropriate clinical setting, coronary angiography will usually identify a ‘culprit artery’ subtending an area of regional wall motion abnormality and additionally may allow definitive treatment of this abnormality. These indications are discussed later.

### RISK STRATIFICATION OF ACUTE CORONARY SYNDROME (FIGURE 16.9)

An immediate goal is to identify patients with STEMI, who will then benefit from reperfusion therapy. This is almost always done on the basis of the presenting ECG.

### STEMI

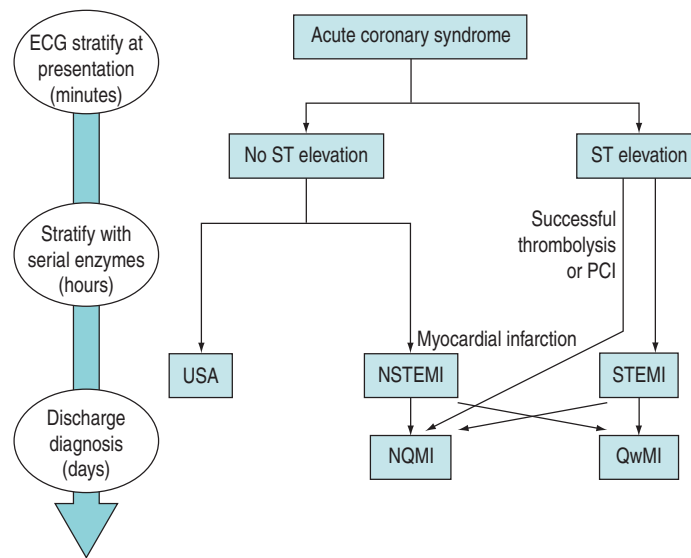

STEMI (including new, presumed new LBBB) with persistent pain is the most lethal form of ACS and is usually due to complete occlusion of a coronary artery (> 90% of patients).<sup>5</sup> It is an indication for reperfusion therapy. Such therapy may be successful and significantly reduce the size of the potential infarction, although some rise in troponin is usually inevitable. Patients who develop ST-segment elevation after admission should also then be stratified to this group.

### NSTEMACS

Patients have ischaemic chest pain but have ‘non-specific’ ECG changes (normal, ST-segment depression or minimal elevation, T-wave inversion). After serial biomarker testing, these patients will later prove to have either USA pectoris if troponins remain normal or NSTEMI (elevated troponin).

The therapy of NSTEMI aligns more clinically with that of USA than with that of STEMI. These two conditions, both forms of NSTEMACS, represent a spectrum of disease and require common treatments directed at platelet inactivation and ‘plaque stabilisation’. The term ‘NSTEMACS’ recognises that they are clinically indistinguishable at presentation. The more severe the ischaemia,

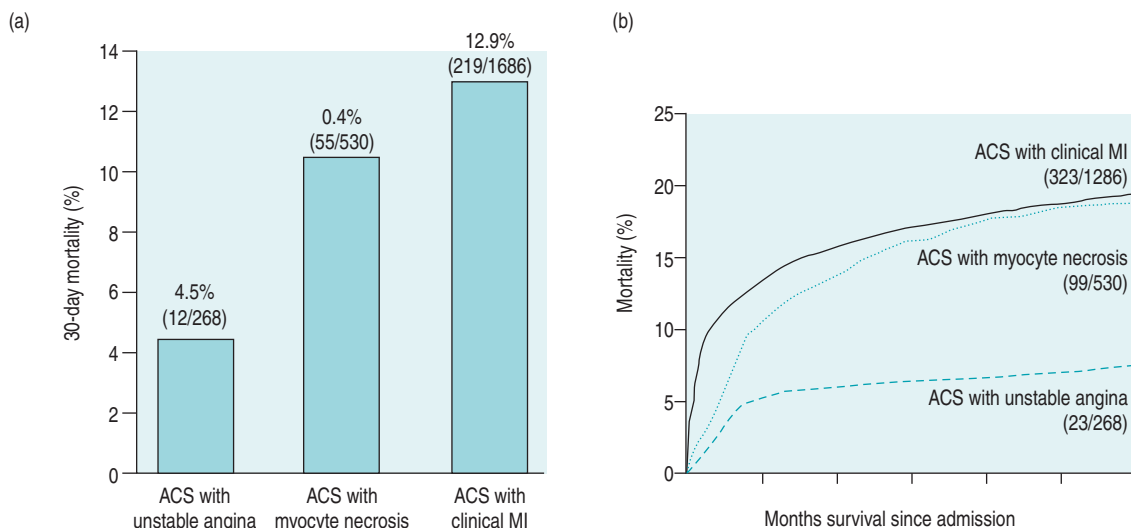

**Figure 16.9** Immediate stratification of acute coronary syndrome (ACS) into those with and without ST-segment elevation identifies patients requiring reperfusion therapy. Early and serial biomarker results in non-ST-segment elevation acute coronary syndrome (NSTEACS) identify patients with unstable angina (normal levels) and those with NSTEMI (elevated levels). Discharge electrocardiogram identifies patients who have sustained Q-wave myocardial infarction (QwMI) and non-Q-wave myocardial infarction (NQwMI). Successful reperfusion therapy may avert or limit the extent of Q-wave development. USA, unstable angina; PCI, percutaneous coronary intervention.

the higher the need for more aggressive anticoagulation and invasive procedures. Early diagnostic classification using both ECG and troponins allows early risk stratification and evidence-based therapy. Only 35–75% of patients have evidence of coronary thrombus formation and thrombolytic therapy is not beneficial in this group. Indeed, it is associated with worse outcomes.<sup>5,14</sup>

Figure 16.10 displays the incidence of major coronary events over the following 12 months in patients presenting with and without ST-segment elevation. ST-segment depression has lesser early mortality but a similar or higher mortality at 6 months and at 10 years than those presenting with ST-segment elevation.<sup>15,16</sup> Features that correlate with risk are:

**Figure 16.10** (a) Thirty-day mortality according to British Cardiac Society category. (b) Kaplan–Meier survival area curves for events from admission to 6 months. ACS, acute coronary syndrome. (Reproduced from Das R, Kilcullen N, Morrell C *et al.* The British Cardiac Society Working Group definition of myocardial infarction: implications for practice. *Heart* 2006; **92**: 21–6 with permission.)

- refractory angina with ischaemic ECG changes
- ischaemia associated with haemodynamic instability or arrhythmia
- recurrent ST-segment change with elevated cTn levels

Q-wave MI (QwMI) or non-Q-wave MI (NqwMI) are older terms used to describe MI. The 10-year mortality of QwMI (70%) is 10% higher than that of QwMI.<sup>16</sup>

## IMMEDIATE MANAGEMENT OF ACUTE CORONARY SYNDROMES

### PREHOSPITAL CARE

- 50% of deaths from MI occur within the first hour of symptom onset. These deaths are usually due to ventricular fibrillation (VF). Treatment is defibrillation.

Review of trials comparing prehospital to in-hospital thrombolysis suggests a 17% decrease (95% confidence interval, 2–29%) in 30-day mortality.<sup>17</sup>

### IMMEDIATE HOSPITAL CARE

1. Cardiac monitoring
2. Oxygen via facemask (6–8 l/min)
3. ECG (12-lead) should be taken within 5 min of arrival
4. Aspirin at 160–325 mg should be chewed and swallowed on arrival. IV aspirin can be given if necessary. Clopidogrel can be given if there is aspirin sensitivity or high risk<sup>4</sup>
5. Sublingual nitroglycerine (GTN) may have beneficial effects. Side-effects include hypotensive reactions and a hypotensive bradycardic response (the Bezold-Jarisch reflex)
6. Venous access is usually established
7. Pain relief should be provided. Pain produces catecholamines which increase ischaemia. GTN, reassurance and small incremental boluses (1–2 mg) of morphine, repeated until pain is relieved, can be given
8. Thrombolytic therapy should be considered for all those patients with ST-segment elevation or presumed new LBBB (STEMI) who have no major contraindication (Figure 16.11) and arrive within clinical timeframes
9. Emergent angioplasty (or rapid transfer to a centre capable of this) should be considered for these patients who have:
  - presented to a centre of excellence
  - a contraindication to thrombolytic therapy
  - cardiogenic shock
  - high risk with anticipated moderate response to thrombolytic therapy
10.  $\beta$ -adrenergic blockers (oral) should be commenced in haemodynamically stable patients as soon as possible (usually after thrombolytic therapy has been given<sup>18</sup> or before PCI)<sup>5,19</sup>
11. Pulmonary oedema if present is treated with upright posture, IV furosemide (40 mg furosemide) IV, GTN or IV nitrates and if severe, with continuous positive airway pressure ventilation
12. Prophylactic antiarrhythmics are *not* administered

Reperfusion therapy. Presentation $\leq$ 12 hours with ACS, unrelieved by GTN and:
<ul style="list-style-type: none"> <li>● ST segment elevation in 2 or more contiguous leads <math>&gt;</math> 2 mm in chest leads ( <math>V_2 - V_6</math> ) OR <math>&gt;</math> 1 mm in limb leads ( I, aVL, II, III, aVF )</li> </ul> <p style="text-align: right;"><b>OR</b></p>
<ul style="list-style-type: none"> <li>● New-onset LBBB ( include presumed new-onset)</li> </ul> <p style="text-align: right;"><b>OR</b></p>
<ul style="list-style-type: none"> <li>● Posterior infarction (Dominant R wave and ST depression <math>\geq</math> 2 mm in <math>V_1 - V_2</math>)</li> </ul> <p style="text-align: right;"><b>OR</b></p>
<ul style="list-style-type: none"> <li>● Presentation 12 – 24 hours after onset of ACS with continuing pain and evidence of evolving infarction</li> </ul>

Figure 16.11 Typical indications for reperfusion therapy in acute myocardial infarction.

## ACUTE MANAGEMENT OF STEMI (FIGURE 16.12)

### REPERFUSION THERAPY

Prompt initiation of reperfusion therapy (mechanical or pharmacologic) is the ‘gold standard’ for STEMI therapy and is far superior to placebo.

Reperfusion therapy should be considered for all patients presenting within 12 h of onset of STEMI.<sup>5,20</sup>

Indications and contraindications are given in Figures 16.11 and 16.13. Restoration of patency reduces infarct size, preserves LV function, reduces mortality and prolongs survival.

Strategies to achieve reperfusion can include:

1. fibrinolytic (thrombolytic) therapy
2. PCI, e.g. angioplasty with or without stent insertion
3. urgent CABG

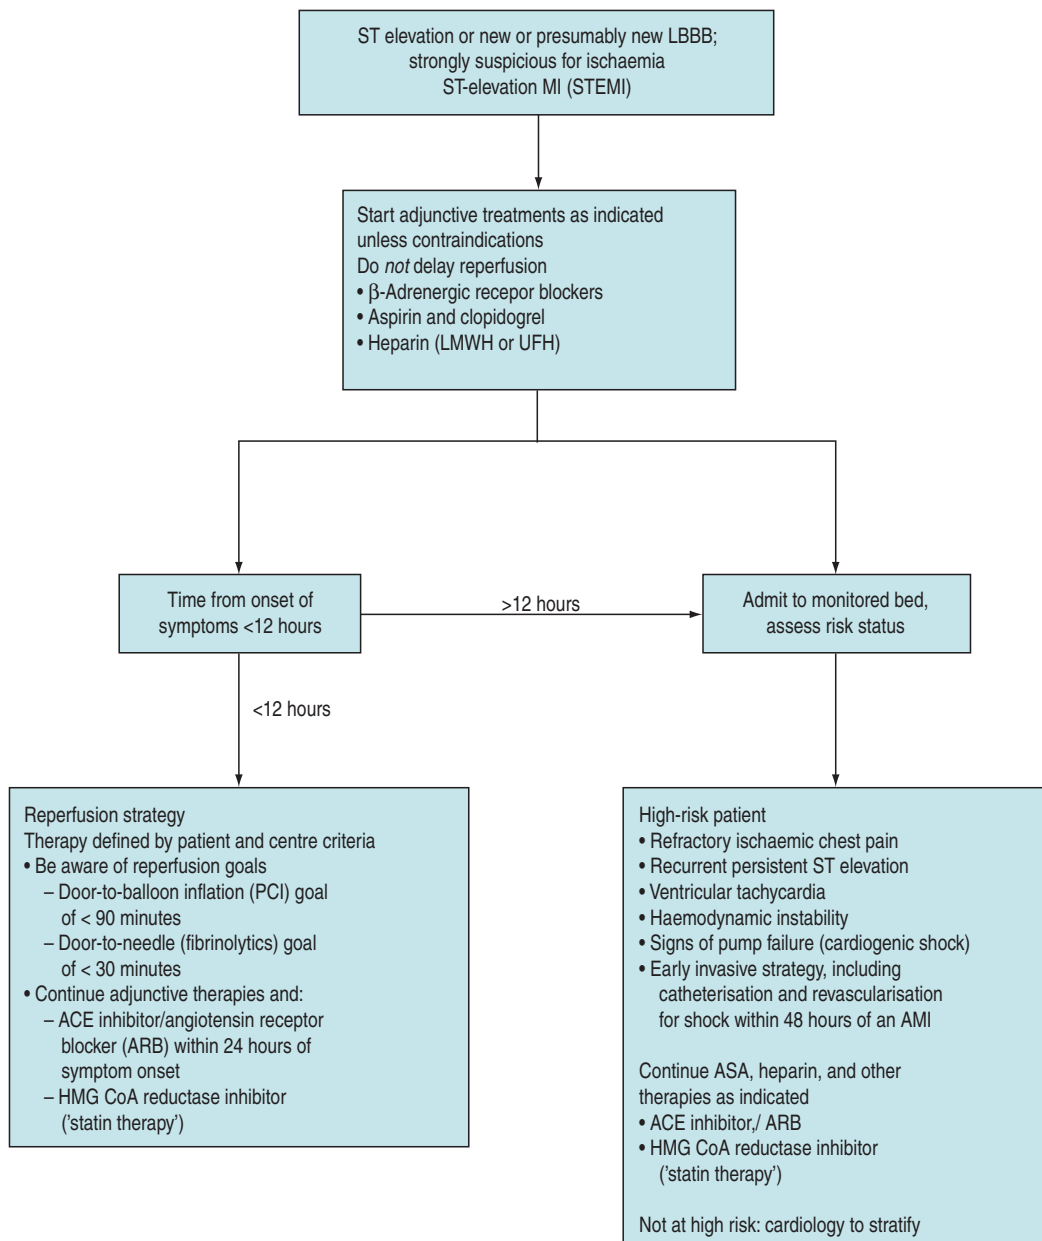

Factors that influence treatment choice and outcome are:<sup>5</sup>

- skill and expertise of admitting hospital (availability of PCI)
- time since onset of symptoms
- age and comorbid illness (particularly risk of bleeding and stroke)
- haemodynamic status
- previous PCI or CABG

### PERCUTANEOUS TRANSLUMINAL CORONARY INTERVENTION

When delivered in centres of excellence (door to balloon time  $<$  90 min), primary PCI is superior to thrombolytic therapy, with reduced short-term mortality (5.3% versus 7.4%), nonfatal reinfarction (2.5% versus 6.8%) and stroke (1.0 versus 2.0%).

The survival benefit of primary PCI compared with thrombolytic therapy is of the order of 20 lives per

**Figure 16.12** Management of ACS with ST-segment Elevation (STEMI). Aspirin, β-blockers and heparin (except if streptokinase used) should be given to all patients without contraindications. Immediate reperfusion with thrombolysis (available in all centres) should be commenced. Immediate PCI is preferred in centres of excellence, where there are contraindications to thrombolysis or where risk favours expedient transfer for such therapy. Glycoprotein IIb/IIIa receptor blockers may reduce complications during PCI.

1000 patients treated. These benefits are not uniform and are significantly influenced by its better outcomes in high-risk patients.

Urgent PCI in STEMI should be strongly considered in patients with:

- presentation to cardiological centres of excellence
- contraindications to thrombolysis

- high risk but with predicted small or moderate benefit from thrombolytic therapy (e.g. elderly, diabetic and with presentation beyond 3 h)
- cardiogenic shock even up to 12–36 h after infarction<sup>21</sup> (see Chapter 20)
- failed thrombolysis
- previous CABG

**Absolute contraindications**

- Previous haemorrhagic stroke
- Other stroke or cerebrovascular accident  $\leq 6$  months
- Intracranial neoplasm
- Active internal bleeding  $\leq 2$  weeks (menses excluded)
- Aortic dissection, known or suspected

**Relative contraindications (advisory following clinical consideration)**

- Severe uncontrolled hypertension on presentation ( $\geq 180/110$  mmHg)
- Oral anticoagulation therapy (INR  $> 2.5$ ); known bleeding diathesis
- Recent major trauma, surgery ( $\leq 4$  weeks) including head trauma
- Pregnancy
- Traumatic CPR
- Active peptic ulcer disease
- Previous allergic reaction to drug to be used
- Recent streptokinase or anistreplase ( $\leq 5$  days). Use different agent (risk of allergy, antibodies may reduce effectiveness)
- History of prior CVA or intracerebral pathology not covered in contraindications
- History of chronic hypertension

Specialist opinion should be sought urgently where doubt exists. Patients with contraindications may still benefit from urgent coronary angioplasty.

**Figure 16.13** Contraindications and cautions for fibrinolytic use in myocardial infarction (advisory following clinical consideration). INR, international normalised ratio; CPR, cardiopulmonary resuscitation; CVA, cerebrovascular accident.

Very few patients have contraindications to PCI,<sup>17</sup> although caution is needed in those at risk of contrast-associated renal failure.

## THROMBOLYTIC THERAPY

- Thrombolytic therapy (versus placebo) of patients with ST-elevation and/or new LBBB results in a significant mortality reduction (10.9% versus 13.4%; relative risk reduction 19%), a reduction of approximately 20 deaths per 1000 patients treated.<sup>5,14</sup>
- Outcomes are critically dependent upon time from symptom onset to administration of therapy. A goal is 'door to needle time' of less than 30 min. Delay is associated with excess mortality.

Thrombolysis within 6 h of symptom onset saves 30 lives per 1000 patients treated; within 7–12 h, the rate is 20 lives per 1000 patients treated, but there is no overall benefit for therapy beyond this time. Up to 40 lives per 1000 could be saved (relative risk reduction 50%) if treatment was given in the first hour.<sup>22</sup> Benefit is still present

at 20-year follow-up.<sup>23</sup> Largest benefits are seen in anterior infarction (3.7% absolute mortality reduction), less in inferior (0.8% reduction).<sup>5,14,24</sup>

Age has a major impact upon survival following STEMI. Compared with controls thrombolysis reduces mortality at age  $< 55$  years (3.4% versus 4.6%), age 55–64 years (7.2% versus 8.9%, 18 lives per 1000 patients treated), age 65–75 years (11.1% versus 12.7%, 27 lives per 1000 patients treated) and age  $> 75$  years (24.3% versus 25.3%, 10 lives per 1000). Thus, although the relative reduction in elderly patients is small (4%), the absolute reduction in mortality is still significant.<sup>14</sup>

### THROMBOLYTIC AGENTS (FIBRINOLYTIC AGENTS)

Commonly licensed thrombolytic agents are streptokinase, tissue plasminogen activator (t-PA), alteplase (rt-PA), reteplase and tenecteplase. These drugs promote the conversion of plasminogen to plasmin, which then lyses fibrin thrombi. The fibrinolytic agents approved for therapy of STEMI differ in a number of ways, including fibrin specificity.

- Streptokinase is a first-generation fibrinolytic drug and is considered non-specific. It converts plasminogen to plasmin with a marked fall in circulating fibrinogen and other factors, resulting in a systemic lytic state. Streptokinase has a prolonged thrombolytic effect and concomitant IV heparin increases bleeding and rate of cerebral haemorrhage.<sup>5,24,25</sup> It is antigenic (beware previous exposure or recent streptococcal infection) and can result in hypotension and bradycardia, most evident in patients with inferior MI.
- t-PA, a non-antigenic, more fibrin-selective, shorter-acting proteolytic enzyme produced by vascular endothelium, was used as the basis for second-generation fibrinolytic agents (alteplase, recombinant t-PA or rt-PA). By acting more directly at the fibrin surface, and with less degradation of circulating fibrinogen, t-PA is associated with less systemic bleeding. An initial bolus of t-PA with subsequent infusion (accelerated regimen) produces higher patency rates than streptokinase. It has generally been used as the benchmark or control arm in trials.
- Third-generation fibrinolytic agents (reteplase, tenecteplase) are bioengineered products of t-PA with longer half-lives. These agents have gained popularity because they appear to have similar efficacy and side-effect profiles but are simpler to administer.

Major and minor contraindications are shown in Figure 16.13.

### SIDE-EFFECTS AND CHOICE OF AGENT

Although newer-generation fibrin-specific agents that are available as a bolus (reteplase/tenecteplase) are generally the fibrinolytics of choice, streptokinase may still be a cost-effective treatment in many.

More efficient (fibrin-specific) thrombolytic agents improved upon the initial results of streptokinase. In

Global Utilization of Streptokinase and Tissue Plasminogen Activator to Treat Occluded Arteries (GUSTO-1), accelerated rt-PA regimens were shown to reduce mortality compared to streptokinase (6.3% versus 7.3%, relative rate 14% reduction), but at the price of a small excess of haemorrhagic strokes.<sup>26,27</sup> This represented an extra 10 lives saved per 1000 patients.

The tPA congeners reteplase and tenecteplase have very short initial half-lives, allowing convenient bolus dose administration. Trials of these agents against 'accelerated rt-PA' demonstrated equivalence.<sup>28</sup> Accordingly these agents have come into frequent use because of their ease of administration. Tenecteplase can be given as a single agent, making it useful for prehospital and emergency hospital use.

Aggressive thrombolysis regimens are associated with lower all-cause mortality rates despite higher rates of cerebral haemorrhage<sup>5</sup> that are fatal in 40–60% of cases.<sup>25</sup> Of concern with these regimens is that the number of non-fatal strokes (severe disability occurs in 50%) can be problematic in high-risk groups. Accelerated t-PA regimens may result in 5 disabled stroke survivors per 1000 patients treated; streptokinase with subcutaneous heparin may result in 3 per 1000 patients treated.<sup>25</sup> Age, recent stroke and hypertension on arrival significantly increase the risk of both lethal and non-lethal stroke. Since these patients were often excluded from trials, specialist input is required on a case-by-case basis to ascertain whether a less aggressive fibrinolytic agent (streptokinase) may be of use.<sup>26</sup> Alternatively, strong consideration is given to PCI when thrombolysis is likely to be associated with a high incidence of lethal or non-lethal stroke.

Failure to adjust the dose of fibrinolytic correctly to body weight may be associated with increased mortality and intracerebral haemorrhage.<sup>17</sup>

### PRIMARY PCI VERSUS THROMBOLYTIC THERAPY

Despite the advantages of PCI over thrombolysis, many patients present to centres that do not offer primary PCI. Given the advantage of PCI over thrombolysis, the possible benefit of transfer to such a centre needs to be considered. Transfer, however, involves an inherent delay and, if this is prolonged, then the advantage of more reliable revascularisation may be rapidly removed by the death of myocardium occurring as a result of the delay.<sup>17,29</sup> Studies of groups of patients suggest that this advantage for groups may be lost if the transfer adds an additional 60–110 min to the process. This may represent an erosion of PCI's mortality advantage of 0.29–0.40% for every 10-min delay. Well-developed systems need to be in place to minimise transport delays.

The significance of transfer for an individual patient will vary significantly. The incremental effect of delay is most marked in patients who present early. The current results from thrombolytic therapy in patients presenting early (< 3 h) are very good as fresh clots seem more likely to be lysed. However transfer may be advisable in patients

at high risk of bleeding or where presentation is late and where, despite thrombolysis, baseline or predicted mortality is high.

### INVASIVE STRATEGY (PCI) IS CLEARLY SUPERIOR TO THROMBOLYSIS IF

- There are contraindications to thrombolytic therapy
- There is cardiogenic shock
- Angiography is needed to determine diagnosis and where an occluding lesion is found

### INVASIVE STRATEGY (PCI) IS GENERALLY PREFERRED (CONSIDER TRANSFER) IF

- Skilled PCI lab is available with surgical back-up:<sup>17</sup>
  - Medical contact-to-balloon or door-to-balloon is < 90 min
  - (Door-to-balloon) – (door-to-needle) is < 1 hour and specialist centre
- High risk from STEMI:
  - Age > 75 years
  - Extensive anterior infarction with late presentation
  - High risk of bleeding
  - Previous MI or CABG
  - Killip class is  $\geq 3$
- Late presentation:<sup>17</sup>
  - Symptom onset was > 3 hours ago

### FIBRINOLYSIS GENERALLY PREFERRED IF:<sup>17</sup>

- Early presentation (3 hours from symptom onset and delay to invasive strategy)
- Invasive strategy is not an option:
  - Catheterisation lab occupied or not available
  - Vascular access difficulties
  - Lack of access to skilled PCI lab
- Delay to invasive strategy:
  - Prolonged transport
  - (Door-to-balloon) – (door-to-needle) is > 1 hour and specialist centre
  - Medical contact-to-balloon or door-to-balloon is > 90 minutes

There is increasing evidence that, in the presence of failed thrombolysis where predicted mortality is high, rescue PCI confers survival benefit.<sup>18</sup> Trials of 'facilitated PCI' where pharmacological therapy is routinely followed immediately by PCI are controversial and current evidence favours worse outcomes with this routine approach.<sup>17,18</sup>

### ADJUNCTIVE THERAPY USED WITH THROMBOLYSIS AND REPERFUSION (FIGURE 16.14)

- Improvement in adjunctive or supportive reperfusion therapies has been the major driver of improved outcomes from reperfusion strategies, contributing more than the development of newer antifibrinolytics.
- Compliance with guidelines for administration of these therapies is likely to improve outcomes significantly.

Acute intervention	Patients (n)	RCTs (n)
Intravenous thrombolytics	58 600	9
Aspirin	18 773	9
Anticoagulant	4 075	7
β-blocker	28 970	29
Nitrates	81 908	22
ACE inhibitors	100 963	15
Magnesium	60 366	2
Prophylactic lidocaine	12 385	21
Calcium antagonists	6 420	16

Early treatment of acute myocardial infarction

**Figure 16.14** Effect of acute (early) interventions upon mortality following acute myocardial infarction. Results are from meta-analyses. Urgent percutaneous coronary intervention (not shown) has not been compared to placebo and offers superior results to thrombolysis for patients who present to centres of excellence. RCT, randomised controlled trial; ACE, angiotensin-converting enzyme.

Adjunctive therapy is necessary after thrombolysis due to the following:

- About 50% of patients fail to obtain or sustain coronary artery patency.
- The underlying artery remains unstable, evidenced by:
  - angiographic reocclusion in 30%
  - recurrence of ischaemia in 20%
- Current plasminogen activators (thrombolytics) destroy fibrin strands of ‘red thrombus’. They have little effect on underlying exposed thrombin and indeed may be prothrombotic, requiring concomitant anti-thrombin (e.g. heparin) or anticoagulant therapy.
- Antiplatelet therapies are needed to ‘pacify’ underlying platelet-rich ‘white thrombus’ and plaque.

The major complication of adjunctive therapy is generally an increase in bleeding.

### ASPIRIN AND CLOPIDOGREL

All patients undergoing reperfusion therapy for STEMI (PCI or fibrinolysis) should be given aspirin and clopidogrel unless contraindicated.<sup>18</sup>

Aspirin is one of the most significant and cost-effective treatments for STEMI. Given acutely in the second International Study of Infarct Survival (ISIS-2) it reduced mortality by 23% and gave a nearly 50% reduction in reinfarction and stroke. Streptokinase also reduced mortality (by 25%), while the combination had an additive effect and reduced mortality by 42%.<sup>24,30</sup> Treatment for a mean duration of 1 month resulted in approximately 25 fewer deaths and 10–15 fewer episodes of non-fatal reinfarction and non-fatal stroke for every 1000 patients treated.<sup>30</sup> It does not appear to increase bleeding and benefit is still present after 10 years.

Clopidogrel confers significant additional benefit. Given in conjunction with thrombolytics and aspirin, it reduces the risk of early vessel reocclusion without a significant rise in bleeding.<sup>29,31</sup> Patients who undergo PCI and have a stent inserted also benefit if they have received clopidogrel. Benefit is less evident in patients who undergo PCI but do not have a stent placed, and bleeding is problematic.

### GLYCOPROTEIN IIB/IIIA INHIBITORS

It is reasonable to use abciximab with primary PCI, but GPIs offer little benefit in patients treated with thrombolytics (full or half-dose).

In theory, GPIs override the platelet activation caused by plasminogen activators, improving patency rates and allowing better reperfusion of small vessels beyond the occluding thrombus. In the setting of PCI, they are proven to be a most important adjunct to the procedure if a stent is placed or lesion dilated. Trials of GPIs in combination with full-dose thrombolytics found increased bleeding. These trials were done with half-dose thrombolytics. Results were again disappointing, with increased bleeding (especially in the elderly) but no survival benefit. In STEMI patients who have not received reperfusion therapy, GPIs do not appear to confer benefit.<sup>29,31,32</sup>

### UNFRACTIONATED HEPARIN (UFH, STANDARD) AND LOW-MOLECULAR-WEIGHT HEPARIN

Antithrombin therapy is generally given in combination with PCI or with fibrin-specific fibrinolytic agents. The net benefit-to-risk ratio of using thrombin inhibitors in MI is not clear, however.

Prior to the use of fibrinolytics and aspirin, a limited number of small trials suggested that UFH reduced mortality (from 13.1% to 9.2%, 20–25% relative rate reduction). With the introduction of fibrinolytics and aspirin, UFH administration was continued. It was usually administered for 24–48 h after the fibrin-specific agents alteplase, reteplase or tenecteplase, reflecting the basis on which the drugs were trialled and licensed. Heparins do not lyse clot, but may decrease rethrombosis.

Despite UFH use, few trials (1239 patients) examined whether it added survival benefit to patients already treated with both thrombolytics and aspirin. At most the effect of UFH seems to be small (perhaps 5 lives saved per 1000 patients treated) and increased bleeding can be problematic.<sup>24,33</sup>

LMWHs are produced by chemical or enzymatic depolymerisation of UFH. Their theoretical advantages include:

- predictable pharmacokinetic profiles and anticoagulant response
- enhanced anti-Xa activity and less affected by platelet factors
- weight-adjusted dosing does not require activated partial thromboplastin time monitoring
- convenient to administer and do not require an IV line, although acquisition costs are higher than for UFH
- lower incidence of thrombocytopenia, skin necrosis, hypersensitivity reactions and catheter-related infections

Comparison of UFH and LMWH has often proven difficult because of large variations in duration of therapy. LMWH is probably superior<sup>17,33–35</sup> to UFH, resulting in lower rates of reinfarction, although the bleeding can be problematic in high-risk patients and caution should be used in this group.<sup>17</sup>

Meta-analysis<sup>34</sup> of LMWH versus placebo has suggested that, across the whole ACS spectrum, adjunctive antithrombin therapy with enoxaparin is associated with significantly superior efficacy. Among STEMI<sup>34</sup> patients, approximately 21 death or MI events were prevented for every 1000 patients treated with enoxaparin, at the cost of an increase of 4 non-fatal major bleeds.

Despite the increasing use of LMWHs, UFH may still be used where bleeding risk is high or where urgent PCI is anticipated.

The pentasaccharide factor Xa inhibitor fondaparinux has recently demonstrated a moderate reduction in mortality and reinfarction over ‘usual care’ (placebo or UFH). These benefits were seen without an increase in bleeding.<sup>36</sup> Like LMWH it has the advantage of ease of administration and absence of need for monitoring but is associated with fewer bleeding complications. Benefits were present in patients at higher risk and not undergoing PCI. End-catheter thrombus was problematic in patients undergoing PCI, suggesting the need for UFH if this therapy is subsequently required. Some benefit was seen in patients who did not receive reperfusion therapy.<sup>36</sup>

## β-BLOCKERS

Haemodynamically stable patients should commence oral β-blockers within 24 h of the onset of symptoms unless contraindicated (pulmonary oedema, asthma, hypotension, bradycardia, advanced atrioventricular block).

Significant benefit from IV β-blockers was seen in the prethrombolysis era, but benefits appear small or absent in the postthrombolysis era.<sup>18</sup> More recent studies have suggested that the use of IV β-blockers is associated with a decrease in reinfarction and VF but with an increase in cardiogenic shock, producing no overall benefit. IV therapy may be useful in patients with hypertension or tachycardia (although it is wise to assess LV function, perhaps with echocardiography). IV β-blockers given to patients receiving PCI produce an early absolute mortality reduction of 1.7%: the benefit is confined to patients not on β-blockers at time of admission.<sup>19</sup>

## OTHER THERAPIES

Although nitrates may have had a small benefit in prethrombolysis days, there is little evidence of outcome benefit in the postthrombolysis era and indeed complicating hypotension may be harmful. Glucose–insulin–potassium therapies have not been shown to provide benefit under trial conditions.<sup>37</sup>

## COMPLICATIONS OF MYOCARDIAL INFARCTION (FIGURE 16.15)

### ARRHYTHMIAS

Rhythm disturbance occurs in nearly all patients following acute MI and is most likely within the first few hours of onset and during reperfusion. There has been a decline in the incidence of VF from approximately 4.5% of admissions to 1% of admissions with MI. This decrease probably reflects the effect of thrombolytic therapies and better maintenance of electrolytes.

- Correct hypoxia, hypovolaemia or acid–base disturbances.
- Maintain serum potassium in the normal range (4.0–5.0 mmol/l).
- Maintain the serum magnesium level.

Prophylactic lidocaine tends to increase mortality and is thus reserved for the treatment of life-threatening ventricular arrhythmias. Prophylactic or routine IV magnesium (< 4 h) was of benefit in the Second Leicester Intravenous Magnesium Intervention Trial (LIMIT II) study but not in the larger ISIS-4 study, and is not of proven benefit.<sup>5</sup>

### FAILED THROMBOLYSIS (RESCUE PCI)

A number of patients with STEMI will fail to show resolution of ST-segment elevation with fibrinolysis, suggesting failed reperfusion. Whether this should be treated with further fibrinolysis or PCI, or whether no

Diagnosis	CVP	PAOP	CO	Other findings on PAC	Echocardiography
<b>Mechanical complications</b>					
Free wall rupture	↑	↑	↓↓	Usually tamponade physiology: RA mean, RV and PA end-diastolic, and PAOP pressures are high and within 5mmHg	Pericardial effusion with tamponade and RV diastolic collapse; may visualise pseudoaneurysm
Acute ventricular septal defect	↑	↑	↓↓	Left-to-right shunt with O <sub>2</sub> step-up at RV level; V waves may be seen in PAOP tracing	Visualisation of left-to-right shunting with colour Doppler; can sometimes visualise defect as well
Acute mitral regurgitation	↑↑	↑↑	↓↓	V waves in PAOP tracing	Regurgitant jet apparent on colour Doppler; can diagnose papillary muscle rupture with flail leaflet
RV infarction	↑↑	↓ or normal	↓↓		RV dysfunction
Pump failure (cardiogenic shock)	↑↑	↑↑	↓↓		Decreased overall LV performance; regional wall motion abnormalities; dyskinctic or aneurysmal segments

CVP, central venous pressure; PAOP, pulmonary artery occlusion pressure; CO, cardiac output; PAC, pulmonary artery catheterisation; RV, right ventricular; RA, right atrial; PA, pulmonary artery

**Figure 16.15** Mechanical complications of myocardial infarction. CVP, central venous pressure; PAOP, pulmonary artery occlusion pressure; CO, cardiac output; PAC, pulmonary artery catheterisation; RV, right ventricular; RA, right atrial; PA, pulmonary artery.

intervention should be undertaken, has been uncertain. Meta-analysis of a small number of trials suggests that further thrombolysis is not associated with survival or reinfarction benefit and indeed may be harmful. Rescue PCI, compared to conservative management, conferred no survival benefit but was associated with significant reductions in heart failure, requiring 9 patients to be treated to achieve this benefit. Treatment was associated with an increased risk of bleeding and possibly stroke. Consideration for rescue PCI should probably be considered on a case-by-case basis; most benefit is likely to be achieved in shocked or haemodynamically unstable patients.

## CARDIAC FAILURE

LV dysfunction with the clinical signs of failure occurs in up to 30–40% of patients. It usually develops when the abnormally contracting segment exceeds 30% of the LV circumference: cardiogenic shock or death results when it exceeds 40%. It is more common in the setting of previous infarction, and is associated with a poor short- and long-term prognosis. With large MI there is progressive thinning of the affected myocardium, with stretching and dilatation of the ventricle, and sometimes frank aneurysm formation.

Angiotensin-converting enzyme (ACE) inhibitors appear to limit dilatation, preserve LV function and improve prognosis. Benefits are maximal in those with poor LV function. ACE inhibitors are thus recommended for all patients with significant LV dysfunction and are usually started early following MI. Captopril has a short half-life and may be started at very small doses in ICU patients (6.25 mg t.d.s.) if the systolic blood pressure is

> 100 mmHg (13.3 kPa). Lower starting doses may be considered (e.g. 1–3 mg t.d.s.) in hypotensive but otherwise stable patients. The dose is titrated upwards and a longer-acting agent may be substituted prior to discharge.

RV failure secondary to RV infarction<sup>38</sup> should be distinguished from RV failure secondary to LV failure and should be considered in any patient with inferior MI. It is associated with significantly increased mortality. These patients have a markedly elevated jugular venous pressure with little or no pulmonary congestion. Treatment principles are different to those for LV dysfunction. Patients with RV infarction often respond to volume loading and it is important to maintain RV preload. The latter is guided by clinical response and echocardiography. Pulmonary flotation catheters, seeking to maintain an optimal LV filling pressure at around 16–18 mmHg (2.1–2.4 kPa), are now used less often. Diuretic therapy, afterload reduction and unrecognised hypovolaemia may aggravate hypotension and renal insufficiency in these patients.

## CARDIOGENIC SHOCK (SEE FIGURE 16.15)

Mortality from cardiogenic shock remains very high (55–70%)<sup>39</sup> and is the major cause of hospital mortality from STEMI. Patients with cardiogenic shock may have ‘stunned’ myocardium that is capable of improvement with revascularisation and initial intensive medical support. Patients presenting with cardiogenic shock are treated with acute interventional revascularisation (PCI or CABG) in preference to thrombolysis and medical management: the benefits are still present beyond 5 years (survival 32.8% versus 19.6%).<sup>21</sup>

### POSTINFARCTION ANGINA AND REINFARCTION

Postinfarction angina unresponsive to medical therapy or with significant ECG changes is an indication for aggressive anti-ischaemic therapy and early PCI. Reinfarction in the 10 days following MI occurs in up to 5–10%; it can be treated with further thrombolysis or angioplasty. Where streptokinase has previously been given, t-PA is preferred because of the possible presence of antibodies that may neutralise activity or cause anaphylaxis.

### MITRAL REGURGITATION

Transient mitral valve dysfunction is common after MI. More severe, rupture of a papillary muscle and severe mitral regurgitation occur in about 4% of patients. A decrescendo systolic murmur may be present rather than the typical pansystolic murmur of chronic regurgitation. Posterior leaflet rupture is most common as it receives its blood supply from the dominant coronary artery (usually the RCA), whereas the anterior leaflet has a dual blood supply.

It can complicate even relatively small MI and the diagnosis should be considered if heart failure is disproportionate to the infarct size, even if a murmur cannot be heard. Surgery is usually required; pharmacological and mechanical afterload reduction often provides a bridge.

### CARDIAC RUPTURE<sup>20</sup>

Rupture of the interventricular septum occurs in about 1–2% of cases of MI, usually in large infarctions (60% of cases). Anterior and inferior infarctions are equally represented.

- It is often heralded by a new long systolic murmur which initially may be soft or absent and the patient may not be haemodynamically compromised. Diagnosis is best confirmed by echocardiography.
- Almost always there is progressive clinical deterioration (untreated mortality of 54% at 1 week and 92% at 1 year). Surgical repair is considered as soon as the diagnosis is made; intra-aortic balloon counterpulsation often provides a bridge to surgery.

Free wall rupture occurs in 1–3% of all hospitalised patients with MI and often occurs very early. Acute rupture of the LV free wall is usually catastrophic, resulting in pulseless electrical activity and death. Subacute rupture (leaking blood is contained by pericardium forming a false aneurysm) is less common and may mimic reinfarction. It requires urgent surgery.

### SYSTEMIC EMBOLI

Embolic (ischaemic) stroke occurs in approximately 1% of patients during their hospital admission and in 2% by 12 months.<sup>40</sup> Most of these cases occur following extensive anterior MI.<sup>41</sup>

- 30–40% of anterior Q-wave MIs may be complicated by mural thrombus (echocardiography). Embolisation is most frequent with large or protruding emboli and is uncommon following inferior infarction.
- 5–10% of these may undergo embolisation, usually within the first 10 days.

### MANAGEMENT

- The patient is usually put on anticoagulant therapy for  $\geq 3$  months (initial heparin, then warfarin) if mural thrombus is proven or if extensive anterior regional wall motion abnormality suggests high risk.
- Extensive anterior-wall motion abnormality is best proven by echocardiography. Clinicians should have a high index of suspicion in the presence of large anterior infarction.
- Patients with poor LV function remain at long-term risk of embolic stroke.<sup>41</sup>

### POST-MI INJURY SYNDROME (DRESSLER'S SYNDROME) AND PERICARDITIS

Pericarditis is a common early complication of extensive anterior and inferior infarction.

- Pericardial rub may be heard in 10–15% of patients with anterior MI, less often with inferior infarction.
- It occurs 24–72 hours after infarction and may mimic ischaemia.
- It is best treated with high-dose aspirin or non-steroidal anti-inflammatory medications.

Dressler's syndrome is now uncommon (< 1–3%) but is thought to be an immunopathic response to myocardial necrosis. It is characterised by fever, elevated erythrocyte sedimentation rate, a pericardial rub, pleuropericardial pain and arthralgia, and may occur some weeks after MI.

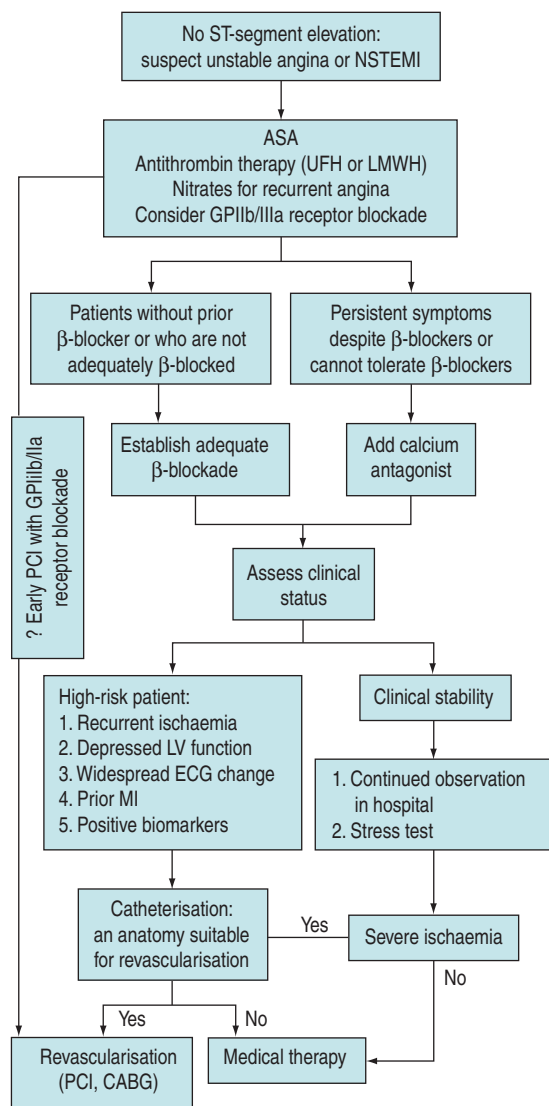

### MANAGEMENT OF UNSTABLE ANGINA AND NSTEMI (NSTEMACS) (FIGURE 16.16)

NSTEMACS result from the development of non-occluding thrombus upon unstable plaque. Superimposed vasospasm and microembolisation may aggravate myocardial ischaemia. Therapies are directed at 'white thrombus' and plaque stabilisation, and at reduction of myocardial oxygen demand.

General principles of treatment are:

- immediate relief of ischaemic symptoms
- immediate introduction of antiplatelet therapy, usually in conjunction with an antithrombin agent, to stabilise plaque and prevent complete artery occlusion
- determination of benefits of early invasive versus medical therapy

Thrombolytic agents are generally contraindicated in the treatment of NSTEMACS; their routine administration is associated with poorer outcome.<sup>14,42</sup>

**Figure 16.16** Management of acute coronary syndrome without ST-segment elevation. Aspirin, heparin and beta-blockers are administered to all without contraindications; nitrates are given for symptom control. Patients at intermediary or high risk may have best outcomes following early percutaneous coronary intervention with intravenous glycoprotein IIb/IIIa receptor blockade. Patients who stabilise may be treated medically followed by stress testing to screen for inducible myocardial ischaemia. ASA, acetylsalicylic acid; UFH, unfractionated heparin; LMWH, low-molecular-weight heparin; GP, glycoprotein; PCI, percutaneous coronary intervention; LV, left ventricle; ECG, electrocardiogram; MI, myocardial infarction; CABG, coronary artery bypass grafting. (Modified from Ryan TJ, Antman EM, Brooks NH *et al.* 1999 update: ACC/AHA guidelines for the management of patients with acute myocardial infarction. A report of the American College of Cardiology/American Heart Association Task Force on Practice Guidelines (Committee on Management of Acute Myocardial Infarction). *J Am Coll Cardiol* 1999; **34**: 890–911.)

## EARLY INVASIVE VERSUS MEDICAL THERAPY IN NSTEMACS

While medical therapy is introduced to all patients, keen observation should be continued for signs of instability which suggest that an invasive approach is appropriate. Prior to the introduction of potent antiplatelet inhibitors as ‘upstream therapy’ and coronary stents, early invasive therapy was associated with minimal benefit or with adverse outcome despite its theoretical attractiveness.<sup>43</sup> The development of better adjunctive agents (principally GPI blockers) has led to more recent studies suggesting that early invasive strategies are associated with reduced rates of MI and death.<sup>44</sup> The benefits of PCI are dependent upon the baseline risk to the patient. Emergent PCI is demonstrated to offer clinical benefit to patients with high-risk features such as elevated troponins, recurrent chest pain and recurrent ECG changes.<sup>43</sup>

## ANTI-ISCHAEMIC AGENTS

- β-blockers** assist symptom control. β-blockers, administered orally, should be started in the absence of contraindications. Caution is suggested in the early use of IV β-blockers, which should be targeted to specific indications and should be avoided with haemodynamic instability and heart failure.<sup>4</sup> IV therapy may be warranted for high-risk patients (e.g. with ongoing pain and hypertension) without contraindication to therapy. In these patients, metoprolol at 5 mg IV is commonly given incrementally every 5 min until symptoms are relieved, side-effects are experienced or a dose of 15 mg is reached. Ideally medication is titrated to attain a heart rate of 55–60 beats/min.
- Nitrates.** Sublingual nitroglycerine 300–600 μg is usually given in two doses at least some minutes apart (monitoring blood pressure) to relieve ischaemic pain. Patients with ongoing pain may receive IV nitrates. Evidence of improved outcome is lacking. Hypotension is a contraindication.
- Calcium channel blockers** may provide symptom relief when there are problems with β-blockers and nitrates. They may have a neutral or negative effect on mortality and progression to MI. Nifedipine without concomitant beta-blocker may increase mortality.<sup>5</sup> As sole agent, only those agents that reduce heart rate should be used (e.g. diltiazem or verapamil).<sup>20</sup>

## ANTIPLATELET THERAPIES

- Aspirin** (acetylsalicylic acid) decreases ‘death or non-fatal MI’ in patients with NSTEMACS by approximately 50%.<sup>30,45</sup>
- Clopidogrel** (in combination with aspirin) was demonstrated in the Clopidogrel in Unstable angina to prevent Recurrent Events (CURE) study to produce a

20% reduction in adverse events (compared to aspirin alone) when commenced early and continued in patients with NSTEMI. Reduction was mainly in MI. Significant early in-hospital benefit was seen.<sup>46</sup> Clopidogrel is preferred to ticlopidine, its older thienopyridine relative. (Clopidogrel is generally used in conjunction with aspirin in NSTEMI regardless of whether a conservative or invasive approach is planned. Its introduction or continuation should be reviewed if CABG is immediately imminent.<sup>29,31</sup>)

3. *GP IIb/IIIa receptor blockers* reduce the 30-day risk of non-fatal MI by 38%<sup>47,48</sup> in NSTEMI patients undergoing PCI. Benefit seems to be confined to high-risk patients (elevated troponins) undergoing PCI. Pre-treatment with tirofiban may be useful in this group.<sup>29,31,49</sup> They have not been shown to be beneficial in the routine management of 'medically treated' patients (GUSTO-IV-ACS).<sup>50</sup>

### ANTITHROMBINS AND ANTICOAGULANTS

*Heparins* significantly reduce the composite of 'MI or death' in NSTEMI patients receiving aspirin, although the endpoint of mortality alone has not been significant. The same is true of LMWHs.

Meta-analyses that compared regimens of LMWHs to regimens of UFH found a minimal or less significant reduction in the composite of 'death, MI and need for urgent revascularisation' in favour of LMWHs than found when compared in STEMI patients.<sup>33–35,51</sup> However, despite higher acquisition costs, their simplicity, lack of need for monitoring and acceptable safety profile perhaps favour their administration.

Fondaparinux compared to enoxaparin in NSTEMI had similar early efficacy but appeared to do so with fewer bleeding complications. At later follow-up, fondaparinux was associated with lower mortality and cerebrovascular accidents; most of the benefit seemed to accrue from its

lesser bleeding rate.<sup>52</sup> Substitution of fondaparinux for enoxaparin might save 6 lives per 1000 patients treated and might result in 19 less bleeds. There is concern that fondaparinux is not sufficient to prevent stent occlusion and concomitant UFH use is recommended in patients undergoing PCI.

### ONGOING AND DISCHARGE CARE OF ACS (SECONDARY PREVENTION) (FIGURE 16.17)

A number of therapies have been studied in the long-term (secondary) treatment of ACS, both STEMI and NSTEMI:

1. *Aspirin* (75–160 mg/day) should be continued unless there are strong contraindications. In the first 2 years after MI, aspirin therapy results in an absolute decrease of approximately 36 vascular events (vascular death or non-fatal MI or stroke) for every 1000 patients treated.<sup>30</sup>
2. *Clopidogrel* is generally continued throughout the hospital stay in both STEMI<sup>18</sup> and NSTEMI. In patients who have undergone PCI, continued treatment after discharge is beneficial, although the duration of that treatment is unknown and dependent upon the nature of the stent placed. Given in conjunction with aspirin, clopidogrel is proven to be of benefit when administered long-term to patients at high risk of future cardiovascular events (the CURE study),<sup>46</sup> although it is associated with an increased risk of bleeding. Clopidogrel is also a useful treatment in patients with aspirin resistance.
3. *β-blockers* significantly reduce the incidence of sudden and non-sudden cardiac death in survivors of MI. Benefit is prolonged and is most marked in high-risk patients, for example those with extensive anterior infarction. Given at the time of MI and continued orally, β-blockers have an early and significant effect on mortality, which is apparent at 7 days, although therapy is not appropriate in patients with

Figure 16.17 Late intervention in acute myocardial infarction.

contraindications.<sup>18</sup> Long-term administration after MI is also associated with survival and reinfarction benefit.<sup>53,54</sup>

4. *ACE inhibitors* are recommended in the treatment of all patients recovering from MI.<sup>55</sup> They significantly reduce mortality in high-risk patients or with symptomatic failure when commenced during recovery from MI. Patients with anterior MI and ejection fraction < 40% maintained on long-term ACE inhibitor therapy may experience a 20% relative reduction in mortality<sup>56,57</sup> and a significant reduction in the incidence of LV failure. Benefit is still seen at 4 years post-treatment.<sup>56</sup> Very early introduction of ACE inhibitors (within 36 h of infarction) may also reduce mortality. In patients intolerant of ACE inhibitors an ACE receptor blocker may be used.<sup>55</sup>

The aldosterone antagonist eplerenone reduces mortality in asymptomatic patients with low EF post-MI and already receiving  $\beta$ -blockers and ACE inhibitors (see Chapter 20).

5. *Lipid-lowering agents.* Statins should be commenced in hospital for all patients with ACS. Benefit is maximal in patients with elevated cholesterol and other factors, but benefit is present at all cholesterol levels. Lowering elevated cholesterol concentrations following MI results in a decrease in mortality and reinfarction.<sup>58</sup> Although data are conflicting, benefit may be evident within 30 days and therapy should be commenced as early as possible. It is thought that statins reduce hypercholesterolaemia and inflammation, stabilising the lipid core, and early introduction may be beneficial.
6. *Other anti-ischaemia agents:*
  - Routine use of calcium channel blockers does not improve outcome and certain agents have been suggested to cause harm. They may be of symptomatic use in patients intolerant of  $\beta$ -blockers or where a concomitant antihypertensive effect is needed.<sup>5,20</sup>
  - Carvedilol may be of benefit in patients with ACS.
7. *Antiarrhythmic therapy* is not routinely continued. In the Cardiac Arrhythmia Suppression Trial (CAST), prolonged flecainide therapy was used to suppress ventricular ectopy. Despite doing so, mortality was increased.<sup>59</sup> Amiodarone in low doses (200 mg/day) may reduce mortality, but results of definitive trials are awaited and it has significant side-effects. It cannot currently be recommended as routine therapy. For patients with actual or who are at high risk of ventricular arrhythmia, consideration may be given to long-term amiodarone or use of an implantable defibrillator.
8. *Warfarin* given alone or in combination with aspirin is associated with lower rates of a composite of 'death, reinfarction and thromboembolic stroke'. Concerns about bleeding (especially in the elderly) probably still see its clinical application restricted. Warfarin is useful for patients with proven myocardial thrombus, a large area of regional wall motion abnormality or a generalised thrombotic tendency.<sup>5</sup>

9. *Lifestyle advice* is most important and all patients should cease smoking and receive advice on exercise and diet. Diabetes should be tightly controlled.

## MYOCARDIAL INFARCTION IN THE INTENSIVE CARE UNIT

Myocardial ischaemia is a common problem in the ICU. It also commonly complicates perioperative care of major surgery, with mortality of up to 15–25%. Diagnostic criteria are uncertain but a system has been proposed by Devereaux *et al.*<sup>60</sup> There are few randomised controlled trials to guide therapy of postoperative infarction, or infarction complicating the care of the critically ill. Many patients with such presentations were excluded from trials of ACS therapy.

The pathophysiology of postoperative infarction and infarction in ICU patients is probably different to that of ACS.<sup>61</sup> Studies suggest that, in the presence of severe ischaemia, left main disease and triple-vessel disease are common and that ischaemia is secondary to oxygen supply-and-demand problems rather than thrombosis. However, data on this are conflicting.<sup>61</sup> The absence of thrombosis as an underlying pathological mechanism in many suggests that standard aggressive 'antithrombus' therapies will have different risk-benefit profiles, and that harm is exacerbated by the often high bleeding risk of these patients.

The patient with significant ST-segment elevation and haemodynamic instability in the ICU presents a difficult problem. Where underlying coronary artery is considered likely, an invasive approach is usually necessary. Thrombolysis is usually precluded by bleeding risk and by uncertainty regarding the causative process. Angiography will allow diagnosis and intervention if necessary; however, the use of adjunctive therapy (short- and intermediate-term) may be associated with significant bleeding. Reversible factors such as hypoxia, severe anaemia, anxiety and tachycardia must all be controlled where possible. Hypotension may limit the ability to administer  $\beta$ -blockers and control tachycardia.

Echocardiography may be useful in confirming regional wall motion abnormality and in confirming the amount of myocardium at risk. Of interest is the Takotsubo syndrome, where anterior ST-segment elevation and apical ballooning on echocardiography, often in association with elevated troponins, may occur in the presence of normal coronary arteries.<sup>9,10</sup>

## BLEEDING COMPLICATIONS POSTREPERFUSION THERAPY

The increased use of aggressive fibrinolytic regimens and of adjunctive reperfusion agents has led to troublesome bleeding in some patients. Some knowledge of reversal of these agents is necessary.<sup>62</sup>

1. **GPIIb/IIIa blockers.** Abciximab, a chimeric monoclonal antibody, has a short half-life, but antiplatelet activity is still prolonged at 24–48 h. Fortunately transfused platelets are not affected and will assist with bleeding reversal. The newer agents tirofiban and eptifibatid have very short half-lives and antiplatelet action returns to normal 4–8 h after discontinuation. During this period, however, antiplatelet action is profound. It is suggested that administration of fresh frozen plasma (8 units) and platelets (2 units) is likely necessary to reverse antiplatelet action.<sup>62</sup>
2. **Clopidogrel.** It is recommended that clopidogrel be ceased at least 5 days before elective CABG, but this is not always possible in emergent surgery or in unstable cases. Major bleeding rates may approach 10% in these cases. Pharmacology suggests that platelet transfusions are necessary to moderate this but dose is unknown.
3. **LMWHs.** Reversal of LMWHs with protamine is variable and incomplete, even with doses of 100 mg. Protamine may reverse up to 60% of LMWH action. It is suggested that doses of protamine should equal doses of enoxaparin administered on a milligram-per-milligram scale.
4. **Fibrinolytic agents.** In the setting of life-threatening bleeding, large doses of cryoprecipitate (10–20 units) may be required to replete fibrinogen (target > 1 g/l) and coagulation factors (especially factor VIII). Fresh frozen plasma may supplement factor V and VIII levels. Platelet transfusions at high dose may replace platelets and supplement factor V levels. ε-Aminocaproic acid at a dose of 5 g (0.1 g/kg) over 30–60 min followed by continuous infusion (0.5–1.0 g/h) may assist with bleeding control.<sup>62</sup>

### OUTCOME OF MYOCARDIAL INFARCTION

The in-hospital mortality from acute MI has been steadily decreasing over the past three decades from 15% to 30% in the 1970s to approximately 10% in 1980 and now to around 8–9% in the new millennium.<sup>1</sup> Despite improved mortality, 60% of all deaths occur within the first hour (usually from VF), and usually before reaching a medical facility.<sup>1</sup> Modern management of acute MI has undoubtedly contributed to decreased mortality. Further significant reductions in mortality must come from management strategies within the first hours of the onset of symptoms.

The major in-hospital changes are likely to come from:<sup>63</sup>

- better hospital organisation to increase access to PCI
- increased use of adjuvant therapies and discharge medications
- increased rates of thrombolysis or PCI in eligible patients

The latter cannot be underestimated. In one study, the in-hospital mortality was 5.7% for those who received thrombolysis but 14.8% for those who were eligible for but did not receive such therapy (9.3% versus 18% in eligible women who did not receive therapy, 10.5% versus 19% in eligible elderly). Up to 24% of eligible patients do not receive reperfusion therapy.<sup>63</sup>

### NEW INFORMATION

The conclusions can be summarised.

- Cardiac troponin level is frequently increased in hospitalized patients in the absence of an ACS
- it portends poor short- and long-term outcomes
- Most of these patients have an alternative explanation for cardiac troponin increase
- Cardiac diagnostic procedures are frequently unhelpful in excluding a non-ACS-related troponin increase

Essentially Troponin I level had poor accuracy in discriminating patients with and without ACS. Alternative diagnoses included; sepsis, acute left heart failure, cerebrovascular events and a wide range of other conditions.

# Adult cardiopulmonary resuscitation

Peter T Morley

The incidence and outcomes of cardiac arrests appeared not to have changed dramatically over a number of decades. However, a number of recent advances offer significant promise in our attempts to increase neurologically intact survival.

## PREVALENCE AND OUTCOMES OF CARDIAC ARRESTS

Approximately 75% of deaths from cardiac arrests occur in the pre-hospital setting.<sup>1</sup> Cardiac arrests in the community occur at approximately 50–150/100 000 person-years.<sup>2–4</sup> This incidence (and the outcome) is dramatically affected by the definition of the denominator (e.g. all cardiac arrests (89/100 000 person-years) versus those with a presumed cardiac cause and where resuscitation was attempted (31/100 000 person-years)<sup>3</sup>).

In-hospital cardiac arrests occur at approximately 1–5/1000 admissions,<sup>5,6</sup> with a similar denominator effect (as the majority of in-hospital cardiac deaths are expected and occur without attempts at resuscitation<sup>7</sup>).

The majority of cardiac arrests in both pre- and in-hospital settings appear to be of cardiac origin, but the underlying causes, comorbidities and presenting rhythms vary significantly between studies.<sup>4,6,8,9</sup>

Outcomes of cardiac arrests are variable depending on the origin of the report, and are also critically dependent on the denominator.<sup>2,3,10</sup> The best outcomes from a cardiac arrest (near 100%) occur in the electrophysiology laboratory (where ventricular fibrillation [VF] is often deliberately induced). The outcomes from in-hospital cardiac arrest are surprisingly good (hospital discharge as high as 42%) despite significant comorbidities, and are probably related to their early detection and the early arrival of the advanced life support (ALS) team.<sup>6</sup>

## INTERNATIONAL REVIEW PROCESS

Since the formation of the International Liaison Committee on Resuscitation in 1992, a cooperative international evaluation of the resuscitation science has resulted in the publication of international guidelines in 2000<sup>11</sup> and an international consensus on resuscitation science in 2005.<sup>12</sup> The published guidelines of the major resuscitation councils

throughout the world (including the American Heart Association,<sup>13</sup> the Australian Resuscitation Council ([www.resus.org.au](http://www.resus.org.au)) and the European Resuscitation Council<sup>14</sup>) are based on this document. The process for the 2005 consensus on resuscitation science involved the review of 276 topics by 281 international contributors, with the completion of 403 worksheets<sup>15</sup> (completed worksheets available at [www.c2005.org](http://www.c2005.org)). This science review process continues to be refined and a new consensus on resuscitation science document is planned for publication in 2010.

## IMPORTANCE OF CHAIN OF SURVIVAL

The term ‘chain of survival’ has been used to define the important links in the chain for the resuscitation process.<sup>10</sup> The key links, which apply to both in- and out-of-hospital cardiac arrests, are: early recognition and the summoning of help, early basic life support (BLS), early access to defibrillation and early ALS, including postresuscitation care.<sup>10</sup>

## RECENT CHANGES TO GUIDELINES

As a result of the science review published in 2005,<sup>12</sup> a number of important changes have been made to the guidelines for both basic and ALS.

In summary, the BLS changes include:

- commencing cardiopulmonary resuscitation (CPR) where there are no signs of life (unconscious/unresponsive, not breathing normally and not moving)
- two initial breaths instead of five
- a uniform compression-to-ventilation ratio of 30:2 for infants, children and adults (regardless of the number of rescuers)<sup>16</sup>

The ALS changes include:

- refocusing on the provision of good CPR (including minimising the interruptions to CPR)
- minimising the potential harm associated with ventilation
- maximising the likelihood of successful defibrillation (using a single-shock strategy and appropriate energy levels)<sup>17</sup>

These changes are discussed in more detail in the sections that follow.

**BASIC LIFE SUPPORT**

The general flow of BLS management is provided in the Australian Resuscitation Council BLS flowchart ([www.resus.org.au](http://www.resus.org.au); Figure 17.1).

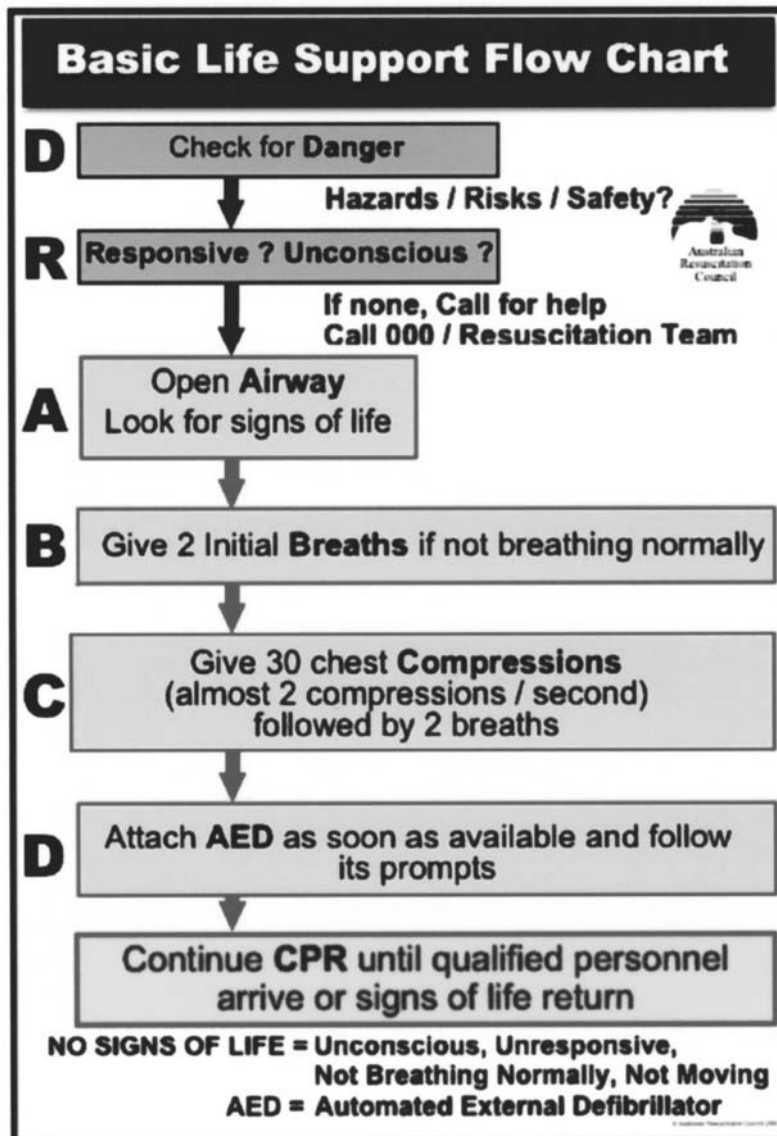

**COMMENCEMENT OF CPR**

The use of a pulse check as a means of determining the need for external cardiac compressions was downplayed in the 2000 guidelines, largely as a result of the review of a number of papers suggesting that even experienced providers may have difficulty in accurately assessing the presence or absence of a pulse.<sup>18</sup> This was again confirmed in the current guidelines, where it has been recommended that CPR be commenced if the victim has no signs of life

(unconscious/unresponsive, not breathing normally and not moving).<sup>16</sup> An appropriately trained ALS provider can check for a central pulse (e.g. carotid) for up to 10 seconds during this period of assessment for signs of life.

**EXTERNAL CARDIAC COMPRESSION****SITE OF COMPRESSION**

The desired compression point for CPR in adults is over the lower half of the sternum. Compressions that are provided higher than this become less effective, and compressions lower than this are also less effective and have an increased risk of damage to intra-abdominal organs. Previous techniques that were widely taught to find this compression point may have introduced delays in commencing and recommencing chest compressions.

**Figure 17.1** Basic life support flowchart. (Reproduced from the Australian Resuscitation Council ([www.resus.org.au](http://www.resus.org.au)), with permission.)

To minimise pauses between ventilations and compressions, it is reasonable for laypeople and health care professionals to be taught to position the heel of their dominant hand in the centre of the chest of an adult victim (with the non-dominant hand on top).<sup>2</sup>

#### RATE OF COMPRESSION

The optimal rate of cardiac compression during cardiac arrest in adults has not yet been determined.<sup>2</sup> In a recent human study,<sup>19</sup> lower rates (e.g. < 80/min) were associated with worse outcomes and higher rates (> 120/min) with more fatigue and no benefits. It is recommended that chest compressions should be performed at a rate of approximately 100 compressions/minute.

#### DEPTH OF COMPRESSION

The ideal depth of compression is unknown. Compression depth is usually inadequate when it is measured in either manikin studies or actual cardiac arrests, and increasing depth of compression appears to be associated with higher defibrillation success.<sup>20</sup> It is currently recommended that, when performing chest compressions in adults, the chest should be compressed by at least 4–5 cm (or approximately one-third of its depth).

#### MINIMISE INTERRUPTIONS TO COMPRESSIONS

Interruptions in chest compressions ('hands-off time') are common, often prolonged, and are associated with a decrease in coronary perfusion pressure and a decreased likelihood of defibrillation success.<sup>20–22</sup> These adverse effects commence within 10 seconds, but appear to be at least partially reversible with the commencement of chest compressions.<sup>23</sup> It is recommended that CPR (initial breaths, then chest compressions) be commenced as soon as the victim is confirmed to have no signs of life. Pauses in compressions for rhythm recognition or specific interventions (such as ventilations, defibrillation or intubation) should be minimised.

#### COMPRESSION–VENTILATION RATIO

The minute ventilation requirements during cardiac arrest are less than that in the non-arrested state, so the respiratory rate can be decreased. To increase the number of compressions given per minute, minimise interruptions to chest compressions and simplify instruction for teaching and skills retention, a single compression-to-ventilation ratio of 30:2 is recommended for adult BLS before the airway is secured (irrespective of the number of rescuers).<sup>2</sup> The tidal breath should be delivered within 1 second, and the desired tidal volume to be delivered is one that results in a visible chest rise.<sup>2</sup>

#### MONITORING THE QUALITY OF CPR

A number of different techniques are available to monitor the quality of CPR, some of which are more applicable to

**Table 17.1** Utility of end-tidal carbon dioxide (ETCO<sub>2</sub>) monitoring during cardiac arrest<sup>24</sup>

##### Cardiovascular (absolute value of ETCO<sub>2</sub>)

Falls immediately at the onset of cardiac arrest  
Increases immediately with chest compressions  
Provides a linear correlation with cardiac index  
Allows early detection of return of spontaneous circulation (sudden increase)

##### Respiratory (ETCO<sub>2</sub> waveform)

Allows assessment of endotracheal tube placement  
Allows assessment of expiratory flow limitation

##### Prognosis (absolute value of ETCO<sub>2</sub>)

Predicts successful resuscitation

ALS. Simple monitoring techniques include observation of the rate, depth and positioning of chest compressions, the rate and depth of ventilation and palpation of central pulses. Additional monitoring techniques that can be used include end-tidal carbon dioxide (Table 17.1), mechanical devices (e.g. for monitoring the depth of compressions) and new monitor/defibrillators (e.g. for monitoring the depth and rate of compressions and ventilation). Feedback from these devices can improve the quality of CPR and should result in improved outcomes.<sup>24</sup>

#### 'COMPRESSION-ONLY' CPR

Increasing anxiety about the performance of mouth-to-mouth ventilation has required the consideration of an alternative approach to traditional bystander CPR. A number of animal studies have suggested that ventilation may not be necessary during the initial phase of resuscitation from an arrest of a cardiac cause (e.g. where VF was electrically induced).<sup>2</sup> Recent research in human out-of-hospital cardiac arrests suggests that outcomes are not worse and may actually be better if ventilation is not initially attempted,<sup>25,26</sup> although no studies have compared 'compression-only' CPR with the BLS protocols that are currently recommended. It is recommended that if rescuers are unable, not trained, or unwilling to perform mouth-to-mouth ventilation (rescue breathing) then they should perform 'compression-only' CPR.

#### DEFIBRILLATION

Defibrillation is no longer only the domain of ALS. BLS providers are now often taught how to use an automated external defibrillator (AED). ALS providers can use defibrillators in automated or manual modes. Defibrillation remains the definitive treatment for VF, and it requires an appropriate combination of defibrillator waveform and energy level. Recent research has emphasised the importance of the timing of defibrillation in relation to other interventions.

### EARLY DEFIBRILLATION VERSUS CPR BEFORE DEFIBRILLATION

The timing of defibrillation with regard to other interventions appears crucial. The traditional approach to the treatment of a shockable rhythm during cardiac arrest has been to perform defibrillation as soon as possible. In the scenario of recent-onset VF, this still holds, and the best outcomes are associated with defibrillation within 3 minutes (e.g. in electrophysiology labs or coronary care units). However, in situations where the VF has persisted for more than a few minutes, an initial period of CPR may actually improve the likelihood of shock success, and result in better outcomes.<sup>23,27,28</sup>

### WAVEFORM FOR DEFIBRILLATION

No specific defibrillator waveform (either monophasic or biphasic) is consistently associated with a greater incidence of return of spontaneous circulation (ROSC) or increased hospital discharge rates from cardiac arrest due to VF.<sup>29</sup> Defibrillation with biphasic waveforms (either truncated exponential or rectilinear), using equal or lower energy levels, appears at least as effective for termination of VF as monophasic waveforms.<sup>30,31</sup>

### ENERGY LEVELS

Recommendations for energy levels to be used for defibrillation vary according to the type of defibrillator (and the specific waveform) that the rescuers are using. Previous recommendations regarding energy levels were based on studies using monophasic waveforms that demonstrated increased heart block with higher energy levels. Current recommendations are based on maximising the likelihood of the success of each shock. The recommended energy level for defibrillation in adults where monophasic defibrillators are used is 360 J for all shocks. When using biphasic waveforms, the energy level should be set at 200 J for all shocks, unless there are relevant clinical data for the specific defibrillator that suggest that an alternative energy level provides adequate shock success (e.g. > 90%). There is no consistent evidence (e.g. survival benefit) to suggest that an escalation of energy levels is required for subsequent shocks.<sup>29,32</sup>

### SINGLE-SHOCK TECHNIQUE

The use of a single-shock strategy for defibrillation is now recommended (i.e. deliver a single shock and then immediately commence CPR, rather than deliver up to three shocks in a sequence). This strategy has been proposed to decrease the interruptions to chest compressions which occur as a result of the repeated assessment of rhythm and signs of life that were inherent in the stacked-shock approach.<sup>29</sup> This protocol would be of particular benefit in scenarios where there is a significant time required for rhythm recognition and recharging of the defibrillator (i.e. > 10 seconds), such as with AEDs. The benefits of this

strategy are clearly dependent on the quality of CPR, as the next shock will be delayed for at least 2 minutes while CPR is performed.

The Australian Resuscitation Council does however recommend the retention of a stacked-shock strategy (up to three shocks as necessary) in a specific circumstance: for the first defibrillation attempt in a witnessed arrest, where a manual defibrillator is immediately available, and the time required for rhythm recognition and charging of the defibrillator is short (e.g. < 10 seconds), resulting in delivery of the (up to) three shocks within 30 seconds. All subsequent shocks should be given using a single-shock strategy (see [www.resus.org.au](http://www.resus.org.au)).

## ADVANCED LIFE SUPPORT

The role of ALS is clearly established in the management of cardiac arrests. Interestingly, in itself, the provision of ALS (apart from defibrillation) has not been clearly demonstrated to be associated with improved outcomes. A number of these techniques are listed below; some of these are only available in the in-hospital setting.

### ADVANCED LIFE SUPPORT FLOWCHART

The recommended sequence of treatment to be followed is designated on the ALS flowchart of the Australian Resuscitation Council ([www.resus.org.au](http://www.resus.org.au); Figure 17.2). This is designed to be used as an aide-mémoire and a teaching tool.

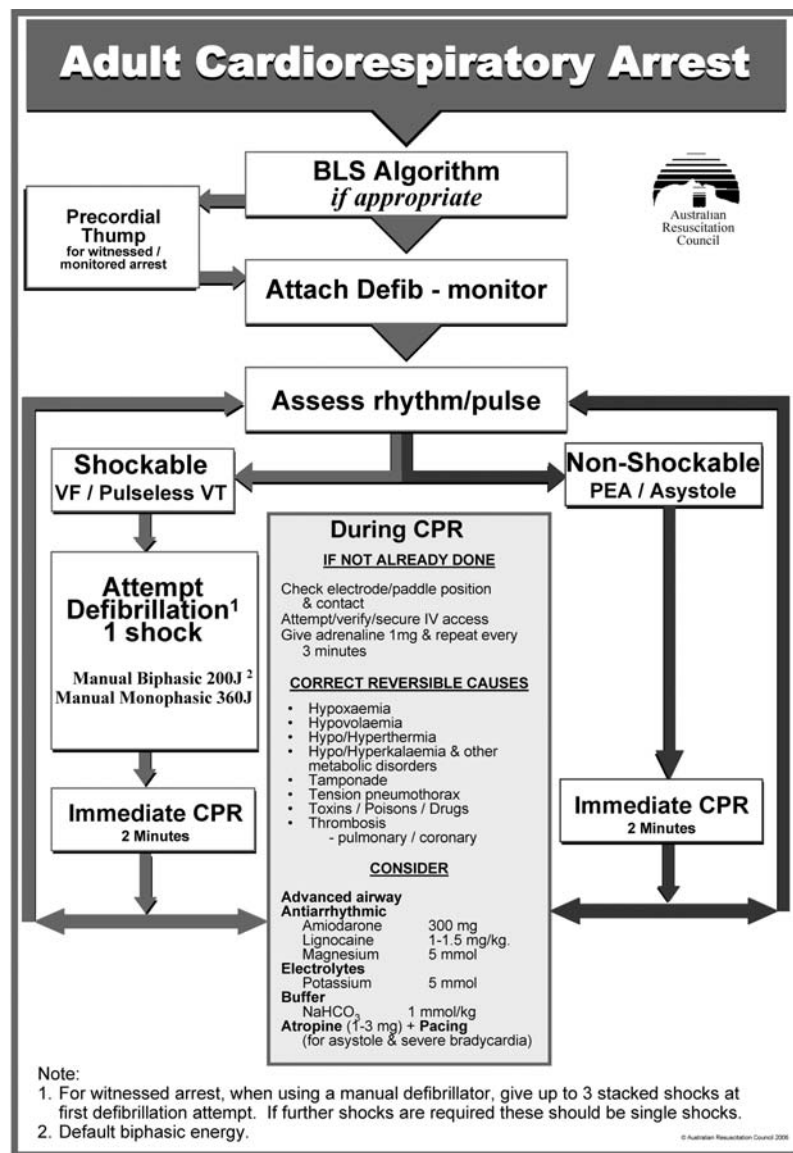

### PRECORDIAL THUMP

The provision of a precordial thump in a witnessed and monitored arrest due to a shockable rhythm may be of value if a defibrillator is not immediately available.<sup>29</sup> However the technique is not without risks, and should not delay defibrillation.

### CHEST COMPRESSIONS

The provision of good BLS is an essential part of the ALS management of both shockable and non-shockable rhythms. Interruptions to chest compressions for definitive procedures or interventions should be kept as brief as possible. Chest compressions should be continued up until defibrillation, and should be commenced again immediately following defibrillation (without checking the rhythm) and continued for at least 2 minutes unless signs of life return. Even if defibrillation has successfully reverted the rhythm into one that could generate a pulse, in the vast majority of cases this is not initially associated with an output.<sup>33</sup> Immediate compressions in these situations avoid the detrimental effects of prolonged interruptions in compressions, maintain the coronary perfusion pressure and are not associated with an increased risk of refibrillation.<sup>34</sup> After each 2 minutes of CPR (or if signs

**Figure 17.2** Advanced life support flowchart. (Reproduced from the Australian Resuscitation Council (www.resus.org.au), with permission.)

of life return), the underlying rhythm should be checked, and if a rhythm compatible with a return of spontaneous circulation is observed at this stage, then the pulse should also be checked.

#### AIRWAY MANAGEMENT DURING CPR

There are no data to support the routine use of any specific approach to airway management during cardiac arrest.<sup>35</sup> Despite this, endotracheal intubation remains the gold standard for airway maintenance and airway protection in CPR. If the victim is unconscious and has no gag reflex, and a trained operator is available, endotracheal intubation should be performed at the first

appropriate opportunity, and the patient ventilated with 100% oxygen. The endotracheal tube provides optimal isolation and patency of the airway, allows suctioning of the airway and also provides access for the delivery of some drugs (e.g. adrenaline (epinephrine), lidocaine and atropine). However, attempts at endotracheal intubation should not interrupt cardiac compressions for more than 20 seconds. The routine use of an endotracheal tube during cardiac arrest management has not been shown to improve outcomes, and without adequate training and experience the incidence of complications, such as unrecognised oesophageal intubation, is unacceptably high. Alternatives to the endotracheal tube that have been studied during CPR include the bag-valve mask and other

advanced airway devices such as the laryngeal mask airway and oesophageal–tracheal combitube.<sup>35</sup> The training and experience of the resuscitation team members and availability of such devices will determine the appropriate choice for airway adjunct.

### VENTILATION DURING CPR

The minute ventilation requirements during cardiac arrest are less than those required in the non-arrested state. Hyperventilation during cardiac arrest is associated with increased intrathoracic pressure, decreased coronary and cerebral perfusion and, at least in animals, a decreased rate of return of spontaneous circulation.<sup>36</sup> A compression-to-ventilation ratio of 30:2 is recommended before the airway is secured, and after the airway is secured the recommended ventilation rate is 8–10/min.<sup>2</sup> One way to provide this, and to minimise interruptions to compressions, is to use a compression-to-ventilation ratio of 15:1 once the airway is secured ([www.resus.com.au](http://www.resus.com.au)). If there is a concern about potential gas trapping, a period of disconnection from the ventilation circuit may be beneficial.<sup>35</sup> The tidal volume recommended is one that results in a visible chest rise.<sup>2</sup>

### IDENTIFICATION OF REVERSIBLE CAUSES

Irrespective of the initial or subsequent rhythms, cardiac arrests can be precipitated or perpetuated by a number of conditions, which, if not detected and corrected, may prevent successful resuscitation. These ‘reversible causes’ are categorised in the ALS algorithm as the ‘4Hs and 4Ts’ ([www.resus.org.au](http://www.resus.org.au); see Figure 17.2). A number of techniques are available to assist in the diagnosis and exclusion of these conditions (ranging from a good history, through careful clinical examination to investigations and interventions).<sup>24</sup> Echocardiography can potentially diagnose (or help exclude) a number of cardiac and non-cardiac reversible causes (Table 17.2). Transoesophageal echocardiography requires a more skilled technician, but useful information can be obtained after minimal training with the transthoracic approach.<sup>24</sup>

### DRUGS DURING CPR

Although various drugs are recommended for use during the management of cardiac arrests, there are no placebo-controlled studies that show that the routine use of any drugs at any stage during human cardiac arrest increase survival to hospital discharge.<sup>35</sup>

### VASOPRESSORS

The putative beneficial effects of vasopressors during cardiac arrest are to increase the perfusion pressure to heart and brain. No vasopressor has been shown to improve

**Table 17.2** Potentially useful diagnoses detectable by echocardiography<sup>24</sup>

Hypovolaemia*
Tamponade* (pericardial)

Ventricular rupture
Aortic dissection
Massive pleural effusion

\*Reversible causes listed in the ‘4Hs and 4Ts’ ([www.resus.org.au](http://www.resus.org.au)).

long-term survival when compared with placebo for the management of cardiac arrests,<sup>35</sup> but despite this lack of confirmatory evidence, it is reasonable to continue to use a vasopressor routinely in the management of cardiac arrests. There are insufficient data to support any particular drug or combination of drugs.<sup>35</sup> Adrenaline remains the vasopressor of choice during the management of cardiac arrest (1 mg every 3 min). Vasopressin is an alternative drug, but studies have been unable to demonstrate any consistent benefit.<sup>35,37</sup>

### ANTIARRHYTHMICS

No antiarrhythmic drug has been shown to improve long-term survival when compared with placebo for the management of cardiac arrests.<sup>35</sup> However, administration of amiodarone (300 mg or 5 mg/kg) for shock-refractory VF has been associated with an increased survival to hospital when compared with either placebo<sup>38</sup> or lidocaine.<sup>39</sup> Either amiodarone or lidocaine (but not both) should be considered in those patients still in VF after repeated attempts at defibrillation (including attempted defibrillation after the administration of adrenaline) have failed.

### OTHER DRUGS

Other drugs that are listed in the ALS flowchart to be considered during cardiac arrest include electrolytes (such as magnesium or potassium), atropine and sodium bicarbonate ([www.resus.org.au](http://www.resus.org.au); see Figure 17.2). Additional specific drugs may be indicated depending on the specific circumstances of the arrest (see summary in Table 17.3).<sup>40–42</sup>

### ADJUNCTS TO CPR

Many technologies and techniques have been evaluated as adjuncts to CPR in an attempt to improve survival in the management of cardiac arrests, but none have

**Table 17.3** Cardiac arrest medications in specific circumstances<sup>40–42</sup>

Medication	Potential indications
Adrenaline (epinephrine)	Beta-blocker/calcium channel blocker toxicity
Atropine	Cholinergic/cardiac glycoside toxicity
Benzodiazepines	Sympathomimetic toxicity
Calcium	Hypocalcaemia, hypermagnesaemia, hyperkalaemia, beta-blocker/calcium channel blocker toxicity
Digoxin-specific antibodies	Cardiac glycoside toxicity
Flumazenil	Benzodiazepine toxicity
Glucagon	Beta-blocker/calcium channel blocker toxicity
Magnesium	Hypomagnesaemia, hypokalaemia, hypercalcaemia, tricyclic antidepressant/cardiac glycoside toxicity, torsade de pointes
Naloxone	Opioid toxicity
Potassium	Hypokalaemia
Pyridoxine	Isoniazid toxicity
Sodium bicarbonate	Hyperkalaemia, tricyclic antidepressant/sodium channel blocker toxicity

been consistently associated with improved outcomes.<sup>35</sup> Active-compression decompression (ACD) CPR is the most widely evaluated technique, but it has not been associated with improved long-term survival.<sup>35</sup> An automated version of ACD CPR has been developed (LUCAS) and is currently being evaluated. A modification of vest CPR (the load-distributing band) has had recent conflicting results.<sup>43,44</sup> The impedance threshold valve appears promising (especially in combination with ACD CPR), and there has also been a resurgence of interest in extracorporeal techniques. At this stage there is insufficient supportive evidence to recommend the routine use of any of these adjunctive techniques.<sup>35</sup>

### POSTRESUSCITATION CARE

The missing link in research in resuscitation has for a long time been the period of care after the return of spontaneous circulation. Survival after cardiac arrest is largely dependent on the patient's comorbidities and the initial

hypoxic insults to the heart and brain. However it can also be influenced by subsequent complications (including secondary insults and the ensuing systemic inflammatory response).

### INDUCED HYPOTHERMIA

Induced hypothermia has been used for postcardiac arrest management since the late 1950s, but it was brought to the attention of the wider medical community with the publication of two randomised controlled trials in 2002.<sup>45,46</sup> Both of these trials, in unconscious but haemodynamically stable survivors of out-of-hospital cardiac arrests due to VF, demonstrated improved neurologically intact survival with a 12–24-hour period of induced hypothermia (32–34°C).

Mild hypothermia is associated with a number of potential beneficial effects in the postarrest patient, but also a number of potential adverse effects (Table 17.4).<sup>47</sup> During hypothermia, the sedation and/or paralysis that may be needed to prevent the adverse effects of shivering may in turn mask seizure activity. Several techniques are available to cool patients, ranging from cold intravenous fluids through to commercial devices,<sup>45–47</sup> and these continue to be evaluated.

It is recommended that unconscious but haemodynamically stable survivors of out-of-hospital cardiac arrests due to VF should be cooled to 32–34°C for 12–24 hours. A period of induced hypothermia should also be considered for cardiac arrests due to other rhythms, as well as in-hospital arrests.<sup>35,48</sup>

### OTHER FACTORS IN POSTRESUSCITATION CARE

Clearly other factors are important in the postarrest period, but studies are limited.<sup>35</sup> It is likely that hyperventilation and the resultant cerebral vasoconstriction are potentially harmful. Tight blood glucose control may be beneficial but its use remains controversial. Maintenance of cerebral perfusion, adequate oxygenation, treatment of seizures and good supportive care are likely to be beneficial. Norwegian investigators were able to double their survival to hospital discharge (with a favourable neurological outcome) for out-of-hospital cardiac arrests by introducing a standardised postresuscitation protocol. This protocol focused on vital organ function, including the use of therapeutic hypothermia, percutaneous coronary interventions (PCI) and the control of haemodynamics (mean arterial pressure (MAP) > 65 mmHg), blood glucose (5–8 mmol/l), ventilation (normocapnia) and seizures.<sup>49</sup>

### BLOOD PRESSURE CONTROL

There are limited human data to guide hemodynamic management after cardiac arrest. Reported successful blood pressure goals have varied from a period of relative

**Table 17.4** Potential risks and benefits of induced hypothermia after cardiac arrest<sup>47</sup>**Potential neurological benefits**

Decreased cerebral oxygen consumption (6–7%/°C)  
 Decreased excitatory amino acids (especially glutamate)  
 Decreased free radical formation/oxidative stress  
 Decreased neuron-specific enolase  
 Decreased cerebral lactate  
 Decreased cerebral oedema  
 Decreased intracranial pressure  
 Decreased cell-destructive enzymes  
 Decreased expression of intercellular adhesion molecule-1 (ICAM-1)  
 Decreased neutrophil migration to ischaemic tissue  
 Downregulates ongoing inflammatory response  
 Anticonvulsant effects  
 Better redistribution of blood to ischaemic areas  
 Increased neurotrophic factors

**Potential risks****Cardiovascular**

Bradycardia  
 Vasoconstriction  
 Arrhythmias (uncommon at 33°C)

**Haematological**

Decreased numbers/function of white blood cells  
 Decreased numbers/function of platelets  
 Prolonged clotting times

**Gastrointestinal**

Decreased gut motility  
 Hyperglycaemia

**Renal**

Renal dysfunction  
 Diuresis

**Metabolic**

Hypokalaemia  
 Hypophosphataemia

**Musculoskeletal**

Shivering (with associated lactic acidosis)\*

\*Sedation and/or paralysis to control shivering may mask ongoing seizure activity.

hypertension (MAP 90–100 mmHg<sup>45</sup>) to more standard goals (MAP > 65–70 mmHg<sup>49</sup>). It is recommended to aim for a blood pressure equal to the patient's usual blood pressure or a systolic pressure greater than 100 mmHg.

**GLUCOSE CONTROL**

Tight blood glucose control (to normoglycaemia) in one study involving critically ill surgical patients improved survival,<sup>50</sup> but this has not been replicated in subsequent studies.<sup>51</sup> There is a large amount of circumstantial evidence to suggest that hyperglycaemia should be avoided but the optimal target for control is unknown.

**PERCUTANEOUS CORONARY INTERVENTION**

Thrombolysis and PCI are the mainstay of management after acute coronary syndromes. PCI has been used successfully when indicated in the early period after recovery of spontaneous circulation, and should be considered as part of routine postarrest care.<sup>49,52</sup>

**MEDICAL EMERGENCY TEAMS (MET)**

It has long been recognised that in-hospital cardiac arrests are usually preceded by some deterioration in physiological criteria.<sup>7,53</sup> A number of different mechanisms have been proposed to respond to these early signs.<sup>35</sup> The most common of these are variations of an MET (usually involving a multidisciplinary response to a single abnormality<sup>5</sup>) and early-warning systems (a response to an accumulated score). Commonly used criteria to initiate a MET call include:

- a threatened airway
- a respiratory rate (< 5 or > 36 breaths per minute)
- a pulse rate (< 40 or > 140 beats/min)
- a systolic blood pressure (< 90 mmHg)
- a fall in Glasgow Coma Score of 2 points
- prolonged seizures<sup>5,7</sup>

**OUTCOMES**

Promising data from studies using historical controls (or before-and-after methodology) suggested that the introduction of an MET response resulted in a number of benefits, including reductions in hospital deaths and cardiac arrest rates, and improved outcomes following cardiac arrest.<sup>35</sup> A large prospective cluster randomised study was performed in an attempt to confirm these benefits,<sup>5</sup> but it was unable to demonstrate any statistically significant improvement in outcomes (see Chapter 2).

**PRE-MET**

Recent observations have confirmed that minor derangements in vital signs predict adverse clinical outcomes.<sup>54,55</sup> Many of these derangements occur at a level that would not elicit either an MET call or an early-warning system response,<sup>55</sup> therefore ward-based systems are required to respond to these factors.

**PROGNOSTICATION**

It is impossible to predict accurately the degree of neurological recovery during or immediately after a cardiac arrest.<sup>35,56</sup> Relying on the neurologic examination during cardiac arrest to predict outcome is not recommended and should not be used as it has insufficient negative

predictive value.<sup>35</sup> After cessation of sedation (and/or induced hypothermia), the probability of awakening decreases with each day of coma. Clinical examination (absence of pupillary response or motor response to pain on day 3), somatosensory evoked potentials and electroencephalography offer the best prognostic estimates<sup>35,56</sup> (www.resus.org.au).

## SUMMARY

Improved outcomes after cardiac arrest are now anticipated to occur as a result of a number of advances in management and the ongoing science evaluation process. Improvements within each link of the chain of survival are anticipated. These include: earlier recognition and activation of the emergency response (including MET and pre-MET); good BLS (maximising quality of and minimising interruptions to chest compressions); optimised defibrillation (with an appropriate sequence of CPR, and using optimal energy levels for the waveform used); and early and appropriate ALS with more focus on the period of postresuscitation care.

# Management of cardiac arrhythmias

Andrew Holt

## CARDIAC ELECTROPHYSIOLOGY

The electrophysiological properties of cardiac cells are important in understanding cardiac arrhythmias and their management. Cardiac cells undergo cyclical depolarisation and repolarisation to form an action potential. The shape and duration of each action potential are determined by the activity of ion channel protein complexes on the myocyte surface. These highly selective ion channels determine the rate of ion flux which in turn determines the magnitude and rate of change of myocyte membrane potential. Many of these ion channels are the molecular targets for antiarrhythmic drugs.

Ion channel function can be affected by:

- genetic mutations of channel proteins
- changes in functional expression of channel protein genes
- acute ischaemia
- autonomic tone
- myocardial scarring
- electrolyte concentration

The spectrum of cardiac action potentials varies from *fast-response* cells – conducting and contractile myocytes (Figure 18.1a) – to *slow-response* cells of pacemaker myocytes – sinoatrial (SA) and atrioventricular (AV) nodes (Figure 18.1b). Fast myocytes lose their characteristic action potential and behave more like slow myocytes when ischaemic. The action potential is divided into five phases, as follows.

### PHASE 0

In fast myocytes (Figure 18.1a) rapid depolarisation occurs due to activation of voltage-dependent  $\text{Na}^+$  channels. Activation is initiated in an all-or-none response once the threshold is reached. The  $\text{Na}^+$  channels are inactivated as membrane potential rises to +30 mV and remain inactivated until repolarisation occurs. Rapidity of depolarisation determines speed of conduction. In slow-response myocytes depolarisation does not involve  $\text{Na}^+$  channels and the slower rate of depolarisation is due to a slow inward  $\text{Ca}^{2+}$  current via L- and T-type voltage-dependent  $\text{Ca}^{2+}$  channels.

### PHASE 1

Early rapid incomplete repolarisation to approximately 0 mV occurs due to activation of transient outward current from  $\text{I}_{\text{TO1}}$  and  $\text{I}_{\text{TO2}}$   $\text{K}^+$  channels. Slow myocytes do not exhibit phase 1 or 2 characteristics (Figure 18.1b).

### PHASE 2

The prolonged plateau repolarisation of fast myocytes is a consequence of low membrane conductance to all ions. The decreasing inward  $\text{Ca}^{2+}$  current of L- and T-type  $\text{Ca}^{2+}$  channels is initially balanced and then overcome by the outward  $\text{K}^+$  current of the delayed rectifiers or the  $\text{I}_{\text{k}}$  family of  $\text{K}^+$  channels. During this phase the rise in  $[\text{Ca}^{2+}]_{\text{i}}$  is the trigger to release sarcoplasmic reticulum stores of  $\text{Ca}^{2+}$  and initiate the contractile process.

### PHASE 3

Relatively rapid repolarisation occurs as outward  $\text{K}^+$  current of the delayed rectifiers increases. The  $\text{I}_{\text{kr}}$   $\text{K}^+$  channel, one of the  $\text{I}_{\text{k}}$  delayed rectifiers, is the common mechanism whereby antiarrhythmic drugs prolong the action potential and refractoriness.

### PHASE 4

This is a stable electrical state in fast non-pacemaker myocytes. In slow pacemaker myocytes the resting membrane potential (RMP) slowly depolarises until the action potential threshold is reached (Figure 18.1b). This inward or pacemaker current is due to  $\text{I}_{\text{f}}$   $\text{K}^+$  channels.

Fast-response and slow-response myocytes also have important differences in properties of refractoriness. In fast myocytes,  $\text{Na}^+$  channels are progressively reactivated during phase 3 repolarisation as the membrane potential becomes more negative. When an extra stimulus occurs during phase 3, the magnitude of the resulting inward  $\text{Na}^+$  current and likelihood of impulse propagation depend on the number of reactivated  $\text{Na}^+$  channels. Refractoriness is therefore determined by the voltage-dependent recovery of  $\text{Na}^+$  channels. The absolute refractory period (Figure 18.1) is that minimum time needed for recovery

**Figure 18.1** (a) Action potential in a fast-response, non-pacemaker myocyte: phases 0–4, resting membrane potential  $-80$  mV, absolute refractory period (ARP) and relative refractory period (RRP). (b) Action potential in a slow-response, pacemaker myocyte. The upward slope of phase 4, on reaching threshold potential, results in an action potential.

of sufficient  $\text{Na}^+$  channels for a stimulus to result in impulse propagation. However, once propagation in fast myocytes occurs, conduction velocity is normal. In contrast, slow-response or  $\text{Ca}^{2+}$  channel-dependent myocytes exhibit time-dependent refractoriness. Even after full repolarisation further time is needed before all  $\text{Ca}^{2+}$  channels are reactivated. Stimuli during this period produce reduced  $\text{Ca}^{2+}$  current and the propagation velocity of any resulting impulse is reduced. The conduction velocity independence of premature action potentials with fast-response myocytes is lost in the setting of  $\text{Na}^+$  channel-blocking drugs or ischaemia because they behave increasingly like slow-response myocytes with resulting slowed impulse conduction.

### GENETIC BASIS TO ARRHYTHMIA<sup>1</sup>

In the absence of structural abnormalities of the heart, primary electrical disease is associated with mutations in ion channel genes. The long-QT syndrome (LQTS), short-QT syndrome, Brugada syndrome (idiopathic ventricular fibrillation (VF)) and catecholaminergic polymorphic ventricular tachycardia (VT: causes of sudden cardiac death (SCD) in the young) are examples of primary electrical disease where genetic mutations encoding for ion channel proteins have been characterised. The ion channel basis of congenital LQTS has been verified with the discovery of disease-causing mutations in the *KCNQ1*,

*KCNH2* and *SCN5A* genes that encode for the cardiac delayed rectifier  $\text{K}^+$  ( $\text{I}_{\text{Ks}}$ ,  $\text{I}_{\text{Kr}}$ ) and sodium ( $\text{I}_{\text{Na}}$ ) channels respectively. Single-gene mutations can also give rise to more than one distinct syndrome with mutation of the *SCN5A* gene producing both LQTS and Brugada syndromes. This phenotype complexity is presumably the result of interactions between gene expression and environmental factors or the effect of other modifier genes.

Genetic mutations can result in increased or decreased ion channel function. Mutations to the gene *KCNQ1* encoding for  $\text{I}_{\text{Ks}}$   $\text{K}^+$  channel can result in:

- reduced function, impaired repolarisation and LQTS type 1
- increased function, accelerated repolarisation and short-QT syndrome, which is also associated with SCD

Inheritable forms of structural ventricular disease are associated with atrial arrhythmias and SCD. Examples include hypertrophic and dilated cardiomyopathies and arrhythmogenic right ventricular dysplasia which are linked to mutations in sarcomeric, cytoskeletal and intercellular junction proteins, respectively.

The risk of cardiac arrhythmias and SCD in the setting of acquired structural heart disease such as ischaemic heart disease is in part genetically determined. Studies demonstrate an increased risk of SCD in patients who have a parental history of cardiac arrest.

### MOLECULAR BASIS TO ARRHYTHMIA<sup>1</sup>

Structural and electrical remodelling in response to myocardial injury, altered haemodynamic loads and changes in neurohumoral signalling lead to alterations in:

- ion channel function
- intracellular calcium handling
- intercellular communication
- composition of intercellular matrix

All of these factors lead to heterogeneous slowing of conduction velocity and prolonged refractoriness.

Tachycardic remodelling of the atrium is associated with:

- reduced functional expression of L-type  $\text{Ca}^{2+}$  channels, intracellular  $\text{Ca}^{2+}$  overload and shortening action potential duration

Heart failure is associated with:

- downregulation of each of the major repolarising  $\text{K}^+$  currents, prolonging repolarisation and resulting insusceptibility to early afterdepolarisation (EADs). As these changes are heterogeneous they also create the substrate for re-entrant arrhythmias
- reduced  $\text{Na}^+$  channel density decreasing conduction velocity

- increased expression of  $\text{Na}^+$ - $\text{Ca}^{2+}$  exchanger protein, leading to intracellular  $\text{Ca}^{2+}$  overload and predisposition to delayed afterdepolarisation (DAD)-mediated arrhythmia

Intercellular ion channels or connexins at gap junctions are decreased and redistributed from the intercalated disc to lateral cell borders, slowing conduction velocity and uncoupling myocytes.

Myocardial infarction scar produces:

- heterogeneous action potential duration with zones of healing myocytes with shortened action potential and surrounding hypertrophic myocytes with prolonged action potentials
- potential anatomical circuits due to fibrous tissue separating myocyte bundles

### ARRHYTHMOGENIC MECHANISMS<sup>2-4</sup>

Many factors in isolation or combination give rise to the substrate of arrhythmogenesis (Figure 18.2). Arrhythmia may arise from abnormalities of impulse generation or conduction. Table 18.1 demonstrates the relationship between mechanism and type of arrhythmia, and desired antiarrhythmic effect.

### ABNORMAL IMPULSE GENERATION (TABLE 18.2)

#### ENHANCED NORMAL AUTOMATICITY

Automaticity is the property of spontaneous impulse generation by cardiac fibres. This results from spontaneous depolarisation during phase 4, due to an inward current carried by  $\text{K}^+$  in SA node or subsidiary pacemaker myocytes.

#### ABNORMAL AUTOMATICITY

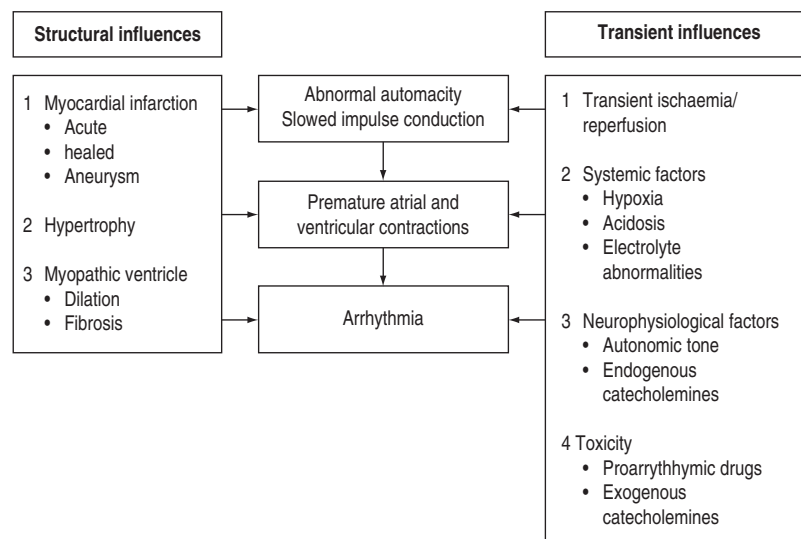

Abnormal automaticity is the mechanism by which spontaneous impulses are generated in fibres that are partially depolarised by a pathological process. This less negative RMP is associated with inactivation of the normal ionic currents of phase 4 depolarisation and the pacemaker potential results from inward  $\text{Na}^+$  and  $\text{Ca}^{2+}$  currents and is not readily susceptible to overdrive suppression from normal pacemaker activity. Due to their less negative membrane potentials, these abnormal automatic fibres inactivate the phase 0 fast inward  $\text{Na}^+$  current, resulting in an impaired rate of impulse conduction (as well as contractility) which further contributes to arrhythmia. In this setting,  $\text{Ca}^{2+}$  carries the major inward current on depolarisation in these fibres.

#### TRIGGERED ACTIVITY

Abnormal impulse generation from triggered activity originates from oscillations in the membrane potential that are initiated or triggered by a preceding action potential. There are two types of oscillations, EAD and DAD. EAD occurs during phase 2 or 3 of the action potential, whereas DAD occurs after the termination of depolarisation. The signal-averaged electrocardiograph (ECG) can detect after-depolarisations.

1. EAD appear as subthreshold humps during the plateau or depolarisation phases. On reaching threshold, single or multiple action potentials can be induced. Plateau EAD are caused by an increased inward  $\text{Ca}^{2+}$  current (at this level of membrane potential, fast inward  $\text{Na}^+$  channels are inactivated) and produce slow rising and propagating action potentials. Phase 3 EAD are caused by a reduction in outward  $\text{K}^+$  currents and produce relatively rapidly rising and propagating action potentials. EAD amplitude and likelihood of triggered arrhythmia increase as driving rate decreases and action potential is prolonged.

Figure 18.2 Factors that combine to form the substrate of arrhythmogenesis.

**Table 18.1** Classification of mechanisms of arrhythmia and desired antiarrhythmic drug action

Mechanism of arrhythmia	Arrhythmia	Antiarrhythmic effect	Representative drugs
<b>Automaticity-enhanced</b>			
Normal	Inappropriate sinus tachycardia	Decrease phase 4 depolarisation	$\beta$ -blocker
Abnormal	Unifocal atrial tachycardia	Hyperpolarise or decrease phase 4 depolarisation	Sodium channel blockers
	Unifocal atrial tachycardia Accelerated idioventricular rhythms VT post myocardial infarction		Calcium or sodium channel blockers $M_2$ agonists
<b>Triggered activity</b>			
Early afterdepolarisation (EAD)	Torsade de pointes	Shorten action potential or suppress EAD	Increase heart rate with $\beta$ -agonists or vagolytic agents, calcium channel blockers, $\beta$ -blockers or magnesium
	Digitalis-induced arrhythmias Some VT		
Delayed afterdepolarisation (DAD)		Decrease calcium overload or suppress DAD	Calcium or sodium channel blockers, $\beta$ -blockers, adenosine
<b>Re-entry: sodium channel-dependent</b>			
Long excitable gap	Afl type 1	Depress conduction and excitability Prolong refractory period	Sodium channel blockers Potassium channel blockers
	Circus movement tachycardia in Wolff–Parkinson–White syndrome (WPW)		
Short excitable gap	Monomorphic VT		
	Afl type 2		
	Atrial fibrillation		
	Circus movement tachycardia in WPW		
	Polymorphic and monomorphic VT		
	Bundle branch re-entry		
	Ventricular fibrillation		
<b>Re-entry: calcium channel-dependent</b>			
	Atrioventricular nodal re-entrant tachycardia	Depress conduction and excitability	Calcium channel blockers
	Circus movement tachycardia in WPW		
	VT		

VT, ventricular tachycardia.

(Modified with permission from Task Force of the Working Group on Arrhythmias of the European Society of Cardiology. The Sicilian gambit: a new approach to the classification of antiarrhythmic drugs based on their actions on arrhythmogenic mechanisms. *Circulation* 1991; **84**: 1831–51.)

Tachyarrhythmias induced by EAD are more likely to occur on the background of a bradycardia.

- DAD are produced by  $\text{Na}^+$ - $\text{Ca}^{2+}$  exchanger current-induced oscillations in inward calcium current. These oscillations are caused by  $[\text{Ca}^{2+}]_i$  overload saturating sarcoplasmic reticulum sequestration mechanisms, thereby leading to  $\text{Ca}^{2+}$ -induced  $\text{Ca}^{2+}$  release. Unlike EAD, DAD depend on previous rapid rhythm for their initiation.

### ABNORMAL IMPULSE CONDUCTION<sup>5</sup>

Abnormal impulse conduction may cause an arrhythmia by the phenomena of re-entry. Re-entry describes the re-excitation of an area or entire heart by a circulating

impulse. Although the classic ‘bifurcating Purkinje fibre’ model of Schmitt and Erlanger has given way to a much more complex picture, the essential electrophysiological requirements for re-entrant excitation remain. Requirements for re-entry are (Figure 18.3):

- conduction block in one limb of the circuit
- slowed conduction in the other limb
- the impulse returns back along the limb initially blocked to re-enter and re-excite the pathway proximal to the block and complete the re-entry pathway

When these properties are present, the chance of a circulating impulse producing re-entrant excitation depends on pathway geometry, the electrical properties and length of the depressed area and conduction velocity within each

**Table 18.2** Causes of abnormal impulse generation

Enhanced normal automaticity	Adrenergic stimulation
Abnormal automaticity	Ischaemia
Early afterdepolarisations	Hypoxia
	Hypercapnia
	Catecholamines
	Class IA antiarrhythmic drugs
	Class III antiarrhythmic drugs
	Other drugs that prolong repolarisation
Delayed afterdepolarisations	Digoxin toxicity
	Increased intracellular $\text{Na}^+$
	Decreased extracellular $\text{K}^+$
	Increased intracellular $\text{Ca}^{2+}$
	Intracellular $\text{Ca}^{2+}$ overload
	Myocardial infarction
	Reperfusion after ischaemia

**Figure 18.3** Re-entrant excitation. (a) Normal cardiac impulse conduction results in the impulse being extinguished. (b) Conduction down one limb is blocked by segment of refractory tissue (excitable gap). (c) The impulse is conducted back up the limb and arrives at the excitable gap which has recovered from refractoriness and retrograde conduction is complete. If geometry and electrical properties are favourable, the excitable gap circulates around the re-entry loop and arrhythmia is initiated.

component. The segment of the re-entry pathway that is initially refractory and therefore blocks conduction down one limb and recovers in time to conduct the return impulse is termed the ‘excitable gap’. Therefore, the generation and subsequent maintenance of a circuit depend on this excitable gap of non-refractory tissue circulating between the advancing depolarising wave front and the repolarising tail. The resulting re-entrant impulse can be self-terminating, causing ectopic beats, or lead to atrial or ventricular tachyarrhythmias.

Risk of re-entry can be further modelled and quantified. Cardiac wavelength ( $\lambda$ ) is the physical distance an electrical impulse travels in one refractory period.  $\lambda$  equals conduction velocity  $\times$  refractory period (or action potential duration). Re-entry is critically dependent on the  $\lambda$  being

shorter than the potential reentrant pathway. If  $\lambda$  exceeds the path length then the advancing impulse encroaches on the refractory tail and re-entry is terminated. Reducing  $\lambda$  (decreasing conduction velocity or refractory period) promotes re-entry circuits.

Re-entry may be terminated by:

- increasing conduction velocity: the excitable gap is abolished by the wave front arriving too early and meeting refractory tissue
- increasing refractory period: the excitable gap is lost
- slowing conduction: a unidirectional block can be converted into a complete block

Ordered re-entry occurs along anatomical pathways which are ‘macroscopic’ loops (macro-re-entry), as in Wolff–Parkinson–White (WPW) syndrome. Functional circuits can be created following myocardial infarction, resulting in VT. ‘Microscopic’ loops (micro-re-entry) occur at the level of single fibres where antegrade and retrograde impulse propagation occurs in parallel fibres. Random re-entry refers to the generation of a circulating impulse, not from a fixed circuit but from constantly changing electrophysiologically distinct fibres or pathways created by the circulating impulse, resulting in atrial fibrillation (AF) or VF.

The cellular properties that lead to impaired conduction include:

- inactivation of the phase 0 fast  $\text{Na}^+$  channels, which reduces both the magnitude and rate of propagation of any resultant action potential
- intercellular uncoupling, which increases resistance to action potential propagation and slows conduction. Intercellular coupling is reduced by ischaemia,  $[\text{Ca}^{2+}]_i$  overload, acidosis and reduced expression of intercellular ion channel connexin proteins in diseases such as chronic heart failure

#### ELECTROPHYSIOLOGICAL EFFECTS OF ISCHAEMIA

Both hypoxia and acidosis are implicated in the production of a less negative RMP in ischaemia. A rise in extracellular  $\text{K}^+$  results from impairment of the adenosine triphosphate (ATP)-dependent  $\text{K}^+$  inward channels. As  $[\text{K}^+]_o/[\text{K}^+]_i$  is the major determinant of the RMP, intracellular  $\text{K}^+$  loss results in a less negative RMP.

The consequences of this are:

- abnormal automaticity
- inactivation of the fast inward  $\text{Na}^+$  channels, which slows the conduction velocity

#### ELECTROLYTE ABNORMALITIES AND ARRHYTHMIA<sup>6</sup>

##### POTASSIUM

Hyper- and hypokalaemia both cause arrhythmia mediated by the resultant changes in RMP (Table 18.3). In ischaemia, hyperkalaemia at the local tissue level caused by a

Table 18.3 Arrhythmogenic effects of potassium disturbance

	Arrhythmogenic effects	Electrocardiogram changes	Arrhythmia
Hyperkalaemia	Less negative RMP Inactivation of fast Na <sup>+</sup> channels Slowed conduction velocity	Peaked T-waves Widening of P-wave and QRS complex	Sinus node suppression Atrioventricular block Ventricular fibrillation
Hypokalaemia	Prolongation of rapid repolarisation Hyperpolarisation of RMP Increased pacemaker activity in Purkinje and ventricular fibres	U-waves ST-segment and T-wave changes	Atrial and ventricular ectopy Atrial and ventricular ectopy tachyarrhythmias

RMP, resting membrane potential.

pathological extracellular shift of K<sup>+</sup> is the major factor contributing to ventricular arrhythmia in this setting. In hypokalaemia, the dispersion of pacemaker activity and the effect on repolarisation are similar to the electrophysiological effects of cardiac glycosides and β-adrenergic agonists, and it is not surprising that a combination of these factors is associated with an increased incidence of arrhythmia. The increased risk of death in hypertensive patients treated with thiazide diuretics has been attributed to hypokalaemic (and possibly hypomagnesaemic)-induced arrhythmia (Multiple Risk Factor Intervention Trial). Thiazide-induced hypokalaemic ventricular ectopy is worsened by exercise.<sup>7</sup> Hypokalaemia is associated with VF and VT following acute myocardial infarction (AMI). The increased incidence of VF/VT with a serum K<sup>+</sup> less than 3.5 mmol/l is clearly established and the probability of VT increases as the serum K<sup>+</sup> decreases. During AMI the incidence of VF/VT was 15% at 4.5 mmol/l, 38% at 3.5 mmol/l, 55% at 3.0 mmol/l and 67% at 2.5 mmol/l.<sup>8</sup>

### MAGNESIUM

The antiarrhythmic properties of Mg<sup>2+</sup> are clearly established but a causal relationship between hypomagnesaemia and arrhythmia is largely circumstantial. Decreased extracellular Mg<sup>2+</sup> by itself has little effect on the electrophysiological properties of myocytes or the ECG. Hypomagnesaemia has been implicated in the genesis of VT/VF in patients with hypertension and heart failure receiving thiazide or loop diuretics, acute alcohol intoxication or withdrawal and possibly with AMI. The product of K<sup>+</sup> and Mg<sup>2+</sup> is the best predictor of arrhythmia in hypertensive patients taking thiazide diuretics.<sup>9</sup>

### AUTONOMIC NERVOUS SYSTEM AND VENTRICULAR ARRHYTHMIA<sup>10</sup>

The autonomic nervous system, particularly vagal tone, has a significant effect on the occurrence of post myocardial infarction VF, as seen by the following:

- High vagal tone is associated with better outcome and less susceptibility to exercise-induced VF with new ischaemia in animal models.

- Post myocardial infarction exercise training results in an increased vagal tone, which inhibits induced VF.
- Implantable electrical vagal stimulation and muscarinic agents, including edrophonium, are protective.
- The protection is not heart rate-related as the protection remains even when atrial pacing is used to maintain the heart rate.
- The administration of atropine increases the likelihood of developing VF.

Vagal tone can be measured by variability in the heart rate (RR interval) or blood pressure rise induced by the pressor agent phenylephrine. Heart rate variability is considered a measure of tonic vagal activity whereas the phenylephrine method is considered a measure of magnitude of the vagal reflex in response to stimulus. A reduced vagal tone has been found postinfarction in humans, which returns to normal over a 3–6-month period. There is no relationship between vagal tone and ejection fraction and the origin of reduced vagal tone postinfarction appears to be due to afferent stimulation in response to necrotic tissue and impaired cardiac contractile geometry. This reduced vagal tone has also been shown to be predictive of mortality and inducibility of arrhythmia at electrophysiological study (EPS).

### PROARRHYTHMIC EFFECTS OF ANTIARRHYTHMIC DRUGS<sup>11,12</sup>

Concomitant proarrhythmia with the use of antiarrhythmic drugs is increasingly recognised. The 'quinidine syncope' due to VF and polymorphic VT at therapeutic concentrations was also seen with disopyramide. The Cardiac Arrhythmia Suppression Trial (CAST) clearly defined the magnitude of this deleterious side-effect in drugs that were previously perceived to be of benefit.<sup>13</sup> This study, which involved flecainide, encainide and morizicine (a class IA drug), was terminated early because of adverse outcome in the flecainide and encainide groups (relative risk of arrhythmic death or non-fatal cardiac arrest of 3.6, 95% confidence interval (CI) 1.7–8.5). Proarrhythmia is reported between 5.9% and 15.8% depending on agent, clinical setting and definition of proarrhythmia, and now considered ubiquitous with all antiarrhythmic drugs.

Proarrhythmia has been defined as an increase in frequency of ventricular ectopic beat (VEB) or aggravation of the target arrhythmia on Holter monitor or exercise test. Manifestations of proarrhythmia not only include VEB, monomorphic and polymorphic VT and VF, but also bradyarrhythmias and Afl with 1:1 AV conduction. Most proarrhythmic events occur soon after starting the drug, but late arrhythmias are also a significant problem.

Proarrhythmia appears to be correlated with the degree of drug-induced QT prolongation or characteristics of sodium channel blockade. Sodium channel blocking agents with a long time constant for recovery of the sodium channel blockade cause more pronounced blockade, even at slow heart rates, slow conduction to a greater extent and are mostly proarrhythmic. Agents with a short time constant of sodium channel blockade, where sodium channel blockade is more pronounced at fast heart rates (e.g. class IB: lidocaine and mexiletine) are less proarrhythmic than drugs with long time constants (e.g. class IC: flecainide and propafenone). Class III drugs and quinidine proarrhythmia correlate with degree of QT prolongation.

The mechanism of drug proarrhythmia is probably via both slowing of conduction and abnormal automaticity. Paradoxically slowing conduction, which may block a re-entry circuit, may also create the very substrate needed for re-entry, unidirectional block and an excitable gap. The existence of a re-entrant circuit requires the circulating wave front of the impulse not to catch up with the refractory tissue behind the tail. Re-entry is more likely to occur with a shorter refractory period and reduced conduction velocity (Figure 18.4).<sup>11</sup>

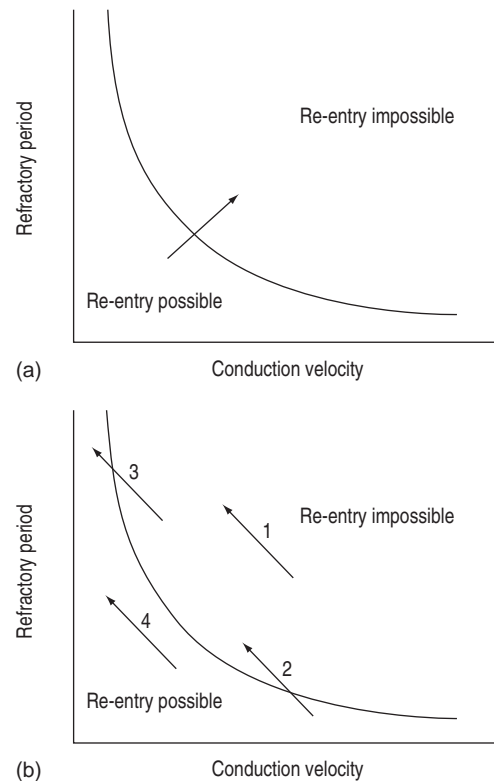

Increasing conduction velocity is an ideal antiarrhythmic property but there are no antiarrhythmic drugs that accelerate conduction. However antiarrhythmic drugs readily slow conduction and the degree of conduction slowing and therefore proarrhythmic tendency correlates with the potency of antiarrhythmic properties.

Prolonging the refractory period is also an ideal antiarrhythmic property, which increases the likelihood of abolishing any excitable gap by ensuring the wave front of a re-entrant circuit meets refractory tissue. The potency of class IA and III antiarrhythmic agents is dependent on the prolongation of the refractory period. This property is also protective against proarrhythmia due to re-entry mechanism. The effect of class IB agents on shortening the refractory period will contribute to proarrhythmia by this mechanism in this class.

Surface mapping of the heart has been used to quantify proarrhythmic effect. The scale of potency of proarrhythmia has been found to be:

flecainide > propafenone > quinidine > disopyramide > procainamide > mexiletine > lidocaine > sotalol<sup>11</sup>

Amiodarone was not included in this study but presumably its proarrhythmic potential is similar to other class III agents and less than the class I agents.

**Figure 18.4** (a) Graph of refractory period of an excitable gap versus its conduction velocity around a theoretical re-entrant circuit. When conduction velocity is high enough so that refractory period of excitable gap exceeds circuit time, re-entry is impossible. Arrow demonstrates the action of an 'ideal' antiarrhythmic drug, which prolongs refractory period and increases conduction velocity. (b) With antiarrhythmic drugs that increase refractory period and slow conduction, the net effect of an antiarrhythmic drug may have no effect on proarrhythmia (arrows 1 and 4), decrease proarrhythmia (arrow 2) or increase proarrhythmia (arrow 3) depending on properties of a potential re-entrant circuit. (Adapted from Schwartz PJ, La Rovere MT, Vanoli E. Autonomic nervous system and sudden cardiac death. *Circulation* 1992; **85** (suppl. 1): 77–91 with permission.)

Antiarrhythmic drugs are effective at suppressing abnormal automaticity, with the exception of triggered automaticity due to EAD. Class IA, class III and many non-antiarrhythmic drugs can produce proarrhythmia via EAD. These drugs increase not only the frequency of EAD, but also the likelihood of them leading to triggered tachyarrhythmias. Slowing repolarisation, which leads to QT prolongation and slower heart rate, is central to this increased frequency and sensitivity to EAD. EAD manifests as prominent and bizarre T-U waves on the ECG and, if triggered activity results, VEB and ventricular tachyarrhythmias may occur. Torsade de pointes is the classical resulting arrhythmia, although less classical

**Table 18.4** Factors facilitating antiarrhythmic drug proarrhythmia

Toxic blood levels due to excessive dose or reduced clearance from old age, heart failure, renal disease or hepatic disease
Severe left ventricular dysfunction. Ejection fraction less than 35%
Pre-existing arrhythmia or arrhythmia substrate
Digoxin therapy
Hypokalaemia or hypomagnesaemia
Bradycardia
Combinations of antiarrhythmic drugs and concomitant drugs with similar toxicity

(Adapted from Campbell TJ. Proarrhythmic actions of antiarrhythmic drugs: a review. *Aust NZ J Med* 1990; **20**: 275–82, with permission.)

polymorphic VT and VF result. Risk of proarrhythmia via this mechanism correlates with the degree of QT prolongation.

All antiarrhythmic drugs are capable of producing bradyarrhythmias via decreasing normal automaticity and slowing conduction. Digoxin can be proarrhythmic via the production of triggered activity due to DAD.

Antiarrhythmic drug proarrhythmia is facilitated by several factors, which are frequently found in patients on antiarrhythmic drugs or with heart disease (Table 18.4).

## MANAGEMENT OF THE PATIENT WITH A CARDIAC ARRHYTHMIA

### HISTORY AND PHYSICAL EXAMINATION

A careful history is important. Specific questions should confirm or exclude palpitations, syncope, chest pain, shortness of breath, ischaemic heart disease (especially previous myocardial infarction), congestive cardiac failure, valvular heart disease, thyrotoxicosis and diuretic therapy without adequate potassium supplements. A family history is helpful for arrhythmias associated with inherited disorders (e.g. LQTS and hypertrophic obstructive cardiomyopathy). The physical examination looks for underlying structural heart disease and signs to assist diagnosis, and assesses haemodynamic consequences of the arrhythmia.

### VAGAL MANOEUVRES

Vagal manoeuvres may be undertaken during examination. These reflexly increase vagal tone, thereby prolonging AV node conduction and refractoriness. The effect may be:

- transient slowing of sinus tachycardia as SA nodal discharge rate is slowed
- termination of AV nodal re-entry tachycardia (AVNRT) and AV re-entry tachycardias (AVRT)
- unmasking (but not reversion) of atrial tachycardia, flutter (Figure 18.5) and fibrillation.

VT is not affected. Carotid sinus massage is most commonly used. Valsalva manoeuvre or iced water to the face may be useful. Eyeball pressure should be avoided as eye damage may result. Carotid sinus massage is performed with the patient supine, with head extended and turned away from the side to be massaged. After auscultation to exclude carotid bruits, the carotid bifurcation is gently palpated by placing two fingers anterior to the sternocleidomastoid muscle, just below the angle of the jaw. Massage is applied one side at a time, and never both sides simultaneously. It is contraindicated in those with known or suspected cerebrovascular disease.

### INVESTIGATIONS

A 12-lead ECG should be recorded with a longer rhythm strip (usually lead II or V<sub>1</sub>). If P-waves are not visible, atrial activity may be recorded using an oesophageal electrode or pacing lead, or via a central venous catheter or the right atrial injectate port of a pulmonary artery catheter, using 20% saline and a bedside monitor.<sup>14</sup>

Holter monitoring requires prolonged (usually 24–72 h), non-invasive, ambulatory ECG monitoring, sometimes combined with exercise testing.

EPS, which involves invasive electrophysiological testing with programmed electrical stimulation, attempts to reproduce the spontaneously occurring arrhythmia.<sup>15,16</sup> EPS is not clearly superior to Holter monitoring in evaluating drug treatment for ventricular arrhythmias.

Other investigative techniques being studied include signal-averaged ECG, heart rate variability and electrical alternans measurement.<sup>10,17</sup>

**Figure 18.5** Atrial flutter with 2:1 atrioventricular (AV) block. Carotid sinus massage (CSM) increases AV block to 4:1 then 6:1.

### MANAGEMENT OF SPECIFIC ARRHYTHMIAS

Treatment has two aspects: acute termination of the arrhythmia and long-term prophylaxis. The decision whether to treat depends on the rhythm diagnosis, haemodynamic consequences, aetiology of the arrhythmia and the prognosis (e.g. risks of sudden death or long-term complications).

### ECTOPIC BEATS

These are premature impulses originating from the atria, AV junction or ventricles. The coupling interval (time between the ectopic and the preceding beat) is shorter than the cycle duration of the dominant rhythm.

### PREMATURE VENTRICULAR ECTOPIC BEATS

These are also known as ventricular premature beats and ventricular premature complexes. The ventricle is not normally activated via the rapidly conducting bundle branches, and a wide QRS complex results from slow ventricular conduction.

### ECG

There is no preceding P-wave.

- Premature complexes occur before the next expected QRS
- QRS is wide ( $> 120$  ms)
- T-wave of opposite polarity to the QRS (Figure 18.6)
- VEB is not conducted retrogradely to the SA node.
- SA node is therefore not reset, and there is temporary AV dissociation with a full compensatory pause; the interval between the normal QRS complexes on either side of the VEB will usually be twice that of the dominant sinus rhythm.

Occasionally VEB may not produce any pause, and are said to be interpolated (see Figure 18.6). Interpolated VEB occur when the background sinus rhythm is slow. The retrograde conduction into the AV node renders it partially refractory to the next impulse and its conduction through the AV node is slowed and the PR interval is prolonged. A VEB following each sinus beat is ventricular bigeminy (Figure 18.7). Ventricular trigeminy refers to recurring sequences of a VEB followed by two sinus beats. Two VEB in succession are a couplet (Figure 18.8), and three, a triplet.

**Figure 18.6** Sinus rhythm with an interpolated ventricular ectopic beat (VEB) without a compensatory pause and a VEB with a following non-conducted P-wave, resulting in a compensatory pause.

**Figure 18.7** Sinus rhythm with ventricular bigeminy.

**Figure 18.8** Atrial fibrillation with a ventricular couplet.

**CLINICAL**

Even when frequent, complex, or in short runs of non-sustained VT, VEB are not associated with risk of sudden death in asymptomatic healthy adults.<sup>18</sup> However, there is increased risk of cardiovascular death with:

- exercise-induced VEB: risk of death 2.53 (95% CI 1.65–3.88)<sup>19</sup>
- AMI and VEB. Frequent and complex VEB often precede VF or sustained VT and are a marker of risk of subsequent SCD

Apart from ischaemic heart disease, VEB may be associated with cardiomyopathy, valvular disease, myocarditis and non-cardiac precipitating factors (e.g. electrolyte and acid-base disturbances, hypoxia and drugs such as digoxin).

**TREATMENT**

Drug treatment of VEB is rarely indicated and may be dangerous.

- Correct potassium and magnesium.
- Severely symptomatic patients with frequent complex VEB may benefit from judicious  $\beta$ -blockade.
- The underlying cause of VEB is often more clinically relevant than the arrhythmia. Following myocardial infarction,  $\beta$ -adrenergic blockers, which are indicated for long-term benefit, will also likely suppress VEB.
- Prophylactic lidocaine following AMI will increase total mortality and has been abandoned.<sup>20,21</sup>
- Attempts at long-term VEB suppression with class IC agents (flecainide and encainide), even if successful, increase mortality.<sup>13</sup>

### SUPRAVENTRICULAR TACHYCARDIAS<sup>22,23</sup> (TABLE 18.5)

Supraventricular tachycardias (SVT) are any tachycardias that require atrial or AV nodal tissue for their initiation and maintenance.

- SVT are usually conducted rapidly through the bundle branches so that QRS complexes are narrow.
- All narrow-complex tachycardias are SVT and wide-complex tachycardias are usually ventricular.
- However, SVT may be wide-complex in the setting of bundle branch block (BBB) and pre-excitation.

A clinically useful classification divides SVT into AV node-dependent and AV node-independent.

Distinguishing between AV node-dependent and independent SVTs can be difficult. Vagal manoeuvres or drugs that prolong AV nodal refractoriness (e.g. adenosine) may assist in diagnosis:

- Temporary AV block with unchanged atrial rate indicates AV node independence.
- Slowing or reversion of the tachycardia diagnoses AV dependence.

**Table 18.5** Classification of supraventricular tachycardias

**Atrioventricular (AV) node-dependent**

AV nodal re-entry tachycardia: re-entry within the AV node  
 AV re-entry tachycardia: re-entry includes accessory pathway between atria and ventricles  
 Accelerated idionodal rhythm: increased automaticity of AV nodea

**AV node-independent**

Atrial flutter: re-entry confined to atria  
 Atrial fibrillation: multiple re-entry circuits confined to atria  
 Unifocal atrial tachycardia: usually due to increased automaticity  
 Multifocal atrial tachycardia: increased automaticity or triggered activity  
 Others: sinus node re-entry tachycardia

**AV NODE-DEPENDENT SVT**

In these SVT, sometimes referred to as junctional tachycardias, the re-entry circuit or ectopic focus involves the AV node or junction. Blocking the AV node with drugs such as adenosine or vagal manoeuvres will terminate these SVT.

**AV NODE-INDEPENDENT SVT**

Also referred to as atrial tachycardias, the atrial tissue only is required for the initiation and maintenance of the tachycardia. Blocking the AV node will not terminate these SVT; it will merely slow ventricular rate.

### AV NODAL RE-ENTRY TACHYCARDIA (AVNRT) (FIGURE 18.9)

Re-entry tachycardia is confined to the AV node. Antegrade conduction to the ventricles usually occurs over the slow pathway and retrograde conduction over the fast pathway.

**ECG**

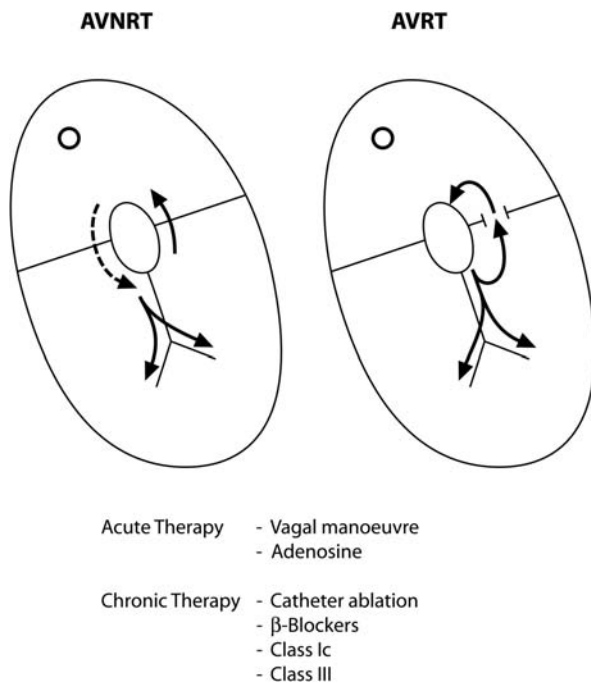

There is regular narrow-complex tachycardia (140–220 beats/min) with abrupt onset and termination. P-waves are not usually observed as they are buried in the QRS complexes (Figure 18.10).

**CLINICAL**

AVNRT is a common arrhythmia that is not usually associated with structural heart disease. The major symptom is palpitations.

**TREATMENT**

Vagal manoeuvres slow conduction through the AV node and may 'break' the tachycardia. If carotid sinus massage fails, adenosine is the drug of choice and nearly all AVNRT will revert with adenosine.<sup>24,25</sup> Verapamil has been used in the past, but causes hypotension, which may be prolonged if cardiac function is depressed or patients are receiving  $\beta$ -adrenergic blockers. Sotalol,

**Figure 18.9** Arteriovenous nodal re-entry tachycardia (AVNRT) has both pathways in the AV node. The conduction occurs over the slow pathway and retrogradely over the fast pathway. AV re-entry tachycardia (AVRT) involves antegrade conduction through the AV node and retrograde conduction through an accessory pathway.

amiodarone and flecainide may also be effective but are rarely used. Rapid atrial pacing will usually terminate AVNRT but is rarely needed.

Cardioversion is occasionally necessary when drugs are ineffective or when severe haemodynamic instability is present.

**Figure 18.10** Arteriovenous nodal re-entry tachycardia (AVNRT). Narrow QRS tachycardia at 160 beats/min. P-waves are not apparent and are buried in the QRS complex.

### PREVENTION

Troublesome recurring episodes of AVNRT can be cured by radiofrequency ablation, using a transvenous catheter to interrupt the re-entrant circuit permanently.<sup>26</sup>

### AV RE-ENTRY TACHYCARDIA (SEE FIGURE 18.9)

The re-entry pathway consists of the AV node and an accessory pathway, which bypasses the AV node. The accessory pathway may be evident during sinus rhythm, with the ECG showing pre-excitation: short PR interval, delta wave and widening of the QRS (see WPW, below, under pre-excitation syndrome). However, in 25% of cases, the accessory pathway conducts only retrogradely from ventricle to atria and the ECG pre-excitation will be concealed in sinus rhythm. Orthodromic AVRT, with antegrade nodal and retrograde accessory pathway circuit, is the most common regular SVT in patients with accessory pathway.

### ECG

The ECG is similar to AVNRT. The length of the re-entry circuit is however greater, and the accessory AV pathway is some distance from the AV node. It therefore takes longer for the impulse to be conducted backwards to the atria, and so the retrograde P-wave usually occurs after the QRS, sometimes at some distance, and is inverted in leads II, III and aVF (Figure 18.11 and 18.12).

### CLINICAL

AVRT is similar to AVNRT, although antegrade conduction over the accessory pathway may be very rapid with WPW, if AF occurs.

### TREATMENT<sup>24,25</sup>

Acute treatment is identical to AVNRT, but verapamil should be avoided in WPW syndrome, as it may block the AV node, facilitating very rapid conduction to the ventricles via the accessory pathway.<sup>27</sup>

**Figure 18.11** Arteriovenous re-entry tachycardia (AVRT). Narrow QRS tachycardia at 135 beats/min. Inverted P-wave in leads I, II, III and aVF just following the QRS complex.

**Figure 18.12** Arteriovenous re-entry tachycardia (AVRT). Rate is 214 beats/min. P-wave deflection is just seen on the upslope of the T-wave in lead V<sub>1</sub>.

#### PREVENTION

Drugs such as sotalol and flecainide may prevent recurrence of the tachycardia. Radiofrequency ablation of the accessory pathway is usually curative.<sup>26</sup>

#### ACCELERATED IDIONODAL RHYTHM

Increased automaticity of the AV junction (above the inherent discharge rate of 40–60 beats/min) is the usual cause of this arrhythmia. The often-used term ‘non-paroxysmal AV junctional tachycardia’ is cumbersome

and misleading: junctional rate is commonly 60–100 beats/min, not strictly a tachycardia. AV dissociation is often present, but there may be synchronisation of the two pacemakers – so-called isorhythmic dissociation.

#### ECG

There are narrow complexes on the ECG at a regular rate (60–130 beats/min) (Figure 18.13), often with independent atrial activity. With isorhythmic dissociation, P-wave is either fixed relative to the QRS complex (usually just after) or oscillates to and fro across the QRS in a rhythmical manner.

**Figure 18.13** Accelerated idionodal rhythm: 105 beats/min. Inverted P-wave is immediately following the QRS complex in leads II, III and aVF.

#### CLINICAL

It may be observed in normal persons, but is often associated with structural heart disease, especially following inferior myocardial infarction. Digoxin intoxication is another important cause.

#### TREATMENT

In most cases, the rhythm is transient and well tolerated, and no treatment is required. Treatment is otherwise directed towards the underlying cause.

#### UNIFOCAL ATRIAL TACHYCARDIA

This is sometimes called ectopic atrial tachycardia to distinguish it from the atrial tachycardias (referring collectively

to unifocal atrial tachycardia, Afl and AF). However, it is inappropriate to call atrial tachycardia paroxysmal atrial tachycardia. Paroxysmal, by definition, indicates an abrupt onset and termination, which applies less commonly to unifocal atrial tachycardia. Vagal manoeuvres will not terminate this arrhythmia, but AV block may be induced, or increased if already present.

#### ECG

P-wave morphology is abnormal but monomorphic. Atrial rate is often 130–160 beats/min, and may occasionally exceed 200 beats/min. Atrial rate distinguishes unifocal atrial tachycardia from atrial flutter (Afl), with Afl greater than 250 beats/min. The QRS complexes will usually be narrow (Figure 18.14). AV block is common (Figure 18.15).

**Figure 18.14** Unifocal atrial tachycardia with 1:1 arteriovenous conduction; rate is 140 beats/min. Large, inverted P-waves are seen in lead II.

**Figure 18.15** Unifocal atrial tachycardia with 2:1 arteriovenous conduction. Atrial rate is 170 beats/min.

#### CLINICAL

Digitalis intoxication is the most common cause, especially when AV block is present. Other causes include myocardial infarction, chronic lung disease and metabolic disturbances.

#### TREATMENT<sup>25</sup>

If applicable, digitalis is stopped and the toxicity treated. Otherwise digoxin may be used to control the ventricular rate.  $\beta$ -Adrenergic blockers or amiodarone are alternatives. Rapid atrial pacing may be ineffective if the arrhythmia is due to increased automaticity, although it may increase AV block, thereby slowing ventricular rate. Synchronised DC shock may be necessary, but is avoided if digitalis intoxication is suspected.

#### MULTIFOCAL ATRIAL TACHYCARDIA<sup>28</sup>

Multifocal atrial tachycardia (MAT) is defined as an atrial rhythm, with a rate greater than 100 beats/min, with organised, discrete non-sinus P-waves having at least three different forms in the same ECG trace. The baseline between P-waves is isoelectric, and the PP, PR and RR intervals are irregular. This is an uncommon arrhythmia, also known as chaotic or mixed atrial tachycardia.

#### ECG

There are irregular atrial rates, usually 100–130 beats/min, with varying P-wave morphology (at least three different P-wave morphologies and varying PR interval) and some degree of AV block (Figure 18.16). Most P-waves are conducted to the ventricles, usually with narrow QRS complexes.

#### CLINICAL

MAT is often misdiagnosed and inappropriately treated as AF. This rhythm occurs most commonly in critically ill elderly patients with chronic lung disease and often cor pulmonale, and is associated with a very high mortality from underlying disease. Theophylline has been implicated as a precipitating cause, and rarely digoxin.

**Figure 18.16** Multifocal atrial tachycardia with the rate about 130 beats/min. There is varying P-wave morphology and PR intervals. Note the wide complex preceded by a P-wave. The aberrant intraventricular conduction is related to the long-short cycle length sequence.

**TREATMENT**

Treatment should correct the underlying cause (e.g. treatment of cardiorespiratory failure, electrolyte and acid–base abnormalities and theophylline toxicity). Spontaneous reversion is common, and few patients require antiarrhythmic therapy. Magnesium is the drug of choice for acute control.<sup>29</sup>  $\beta$ -Blockers are probably more effective than diltiazem, but because of the common association of MAT with obstructive lung disease have limited utility.<sup>30</sup> Digoxin and cardioversion are ineffective, which highlights the need to differentiate MAT from AF. Longer-term control is best achieved with diltiazem in patients with good left ventricular (LV) function and amiodarone in those without.

**ATRIAL FLUTTER<sup>31</sup>**

Atrial rate during classical Afl is 250–350 beats/min, and in most cases, close to 300 beats/min. Afl is due to a single re-entry circuit lying within the right atrium and the wave of depolarisation in most patients is anticlockwise. If the right atrium is significantly enlarged the rate may be considerably slower. Studies in patients who had recently undergone cardiac surgery subdivided Afl into type I and II on the basis of rate and typical responses to atrial pacing.

Type I flutter was slower – rate 240–320 beats/min – and was readily entrained with overdrive pacing. Type II flutter was faster than type I, with rates of 340–430 beats/min. Type II flutter could not be entrained or terminated by pacing. Type II is thought to arise from a circus pathway with a very short excitable gap.

**Figure 18.17** Atrial flutter with 2:1 arteriovenous conduction. Atrial rate is 270 beats/min (arrows  $V_1$ ) and ventricular 135 beats/min. Characteristic ‘sawtooth’ inverted flutter waves are evident in leads II, III and aVF.

**Figure 18.18** Atrial flutter with 2:1 arteriovenous (AV) conduction. Inverted flutter waves are difficult to differentiate from T-waves. Rate of 144 beats/min confirms atrial flutter with 2:1 AV conduction.

**ECG**

Afl waves (characteristic sawtooth appearance with no isoelectric baseline) are best seen in  $V_1$  (Figure 18.17) or aVF, but leads II and III may also be useful. The flutter waves are usually negative in aVF. Rapid QRS waves may obscure typical flutter waves, and vagal manoeuvres may unmask them (see Figure 18.5). AV conduction block (usually 2:1) is usually present, so that alternate flutter waves are conducted to the ventricles, with a ventricular rate close to 150 beats/min. Frequently flutter waves are not obvious and a ventricular rate of 150 beats/min leads to the presumption of Afl (Figure 18.18). Type II Afl results in greater atrial and ventricular rates (Figure 18.19). Treatment with drugs that affect AV node conduction may lead to higher degrees of AV block (Figure 18.20) and/or variable AV block with irregular QRS duration. Rarely, Afl with 1:1 conduction occurs. This is usually associated with sympathetic overactivity or class I antiarrhythmic drugs (which slow atrial discharge rate to 200 beats/min, thereby allowing each atrial impulse to be conducted) (Figure 18.21). QRS complexes are usually narrow, as conduction through the bundle branches is normal.

**CLINICAL**

AFL is less common than AF. It may occur in ischaemic heart disease, cardiomyopathy, rheumatic heart disease and thyrotoxicosis, and after cardiac surgery.

**TREATMENT<sup>25</sup>**

No drug will reliably terminate Afl, although ibutilide and dofetilide have been shown to be most likely to result in

**Figure 18.19** Atrial flutter with 2:1 arteriovenous conduction. Type II atrial flutter is confirmed by the rapid atrial rate of 380 beats/min.

pharmacological reversion. Attempts at slowing ventricular rate by drugs that will increase the degree of AV block are worthwhile in the first instance. Drugs such as digoxin, diltiazem,  $\beta$ -adrenergic blockers, sotalol and amiodarone may be tried; the choice depends on LV function. Flecainide and procainamide may occasionally be effective at terminating Afl. However, class IA and IC drugs may lead to 1:1 AV conduction. Class I drugs should probably be avoided unless ventricular response has been slowed with calcium channel or  $\beta$ -adrenergic blocking drugs.

Synchronised DC cardioversion, often with low energies (25–50 J), is a reliable treatment option. Rapid atrial pacing faster than the flutter rate will terminate classical or type I Afl in most patients.

Anticoagulation guidelines are the same as that for AF, although there are less supporting data.

### PREVENTION

Prevention is difficult. Drugs used include sotalol and amiodarone at low doses. Class IC agents (e.g. flecainide) may be used in patients without significant structural heart disease. Increasingly recurrent or refractory Afl may be cured by radiofrequency ablation to create a linear lesion between the inferior tricuspid annulus and the eustachian ridge at the anterior margin of the inferior vena cava to interrupt the re-entry circuit.<sup>26</sup>

### ATRIAL FIBRILLATION<sup>32</sup>

AF is the most common arrhythmia requiring treatment and/or hospital admission. The incidence increases with age: 5% of individuals over 70 years have this arrhythmia. There is also an age-independent increase in frequency due to increase in obesity and obstructive sleep apnoea. LV dysfunction increases risk of AF (4.5-fold in men and 5.9 in women) with atrial stretch and fibrosis causing electrical and atrial ionic channel remodelling.

AF is common in:

- congestive cardiac failure (40%)
- coronary artery bypass grafting (25–50%)
- critically ill patients (15%)

Idiopathic or lone AF (i.e. with no structural heart disease or precipitating factor) in someone aged under 60 years has an excellent prognosis; however, AF developing after cardiac surgery, for instance, is associated with increased stroke, life-threatening arrhythmias and longer hospital stays.

### ECG

Atrial activity is chaotic with rapid (350–600 beats/min) and irregular depolarisations varying in amplitude and

**Figure 18.20** Atrial flutter varying between 3:1 and 4:1 arteriovenous (AV) conduction due to drug effect slowing AV node conduction.

**Figure 18.21** Atrial flutter with 1:1 conduction with a rate of 240 beats/min. Up-sloping of ST segment is easily mistaken as part of the QRS complex, giving the appearance of a broad QRS tachycardia in some leads. Lead III shows true narrow width of QRS complex.

**Figure 18.22** Atrial fibrillation. Irregular fibrillation waves with varying amplitude and morphology.

**Figure 18.23** Atrial fibrillation with rapid ventricular rate. Ventricular irregularity and fibrillation waves are less evident when the rate is rapid.

morphology (fibrillation waves). Ventricular response is irregularly irregular (Figure 18.22). Most atrial impulses are not conducted to the ventricles, resulting in an untreated ventricular rate of 100–180 beats/min. QRS complexes will usually be narrow. When the ventricular rate is very rapid or very slow, ventricular irregularity may be missed (Figure 18.23).

#### CLINICAL

AF is more common in patients with underlying heart disease (particularly those with a dilated left atrium) and abnormal atrial electrophysiology. Causes include ischaemic and valvular heart disease, pericarditis, hypertension, cardiac failure, thyrotoxicosis and alcohol abuse. AF may also occur after cardiac surgery and thoracotomy. AF can be chronic, or intermittent with paroxysmal attacks. Chronic AF has a poorer prognosis.

AF is associated with:

- adverse haemodynamic effects. Rapid ventricular rate and loss of atrial systole may increase pulmonary capillary wedge pressure, while stroke volume and cardiac output decline
- systemic embolism and stroke
- tachycardiomyopathy. Reversible global cardiomyopathy secondary to rapid heart rate. Assessing LV function with echocardiogram before and after AV node ablation for AF refractory to medical therapy suggests that 10% of patients with AF have AF-induced tachycardiomyopathy<sup>33</sup>

#### TREATMENT<sup>25,34,35</sup>

The goals of treatment include ventricular rate control, anticoagulation where appropriate and conversion to sinus rhythm. There is increasing evidence available on the 'rate versus rhythm' control debate. Results from several recent major studies have challenged the previous belief that achievement of sinus rhythm is important in the long term (Table 18.6). When comparing control of ventricular rate versus reversion to sinus rhythm no clear survival benefit is

apparent. However composite end-points of death, stroke and recurrent hospitalisation favour rate control only.<sup>36–39</sup>

The possible reasons why rhythm control has not been shown to be superior include:

- Trials have included predominantly elderly high-risk patients.
- Sinus rhythm is difficult to achieve (39–63%).
- Rate control strategies can result in sinus rhythm in up to 35% of patients.
- Underlying heart disease that initiates the AF persists.
- There may be antiarrhythmic drug side-effects.
- Anticoagulation is still required even if rhythm control is successful.

However rhythm control (if possible) appears superior in patients with LV dysfunction, with both amiodarone and dofetilide reducing mortality when sinus rhythm is achieved.<sup>40,41</sup> The paucity of data in younger patients (less than 60 years) favours initial attempts at rhythm control, particularly in those with structurally normal hearts, in the hope that progressive atrial electrical and anatomical remodelling is prevented.

#### RECENT ONSET OR PAROXYSMAL AF

##### VENTRICULAR RATE CONTROL

The urgency of ventricular rate control depends on the clinical situation and spontaneous reversion of AF is common. Treatment may not be necessary, and a reasonable strategy is based on clinical status:

- Haemodynamically unstable with rapid ventricular rate requires immediate synchronised DC shock (in addition to drug therapy) to control rate urgently.
- Haemodynamically stable, symptomatic with depressed LV function: semiurgent synchronised DC shock or drug therapy, digoxin or amiodarone to control ventricular rate.
- Haemodynamically stable, symptomatic, normal LV function: control of ventricular response with

Table 18.6 Atrial fibrillation rate versus rhythm control debate

β-adrenergic blockers, diltiazem, digoxin (poor control with exertion and settings with increased sympathetic tone), magnesium (short-term), amiodarone or sotalol.

- Haemodynamically stable, with no structural heart disease and minimal or no symptoms: no immediate treatment is an option. Most cases will revert spontaneously within 24 h. Single-dose flecainide for paroxysmal AF has been recommended (contraindicated in patients with structural heart disease).<sup>42</sup>

Ideal rate control can be defined as a resting heart rate of 80 beats/min, peak rate of 110 beats/min with 6-minute walk and an average of 100 beats/min.

### CONVERSION TO SINUS RHYTHM

Antiarrhythmic drugs or DC shock cardioversion can be used. The likelihood of short- and long-term success depends on the clinical situation. Conversion to sinus rhythm is more important in young patients and those with heart failure. Maintenance of sinus rhythm is

problematic: sinus rhythm at 1 year is 60% with amiodarone and 40% with sotalol, and associated with significant drug cardiac and extracardiac toxicities. The risk of stroke and need for antithrombotic therapy due to frequent AF recurrences, which may be asymptomatic, remain. Achieving sinus rhythm (especially greater than 60 years) is less important than previously thought.<sup>36</sup>

### DC SHOCK CARADIOVERSION

DC shock cardioversion is indicated either before 24–48 h or after appropriate anticoagulation protocol. Combining DC shock with antiarrhythmic drugs to promote maintenance of sinus rhythm is favoured, especially if risk factors for relapse exist. Cardioversion is less likely to be successful if:

- AF has been present for over 1 year
- left atrial size is greater than 45 mm
- untreated conditions are present, e.g. thyrotoxicosis, valvular heart disease and heart failure

Critically ill patients who are septic, postoperative or on drugs such as catecholamines are likely to relapse.

#### ANTICOAGULATION AND CARDIOVERSION<sup>43,44</sup>

Loss of atrial contraction with AF is associated with stasis of blood flow and formation of blood clots in the left atrium, particularly the atrial appendage. Reversion to sinus rhythm and return of more effective atrial contraction may cause expulsion of any atrial clots and systemic emboli. Once AF has been present for more than 48 h – some authors stipulate 24 h – the risk of systemic emboli is significant and anticoagulation is required prior to DC shock cardioversion. The current recommended period of anticoagulation prior to DC shock cardioversion is 3 weeks. This 3-week period can be shortened to 1 day for heparin and 5 days for warfarin if the left atrium can be demonstrated free of clot using transoesophageal echocardiography. With this accelerated approach heparin dose should be titrated to an activated partial thromboplastin time 2–3 times control or warfarin to produce an international normalised ratio (INR) of 2.0–3.0. In many clinical situations such as recent surgery or other bleeding risks, anticoagulation is contraindicated and elective cardioversion should be delayed until recommended anticoagulation cover is safe. Following successful cardioversion to sinus rhythm the risk of systemic embolism continues as the propensity to form atrial clot remains due to atrial contractile stunning and anticoagulation should be continued for 4–6 weeks.

#### ANTIARRHYTHMIC DRUGS

The drugs used for ventricular rate control – digoxin, diltiazem and  $\beta$ -adrenergic blockers – are unlikely to result in pharmacological cardioversion.

Antiarrhythmic drugs that may cardiovert are unfortunately relatively ineffective and may possibly be dangerous. They are more effective at retaining sinus rhythm. About 50% will remain in sinus rhythm 1 year after cardioversion with drugs and 25% without drugs.

Quinidine is more effective than placebo, but increases mortality through proarrhythmia (generally class IA and IC antiarrhythmic drugs are contraindicated). Ibutilide and dofetilide are newer antiarrhythmic drugs with particular success at pharmacological cardioversion. Pretreatment with ibutilide increased DC shock cardioversion from 72% for placebo to 100%. In placebo failures, crossover to ibutilide resulted in a 100% success rate with subsequent cardioversion. Ibutilide also resulted in reduction in DC shock energy required from  $228 \pm 93$  J to  $166 \pm 80$  J. However, ibutilide was associated with a 3% incidence of sustained polymorphous VT.<sup>45</sup> Dofetilide appears to cardiovert AF and Afl pharmacologically in about a third of patients (intravenous (IV) better than oral, recent onset better than prolonged and Afl may be more responsive than AF). Dofetilide is far superior to placebo and sotalol, with similar recurrence rates to amiodarone.<sup>46</sup>

Other drugs currently used to promote onset of sinus rhythm and prevent AF relapse include amiodarone, sotalol, procainamide, flecainide and propafenone. Amiodarone was found to be superior in preventing AF recurrence with a recurrence rate of 35% compared to a recurrence rate of 63% for sotalol and propafenone.<sup>47</sup>

The factors dictating choice are:

- degree of LV depression: amiodarone has the least and flecainide the greatest
- risk of proarrhythmia: worse with flecainide and propafenone
- long term side-effect profile: amiodarone is the worst

When using amiodarone for prevention of AF recurrence there was an 18% incidence of adverse effects versus 11% for sotalol and propafenone.<sup>47</sup>

#### ATRIAL FIBRILLATION ABLATION THERAPY

Ablation techniques for AF have been continuously refined since the original Maze III surgical procedure which involved numerous atrial incisions to form a maze-like pattern of scarring, blocking propagation of arrhythmia. The utility of this procedure was limited because it was surgical, with longer bypass times, post-operative bleeding and impaired atrial contractility. The magnitude of this original procedure was based on the belief that the entire atrium was involved in the initiation and maintenance of the fibrillatory conduction. This may be true for long-standing AF but paroxysmal AF appears to originate primarily at the junction of the left atrium and pulmonary veins. AF in 94% of patients is initiated by rapid discharges from one or more foci at or near the pulmonary vein orifices.<sup>48</sup> Atrial tissue in this area has heterogeneous electrophysiological properties and there is also clustering of vagal inputs, which creates substrate for rapid discharges that initiate microre-entrant circuits or 'rotors'. These high-frequency periodic rotors send spiral wave fronts of activation into surrounding atria. Localised ablation of a single dominant foci and rotor is inadequate as there are usually multiple foci.

There is renewed interest in surgical AF ablation therapy in conjunction with cardiac surgery. Complications have been reduced with energy (cryotherapy, radiofrequency) rather than incisions and the extent of lesions reduced. The minimum lesion set is now considered to be encirclement of pulmonary veins, linear lesion from the inferior pulmonary vein to mitral annulus and from the coronary sinus to the inferior vena cava.

Left atrial catheter (transatrial septum) AF ablation isolating all four pulmonary veins using radiofrequency is being heralded as the possible AF cure. Results are improving as all pulmonary veins are now isolated and the encircling lesion is clear of the pulmonary vein antrum (reducing pulmonary vein stenosis). Success rates of 81% (75–88%) free of AF and off drugs are reported. Success appears long-term as recurrence

occurs early. A further 10–20% may become responsive to antiarrhythmic drugs which were previously ineffective. Repeating the procedure can increase success to >90% with failure only in patients found to have extensive atrial scarring (predicting and excluding patients with this extensive atrial scarring is a major future challenge). Although not yet the universal cure the results are two- to threefold better than antiarrhythmic drugs alone.

Complication rates are also falling associated with:

- intracardiac echocardiography ensuring safer transeptal puncture and positioning of isolating lesions clear of the pulmonary vein antra
- higher levels of procedural anticoagulation
- strict limitations on radiofrequency energy output

Transient ischaemic attacks, strokes, tamponade/perforation and symptomatic pulmonary vein stenosis are all well below 1% respectively. Proarrhythmia resulting from re-entrant tachycardias from incomplete ablative lesions is more common. Some are advocating ablation as first-line treatment whereas most are selecting younger patients (less than 70 years) with paroxysmal AF for whom antiarrhythmic therapy has failed, left atrial diameter is less than 5 cm and ejection fraction is greater than 40%.<sup>26</sup> Head-to-head studies comparing ablation and antiarrhythmic drugs are appearing with suggested survival benefit, improved quality of life, reduced adverse effects and cost-effectiveness after approximately 3 years with catheter AF ablation therapy.<sup>49,50</sup>

### CHRONIC ATRIAL FIBRILLATION

Although most patients undergo at least one attempt at cardioversion to sinus rhythm, many are left in chronic AF, particularly those with dilated atria, poor LV function and valvular heart disease. In this setting, treatment aims at ventricular rate control and prevention of embolic stroke.

### VENTRICULAR RATE CONTROL

Digoxin is often the drug of choice, particularly in patients with poor LV function. It is often ineffective at controlling ventricular rate during exercise and physiological stress. Judicious addition of a small dose of a  $\beta$ -adrenergic blocker may improve digoxin control. Amiodarone is particularly useful in patients with poor LV function. Higher-dose  $\beta$ -adrenergic blocker, diltiazem, sotalol or flecainide can be used in patients with good LV function. Rarely, His-bundle ablation with permanent cardiac pacing may be required for severe cases refractory to drug therapy.

### ANTICOAGULATION FOR CHRONIC ATRIAL FIBRILLATION

Consider for all patients, especially those with risk factors (Table 18.7).

**Table 18.7** Prognostic factors for ischaemic stroke and systemic embolism in patients with atrial fibrillation

<b>High</b>	Previous stroke, transient ischaemic attack, systemic embolism Mitral stenosis Prosthetic heart valve
<b>Moderate</b>	Age > 75 years Left atrial size > 45 mm Hypertension Congestive cardiac failure Diabetes mellitus Left ventricular ejection fraction < 35%
<b>Low</b>	Female Age 65–74 years Coronary artery disease Thyrotoxicosis

### VALVULAR ATRIAL FIBRILLATION

A seventeen-fold increased risk of embolic stroke with rheumatic mitral valve disease requires warfarin (INR 2–3). With prosthetic valves there is a similar target range of INR, though the exact level is dependent on type of valve.

### NON-VALVULAR ATRIAL FIBRILLATION

The risk of stroke is determined by CHADS<sub>2</sub> score (assign 1 point for congestive heart failure, hypertension, age = 75 years and diabetes mellitus, and 2 points for stroke/TIA)<sup>51</sup> (Tables 18.8 and 18.9).

The treatment options are discussed below.

### WARFARIN

Adjusted-dose warfarin reduces relative risk of stroke by 62%. The absolute risk reduction is 2.8% per year for primary and 8.4% per year for secondary prevention, although intracranial haemorrhage occurs (0.3% per year). Low-dose warfarin (INR 1.5–2.0) is less effective than an INR of 2.0–3.0 but has fewer haemorrhagic complications. Embolic stroke rate doubles as INR falls from 2.0 to 1.7, and is markedly higher at an INR of 1.3 compared to 2.0.<sup>43,52</sup>

**Table 18.8** CHADS<sub>2</sub> score stroke risk stratification in non-valvular atrial fibrillation

Prognostic factor	Relative risk*	CHADS <sub>2</sub> score
Congestive heart failure (ejection fraction < 35%)	1.4	1
History of hypertension	1.6	1
Age 75 years	1.4	1
Diabetes mellitus	1.7	1
Stroke or transient ischaemic attack in past	2.5	2

\*Relative risk without any antithrombotic treatment compared to atrial fibrillation patients without these prognostic factors.

CHADS<sub>2</sub>, congestive heart failure, hypertension, age = 75 years and diabetes mellitus, and 2 points for stroke/transient ischaemic attack.

**Table 18.9** The adjusted annual stroke rate in non-valvular atrial fibrillation without any antithrombotic treatment

CHADS <sub>2</sub> score	Adjusted stroke rate	
	%/year	95% CI
0	1.9	1.2–3.0
1	2.8	2.0–3.8
2	4.0	3.1–5.1
3	5.9	4.6–7.3
4	8.5	6.3–11.1
5	12.5	8.2–17.5
6	18.2	10.5–27.4

CHADS<sub>2</sub>, congestive heart failure, hypertension, age = 75 years and diabetes mellitus, and 2 points for stroke/transient ischaemic attack; CI, confidence interval.

### ASPIRIN

Aspirin has reduced efficacy when compared with warfarin, with a 22% relative risk reduction and an absolute risk reduction of 1.5% and 2.5% per year for primary and secondary prevention. Warfarin compared with aspirin for AF will prevent 23 strokes and result in nine additional major bleeds per 1000 patients per year.

### CLOPIDOGRIL PLUS ASPIRIN

Although warfarin is better under ideal circumstances, poor INR control will readily erode this benefit.

### WARFARIN COMBINED WITH ANTIPLATELET THERAPY

There is no benefit over warfarin alone.

### Recommendations for anticoagulation in patients with atrial fibrillation

#### Non-valvular AF

- CHADS<sub>2</sub> score = 0: aspirin
- CHADS<sub>2</sub> score = 1: either aspirin or warfarin
- CHADS<sub>2</sub> score = 2: warfarin

#### Valvular AF

- Warfarin

Risk of haemorrhage is reduced by keeping INR = 3, systolic blood pressure < 135 mmHg and avoiding antiplatelet drugs.

Temporary cessation of anticoagulation for AF with surgery is a common problem. Valvular AF requires heparin or enoxiparin until surgery and recommencement of heparin/enoxiparin, then warfarin as soon as safely possible. Non-valvular CHADS<sub>2</sub> score = 1 can have anticoagulation withheld with minimal risk. Non-valvular CHADS<sub>2</sub> score = 2 is increasingly managed as valvular AF.

Angioplasty and stenting of coronary arteries require aspirin and clopidogrel to maintain stent patency. Stenting in patients already on warfarin for AF is a common problem.

### Recommendations for AF patients requiring coronary artery stenting

- Non-valvular CHADS<sub>2</sub> score = 1: cease warfarin as aspirin and clopidogrel are started
- Valvular AF and non-valvular with CHADS<sub>2</sub> score = 2: add aspirin and clopidogrel to continued warfarin treatment

### PRE-EXCITATION SYNDROME

Pre-excitation syndromes have an additional or accessory AV pathway. The term 'WPW syndrome' is usually applied when tachyarrhythmias are present.

#### ECG

During sinus rhythm, an atrial impulse will reach the ventricles via both the AV node and the accessory AV pathway. The latter conducts the atrial impulse to the ventricles before the AV node, resulting in ventricular pre-excitation and a short PR interval. On reaching the ventricles, the pre-excitation impulse is not conducted via the specialised conducting system. Hence, early ventricular activation will be slowed, resulting in a slurred upstroke of the QRS complex, the so-called delta ( $\delta$ ) wave (Figure 18.24). The abnormal ventricular activation also gives rise to secondary S-T segment and T-wave abnormalities.  $\delta$ -wave polarity in a 12-lead ECG may help localise the anatomical position of the accessory pathway. Type A WPW is characterised by upright QRS deflections in the right precordial leads (tall R-waves in V<sub>1</sub> and V<sub>2</sub>) (Figure 18.25). In type A WPW the accessory pathway is usually situated on the left with pre-excitation of the left ventricle. Type B WPW has a dominantly negative QRS complex in V<sub>1</sub> and the accessory pathway tends to be on the right with pre-excitation of the right ventricle (Figure 18.26).

**Figure 18.24** Ventricular pre-excitation via accessory pathway giving rise to a slurred upstroke and widened QRS complex.

**Figure 18.25** Type A Wolff–Parkinson–White syndrome with positive R-waves in the right precordial leads, short PR interval and  $\delta$ -wave giving rise to a wide QRS complex.

**Figure 18.26** Type B Wolff–Parkinson–White syndrome with a negative QRS deflection in  $V_1$ .

### CLINICAL

AVRT or AF can occur with WPW. During AVRT, the re-entry impulse usually travels down the AV node and back up the accessory pathway. Ventricular activation is via the normal conducting pathways and the QRS will be narrow. Occasionally, the re-entry impulse may pass in the opposite direction (down the accessory pathway and up the AV node), resulting in a wide QRS-complex tachycardia due to abnormal slow ventricular activation. Treatment is the same as for AVRT (i.e. IV adenosine). AF is uncommon in WPW, but may be life-threatening. Most impulses are conducted via the accessory pathway, leading to wide QRS complexes. The ECG of WPW with AF usually shows rapid, irregular QRS complexes with variable QRS width (Figure 18.27). Ventricular response is very rapid, leading to hypotension or cardiogenic shock. This arrhythmia may degenerate to VF.

### TREATMENT<sup>25</sup>

Treatment usually involves synchronised DC shock. Antiarrhythmic drugs may be used when patients are haemodynamically stable and the ventricular rate is not excessively rapid.

- Drugs that prolong the refractory period of the accessory pathway are useful (e.g. sotalol, amiodarone, flecainide and procainamide).
- Drugs that shorten the refractory period (e.g. digoxin) are contraindicated as they may accelerate ventricular rate.
- Verapamil and lidocaine may increase the ventricular rate during AF, and are also best avoided.<sup>26</sup>
- $\beta$ -Adrenergic blockers have no effect on the refractory period of the accessory pathway.

Long-term management by radiofrequency ablation of the accessory pathway is effective in selected patients.<sup>25</sup>

**Figure 18.27** Wolff–Parkinson–White syndrome with atrial fibrillation. Rapid rate and irregularity of the broad QRS complexes help to distinguish from ventricular tachycardia.

### VENTRICULAR TACHYCARDIA

VT is defined as three or more VEB at a rate greater than 130 beats/min, and may exceed 300 beats/min. VT lasting over 30 s is considered to be sustained. Non-sustained VT may not cause symptoms, but is associated with increased mortality in certain patients (e.g. after myocardial infarction). VT may be monomorphic (i.e. same QRS morphology) (Figure 18.28) or polymorphic (varying QRS morphology).

### MONOMORPHIC VENTRICULAR TACHYCARDIA

This is the most common form of VT. It is commonly associated with previous myocardial infarction, and often causes symptoms (e.g. palpitations, shortness of breath, chest pain or syncope). It may result in cardiac arrest, due to the tachycardia itself or degeneration into VF. The most common mechanism is re-entry secondary to inhomogeneous activation of the myocardium and slow conduction through scar tissue from a previous myocardial infarction. AV dissociation (i.e. independent atrial and ventricular activity) (Figure 18.29) is present in about 75% of instances, whereas retrograde ventricle to atrial conduction occurs in about 25%. AV dissociation is virtually diagnostic for VT during a wide-complex

tachycardia, but ECG recognition of independent (and slower) atrial activity can be difficult (Figure 18.30). VT is the most common cause of a wide-complex tachycardia (QRS > 120 ms) and any such tachycardia should be considered VT until proven otherwise. Mistakes in diagnosis are common: SVT with aberrant conduction is often mistaken for VT. Inappropriate treatment based on incorrect diagnosis can have disastrous consequences.

### ECG

Older criteria (e.g. QRS > 140 ms and extreme electrical axis changes) are unhelpful in rhythm diagnosis.<sup>53</sup> ECG criteria initially proposed by Wellens and revised by Brugada *et al.* permit accurate diagnosis in four sequential steps (Figure 18.31).<sup>54–56</sup>

The sensitivity of these four consecutive steps was 0.987, with a specificity of 0.965.

- Step 1: is an RS complex present in any precordial lead? (QR, QRS, QS, monophasic R and rSR are not considered RS complexes.) If not (Figure 18.32), the diagnosis is VT.
- Step 2: if an RS is present, then measure the duration of the R-to-S nadir (lowest part of the S-wave). If this duration is > 100 ms in any V lead (Figure 18.33), the rhythm is VT.

**Figure 18.28** Monomorphic ventricular tachycardia preceded by a ventricular couplet.

**Figure 18.29** Ventricular tachycardia with obvious arteriovenous dissociation and independent P-waves are highlighted with arrows in lead II.

**Figure 18.30** Ventricular tachycardia. Independent atrial activity can be difficult to see. Dissociated P-waves can just be seen in leads I and V<sub>5</sub>.

**Sequential ECG Criteria of Brugada for Diagnosis of Ventricular Tachycardia**

- |  |        |    |
|--|--------|----|
| 1. Absent RS complex in all V leads    | →      | VT |
| 2. R to S nadir >100msec in any V lead | →      | VT |
| 3. Atrio-ventricular dissociation      | →      | VT |
| 4. Typical/Classical BBB pattern       | → No → | VT |
- ↓
- Yes**
- ↓
- SVT**

**Figure 18.31** Algorithm proposed by Brugada *et al.*<sup>54</sup> to diagnose ventricular tachycardia in the setting of a broad QRS-complex tachycardia.

• Step 3: if RS < 100 ms, then AV dissociation is searched for (more QRS complexes than P-waves (see Figures 18.29 and 18.30)). Indirect evidence of AV dissociation such as capture or fusion beats may be present. Capture beats occur when atrial sinus impulses reach the AV node when it is no longer refractory from retrograde conduction of ventricular discharges: the AV node and ventricle are then ‘captured’ by the sinus impulse. The resultant QRS will occur earlier than the next expected VT complex and the QRS morphology will be that of the ‘normal’ underlying complexes for that patient. Similarly, a sinus impulse can penetrate the AV and ‘fuse’ with an already depolarising ventricle from the ectopic focus initiating the VT. The resulting QRS morphology of a fusion beat will be variable and depend on the relative contribution of the supraventricular and ventricular impulses to ventricular activation. Even a single capture or fusion beat confirms AV dissociation and VT (Figure 18.34).

**Figure 18.32** (a, b) Ventricular tachycardia. Broad QRS-complex tachycardia with absence of RS complex in all precordial leads.

**Figure 18.33** Ventricular tachycardia. Time duration of R to the nadir of the negative S-wave is 120 ms. Note also independent P-waves in lead V<sub>1</sub>.

- Step 4: If AV dissociation is not present, then decide whether the wide QRS has a right or left BBB pattern. If the BBB is typical in both V<sub>1</sub> and V<sub>6</sub> leads, the rhythm is supraventricular in origin (see the section on BBB, below). If there are any atypical features, the rhythm is considered to be VT (see Figures 18.33 and 18.39, below).

Termination of a wide-complex tachycardia by IV adenosine strongly suggests the arrhythmia as SVT. However, adenosine in this setting has the risk of destabilising VT when blood pressure is barely compensated by vasodilatation or acceleration of accessory pathway conduction, and is not recommended by International Liaison Committee on Resuscitation (ILCOR) as a diagnostic strategy in wide-complex tachycardia.<sup>25</sup> Demonstration of AV dissociation by intracardiac ECG from a central venous catheter or a transvenous pacing lead signifies VT.

#### CLINICAL

The major cause of VT is significant coronary artery disease. Other causes include cardiomyopathy, myocarditis and valvular heart disease. Symptoms will depend on the ventricular rate, duration of tachycardia and underlying cardiac function. There are not necessarily any haemodynamic differences between VT and SVT with aberrant conduction but haemodynamic instability mandates management as for VT.

#### TREATMENT<sup>25,57</sup>

DC shock is indicated if a patient is haemodynamically unstable. Antiarrhythmic drug trial is indicated in haemodynamically stable VT.

- Amiodarone may terminate VT: there is less negative inotropy action but delayed effect.
- Sotalol and procainamide are more effective than lidocaine but are associated with significant myocardial depression.

- Although traditionally indicated, there are now doubts about the efficacy of lidocaine.

If drugs are ineffective, synchronised DC shock is indicated. Rapid right ventricular pacing may also be effective.

Long-term prevention of VT and sudden death is difficult. Sotalol guided by Holter ECG or electrophysiological testing, and empirical (i.e. non-guided) amiodarone are superior to other drugs in preventing arrhythmia recurrences. Empirical  $\beta$ -adrenergic blockers also have a role. Implantable defibrillators can recognise and automatically terminate VT by rapid ventricular pacing or, if this fails, by internal DC cardioversion, which may be life-saving.

#### POLYMORPHIC VENTRICULAR TACHYCARDIA AND TORSADE DE POINTES

This arrhythmia has QRS complexes at 200 beats/min or greater, which change in amplitude and axis so that they appear to twist around the baseline (Figure 18.35). Torsade de pointes usually has prolonged QT during sinus rhythm, and U-waves are often present (see section on long-QT syndrome, below). However, polymorphic VT may be associated with a normal QT interval in settings such as myocardial ischaemia, infarction or post cardiac surgery.

#### TREATMENT

Polymorphic VT associated with a normal QT interval during sinus rhythm (e.g. following AMI) should be treated in the same way as monomorphic VT. (See section on treatment of long-QT and polymorphic VT, below.)

#### ACCELERATED IDIOVENTRICULAR RHYTHM (AIVR)

This is often inappropriately called slow VT. Increased automaticity is probably the mechanism responsible for this relatively benign arrhythmia.

**Figure 18.34** Ventricular tachycardia with a highlighted premature capture beat followed by a fusion beat showing transitional QRS morphology between the underlying normal QRS and VT complex. Note also independent P-waves.

**Figure 18.35** Torsade de pointes preceded by multifocal ventricular ectopic beats.

### ECG

There is a wide QRS with a rate of 60–110 beats/min (Figure 18.36). Sinus rate is often only slightly slower than the arrhythmia, so the dominant rhythm may be intermittent AIVR and sinus rhythm. Fusion beats are therefore common.

### CLINICAL

The rhythm is commonly encountered in inferior myocardial infarction. AIVR may be misdiagnosed as VT. Occasionally, AIVR causes haemodynamic deterioration, usually due to loss of atrial systole. Increasing the atrial rate with either atropine or atrial pacing may then be necessary.

### VENTRICULAR FIBRILLATION

VF always causes haemodynamic collapse, loss of consciousness and death if not immediately treated. Of patients resuscitated from VF, 20–30% have sustained an AMI, and 75% have coronary artery disease. VF (and VT) unassociated with AMI is likely to be recurrent; 50% die within 3 years.

### ECG

The ECG shows irregular waves of varying morphology and amplitude (Figure 18.37).

### CLINICAL

VF is usually associated with ischaemic heart disease, although other causes include cardiomyopathy, anti-arrhythmic drugs, severe hypoxia and non-synchronised DC cardioversion.

### TREATMENT<sup>57</sup>

Give an immediate non-synchronised DC shock at 200 J, and if ineffective, repeated at 200–360 and 360 J (or biphasic equivalent). Time should not be wasted with basic life support if immediate defibrillation can be delivered.

**Figure 18.36** Sinus rhythm with short runs of accelerated idioventricular rhythm. Note frequent fusion beats as sinus rate is similar to the accelerated idioventricular rate.

**Figure 18.37** Ventricular fibrillation with waves of varying morphology and amplitude.

If DC shock sequence fails, basic and advanced life support aiming to maximise coronary blood flow with chest compressions and vasopressors is crucial to cardiac success. Until recently, any role of antiarrhythmic drugs in DC shock-resistant VF has been traditional rather than proven. Recommendations have varied from lidocaine and bretyllium to amiodarone. The ILCOR currently recommends consideration of a range of antiarrhythmic drugs, including amiodarone, lidocaine, magnesium and procainamide. Recent studies indicate amiodarone as the drug of choice for DC shock-resistant VF. Amiodarone (300 mg) was superior to lidocaine and, in another study, 5 mg/kg followed by 2.5 mg/kg if required was superior to lidocaine. There is an incidence of bradycardia and hypotension but no difference in adverse effect profile between lidocaine and this sizeable amiodarone dose.<sup>58,59</sup> After return of circulation, appropriate antiarrhythmic therapy is less clear but the role of lidocaine continues to disappear. Precipitating factors should be sought and treated (for long-term management issues, see the section on sudden cardiac death, below).

#### RIGHT BUNDLE BRANCH BLOCK (FIGURE 18.38)

In right BBB (RBBB) the normal rapid coordinated depolarisation of the right ventricle is lost due to conduction block in the right branch of the bundle of His. There is normal rapid depolarisation of the septum and the initial deflection of the QRS is not altered. The activation of the free wall of the left ventricle is also normal. However the final activation of the free wall of the right ventricle is slow and anomalous, leading to a broad QRS.

#### ECG

The ECG shows wide QRS (> 120 ms) and the QRS morphology in the right ventricular leads  $V_1$  and  $V_2$  is often M-shaped. This results in two R-waves, with the smaller of the R-waves being designated 'r' and the larger 'R'. The classical pattern is the M-shaped rSR in  $V_1$  or  $V_2$  and a broad S-wave in LV leads, especially I and  $V_6$ . In  $V_1$  the R-wave is greater in amplitude than the R-wave. In  $V_6$  the R-wave is greater than any S-wave present. Partial RBBB is identical, except the QRS duration is 110–120 ms.

#### CLINICAL

RBBB may be a normal variant, but may occur with massive pulmonary embolism, right ventricular hypertrophy, ischaemic heart disease and congenital heart disease (note that myocardial infarction can be diagnosed in the presence of RBBB).

#### LEFT BUNDLE BRANCH BLOCK (FIGURE 18.39)

In left BBB (LBBB), there is delayed and anomalous activation of the interventricular septum from right to left (i.e. in the opposite direction to normal) and the free wall of the left ventricle.

#### ECG

There is a wide QRS (> 120 ms) and in  $V_1$  the characteristic morphology shows an rS or QS. In  $V_6$  there are primary and secondary R-waves (RR'), often resulting in M-shaped or plateau morphology. Q-waves are never seen in LV leads ( $V_4$ – $V_6$ ) (note that myocardial infarction cannot usually be diagnosed in the presence of LBBB). Partial LBBB is similar, except that the QRS duration is 110–120 ms.

#### CLINICAL

LBBB is often associated with heart disease such as coronary artery disease, cardiomyopathy or LV hypertrophy. LBBB makes diagnosis of myocardial infarction difficult and the development of a new LBBB fulfils ECG criteria of acute infarction.

#### HEMIBLOCKS

The left branch of the bundle of His divides into the left anterosuperior division supplying the anterior superior lateral wall of the left ventricle and the posteroinferior division supplying the posterior inferior diaphragmatic surface of the left ventricle. Although block can occur in either division it is more common in the anterosuperior division, as it is more vulnerable to disease processes due to its longer course and thinner dimension. The anterosuperior division runs close to the aortic valve and tends to be involved in degenerative processes affecting this valve.

**Figure 18.38** Right bundle branch block (RBBB) with characteristic M-shaped rSR complex in lead  $V_1$  and Rs complex in  $V_6$ .

The posteroinferior division is shorter and thicker and, unlike the anteroseptal division, has a double blood supply.

#### LEFT ANTERIOR HEMIBLOCK

There is left-axis deviation (usually lead I predominantly positive, leads II and III predominantly negative) with initial R-wave in inferior leads (II, III, aVF).

#### LEFT POSTERIOR HEMIBLOCK

There is usually right-axis deviation (lead I predominantly negative and lead III predominantly positive). Other causes of right-axis deviation (e.g. right ventricular hypertrophy) need to be excluded.

#### CLINICAL

RBBB with either left anterior hemiblock (Figure 18.40) or left posterior hemiblock indicates an extensive conduction defect and a poor prognosis (high risk of complete heart block), especially in AML.

#### HYPERKALAEMIA

A high serum  $K^+$  can produce ECG changes (Figure 18.41). Early changes consist of tall peaked T-waves with reduced P-wave amplitude. Progressive widening of the QRS may be confused with BBB. Cardiac arrest may eventually occur.

#### ATRIOVENTRICULAR BLOCK<sup>57</sup>

AV block is a delay or failure of impulse conduction from the atria to the ventricles. AV block is classified according to whether conduction of atrial impulses is delayed (first-degree), blocked intermittently (second-degree) or blocked completely (third-degree).

#### FIRST-DEGREE AV BLOCK

##### ECG

PR interval (measured from the onset of the P-wave to the onset of the QRS) exceeds 200 ms (Figure 18.42).

**Figure 18.39** Left bundle branch block (LBBB).

Each P-wave is followed by a QRS. PR intervals may be prolonged to such a degree that the P-wave is buried in the previous T-wave or even QRS.

#### CLINICAL

First-degree AV block is commonly associated with increased vagal tone, and occasionally with drugs (especially digoxin), ischaemic heart disease (particularly inferior myocardial infarction) and rheumatic fever. It usually causes no symptoms and requires no treatment. If associated with digoxin, the drug should be ceased or the dose decreased.

#### SECOND-DEGREE AV BLOCK

Second-degree AV block is characterised by intermittent failure of AV conduction and is classified into Mobitz types I and II. Second-degree AV block can occur in SVTs; however the conduction block is a physiological 'protective' mechanism in the setting of rapid atrial impulses.

#### MOBITZ TYPE I (WENCKEBACH)

Delay in AV conduction increases with each atrial impulse until an atrial impulse fails to conduct. This is usually a repetitive pattern which may or may not begin with first-degree AV block. The level of AV block in type I is usually in the AV node itself and can be physiological (increased vagal tone) as well as pathological.

#### ECG

There is progressive lengthening of the PR interval over successive cardiac cycles, culminating in a non-conducted P-wave, resulting in a missed beat (Figure 18.43). Type I is common in fit healthy people in the presence of high levels of resting vagal tone (Figure 18.44).

#### CLINICAL

The condition is generally benign and does not carry the adverse likelihood of progression to complete AV block, although it may occur with inferior infarction. Treatment is rarely necessary.

**Figure 18.40** Right bundle branch block with left anterior hemiblock. There is left-axis deviation (mean frontal axis of  $-75^\circ$ ) and small R-waves in II, III and aVF.

**Figure 18.41** Sinus rhythm with peaked 'tent-shaped' T-waves in a patient with a serum potassium of 7.6 mmol/l.

### MOBITZ TYPE II

There is intermittent failure of conduction of atrial impulses to the ventricles without preceding increases in the PR interval. The ratio of conducted to non-conducted atrial impulses varies, e.g. every second or fourth atrial impulse may be conducted (i.e. 2:1 or 4:1 second-degree AV block). The lesion causing type ?? is usually situated in the bundle of His and is always pathological.

#### ECG

PR interval remains constant prior to the blocked P-wave. There is always a constant P-QRS-wave ratio: the P-waves are two (Figure 18.45), three (rare) or four times more frequent than QRS-waves.

#### CLINICAL

It is likely to be associated with structural heart disease. Slower symptomatic ventricular rates may require pacing. The AV block may be intermittent or persistent. The

adverse prognosis relates to the frequency of progression to complete AV block.

### THIRD-DEGREE (COMPLETE) AV BLOCK

This rhythm occurs when no atrial impulses are conducted to the ventricles; atrial and ventricular contraction are dissociated. The SA node usually continues to depolarise the atria, whereas ventricular activation depends on a standby escape pacemaker located below the block. The escape pacemaker may be close to the His bundle (narrow QRS, stable pacemaker usually 40–60 beats/min) (Figure 18.46), or more distal in ventricular tissue (wide QRS, relatively unstable pacemaker with a rate of 20–40 beats/min) (Figure 18.47). If no ectopic escape pacemaker emerges, ventricular asystole will occur, resulting in a Stokes–Adams attack, or death if the episode is prolonged. Torsade de pointes may also occur associated with the bradycardia.

**Figure 18.42** Sinus rhythm with first-degree AV block. The PR interval is 360 ms. Note inferior-wall myocardial infarction with Q-waves in II, III and aVF.

**Figure 18.43** Mobitz type I (Wenckebach) second-degree arteriovenous block. Progressive lengthening of PR interval results in the failure of the second and sixth P-wave to be conducted.

**Figure 18.44** Intermittent type I second-degree arteriovenous block in a healthy male with obvious background sinus arrhythmia. Constant PR interval of 0.14 s suddenly increases to 0.22 s and next P-wave is not conducted.

**Figure 18.45** Mobitz type II second-degree arteriovenous (AV) block. Persistent 2:1 AV block with the atrial rate at 108 beats/min and the ventricular rate 54 beats/min.

**Figure 18.46** Leads I, aVR, V<sub>1</sub> and V<sub>4</sub> showing third-degree arteriovenous block. Complete dissociation of atrial activity at a rate of 107 beats/min and the ventricular rate at 46 beats/min. The escape rhythm is junctional (high up in the bundle of His) with a narrow QRS morphology.

**Figure 18.47** Third-degree arteriovenous block with an atrial rhythm at 135 beats/min and a broad distal ventricular escape rhythm which is unstable at a rate of 30 beats/min.

### EKG

The ECG shows normal regular P-waves completely dissociated from QRS complexes. The QRS rate is always significantly slower than the P-wave rate and may be very slow at times.

### CLINICAL

Idiopathic fibrosis of the conduction system is the most common cause. Other causes include myocardial infarction, valvular heart disease, cardiac surgery and a congenital form of complete heart block. Cardiac pacing is usually required to increase heart rate and cardiac output. Congenital forms often have a relatively fast escape ventricular rate, and patients may remain asymptomatic for many years.

### SICK-SINUS SYNDROME

This consists of a number of sinus node abnormalities, including inappropriate sinus bradycardia, SA blocks or sinus arrest. When sinus bradycardia or SA block occurs, junctional escape rhythms are common. There may also be abnormalities of AV conduction. Paroxysms of AF or Afl may alternate with episodes of bradycardia (bradycardia-tachycardia syndrome) (Figure 18.48).

**Figure 18.48** Characteristic findings in sick-sinus syndrome. Episodic atrial tachycardias (atrial flutter with variable block in this instance) with periods of sinus arrest and very slow ventricular escape rhythm upon spontaneous termination. CSM, carotid sinus massage.

### CLINICAL

The bradycardias associated with sick-sinus syndrome (SSS) may result in syncope or near-syncope. SSS is often not associated with structural heart disease, but may occur with ischaemic and congenital heart disease.

### TREATMENT

Cardiac pacing is usually required to control bradycardia symptoms. Atropine and low-dose isoprenaline may be useful prior to pacing, in the haemodynamically compromised patient. Bradycardia-tachycardia syndrome may require both pacing (for the bradycardia) and anti-arrhythmic drugs (for the tachycardia). Anticoagulation needs to be considered if episodes of AF occur.

### CRITICALLY ILL PATIENTS AND ARRHYTHMIA<sup>60</sup>

In the general population or critically ill patients, excluding acute coronary syndromes and cardiac surgical patients, arrhythmia is common. The documented incidence is as high as 78%; however, the incidence of arrhythmia that requires treatment is much lower, at 15–30%. SVT are by far the most common arrhythmia that requires treatment.

AF, Afl and unifocal atrial tachycardias are the most frequent, in descending order. These SVTs are rarely the cause of admission but develop early in the admission, the majority by day 2. In critically ill patients, SVTs often result in:

- adverse myocardial oxygen supply–demand balance
- compromised blood pressure, cardiac output and systemic oxygen delivery
- impaired end-organ function such as oliguria and worsening gas exchange

The development of SVT in a critically ill patient is associated with a significant increase in mortality, especially in patients with sepsis and respiratory failure. Incidence of SVT is increased with:

- elderly patients
- evidence or past history of heart disease
- haemodynamic features of diastolic failure with elevated pulmonary artery occlusion pressure
- catecholamine infusion

The actual dose of the catecholamine infusion does not appear to be important and, although electrolyte disturbances are common in critically ill patients, low plasma potassium and magnesium levels do not appear to be important predictors of SVT development. The incidence of SVT, particularly AF, is so high in elderly patients with heart disease on a catecholamine infusion that consideration of prophylactic strategies is worthwhile.

### TREATMENT OF SUPRAVENTRICULAR TACHYCARDIA IN CRITICALLY ILL PATIENTS

Continuing arrhythmogenic and chronotropic factors make rate control difficult.

- Digoxin often results in poor rate control due to persisting endogenous and exogenous sympathomimetic tone. The inotropic and vasopressor effects of acute digitalisation are beneficial. Digoxin (10 µg/kg) has been shown to provide superior circulatory support to dopamine at 8 µg/kg per min in septic patients.<sup>61</sup>
- Irrespective of plasma levels, magnesium has been shown to be effective at rate control; however, hypotension due to vasodilatation can be seen.
- Amiodarone is particularly effective and has allowed reliable acute rate control over a period of days in critically ill patients with circulatory shock requiring catecholamine infusions.<sup>62</sup> It can cause hypotension if patients are rapidly loaded. In another study, magnesium was at least as effective as amiodarone in rate control and time to reversion to sinus rhythm.<sup>63</sup>
- Other agents, such as diltiazem, sotalol and procainamide, are associated with prohibitive myocardial depression and hypotension.

Urgent cardioversion is indicated in unstable patients. The likelihood of remaining in sinus rhythm in the setting of high endogenous and exogenous sympathomimetic

tone is low without concomitant use of an antiarrhythmic drug. Cardioversion is best reserved for hastening onset of sinus rhythm once a drug like amiodarone has controlled rate. Cardioversion should at least be attempted within 24–48 h of onset in the hope that embolic and anticoagulation issues are avoided.

### MYOCARDIAL INFARCTION AND ARRHYTHMIA<sup>21</sup>

Arrhythmia is common following AMI. While early arrhythmia contributes significantly to mortality, treatment is largely expectant and secondary to re-establishing coronary blood flow, minimising infarct size and treating ongoing ischaemia and heart failure. Late ventricular arrhythmia is particularly challenging, as selecting patients at risk is difficult and treatment options are limited.

### MANAGEMENT OF ACUTE MYOCARDIAL INFARCTION AND ARRHYTHMIA CONTROL

Modern management of AMI, although targeted to prevent or reduce infarct size, has also been very effective in reducing arrhythmia incidence and sequelae. Numerous studies have documented transient ventricular arrhythmias at the time of reperfusion resulting from thrombolysis and acute angioplasty. However, the most common arrhythmias seen in this setting are VEB, AIVRs and non-sustained VT, rather than VF or sustained VT.

Meta-analysis of thrombolytic trials has shown no increase in early VF following thrombolytic therapy in the first 24 h. The likelihood of developing VF at any time during a hospital episode is reduced following thrombolytic therapy but the risk of developing VT is increased. The mechanism of reperfusion arrhythmia is believed to be related to intracellular calcium overload and the resulting triggered activity in the form of DAD. Dipyridamole, which inhibits the cellular uptake of adenosine, has been shown to be effective in preventing and treating reperfusion ventricular arrhythmia.

Prior to the introduction of thrombolytic therapy, β-adrenergic receptor blockers significantly reduced the incidence of early VEB and VF. However, following routine use of thrombolytic therapy, the benefit of β-blockers relates to a reduction in postinfarction ischaemia and subsequent infarction.

The early work demonstrating survival benefit of magnesium was initially thought to be due to the prevention of arrhythmia.<sup>64</sup> However, the Leicester Intravenous Magnesium Intervention Trial (LIMIT-2) found the improved survival not to be related to a reduction in arrhythmia.<sup>65</sup> Subsequent studies in the thrombolytic era have failed to show any benefit at all with magnesium, although debate regarding optimal time of administration persists. Magnesium may have a role in patients in whom β-adrenergic blockers or thrombolytic therapy are contraindicated.

### ELECTROLYTE CONCENTRATIONS AND ARRHYTHMIA FOLLOWING ACUTE MYOCARDIAL INFARCTION

Serum potassium following AMI is negatively correlated with the incidence of VEB and VT, with the probability of VT falling until serum potassium exceeds 4.5 mmol/l.<sup>8</sup> There is no evidence that magnesium levels in this setting have any effect on ventricular arrhythmia. Nonetheless, ILCOR recommendations not only include the maintenance of serum potassium greater than 4.0 mmol/l, but also serum magnesium levels greater than 1.0 mmol/l.

### BRADYARRHYTHMIAS POST ACUTE MYOCARDIAL INFARCTION

One-third of patients with AMI develop sinus bradycardia because of increased vagal tone. In inferior infarcts due to occlusion of the right coronary artery, bradyarrhythmia is due to ischaemia of the SA and AV nodes. Reperfusion of the right coronary artery can also lead to sinus bradycardia and heart block that is due to accumulation of adenosine in nodal tissue. Bradycardia in this setting is resistant to atropine.

Second- or third-degree AV block occurs in approximately 20% of AMI patients. High-degree AV block occurs early when present, with 42% presenting with AV block and most, 66%, developing in the first 24 h. Similar to all post-AMI arrhythmias, thrombolytic therapy has reduced the incidence down to 12%. When present, high-degree AV block is associated with an increased mortality. However, high-degree AV block is not an independent predictor, rather a marker of extensive infarction and LV dysfunction.

Treatment is only indicated for sinus bradycardia associated with symptoms, hypotension or signs of poor cardiac output. Most often, first- and second-degree block also do not need treatment. Mobitz type I second-degree block may require treatment and atropine is indicated. However, in Mobitz type II, atropine usually has no effect on infranodal block and may precipitate third-degree block by increasing sinus rate and enhancing block. Atropine may improve heart rate with AV block occurring at the AV node, as demonstrated by a narrow QRS complex, by improving AV conduction or accelerating escape rhythm. Atropine is not indicated for infranodal third-degree block, which is diagnosed by the presence of a new wide QRS complex. When required, atropine is administered, 0.5–1.0 mg every 3 min until signs or symptoms are resolved, up to a maximum of 0.03–0.04 mg/kg. If atropine is not indicated or effective, cardiac pacing is required (Table 18.10). Transcutaneous pacing is indicated for initial management as a bridge until a transvenous temporary pacing wire can be inserted safely and with appropriate sterile technique. With the ready availability of transcutaneous pacing, IV catecholamines for bradyarrhythmias are to be avoided in the setting of AMI.

**Table 18.10** Indications for pacing following myocardial infarction

Haemodynamically unstable bradycardia (< 50 beats/min)
Mobitz type II second-degree atrioventricular block
Third-degree heart block
Bilateral bundle branch block
Left anterior fascicular block
New left bundle branch block
Bundle branch block and first-degree atrioventricular block

### ATRIAL FIBRILLATION POST ACUTE MYOCARDIAL INFARCTION

New-onset AF occurs in 10–15% of AMI. The incidence increases with age, large infarcts, LV hypertrophy and congestive cardiac failure. It is also related to atrial infarction with occlusion of the right coronary artery proximal to the sinus node branch or circumflex proximal to the left atrial circumflex branch. Later in the course of myocardial infarction, AF is related to postinfarct pericarditis.

Thrombolytic therapy has reduced the incidence of AF. In the setting of AMI, AF is usually self-limiting and requires no treatment. If rapid ventricular rates are associated with further ischaemic symptoms or haemodynamic compromise, cardioversion is indicated.  $\beta$ -Blockers, which are indicated in the treatment of AMI anyway, are the initial treatment of choice. Digoxin is not indicated in the setting of acute ischaemia as the likelihood of triggered activity associated with intracellular calcium overload is increased. AF following AMI is associated with an increase in mortality. Systemic emboli following AMI are three times more likely with AF and 50% occur in the first 24 h of onset of AF. For this reason, sustained AF is an indication for anticoagulation prior to the normal 48-h period following AMI.

### VENTRICULAR ARRHYTHMIA POST ACUTE MYOCARDIAL INFARCTION<sup>20,66,67</sup>

VF/VT is the leading cause of mortality following AMI. Fifty per cent of patients dying from AMI do so pre-hospital due to VF/VT. Pre-hospital mortality is being reduced by improved community education, wider application of basic life support and availability of an automated external defibrillator (AED). Following admission to hospital, LV failure is the most common cause of death.

The major risk period for VF is the first 4 h following onset of symptoms, with 4–18% of patients having VF in this period. Once admitted to hospital, 5% develop VF, mostly in this first 4-h period. VF in this early 4-h period is termed ‘primary VF’. VF later in the course of an AMI, usually associated with LV failure or cardiogenic shock, is called ‘secondary VF’.

Thrombolytic therapy has reduced VF incidence. The Gruppo Italiano per lo Studio della Streptochinasi nell’infarto miocardico (GISSI) study<sup>66</sup> found an incidence of primary VF of 3.6% and secondary VF of 0.6%. The overall incidence of ventricular arrhythmia in the Global

Utilization of Streptokinase and Tissue plasminogen activator to treat Occluded arteries (GUSTO-1) report was VF, 4.1%, VT, 3.5% and both, 2.7%.

Primary VF increases in-hospital mortality and complications but not long-term mortality. Complex ventricular arrhythmias, defined as multiform VEB, couplets and non-sustained VT, occur in 35–40% of patients during hospital stay. They occur equally with Q-wave and non Q-wave infarction. Complex ventricular arrhythmia is a risk factor for subsequent VF/VT and SCD, particularly in non-Q-wave infarction. Polymorphous VT is less common after AMI and does not appear to be related to QT prolongation or electrolyte disturbances in the reported cases.

Lidocaine reduces primary VF by 33% but mortality is increased by a similar amount such that there is no net benefit and the third International Study of Infarct Survival (ISIS-3) reported an overall trend to increased mortality.<sup>68</sup> Being more selective as to which patients receive lidocaine has not been possible, as only 50% of patients who develop VF have ‘warning’ ventricular arrhythmia. In the ‘thrombolytic and  $\beta$ -blocker’ era of treatment of AMI, the use of prophylactic lidocaine, or any other antiarrhythmic drug, to prevent VF will have even less benefit. There are no conclusive data to support the use of lidocaine to prevent recurrent VF in those patients who have already suffered an episode of VF. Despite this, a short period of 6–24 h of lidocaine has been advocated.

Patients who survive a late or secondary episode of VF/VT following myocardial infarction require full evaluation for preventive strategies, as do survivors of SCD. All survivors of a myocardial infarction are at an increased risk for SCD but accurate prediction is not feasible. Risk factors that have been shown to be associated with increased risk of a subsequent episode of VF/VT after myocardial infarction include:

- age
- Holter monitoring and demonstration of non-sustained VT, couplets and frequent VEB (i.e. >10 beats/min)
- impaired LV function (i.e. ejection fraction less than 30–40%)
- signal-average ECG and detection of delayed afterpotentials. In patients presenting with SCD after myocardial infarction, 68–87% have an abnormal signal-average ECG. However the positive predictive value is poor, at 15–25%
- demonstrated inducibility of VT postinfarction is associated with increased risk of SCD. However, the positive predictive value is again poor, at 20–30%

Combinations of these risk factors have been evaluated to predict risk after infarction. The combination of delayed potentials on signal-average ECG, LV ejection fraction of less than 40% and non-sustained VT on Holter monitor has been shown to be associated with up to 50% risk of SCD. Currently, there is no agreement on which patients require primary preventive strategies for VF/VT following myocardial infarction.

Using frequent VEB to identify patients at risk following myocardial infarction has been extensively used. There have been 54 randomised trials reported involving more than 20 000 patients using 11 different class I agents.

Class I agents showed no overall benefit on all-cause mortality and class IC agents have excess mortality despite arrhythmia suppression.<sup>13</sup>

Class II antiarrhythmics,  $\beta$ -blockers, have an established and broadening role, with recent evidence showing significant benefit.<sup>69</sup>

Class III agents lack a consistent class effect. Sotalol (Survival with oral D-sotalol: SWORD) was found to increase all-cause mortality and arrhythmia deaths.<sup>70</sup> Amiodarone (Canadian Amiodarone Myocardial Infarction Arrhythmia Trial: CAMIAT) reduces all-cause mortality in patients with frequent VEB post myocardial infarction<sup>71</sup> but another study (European Myocardial Infarction Amiodarone Trial: EMIAT) evaluated amiodarone in patients with ejection fraction less than 40% and found no effect on all-cause mortality but a 35% reduction in arrhythmia deaths.<sup>72</sup> Subsequent analysis of combined CAMIAT and EMIAT data has emphasised the importance of  $\beta$ -blockers. The combination of amiodarone and  $\beta$ -blockers in these post-infarct patients was better than either drug alone.<sup>73</sup>

## CARDIOTHORACIC SURGERY AND ARRHYTHMIA

### SVT AFTER CARDIOTHORACIC SURGERY<sup>74</sup>

AF predominates, with Afl and unifocal atrial tachyarrhythmia also commonly occurring after coronary artery bypass grafting, with an incidence of 11–40% and in over 50% following valvular surgery. In addition to mechanisms found in non-surgical patients, pericardial inflammation or effusion, increased catecholamine production and postoperative autonomic changes are implicated. Major risk factors include:

- previous history of AF
- increasing age
- postoperative withdrawal of  $\beta$ -blocker therapy

Extent of coronary artery disease, postoperative ischaemia, duration of aortic cross-clamping or cardiopulmonary bypass and method of myocardial protection do not influence incidence. SVT post cardiothoracic surgery is not a benign event, with the major consequence being thromboembolic complications. Stroke occurs following coronary artery bypass grafting in 1–6% of patients and postoperative atrial tachyarrhythmias increase the incidence threefold. Other adverse effects include:

- haemodynamic instability
- prolonged inotropic support
- need for intra-aortic balloon pump
- reoperation for bleeding
- longer and more expensive critical care unit and hospital episodes

### PREVENTION OF SUPRAVENTRICULAR TACHYCARDIA<sup>75,76</sup>

Preoperative  $\beta$ -blocker treatment should be continued postoperatively.  $\beta$ -Blockers consistently reduce SVT across many studies with differing agents.

Amiodarone prophylaxis after elective cardiac surgery reduced postoperative AF from 53% to 25%. Diltiazem has also been shown to be effective at SVT prevention and there was associated improvement in haemodynamic variables and rates of myocardial ischaemia. Verapamil is not effective. Esmolol was found to be more effective than diltiazem. Sotalol is also effective but problematic bradycardia and hypotension are greater.<sup>77</sup> Atorvastatin is also effective.<sup>78</sup>

There is no relation between SVT incidence and serum magnesium levels and there are conflicting data relating to the efficacy of prophylactic magnesium. Digoxin has no role in prevention.

### TREATMENT OF SUPRAVENTRICULAR TACHYCARDIA

Treatment is aimed at control of ventricular rate, prevention of thromboembolism and cardioversion.

Digoxin, atenolol, diltiazem and magnesium are appropriate choices to control rate.

In persisting AF, the timing of electrical cardioversion is debatable. Early electrical cardioversion, inside 24–48 h, avoids the need for anticoagulation but is associated with a significant recurrence rate as postoperative arrhythmogenic factors remain. In persistent or recurrent AF, sotalol and amiodarone, depending on myocardial function, are suitable antiarrhythmic drugs and should be continued for 6–12 weeks following cardioversion.

Timing of safe anticoagulation following cardiac surgery is also debatable. Many advocate delaying anticoagulation till 72 h postsurgery, which may be greater than 24–48 h after onset of SVT. Most cardiac surgical patients receive aspirin and low-dose heparin in the early postoperative period, which is likely to reduce risk. However, it is worth noting that, in other AF settings, 325 mg of aspirin decreased thromboembolic but 75 mg did not.

### VENTRICULAR ARRHYTHMIA FOLLOWING CARDIAC SURGERY

Ventricular arrhythmia requiring treatment, DC shock or drug therapy is common following cardiac surgery and occurs in 23% of patients.<sup>79</sup> Arrhythmias requiring DC shock occur in the first 36 h and are associated with:

- advanced age
- failure to use an internal mammary artery conduit (which is likely to reflect preoperative assessment of high risk)
- SVT

The incidence was not related to previous myocardial infarction, ejection fraction of less than 50%, prolonged operative time, perioperative myocardial infarction or reduced number of vessels bypassed. In patients undergoing coronary artery bypass, grafting patients at high risk for sudden death, LV ejection fraction less than 36% and abnormalities on signal-averaged ECG had a 6.3% incidence of sustained VT and 4.3% VF.

VEB are common early on return from surgery, with frequent or complex ectopy associated with adrenergic effects of emerging from anaesthesia and hypokalaemia. The threshold to treat these arrhythmia varies with clinicians. Potassium must be regularly checked and maintained above 4 mmol/l.

If there is accompanying emergent hypertension, in addition to the antiarrhythmic action, the vasodilating properties of magnesium provide an ideal profile at this stage. Patients with VT/VF reverting with DC shock who are haemodynamically stable should have prophylactic antiarrhythmic cover until adrenergic stimulation associated with awakening and weaning from mechanical ventilation is past. Lidocaine has been the agent of choice, but magnesium, amiodarone and sotalol are all more effective. Maintaining antiarrhythmic levels of magnesium may not be conducive to weaning from ventilation. Extrapolating from post myocardial infarct data would support the conversion to  $\beta$ -blockers if there were no contraindications.

A smaller proportion of patients develop malignant VF/VT, most often in association with poor LV function and a postoperative low-cardiac-output state requiring catecholamine infusions. In this setting, ventricular arrhythmia is common, often initiated by short-coupling polymorphous VT (normal QT<sub>c</sub>), due to ongoing ischaemia or reperfusion of ischaemic heart.

- High-dose amiodarone may work best in combination with antiarrhythmic levels of magnesium (1.8–2.0 mmol/l) or lidocaine.
- Many of these patients need an intra-aortic balloon pump to defend coronary artery perfusion pressure not only because of the likely poor LV function and low-output state, but also to minimise the adverse effects of antiarrhythmic drugs and recurrent DC shocks.
- Pacing may be required to counteract bradyarrhythmia associated with escalating doses of antiarrhythmic drugs. Pacing at faster rates (90–110 beats/min, which may not be ideal from a cardiac-output point of view) may be protective against recurrent episodes by promoting homogeneity of depolarisation and suppression of abnormal automaticity. The presence of epicardial or transvenous pacing wires also enables bedside-programmed stimulation and overdrive pacing for termination of recurrent VT, which has fewer deleterious effects than recurrent DC shocks.

**LONG-QT SYNDROME<sup>80</sup>**

The traditional criteria of prolonged QT is corrected heart rate ( $QT_c$ , Bazett's formula, QT divided by the square root of the RR interval) and a  $QT_c$  greater than 0.44 s. This should also be adjusted for age and gender. The causes of LQTS can be divided into acquired and idiopathic (Table 18.11). Common to all causes is a prolongation of repolarisation which creates the substrate for random re-entry, giving rise to polymorphous VT (classically of the torsade de pointes type), particularly under conditions of acute adrenergic arousal.

Action potential prolongation results from either enhancing depolarisation (Na channel,  $I_{Na}$ ) or reducing repolarisation current (delayed rectifier K currents,  $I_{Kr}$  and  $I_{Ks}$ ).

There is less capacity to respond to additional stresses that impair repolarisation such as hypokalaemia, hypomagnesaemia and drugs with class III action.

Prolonged action potential in LQTS predisposes to arrhythmia in two ways:

1. Extended plateau phase of action potential results in susceptibility to EAD-initiated arrhythmia.
2. Heterogeneity of prolonged action potential creates spatial dispersion of repolarisation, leading to regions of refractory block and substrate for re-entrant arrhythmia. This mechanism appears important in pharmacological LQTS.

**Table 18.11** Causes of long-QT syndrome

**Acquired**

## Drugs

Class IA antiarrhythmic drugs

Quinidine, procainamide

Class III antiarrhythmic drugs

Amiodarone, sotalol

Tricyclic antidepressants

Macrolide antibiotics

Phenothiazines

Antihistamines

Cisapride

Myocardial ischaemia/infarction

Hypokalaemia

Cardiomyopathy

Acute myocarditis

Mitral valve prolapse

Acute cerebral injury

Hypothermia

**Idiopathic**

Familial: 90%

Linked to a DNA marker on the short arm of chromosome 11

Autosomal-dominant in most cases

Some cases linked to congenital deafness and autosomal-recessive

Sporadic: 10%

Non-familial – related to new gene mutation

**IDIOPATHIC LQTS<sup>81</sup>**

Idiopathic LQTS is characterised by genetic heterogeneity with mutations in seven gene loci (*LQT1-7*), described below.

*LQT1* involves mutation of gene *KCNQ1* encoding for  $I_{Ks}$   $K^+$  channel, resulting in impaired  $K^+$  repolarising current. This accounts for approximately 50% of idiopathic LQTS, with an incidence of SCD of 0.30%/year, and has an inheritance pattern of both autosomal-dominant and recessive.

*LQT2* involves gene *KCNH2* encoding for  $I_{Kr}$   $K^+$  channel, again resulting in impaired  $K^+$  repolarising current. This accounts for 30–40%, has an incidence of SCD of 0.60%/year and the inheritance pattern is autosomal dominant.

*LQT3* involves gene *SCN5A* encoding for  $I_{Na}$   $Na^+$  channel, resulting in increased  $Na^+$  depolarising current. It accounts for 5–10%, has an incidence of SCD of 0.56%/year and the inheritance pattern is autosomal dominant.

The other described genetic mutations leading to LQTS are rare.

**CLINICAL FEATURES<sup>82</sup>**

Prevalence is estimated to be 1 in 3000–5000.

Thirty per cent of patients with idiopathic LQTS present with unexplained syncope or aborted sudden death (which is often not the first episode). The majority (60%) are identified when family members are screened after syncope or cardiac arrest in a family member. Ten per cent are detected on routine evaluation of ECG. The majority of episodes of syncope or sudden death (60%) are precipitated by emotions, physical activity or auditory stimuli causing acute adrenergic arousal. The degree of  $QT_c$  prolongation is not predictive of syncope or sudden death.

**MANAGEMENT**

The first line of management of polymorphous VT with shock is DC shock, with magnesium being the antiarrhythmic of choice.<sup>83</sup>

- Unresponsive rhythms or recurrence despite magnesium require pharmacological intervention (isoprenaline or adrenaline (epinephrine) depending on blood pressure) or electrical pacing.
- Factors associated with acquired LQTS need to be identified and eliminated.

Strategies for prevention of recurrence in idiopathic LQTS depend on the presentation. Patients who present with or have a history of syncope or aborted sudden death have a high risk of recurrence (5% per year).  $\beta$ -Blockers are the first line of treatment with the goal of reducing the exercise heart rate to less than 130 beats/min. Symptomatic bradycardia following adequate  $\beta$ -blockade requires a permanent pacemaker. Patients with recurrence despite these measures and those with

an early malignant course need stellate sympathetic ganglionectomy. In 5% of these high-risk patients triple therapy fails and an implantable defibrillator is required. Asymptomatic patients with incidental LQTS (< 0.5% per year) and asymptomatic family members (0.5% per year) have a very low risk of syncope or sudden death. It is also very rare for the first episode to be fatal in these two groups so prophylactic measures are generally not required and close follow-up is sufficient.

Class IA, IC and III drugs may increase QT interval and should be avoided in polymorphous VT and torsade de pointes.

### SUDDEN CARDIAC DEATH<sup>8,4</sup>

Arrhythmic causes of SCD can be divided into three categories:

1. primary VT or VF (most common)
2. primary SVT with a very rapid ventricular rate. This is usually associated with the development of AF or flutter in the presence of an accessory AV connection (but can occasionally be due to enhanced conduction over the normal AV conduction system)
3. bradycardia or asystole. Usually the result of an inadequate escape pacemaker mechanism associated with either a high-degree AV block or severe sinus node dysfunction. In addition, some patients with sinus node dysfunction have paroxysmal supraventricular arrhythmia (tachycardia-bradycardia syndrome) that on termination results in an exaggerated overdrive suppression of both the sinus node and escape pacemakers such that the prolonged pause evolves into asystole or VF

The causes of these arrhythmia can be divided into three general categories:

1. ischaemic heart disease. AMI or old myocardial infarction scar
2. non-ischaemic heart disease – cardiomyopathy, valvular heart disease, congenital heart disease, ventricular hypertrophy and cardiac trauma
3. no apparent structural heart disease – primary electrical disease, electrolyte abnormalities, prolonged QT syndromes and drugs

Contributing factors are often multifactorial, particularly the combination of structural heart disease, proarrhythmic drugs and electrolyte abnormalities.

### EVALUATION OF A SURVIVOR OF SCD

Primary prevention of SCD has been disappointing due to difficulties in selecting patients at risk. Regardless of the aetiology of the SCD, the reported recurrence rate is high, at least 30–40% at 1 year. Therefore, in-hospital assessment is critical to establish the underlying cause and to guide therapy.

### CORONARY ARTERY DISEASE AND SUDDEN CARDIAC DEATH

Extensive atherosclerotic coronary artery disease is the most common pathological finding in survivors and non-survivors of SCD. Fewer than 30% have evidence of a recent AMI. A larger proportion (up to 50%) has evidence of coronary artery thrombosis or plaque fissuring and rupture. In those patients not having an AMI, the majority (75%) have coronary artery stenosis (> 50% of lumen), and 60% have three-vessel disease. Approximately 50% have evidence of an old myocardial infarction. The fact that the typical pathological background for SCD is severe epicardial coronary artery disease, with or without an old myocardial infarction and evidence of a new ischaemic syndrome, underlines the central role that coronary artery disease plays in SCD.

### INVESTIGATIONS<sup>15–17</sup>

- chest X-ray: cardiac size, presence of pulmonary oedema
- 12-lead ECG: acute ischaemia, previous infarction, ventricular aneurysm or LV hypertrophy. Abnormalities of rate, rhythm, conduction or sinus node dysfunction. PR interval, QRS complex duration or QT interval. Changes of electrolyte abnormalities
- plasma electrolytes: potassium, magnesium and calcium. Potassium levels may be difficult to interpret after a period of resuscitation
- cardiac enzymes: serial troponin, creatinine phosphokinase with myocardial band fractionation and lactate dehydrogenase to establish the presence of a recent AMI
- plasma blood levels of drugs that affect cardiac rhythm or conduction: while proarrhythmic effects of drugs are more likely at high levels, it should be emphasised that proarrhythmia can occur at normal or low plasma drug levels
- toxicology screen: substance abuse or drug overdose (cocaine, psychotropic drugs), particularly in patients without overt structural heart disease
- 24-h Holter monitor ECG: quantitative analysis of frequency of arrhythmia and to detect silent myocardial ischaemia
- assessment of LV function: LV ejection fraction. Gated pool scan gives a better estimate of global LV systolic function, but echocardiogram will give added diagnostic information such as valvular disease and myocardial hypertrophy. Both studies will detect segmental wall motion abnormalities
- exercise tolerance test: standard exercise ECG or thallium-201 scans. Echocardiogram immediately following exercise may be as informative
- signal-average ECG: averages between 100 and 400 heart beats, for identification of low-amplitude electrical signals, such as afterdepolarisations. These are

found in the terminal portion of the QRS complex and cannot be seen on the 12-lead ECG. Associated with an increased risk of spontaneous and inducible ventricular arrhythmia

- cardiac catheterisation and coronary angiogram: to quantify the degree of coronary artery disease.
- EPS: virtually always indicated to document and characterise ventricular tachyarrhythmia. The initial baseline EPS should be performed in the absence of any antiarrhythmic drugs. Inducibility of sustained ventricular arrhythmias at EPS is associated with worse outlook, with a 5-year risk of SCD of 32% versus 24% in those without inducible arrhythmia, and is an indication for an implantable defibrillator. The inducibility of VT/VF is less common in survivors of SCD (44%) than patients who present with recurrent sustained VT. In patients with sustained monomorphic haemodynamically stable VT, EPS mapping techniques are used to determine the possibility of surgical or catheter ablation. EPS is also important in other causes of SCD other than VT/VF. Patients with ventricular pre-excitation (WPW syndrome) require localisation of the accessory pathway. Propensity to develop complete heart block can be assessed by a His-bundle ECG.

### PREVENTION OF RECURRENT VENTRICULAR ARRHYTHMIA IN SURVIVORS OF SUDDEN CARDIAC DEATH

#### MYOCARDIAL REVASCUARISATION AND SUDDEN CARDIAC DEATH

The Coronary Artery Surgery Study (CASS) registry looked at 13 476 patients with significant operable coronary artery disease and showed an incidence of SCD of 5.2% in the medical arm compared to 1.8% in those assigned to surgery.<sup>85</sup> The precise mechanism of the benefit of surgery in primary prevention is unclear but is probably associated with prevention of ischaemia rather than arrhythmia control. In summary, the near-universal practice of surgical coronary revascularisation in SCD survivors with critical stenoses is based upon this primary prevention data (and the central role that ischaemia and infarction are known to play in arrhythmia substrate) rather than data demonstrating arrhythmia control.

#### ANTIARRHYTHMIC DRUGS AND SUDDEN CARDIAC DEATH<sup>13,70–73</sup>

The CAST study has clearly demonstrated the poor results of antiarrhythmic drug therapy alone in the prevention of arrhythmic SCD. Data from studies in survivors of SCD using amiodarone are conflicting, but generally poor, even with EPS confirmation of lack of inducibility. Certainly patients with an ejection fraction less than 30% do poorly on amiodarone alone. The primary role of antiarrhythmic drugs in the secondary prevention of SCD has all but disappeared, but amiodarone may be indicated if there is demonstrable suppression of

inducible VT at EPS and the patient has an ejection fraction greater than 30–40%.

#### SURGICAL AND CATHETER ABLATION TECHNIQUES AND SUDDEN CARDIAC DEATH<sup>26</sup>

As most sustained ventricular arrhythmias arise from a scar within the myocardium, surgical attempts were made to excise these areas completely. Catheter ablation techniques for VT are suitable for the minority of patients with haemodynamically stable VT who can withstand prolonged mapping procedures. Currently, the success rates for ablative techniques are such that a significant number still need additional preventive therapies.

#### IMPLANTABLE CARDIOVERTER DEFIBRILLATORS AND SUDDEN CARDIAC DEATH

The reduction in SCD and overall cardiac mortality with implantable cardioverter defibrillators (ICDs) has been so spectacular and the results of previous therapies so poor that ICDs were initially introduced with little randomised controlled data. More recently controlled studies have shown:

- reduction in 3-year mortality by 31% compared to antiarrhythmic drug therapy in SCD survivors<sup>86</sup>
- reduced risk of death in patients with poor LV function following myocardial infarction<sup>87</sup>
- improved survival in patients with hypertrophic cardiomyopathy<sup>88</sup>

However, no survival benefit was shown in high-risk patients following coronary artery bypass surgery.

Representative data from several studies are shown in Table 18.12. The benefit of ICD on survival persists for at least 8 years. Current indications are expanding, but the benefit is clear in the following groups of survivors of SCD and patients with documented VT/VF outside the early postinfarct phase:

- non-inducible VT/VF at EPS
- inducible VT/VF resistant to treatment
- VT/VF in patients with LV ejection fractions less than or equal to 30% regardless of results of EPS-directed drug therapy

**Table 18.12** Mortality data for the various treatment regimens for sudden cardiac death

	Sudden death (%)	Total mortality (%)
Implantable cardioverter defibrillator	3.5	13.6
Empirical amiodarone	12.0	34.0
Electrophysiological study-directed drug treatment	14.0	24.0
Surgery	3.7	37.0

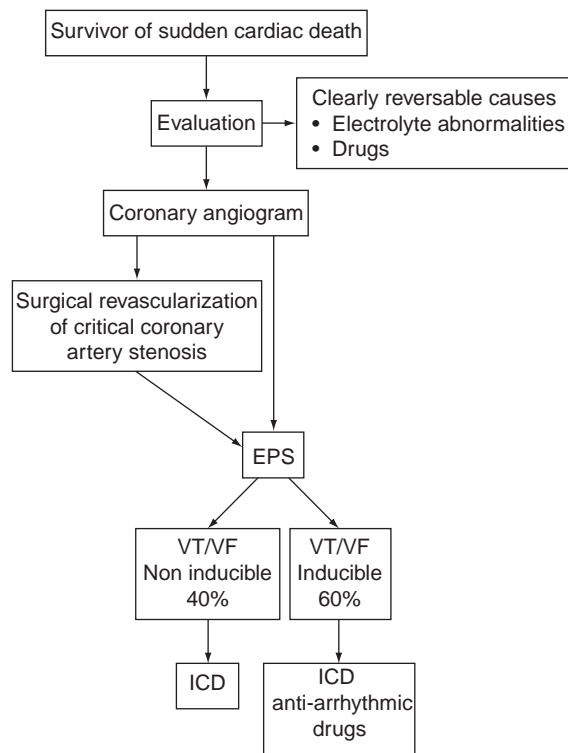

Further developments currently taking place include:

- transvenous catheter placement and subcutaneous patch avoiding the need for thoracotomy
- dual-chamber sensing to improve discrimination between SVT and VT that can be difficult on rate criteria alone, particularly in patients with intraventricular conduction delay
- technological advances reducing size, cost and increasing battery life

Although one of the proposed advantages of ICD is the avoidance of antiarrhythmic drug side-effects, particularly the myocardial depressant effects, current practice usually combines ICD with low-dose amiodarone. This enables improved arrhythmia control by reducing atrial tachyarrhythmia and slowing VT rate, and prolonging battery life by reducing the frequency of arrhythmia. The role of ICD in the management algorithms of SCD is shown in Figure 18.49 and 18.50. Given the current lack of available ICD, some advocate restriction to patients less than 75 years. With wider availability of ICD, fewer patients will be managed on drug-only strategies in the future.

**CLASSIFICATION OF ANTIARRHYTHMIC DRUGS**

The time-honoured physiologically based classification of antiarrhythmic drugs is the Vaughan-Williams classification (Table 18.13), which has been modified over the years. This classification is a hybrid, with classes I and IV representing ion channel blockers, class II representing a receptor blocker and class III representing a change in an electrophysiological variable. The prolongation of repolarisation, the defining effect of

**Figure 18.49** Management algorithm of a survivor of sudden cardiac death. This algorithm does not include the option of an antiarrhythmic drug alone in patients with intact left ventricular function who initially have inducible ventricular tachycardia/fibrillation (VT/VF) that is subsequently found to be suppressible on a drug with electrophysiological studies (EPS). ICD, implantable cardioverter defibrillator.

**Figure 18.50** Patients found to have inducible ventricular tachycardia (VT) or fibrillation (VF) at electrophysiological studies (EPS), with an ejection fraction > 40% and subsequent drug suppression of their VT/VF, can be managed on antiarrhythmic drugs alone.

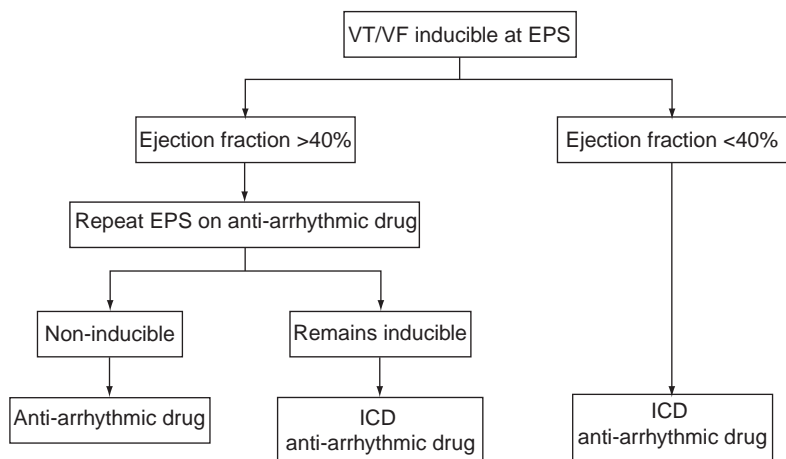

Table 18.13 Vaughan-Williams classification of antiarrhythmic drugs

	Mechanism of action	Effect on action potential	Indicative drugs
Class I Class IA	Sodium channel blockade	Depresses rate of rise of phase 0	Procainamide Disopyramide Quinidine
		Prolongs repolarisation	
Class IB		Shortens repolarisation	
Class IC		Minimal effect on repolarisation	Flecainide Encainide Propafenone
Class II	$\beta$ -Adrenergic receptor blockers		Propranolol Atenolol Metoprolol Esmolol
Class III	Potassium channel blockers	Prolong repolarisation	Amiodarone Sotalol Ibutilide Bretylium
Class IV	Calcium channel blockers		Verapamil Diltiazem

class III agents, can be produced by a block of any one of several  $K^+$  ionic channels (the delayed rectifier potassium current  $IK_r$  responsible for phase 3 repolarisation is the ionic channel target of most class III agents) or from modification of  $Na^+$  or  $Ca^+$  channel function. This classification is also incomplete and does not include cholinergic agonists, digitalis, magnesium and adenosine. For this reason, an alternative classification has been advocated based upon molecular targets for drug action that include ion channels, receptors and pumps/carriers (Table 18.14).<sup>2</sup>

## ANTIARRHYTHMIC DRUGS<sup>68</sup>

### DIGOXIN

Digoxin is a muscarinic subtype 2 receptor ( $M_2$ ) agonist and a highly potent  $Na^+,K^+$ -ATPase pump-blocking agent. Digoxin exerts its antiarrhythmic activity predominantly at the AV node where at lower doses conduction is slowed by the  $M_2$  vagotonic effect. This effect is easily reversed by enhanced sympathetic tone in the setting of exercise, critical illness and postoperative state. At higher concentrations, digoxin has a direct effect on AV node conduction by the  $Na^+,K^+$ -ATPase pump blockade and is more resistant to sympathomimetic effects. The decrease in  $[K^+]_i$  and increase in  $[Na^+]_i$  results in hyperpolarisation, shortening of atrial action potential and an increase in AV nodal refractoriness. There is also increased availability of intracellular  $Na^+$  for the  $Na^+-Ca^{2+}$  exchanger, increasing  $[Ca^{2+}]_i$ , which results in the positive inotropic effects of digoxin, making it an ideal agent in the setting of LV dysfunction. However, the positive

inotropic effects of  $Na^+,K^+$ -ATPase blockade are deleterious in the setting of myocardial ischaemia and other causes of diastolic dysfunction. Digoxin also has weak vasopressor properties when administered as a slow bolus.<sup>61</sup> The major ECG effects of digoxin are PR prolongation and a non-specific alteration in ventricular repolarisation with characteristic reverse-tick S-T segments.

### INDICATIONS AND DOSE

- AF: slowing of ventricular rate only
- loading dose: 15  $\mu$ g/kg IV, typically administered over 30–60 min, but can be given faster
- maintenance dose depends on renal function

### PLASMA LEVELS

Oral bioavailability can be reduced, especially if intestinal microflora-altering antibiotics are coadministered. Therapeutic levels are 0.5–2.0 ng/ml. Plasma levels must be measured during the postdistribution phase some 6–8 h after dose. The elimination half-life is 36 h with normal renal function. Difference between therapeutic and toxic levels can be reduced by hypokalaemia, hypomagnesaemia, hypercalcaemia, hypoxia, cardiac surgery and myocardial ischaemia. Many drugs increase digoxin plasma levels by competing with the renal P-glycoprotein-mediated transport, or by reducing renal blood flow or function.

### CONTRAINDICATIONS

Relative contraindications include myocardial ischaemia/infarction, diastolic heart failure due to hypertrophy and ischaemia, renal failure and hyperkalaemia, planned DC

**Table 18.14** Actions of antiarrhythmic drugs on membrane channels, receptors and ionic pumps in the heart

Drug	Channels			Receptors				Pumps		
	Na <sup>+</sup>			Ca <sup>2+</sup>	K <sup>+</sup>	α	β	M <sub>2</sub>	P	Na <sup>+</sup> ,K <sup>+</sup> ATPase
	Fast	Med	Slow							
Lidocaine	+									
Mexiletine	+									
Phenytoin	+									
Procainamide		+++			++					
Disopyramide		+++			++			+		
Quinidine		+++			++	+		+		
Propafenone		+++					++			
Flecainide			+++		+					
Encainide			+++							
Bretylum					+++	+/-	+/-			
Sotalol					+++		+++			
Amiodarone	+			+	+++	++	++			
Ibutilide					+++					
Dofetilide					+++					
Verapamil	+			+++		++				
Diltiazem				++						
Propranolol	+						+++			
Metoprolol							+++			
Esmolol							+++			
Atropine								+++		
Adenosine									A	
Digoxin								A		+++
Magnesium				+						A

Sodium channel blockers are subdivided into drugs with fast, medium and slow time constant for recovery from block. Receptors α, β-adrenoreceptors, muscarinic subtype 2 (M<sub>2</sub>) and A<sub>1</sub> purinergic (P). Relative blocking potency: low +, moderate ++, high +++. Partial agonist/antagonist: +/- . Agonist: A.

(Modified with permission from Task Force of the Working Group on Arrhythmias of the European Society of Cardiology. The Sicilian gambit: a new approach to the classification of antiarrhythmic drugs based on their actions on arrhythmogenic mechanisms. *Circulation* 1991; **84**: 1831–51.)

shock cardioversion and tachycardia–bradycardia syndromes. Coadministration with other drugs that effect AV nodal conduction, typically β-adrenergic and calcium channel blockers, requires caution.

### ADVERSE EFFECTS

The same increase in [Ca]<sub>i</sub> responsible for the positive inotropic effects of digoxin also forms the basis for toxicity arrhythmia. The increased inward calcium current is responsible for DAD-initiated arrhythmia. Digoxin toxicity can cause virtually any arrhythmia:

- DAD-related tachycardias with impairment of sinus node or AV nodal function
- unifocal atrial tachycardia with AV block is ‘classic’
- ventricular bigeminy and various degrees of AV block occur

With advanced toxicity severe hyperkalaemia due to poisoning of Na<sup>+</sup>,K<sup>+</sup>-ATPase results. Profound bradycardia, which may be unresponsive to pacing, develops.

Any serious toxicity arrhythmia should be treated with antidigoxin Fab fragments. Magnesium is the drug of choice for digoxin-toxic tachyarrhythmias. Digoxin, particularly if

at toxic levels, increases risk of VF precipitated by DC shock. Digoxin toxicity is associated with nausea, disturbances in cognitive function and blurred or yellow vision.

### β-ADRENERGIC BLOCKERS

β-Adrenergic blocking or class II antiarrhythmic drugs have differing properties such as relative cardioselectivity (atenolol, metoprolol), non-cardioselectivity (propranolol), intrinsic sympathomimetic activity (pindolol), lipid solubility and central activity (metoprolol, propranolol) and membrane-depressant effects (propranolol). The antiarrhythmic properties appear to be a class effect and no agent has been shown to be superior. There are data to suggest that the survival benefit of β-adrenergic blockers post myocardial infarction may relate to some extent to the central modulation of autonomic tone of the more lipid-soluble agents. The direct membrane-stabilising or ‘quinidine-like’ effect of propranolol requires doses far greater than those used clinically and is of negligible clinical significance. β-Adrenergic blockers competitively inhibit catecholamine binding at the β-adrenergic receptor sites, which reduces the phase 4 slope of the action potential of pacemaker cells, prolongs their refractoriness

and slows conduction in the AV node. Refractoriness and conduction in the His–Purkinje system are unchanged.  $\beta$ -Adrenergic blockers are most effective in arrhythmia associated with increased cardiac adrenergic stimulation (postoperative states, sepsis, thyrotoxicosis, phaeochromocytoma, exercise or emotion).

### INDICATIONS

#### Supraventricular tachycardias

$\beta$ -Adrenergic blockers may terminate SVT when the AV node is an intrinsic part of the re-entry circuit (AVNRT and AVRT); adenosine is more effective. AF and Afl do not revert with  $\beta$ -adrenergic blockers but the ventricular rate will be slowed.  $\beta$ -adrenergic blockers are effective at preventing SVT following cardiac surgery. Studies involving propranolol and atenolol have produced the best results.  $\beta$ -Adrenergic blockers are effective in MAT, but, as this arrhythmia is most often seen in patients with severe chronic airflow limitation and cor pulmonale, their utility is limited.<sup>30</sup>

#### Ventricular arrhythmias

$\beta$ -Adrenergic blockers are ineffective for the emergency treatment of sustained VT. Empiric prophylactic administration of  $\beta$ -adrenergic blockers appears to be as effective in ventricular arrhythmia prevention as electrophysiologically guided drug methods. However ventricular arrhythmia most often occurs in the setting of poor LV dysfunction and  $\beta$ -adrenergic blockers are either poorly tolerated or contraindicated.

#### Myocardial infarction

Survival in patients with AMI treated with thrombolytics is probably improved by early IV  $\beta$ -adrenergic blockade. There may be other benefits such as decreased incidence of VF and relief of chest pain. Long-term  $\beta$ -adrenergic blockade reduces mortality following myocardial infarction, the benefit being greatest in those at highest risk for sudden death. However, suppression of ventricular ectopy is not a requisite for benefit. Drugs with intrinsic sympathomimetic activity have not been shown to improve survival after AMI.

### ATENOLOL

Atenolol does not have significant central action due to poor lipid solubility and is eliminated predominantly by the kidneys with an elimination half-life of 7–9 h. Care is required in patients with poor or deteriorating renal function.

- loading dose IV: 5 mg every 10 min, maximum 10 mg
- loading dose oral: 50–100 mg
- maintenance dose oral: 50–200 mg/day
- ISIS-1 post-MI regime: 5 mg IV over 5 min, repeated 10 min later if heart rate exceeds 60 beats/min. If heart rate exceeds 40 beats/min 10 min later, oral 50 mg atenolol and continue at 100 mg daily

- SVT prophylaxis following cardiac surgery: 5 mg IV within 3 h of surgery, repeated 24 h later, followed by oral 50 mg daily for 6 days

### METOPROLOL

Metoprolol is lipid-soluble and has significant central action. It is eliminated by the liver with an elimination half-life of 3–4 h.

- loading dose IV: 1–2 mg/min, maximum dose of 15–20 mg
- loading dose oral: 100–200 mg
- maintenance dose oral: 50–100 mg/12-hourly

### PROPRANOLOL

Propranolol has been one of the most studied  $\beta$ -adrenergic blockers for SVT prophylaxis following cardiac surgery.

- dose: 10 mg orally 6-hourly starting the morning after surgery

### ESMOLOL

Esmolol is an ultrashort-acting cardioselective  $\beta$ -adrenergic blocker, which is especially useful for rapid control of ventricular rate in AF or Afl. Esmolol has also been shown to prevent postoperative SVT. The distribution half-life is 2 min and the elimination half-life is 9 min. Esmolol is rapidly metabolised by hydrolysis of the ester linkage, chiefly by the esterases in the cytosol of red blood cells and not by plasma cholinesterases or red cell membrane acetyl-cholinesterase.

- loading dose IV: 500  $\mu$ g/kg over 1 min
- maintenance dose IV: 50  $\mu$ g/kg per min for 4 min. If satisfactory rate control is not achieved, the loading dose should be repeated and the maintenance dose increased to 100  $\mu$ g/kg per min. If control is still not achieved after a further 4 min, then the procedure is repeated with 50  $\mu$ g/kg per min increments in the maintenance infusion until 300  $\mu$ g/kg per min is reached. Further increases in infusion rate are unlikely to be successful.

### CONTRAINDICATIONS

Reversible airways disease and poor LV function are two common relative contraindications, which limit the utility of  $\beta$ -adrenergic blockers in patients with cardiac disease.  $\beta$ -Adrenergic blockers may also be poorly tolerated in diabetics and patients with severe peripheral vascular disease.

### ADVERSE EFFECTS

$\beta$ -Adrenergic blockers, particularly those that are centrally acting, are often poorly tolerated in the long term. These effects include fatigue, hypotension, bradycardia, dry mouth, dizziness, headache and cold extremities.

### CALCIUM CHANNEL BLOCKERS

Calcium channel blockers or class IV antiarrhythmic drugs block the slow calcium channels in cardiac tissue. Verapamil and diltiazem have similar electrophysiological properties. The dihydropyridine group of calcium channel blockers, which include nifedipine, does not have any significant electrophysiological properties. Calcium channel blockers depress the slope of diastolic depolarisation in the SA node cells, the rate of rise of the phase 0 and action potential amplitude in the SA and AV nodal cells. They also slow conduction and prolong the refractory period of the AV node, which results in their main antiarrhythmic actions. Refractoriness of atrial, ventricular and accessory pathway tissue is unchanged. The sinus rate does not usually change significantly because calcium channel blockers induce peripheral vasodilatation, which causes reflex sympathetic stimulation of SA node. Verapamil particularly has marked negative inotropic actions and hypotension is often seen; however, cardiac index is generally maintained because of afterload reduction. Diltiazem has less negative inotropic effect than verapamil.

#### INDICATIONS

- SVT: calcium channel blockers are effective if the AV node is an integral part of the arrhythmia circuit. Verapamil has been superseded by adenosine for the first line of treatment for these with AVNRT and AVRT.
- AF and Afl: slow ventricular response in AF and Afl, but termination of the arrhythmia is uncommon. Verapamil may prolong episodes of AF through a proarrhythmic effect.
- MAT<sup>30</sup>: calcium channel blockers are effective.
- SVT following cardiac surgery: diltiazem has been shown not only to reduce, but also to decrease incidence of ventricular arrhythmia and postoperative ischaemia.
- AF associated with the WPW syndrome: calcium channel blockers may increase the ventricular response and should be avoided if this is suspected.<sup>27</sup>

In general, calcium channel blockers should not be given to patients with a wide-complex tachycardia not only because of the risk of accelerating accessory pathway conduction, but also because their myocardial depressant effects can result in cardiovascular collapse in the setting of VT and pre-existing myocardial dysfunction.

### VERAPAMIL

Verapamil is cleared by the liver with an elimination half-life of 3–8 h. Therapeutic plasma concentration is 0.1–0.15 mg/l. With the availability of adenosine and the better tolerance of diltiazem, the use of verapamil has fallen substantially.

- loading dose IV: 1 mg/min to a maximum of 10–15 mg or 0.15 mg/kg
- maintenance dose IV: 5 mg/kg per min
- maintenance dose oral: 80–120 mg 6–8-hourly

### DILTIAZEM

Diltiazem is cleared by the liver with an elimination half-life of 3.5 h. There is reduced oral absorption and extensive first-pass hepatic metabolism: only 40% of oral dose is available compared with IV.

- loading dose IV: 0.25 mg/kg, followed by 0.35 mg/kg if required
- maintenance dose IV: 5–15 mg per h
- maintenance dose oral: 60–120 mg 6–8-hourly
- SVT prophylaxis following cardiac surgery: 0.1 mg/kg per hour, starting at onset of bypass and continuing for 24 h. The dose can be titrated up for blood pressure control

### MAGNESIUM

Magnesium is an emerging antiarrhythmic agent with a range of indications; however, as an antiarrhythmic agent, magnesium has largely defied classification. Magnesium has many reported electrophysiological effects, including blocking voltage-dependent L-type Ca<sup>2+</sup> channels. Magnesium is a necessary cofactor for the membrane enzyme Na<sup>+</sup>/K<sup>+</sup>-ATPase that provides energy for the membrane Na/K channels.<sup>89</sup> The consequences of magnesium deficiency are as follows:

- Intracellular potassium falls and intracellular sodium rises, leading to a reduction in RMP.
- Intracellular sodium is elevated, increasing the availability of sodium for the Na/Ca counter transport mechanism.
- The resulting elevation in intracellular calcium predisposes to DAD-triggered activity.

Magnesium administration reduces the availability of intracellular Na<sup>+</sup> and therefore this Ca<sup>2+</sup> inward current. The dependency of normal membrane potassium gradients on magnesium is demonstrated by the inability to correct intracellular potassium deficiency with the administration of potassium in the setting of hypomagnesaemia. The antiarrhythmic properties of supranormal levels of magnesium associated with pharmacological doses of magnesium appear to be largely due to augmentation of this physiological role of magnesium. Therefore, magnesium may be best classified as a Na/K pump agonist.

Magnesium in pharmacological doses decreases RMP, resulting in a reduction in automaticity. However, once depolarisation occurs, the maximum rate of depolarisation and action potential amplitude is increased, thereby improving conduction. Action potential duration is increased, thereby increasing absolute refractory period and reducing relative refractory period. The net result is a reduction in the vulnerable period and more synchronous conduction. All of these electrophysiological effects are augmented in the setting of increased extracellular potassium. It is not surprising that the utility of magnesium appears greatest in the setting of ischaemia where loss of potassium from the cell is a major consequence.

A secondary effect is the reduction in the availability of intracellular sodium to contribute to inward calcium flux, producing triggered activity. Magnesium has also been shown to elevate VF and ectopy threshold.<sup>90</sup>

### INDICATIONS

- acute rate control of AF, and has been shown to be as effective as amiodarone<sup>63</sup>
- prevent postoperative SVT following cardiac surgery with varying efficacy
- acute control of MAT
- ventricular arrhythmia associated with triggered activity, such as torsade de pointes and digoxin toxicity<sup>83</sup>
- drug-induced polymorphous VT, particularly that caused by class I agents, can also be terminated with magnesium
- appears very effective at controlling transient ventricular arrhythmia in the setting of ischaemia such as post-infarct and cardiac surgery

### DOSE

- AF rate and MAT control: 0.15 mmol/kg as slow IV push. Subsequent dose recommendation has varied from 60 mmol to 0.1 mmol/kg per h for 24 h. Magnesium levels following 0.1 mmol/kg per h were  $1.92 \pm 0.49$  mmol/l at 24 h
- SVT prophylaxis following cardiac surgery: 20–25 mmol per day for 4 days
- transient ventricular arrhythmia: 10 mmol as a slow IV push, repeated if required
- LLIMIT-2 post myocardial infarction dose: 8 mmol bolus over 5 min, followed by 65 mmol over 24 h. Mean plasma level 1.55 (SD 0.44) mmol/l<sup>65</sup>

### PLASMA LEVELS

Observational data would suggest that plasma levels of magnesium required for potent antiarrhythmic action are at least 1.8 mmol/l.

### ADVERSE EFFECTS

- When administered too rapidly, magnesium can cause hypotension by excessive peripheral vasodilatation; this is associated with an unpleasant hot-flush sensation.
- Prolonged administration or excessive dosing can produce plasma levels associated with skeletal muscle weakness, which can be clinically significant in acute-on-chronic respiratory failure.
- Excessive action can be seen if magnesium is used in the setting of hyperkalaemia, resulting in bradyarrhythmia and heart block.

### PROCAINAMIDE

Procainamide is a class IA antiarrhythmic drug with potent Na<sup>+</sup> channel-blocking activity and intermediate K<sup>+</sup> channel-blocking activity. The Na<sup>+</sup> channel-blocking

action has an intermediate time constant of recovery. Procainamide has similar electrophysiological and ECG effects to quinidine but lacks vagolytic and  $\alpha$ -adrenergic blocking activity:

- decreases automaticity
- increases refractory period
- slows conduction

Procainamide is metabolised to *N*-acetyl procainamide. *N*-acetyl procainamide lacks Na<sup>+</sup> channel-blocking activity, but is equipotent in K<sup>+</sup> channel blockade and prolongation of action potential. The increasing effect of greater refractoriness and QT prolongation with chronic procainamide therapy relates to increased contribution of *N*-acetyl procainamide.

### CLINICAL USE

Procainamide is used to treat both atrial and ventricular arrhythmias.

- IV procainamide is more effective than lidocaine for terminating VT.
- Procainamide controls ventricular rate in AF and Afl.
- It is effective for conversion of AVNRT, AVRT and possibly AF and Afl.
- It controls rapid ventricular rate due to accessory pathway conduction in pre-excitation syndromes and for wide-complex tachycardias that cannot be distinguished as being SVT or VT.

The need to infuse slowly to avoid hypotension is the major barrier to wider use in life-threatening arrhythmia. Maintenance therapy with procainamide is not widely used due to its side-effect profile.

- loading dose IV: 6–17 mg/kg at 20 mg/min until there is arrhythmia control, hypotension ensues or QRS duration increases by more than 50%. Up to 50 mg/min has been used in urgent situations
- maintenance dose IV: 1–4 mg/min
- plasma levels: *N*-acetyl procainamide has a longer duration of action
- adverse effects: as with quinidine, the ventricular response may be accelerated if given for SVT. QT-interval prolongation and torsade de pointes may also occur

A reversible lupus-like syndrome develops in 20–30% of patients receiving procainamide long-term. Other side-effects include gastrointestinal disturbances (less common than with quinidine), central nervous system manifestations and cardiac depression.

### LIDOCAINE

Lidocaine, long considered an important antiarrhythmic drug for ventricular tachyarrhythmia, is now relegated to lower-choice options or missing from most treatment algorithms. Na<sup>+</sup> channel-blocking effect is increased in myocardial ischaemia and is unproven outside acute

ischaemia settings. It has no effect on SA node automaticity, but it depresses automaticity in other pacemaker tissues. Normally, lidocaine has little or no effect on conduction. The ECG shows no changes in sinus rate, PR interval, QRS width or QT interval with lidocaine.

#### CLINICAL USE

Lidocaine has reducing importance.

- It is ineffective against SVT.
- Amiodarone has taken over as the antiarrhythmic of choice for DC shock-resistant VF.<sup>58,59</sup>
- Lidocaine increases the current required for defibrillation, increases the likelihood of post DC shock asystole and therefore is detrimental during an episode of VF.
- Prophylaxis to prevent VF in AMI can no longer be recommended.

Extensive first-pass hepatic metabolism precludes oral use of lidocaine; IV dose should be reduced by 30–50% in severe liver disease or heart failure. The distribution half-life is about 8 min, and the elimination half-life is 1.5 h in normal patients (but may be increased > 10 h in severe heart failure or shock). An initial bolus of IV lidocaine 1.5–2.0 mg/kg over 1–2 min, followed by an infusion of 4 mg/min for 1 h, then 2 mg/min for 2 h, and thereafter 1–2 mg/min, is recommended. Increasing the maintenance infusion rate without an additional bolus requires about 6 h (four elimination half-lives) to reach a steady state. If the initial bolus is ineffective, another bolus of 1 mg/kg may be given after 5 min. Another dosage regimen is 1.5–2.0 mg/kg initially, and 0.8 mg/kg at 8-min intervals for three doses (i.e. three distribution half-lives), and thereafter 1–2 mg/min by infusion. The half-life of lidocaine increases after 24–48 h as the drug in effect inhibits its own hepatic metabolism and dose reduction is required.

#### ADVERSE EFFECTS

Central nervous system toxicity with high plasma concentrations are the most common adverse effects (e.g. dizziness, paraesthesia, confusion, and coma and convulsions). Uncommonly, AV block or cardiac depression may occur. Cimetidine reduces lidocaine clearance, potentially causing toxic drug concentrations.

#### FLECAINIDE

Flecainide exhibits rate-dependent Na<sup>+</sup> channel blockade with slow time constant of recovery, with marked slowing of conduction in all cardiac tissue, and little prolongation of refractoriness.

#### CLINICAL USE

- may revert AVNRT and AVRT, although adenosine and verapamil are more widely used

- useful in SVT, including AF and possibly Afl, particularly in the setting of accessory pathway syndromes
- flecainide has been given in life-threatening VT

Flecainide can be administered IV or orally. If flecainide is deemed necessary for prophylaxis of ventricular arrhythmias, therapy should start with ECG monitoring. In CAST, suppression of VEBs after myocardial infarction with flecainide was associated with increased mortality.<sup>13</sup>

- dose: IV loading 2 mg/kg at 10 mg/min
- oral maintenance: 100–200 mg 12-hourly

#### ADVERSE EFFECTS

- Depression of cardiac contractility. Flecainide is usually contraindicated in patients with abnormal LV function as it can worsen or precipitate heart failure.
- Conduction block. Avoid in high-degree AV block unless a pacemaker is in situ.
- Flecainide increases pacing capture threshold.
- Proarrhythmic events are common, especially in patients with depressed LV function, and may be life-threatening.
- Torsade de pointes may occur, even in patients without structural heart disease.
- Incessant VT may be induced, unresponsive to any therapy, including cardioversion.
- Although flecainide depresses intracardiac conduction, a paradoxical increase in ventricular rate may occur with Afl or fibrillation.
- Central nervous system effects include visual disturbances, dizziness and nausea.

#### PROPafenONE

Propafenone has a similar electrophysiological, haemodynamic and side-effect profile to flecainide and encainide. In addition, propafenone has non-selective  $\beta$ -blocking properties. Similar to flecainide, propafenone could be considered in both ventricular and SVT arrhythmia in the setting of normal LV function. Use of long-term propafenone should probably be limited because of its class IC profile, even though it was not included in the CAST study.

- dose: IV 2 mg/kg at 10 mg/min

#### AMIODARONE

Amiodarone is a potent antiarrhythmic agent with a complex electrophysiological and pharmacological profile. The appealing broad spectrum and haemodynamic stability of amiodarone have resulted in it emerging as the most frequently used antiarrhythmic in critically ill patients. In this setting short-term use predominates

and the formidable side-effect profile is much less significant. Amiodarone:

- prolongs action potential duration
- increases the refractoriness of all cardiac tissue
- has Na<sup>+</sup> channel blockade (class I), antiadrenergic (class II), calcium channel blockade (class IV) and antifibrillatory effects. The Na<sup>+</sup> channel blockade of amiodarone has a fast time constant for recovery
- QT prolongation reflects a global prolongation of repolarisation and is closely associated with its antiarrhythmic effects

When given IV, amiodarone has little immediate class III effect: the major action is on the AV node, causing a delay in intranodal conduction and a prolongation of refractoriness. This probably explains why IV amiodarone controls the ventricular rate in recent-onset AF, but is less effective for termination of this arrhythmia. Administration IV causes some cardiac depression, the magnitude depending on rate of administration and pre-existing LV function. Cardiac index is often unchanged because of its vasodilator properties.

#### CLINICAL USE

It is effective in suppressing both supraventricular and ventricular tachyarrhythmias.

#### SUPRAVENTRICULAR TACHYCARDIA

Amiodarone is effective in terminating and suppressing recurrences of AVNRT and AVRT tachycardias, although adenosine (for acute reversion) or verapamil (acute termination and long-term prophylaxis) is superior. Amiodarone IV is less effective in reverting Afl or AF, but the ventricular rate will slow. Administration over a longer time span (days to weeks) may be more effective in reverting recent-onset AF. In preventing recurrence of AF after reversion, amiodarone is comparable in efficacy to quinidine and flecainide but superior to sotalol and propafenone.<sup>47</sup>

#### DOSE

- Lower doses than that required for ventricular arrhythmia are usually sufficient.
- AVNRT and AVRT reversion AF and Afl rate control: 3–5 mg/kg IV over 10–60 min depending on blood pressure and myocardial function, followed by 0.35–0.5 mg/kg per h. Poor rate control can be improved with additional 1–2 mg/kg boluses.
- Postoperative AF prophylaxis: 200 mg orally 8-hourly for 5 days, followed by daily until hospital discharge.
- Long-term SVT control or AF rate control: 100–200 mg/day orally will usually suffice.

#### VENTRICULAR TACHYARRHYTHMIAS

Amiodarone IV may be effective in treating life-threatening ventricular tachyarrhythmias refractory to other drugs, especially in myocardial infarction and poor LV function. Amiodarone's efficacy in DC shock-resistant VF further confirms a prominent role in this setting.<sup>58,59</sup>

Long-term oral amiodarone is useful in controlling symptomatic VT and VF, especially when other conventional antiarrhythmics have failed. The absence of negative inotropic effect is useful in those with severely depressed LV function, but its many adverse effects limit widespread use. The Cardiac Arrest in Seattle, Conventional versus Amiodarone Drug Evaluation (CASCADE) study demonstrated that empirical amiodarone treatment was superior to guided (non-invasive Holter or EPS) class I drugs in survivors of VF unassociated with AMI. Amiodarone prevented arrhythmia recurrence and decreased the incidence of sudden death. Amiodarone, presumably because it is better tolerated in patients with poor LV function and having less proarrhythmia, can be considered as first-line drug to prevent life-threatening ventricular tachyarrhythmias.<sup>71–73</sup> The rate of arrhythmia control is often slower with ventricular arrhythmia and may take several days to achieve. This delay appears to be independent of dose. The pharmacodynamic basis for this relates to the fact that much of the class III or K<sup>+</sup> channel-blocking activity is due to the amiodarone metabolite, desethylamiodarone, whereas the predominant actions of acute administration of amiodarone are due to its class I and class II activity. The full potency of the class III activity requires several days, at least, for the effects of desethylamiodarone to appear.

#### DOSE

- haemodynamic stable VT: 5–7 mg/kg over 30–60 min, followed by 0.5–0.6 mg/kg per h
- DC shock-resistant VF: 5 mg/kg, followed by 2.5 mg/kg if required<sup>59</sup>
- long-term prevention of ventricular arrhythmia: oral loading with 1200 mg/day for 1–2 weeks, reducing to 400–600 mg/day and then 100–400 mg/day after 2–3 months. The dose should probably not be reduced below 400 mg/day with life-threatening ventricular arrhythmia

#### MYOCARDIAL INFARCTION

Data are limited at present, but amiodarone may improve long-term survival in patients after myocardial infarction.

#### PHARMACOKINETICS

Oral bioavailability of amiodarone is variable at 40–70% with a delayed onset of action (days to weeks); however loading doses reduce this interval. Initial IV dose recommendations were 5–7 mg/kg over 30 min, followed by 50 mg/h. The kinetics of amiodarone have been modelled to four compartments when given acutely. Following a slow IV bolus over 15 min, amiodarone is rapidly distributed to the active compartment ( $t_{1/2}^a = 4.2$  min), with demonstrable prolongation of QTc and antiarrhythmic effect within 2–5 min. Subsequently, amiodarone is progressively redistributed to 'deeper' compartments ( $t_{1/2}^b = 36.6$  min,  $t_{1/2}^c = 4.5$  h and  $t_{1/2}^d = 33.6$  h).<sup>91</sup> This is in contrast to the very prolonged terminal half-life – greater than 50 days – after

long-term treatment. This redistribution of amiodarone explains why repeated boluses are often required in the first 24–48 h of treatment. Transient loading-dose hypotension due to myocardial depression or vasodilatation is dose-, rate- and patient-dependent. A loading dose of 5 mg/kg over 20 min resulted in significant further myocardial depression and a fall in cardiac index, whereas in patients without evidence of heart failure, 5 mg/kg over 1 min resulted in hypotension due to systemic vasodilatation and an increase in cardiac index.<sup>92,93</sup>

### MONITORING

Plasma amiodarone concentrations have poor correlation with arrhythmia control, and therapeutic levels, 1.0–2.5 mg/l, have the greatest utility for avoidance of adverse effects in long-term treatment.

### ADVERSE EFFECTS

Adverse effects will occur in the majority of patients if they receive amiodarone for long enough. Most are reversible when the drug is discontinued. Adverse effects include:

- dermatological: photosensitivity, bluish/grey skin discoloration (slate-blue skin)
- eye: corneal microdeposits (almost 100%) with little or no clinical significance
- gastrointestinal disturbances
- hypo- and hyperthyroidism
- liver dysfunction: asymptomatic increases in liver enzymes are common, and do not require amiodarone cessation unless enzymes are 2–3 times normal; hepatitis is rare
- neuropathy, myopathy and cerebellar abnormalities
- pulmonary toxicity: unexpected acute respiratory distress syndrome has been reported in patients on amiodarone undergoing procedures such as uncomplicated cardiopulmonary bypass surgery and pulmonary angiography. These observations suggest that amiodarone may predispose the lung to acute injury. Pulmonary toxicity is the most serious adverse effect, with a reported incidence of 10% at 3 years. Amiodarone pulmonary toxicity has been reported in one case after 13 days and 11.2 g cumulative dose and 11.2 g over 2 weeks in another. Patients on long-term amiodarone need regular respiratory function testing and an increase in diffusion limitation of carbon monoxide 15% above baseline requires dose modification or cessation. The severe syndrome of shortness of breath, cough and fever with pulmonary crepitations and widespread pulmonary infiltrates on chest X-ray has a mortality of 10%. Immediate discontinuation is necessary. Use of steroids is controversial

Amiodarone interacts with other drugs, potentiating warfarin, digoxin and other antiarrhythmic agents. When administered concurrently, doses of these drugs should be reduced accordingly. On the positive side, long-term amiodarone is unlikely to precipitate or worsen heart failure and proarrhythmias are uncommon.

### SOTALOL

Sotalol prolongs action potential duration, thereby prolonging the effective refractory period in the atria, ventricles, AV node and accessory AV pathways. It is also a potent non-cardioselective  $\beta$ -adrenergic blocker (class II). Sotalol also has antifibrillatory actions which are superior to those of conventional  $\beta$ -blockers. It can worsen heart failure in patients with depressed LV function. The negative inotropic  $\beta$ -blocking effect is slightly offset by a weak positive inotropic effect due to prolongation of the action potential (resulting in more time for calcium influx into contracting myocardial cells).

### CLINICAL USE

Higher doses of sotalol are required to prolong cardiac repolarisation than to cause  $\beta$ -blockade. Sotalol may be administered IV or orally, and is excreted by the kidneys (elimination half-life 15 h); IV dose is 0.5–1.5 mg/kg over 5–20 min. Oral therapy is initiated at 80 mg 12-hourly and increased to 160 mg 12-hourly, although doses of 320 mg 12-hourly have been administered.

### SUPRAVENTRICULAR TACHYCARDIA

- effective in AVNRT and AVRT, although adenosine and verapamil are superior. Long-term sotalol will prevent recurrences of these arrhythmias
- probably ineffective for reversion of AF/Afl, but is effective in preventing recurrence of AF after cardioversion. If AF recurs, heart rate is likely to be well controlled with sotalol
- prevents postoperative SVT

### VENTRICULAR ARRHYTHMIAS

Sotalol is superior to lidocaine to terminate sustained VT, and should be considered a first-line drug in patients without heart failure. Oral sotalol is more effective than class I drugs for the long-term prevention of VT or VF. Guided (Holter or EPS) sotalol and empirical amiodarone are first-line drugs to prevent recurrences of VT and VF over the long term; however, the worse outcome with sotalol in SWORD has significantly reduced the role of sotalol in this setting.<sup>70</sup>

### ADVERSE EFFECTS

Side-effects of sotalol are mainly due to  $\beta$ -blockade (e.g. bronchospasm, heart failure or AV conduction problems) and prolongation of QT proarrhythmia (e.g. torsade de pointes, similar 2% incidence as quinidine, which may occur early during drug titration or later during long-term treatment).

### IBUTILIDE

Ibutilide is an  $I_{Kr}$   $K^+$  channel blocker, which prolongs action potential and increases the refractory period. This agent, with class III effect, is recommended for acute pharmacological conversion of AF and Afl, or as an

adjunct to improve success of DC shock cardioversion. The success rate for ibutilide alone is higher for Afl (50–70%) than that with AF (30–50%) and, as expected, efficacy is greatest in short-term AF/Afl without structural heart disease. The major role of ibutilide appears to be cardioversion pretreatment to facilitate reversion to sinus rhythm from AF.<sup>45</sup> Ibutilide has minimal effect on blood pressure and heart rate and the major adverse effect is proarrhythmia, with torsade de pointes occurring in 3–6% of patients. For this reason, patients should be monitored for at least 6 h after administration. Ibutilide has a short duration of action and other antiarrhythmic drugs are required to maintain sinus rhythm.

#### DOSE

For patients weighing more than 60 kg, 1 mg over 10 min, which can be repeated 10 min later if unsuccessful. In patients weighing less than 60 kg, 0.01 mg/kg is given as initial dose.

#### DOFETILIDE

Dofetilide is one of the latest class III  $I_{Kr}$   $K^+$  channel blockers being investigated in the hope of finding an antiarrhythmic drug for long-term use with amiodarone's efficacy but without its side-effect profile. Dofetilide's emerging role is again in pharmacological cardioversion of AF and Afl (superior to sotalol, similar to amiodarone but inferior to ibutilide) in about 30% of patients. Prevention of recurrence is similar to amiodarone and long-term oral therapy is not associated with increased mortality in post-MI and heart failure patients. It also appears safe in patients with LV dysfunction. Early (first 3 days) proarrhythmia (3.3% of patients developed torsade de pointes) also necessitates monitoring with commencement of therapy.<sup>40,46,94,95</sup>

#### DOSE

Recommended dose is 500 mg orally 12-hourly. Dose requires adjustment for renal function and QT-interval monitoring ( $QT_c$  interval > 500 ms necessitates cessation) for a minimum of 3 days.

#### ADENOSINE

Adenosine stimulates specific  $A_1$  receptors present on the surface of cardiac cells, thereby influencing adenosine-sensitive  $K^+$  channel cyclic adenosine monophosphate production. It slows the sinus rate and prolongs AV node conduction, usually causing transient high-degree AV block. The half-life of adenosine is usually less than 2 min as it is taken up by red blood cells and deaminated in the plasma. This ultrashort half-life is a major advantage over other antiarrhythmic drugs. The effects of adenosine, both antiarrhythmic and haemodynamic, can be antagonised by methylxanthines, especially theophylline and caffeine. Dipyridamole, an adenosine uptake blocker, potentiates the effect of adenosine. Adenosine

effects are prolonged in patients on carbamazepine and in denervated transplanted hearts.

#### CLINICAL USE

- AVNRT and AVRT tachycardias: the drug of choice. Expected reversion rates exceed 90%.<sup>24</sup> The AV nodal-blocking actions of adenosine may unmask atrial activity (e.g. flutter waves in Afl).
- Diagnosis of a wide-complex tachycardia may be assisted by the use of adenosine.
- SVT with intraventricular conduction block will terminate with adenosine, whereas few VTs will revert. Whether adenosine should be used routinely to discriminate between VT and SVT with aberrancy in haemodynamically stable wide-complex tachycardia is unclear. Potential for haemodynamic collapse in VT is real and ILCOR advises against.

Adenosine will not revert AF. Ventricular rate may transiently increase AF associated with the WPW syndrome.

Adenosine is given as a rapid bolus through a large peripheral or central vein followed by a saline flush, at intervals less than 60 s. The usual dose is 6 mg, followed by 12 mg if response is ineffective. Another 18 mg can be given if the last dose was well tolerated.

#### ADVERSE EFFECTS

Most patients experience transient side-effects such as flushing, shortness of breath and chest discomfort. Adenosine should not be given to asthmatic patients as bronchospasm may result.

#### DIRECT CURRENT CARIOVERSION<sup>96</sup>

DC cardioversion/defibrillation is an important treatment option in tachyarrhythmias. In addition to its emergency role in cardiac arrest from VF or VT, urgent DC cardioversion is indicated in haemodynamically unstable VT and sustained SVT that precipitate angina, heart failure or hypotension. More elective DC cardioversion is indicated in haemodynamically stable VT following a trial of antiarrhythmic drug therapy. Cardioversion is most commonly used in AF/Afl once potential precipitants have been eliminated and, again, usually after antiarrhythmic drug treatment to prevent further episodes. Digoxin toxicity is a relative contraindication to DC cardioversion, which should also be used with care in patients on digoxin.

#### MECHANISM OF ACTION

The exact mechanism of action is unknown. DC shocks need to produce a current density that depolarises a critical mass of myocardium, thereby leaving insufficient myocardium to maintain the re-entrant tachycardia and prevent reinitiation. For VF and AF, the critical mass

involves the entire ventricles or atria, whereas for the more organised tachyarrhythmias, VT and Afl, which involve specific re-entrant circuits, regional depolarisation in the path of their circulating wave fronts is all that is required. DC shocks also prolong the refractoriness of myocardium and this effect will contribute to the arrhythmia termination and prevention of immediate recurrence.

### ELECTRICAL ENERGY

Even though the goal is to achieve a certain current through the entire heart, atria or a region depending on the arrhythmia, DC shocks are prescribed as energy measured in joules (J) or watt-seconds. Obviously it would make more sense to be able to deliver a set current. This would prevent delivering inappropriately low currents in patients with high impedance and excessive current flow causing myocardial damage in patients with low impedance. Clinical studies to determine current doses are under way for defibrillation and cardioversion. The optimal current for VF using monophasic damped sinusoidal (MDS) waveform for cardioversion appears to be 30–40 A. Current dosage for biphasic waveform is not available.

### CURRENT WAVEFORM

Modern defibrillators deliver a current, the magnitude of which depends on the prescribed energy and thoracic impedance. This current can be delivered in a number of different waveforms.

MDS defibrillators deliver current that is in a single direction or polarity. They can be further characterised by the rate at which the current pulse returns to zero. MDS waveforms return to zero gradually, whereas truncated exponential waveform return instantaneously. Recent evidence suggests that biphasic waveform for cardioversion (BTE) provide equal efficacy at lower electrical energies. A sequence of two current pulses is generated; the polarity of the second is in the direction opposite to the first. Biphasic waveforms with lower shock energies are associated with fewer ST-segment changes and less postresuscitation myocardial dysfunction and have an ILCOR class IIa recommendation.

### THORACIC IMPEDANCE

The magnitude of current flow is dependent on the resistance to current flow or thoracic impedance. The average adult thoracic impedance is 70–80  $\Omega$ . Factors which determine thoracic impedance include:

- energy selection
- electrode size
- electrode composition
- paddle-to-skin coupling
- distance between electrodes
- number of previous shocks

- time interval between previous and present shock
- pressure on electrodes
- phase of ventilation
- patient's body build
- recent sternotomy

Conductive gel reduces impedance, while hair trapping air between skin and paddle and self-adhesive monitor/defibrillator electrode pads may increase it. There is no clear relationship between body size and energy requirements but compensation for patient-to-patient differences in impedance can be achieved by changes in duration and voltage of shocks, or by a process called burping, which involves releasing the residual membrane charge.

### PADDLE POSITION AND SIZE

ILCOR recommends standard placement of sternum paddle just to the right of the upper sternal border below the clavicle and the apex paddle to the left of the nipple, with the centre of the paddle in the mid-axillary line. Permanent pacemakers and ICD must be avoided as shock may cause malfunction or block current going to the heart. Inevitably, some current passes down the pacemaker lead and it is necessary to check pacing threshold postshock. Other alternative paddle placements can enable avoidance of pacemakers and ICD or perhaps improve current direction. Using self-adhesive electrodes, the sternum electrode can be placed posterior to the heart on the right infrascapular region and the apex on the left precordium. The use of right parasternal and left posterior infrascapula has been advocated for AF because this configuration provides an optimal vector of current delivery to the atria. Large electrodes or paddles have less impedance; however, excessively large electrodes may result in less transmural current flow. The minimum recommended electrode size is 50 cm<sup>2</sup>, with the sum of both electrodes exceeding 150 cm<sup>2</sup>.

### SYNCHRONISED CARDIOVERSION

With cardioversion of atrial tachyarrhythmias and VT, when time permits, synchronisation of DC shock with the R-wave of the QRS complex is required to reduce the possibility of inducing VF by delivering the shock during the relatively refractory portion of the T-wave of the cardiac cycle. Synchronisation in VT may be difficult and misleading because of the wide complex or polymorphous nature. Synchronisation should not delay DC shock in pulseless VT or VT associated with unconsciousness, hypotension or severe pulmonary oedema.

### DIRECT CURRENT SHOCK DOSAGE

Recommendations for energy doses are changing, as biphasic waveform generators become more widely available. Where studied, BTE shocks have been consistently as effective as higher-energy MDS shocks. Recommended

doses are always a balance between that energy likely to generate a critical current flow and an energy not likely to cause functional and morphological damage. Electrical energies greater than 400 J have been reported to cause myocardial necrosis.

- VF and pulseless VT: escalating MDS shocks, starting at 200 J, then 200–300 J and, finally, 360 J. Evidence for sequential escalation of the energy dose is not strong and repeated shocks at the same energy result in increasing current delivery as impedance falls. Repeated non-escalating lower-energy BTE shocks, in the range of 150–175 J, are as effective as escalating MDS recommendations.
- VT: energy dose for cardioversion of VT depends on morphology and rate. For monomorphic VT, synchronised 100 J MDS is the starting energy. For polymorphic VT, synchronised if possible, 200 J MDS is the starting energy and for both stepwise increases if the first shock fails.
- AF: initial energy is synchronised 100–200 J MDS and stepwise increases if first shock fails. Despite obvious concerns for myocardial injury, megadose energy at 720 J has been used with success in large patients with AF refractory to 360 J, without evidence of myocardial injury. Constant-current, rectilinear biphasic waveforms appear to be more effective in cardioverting AF. This biphasic waveform at the low energy of 120 J was superior to 200 J MDS.
- Afl, AVNRT and AVRT: these atrial tachyarrhythmias require least energy and the initial recommended energy is synchronised 50–100 J MDS.

### SEDATION

A separate doctor expert in managing the airway must perform sedation for cardioversion. The dose of the sedating agent is titrated on the basis of patient factors and type of arrhythmia. Patients with poor myocardial function not only need reduced dose, but also onset time is slower because of low cardiac output. Sensitive tachyarrhythmias such as Afl require only low doses, whereas AF is likely to need higher and repeated doses as higher energy and repeated shocks may be necessary. Cardioversions should be performed with standard resuscitation equipment available and preoxygenation is crucial.

### DIGOXIN AND CARDIOVERSION

Digoxin toxicity results in a significant reduction in the threshold for inducing ventricular arrhythmia with DC shock. If digoxin toxicity is a possibility, then reconsideration of the need for cardioversion or at least careful titration of energy is required. Clinical experience would suggest the latter procedure of starting with 10 J MDS, and a stepwise increase thereafter increases safety of DC shock in this setting.

### ANTICOAGULATION FOR CARDIOVERSION<sup>96</sup>

Cardioversion of AF and, to a lesser extent, Afl is associated with catastrophic thromboembolism, especially stroke. Early studies suggested an incidence of up to 6.3% without anticoagulation. It is accepted that the propensity of clots to form in the left atrium after 48 h in AF and for these to be dislodged when sinus rhythm is restored is so high that anticoagulation is indicated prior to cardioversion in AF.

Anticoagulation for 3–4 weeks before cardioversion reduced the risk of embolism by 80%. The risk of thromboembolism following cardioversion continues for a period:

- Echocardiographic findings suggestive of atrial thrombi formation occur in up to 35% of patients postcardioversion.
- Left atrial appendage emptying velocities often decrease despite the development of coordinated electrical activity after cardioversion, presumably because of stunning of mechanical function.

Prolonged AF greater than 48 h requires anticoagulation for 3 weeks prior to cardioversion and warfarin therapy for at least another 4 weeks depending on risk of recurrence of AF.

Transoesophageal echocardiography, which allows detection of thrombi in the left atrial appendage with much greater accuracy, has been found to be a safe means of expediting cardioversion. Anticoagulation with heparin for 1 day or warfarin for 5 days prior to demonstrating the left atrium to be free of thrombi by transoesophageal echocardiography, then 4 weeks of warfarin following cardioversion, was as effective in preventing emboli as the conventional longer anticoagulation regime. However, there was a significant reduction in major haemorrhagic events in the transoesophageal echocardiography-guided, shorter lead-in anticoagulation strategy.

# Cardiac pacing and implantable cardioverter/defibrillators

Karl D Donovan and Bernard E F Hockings

Cardiac pacing has rapidly evolved since its introduction by Zoll in 1952.<sup>1</sup> The technological knowledge gained in pacing has assisted in the even more rapidly advancing field of implantable cardioverter/defibrillators (ICDs). Although implantation and follow-up of permanent pacemakers and ICDs are in the domain of appropriately trained cardiologists, intensive care physicians should be familiar with such devices as a significant number of critically ill patients will have them in situ. It is also essential, when urgent pacing is required, that the intensivist is skilled in all aspects of temporary pacing, including lead insertion and testing.

Cardiac pacing repetitively delivers very low electrical energies to the heart, thus initiating and maintaining cardiac rhythm. Pacing may be temporary, with an external pulse generator, or permanent, with an implanted pulse generator. It is usually associated with the treatment of bradycardia, but rapid atrial or ventricular pacing can be used to terminate certain supraventricular tachycardias (SVTs) and ventricular tachycardias (VTs).

More recently, the indications for cardiac pacing have expanded beyond symptomatic bradycardia and include conditions such as hypertrophic obstructive cardiomyopathy (HOCM), congestive cardiac failure (cardiac resynchronisation therapy: CRT) and prevention of atrial fibrillation (AF).

## CARDIAC PACING IN BRADYARRHYTHMIAS<sup>2,3</sup>

### ELECTRODES

#### UNIPOLAR (FIGURE 19.1)

The pacing lead has only one conducting wire and electrode. Electric current returns to the pacemaker via the body fluids. A unipolar lead is rarely used for temporary pacing, as a skin electrode is also needed for the return current pathway, which may cause muscle twitching. Unipolar systems are sometimes used for permanent pacing. Oversensing of electromagnetic interference (EMI) or skeletal muscle potentials may be a significant problem.

#### BIPOLAR (FIGURE 19.2)

A bipolar lead has two conducting wires surrounded by a layer of insulation. Electric current travels down one wire to an electrode (usually the distal), passes through cardiac tissue to cause depolarisation, and returns to the pacemaker via the second electrode. Inappropriate sensing of EMI or myopotentials is uncommon. Bipolar pacing is the method of choice for temporary pacing. If one limb fails, a bipolar system can be converted to a unipolar system (see Figure 19.1) by connecting the other limb to one pacemaker pole (usually positive). The other pole (usually negative) is connected to an electrocardiogram (ECG) skin electrode to complete a unipolar pacing circuit.

### PACING SITES

#### TRANSVENOUS ENDOCARDIAL PLACEMENT

The pacing lead is passed via a vein to the endocardial surface of the right atrium (RA), or most commonly, the right ventricle (RV). Rarely, the left atrium (LA) may be paced via the coronary sinus.

#### EPICARDIAL PLACEMENT

This is mainly used in conjunction with cardiac surgery, where the electrodes are attached directly to the epicardial surface of the atrium and/or ventricle.

#### TRANSCUTANEOUS EXTERNAL PACING

Transcutaneous pacing patches have high impedance, resulting in better current density and less pain and discomfort. Adequate, adjustable current outputs (50–150 mA) are delivered. Some patients will experience significant pain and may need analgesics. Although transcutaneous pacing can be initiated quickly by personnel unskilled in transvenous pacing, it is only a temporising measure until the latter can be instituted. Reliable transcutaneous pacing has rendered prophylactic temporary transvenous pacing obsolete.

Other pacing modalities such as the transoesophageal route are rarely used. A pacing Swan–Ganz catheter is

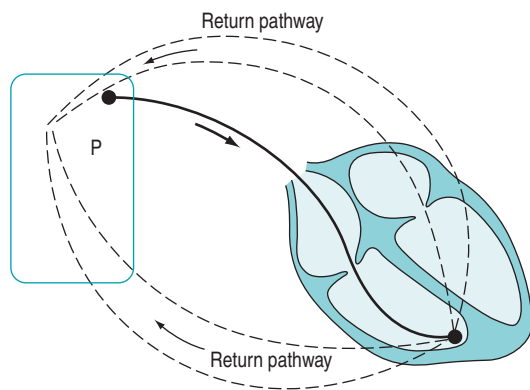

Figure 19.1 Unipolar pacing lead. P, pacemaker.

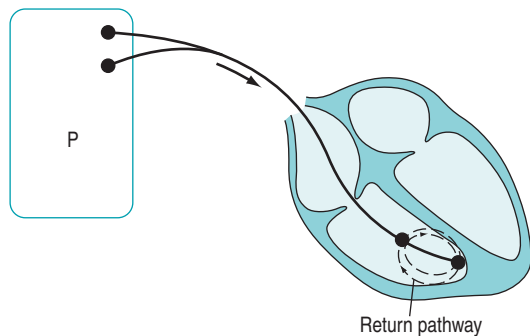

Figure 19.2 Bipolar pacing lead. P, pacemaker.

unstable and should not be relied upon in pacemaker-dependent patients.

## PACING LEADS

### TEMPORARY PACING

#### Ventricular pacing

(5–6 FG). Leads are relatively stiff but still flexible enough to be manipulated under fluoroscopic control to the correct position in the RV. Balloon-tipped leads which, in theory, float into a stable position in the RV are occasionally used in some units when fluoroscopy is not available.

#### Atrial pacing

Atrial leads have a preformed J-tip to hook into the RA appendage, as this usually ensures pacing lead stability with a low pacing threshold and good sensing capacity.

### PERMANENT PACING

Leads for permanent pacing commonly use passive fixation with protrusions close to the tips to ensure wedging or entanglement of the electrode in the trabeculations of the RV. Alternatively, active fixation with myocardial penetration by an extendable screw at the electrode tip is used. Steroid eluting leads may reduce pacing stimulation thresholds. Pacing lead insulation problems remain a limiting factor in pacing lead longevity.

## PACEMAKER MODES

The North American Society of Pacing and Electrophysiology (NASPE) and the British Pacing and Electrophysiology Group (BPEG) developed the NBG code<sup>4</sup> for pacing. It is a generic code used to identify modes of pacing (Table 19.1). The code was updated in 2002 to include multisite pacing therapy (position V).<sup>5</sup>

Table 19.1 The North American and British Group (NBG) pacemaker code

Position I	Position II	Position III	Position IV	Position V
Chamber(s) paced	Chamber(s) sensed	Response to sensing	Rate modulation	Multisite pacing
O = none	O = none	O = none	O = none	O = none
A = atrium	A = atrium	T = triggered	R = rate modulation	A = atrium
V = ventricle	V = ventricle	I = inhibited		V = ventricle
D = dual	D = dual	D = dual		D = dual
(A + V)	(A + V)	(T + I)		(A + V)
<b>Manufacturer's designation only:</b>				
S = single	S = single			
(A or V)	(A or V)			

Note: Positions I–III are used exclusively for antibradycardia function.

(Reproduced from Bernstein AD, Daubert JC, Fletcher RD *et al.* Pacing. *Clin Electrophysiol* 2002; **25**: 260.)

- **Position I:** refers to the chamber(s) paced: A = atrium; V = ventricle; and D = dual chambers, i.e. both A and V.
- **Position II:** refers to chamber(s) in which sensing occurs: A = atrium; V = ventricle; and D = dual chambers, i.e. both A and V.
- **Position III:** refers to the pacemaker's response to a sensed event. This may be:
  - (a) I (inhibition) – a pacemaker's discharge is inhibited (switched off) by a sensed signal, for example, VVI, where ventricular pacing is inhibited by spontaneous ventricular activity.
  - (b) T (triggering) – a pacemaker's discharge is triggered by a sensed signal.
  - (c) D (dual) – both T and I responses can occur. This designation is reserved for dual-chamber systems. A depolarisation sensed in the atrium inhibits the atrial output but triggers ventricular pacing. There is, however, a delay (the AV interval) between the sensed atrial depolarisation and the triggered ventricular pacing which mimics the normal P-R interval. If a spontaneous ventricular depolarisation is sensed, ventricular pacing is inhibited.
- **Position IV:** refers to R or rate modulation. An R indicates that the pacemaker incorporates a sensor to vary the pacemaker independently of intrinsic cardiac activity. A sensor,<sup>6</sup> in effect an artificial sinoatrial (SA) node, increases or decreases the heart rate according to the body's metabolic needs. Two different sensors are widely used:
  1. Activity sensors with vibration detectors (accelerometer or piezoelectric crystal) have the disadvantage that they may respond to non-physiological stimuli, for example, pacing rate increase may occur when the patient is using an electrical drill. On occasions this response can be used to good effect, for example, an inappropriate bradycardia in a shocked patient with a rate-adaptive (activity sensor) permanent pacemaker can usually be speeded up by tapping the skin over the unit.
  2. Minute ventilation sensors (respiratory rate times tidal volume, which is estimated by measuring impedance differences between the pacing electrode and the pacemaker unit) rely on minute volume changes to alter the pacing rate. This sensor may occasionally inappropriately accelerate the pacing rate, for example, in a mechanically ventilated patient requiring a large minute volume. Changing the 'upper rate' limit of the pacemaker or switching the rate-adaptive function 'off' will usually solve the problem.

Other sensors, such as ventricular paced Q-T interval systems, have also been successfully used in clinical practice. Recently, rate-adaptive systems with dual sensors, where one sensor cross-checks the other and only responds if both sensors are receiving consistent data, have become available.

All modern permanent pacemakers are programmable, i.e. multiple pacing parameters, such as

current output, rate and mode, can be changed by an external device (programmer).

- **Position V:** is now used to indicate whether multisite pacing is present: O = none of the cardiac chambers; A = one or both atria; V = one or both ventricles; or D = any combination of atria and ventricles, e.g. the code for a patient with dual-chamber, rate-adaptive pacing (DDDR) and biventricular pacing is DDDRV.

## SPECIFIC PACING MODES

The three-position code (Figure 19.3) is adequate to describe emergency temporary pacing and most forms of permanent pacing in the intensive care unit (ICU) (Table 19.2).

### SINGLE-CHAMBER PACING

1. AOO and VOO (asynchronous atrial and ventricular) pacing. There is no ability to sense cardiac activity (Figure 19.4). Such pacing is virtually obsolete, except in some pacing emergencies (see later).
2. AAI (atrial demand) pacing. This is indicated for sinus bradycardia provided AV conduction is intact (to maintain AV synchrony).
3. VVI (ventricular demand) pacing (Figure 19.5). This is the most commonly used mode and the mode of choice in life-threatening bradyarrhythmias. Spontaneous cardiac rhythm is sensed, and there is minimal danger of pacemaker-induced ventricular tachyarrhythmia (Figure 19.6). AV synchrony is, however, lost and there is no 'speed-up for need'.

### DUAL-CHAMBER PACING

Two sets of electrodes are required (atrial and ventricular).

#### DVI (AV SEQUENTIAL) PACING

Atria and ventricles are paced in sequence (Figure 19.7). After a stimulus is delivered to the atrium, there is a delay and an impulse is then delivered after atrial stimulation, to the ventricles. If AV conduction is successful, the ventricular output of the pacemaker is inhibited; otherwise the ventricle is paced. The advantage of this mode is that the atria and ventricles usually contract in sequence. To maintain AV synchrony in the absence of atrial sensing, the pacemaker discharge rate must be greater than the spontaneous atrial rate; asynchronous atrial pacing can precipitate AF. Self-inhibition ('cross-talk') can occasionally occur, that is, inappropriate detection of the atrial pacing stimulus by the ventricular channel. If there is no escape rhythm, asystole may result. DVI pacing is indicated when there is impaired AV conduction with an atrial bradycardia. It is of no value when atrial tachyarrhythmias are present.

**Figure 19.3** Examples of pacemaker modes and their three-position (letter) codes. P, pacemaker; S, sensing.

**Table 19.2** Examples of pacemaker modes

Code	Common description	Common description	Comment
VOO	Paces the ventricle, no sensing	Fixed-rate, asynchronous	Obsolete – except for pacemaker testing and ‘emergency’ pacing
VVI	Paces the ventricle, senses ventricular activity, ventricular activity inhibits the pacemaker	Ventricular demand	Most commonly used in life-threatening bradycardia
AAI	Paces the atrium, senses atrial activity, atrial activity inhibits the pacemaker	Atrial demand	Indicated in sinus bradycardia with intact AV conduction
VAT	Paces the ventricle, senses atrial activity, atrial activity triggers ventricular pacing	Atrial synchronised, P-wave triggered	Obsolete – replaced by VDD and DDD
DVI	Paces both atrium and ventricle, senses only ventricular activity, ventricular activity inhibits atrial and ventricular pacing	AV sequential	Commonly used dual-chamber pacing mode in ICU
VDD	Paces the ventricle only, senses atrial and ventricular activity	Atrial synchronous, ventricular inhibited	May be useful when normal sinus rhythm is present with a high-degree AV block
DDD	Paces and senses both atrium and ventricle: atrial activity triggers ventricular pacing	DDD	Often ideal but more complicated
DDI	Paces and senses both atrium and ventricle. Atrial activity not tracked; thus atrial tachyarrhythmias do not trigger rapid atrial pacing	AV sequential, non-P synchronous	Useful for sinus bradycardia with AV block and intermittent atrial tachyarrhythmias

AV, atrioventricular; ICU, intensive care unit.

Figure 19.4 Fixed-rate ventricular pacing V00. P, pacemaker.

Figure 19.5 Ventricular demand pacing VVI. P, pacemaker; S, sensing.

Figure 19.6 Non-sensing of QRS (see first two beats). Pacing spikes (arrows) fall on the T-wave with subsequent pacemaker-induced ventricular tachycardia.

#### VDD (ATRIAL SYNCHRONOUS VENTRICULAR INHIBITED) PACING

This mode paces only the ventricle. Sensing takes place in both atrium and ventricle. A sensed P-wave triggers ventricular pacing. VDD pacing is used in some permanent pacemaker systems as a single-lead system capable of pacing the ventricle in response to atrial sensing (from an electrode situated in the intra-atrial part of the lead) with ventricular electrodes at the apex of the RV.

#### DDD PACING

There is pacing and sensing in both chambers (Figure 19.8). An atrial impulse will trigger a ventricular output and

simultaneously inhibit an atrial output. If the impulse is conducted normally to the ventricle, the ventricular output is then inhibited, as with the DVI mode. Upper rate-limiters prevent the pacemaker from following excessive atrial activity with paced ventricular responses. DDD pacemaker function depends on the underlying cardiac rhythm:

1. atrial bradycardia with intact AV conduction – atrial pacing
2. normal sinus rhythm with high-degree AV block – tracking of P-waves with synchronised ventricular pacing
3. sinus bradycardia with AV block – pacing the atria and ventricles sequentially
4. normal sinus rhythm and AV conduction – inhibition of both atrial and ventricular pacing

Self-inhibition can be prevented by introducing a ventricular blanking (refractory) period coinciding with the atrial pacing stimulus. With DDD and VDD pacing, re-entry pacemaker-mediated ‘endless-loop’ tachycardias are possible.<sup>7</sup> These are commonly initiated by a ventricular premature beat (Figure 19.9) conducted retrogradely to the atria, where it is sensed and ventricular pacing is triggered with an endless loop: the circuit’s anterograde limb is the pacemaker, and the retrograde limb is via the AV

Figure 19.7 Atrioventricular sequential demand pacing DVI. P, pacemaker; S, sensing.

Figure 19.8 DDD pacing. P, pacing; S, sensing.

Figure 19.9 Pacemaker-mediated 'endless-loop' tachycardia: (i) under normal conditions (first beat) there is no conduction from the ventricles to the atria because of ventriculoatrial block or because the atrial and ventricular impulses collide and extinguish each other in the atrioventricular node; (ii) if a ventricular premature beat (VPB) is conducted retrogradely to the atria (second beat), inducing an inverted 'p'-wave, this may be sensed by the pacemaker (P) which then triggers a ventricular paced beat (third beat); (iii) if the paced ventricular beat is then retrogradely conducted from the ventricle to the atria and sensed, an 'endless loop' may occur (beats 4, 5); that is, pace ventricle VA conduction 'p' wave (sensed) ventricular pace, and so forth.

node. Conversion to asynchronous (non-sensing) mode or DDI or increasing the postventricular atrial refractory period (PVARP) will prevent endless-loop tachycardia.

#### **DDI PACING (AV SEQUENTIAL, NON-P-WAVE SYNCHRONOUS)**

Sensing occurs in both atria and ventricle, but sensed atrial events do not trigger ventricular pacing. This mode prevents endless-loop tachycardias or tracking of SVTs. It is also useful in patients with SA node dysfunction and episodes of atrial tachyarrhythmias, although DDD (R) with mode switching (ability to change to DDI, DDIR, DVI or DVIR with the onset of an atrial tachyarrhythmia) is preferable. During atrial tachyarrhythmias, the DDI pacemaker will simply pace the ventricle at its back-up rate and not track the tachycardia.

#### **HAEMODYNAMICS OF CARDIAC PACING**

In the normal heart, cardiac output increases three- to fourfold during exercise, due mainly to increased heart rate and increases in stroke volume. Atrioventricular synchrony – the normal activation sequence of the heart in which the atria contract first and then, after an appropriate delay, the ventricles contract – contributes only about 20% of cardiac output.<sup>8</sup> Thus the ability of pacemakers to increase heart rate is paramount, although AV synchrony may on occasions be vital (e.g. in low-cardiac-output states). Many permanent pacemakers are rate-adaptive. When temporary pacing is used, the arbitrary back-up rate of 70–80 beats/min may need to be increased if oxygen delivery is inadequate. For life-threatening bradyarrhythmias, increasing heart rate with VVI mode pacing is the treatment of choice. Permanent VVIR pacing (most commonly using an activity or respiration sensor) will allow heart rate modulation. However, in the ICU, adaptive rate changes may not occur. For example, no activity will be sensed in a patient with septic shock, even when the cardiac output is low.

During VVI and VVIR pacing the atria and ventricles beat independently and AV synchrony is lost. Occasionally this can have deleterious effects and cause a ‘pacemaker syndrome’.<sup>9</sup> The pacemaker syndrome is, however, a complex of clinical signs and symptoms associated with loss of AV synchrony. A fall in blood pressure coinciding with the onset of ventricular pacing is consistent with the pacemaker syndrome. It was initially recognised with VVI pacing but can occur with any pacing mode if there is AV dissociation, and can be compared to the effects in patients with complete heart block and AV dissociation. The atria contract against closed AV valves with significant regurgitation of blood into the pulmonary and systemic circulation. Blood pressure, stroke volume and cardiac output may fall. The pacemaker syndrome can be eliminated by restoring AV synchrony.

Emergency and long-term haemodynamic effects of DDD or AAI pacing are generally superior to VVI

pacing. In studies of patients with permanent pacing, there is a consistent lower mortality with DDD or AAI pacing compared to VVI pacing, and a significantly lower incidence of AF.<sup>2</sup> DDD and/or DVI pacing requires two pacing leads, one each in the RA and RV. Under appropriate conditions AAI and DVI pacing provide AV synchrony but not rate adaptation. DDD pacing will usually ensure AV synchrony and heart rate responsiveness, provided the SA node is normal.

Dual-chamber pacemakers require the AV interval to be set as close as possible to the normal P-R interval (140–200 ms). Traditionally, the pacing AV interval is arbitrarily set at about 150–200 ms. If interatrial conduction time (between the RA and LA) is significantly prolonged, the LV may contract before or at the same time as the LA, causing DDD pacemaker syndrome<sup>10</sup> with decreased stroke volume and cardiac output (due to LA contraction against a closed mitral valve). Hence, if there is evidence of inadequate cardiac output or impaired oxygen delivery, the AV interval may need to be increased appropriately, or optimised using thermodilution cardiac output or echocardiographic techniques at various AV intervals.

#### **INDICATIONS FOR CARDIAC PACING IN BRADYARRHYTHMIAS**

##### **TEMPORARY PACING**

Cardiac pacing is indicated for any sustained symptomatic bradycardia that does not promptly respond to medical treatment. Pacing may also be indicated if a bradycardia predisposes to malignant ventricular arrhythmias. The decision to pace is based on bradycardia associated with haemodynamic deterioration, and not on the specific rhythm disturbance. For example, pacing is indicated in a patient with AF and a ventricular response of 50/min associated with a blood pressure of 70/40 mmHg (9.3/5.3 kPa), cardiac failure and oliguria. Pacing is not indicated in an asymptomatic normotensive patient with an inferior infarction, complete heart block and a ventricular rate of 45/min.

Temporary pacing is indicated for the treatment of heart block or sinus bradycardia after cardiac surgery. In high-risk patients, for example, aortic or mitral valve replacement, prophylactic epicardial electrodes are often attached during surgery. DDD (dual-chamber) epicardial pacing has been shown to increase cardiac output at any given heart rate compared to VVI (single-chamber) pacing.<sup>11</sup> Temporary perioperative cardiac pacing strategies to increase stroke volume and cardiac output include optimisation of AV delay and occasionally multisite pacing.<sup>12</sup> Temporary pacing may be required for bradycardia during cardiac catheterisation and percutaneous transluminal coronary angioplasty. Asymptomatic patients with bifascicular block do not require prophylactic pacing prior to general anaesthesia, although transcutaneous pacing should be readily available. Patients with second- or

**Table 19.3** Complete atrioventricular (AV) block in acute myocardial infarction

Feature	Inferior	Anterior
Onset	Slow (usually via Mobitz 1)	Sudden (usually via Mobitz II)
QRS complex	Narrow	Wide
Ventricular rate	>45 beats/min	<45 beats/min (often 20–30 beats/min)
Escape pacemaker	Stable	Unstable
Drug response (e.g. atropine)	Yes	No
Haemodynamic effects	No (usually)	Yes
Permanent pacing	No (usually)	Yes (if high-degree AV block persists)
Prognosis	Good	Very poor

third-degree AV block should be paced prior to general anaesthesia and surgery.

Caution should be exercised in patients with acute myocardial infarction as many patients will have received thrombolytic agents; central venous cannulation should be avoided, although if necessary the femoral vein can be used. Prognosis is related to infarct size rather than the degree of AV block. Transcutaneous pacing obviates the need for prophylactic temporary transvenous pacing leads in high-risk patients. Pacing is sometimes required for patients with anterior or inferior myocardial infarction (Table 19.3).

### PERMANENT PACING

Guidelines for permanent pacing have been published.<sup>13</sup>

- Class I.** Indicated. For example, chronic symptomatic second- or third-degree AV block, SA node dysfunction with documented symptomatic bradycardia and recurrent syncope associated with hypersensitive carotid sinus.
- Class II–IIa.** Good supportive evidence. For example, asymptomatic complete AV block with average ventricular rate >40/min in an awake patient. **IIb.** Weak supportive evidence. For example, first-degree heart block (>0.3 seconds) in patients with depressed left ventricular function and symptoms of left ventricular failure.
- Class III.** Pacing is not indicated. For example, in asymptomatic first-degree heart block or reversible AV block secondary to drug toxicity.

### OTHER INDICATIONS

There are also non-bradycardia indications for pacing for haemodynamic improvement. Evolving indications include the following:<sup>2,3</sup>

- HOCM.** Pacing is usually reserved for symptomatic patients with a high gradient in the left ventricular outflow tract (LVOT). DDD pacing with a short AV interval causes RV apical activation with altered septal activation, thereby decreasing both the LVOT gradient and systolic anterior motion (SAM) of the mitral valve. The results of trials to date have been mixed and it is unclear whether pacing is a preferred treatment option for HOCM. Currently, it is a class IIb indication (weak supportive evidence).
- Heart failure.** A significant number of patients with dilated cardiomyopathy have an intraventricular conduction disturbance, usually left bundle branch block (LBBB) with significant ventricular dyssynchronisation and associated paradoxical septal motion and mitral regurgitation. CRT refers to re-establishing synchronous contraction between the left ventricular free wall and the ventricular septum, resulting in improvements in LV performance. Generally, CRT has been used to describe biventricular or multisite ventricular pacing. CRT improves the symptoms of heart failure and improves survival in specific patient groups. In the most recent American College of Cardiology/American Heart Association Task Force on Practice Guidelines<sup>13</sup> for pacing, biventricular pacing is included as a class IIa indication in medically refractory symptomatic New York Heart Association class III/IV patients with idiopathic dilated or ischaemic cardiomyopathy, prolonged QRS (>130 ms), left ventricular end-diastolic diameter >55 mm and left ventricular ejection fraction <0.35. The underlying rhythm should be sinus or AF with a ventricular response slow enough to allow continuous biventricular stimulation and capture. The chronic use of CRT via a permanently implantable biventricular pacemaker (the LV lead is usually passed via a tributary of the coronary sinus to the epicardial surface of the LV) is gaining widespread acceptance for treatment of heart failure. Biventricular pacing is usually reserved for permanent pacing. Temporary biventricular pacing with a temporary transvenous pacemaker lead passed to a coronary vein via the coronary sinus has been used successfully in cardiogenic shock and high-degree AV block.<sup>14</sup> More recently, permanent devices combining CRT and implantable defibrillators have been developed.
- AF prevention.** Atrial pacing may be effective in preventing episodes of paroxysmal AF. Most trials have been performed in patients requiring permanent pacing for bradycardia who also incidentally have episodes of paroxysmal AF. Synchronous dual-site pacing of either RA and LA or two different RA sites may be superior to single-site atrial pacing by virtue of

decreasing dispersion of refractoriness.<sup>15</sup> Single-site RA pacing (back-up rate slightly faster than intrinsic sinus rhythm, usually 80–110 beats/min) decreases the incidence of AF after cardiac surgery.<sup>16,17</sup> Dual-site, RA and LA, or two-site RA are more complicated but may be superior to single-site RA pacing for AF prevention.<sup>18,19</sup>

### ELECTROMAGNETIC INTERFERENCE

Any signal that can be sensed by the pacemaker, or ICD, constitutes EMI and can cause pacing problems such as failure to pace (inappropriate sensing), asynchronous pacing ('safety pacing' when excess 'noise' is detected), pacemaker reprogramming and occasionally damage to the pacemaker (DC shock, diathermy) or the heart itself. The most important source of potentially harmful electromagnetic radiation in hospitals is magnetic resonance imaging (MRI). MRI is generally considered to be contraindicated in patients with a pacemaker or ICD. Recently, several studies have demonstrated the potential for MRI to be performed in pacemaker or ICD patients.<sup>20</sup> The risks presented by MRI must be outweighed by the diagnostic benefit of this powerful imaging modality on a case-by-case assessment.

In critically ill patients, potential EMI sources include DC shocks, diathermy and possibly mobile telephones. In general, mobile telephones, especially analogue systems, are reasonably safe. Digital telephones have a greater theoretical risk for EMI and it is recommended that telephones do not come into close contact with the pacemaker, for example the mobile telephone should not be rested on the skin over the implanted device. If there is any doubt the pacemaker (or ICD) should be checked and reprogrammed.

### CARDIOVERSION/DEFIBRILLATION IN PATIENTS WITH A PERMANENT PACEMAKER (OR ICD)

Place paddles in the anterior–posterior position, at least 10 cm from the unit. Make sure a suitable programmer is available and check the pacemaker (or ICD) afterwards. In patients with a temporary transvenous pacemaker, keep the external unit and the leads well away from the paddles.

### DIATHERMY

Bipolar diathermy should be used whenever possible. When diathermy is used in pacemaker-dependent patients, it may be safer to change the mode to asynchronous pacing. This can be achieved in permanent pacemakers by reprogramming the pacemaker: close liaison with the patient's cardiologist is very important. In an

emergency (e.g. asystole in a patient whose pacemaker is inhibited by diathermy), placing a magnet over the permanent pacemaker will usually result in a fixed-rate mode. Modern pacemakers may not be magnet-responsive, but they are also less likely to be affected by diathermy. Patients with temporary transvenous pacing can be switched to VOO or DOO mode. ICD devices should be switched off before diathermy is used. In contradistinction to pacemakers, placing a magnet over the ICD will deactivate the unit, although pacing functions will not be altered. After surgery the pacemaker or ICD should be tested and reprogrammed appropriately.

### TECHNIQUE OF TEMPORARY TRANSVENOUS PACING

#### VENTRICULAR PACING

A sterile technique is mandatory. In emergencies, transcutaneous pacing (VVI) is used first while transvenous VVI pacing is being prepared. A bipolar lead introduced under fluoroscopic control is most commonly used.

Percutaneous insertion via the right internal jugular vein probably offers least complications with ease of manipulation and stability of the lead. The infraclavicular (subclavian vein) approach allows more freedom for patient arm movement. Antecubital veins are associated with lead instability and thrombophlebitis. The femoral vein is best avoided except in patients who have received thrombolytic agents, because of problems with sterility and increased risk of deep-vein thrombosis. The pacing lead is introduced using the Seldinger technique and manipulated under fluoroscopic control to the apex of the RV (Figure 19.10). After the lead has been manipulated to a satisfactory position, a chest X-ray should be

**Figure 19.10** Characteristic appearance of temporary transvenous pacing leads ideally positioned in (a) the right atrium (right atrial appendage) and (b) apex of right ventricle.

obtained to exclude pneumothorax and to confirm adequate lead positioning. The lead should be sutured to the skin at two different sites: one where the lead exits the skin, and a second to a loop formed with the lead. Occasionally, transvenous RV pacing may not be feasible, owing to the presence of a prosthetic tricuspid valve or a congenital anomaly.

### ATRIAL PACING

Insertion of the atrial J-lead is similar to that of the ventricular lead. Correct positioning requires experience. The right atrial appendage is anterior and medial, and the tip is advanced anteriorly and to the patient's left, after passing from the superior vena cava to the RA (see Figure 19.10). The correct position can be confirmed by a lateral chest X-ray or fluoroscopy.

### DUAL-CHAMBER PACING

Modern external pacemakers are available (Figure 19.11) which will pace in all modes. These units are small, easy to use and can fit into a small pouch suitable for mobile patients.

### TESTING THE PACING LEADS

Pacing threshold and sensing should be tested adequately using the external pacemaker.

#### Pacing threshold

The lead is attached to the external pulse generator with the distal electrode connected to the negative pacemaker terminal. The cardiac chamber is then paced at 5–10 beats/min faster than patient heart rate, while the pulse generator's output is slowly decreased until consistent

capture outside the myocardial refractory period is lost. Threshold testing is always performed at an identical pulse duration, usually 0.5–1.0 ms. Ideally, ventricular pacing threshold should be 1.0 mA and the atrial threshold 2.0 mA. Pacemaker output is usually set at 2–3 times pacing threshold and always > 3 mA to allow a reasonable safety margin. After acute myocardial infarction the amplitude must not be set higher than necessary, as inadvertent pacing during the vulnerable period of the cardiac cycle may result in VT or ventricular fibrillation (VF).

#### Sensing

A pacemaker senses the potential difference between the two pacing electrodes. The amplitude of the ventricular signal is commonly 5–15 mV and the atrial signal 2–5 mV. Modern external pacemakers can sense signals as small as 0.8 mV for the ventricle, and 0.4 mV for atrial depolarisation. Before testing the sensitivity, pacing output is set at zero, thereby avoiding potentially dangerous competition between the pacemaker and the spontaneous cardiac rhythm. Pacing rate is then set lower than the spontaneous rate of the tested cardiac chamber, and the pacemaker sensitivity is decreased until there is competition between paced and spontaneous cardiac rhythms. The pacemaker sensitivity is then set at twice that value. This involves reducing the numerical sensitivity value (e.g. changing sensitivity from 2.0 to 1.0 mV will double the sensitivity). Testing pacemaker sensing should not be attempted in pacemaker-dependent patients.

Assessment of sensing is important, particularly in inferior infarction with RV involvement, when the intracardiac ventricular signal may be very small and not sensed. This resultant competition between pacemaker and spontaneous cardiac rhythm can initiate VT (see Figure 19.6) or VF.

### COMPLICATIONS OF TEMPORARY PACING<sup>21</sup>

Temporary transvenous pacemaker insertions should have a low complication rate. There are, however, problems when inexperienced and/or inadequately trained operators insert the pacing lead. Several studies from the UK report complications in a third to a half of all cases.<sup>22,23</sup> Temporary pacing involves two components: (1) obtaining central venous access; and (2) intracardiac placement of the pacing lead. Complications include:

- those associated with central venous line insertion, such as pneumothorax, haemothorax, arterial puncture, AV fistula. Perforation of the RV can occur, but rarely results in cardiac tamponade
- undersensing, with pacemaker-induced arrhythmias; oversensing, with pacemaker inhibition and loss of pacing stimuli; and failure to capture, usually due to device defects, unstable lead position, increasing pacing threshold and occasionally RV perforation

**Figure 19.11** External pacemakers. Medtronic, Inc. (i) Model 5388 (dual-chamber); (ii) model 5348 (single-chamber). Both are capable of rapid pacing for certain tachycardias (see text).

- extracardiac stimulation, usually diaphragmatic (may be associated with RV perforation) and local muscle stimulation can also occur
  - thrombus formation and infection occasionally
6. External transcutaneous pacing should be immediately available and commenced while a new pacing system is being inserted.
  7. Cardiopulmonary resuscitation and positive chronotropic drugs such as atropine, isoprenaline or adrenaline (epinephrine) should be available.

### FAILURE TO PACE

A life-threatening situation may arise if the pacemaker suddenly fails. The following is an ordered approach to such an emergency:

1. Make sure the pacemaker is switched on and connected to the pacing lead(s).
2. The pacemaker output should be increased to its maximum setting (usually 20 mA or 10 V).
3. Asynchronous DOO/VOO mode(s) is selected to prevent oversensing.
4. Connect the pacemaker directly to the pacing lead, as occasionally the connecting wires may be faulty.
5. Give consideration to replacing the pacemaker unit or the batteries.

### PACEMAKER PROGRAMMING

An external programmer emits signals capable of changing ('programming') various pacing parameters (Table 19.4). Virtually all modern permanent pacemakers are capable of programming rate, voltage, output, pulse width, sensitivity, mode and AV interval. Programmability is also helpful in assessing various pacemaker problems. The pacemaker format best suited to a particular patient's needs may change with time, and programmability enables optimal pacemaker function to be achieved, i.e. 'prescribed'. Pacing changes may be indicated under certain circumstances, for example, decreased pacing rate in a patient with angina or acute myocardial infarction to reduce myocardial oxygen consumption, or increased rate in a patient with haemorrhagic shock.

**Table 19.4** Multiprogrammable permanent dual-chamber pacemakers

Parameter	Adjustment	Comments
Rate	Increase	Increase cardiac output
	Decrease	Reduce myocardial oxygen consumption To assess underlying cardiac rhythm
Output	Increase	Increasing output may result in successful pacing when there is failure to capture Increases battery life
	Decrease	
Sensitivity	Increase	Reducing numerical value increases sensing ability May cause oversensing occasionally
	Decrease	Increasing numerical value decreases sensing ability Useful in oversensing, e.g. T-wave sensing
Mode	DDD to DDI	To prevent endless-loop tachycardias and to prevent tracking of episodic atrial tachyarrhythmias Mode switching can be automated and programmed either 'on' or 'off'
Atrioventricular interval (AVI)	Increase/ decrease	To optimise stroke volume and cardiac output AVI can be rate-adaptive, i.e. AVI shortens as the heart rate increases
Refractory period (atrial/ ventricular)	Increase	To minimise oversensing, e.g. to prevent ventricular sensing in AAI pacing
	Decrease	To optimise sensing under certain circumstances
Hysteresis		To preserve AV synchrony by delaying the onset of VVI pacing until the spontaneous heart rate is significantly less than the back-up ventricular pacing rate
Polarity	Unipolar mode	To improve sensing. Occasionally to allow pacing to continue when fracture of the other conducting wire occurs
	Bipolar mode	To prevent oversensing, e.g. muscle potentials

### CARDIAC PACING IN TACHYARRHYTHMIAS

Certain tachyarrhythmias may be treated safely and effectively by rapid pacing and/or premature electrical stimulation. These include:

- AV nodal re-entry tachycardia (AVNRT)
- AV re-entry tachycardia (AVRT)
- atrial flutter
- unifocal atrial tachycardia
- ventricular tachycardia

AVNRT and AVRT rarely require rapid atrial pacing as treatment with drugs such as adenosine or verapamil is usually successful. Atrial flutter, however, is often resistant to drug therapy, and rapid atrial pacing will usually convert it to sinus rhythm. When unifocal atrial tachycardia is associated with an atrial re-entry circuit, rapid atrial pacing will often revert this arrhythmia; conversely, when due to automatic focus discharging at a rapid rate, the arrhythmia is usually incessant and will respond only intermittently, if at all, to atrial pacing. Occasionally, dual-chamber pacing with a short AV interval can be used to prevent drug-resistant AVNRT or AVRT. Rapid continuous atrial pacing can be used to slow ventricular rate during resistant SVTs associated with a rapid ventricular response, by inducing AF and a high degree of AV block. Sustained VT is responsive to rapid ventricular pacing, but this should not be used for very rapid ventricular rates (e.g. >300/min), or when severe haemodynamic compromise is present, as immediate DC cardioversion is indicated. Rapid cardiac pacing may at times have advantages over DC cardioversion (Table 19.5) and drug therapy (Table 19.6), but is of no value in sinus tachycardia, AF and VF (Table 19.7).

**Table 19.5** Pacing versus cardioversion for the treatment of tachyarrhythmias

- Pacing may assist in rhythm diagnosis
- Pacing may be used (cautiously) in digitalis intoxication
- Pacing does not require a general anaesthetic
- Pacing avoids complications of DC shock, especially myocardial depression
- Repeated reversions are easier with pacing
- Standby pacing is immediately available if bradycardia or asystole occurs after electrical reversion

**Table 19.6** Pacing versus drug therapy for the treatment of tachyarrhythmias

- Pacing may aid in arrhythmia diagnosis
- Pacing avoids drug-induced cardiac depression and other drug side-effects
- Pacing can be used when drug therapy has failed
- Termination of the tachycardia with pacing is often immediate
- Standby pacing is immediately available

**Table 19.7** Indications for rapid cardiac pacing in suitable arrhythmias

- Failure of drug therapy
- Recurrent arrhythmias
- Contraindication for cardioversion (e.g. digitalis intoxication)
- Aid to arrhythmia diagnosis (e.g. wide-complex tachycardia to differentiate ventricular tachycardia from supraventricular tachycardia)

### TORSADE DES POINTES

Only re-entrant monomorphic VT can be reverted with rapid ventricular pacing. In the acquired long QT syndrome the polymorphic tachycardia of torsade des pointes is invariably preceded/precipitated by pauses or bradycardia. Torsade des pointes can usually be prevented by pacing the atrium or the ventricle at 90–110 beats/min.

### SUPRAVENTRICULAR TACHYARRHYTHMIAS

The pacing lead is manipulated to a suitable position in the RA. Atrial pacing is started at a slow rate (e.g. 60–80/min) and slowly increased to about 10–20% faster than the spontaneous atrial rate. Inadvertent ventricular pacing, especially at rapid rates, must be avoided. The atrium is paced for about 30 seconds and the pacemaker is then switched off. Normal sinus rhythm should ensue (Figure 19.12). If not, the pacing lead is manipulated to a different position and/or a faster pacing rate is tried. A more prolonged pacing period may be effective. If sinus rhythm still does not result, AF is deliberately precipitated by rapid atrial pacing at 400–800/min. This is an unstable rhythm which usually reverts spontaneously to normal sinus rhythm. AF persists occasionally, but the ventricular rate is usually slower and more responsive to drug therapy than with SVT.

### VENTRICULAR TACHYCARDIA

Useful techniques to pace VT include the following:

1. Ventricular burst pacing (similar to rapid atrial pacing) is simple and effective. The ventricle is paced at a rate about 120% of the spontaneous VT rate for 5–10 beats. Normal sinus rhythm should ensue (Figure 19.13). Potential complications include entrainment (Figure 19.14), that is, speeding up of VT, and occasionally precipitation of VF. Trained personnel, a defibrillator and resuscitation facilities must be available.
2. Underdrive ventricular pacing at rates less than that of the tachycardia may occasionally be successful.
3. Overdrive atrial pacing may be useful if there is 1:1 AV conduction and the ventricular rate is relatively slow (e.g. 120–180/min).

**Figure 19.12** Narrow-complex tachycardia. Rapid atrial pacing with atrial capture results in sinus rhythm on cessation of pacing.

**Figure 19.13** Wide-complex tachycardia. Ventricular burst pacing with ventricular capture results in normal sinus rhythm on cessation of pacing.

**Figure 19.14** Example of entrainment. Wide-complex tachycardia is followed by ventricular burst pacing. When pacing is discontinued, a wide-complex tachycardia of opposite polarity is precipitated.

## IMPLANTABLE CARADIOVERTER/DEFIBRILLATOR<sup>2</sup>

This is an implantable device which can recognise and automatically terminate VT and VF. Guidelines<sup>13</sup> have been published for ICD implantation; nevertheless, this is a rapidly evolving field with many trials in progress. ICDs are of proven survival benefit (class I) in patients who have had a cardiac arrest due to VF or VT, not due to transient or reversible cause. In other clinical situations ICD implantation may be a reasonable approach, for example, syncope with inducible VT at electrophysiology study which is poorly tolerated haemodynamically, and antiarrhythmic drugs are ineffective and/or contraindicated. A trial<sup>24</sup> in over 1200 patients with recent myocardial infarction (> 1 month) and low LV ejection fraction (30%) has demonstrated a decrease in mortality when prophylactic ICD implantation was compared to conventional treatment. ICDs are standard therapy to prevent sudden cardiac death in such high-risk patients.

Virtually all ICD systems are implanted transvenously and include antitachycardia pacing and back-up ventricular bradycardia pacing, dual-chamber pacing with rate-adaptive options. Single- or dual-chamber ICDs may be implanted. One trial<sup>25</sup> suggests that single-chamber ICDs may be superior to dual-chamber ICDs in patients who do not have an associated bradycardia. Current devices continuously monitor the patient's heart rate and deliver

therapy when the heart rate exceeds a predetermined limit. There is a graded response which is programmable:

1. 'slow' VT (e.g. ventricular rate 160–180/min) – antitachycardia pacing, that is, pacing at a rate faster than the intrinsic rate. If this is unsuccessful, antitachycardia pacing might be attempted at a faster rate; or
2. DC shock(s) (synchronised during VT, asynchronous during VF), initially at low energies. If unsuccessful, then high-energy shocks are delivered. All shocks are biphasic as these are more efficient and require lower energies than monophasic waveforms
3. pacing back-up (single- or dual-chamber) is usually available if there is a significant bradycardia after cardioversion/defibrillation

## COMPLICATIONS

Occasionally, multiple ICD discharges occur. This is a true clinical emergency. Shocks may be appropriate or inappropriate. Frequent malignant ventricular arrhythmias may result in multiple appropriate discharges. If DC shocks are unsuccessful, the device may need to be reprogrammed to deliver higher-energy shocks; conversely, if the multiple shocks are successful in defibrillating the patient during an arrhythmia 'storm', then the ICD device should probably be inactivated and external transthoracic defibrillation and antiarrhythmic drug therapy should be given as required. This will save battery power and allow the patient's ICD system to be tested later. If inappropriate ICD shocks arise, the ICD device should be switched off at once. The most common reason for inappropriate shocks is AF or some other SVT. Reprogramming the device may solve the problem. Occasionally sensing of EMI may cause ICD discharge. Avoidance of EMI source and/or reprogramming may be necessary. Nerve stimulators have been sensed by an ICD.

# Acute heart failure

David Treacher

The pattern of heart failure seen in the community, out-patients clinics and specialist cardiac wards is dominated by the acute coronary syndromes and chronic heart failure, predominantly caused by ischaemic heart disease and hypertension.<sup>1,2</sup> Heart failure is the commonest cause of hospital admission in people over 65 years of age and it has been estimated that in North America and Europe over 15 million patients have heart failure and 1.5 million new cases are diagnosed each year.<sup>3</sup> Patients present with chest pain, shortness of breath, fatigue and oedema and will usually have single-organ failure. Management focuses on reducing cardiac work to relieve symptoms and prevent further myocardial damage.<sup>4,5</sup>

Patients either admitted with or who develop acute heart failure on the intensive care unit (ICU) frequently have overt or occult underlying coronary artery disease, but will usually have significant other organ dysfunction. Management in this setting focuses on both improving global and regional oxygen delivery and maintaining perfusion pressure, often with the use of drugs that stimulate rather than rest the myocardium.<sup>6-8</sup> The resolution of this apparent paradox requires that for each patient management should attempt to achieve the frequently difficult balance between the best interests of the myocardium and the circulatory requirements of the other vital organs. The critical care physician should target the minimum necessary oxygen delivery and arterial pressure to maintain other organ function at maximum cardiac efficiency (e.g. ensuring adequate fluid resuscitation before starting beta-agonists) so that cardiac work and the risk of myocardial ischaemia and necrosis from exuberant beta-agonist use are minimised and the cardiologist should consider the wider circulation and other organ requirements when instituting strategies to protect the myocardium.

## DIAGNOSIS OF ACUTE HEART FAILURE

The diagnosis of acute heart failure in critically ill patients can be more difficult than is commonly recognised. Although the underlying pathology in most patients with acute heart failure on intensive care will be coronary artery disease, other diagnoses must be considered (Table 20.1).

It is also important to reassess critically the patient referred with a diagnosis of acute heart failure to decide

whether this is indeed the primary problem. The history, examination and initial investigations with routine blood tests, electrocardiogram (ECG) and chest X-ray may be compatible with this diagnosis but many such patients are elderly with multiple comorbidities and deciding whether the patient is suffering from a primary myocardial pathology as opposed to a pulmonary problem or indeed systemic sepsis<sup>9</sup> can be difficult. Equally, patients believed to have a primary respiratory problem may fail to wean from ventilatory support because of a failure to realise that they have left ventricular failure with a high left atrial pressure and incipient pulmonary oedema, causing a reduction in pulmonary compliance, an increased work of breathing and respiratory distress when ventilatory support is withdrawn.

Further investigations that can help to confirm or refute an initial diagnosis of acute heart failure are echocardiography and the measurement of recently available biomarkers such as troponin and brain natriuretic peptide.

## ECHOCARDIOGRAPHY (SEE CHAPTER 23)

Echocardiography is an extremely valuable investigation in the management of the critically ill patient with acute heart failure<sup>10</sup> and the modern critical care physician should at least be able to perform a basic examination. It will frequently establish the underlying cardiac pathology and can be used to monitor the response to treatment. It will:

1. identify pericardial effusions and determine whether ventricular filling is impaired (tamponade) and whether drainage is indicated. However, ultimately tamponade is a clinical diagnosis based on the full haemodynamic picture in the context of pericardial fluid demonstrated on the echocardiogram. Many of the diagnostic features related to alterations with respiration are affected by positive-pressure ventilation and drainage may be appropriate even if such classic echocardiographic criteria are not present. Even small effusions may cause tamponade since it is the rate of accumulation of fluid rather than the amount of fluid that determines the degree of cardiac compromise
2. identify obstruction to cardiac filling from other intrathoracic space-occupying lesions that increase

**Table 20.1** Causes of acute heart failure on the intensive care unit

Coronary artery disease
Infection – systemic sepsis, <sup>9</sup> myocarditis
Mechanical – endocarditis, pulmonary emboli, valve problems, septal defects, tamponade, high intrathoracic pressure with inadequate preload
Drugs – beta-blockers, calcium antagonists, cytotoxic therapy
Hypoxaemia
Metabolic – acidaemia, thiamine deficiency, hypocalcaemia, hypophosphataemia
Myocardial contusion – blunt thoracic trauma
Myocardial infiltration – tumour, sarcoidosis, amyloidosis
Vasculitis – rare

intrathoracic pressure, particularly in ventilated patients (pleural effusion, alveolar gas trapping in asthma)

3. assess adequacy of *volume* preload of left ventricle, particularly in the context of raised preload *pressures* and monitor response to fluid challenge
4. identify primary valvular heart disease (critical aortic stenosis, acute mitral regurgitation from papillary muscle rupture, acute endocarditis) when urgent surgery is indicated and distinguish this from functional valvular regurgitation due to primary ventricular disease for which surgery could be lethal
5. identify septal defects, regional wall motion abnormalities and aneurysmal dilatation from recent or previous myocardial infarction
6. identify the presence of intracardiac thrombus or clot
7. identify increased end-systolic and diastolic dimensions, indicating ventricular contractile failure. However the use of ejection fraction as an index of ventricular dysfunction can be misleading, especially in patients on inotropic drugs
8. identify diastolic dysfunction when high-pressure preload measurements fail to reflect true volume preload and extra fluid volume may be indicated
9. identify pulmonary hypertension associated with tricuspid regurgitation when an estimate of pulmonary artery (PA) pressure can be made

The images obtained with transthoracic echocardiography (TTE) may be poor in ventilated patients but the experienced operator can achieve considerable improvement using microbubble contrast techniques.<sup>11</sup>

Transoesophageal echo (TOE) gives excellent views of the aorta (dissections), the atria and left heart valves and is indicated if transthoracic views are very difficult to obtain or if better resolution is required. Right heart structures and the left ventricle are less well imaged.

### MEASUREMENT OF TROPONIN AND BRAIN NATRIURETIC PEPTIDE

Myocardial injury and the development of acute heart failure are common but frequently unrecognised complications of critical illness occurring not only in patients with an overt acute coronary syndrome but also in other conditions such as sepsis and major pulmonary embolism (PE).<sup>12</sup> Relying on blood tests alone to establish a diagnosis or to plan management is inadvisable but, when interpreted in conjunction with the wider clinical picture, brain-type natriuretic peptide (BNP) and cardiac troponin are two tests that are becoming routinely available and appear to be sensitive markers of myocardial stress and necrosis and to have significant prognostic significance.

### BRAIN-TYPE NATRIURETIC PEPTIDE

BNP was first isolated from porcine brain but the major source is the ventricular myocardium. The main stimulus for synthesis and release is myocardial wall stress. As a triage tool in the emergency department it is able to discriminate patients with heart failure from those with pulmonary or other non-cardiac causes for acute dyspnoea and has been shown to reduce rates of ICU admission, length of hospital stay and cost.<sup>13</sup> Several studies have demonstrated that, below a cut-off of 100 pg/ml, BNP has a sensitivity of almost 90% and a specificity approaching 80% as a test for excluding heart failure.<sup>14</sup> It is now included in both the European and UK National Institute for Clinical Excellence guidelines for the management of heart failure<sup>15,16</sup> and BNP has also been shown to be a marker of myocardial dysfunction and prognosis in severe sepsis.<sup>17</sup>

### CARDIAC TROPONIN I AND T (cTnI, cTnT)

Troponin is part of the thin filament of the myocyte contractile apparatus and has three subunits: (1) I, which binds actin to inhibit actin-myosin contraction; (2) T, which binds tropomyosin to facilitate contraction; and (3) C, which binds calcium ions. The cardiac isoforms cTnI and cTnT are specific to the heart and can be measured in the blood after myocyte necrosis with 50% release by 4 hours, peaking at 12–24 hours and remaining elevated for up to 10 days. It is far more sensitive than the traditional cardiac enzyme tests such as creatine kinase and indeed it has substantially changed the diagnosis and management of acute myocardial infarction, as reflected in the new guidelines issued by the European Society of Cardiology<sup>15</sup> and American College of Cardiologists. Troponin may be released in conditions other than acute coronary ischaemia<sup>18</sup> such as sepsis and after chemotherapy and in the absence of evidence of myocardial necrosis as in acute heart failure or major PE, where it is believed that the acute ventricular dilatation causes increased membrane permeability. Raised troponin levels are also associated with increased morbidity and mortality in surgical ICU patients.<sup>19</sup>

In combination with BNP, cTnI is valuable in screening for massive PE: in massive and submassive PE both are raised and further investigation with computed tomography pulmonary angiogram (CTPA) is indicated but in minor PE both will be negative.

Raised levels of either of these markers, but particularly BNP indicating early myocardial stress, may have an important role in alerting the clinician to impending myocardial failure and the need to review the use of drugs that stimulate the myocardium and to consider the introduction of a beta-blocker, particularly in the context of tachycardia.

It should be remembered that, for critically ill patients with acute heart failure not resulting from primary myocardial infarction, if the precipitating cause is successfully treated without significant myocardial necrosis occurring, the acute heart failure will resolve, cardiac function will return to its pre-morbid state and the prognosis will be improved.

The remainder of this chapter addresses the assessment and principles of management of ventricular function in patients admitted to the ICU with acute heart failure. This inevitably involves reference to circulatory failure and the state of the peripheral circulation but the more detailed aspects of oxygen delivery and control of the regional and microcirculation are considered elsewhere<sup>20</sup> (see Chapters 11 and 12), as are the acute coronary syndromes<sup>2</sup> (see Chapter 16) and chronic heart failure.<sup>1</sup>

### CIRCULATORY FAILURE OR 'SHOCK'

The principal function of the heart is the generation of the energy necessary to perfuse the lungs with venous blood and to propel the oxygenated arterial blood through the systemic circulation at a rate and pressure that ensure that the fluctuating metabolic requirements of the various organs are met at rest and during exercise. This should be performed at maximum efficiency so that the work performed is not at the cost of unnecessarily high myocardial energy expenditure and the risk of myocardial ischaemia is minimised.

Failure to maintain an adequate oxygen supply to the tissues with the consequent development of anaerobic cellular metabolism defines circulatory failure or 'shock', a term that benefits from brevity but little else since it implies neither cause nor prognosis, but its use is now widespread and inescapable. Table 20.2 classifies circulatory 'shock'.

In considering these causes of circulatory failure, several points require emphasis:

1. Acute heart failure resulting in cardiogenic shock is not a pathological diagnosis but a collective term that embraces all causes of myocardial failure. Treatment must focus on the underlying diagnosis.
2. Patients admitted to ICU may have acute heart failure either as the primary reason for admission, e.g. severe myocardial infarction, or develop it as part of multiple

**Table 20.2** Major categories of circulatory failure or 'shock'

Cardiogenic	Myocardial infarction, myocarditis, vasculitis, valve dysfunction (e.g. critical aortic stenosis, mitral regurgitation, acute endocarditis), post cardiac bypass surgery, drug overdose ( $\beta$ -blockers, calcium antagonists)
Hypovolaemic	Haemorrhage, burns, gastrointestinal fluid loss
Obstructive	Pulmonary embolus, cardiac tamponade, tension pneumothorax
Anaphylactic	Drugs, blood transfusion, insect sting
Septic	Bacterial infection, non-infective inflammatory conditions, e.g. pancreatitis, burns, trauma
Neurogenic	Intracranial haemorrhage, brainstem compression, spinal cord injury

organ failure triggered by an extracardiac cause, frequently the delayed or ineffective treatment of severe sepsis.

3. Pre-existing cardiac disease, usually ischaemic heart disease, is an important factor in determining the physiological response to critical illness. Several studies investigating the effect of manipulating oxygen delivery have demonstrated the poor prognosis associated with the inability of the heart to achieve a hyperdynamic response to critical illness either spontaneously or with volume loading and inotropic support.<sup>7,8,21</sup> Preoperative assessment with exercise testing is probably appropriate for all patients undergoing major surgery as a means of identifying those with poor physiological reserve so that the true risk of surgery can be identified and perioperative management planned accordingly.
4. Although hypotension is often considered to be the cardinal sign of circulatory failure, other global features (persistent tachycardia, confusion, tachypnoea, impaired peripheral perfusion, progressive metabolic acidemia) occur earlier since the body has powerful homeostatic mechanisms that maintain pressure at the expense of flow.
5. The heart must provide its own blood supply and, if coronary blood flow does not match myocardial oxygen requirements, coronary ischaemia develops and cardiac and global circulatory failure may ensue.<sup>22</sup>
6. The primary problem in hypovolaemic, cardiogenic and obstructive shock is a progressive decline in cardiac output (CO) and global oxygen delivery, which, if not corrected, leads to secondary failure of the peripheral circulation and progressive organ dysfunction. In septic, anaphylactic and neurogenic shock, however, the primary problem is the loss of control of the peripheral circulation resulting in systemic hypotension and disordered distribution of blood flow, although CO and global oxygen delivery are usually increased.<sup>23</sup>
7. Although a primary cause for the circulatory failure may be identified, other causes may contribute to the

evolution of the final pathology. For example, in septic shock the initial and major derangement is peripheral: it is characterised by microcirculatory chaos triggered by cytokine release, white-cell activation, disruption of the coagulation cascade resulting in microthrombi that occlude the microvasculature and endothelial disruption resulting in interstitial oedema. This same process occurs in the coronary microvasculature impairing myocyte function.<sup>24</sup> There is also widespread loss of fluid from the intravascular to the extravascular space, resulting in hypovolaemia. The primary peripheral circulatory failure may therefore be compounded by both cardiogenic and hypovolaemic shock.

8. 'Early' and 'late' shock are terms that reflect the association between the duration and severity of the circulatory derangement and prognosis. Early intervention in circulatory shock has a major impact on survival.<sup>25</sup> If treatment is delayed until organ failure is established, the underlying pathological processes are frequently irreversible.
9. Although not a true 'mixed' venous sample, the oxygen saturation of blood taken from an internal jugular ( $S_{ij}O_2$ ) or subclavian cannula has been shown to be valuable in assessing whether global oxygen delivery ( $DO_2$ ) is adequate for global tissue oxygen consumption. A value < 70% should prompt consideration of whether a fluid challenge or other strategy to increase  $DO_2$  is indicated. A value > 70% is not necessarily reassuring in patients with established hyperdynamic shock as this may reflect an inability of the tissues to extract and utilise oxygen.

### ASSESSMENT OF VENTRICULAR FUNCTION

Making the considerable assumption that the circulation can be analysed as a constant-flow, fixed-compliance system, six key measurements traditionally define ventricular performance:

- Right and left atrial pressures (RAP, LAP or ventricular preload)
- Mean systemic and pulmonary arterial pressures (MAP, PAP or ventricular afterload)
- Heart rate (HR)
- CO ( $Q_t$ )

Table 20.3 illustrates typical values in normal subjects and in the common causes of circulatory failure with calculation of the associated vascular resistances and oxygen delivery. The values quoted are merely examples that indicate the pattern of circulatory derangement produced by these pathologies: pre-existing cardiopulmonary disease and the severity of the condition will affect the precise figures obtained in individual cases and the response to vasoactive therapy.

Stroke volume (SV) is calculated from CO and heart rate:

$$SV = Q_t / HR$$

Three factors determine stroke volume: (1) preload; (2) afterload; and (3) myocardial contractility.

### VENTRICULAR PRELOAD

Ventricular preload, traditionally assessed from the atrial filling pressures, determines the end-diastolic ventricular volume, which, according to Starling's law of the heart and depending on ventricular contractility, dictates the stroke work generated by each ventricle at the next cardiac contraction. The resulting stroke volume depends on the resistance or afterload that confronts the ventricle.<sup>26</sup>

On the general ward the jugular venous pressure (JVP) is measured from the sternal angle but in ICU vascular pressures are measured from the mid-axillary line in the fifth intercostal space. From this reference point, in the supine position, the normal RAP is between 4 and 8 mmHg and the LAP, or wedge pressure, is between 8 and 12 mmHg. Relative changes in either the contractility of the two ventricles or the respective vascular resistances will change the relationship between the atrial pressures, which must then be independently assessed.<sup>27</sup>

The predominant factor determining preload is venous return, which depends on the intravascular volume and venous tone, which is controlled by the autonomic nervous system, circulating catecholamine levels and local factors, particularly  $PO_2$ ,  $PCO_2$  and pH.

The systemic venous bed is the major intravascular capacitance or reservoir of the circulation with a compliance that can vary from 30 to over 300 ml/mmHg and which provides a buffer against the effects of intravascular volume loss. It also explains the response observed in major haemorrhage and subsequent transfusion. As volume is lost, venous tone increases, preventing the large falls in atrial filling pressures and CO that would otherwise occur. If the equivalent volume is returned over the subsequent few hours the RAP gradually returns to normal as the intravascular volume is restored and the reflex increase in sympathetic tone abates. However, rapid reinfusion of the same volume does not allow sufficient time for the venous and arteriolar tone to fall and may result in the LAP rising to a level that precipitates pulmonary oedema, although the intravascular volume has only been returned to the prehaemorrhage level and left ventricular function is normal (Figure 20.1).

If the preload is low and either blood pressure or CO is inadequate, the priority is volume loading to restore intravascular volume and venous return.

Raised preload pressures reflect: (1) high intravascular volume; (2) impaired myocardial contractility; or (3) increased afterload.

Preload may be reduced by:

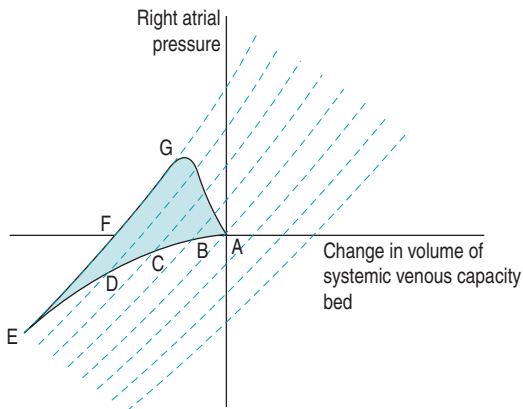

- removing volume from the circulation (diuretics, venesection, haemofiltration) or increasing the capacity of the vascular bed with venodilator therapy (e.g. glyceryl trinitrate, morphine<sup>28</sup>)
- improving contractility
- reducing afterload<sup>29</sup>

Table 20.3 Measurements in a normal 75-kg adult and in various conditions causing circulatory 'shock'

	RAP (mmHg)	LAP (mmHg)	PAP (mmHg)	MAP (mmHg)	HR (per min)	Cardiac output (l/min)	SVR* PVR*	Stroke work (g.m)		Venous compliance (ml/mmHg)	CaO <sub>2</sub> (l/100 ml)	DO <sub>2</sub> (ml/min)	
								LV	RV				
Normal	5	10	15	90	70	5.0	17	1.0	78	10	300	20	1000
Major haemorrhage	0	3	10	80	100	3.2	25	2.2	34	4.4	40	16	510
Left ventricular failure	7	19	23	90	100	3.6	23	1.1	35	8	80	18	650
Cardiac tamponade	14	16	19	65	110	2.3	22	1.3	14	1.4	50	20	460
Major PE	10	6	35	70	110	2.6	23	11.0	21	8	40	16	420
Exacerbation of COAD	10	9	35	80	100	6.5	11	4.0	63	22	150	13	850
Septic shock:													
(i) pre-volume	2	7	17	49	130	4.2	11	2.4	18	7	350	15	630
(ii) post-volume	10	14	25	68	120	8.0	7	1.4	49	14	200	14	1120

Typical circulatory measurements in a normal adult and in various cardiorespiratory conditions that may cause shock. The severity of the condition and pre-existing cardiorespiratory disease will affect the precise figures obtained in individual cases.

Pressures referenced to zero at mid-axillary line in supine patient. Subtract vertical distance from mid-axilla to sternal angle (approximately 5–7 mmHg) if sternal angle used as reference point. LV, Left ventricle; RV, right ventricle; CaO<sub>2</sub>, arterial oxygen content; DO<sub>2</sub>, global oxygen delivery; PAP/MAP, mean pulmonary artery/arterial pressure; SVR\*/PVR\*, systemic/pulmonary vascular resistance × 80 to give SI units: dyn·s·cm<sup>-5</sup>.

**Figure 20.1** Venous compliance curves. Each dotted line represents a line of constant venous compliance ranging from low compliance (increased tone) on the left to increased compliance (reduced tone) on the right. Line ABCDE shows the effect of progressive haemorrhage with the reduction in venous compliance limiting the fall in atrial pressure. Line EFGA shows the effect of rapid reinfusion of the same volume that was removed but at a rate that does not allow the sympathetically mediated increase in venous tone to abate. Each dotted line represents a line of constant venous compliance ranging from minimum on the left to diminished venous tone on the right.

In assessing preload, end-diastolic *volume* rather than pressure is relevant and when interpreting atrial *pressures* as measures of preload, two points must be considered:

1. Intravascular pressure ( $P_v$ ) measurements are misleading if the intrathoracic pressure ( $P_t$ ) is raised, since the true distending pressure that determines ventricular

end-diastolic volume is the transmural pressure ( $P_v - P_t$ ). This is particularly relevant if there is significant alveolar gas trapping generating intrinsic or auto positive end-expiratory pressure (PEEP), as in asthma, and positive-pressure ventilation with high PEEP levels and an inverse inspiratory-to-expiratory time ratio.<sup>30,31</sup>

2. When the ventricle is dilated and poorly compliant, the end-diastolic pressure–volume relationship is not necessarily linear and *pressure* will not necessarily reflect the adequacy of *volume* preload.

Alternative methods of assessing ventricular preload are discussed later in this chapter under “Assessment of intravascular volume status” and in Chapter 12.

### VENTRICULAR AFTERLOAD

The vascular resistance against which each ventricle works is calculated, by analogy with Ohm’s law, as the pressure gradient across the vascular bed divided by the CO (Table 20.4).

Circulatory management requires a clear understanding of this relationship between pressure, flow and resistance. If ventricular work is constant, increased vascular resistances produce higher pressures but with a lower CO. A systemic dilator such as sodium nitroprusside will reduce systemic resistance and blood pressure and increase CO. Although such manipulation is attractive in increasing CO for the same cardiac work, it is important to maintain a blood pressure that ensures appropriate distribution of blood flow and a diastolic pressure sufficient to maintain coronary artery perfusion, particularly in patients with known ischaemic heart disease or pre-existing hypertension.

The effects of some of the commonly used vasoactive agents are shown in Table 20.5 and considered in more detail later (see Chapters 79 and 80).

**Table 20.4** Calculation of ventricular afterload and stroke work

Systemic vascular resistance (SVR) = $[(\text{MAP} - \text{RAP})/Q_t] \times 80 \text{ dyn.s.cm}^{-5}$
= $[(90 - 5)/5] \times 80 = 1360 \text{ dyn.s.cm}^{-5}$
SVRI = $\text{SVR} \times \text{BSA} = 1360 \times 1.65 = 2244 \text{ dyn.s.cm}^{-9}$
Pulmonary vascular resistance (PVR) = $[(\text{PAP} - \text{LAP})/Q_t] \times 80 \text{ dyn.s.cm}^{-5}$
= $[(15 - 5)/5] \times 80 = 160 \text{ dyn.s.cm}^{-5}$
PVRI = $\text{PVR} \times \text{BSA} = 160 \times 1.65 = 264 \text{ dyn.s.cm}^{-9}$
Stroke volume (SV) = $Q_t/\text{HR} = 72 \text{ ml}$
Stroke volume index (SVI) = $72/1.65 = 44 \text{ ml/m}^2$
Ventricular stroke work (VSV) = $\text{SV} \times (\text{afterload} - \text{preload})$
LVS = $\text{SV} \times (\text{MAP} - \text{LAP}) \times 0.0136 \text{ g.m}$
= $72 \times (90 - 10) \times 0.0136 = 78 \text{ g.m}$
LVS = $78/1.65 = 47 \text{ g.m}$
RVS = $\text{SV} \times (\text{PAP} - \text{RAP}) \times 0.0136 \text{ g.m}$
= $72 \times (15 - 5) \times 0.0136 = 10 \text{ g.m}$
RVS = $10/1.65 = 6 \text{ g.m}$

MAP, mean arterial pressure; PAP, mean pulmonary artery pressure.

Pressures are measured in mmHg, cardiac output ( $Q_t$ ) in l/min.

Values for resistance, stroke work are frequently indexed by dividing by the patient’s body surface area (BSA) derived from height and weight.

In calculating ventricular stroke work, 0.0136 converts from ml.mmHg to SI units of g.m.

Example calculations assume a normal 75-kg individual with BSA 1.65 m<sup>2</sup>.

**Table 20.5** Circulatory effects of commonly used vasoactive drug infusions

Drug	Receptors	Cardiac contractility	Heart rate	Blood pressure	Cardiac output	Splanchnic blood flow	SVR	PVR
Dopamine ( $<5 \mu\text{g/kg per min}$ )	DA1, $\beta$ 1, $\alpha$	+	0/+	0/+	+	0/+	0/+	0/+
( $>5 \mu\text{g/kg per min}$ )	$\beta$ 1, $\alpha$ , DA1, $\beta$ 2	++	+	+	++	0	+	+
Epinephrine	$\beta$ 1, $\alpha$ , $\beta$ 2	++	+	++	+++	–	+	+
Norepinephrine	$\alpha$ , $\beta$ 1	0/+	0	++	–	–	++	++
Isoprenaline	$\beta$ 1, $\beta$ 2	+	++	+/0	+	0/+	–	–
Dobutamine	$\beta$ 1, $\beta$ 2, $\alpha$	+	+	+/0/–	++	0	–	–
Dopexamine	$\beta$ 2, DA1, DA2	+	+	0	+	+	–	–
Glyceryl trinitrate	via NO	0	+	–	+	+	–	–
Nitroprusside	via NO	0	+	–	+	+	–	–
Milrinone	PDE	+	+	–	++	0/+	–	–
Nitric oxide (inhaled)	via NO	0	0	0	0/+	0	0	–
Prostacyclin		0	+	–	+	+	–	–

+, increases; 0, no change; –, decreases.

These effects are guidelines only. The response will depend on the circulatory state of the patient when the drug is started and the differential effects on  $\alpha$ ,  $\beta$ , dopamine (DA1, DA2), phosphodiesterase (PDE) receptors and nitric oxide/cGMP with increasing dose.

### VENTRICULAR CONTRACTILITY AND EFFICIENCY

The work that the ventricle performs under given loading conditions defines contractility.

For each ventricle it may be expressed mathematically as the gradient and intercept of the relationship between atrial filling pressure and stroke work (Figure 20.2). The resulting stroke volume varies with the resistance of the vascular bed into which the ventricle is ejecting. Although the right ventricle generates a much smaller stroke work, the afterload (pulmonary vascular resistance) against which it ejects is correspondingly lower since the right and left ventricular stroke volumes must necessarily be the same over time.

The work generated by each ventricle with each heart beat is the ventricular stroke work and is calculated as shown in Table 20.4.

Consideration of ventricular work is important since optimum circulatory management requires that the necessary pressures and flows to maintain satisfactory organ perfusion and oxygen delivery are achieved at maximum cardiac efficiency, i.e. for the minimum ventricular work to avoid myocardial ischaemia.

Left ventricular efficiency is the ratio of work output to energy input and may be less than 20% in patients with acute heart failure, with over 80% of energy lost as heat. A technique, based on thermodynamic principles and requiring only measurement of temperature and oxygen content difference across the left ventricular capillary bed, is simpler, clinically applicable and more accurate than earlier methods.<sup>32</sup> It will allow selection of therapies

based on both global circulatory and myocardial metabolic considerations.

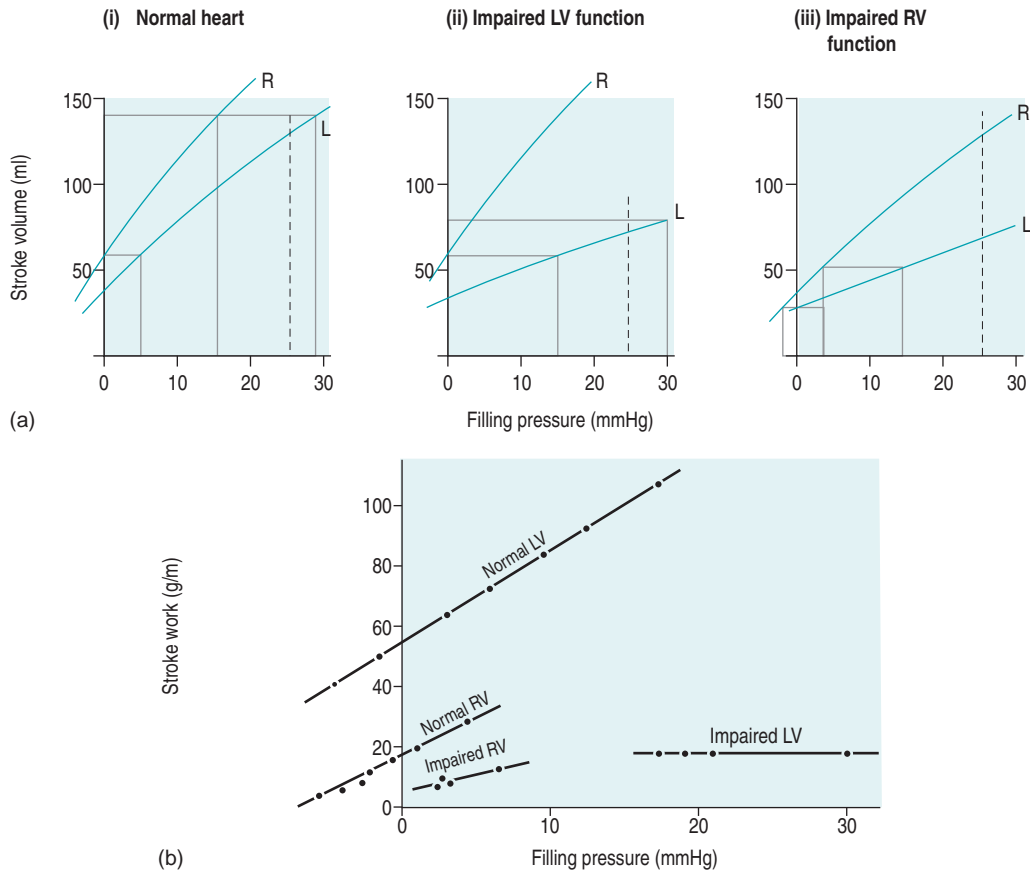

If circulatory failure is due to impaired myocardial contractility, as defined by a 'flattened' stroke work/filling pressure equation (see Figure 20.2), the atrial pressures will often already be raised. Provided such pressures reflect volume preload, further increases are not helpful since the ventricle becomes increasingly distended with high wall tension, as predicted by Laplace's law:

$$\text{Wall tension} = (\text{intraventricular pressure} \times \text{radius}) \div (\text{wall thickness} \times 2)$$

This increase in wall tension compromises myocardial blood supply, particularly epicardial to endocardial blood flow, resulting in endocardial ischaemia, further impairment of ventricular contractility and the risk of pulmonary oedema developing.

The remaining therapeutic options are:

- *Reduce afterload* using an arteriolar dilator (nitrates,  $\alpha$ -blocker, phosphodiesterase inhibitor, angiotensin-converting enzyme (ACE) inhibitor), although this strategy is frequently limited by the resulting fall in systemic pressure.<sup>33</sup>
- *Increase myocardial contractility*, either by removing negatively inotropic influences (acidaemia, hyperkalaemia, drugs, e.g.  $\beta$ -blockers) or by using a positive inotrope, which may be defined as an agent that increases the gradient of the stroke work to filling pressure relationship, resulting in a larger stroke volume for the same pre- and afterload pressures. When considering

**Figure 20.2** Ventricular function curves. (a) Relationship between stroke volume (ml) and atrial filling pressure for left (L) and right (R) ventricles in patients with normal and impaired ventricular function. (b) Relationship between stroke work (g.m) and atrial filling pressure (in mmHg) for the left (L) and right (R) ventricles for a normal subject and a patient with severe left and right ventricular failure.

the use of an inotropic agent (Table 20.5), the adverse effects of vasoactive agents on ventricular efficiency, metabolic rate and regional distribution of flow should be considered.<sup>34</sup>

### HEART RATE AND RHYTHM

In cardiac failure the stroke volume is usually constant for rates up to 100/min and thereafter falls as restriction of diastolic filling time limits end-diastolic volume. Increasing the heart rate from 70 to 90/min will increase CO by almost 30%. Achieving this with a chronotrope such as the  $\beta_1$ -agonist isoproterenol increases myocardial work and oxygen consumption and also ventricular irritability. In patients with ischaemic heart disease and particularly after a recent myocardial infarction, atrial or atrioventricular sequential pacing (which maintains coordinated atrial

contraction in heart block) improves haemodynamics without stimulating myocardial metabolism and increasing myocardial irritability.<sup>35</sup>

Heart rates above 110 beats/min, particularly with an irregular rhythm, should be controlled by either drugs or DC cardioversion after ensuring that plasma potassium and magnesium levels have been corrected. If the rhythm is supraventricular and unstable with intermittent periods of sinus rhythm, pharmacological control is indicated using either digoxin or amiodarone. Digoxin is appropriate for atrial fibrillation and has a temporary positive inotropic effect.<sup>36</sup> However amiodarone is suitable for all supraventricular rhythms and is more likely to restore sinus rhythm. A meta-analysis showed that, used prophylactically, it reduced the rate of arrhythmic episodes and sudden death in patients with recent myocardial infarction or congestive cardiac failure.<sup>37</sup> It is however a negative inotrope and this can be significant in the patient with severe heart failure.

A fixed rate of 150/min suggests atrial flutter and should prompt careful inspection of the ECG and a trial of adenosine. A persistent sinus tachycardia unexplained by fever may be due to hypovolaemia, pain or anxiety.

#### ASSESSMENT OF MYOCARDIAL FUNCTION

Of the six key circulatory variables that define ventricular function, three (RAP, MAP and HR) can be assessed clinically and are routinely monitored in ICU patients. However additional monitoring, traditionally using the PA catheter, is required to *measure* the other variables (LAP, PAP and  $Q_t$ ) and answer the questions:

1. Is further intravascular volume indicated?
2. Is CO too low and compromising global oxygen delivery?
3. Is dilator, constrictor or inotropic therapy appropriate?

It is certainly not always necessary to use invasive monitoring.<sup>38</sup> Initial management can be based on clinical assessment of intravascular volume and CO. The discipline of committing to an estimate of these key variables ensures that both the analysis of the circulation and the approach to treatment are logical. Further monitoring should be instituted if the initial management does not produce clinical improvement. Alternative, less invasive methods are available for assessing CO such as transoesophageal Doppler,<sup>39</sup> lithium dilution,<sup>40</sup> continuous CO by pulse contour analysis (PiCCO) and echocardiography<sup>10</sup> – techniques which can also provide data on the volume rather than pressure preload of the left ventricle. Table 20.6 lists some features of the techniques available for measuring CO and whether they provide information on left ventricular preload. Further details of circulatory monitoring and these other techniques are described in

the section on haemodynamic monitoring (see Chapter 12). A recent International Consensus Conference produced guidelines for the haemodynamic monitoring and management of patients with shock.<sup>41</sup>

#### KEY POINTS WHEN ASSESSING CARDIAC FUNCTION

- Pressure is no guarantee of flow
- Trends and changes are more important than a single observation
- Dynamic tests (fluid challenge, pulse pressure variation with respiration) are more revealing than static tests (RAP, central venous pressure)
- Monitoring devices may be complex with many potential sources of error, e.g. ‘blocked’ catheters, failure to re-level the transducer after a change in the patient’s position. Readings should always be interpreted with care and in conjunction with clinical assessment
- Invasive monitoring has its own hazards (infection, trauma, immobility) and should be removed if no longer required

#### PULMONARY ARTERY CATHETERISATION

This remains *one of* the most widely used methods for measurement of left atrial and PA pressures and assessment of CO using the thermodilution technique.<sup>42</sup> Although generally viewed as the ‘gold standard’ for determining CO, the error is at least 10%, even with fastidious attention to technical detail.

Inflation of the balloon at the end of the catheter provides a PA occlusion or wedge pressure, which reflects left atrial pressure provided there are no significant

**Table 20.6** Comparison of methods for assessing cardiac output

Method	Invasion/risk	Ventricular preload assessed	Complexity	Measurement error	Cost
<b>Indicator dilution</b>					
Thermodilution (using PA catheter)	+++	From ‘wedge’ pressure	++	+	++

**Table 20.7** Indications for pulmonary arterial catheterisation in patients with heart failure

Failure to improve with initial circulatory management and uncertainty about adequacy of cardiac output and relationship between atrial filling pressures
Assessment of left ventricular preload when the relationship between right and left atrial pressures is uncertain due to recent myocardial infarction, valvular abnormalities or high pulmonary vascular resistance. A low wedge pressure indicates that further volume is indicated but a high value does not necessarily exclude the need for further volume
Measurement of cardiac output by thermodilution to direct appropriate choice of vasoactive drug and to manipulate therapy, particularly when high doses are being used
Need to monitor pulmonary arterial pressures and assess right ventricular function

pulmonary vascular bed abnormalities, as occur in chronic obstructive airways disease and long-standing mitral valve disease. Despite obtaining a good-quality wedge tracing, the measurement must be interpreted with caution since increased intrathoracic pressure and diastolic dysfunction make this pressure measurement an unreliable index of true left ventricular volume preload.

The focus on ‘goal-directed therapy’ led to the widespread use of PA catheters, but their indiscriminate use was challenged by a multicentre case-controlled study which suggested that patients managed with a PA catheter had a poorer outcome than those managed without such intervention.<sup>43</sup> This study probably reflected the enthusiasm for inappropriate goal-directed therapy prevalent at that time, poor training in the use of the catheter and an inability of clinicians to respond appropriately to the data obtained.<sup>44</sup>

Table 20.7 lists the indications for PA catheterisation in heart failure. Other aspects of haemodynamic monitoring are discussed in Chapter 12.

### ASSESSMENT OF INTRAVASCULAR VOLUME STATUS

#### CLINICAL

This is conventionally based on measurement of the right atrial filling pressure and the assumption that a normal relationship exists between the atrial filling pressures, which is not necessarily valid in the critically ill patient, particularly in cardiogenic shock.<sup>27</sup> Although values < 12 mmHg suggest hypovolaemia, higher levels are more difficult to interpret, particularly in the ventilated patient. The RAP should therefore be interpreted carefully and in light of other clinical evidence. However such static tests for assessing the intravascular volume are less

valuable than dynamic tests, such as the fluid challenge and the effect of positive-pressure ventilation, which assess the circulatory response to an intervention.

Intravascular volume depletion is suggested if hypotension is precipitated by sedation, analgesia and postural change. In the patient receiving positive-pressure ventilation respiratory fluctuation in the arterial pressure tracing also suggests relative hypovolaemia. This is confirmed if brief disconnection from the ventilator causes the blood pressure to rise and venous pressure to fall: the measurement off the ventilator more accurately reflects the ventricular end-diastolic *transmural* pressure. This manoeuvre is relatively contraindicated in patients with acute respiratory distress syndrome since loss of positive end-expiratory pressure may cause widespread alveolar collapse.

#### FLUID CHALLENGE

If hypovolaemia is suspected, 200 ml of colloid should be administered and the impact on blood pressure, flow and preload observed. In the volume-depleted patient blood pressure and flow will increase with only a small, transient increase in filling pressure. While pulmonary gas exchange remains satisfactory there is less anxiety about giving further colloid. Sufficient volume will have been given when either the target pressures are achieved and the evidence of poor peripheral perfusion and organ dysfunction has resolved, or when there is a sustained rise in filling pressures to a level above which there is a risk of pulmonary oedema developing.

Deciding on the appropriate fluid volume to give in sepsis can be difficult and frequently represents a balance between giving sufficient volume to prevent the use of excessive doses of constricting inotropes and giving excessive amounts with consequent tissue oedema and deterioration in pulmonary gas exchange.

If there is concern about administering even 200 ml of fluid, a reversible fluid challenge can be given in sedated patients by elevating the legs to 60° from the horizontal for 2 minutes.

#### VALSALVA MANOEUVRE

The effect of changes in intrathoracic pressure can be used to assess intrathoracic blood volume and provide an estimate of true left ventricular preload. Figure 20.3 shows the classic Valsalva response in a normal subject and in a patient with a high intrathoracic blood volume. If a normal-type trace is observed on the monitor, further volume is indicated, whereas a square-wave response indicates an adequate left ventricular volume preload.<sup>45</sup> This response can be quantified by calculating the ratio of the pulse pressure during phase 2 of the manoeuvre to the baseline value. This correlates with measurements of PA wedge pressure<sup>46</sup> and can be applied at the bedside in sedated, ventilated patients.<sup>47</sup> However, if the patient is breathing spontaneously, this test is difficult both to perform and to interpret.

**Figure 20.3** Valsalva traces. (a) Normal pulse pressure response to Valsalva's manoeuvre. (b) Square-wave pulse pressure response to Valsalva's manoeuvre.

### ECHOCARDIOGRAPHY

Echocardiography is useful in identifying inadequate volume preload and the need for further fluid resuscitation, particularly when the preload pressures are high, as may occur with diastolic dysfunction. Performing serial studies to assess the response to therapy (fluid challenge, starting vasoactive therapy, changing ventilator settings) can be particularly valuable.

### MANAGEMENT OF CARDIAC FUNCTION IN THE CRITICALLY ILL

Circulatory management should be regularly reviewed in the critically ill patient. Following initial assessment and with knowledge of the primary diagnosis, the need for extra monitoring should be decided, provisional targets should be set for fluid balance, ventricular preload, mean and diastolic arterial pressures and a management plan agreed on how to achieve these goals. Generally a MAP

> 65 mmHg with diastolic pressure > 50 mmHg is acceptable but adequate cerebral, coronary, splanchnic and renal perfusion may require higher pressures, particularly in the elderly patient with pre-existing hypertension or widespread atheroma.

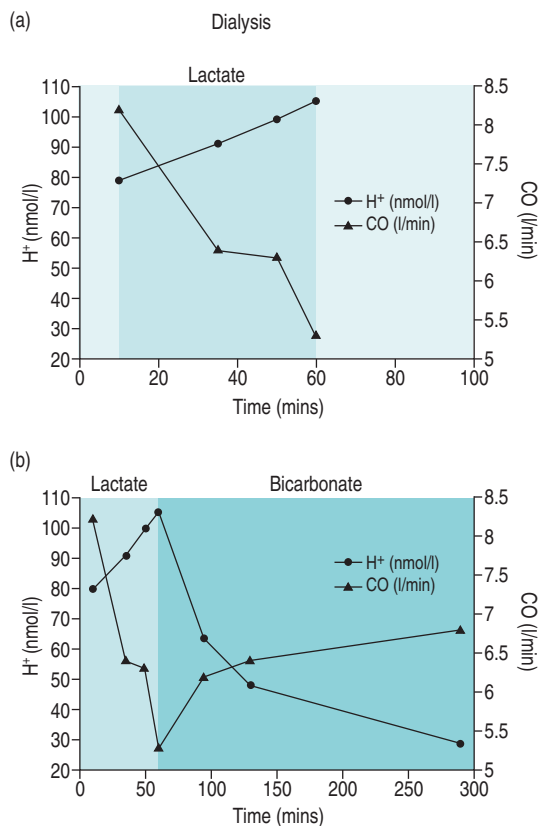

### CORRECTION OF METABOLIC FACTORS

The following metabolic factors should be promptly corrected:

- hypoxaemia:  $P_{O_2} < 8$  kPa
- acidaemia:  $pH < 7.20$
- hyperkalaemia:  $K^+ > 5.5$  mmol/l
- hypomagnesaemia:  $Mg^{2+} < 0.9$  mmol/l
- hypocalcaemia: ionised  $Ca^{2+} < 1.0$  mmol/l
- hypophosphataemia:  $PO_4^- < 0.8$  mmol/l
- anaemia:  $Hb < 9$  g%
- thiamine deficiency (malnutrition, excess alcohol, diuretic or digoxin treatment)

Metabolic acidaemia with  $\text{pH} < 7.20$  or base deficit  $> 10$  mmol/l should be corrected since myocardial contractility increases linearly with rising pH to values  $> 7.40$ . The suggestion that sodium bicarbonate should not be used as it produces a damaging paradoxical intracellular acidosis is misleading since the experiments demonstrating this effect were performed in vitro using non-physiological solutions, within a closed system that allowed no correction for any rise in carbon dioxide concentration and in which the sodium bicarbonate was given by bolus rather than by slow infusion.<sup>48</sup> The case for using bicarbonate to correct a metabolic acidaemia in the clinical setting has been recognised<sup>49</sup> and is supported by studies looking at the use of bicarbonate rather than lactate as the buffer solution in haemofiltration.<sup>50</sup> Figure 20.4 shows the effect of correcting a severe metabolic acidaemia on CO by changing from lactate to bicarbonate haemofiltration.

Although a prospective randomised study demonstrated an improved survival for critically patients if haemoglobin concentration was maintained at 7–9 g% rather than at 10–12 g%, this did not apply to the elderly and those with coronary artery disease, in whom the haemoglobin level should be maintained  $> 9$  g%.<sup>51</sup>

**Figure 20.4** Effect of dialysis: (a) rising hydrogen ions and falling CO with lactate buffer dialysis; (b) change to bicarbonate buffer – there is falling hydrogen ion concentration and a rising cardiac output.

Patients with poor dietary thiamine intake, chronic alcohol abuse and those on chronic furosemide or digoxin therapy are at risk of thiamine deficiency, resulting in impaired myocardial function. Oral thiamine (200 mg/day) improves left ventricular function in these patients.<sup>52</sup>

#### SELECTION OF APPROPRIATE VASOACTIVE AGENTS (SEE CHAPTER 82)

The choice of vasoactive agent when treating acute heart failure represents a balance between the global circulatory requirements and those of a stressed myocardium. The properties of commonly used agents are shown in Table 20.5.

The impact of these drugs in individual patients will be influenced by the baseline state of the circulation, i.e. if either intensely constricted or dilated, the same drug will potentially produce different effects on pressure, flow and its distribution. The initial choice of vasoactive agent will depend on the mean arterial pressure (MAP), CO and derived systemic vascular resistance (SVR). For example:

- CO and MAP are both low with a high SVR: an inotropic and dilating (inodilator) effect is required and dobutamine would be appropriate. If CO rises but MAP falls, as may happen with dobutamine, and a more powerful inotropic effect is required, a combination of adrenaline (epinephrine) and glyceryl trinitrate is appropriate. However, increasing doses of adrenaline risk myocardial ischaemia with ventricular irritability and splanchnic ischaemia and the development of lactic acidosis.<sup>53</sup>
- MAP and SVR are low with high CO – this is frequently seen in sepsis: arteriolar constriction with noradrenaline (norepinephrine) is indicated after adequate volume resuscitation.
- MAP is at or above target but CO is low with raised SVR: a dilating agent (nitrate, e.g. glyceryl trinitrate) or an inodilator is appropriate.

When pulmonary vascular resistance and RAP are acutely raised, a pulmonary vasodilator to offload the right ventricle and maintain CO is required: a nitrate or  $\beta$ -agonist would be appropriate but hypotension may result from arteriolar dilatation and hypoxaemia can develop due to increased ventilation–perfusion mismatch.

Dopamine has been widely used in the erroneous belief that it selectively improves renal blood flow. However, if the patient has been fully volume-resuscitated and a modest inotropic effect with only a small increase in SVR and a natriuretic effect are required, then a low-dose dopamine infusion ( $< 4$   $\mu\text{mol/kg}$  per min) is appropriate.<sup>54</sup>

Dopexamine is used to improve splanchnic blood flow but, despite reported benefits when used with volume loading in perioperative patients,<sup>55</sup> there is little evidence of outcome benefit in established shock.

Patients with chronic heart failure and those receiving long-term  $\beta$ -agonist infusion often develop tolerance with reduced catecholamine receptor responsiveness, resulting in less effect in raising intracellular cyclic adenosine monophosphate (cAMP) levels and increasing myocardial contractility. Phosphodiesterase inhibitors (enoximone, milrinone) offer an alternative strategy. Milrinone competitively inhibits the phosphodiesterase III isoenzyme, responsible for the breakdown of cAMP, thereby increasing intracellular cAMP levels and improving myocardial contractility independent of  $\beta$ -receptor stimulation. There is also improvement in ventricular diastolic relaxation. However, these agents are powerful vasodilators and hypotension frequently limits their use or requires a noradrenaline infusion. The dose should be reduced in renal failure.

Levosimendan is an intracellular calcium sensitiser and bypasses the receptors through which other inotropic agents act. Administered as an infusion over 3 days, it has a long-lasting metabolite which results in any improvement in myocardial contractility being sustained for several weeks.<sup>56</sup> It has mainly been used in chronic heart failure and its role in severe acute heart failure and cardiogenic shock following acute myocardial infarction is uncertain but promising. As a potassium channel blocker, it dilates smooth muscle and may cause hypotension. In the patient with severe heart failure already on inotropic drugs, treatment should start with a low-dose infusion (0.05  $\mu\text{g}/\text{kg}$  per min) and no loading dose should be given. If tachycardia develops or persists it is theoretically logical to consider addition of a beta-blocker but it is advisable to start with a small dose of a short-acting drug such as metoprolol or esmolol.

### BETA-BLOCKADE

The use of  $\beta$ -blockers in patients with heart failure remains controversial. Large studies have demonstrated their benefit early after acute myocardial infarction<sup>4,57</sup> and atenolol given intravenously perioperatively produces a survival benefit for up to 2 years after non-cardiac surgery in patients deemed to be at high risk of coronary artery disease.<sup>58</sup> This evidence would appear to conflict with an increasing number of studies of perioperative optimisation that show benefit from increasing oxygen delivery with volume loading and the use of  $\beta$ -agonists.<sup>55</sup> The explanation may be that in surgical patients the majority of the benefit derives from achieving adequate volume resuscitation and the additional use of a  $\beta$ -agonist is beneficial if the CO and oxygen delivery remain inadequate and the heart rate is less than 100/min, whereas the subset of patients with underlying coronary artery disease and a persisting tachycardia after fluid resuscitation may benefit from  $\beta$ -blockade rather than  $\beta$ -stimulation.

### MECHANICAL SUPPORT FOR THE HEART

Continuous positive airway pressure (CPAP) by face-mask<sup>59</sup> and invasive positive-pressure ventilation are the

most common forms of mechanical support provided in heart failure. The benefits result from improved oxygenation and reducing or eliminating the work of breathing, which may account for up to 30% of oxygen consumption.<sup>60</sup> This reduction in oxygen consumption reduces left ventricular workload and alleviates myocardial ischaemia. When instituting mechanical ventilation the clinician must be prepared to give volume and even adrenaline as the sedation and other anaesthetic agents given for intubation will reduce endogenous levels of catecholamines, producing arteriolar and venular dilatation and potentially catastrophic hypotension.

The intra-aortic counterpulsation balloon pump (IABP) is physiologically attractive since it both improves coronary and peripheral circulatory perfusion and decreases cardiac work. This results in a more efficient cardiac performance and improved myocardial oxygenation.<sup>61</sup>

Left ventricular assist devices (LVAD) can temporarily take over myocardial function but are only indicated if all other treatment options have been explored and improvement in myocardial function can be anticipated.<sup>62</sup> There are significant problems with bleeding, infection, thromboembolism and stroke. Both IABP and LVAD should be viewed as 'bridges to recovery' after cardiac surgery or recent myocardial infarction or when there is a realistic prospect of cardiac transplantation.

### CARDIOGENIC SHOCK AFTER ACUTE MYOCARDIAL INFARCTION

In patients admitted to intensive care with cardiogenic shock resulting from an acute myocardial infarction, some additional points should be noted:

- The effects of management on myocardial oxygenation must be considered as well as global circulatory targets.
- Although the patient may be ventilated on ICU, therapies demonstrated to improve myocardial salvage must not be overlooked or delayed. Thrombolysis may be contraindicated but the benefits of aspirin alone are significant if given in the early hours after infarction; if necessary the aspirin can be given rectally.  $\beta$ -blockers<sup>57</sup> and an ACE inhibitor<sup>63</sup> should be started as soon as possible but bradycardia, heart block, hypotension and impairment of renal function may cause delay. A trial of a short-acting beta-blocker, either a low-dose esmolol infusion or a small dose of metoprolol may be appropriate, particularly if there is a tachycardia, since studies have suggested that the benefit from beta-blockers may be even greater in patients with heart failure.<sup>57</sup> Patients with left ventricular dysfunction and heart failure should also be started on an aldosterone receptor antagonist therapy, such as spironolactone or eplerenone<sup>64</sup> which reduce BNP levels and cardiac morbidity and mortality. Urgent coronary angiography to allow angioplasty and stenting should be considered and the early use of an intra-aortic balloon pump<sup>65</sup> is preferable to escalating doses of inotropic drugs.

- In patients admitted following an arrest witnessed out of hospital, therapeutic hypothermia (cooling to 32–34°C) has been shown to be beneficial but, if planned, this should not prevent other interventions such as primary angioplasty being performed if appropriate. It must also be realised that monitoring the patient is more complex in the hypothermic patient since paralysis is often necessary to prevent shivering, most of the techniques for CO measurement are invalidated and both bedside assessment of the circulation and interpretation of acid–base and lactate data are difficult.
- It is important to recognise:
  - right ventricular infarction (ST elevation in lead V<sub>4</sub>R) since further monitoring may be necessary to ensure appropriate volume loading and to direct therapy to offload the right ventricle<sup>66</sup>
  - the development of either a ventricular septal defect or mitral regurgitation from papillary rupture since insertion of an intra-aortic balloon pump and urgent surgery may be indicated<sup>67</sup>

# Valvular and congenital heart disease

John E Sanderson

## VALVULAR HEART DISEASE

Valvular heart disease is still a common cause for symptoms and disability worldwide. In most economically developed countries the main cause is no longer rheumatic heart disease: congenital valve abnormalities such as mitral valve prolapse and bicuspid aortic valves, degenerative valve disease or infective endocarditis are more common causes.<sup>1</sup> However, in many parts of the world, rheumatic fever and rheumatic heart disease are still major health problems, especially in the young.<sup>2,3</sup> Diseases of heart valves produce stenosis, incompetence or both.

## RHEUMATIC FEVER

This acute febrile illness is due to a cross-reaction following a group A  $\beta$ -haemolytic streptococci pharyngitis, which causes inflammatory lesions involving the joints, heart and subcutaneous tissues. It presents with polyarthritides, carditis, subcutaneous nodules, rash (erythema marginatum) and chorea. Carditis consists of:

- murmurs (most commonly mitral, aortic regurgitation or the mid diastolic Carey–Coombs murmur)
- pericarditis
- cardiomegaly
- congestive heart failure<sup>4</sup>

Chronic rheumatic heart disease occurs in about 40% of those with apical and basal diastolic murmurs, and 70% with heart failure or pericarditis during the acute attacks. It is still common in the Middle East, India, Africa and South America, and causes 20–40% of all cardiovascular disease in the Third World.<sup>2</sup> It is now rare in North America, western Europe, Australasia and parts of Asia.

## MITRAL STENOSIS

Rheumatic fever is the main cause of mitral stenosis; rarer causes are:

- left atrial myxoma
- ball-valve thrombus
- calcification of the annulus
- systemic lupus erythematosus

Scarring or fibrosis of the valves, especially at the edges and sometimes involving the subvalvular apparatus, causes narrowing and hence increased left atrial pressure, pulmonary venous hypertension and pulmonary arterial hypertension. Thus the lungs and right ventricle suffer the most burden. Main symptoms are breathlessness on exertion, recurrent bronchitis, fatigue, palpitations due to paroxysmal atrial fibrillation (AF), haemoptysis and stroke. The onset of AF is usually associated with marked symptomatic deterioration and significantly increases the risk for left atrial thrombus formation and embolism.

Classic signs of mitral stenosis are:

- mitral facies (peripheral cyanosis on the cheeks)
- a small-volume pulse which may be irregular (AF is common)
- right ventricular hypertrophy
- a tapping apex due to a palpable first heart sound
- a loud first heart sound, and an opening snap with a rumbling diastolic murmur

The first clue to the diagnosis is often the loud first heart sound, which should prompt a careful search for the diastolic rumble which may be soft, low-pitched and localised to the apex. An opening snap is present if the valve is not calcified and this occurs 0.04–0.10 s after S<sub>2</sub>.

An electrocardiogram (ECG) shows a broad P-wave in lead 2 due to left atrial hypertrophy. Chest X-ray shows an enlarged left atrium and appendage, prominent upper-lobe pulmonary veins, but heart size is usually within normal limits. The diagnosis can readily be confirmed by echocardiography, which allows assessment of the valve anatomy, and estimation of valve area and gradient. Severe stenosis is considered to be present if the valve area is  $< 1 \text{ cm}^2$  (Figure 21.1).

Treatment is the use of  $\beta$ -blockers to slow the heart rate and increase diastolic filling time diuretics, and digoxin is given if the patient is in AF. Anticoagulation is essential if there is significant mitral stenosis and AF. Mitral balloon valvuloplasty has been shown to be very successful therapy with excellent long-term outcome, and compares well with surgical treatment.<sup>5</sup> The main contraindications to balloon valvuloplasty are significant mitral regurgitation and heavy calcification when mutual valve replacement should be done.

**Figure 21.1** Mitral stenosis. Thickened and calcified anterior and posterior mitral valve leaflets with reduced opening. LV, left ventricle; LA, left atrium.

### MITRAL REGURGITATION

There is a considerable difference between acute and chronic mitral regurgitation (Table 21.1). In chronic mitral regurgitation, there is time for the left ventricle and left atrium to adapt to the increasing regurgitation, leading to their gradual enlargement. In acute mitral regurgitation, the sudden pressure overload of the left atrium and pulmonary veins leads to severe pulmonary oedema. The treatment for acute mitral regurgitation is urgent surgery. The management of chronic mitral regurgitation is more difficult. Initially, medical therapy can be helpful, but the probability of postoperative death or persistent severe heart failure after valve replacement increases abruptly when the left ventricular (LV) end-systolic diameter exceeds 45 mm on echocardiography, or ejection fraction falls below 60%.<sup>6</sup> In patients without mitral stenosis, mitral valve repair is preferable to replacement, and evidence suggests that preservation of the chordae improves postoperative LV function.<sup>7</sup>

### MITRAL VALVE PROLAPSE<sup>8</sup>

This is a common condition affecting 5% of the adult population – more women than men. It has a number of synonyms, such as Barlow and click–murmur syndrome. It is due to myxomatous degeneration of the valve, with redundancy of the leaflets, which may affect both the

anterior and posterior valves. At the end of diastole, the valve closes normally, but as LV pressure rises during systole, a portion of the valve leaflet prolapses in the left atrium, with associated regurgitation. It is usually mild, but can progress and become more severe, and, rarely, the chordae may rupture to produce severe acute regurgitation.

Mitral valve prolapse is usually asymptomatic, but a wide variety of symptoms have been associated, including odd chest pains, palpitations and fatigue. On examination, typical findings are a mid-systolic click and a late systolic murmur, which are separated from the first heart sound, but usually reaching the second heart sound. The murmur may have a crescendo/decrescendo quality. It is usually louder with the Valsalva manoeuvre and on standing. As the prolapse worsens with age the murmur becomes more pansystolic. Echocardiography is diagnostic, and can accurately assess the degree of severity of mitral valve prolapse (Figure 21.2). In most patients, mitral prolapse is a benign condition with a good prognosis. It poses a risk for infective endocarditis, which then leads to a substantial risk of death and need for mitral valve surgery.<sup>9</sup> There is a very small increased incidence of embolic neurological ischaemic events.

### AORTIC STENOSIS

The commonest cause of aortic stenosis is degeneration of a bicuspid aortic valve. Valve stenosis leads to increased LV systolic pressure, LV hypertrophy and reduced LV compliance. The increased LV work may induce subendocardial ischaemia, arrhythmias and sudden death.

The main symptoms are angina, syncope and breathlessness. Typical findings on examination are a slowly rising small-volume pulse, evidence of LV hypertrophy without an enlarged heart, and a harsh ejection systolic murmur radiating into the neck. If the valve is calcified, there is no click and the  $A_2$  is soft.

An ECG confirms LV hypertrophy. The chest X-ray may show:

- a normal heart size
- a poststenotic dilatation in the ascending aorta
- presence of calcification

Echocardiography is diagnostic, and allows the measurement of the aortic valve area, gradient and the degree of aortic incompetence (Figure 21.3).

Medical treatment is not effective. Valve replacement should be performed as soon as the patient is symptomatic, if asymptomatic with LV systolic dysfunction, or if the jet velocity is  $> 4$  m/s in patients undergoing coronary artery bypass surgery.<sup>10</sup>

### AORTIC REGURGITATION

Like mitral regurgitation, the features of chronic and acute aortic regurgitation are different. Chronic aortic regurgitation has a number of causes, including:

- rheumatic, connective tissue disorders (e.g. ankylosing spondylitis, Reiter's syndrome and rheumatoid disease)
- syphilitic aortitis
- cystic medial necrosis (Marfan's syndrome)
- aortic root dilatation due to hypertension
- a congenital bicuspid aortic valve
- endocarditis, which can produce aortic regurgitation in a normal valve

The leak from the aorta increases LV volume, causing LV dilatation and LV hypertrophy. Initially, this is well tolerated but eventually LV function declines.

Main symptoms are fatigue and dyspnoea. Typical findings on examination are a large-volume, bounding, wide pulse pressure which is collapsing in nature. Other classical physical signs include Corrigan's (visible carotid pulsation) and nail bed capillary pulsation (Quincke sign), which all reflect the rapid run-off. The heart is usually enlarged with a displaced apex, and there is a high-pitched early diastolic blowing murmur which radiates from the left sternal edge to the apex. There may be a mid-diastolic murmur (Austin Flint) due to

the regurgitant aortic jet hitting the anterior mitral valve leaflet.

An ECG shows LV hypertrophy, usually with a strain pattern. A chest X-ray shows an enlarged heart with a dilated aorta. Echocardiography is diagnostic and can demonstrate the degree of aortic regurgitation, LV size and function.

The decision to undertake aortic valve replacement in patients with pure aortic regurgitation is difficult. Many patients can survive despite enlarged left ventricles. In general, patients should be advised to have an operation before LV end-systolic dimension exceeds 55 mm or ejection fraction < 60%. Medical therapy with vasodilators such as nifedipine or angiotensin-converting enzyme inhibitors may delay the need for valve replacement.<sup>6,11</sup> However, surgery should not be delayed for too long, otherwise irreversible LV dysfunction ensues.

Acute aortic regurgitation is a severe disease with a high mortality, usually due to endocarditis (*Staphylococcus* or *Pneumococcus*).<sup>12</sup> There is acute LV diastolic pressure and volume overload, which leads to severe pulmonary oedema without LV dilatation. It can be difficult to diagnose

**Table 21.1** Mitral regurgitation

	Chronic	Acute
Causes	Mitral valve prolapse Rheumatic heart disease LV dilatation (IHD, cardiomyopathies, etc.) Prosthetic valves	Ruptured chordae Ruptured papillary muscle Perforation of leaflet Prosthetic valves
Physiology	LV volume overload LV dilatation and hypertrophy Increased LA size (mean pressure normal initially because of increased compliance)	Sudden pressure overload of LA and pulmonary veins No change in LV dimension LA may be normal size
Symptoms	Asymptomatic initially Fatigue Dyspnoea	Severe dyspnoea
Examination	Pansystolic apical murmur radiating to axilla/lower sternal edge Third heart sound	Harsh pansystolic murmur radiating to axilla and back Third heart sound
Electrocardiogram	LV hypertrophy LA hypertrophy	No change (or acute MI)
Chest X-ray	Increased-size LV Increased-size LA	Normal LV and LA dimension Pulmonary oedema
Echocardiography	Diagnostic	Diagnostic
Treatment	Vasodilators and ACE inhibitors (reduce afterload) Diuretics and digitalis Surgery if symptoms and LV size increase (before LV end-systolic diameter > 4.5 cm or LV ejection fraction < 60%)	Preload and afterload reduction and prepare for urgent surgery

MI, myocardial infarction; LV, left ventricle/ventricular; IHD, ischaemic heart disease; IE, infective endocarditis; LA, left atrium/atrial; ACE, angiotensin-converting enzyme.

**Figure 21.2** Mitral valve prolapse with bowing of the anterior mitral valve leaflet with enlargement of the left atrium but normal left ventricle size.

**Figure 21.3** Aortic stenosis. A calcified thickened valve with reduced opening and the presence of left ventricular hypertrophy.

clinically, because the early diastolic murmur is very short and soft. An echocardiogram, however, is completely diagnostic, and can demonstrate severe aortic regurgitation, and, more importantly, early closure of the mitral valve. The treatment is urgent surgery without delay.

### TRICUSPID REGURGITATION

Tricuspid regurgitation is usually secondary to right ventricular (RV) dilatation/hypertrophy because of pulmonary hypertension. However, increasingly, infective endocarditis (usually *Staphylococcus*) in drug addicts is a common cause.<sup>13</sup> The diagnosis is made by the presence of large V-waves in the jugular venous pressure, pansystolic murmur at the left sternal edge and echocardiography. Surgery may be necessary if the degree of valvular regurgitation is severe.

### INFECTIVE ENDOCARDITIS

This is one of the most important diagnoses not to miss because untreated it is lethal.<sup>14,15</sup> A delay in diagnosis considerably lowers the probability of survival. The old adage that 'fever + murmur = endocarditis' until proven otherwise remains true. In fact any unexplained illness in a patient with a murmur should raise the question of infective endocarditis. The pattern of infective endocarditis is changing; it may be acquired in the community but increasingly in hospitals particularly as a result of procedures involving vascular catheterization, especially in elderly patients. Prior invasive procedures are more common than dental procedures as a cause. Consequently *Staphylococcus aureus* is now more common than *Streptococcus viridans* or enterococci in blood cultures. Infective endocarditis may also affect native valves that were previously thought to be normal and increasingly is a problem associated with intravenous drug abuse.

Clinical features of chronic endocarditis may be misleading. The symptoms are vague ill health, weight loss, malaise with night sweats and mild fever, and many patients are assumed to have influenza. In more chronic cases, there may be nail and conjunctival splinter haemorrhages, clubbing, splenomegaly and anaemia. Regurgitant murmurs (aortic, mitral or tricuspid) are usually present, and heart failure is a bad prognostic sign. Emboli may occur, causing strokes. Cerebral mycotic aneurysms are frequently lethal due to late rupture, which may occur many months after successful treatment of infective endocarditis (see Appendix).

### NATIVE VALVE ENDOCARDITIS (NVE)

Most community-acquired NVE is now more likely to be caused by *Staphylococcus aureus* and by coagulase-negative staphylococci than by the classical oral viridans streptococci. Enterococci are a less common cause but their incidence is increasing. In staphylococcal infective endocarditis the skin lesion may be quite trivial. Some strains of staphylococci are particularly virulent and can attack a previously normal valve, whereas streptococci and enterococci seem to infect only previously abnormal valves. Hospital-acquired NVE is almost always caused by staphylococci but occasionally coagulase-negative staphylococci and often *S. epidermidis* may be responsible. Increasingly, more cases of methicillin-resistant *S. aureus* (MRSA) endocarditis are being seen, usually from intravascular access site infections.

### PROSTHETIC VALVE ENDOCARDITIS (PVE)

The risk of infection is always present. Preventive measures are extremely important in these patients as prosthetic PVE is a cardiological disaster. Even in the best centres, mortality remains high and reoperation is often necessary. The distinction between early infective endocarditis (theatre infection) and late infective endocarditis (community-acquired) is artificial as bacteria acquired in the theatre (such as *S. epidermidis*) may present many months or even longer after surgery. Since the infection involves the sewing ring, vegetations may not be present but more commonly paraprosthetic leaks or abscesses are found: these usually require transoesophageal echocardiography, cardiac magnetic resonance imaging (MRI) or computed tomography (CT) scanning to visualise.

### INTRAVENOUS DRUG ABUSE

Infection usually affects the tricuspid valve and the condition is frequently misdiagnosed as pneumonia. Vegetations from the tricuspid valve embolise into the lung, causing patchy infarction with infection. Paradoxical embolism may occur into the systemic circulation through a patent foramen ovale or atrial septal defect, helped by a high right atrial pressure secondary to the tricuspid regurgitation. Infected vegetations can cause cerebral, splenic or peripheral infarction. The tricuspid murmur may be very soft and the degree of tricuspid regurgitation may not be severe. The diagnosis therefore is not always obvious and will always need to be considered in any intravenous drug addict with a fever.

### DIAGNOSIS OF INFECTIVE ENDOCARDITIS

The most important investigation remains the blood culture (three sets) before antibiotics are given. Although echocardiography is extremely useful in infective endocarditis, there is a misconception that endocarditis can be diagnosed or excluded by echocardiography. This is not true. Vegetations may be small and not visualised, and large vegetations may be old and sterile. It is not necessary to delay taking blood cultures while waiting for a spike of temperature. It is probably also not necessary to take samples from different sites. Levels of C-reactive protein will usually be elevated in infective endocarditis. The peripheral white cell count is often very high in those infections caused by *Staphylococcus* but may be normal in those caused by less virulent organisms. Occasionally, patients have so-called blood culture-negative infective endocarditis despite convincing clinical and echocardiographic evidence. In these cases, it is important to look specifically for other organisms such as fastidious bacteria and fungi (or suspect previous antibiotic therapy). Q fever due to *Coxiella burnetii* is common in certain areas such as Canada and parts of the USA and it can be caught from household cats. Diagnosis can be difficult as the illness is often indolent and fever may be absent. Serology is necessary to make the diagnosis, although *C. burnetii* antibodies cross-react with *Bartonella* species. Often the diagnosis is only made by histology of a replaced valve.

**Figure 21.4** A large vegetation can be seen on the anterior mitral valve leaflet during transoesophageal echocardiography.

Echocardiography may show vegetations if they are > 3 mm and will give useful information on the degree of regurgitation, any intramyocardial spread (abscess formation) and LV function. Transoesophageal echocardiography is much more useful than transthoracic, particularly for mitral valve endocarditis or PVE and the detection of an abscess (Figure 21.4).<sup>16</sup>

### TREATMENT

In acute endocarditis treatment should not be delayed while awaiting the results of blood cultures, although this may be acceptable in the patient who has been unwell for weeks or months. There are a number of guidelines for antibiotic treatment which can be consulted<sup>17</sup> (for current antibiotic treatment, see Tables 21.2, 21.3 and 21.4). The duration of treatment is traditionally 6 weeks. However, shorter courses with oral therapy have been successfully used for sensitive *Streptococcus* infections. Treatment of *C. burnetii* requires treatment for 18 months to 3 years with multiple antibiotics. Current recommendations for prophylaxis can be found in appendix.

### PERSISTENT FEVER

A number of possibilities need to be considered, including infection elsewhere either in the heart or outside, such as an infection of a central line which should be removed and sent for culture. Abscesses, paravalvular or intracardiac, are an important cause of persistent or recurrent fever and require surgery. It is nearly always impossible to eradicate an abscess by medical therapy only, and it is generally better to undertake surgery earlier than later. In some patients who appear to be well controlled, an abscess may be detected by transoesophageal

**Table 21.2** Antibiotic treatment for infective endocarditis caused by penicillin-susceptible (MIC < 0.1 mg/l) or penicillin relatively resistant (0.1 < MIC ≤ 0.5 mg/l) streptococcal endocarditis

	No allergy to penicillin		Allergy to penicillin		Duration
	Drug	Dosage	Drug	Dosage	
<b>Penicillin-susceptible streptococci (MIC &lt; 0.1 mg/l)</b>					
Non-complicated native valve IE	Penicillin G or amoxicillin	200–300 000 U/kg per day 100 mg/kg per day	Vancomycin or teicoplanin	30 mg/kg per day 6–10 mg/kg per day	2 weeks combination or 4 weeks β-lactam
	or ceftriaxone ± gentamicin*	2 g/day 3–5 mg/kg per day	± gentamicin*	3–5 mg/kg per day	
Complicated and/or prosthetic valve IE	Penicillin G or amoxicillin	200–300 000 U/kg per day 100 mg/kg per day	Vancomycin or teicoplanin	30 mg/kg per day 6–10 mg/kg per day	2 weeks combination + 2–4 weeks β-lactam
	+ gentamicin*	3–5 mg/kg per day	± gentamicin*	3–5 mg/kg per day	
<b>Penicillin-relatively resistant streptococci G<sup>†</sup> (0.1 &lt; MIC ≤ 0.5 mg/l)</b>					
Non-complicated native valve IE	Penicillin G or amoxicillin	300–400 000 U/kg per day 200 mg/kg per day	Vancomycin or teicoplanin	30 mg/kg per day 6–10 mg/kg per day	2 weeks combination + 2 weeks β-lactam
	+ gentamicin*	3–5 mg/kg per day	+ gentamicin*	3–5 mg/kg per day	
Complicated and/or prosthetic valve IE	Penicillin G or amoxicillin	300–400 000 U/kg per day 200 mg/kg per day	Vancomycin or teicoplanin	30 mg/kg per day 6–10 mg/kg per day	2 weeks combination + 2–4 weeks β-lactam
	+ gentamicin*	3–5 mg/kg per day	+ gentamicin*	3–5 mg/kg per day	

IE, infective endocarditis; MBC, minimal bactericidal concentration; MIC, minimal inhibitory concentration.

\*Other choice: netilmicin (5–6 mg/kg per day); for both drugs, once-daily administration.

†Including tolerant streptococci (MBC/MIC >32), for which amoxicillin is to be preferred to penicillin.

Hoen B. Epidemiology and antibiotic treatment of infective endocarditis: an update. *Heart* 2006; **92**: 1694–700.

echocardiography, but after stopping the antibiotics the infection will recur (Figure 21.5). Extracardiac infection may be due to a mycotic aneurysm which can cause fever or metastatic infection. Mycotic aneurysms of the brain can be a particular problem and may lead to rupture many months or even years later.

#### ROLE OF SURGERY

If the patient is not recovering or the fever is not under control, then surgery should always be considered. Major indications are haemodynamic deterioration with increasing aortic or mitral regurgitation and an abscess. Staphylococcal endocarditis in particular may cause rapid destruction of the valve and require urgent surgery. Infections by fungi nearly always require surgery, as does infective endocarditis due to Q fever. The question of surgery to prevent embolism in a patient with a large vegetation is sometimes difficult. Vegetations > 10 mm in diameter are associated with an increased risk of embolism but it has not been shown that this is a necessary indication for surgery. If there is existing severe regurgitation then the decision to operate is easier. In general, if a large vegetation is seen then it is best to operate early, as after antibiotic therapy there is a lower risk of embolism. It is a general principle that surgery should be considered early and it is not necessary to wait for antibiotic treatment to

take effect. Late surgery will always be more difficult with increasing complexity of the operation, difficulty in suturing the new valve because of destruction of the valve ring, and increased complications such as renal failure.

#### CONGENITAL HEART DISEASE IN ADULTS

The number of adults with congenital heart disease is steadily increasing, and includes not only patients with congenital heart disease who have survived into adulthood, but an increasing number of patients who have had cardiac surgery. The commonest congenital conditions found in adults are ostium secundum atrial septal defects, pulmonary valve stenosis, patent ductus arteriosus, uncomplicated congenitally corrected transposition of the great arteries, small panmembranous ventricular septal defects and Fallot's tetralogy.

#### OSTIUM SECUNDUM ATRIAL SEPTAL DEFECT

This is the commonest congenital cardiac abnormality in adults. It is often unrecognised because symptoms may be absent and the physical signs are subtle. Older patients may develop atrial fibrillation and cardiac failure. Paradoxical emboli through the defect are rare.

**Table 21.3** Antibiotic treatment for enterococcal, nutritionally variant and penicillin-resistant (MIC > 0.5 mg/l) streptococcal endocarditis

Condition	No allergy to penicillin		Allergy to penicillin		Duration
	Drug	Dosage	Drug	Dosage	
Enterococcal strain susceptible to penicillin, aminoglycosides and vancomycin	Amoxicillin	200 mg/kg per day	Vancomycin	30 mg/kg per day	4–6 weeks <sup>†</sup>
	or penicillin G	300–400 000 U/kg per day	or teicoplanin	6–10 mg/kg per day

\*Two or three daily doses.

<sup>†</sup>Duration of aminoglycoside administration could be shortened to 2–3 weeks; the total duration of treatment should be 6 weeks when vancomycin or teicoplanin is used.

<sup>‡</sup>Two daily doses.

Hoen B. Epidemiology and antibiotic treatment of infective endocarditis: an update. *Heart* 2006; **92**: 1694–700.

Examination typically shows a pulmonary ejection systolic murmur with a wide and fixed second heart sound.

ECG usually shows a right bundle branch block (and a left axis deviation with a primum defect). Chest X-ray will show pulmonary plethora.

Echocardiography, especially transoesophageal echocardiography, can demonstrate the defect and give an estimate of the pulmonary artery pressure. There is an increased risk of developing Eisenmenger's syndrome but no risk of endocarditis. Many patients can live to a good age but overall life expectancy is not normal. Closure is by surgery or more usually now an occluder

introduced percutaneously is usually recommended if the size of the shunt is > 1.5:1.0. Patent foramen ovale can now also be closed percutaneously. This is often done if there is evidence of paradoxical emboli.<sup>18</sup>

### PATENT DUCTUS ARTERIOSUS

This congenital abnormality is often asymptomatic and survival is usual. At the age of about 20, the risk of infective endocarditis increases, and at the age of about 30, patients with sizeable left-to-right shunts will begin to develop cardiac failure. Patients with significant shunts should have

oxa, oxacillin; R, resistant; S, susceptible.

\*Valve replacement should be considered, inasmuch as IE develops early after valve implantation.

<sup>†</sup>Other choices: cloxacillin 100–150 mg/kg per day; cefamandole 75–100 mg/kg per day.

<sup>‡</sup>Other choice: netilmicin (5–6 mg/kg per day).

<sup>§</sup>Other choice: teicoplanin, target serum trough concentrations 25–30 mg/l.

<sup>¶</sup>If strain resistant to rifampicin, combine vancomycin with one or two other antistaphylococcal drugs, according to susceptibility pattern.

\*\*The use of a cephalosporin is not recommended in patients with a history of anaphylactic reaction to penicillin.

Hoern B. Epidemiology and antibiotic treatment of infective endocarditis: an update. *Heart* 2006; **92**: 1694–700.

the patent ductus arteriosus closed by surgery or, increasingly, by transcatheter using an umbrella device.<sup>19</sup>

is not haemodynamically significant but a risk for endocarditis.

### VENTRICULAR SEPTAL DEFECTS

These are very common at birth but are seldom found in adults. The occasional adult will survive with a persistent small perimembranous ventricular septal defect which

### FALLOT'S TETRALOGY

This is the cyanotic malformation most frequently associated with survival to adulthood. In these patients, the pulmonary stenosis is usually sufficient to prevent excessive pulmonary blood flow, but not so severe as to cause

**Figure 21.5** Abscess cavities seen in the aortic root during transoesophageal echocardiography.

large degrees of shunting from the right to the left ventricle. An increasing number of patients who have had complete repair are surviving into adulthood, and overall outcome is excellent.<sup>20</sup> The 30-year actuarial survival rate is 90% of the expected, and late health status is very good. However, in some RV fibrosis and damage may lead to ventricular arrhythmias and sudden death. Also there is an increased risk of conduction defects (heart block).

## NON-CARDIAC SURGERY

### CYANOTIC CONGENITAL HEART DISEASE

These patients have an increased risk of acute cholecystitis caused by calcium bilirubinate stones, and cholecystectomy is a procedure to be anticipated. Blood taken for phlebotomy can be stored for transfusion later. Oxygen inhalation appears to be desirable. Care must be taken with all intravenous lines, infusions and drugs, so that air is not introduced because of the risk of systemic embolism. If patients with Fallot's tetralogy have a sudden fall in blood pressure because of a fall in systemic resistance, intense cyanosis and occasionally death may occur. Conversely, a sudden rise in systemic resistance may severely depress systemic blood flow. Prophylaxis is required for infective endocarditis. Cyanotic patients with elevated fixed pulmonary vascular resistance (Eisenmenger's syndrome) are not able to respond rapidly to haemodynamic changes. In these patients, a sudden fall or rise in systemic vascular resistance can be very dangerous.

### OSTIUM SECUNDUM ATRIAL SEPTAL DEFECT

In asymptomatic adults with this malformation and with normal pulmonary artery pressure, there is little risk during non-cardiac surgery. However, a rise in peripheral vascular resistance will increase left-to-right shunting; with

hypotension, right-to-left shunting may occur. Systemic paradoxical emboli from leg veins can occur and early mobilisation is recommended.

## CONGENITAL COMPLETE HEART BLOCK

If the QRS is narrow and the subsidiary pacemaker is reliable with a reasonable ventricular rate, then temporary RV pacing is not required. However, all vagotonic stimuli should be minimised. If the QRS complex is wide and there is a relatively slow ventricular response, a temporary pacemaker should be inserted preoperatively.

## APPENDIX

### NICE GUIDANCE

Antimicrobial prophylaxis against infective endocarditis in adults and children undergoing interventional procedures (March 2008)

Antibacterial prophylaxis and chlorhexidine mouthwash are not recommended for the prevention of endocarditis in patients undergoing dental procedures.

Antibacterial prophylaxis is not recommended for the prevention of endocarditis in patients undergoing procedures of the:

- upper and lower respiratory tract (including ear, nose, and throat procedures and bronchoscopy);
- genito-urinary tract (including urological, gynaecological, and obstetric procedures);
- upper and lower gastro-intestinal tract.

Whilst these procedures can cause bacteraemia, there is no clear association with the development of infective endocarditis. Prophylaxis may expose patients to the adverse effects of antimicrobials when the evidence of benefit has not been proven.

Any infection in patients at risk of endocarditis<sup>1</sup> should be investigated promptly and treated appropriately to reduce the risk of endocarditis.

If patients at risk of endocarditis<sup>1</sup> are undergoing a gastro-intestinal or genito-urinary tract procedure at a site where infection is suspected, they should receive appropriate antibacterial therapy that includes cover against organisms that cause endocarditis.

Patients at risk of endocarditis<sup>1</sup> should be:

- advised to maintain good oral hygiene;
- told how to recognise signs of infective endocarditis, and advised when to seek expert advice.

# Intensive care after cardiac surgery

Raymond F Raper

Coronary artery bypass surgery is one of the most frequently undertaken surgical procedures. Because of the prevalence of cardiac disease, cardiac surgery has significant health and economic implications. Intensive care may account for up to 40% of the total hospital costs for these patients and much of the short-term morbidity and mortality is based on perioperative events.

The overall mortality of cardiac surgery is low (approximately 3%). However, this ranges from less than 1% for elective coronary artery bypass grafting to in excess of 30% for more complicated surgery in patients with significant myocardial dysfunction and associated disorders. Usually, intensive care post-cardiac surgery involves a short period of recovery before discharge to the ward but, for a small percentage of patients, at least potentially remediable complications may require the complete intensive care armamentarium, with a highly significant impact on the intensive care unit (ICU) and hospital budgets and resources.

## ORGANISATION

The convergence of large numbers of patients with very similar problems in the cardiac ICU provides an ideal environment for the standardisation of care based on protocols and clinical pathways. One of the traps of post-operative cardiac care is that the sameness of the patients tends to obscure their particularity. Individual patient assessment must carefully address the multisystemic manifestations of cardiovascular and degenerative diseases.

Cardiac surgery involves a continuum of care from presentation to postdischarge management and rehabilitation. The intensive care specialist must be involved in this continuum, not functioning in isolation from surgeons, anaesthetists, cardiologists and family practitioners.

The postoperative stage is largely set by the preoperative and operative phases of management. A component of postoperative management is active participation both in principle and in particular in patient selection and preparation as well as in the conduct of anaesthesia and surgery. Relevant aspects include suitability and preparation for surgery, advanced care planning and more technical issues such as temperature management, invasive monitoring, haemodynamic management and transport.

Movement from the operating theatre to the ICU and later to the ward will only appear seamless if the management systems have been well coordinated in advance.

## CARDIOVASCULAR MANAGEMENT

The first step in the intensive care management of the newly arrived patient who has undergone cardiac surgery involves a simple transfer of ventilation, monitoring and drug administration from transport to ICU systems. This should be structured to minimise disruption.

- Confirm integrity and position of endotracheal and gastric tubes and intravascular catheters.
- Re-establish mechanical ventilation of both lungs.
- Undertake chest radiography; to assess lung expansion, pleural integrity and catheter placement.
- Perform early 12-lead electrocardiography to exclude or identify acute ischaemia.

Management is conveniently dictated by standardised protocols, which should cover investigations, fluid and electrolyte management, vasoactive and other drug administration and mechanical ventilation. Standardisation is probably more important than the particulars of the protocol, which might vary considerably among institutions. Optimal cardiovascular management requires a sound knowledge of normal and abnormal cardiovascular physiology. It also requires an understanding of the haemodynamic changes usually seen in the postoperative patient (Figure 22.1).<sup>1</sup>

## MONITORING

Electrocardiography and continuous invasive blood pressure and central venous pressure monitoring are standard. Flotation pulmonary artery (PA) catheterisation has become somewhat controversial. It is now reasonably well established that PA catheterisation is safe but may not alter outcomes.<sup>2</sup>

- Surgery can be safely undertaken at least in low-risk patients without PA catheterisation.<sup>3</sup>
- Collateral evidence supports PA catheter use in more complicated cases.

**Figure 22.1** Haemodynamic changes following cardiac surgery. Systemic vascular resistance index (SVRI).

- It is essential that the known limitations and complications of PA catheters are considered in usage and interpretation.<sup>4</sup>

Cardiac output measurement by pulse contour analysis and a variety of ultrasound techniques is becoming more commonplace. A precise role for these techniques is not established, especially in the postsurgical patient, where Doppler-enabling windows may be difficult to obtain. Pulse contour analysis is invalidated by intra-aortic counterpulsation. Nevertheless, these techniques and continuous mixed venous saturation monitoring are attractive and very useful in individual patients.

Transoesophageal echocardiography is now almost routine in the operating theatre, at least for more complicated patients. The technique is less suitable for monitoring in the ICU but is helpful in the diagnosis and management of cardiovascular instability in postoperative patients.

## FLUID AND ELECTROLYTE MANAGEMENT

Despite generous intraoperative fluid administration, effective hypovolaemia is common in the early postoperative period, especially as warming with associated vasodilatation occurs.

### RESUSCITATION FLUID

- Use of isotonic fluid is essential.
- No benefit for any particular resuscitation fluid has been established. The suggestion that albumin may not be safe has been essentially dispelled.<sup>5</sup>
- Larger volumes of crystalloid than colloid solutions are required.

Polyuria is frequently observed in the early postoperative period, possibly related to hypothermia, haemodilution and the after-effects of non-pulsatile cardiopulmonary bypass on stretch and baroreceptors. This usually settles within the first 6 hours but often necessitates considerable volume replacement in the meantime.

### POTASSIUM AND MAGNESIUM HOMEOSTASIS

Hypomagnesaemia and hypokalaemia are frequent in the early postoperative stage. These are exacerbated by polyuria. Late hyperkalaemia is also quite common, especially in patients with renal impairment or prior angiotensin-converting enzyme (ACE) inhibitor administration. Treatment for hyperkalaemia is rarely required in the absence of significant renal impairment. Especially in patients with atrial or ventricular ectopy or tachydysrhythmias, potassium and magnesium levels must be maintained in the high normal range.

Calcium homeostasis is generally not threatened by cardiopulmonary bypass. Massive transfusion, however, frequently causes hypocalcaemia. Ionised calcium levels are now easily monitored by ward-based blood gas machines.

## HYPOTENSION

Hypotension is both a consequence and a cause of myocardial dysfunction. The major causes include:

- hypovolaemia
- vasodilation
- pericardial tamponade
- heart failure

Other causes of low cardiac output state (Table 22.1) should be considered and excluded. Whatever the cause, hypotension frequently causes myocardial ischaemia and consequent heart failure, especially if it occurs in the first 12–24 hours postoperatively. Angiography during this time almost always shows a significant reduction in the calibre of native coronary arteries, indicating increased coronary resistance and, presumably, altered coronary vasodilator reserve. Treatment of hypotension is urgent if a spiral of ischaemia and heart failure is to be averted.

**Table 22.1** Low cardiac output

Preload	
●	Hypovolaemia, including haemorrhage
●	Tamponade, pericardial constriction
●	Left ventricular diastolic dysfunction
●	Hypertrophy
●	Ischaemia
●	Oedema
●	Cardiomyopathy
●	Pulmonary hypertension
●	Right ventricular failure
Afterload	
●	Excessive vasoconstriction
●	Aortic stenosis
●	Functional left ventricular obstruction
●	Obstructive cardiomyopathy
●	Systolic anterior motion of the mitral valve
Myocardial function	
●	Mechanical (ventricular septal defect, valve pathology)
●	Cardiomyopathy
●	Ischaemia, postischaemic stunning
●	Metabolic, electrolyte abnormalities, pharmacological depression

**MANAGEMENT**

Successful management of hypotension depends on:

- rapid diagnostic assessment
- diagnosis-specific intervention

Context is very helpful. Early hypotension in patients with well-preserved ventricular function and no obvious ischaemia usually responds well to fluid administration. Patients with poor ventricular function and increasing inotrope requirements are likely to have a more sinister pathophysiology.

Vasoconstrictors may be useful in breaking the cycle of hypotension–ischaemia–hypotension but must be used cautiously in patients with impaired ventricular function, and especially in patients with major vascular or aortic pathology, for whom a hypertensive overshoot may be catastrophic.

**HYPERTENSION**

Complications associated with hypertension include:

- bleeding
- heart failure
- vascular (especially aortic) injury
- myocardial ischaemia

Significant postoperative hypertension is more common in patients having a history of hypertension and with

cessation of  $\beta$ -blockade, but is reasonably common in the early postoperative period. Both absolute pressure and  $dp/dt$  are important factors in vascular injury. Vascular resistance declines over the first few hours (see Figure 22.1), so that therapy during this period is best undertaken with agents with a short duration of action. Nitroglycerine is theoretically more appropriate than nitroprusside because of the possibility of coronary steal with the latter agent.<sup>6</sup> In practice, this is almost never apparent and nitroprusside appears to be more effective. Simple measures such as the provision of adequate analgesia and sedation should also be considered.

The target blood pressure varies with the indication. Excessive reduction of blood pressure risks reducing myocardial oxygen supply more than demand. Under most circumstances, a mean arterial pressure between 90 and 100 mmHg (12.0 and 13.5 kPa) seems optimal.<sup>7</sup> Much lower target pressures may be applicable for the management of heart failure or in the presence of a vulnerable aorta, such as occurs with aortic trauma, dissection or aneurysm. Reduction of  $dp/dt$  with beta-blockade is more important than absolute blood pressure control in the management of aortic dissection.

**LOW CARDIAC OUTPUT**

The aetiology of a low cardiac output following heart surgery is diverse (see Table 22.1). The most common causes include:

- intravascular volume depletion
- systolic heart failure
- pericardial tamponade

Transient, reversible myocardial depression may follow an episode of acute ischaemia (preoperative or intraoperative) and is especially problematic where intraoperative myocardial protection has been difficult or suboptimal. Recognition of a low-output state in the absence of invasive monitoring may be difficult. Many of the usual signs of low output are also consequences of anaesthesia and surgery. Tachycardia may be obscured by drugs, hypothermia and heart disease, and even lactic acidosis may be an unreliable marker in this patient group.<sup>1</sup>

In the early postoperative period, a relatively low cardiac output may not warrant intervention, providing tissue oxygen delivery is adequate. Since beta-blockade is beneficial in the postoperative cardiac patient, beta-agonists should not be used unquestioningly. Nevertheless, optimisation of cardiac function does confer some benefit<sup>8</sup> and intervention is clearly required when tissue oxygen delivery is inadequate.

Low cardiac output is associated with increased gastrointestinal, renal and neurological complications.

**MANAGEMENT OPTIONS**

1. Establish the diagnosis, including aetiology. Distinguishing tamponade from heart failure may require

cardiac imaging with transthoracic or transoesophageal echocardiography. This should be the first recourse when uncertainty remains following conventional haemodynamic assessment. Tamponade may not be detectable using transthoracic echocardiography in the early phase after surgery.<sup>9</sup> The principal role of echocardiography is thus the investigation of possible alternate diagnoses.

2. Correct all easily reversible factors, including hypovolaemia, tamponade, acute myocardial ischaemia, electrolyte abnormalities and dysrhythmias.
3. Vasodilators are helpful in the presence of hypertension and ventricular dilatation. Postsurgical vasodilation after the first 4–8 hours often obviates any ongoing role for these agents.
4. Use of inotropic agents. Because of the associated vasodilatation, ino-constricting agents are frequently required, alone or in combination. Useful agents include:
  - dobutamine, an essentially pure  $\beta_1$ -agonist with inotropic, lusotropic and some chronotropic effects
  - noradrenaline (norepinephrine), metaraminol, vasopressin and high-dose dopamine which, being predominantly vasoconstrictors, are hazardous in the presence of hypovolaemia and should probably not be used alone in the presence of a low cardiac output
  - adrenaline (epinephrine), the metabolic effects of which (especially lactic acidosis) make usage in cardiac surgical patients problematic.<sup>10</sup> Adrenaline is, nevertheless, a potent ino-constrictor and recent studies suggest that it is as effective and as safe as noradrenaline, in the general patient population at least
  - milrinone, which has a long duration of action and potent vasodilating properties. These make milrinone relatively difficult to introduce and to wean. It is, however, a very effective inotropic agent, especially in patients with beta-receptor downregulation
  - levosimendan, a novel calcium-sensitising agent, has a promising role both periooperatively and as rescue therapy for postsurgery heart failure<sup>11</sup>
5. Intra-aortic balloon counterpulsation (IABC; see below).
6. Ventricular assist devices (VAD) are expensive and technically far more demanding than IABC. They are effective in resting the heart while supporting organ and tissue oxygen delivery. Indications for implantation have not been well established but include intractable heart failure, and failure to wean from cardiopulmonary bypass in spite of full cardiovascular support. A combination of haemodynamic and cardiac support-level criteria seems most useful and early utilisation offers improved outcomes.<sup>12,13</sup> Usage is relatively infrequent so that management expertise is difficult to acquire. Some centres thus prefer to re-establish or continue cardiopulmonary bypass as short-term, biventricular support. Most published

VAD data relate to non-surgical patients in whom the role of heart assist devices is increasingly established as both 'bridge to transplant' and as 'destination therapy'.

7. Delayed sternal closure has an established role in improving outcome after cardiac surgery.<sup>14</sup> Cardiac output is increased and inotropic requirement reduced. Subsequent sternal closure has an acceptably low complication rate. The sternum may be left open following an initial attempt at closure or reopened with later deterioration. Sternal retraction may be required.
8. Mechanical ventilation is generally continued throughout the period of low output. This reduces cardiac workload by removing the work of breathing. Positive intrathoracic pressure reduces left ventricular afterload, which is beneficial to the dilated left ventricle. Positive pressure may be detrimental, however, in the presence of diastolic ventricular dysfunction or hypovolaemia, where the reduction in venous return may further reduce ventricular preload.

#### INTRA-AORTIC BALLOON COUNTERPULSATION

IABC has an established role in support of cardiac surgery. Its two actions are: (1) augmentation of diastolic coronary perfusion pressure; and (2) left ventricular afterload reduction. This is achieved by balloon inflation (30–50 ml capacity) within the aorta during diastole and rapid deflation of the balloon immediately before aortic valve opening. The catheter is usually inserted using a Seldinger technique, but can be placed by femoral artery cutdown or directly into the descending thoracic aorta. Timing of inflation and deflation is critical to optimal function. This is best achieved using the pressure waveform and a 1:2 ratio (Figure 22.2).

Inflation is timed to coincide with the dicrotic notch. Deflation is timed to occur as late as possible in diastole,

Figure 22.2 Intra-aortic balloon counterpulsation pressure waveform.

**Table 22.2** Indications for intra-aortic balloon counterpulsation**Prophylactic**

- Cardiac surgery
  - Two of: left main >70%, left ventricular ejection fraction <0.4, unstable angina, reoperation
- Non-cardiac procedures
  - Severe left ventricular impairment, unstable angina
- Failure to wean from cardiopulmonary bypass
- Cardiogenic shock
  - *Reversible* myocardial depression
  - Support for reperfusion, revascularisation
  - Bridge to transport

ensuring that the IABC end-diastolic pressure is lower than the patient's end-diastolic pressure. IABC increases cardiac index and coronary perfusion and reduces left ventricular filling pressure, myocardial lactate production and oxygen extraction percentage.

Indications for IABC are summarised in Table 22.2.

IABC improves:

- mortality in high-risk cardiac surgery<sup>15,16</sup>
- clinical outcomes when used in support of infarct-related, non-surgical coronary reperfusion<sup>17</sup>

IABC is not helpful in the management of cardiogenic shock from irremediable causes except as a bridge to transplant. Complications are:

- limb ischaemia (6–16%)
- vascular trauma, dissection
- infection (cutdown > percutaneous)
- balloon rupture
- bleeding
- thrombocytopenia
- malposition, vascular obstruction
- malfunction, failure to unwrap

Limb ischaemia is the most frequent complication and optimal management requires early recognition based on routine, systematic observation.

**ISCHAEMIA**

Postoperative myocardial ischaemia predicts a more complicated course.<sup>18</sup> Recognition is enhanced by automated multilead ST analysis with confirmatory electrocardiography, although diagnosis may be difficult in the presence of preoperative electrocardiographic abnormalities.

Ischaemia may be due to graft failure. Remedial options include coronary angiography and/or reoperation. Angiography offers the potential for tailored reoperation or non-operative intervention. Management decisions may be influenced by surgical factors such as the availability of further conduit and the state of the native arteries. Thus close liaison among ICU personnel, cardiologists and surgeons is essential.

**DIASTOLIC DYSFUNCTION**

Ventricular hypertrophy is the commonest cause of diastolic dysfunction, and is exacerbated by poor myocardial protection during surgical procedures. Myocardial ischaemia, right ventricular (RV) dilatation and pericardial abnormalities (including tamponade) can also reduce left ventricular volume in spite of elevated filling pressures.<sup>19</sup> Recognition and management can be very difficult.

Diagnosis generally requires:

- demonstration of small ventricular volumes (using echocardiography or other techniques)
- the presence of increased pressures

**MANAGEMENT**

- Treatable causes should be addressed.
- Blood volume must be maintained, with blood transfusion where necessary.
- Maintenance of sinus rhythm is helpful, if not essential.
- Atrial pacing at an enhanced heart rate is often beneficial since the stroke volume is fixed and the diastolic filling time is foreshortened.
- $\beta$ -agonists and milrinone improve diastolic relaxation and hence ventricular compliance.

**DYSRHYTHMIAS**

Ventricular and supraventricular dysrhythmias are common. Prevention and treatment of electrolyte abnormalities may be prophylactic. New occurrence of complex ventricular dysrhythmias should stimulate a search for causal ischaemia and graft malfunction.

- Ventricular fibrillation and pulseless ventricular tachycardia require rapid defibrillation, preferably before external cardiac massage, which may cause mechanical injury poststernotomy. If haemodynamic stability cannot be rapidly restored, open cardiac massage should be instituted.
- Facilities for atrioventricular pacing are essential as transient heart block is common.

**ATRIAL FIBRILLATION (AF)**

AF is the most common complication of cardiac surgery.<sup>20,21</sup> Its incidence varies from 10 to 40% in patients undergoing coronary artery surgery and up to 50% with some valvular procedures. Predisposing factors include a history of AF, valvular heart disease (especially mitral valve pathology), increasing age and prolonged P-wave duration. AF can be effectively treated and its recurrence prevented with intraoperative radiofrequency ablation and left atrial reduction during cardiac surgery.<sup>22</sup> AF is probably less frequently observed following 'off-pump' surgery, and is most frequently encountered around the second and third postoperative

days, but may occur weeks after surgery and hospital discharge.

AF is a potentially serious complication. Apart from discomfort, it may provoke or complicate haemodynamic instability. The major complication of AF, however, is stroke, with an increased risk of approximately threefold. Based on echocardiography, there is the potential for embolic stroke within 3 days of onset of AF.

AF is also associated with:

- increase in inotrope usage
- increased use of IABC
- increased reoperation for bleeding
- prolonged ICU and hospital stay
- increased costs

Several strategies are beneficial in preventing AF:<sup>23</sup>

- $\beta$ -blockade
- amiodarone
- sotalol
- diltiazem
- atrial pacing
- dexamethasone

Treatment should be tempered with an understanding that spontaneous reversion to sinus rhythm is frequent. A treatment strategy is summarised in Table 22.3.

- Beta-blockade is best established.
- Digitalis is not more effective than placebo at reverting AF and may not be helpful in ventricular rate control in the presence of catecholamine stimulation.
- Anticoagulation should be considered where AF persists for longer than 48 hours and in all cases where elective cardioversion is undertaken.
- Early cardioversion tends to be ineffective and potentially harmful and should only be undertaken to correct severe haemodynamic compromise.

**Table 22.3** Management of atrial fibrillation (AF)

<b>Rate control</b>
<ul style="list-style-type: none"> <li>● <math>\beta</math>-blockade</li> <li>● Calcium channel blockers</li> <li>● Amiodarone</li> <li>● Sotalol</li> <li>● Digitalis</li> </ul>

<b>Anticoagulation</b>
<ul style="list-style-type: none"> <li>● Always for elective cardioversion</li> <li>● Consider if atrial fibrillation persists beyond 48 hours</li> </ul>

## RIGHT VENTRICULAR DYSFUNCTION

RV failure following cardiac surgery is reasonably common. Aetiological factors include:

- direct RV ischaemia or infarction
- poor myocardial protection
- anteriorly placed RV
- bypass-related pulmonary hypertension

Management involves:

- volume resuscitation
- maintenance of RV perfusion pressure with vasoconstrictors
- IABC as required
- inotrope administration
- RV afterload reduction

Useful afterload-reducing agents include nitric oxide,<sup>24</sup> prostaglandins and sildenafil.<sup>25</sup> Conventional vasodilators tend to produce excessive systemic vasodilatation. Occasionally, RV balloon counterpulsation or an RV assist device may be required. Delayed sternal closure has an established role.

## EMERGENCY REOPERATION

Emergency re-sternotomy is indicated as part of resuscitation when haemodynamic stability cannot be rapidly re-established with conventional means.<sup>26,27</sup> Advantages compared to closed-chest resuscitation include:

- establishment of the cause of instability
- correction of the cause (e.g. tamponade, kinked graft)
- more effective cardiac massage
- direct establishment of atrial and ventricular pacing

Re-sternotomy also enables the re-establishment of cardiopulmonary bypass and re-grafting or correction of mechanical abnormalities as required. Infectious complications of emergency re-sternotomy are probably increased but the incidence is not prohibitive.

## RESPIRATORY MANAGEMENT

Postoperative mechanical ventilation remains routine in cardiac surgical patients. Immediate extubation appears to offer little patient benefit<sup>28</sup> but may be expedient. Neither is routine ventilation beyond 12 hours essential.<sup>29</sup> Extubation can be safely undertaken with simple protocols. Reintubation is rarely required, but is more likely in older patients with pre-existing lung and vascular disease and impaired ventricular function. Reoperative surgery and bleeding requiring massive transfusion also increase the likelihood of early extubation failure.<sup>30</sup>

Hypoxia is very common in the early postoperative period. It is mostly attributable to atelectasis and responds well to simple measures such as positive end-expiratory pressure (PEEP), prolonged inspiration and simple recruitment manoeuvres. Atelectasis is a consequence of

cardiopulmonary bypass and intraoperative ventilation with high inspired oxygen and without PEEP. Long-term sequelae are rare. Incentive spirometry and chest physiotherapy are commonly utilised in the postoperative period, without good supportive evidence. Early mobilisation appears most beneficial. Adequate analgesia facilitates physiotherapy and mobilisation. Local analgesic initiatives may be helpful<sup>31</sup> whereas some non-steroidal agents may increase the risk of complications.<sup>32</sup>

More sinister causes of hypoxia include severe heart failure and hypoxaemic respiratory failure (acute respiratory distress syndrome: ARDS). The aetiology of ARDS is diverse, but includes shock, massive blood product administration and cardiopulmonary bypass itself. Management is not particular to this group of patients. Occasionally, profound hypoxia accompanies minor atelectasis with moderate pulmonary hypertension. Patent foramen ovale (which is seen in 10–15% of the normal population) with right-to-left intracardiac shunt is the likely mechanism.

Pulmonary embolism is an uncommon complication of cardiac surgery, probably due to bypass-induced platelet dysfunction, routine postoperative antiplatelet therapy and thromboprophylaxis.<sup>33</sup> 'Off-pump' surgery may be associated with an increase in this complication and so may warrant a more aggressive prophylactic regimen.<sup>34</sup>

## POSTOPERATIVE COMPLICATIONS

### HAEMORRHAGE

Excessive postoperative bleeding is a major cause of increased morbidity and mortality. Mechanisms are complex and include preoperative anticoagulation, thrombolysis and antiplatelet therapy as well as activation of haemostatic mechanisms, including fibrinolysis. 'Off-pump' surgery may be associated with excessive bleeding because of administration of anticoagulant and antiplatelet therapy out of fear of early graft closure.

Most studies of pharmacological strategies to minimise postoperative blood loss have involved preoperative or intraoperative intervention. Extrapolation to the postoperative phase is intuitive rather than established. Aprotinin and the lysine analogues aminocaproic acid and tranexamic acid reduce bleeding and exposure to blood and blood products. Aprotinin has been associated with an increased risk of serious end-organ damage.<sup>35</sup> Desmopressin is probably less effective and has been associated with an increased risk of myocardial infarction.<sup>36</sup>

Effective postoperative measures include reversal of residual heparin (including 'heparin rebound') and correction of coagulopathy with blood products. Application of PEEP has been shown to be effective in some studies, but not others. Retransfusion of shed blood reduces

autologous transfusion requirements without apparent side-effects. Controlled tamponade with discontinuation of drain suction and even clamping of drains has also been reported.<sup>37</sup> Finally, at least in reasonably stable patients, reduction of the transfusion threshold to at least 80 g/l reduces exposure to autologous blood transfusion<sup>38</sup> without adverse consequences.

### RENAL FAILURE

Depending on definition and patient groups, acute renal failure is observed in 1–5% of patients undergoing cardiac surgery. Risk factors include increasing age, heart failure, prolonged bypass, diabetes, pre-existing renal impairment and postoperative shock.<sup>39</sup> Surgery without cardiopulmonary bypass may be relatively protective.<sup>40</sup> Morbidity, mortality and costs are significantly increased. Effective preventive strategies beyond careful haemodynamic management and minimisation of associated nephrotoxic insults have not been established. Nevertheless, attention to urine output in the presence of known risk factors appears warranted.

### SHIVERING

Shivering is frequent following cardiac surgery. Mechanisms are complex and not entirely related to core temperature. Shivering causes a significant increase in metabolic rate and hence cardiac workload. This is especially important in the patient with impaired cardiac function and limited reserve. Effective preventive agents include dexamethasone, clonidine, high-dose morphine and external warming. Pethidine effectively reduces the duration of shivering. Short-term neuromuscular blockade is occasionally required.

### STERNAL INFECTION

Deep sternal wound infection is uncommon (0.5–2.5%). Associated morbidity and mortality are significant. Risk factors have been variously reported but consistently include diabetes, obesity and use of internal mammary arteries, especially if bilateral. Other contributing factors include prolonged surgery, chronic lung disease, male sex, low postoperative cardiac output, blood transfusion, sternal reopening and dialysis. Rigid control of blood sugar levels in diabetics<sup>41</sup> and preoperative nasal and oropharyngeal decontamination<sup>42</sup> may help prevent infection.

### NEUROLOGICAL COMPLICATIONS

Neurological complications of cardiac surgery include neuropsychiatric deterioration as a consequence of cardiopulmonary bypass, delirium and a range of peripheral neuropathies, the most frequent of which is a unilateral phrenic nerve palsy. Paraplegia is a recognised complication of thoracic aortic surgery.

The most devastating neurological complication is cerebral infarction. The incidence varies with patient selection, but ranges from 1 to 5%. The pathophysiology is mostly embolic. Risk factors include carotid artery stenosis, hypertension, AF, aortic atheroma, impaired ventricular function and peripheral vascular disease.<sup>43</sup> ‘Off-pump’ surgery is almost certainly protective and other operative techniques may also reduce the incidence.

### GASTROINTESTINAL COMPLICATIONS

Peptic ulcer disease, pancreatitis, cholecystitis, gut ischaemia, ileus and hepatic dysfunction are uncommon (<1%) after cardiac surgery. Morbidity, however, is quite high. Risk factors include increased age, more complicated surgery and postoperative shock. The incidence of gastrointestinal complications may be reduced with ‘off-pump’ surgery.<sup>44</sup>

### LONG-TERM CONSIDERATIONS

Patients surviving cardiac surgery have a continuing risk of disease progression. It is important that effective secondary prevention strategies be considered or recommenced in the postoperative period. Initiatives with proven long term benefit in patients with ischaemic heart disease include anti-platelet therapy, beta blockade, ACE inhibitors, lipid-lowering statins and exercise. Treatment for hypertension, diabetes and other intercurrent disorders should also be reinstated.

A small percentage of patients require long-term ICU management for a variety of complications. Excellent long-term survival and quality of life are possible in this group of patients, especially if the prolonged ICU stay results from pulmonary complications rather than severe heart failure or neurological dysfunction.<sup>45</sup>

### NON-CARDIAC SURGERY

Non-cardiac surgery poses a significant risk to the patient with cardiac disease.<sup>46,47</sup> Postoperative cardiac complications result in significantly increased immediate and late mortality. Simple preoperative assessment enables risk stratification which might lead to deferment or cancellation of non-essential surgery. Indications for specific investigations and treatments are probably not different in the preoperative patient. However, this might be the first time that a cardiac assessment has been undertaken and hence significant cardiac pathology identified. Risk factors are summarised in Table 22.4. Cumulative factors are more than additive. Patients undergoing vascular procedures have a high risk of associated coronary artery disease and should be carefully assessed preoperatively. Perioperative risk can be modified by anaesthetic technique and by optimal medical (or surgical) management of heart disease, which might include myocardial revascularisation.<sup>46</sup>

**Table 22.4** Risk factors for cardiac patients undergoing non-cardiac surgery

- High-risk surgery (abdominal, thoracic, major vascular)
- History of ischaemic heart disease
- History of congestive heart failure
- History of cerebrovascular disease
- Treatment with insulin
- Renal impairment

High risk: three or more factors.

The principles of postoperative management are the same as those outlined for the cardiac surgical patient. The period of risk for cardiac complications extends for some days after surgery and close monitoring to identify and manage events during this time is desirable in high-risk patients. The immediate perioperative period poses risks associated with anaesthesia, bleeding, fluid and electrolyte imbalance, haemodynamic instability and temperature abnormalities. These can be effectively managed. Early reinstatement of protective treatment (aspirin, beta-blockers, ACE inhibition, statins, antihypertensive therapy) may protect against later complications.

# Echocardiography in intensive care

Karl D Donovan and Frances B Colreavy

Echocardiography refers to a group of interrelated ultrasound applications used to examine the heart and great vessels. The reflected and processed sonic waves are displayed on a monitor and the images can be stored on videotape or disk. Echocardiography includes: (1) two-dimensional (2-D) anatomical imaging; (2) M-mode echocardiography, usually obtained with 2-D guidance; and (3) Doppler techniques. Echocardiography is a safe non-invasive technique which is integral to clinical cardiology. More recently, echocardiography has evolved into a powerful diagnostic and management tool in critically ill patients, especially in cardiovascular emergencies of uncertain cause.<sup>1,2</sup>

Cardiologists, although highly skilled in echocardiography, may not appreciate the complex pathophysiology of critically ill patients in intensive care, and they have time commitments elsewhere. Echocardiography is operator-dependent; optimal image acquisition requires both technical knowledge of the machine's capabilities as well as a degree of manual dexterity. As a general rule, echocardiography is not an efficient technique for monitoring haemodynamic indices over the medium term (hours–days) in the intensive care unit (ICU). Echocardiography can help determine whether and when continuous haemodynamic monitoring should be commenced.<sup>3</sup> Repetitive trend measurements, such as stroke volume, cardiac output and pulmonary artery wedge pressure, are more suited to the pulmonary artery catheter. Moreover, intensive care staff are skilled and experienced in its use. Echocardiography technicians are not present in ICU, especially out of hours; intensivists must be able to act as their own sonographers as well as interpreting and reporting on the echographic images obtained. It is important that intensivists acquire all requisite skills so that echocardiography becomes more widely available.

## PRINCIPLES AND TECHNICAL CONSIDERATIONS<sup>4</sup>

Echocardiography uses the reflection of sound waves at tissue boundaries to construct a 2-D image of cardiac structures. The human ear hears only sound waves with a frequency between 20 Hz and 20 kHz; higher frequencies are referred to as ultrasound. Echocardiography uses sound in the frequency 1–10 MHz. A piezo electrical crystal generates and receives the ultrasound waves.

## 2-D ECHOCARDIOGRAPHY

2-D echocardiography is the cornerstone of cardiac ultrasound as Doppler and M-mode are usually performed with reference to the 2-D image. Each 2-D image is defined by the position of the transducer (acoustic window) and image plane which is determined by the axis of the heart and not the spine (Table 23.1).

## M-MODE ECHOCARDIOGRAPHY

Rapidly repeated transmit and receive cycles allow production of images with good resolution. M-mode echocardiography complements 2-D echocardiography. The beam is not scanned but stays in a fixed position, allowing the display of structures along the beam as a function of time. The rapid sampling rate makes identification of thin moving structures, such as valve leaflets, relatively easy. The cursor is usually directed through a 2-D image, giving a one-dimensional slice or 'icepick' view. Distance (depth) is on the vertical and time is on the horizontal axis (Figure 23.1).

## DOPPLER ECHOCARDIOGRAPHY<sup>4,5</sup>

Doppler echocardiography is vital for obtaining haemodynamic information and is an integral part of every echocardiographic study.

The *Doppler effect* is based on changes in sound frequency that occur when a sound source moves towards or away from an observer. One classic example is that of an ambulance siren; as it comes toward a listener, the sound frequency increases (higher pitch) and after the ambulance moves away from the observer the sound frequency decreases (lower pitch).

The *Doppler shift* is the difference between frequencies that are transmitted and received by a transducer after striking red blood cells.

The *Doppler equation* is the mathematical relationship between the Doppler shift and the velocity of red blood cells that produce it.

$$V = C \times \Delta f / 2f_t \times \cos\theta$$

where  $V$  = velocity of blood flow,  $C$  = speed of sound in soft tissue (1540 m/s),  $\Delta f$  = Doppler (frequency) shift:

**Table 23.1** Some standard views in transthoracic and transoesophageal echocardiography

Acoustic window	Image plane
Transthoracic	
Parasternal	Long axis Short axis
Apical	Four-chamber Two-chamber
Subcostal	Long axis Multiple
Transoesophageal*	
Transgastric	e.g. Short axis Long axis
Deep transgastric	e.g. Long axis/five-chamber
Lower transoesophageal	e.g. Four-chamber Two-chamber Long axis
Upper transoesophageal	e.g. Short axis of aortic valve Long axis of aortic valve Right ventricular inflow–outflow

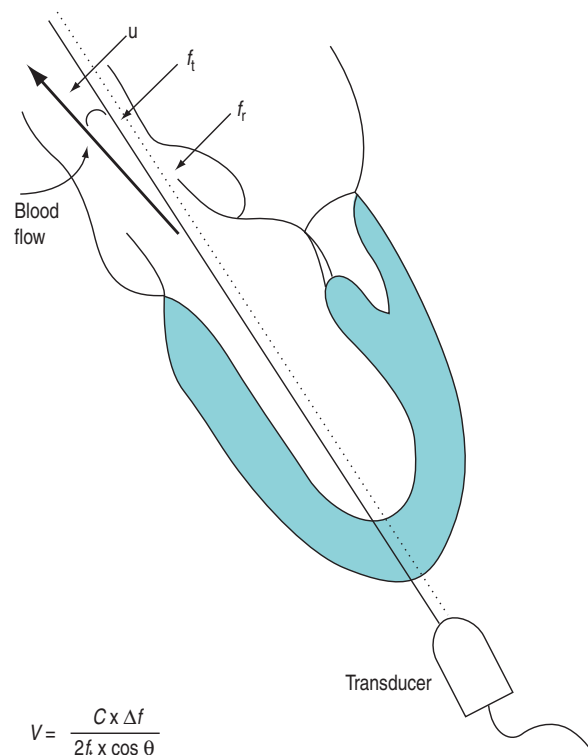

\*Multiple image planes from 0° to 180°.

**Figure 23.1** M-mode echocardiogram guided by M-mode cursor on the two-dimensional (2-D) image (see top). The transducer is anterior with the cursor directed through the right ventricle (RV), intraventricular septum (IVS), mitral valve (MV) and posterior wall (PW) of the left ventricle. The mitral valve leaflets are thickened and there is reduced diastolic slope of the anterior leaflet and the posterior leaflet moves anteriorly during diastole due to commissural fusion.

difference in frequency between received ( $f_r$ ) and transmitted ( $f_t$ ) ultrasound and  $\theta$  = angle between ultrasound beam and direction of blood flow (Figure 23.2). Echocardiographic machines contain computers that automatically calculate the Doppler shift which is then entered into the Doppler equation. Blood flow velocity (m/s) is calculated and displayed on the monitor.

It is very important that the ultrasound beam is parallel or nearly parallel with the direction of blood flow. If

**Figure 23.2** The Doppler equation.

$\theta$  equals 0 then  $\cos \theta$  equals 1; however, if  $\theta > 20^\circ$  then the velocity of blood flow will be significantly underestimated. Doppler data are processed and a spectral display plots instantaneous blood velocities over time. Blood flow velocity can be expressed as peak velocity or mean velocity throughout a cardiac cycle (velocity–time integral: VTI) (Figure 23.3).

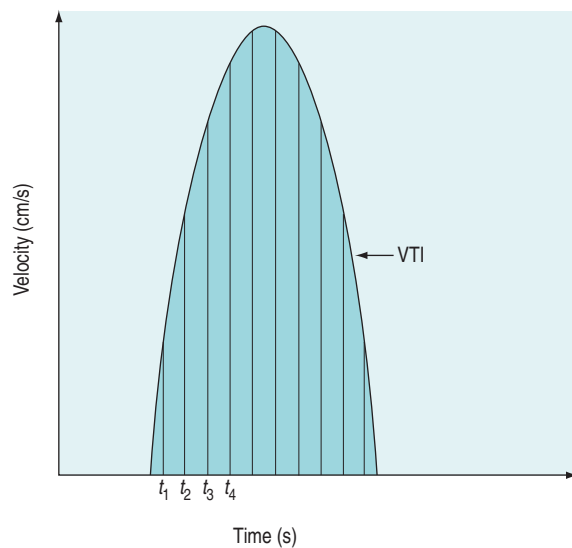

The most common uses of Doppler are pulsed-wave (PW), continuous-wave (CW) and colour-flow Doppler (CFD).

#### PULSED-WAVE DOPPLER

PW Doppler is usually performed with a duplex transducer (2-D and Doppler): a single ultrasound transducer transmits and receives ultrasound signals. Blood flow velocities of a small volume of blood, the sample volume, are obtained at a specific depth so it is useful for velocity measurements at specific sites such as the left ventricular outflow tract (LVOT). Due to technical limitations the maximum measurable velocity is usually  $< 2$  m/s.

#### CONTINUOUS-WAVE DOPPLER

The transducer consists of two crystals: one continuously transmits and the other continuously receives ultrasound waves. It can measure high-velocity blood flow, such as occurs in aortic stenosis. Unlike PW Doppler, CW

**Figure 23.3** Velocity–time integral (VTI: cm/s) = area under the velocity curve: sum of velocities (cm/s) during the ejection time (s);  $t_1$  = time one,  $t_2$  = time two, etc.

Doppler measures all the frequency shifts along the beam path and it is not possible to estimate the velocity at a specific site (range ambiguity).

Blood flow velocities measured by either PW or CW Doppler can be converted to pressure gradients using the simplified Bernoulli equation,  $\Delta P = 4V^2$  (where  $\Delta P$  is the instantaneous pressure gradient and  $V$  is the instantaneous velocity), to provide estimates of pressure.

### COLOUR-FLOW DOPPLER

This is based on PW Doppler principles. Multiple sample volumes are recorded with blood flow velocities encoded in colour (flow towards the probe is coloured red, away

blue) and superimposed on 2-D images. Thus, CFD information displayed includes: (1) direction of blood flow; (2) timing of CFD signals; (3) a crude estimation of blood flow velocity; and (4) laminar flow can be differentiated from turbulent flow.

### THREE-DIMENSIONAL

Three-dimensional (3-D) echocardiography is an evolving technique. Current equipment provides ‘real-time’ 3-D images (Figure 23.4a). The acquisition of a complete volume data set typically requires four sequential cardiac cycles. This 3-D data set must then be viewed and analysed. The full 3-D volume can then be ‘cropped’ so that the interior is exposed (Figure 23.4b). The 3-D volume set can be ‘opened’ in any imaging plane, providing both long- and short-axis views of cardiac structures. The 3-D volumetric probe can also be used for simultaneous acquisition of true real-time biplane (Figure 23.5a) and triplane (Figure 23.5b) images.

### SAFETY

Ultrasound at the power levels used clinically to image cardiac structures has no known adverse biologic effects. Transoesophageal echocardiography (TOE) in trained, experienced hands is a well-developed and safe procedure. Nevertheless, TOE is semi-invasive and serious complications and even deaths have occurred. TOE is contraindicated in the presence of oesophageal stricture or neoplasm. Caution should be exercised in other situations such as previous oesophageal surgery or total gastrectomy. TOE should be deferred in patients with any symptoms of dysphagia until the cause has been found. Oesophageal varices, severe coagulopathy and significant cervical spine abnormalities are relative contraindications to TOE. Routine antibiotic prophylaxis does not appear to be necessary before TOE in intensive care patients.

**Figure 23.4** (a) Real-time volumetric scan (four cardiac cycles) merged into three-dimensional (3-D) volume data set. This large 3-D volume is not identifiable as a cardiac structure. (b) The full 3-D volume has been ‘cropped’, revealing the interior right ventricle, tricuspid valve, right atrium, left ventricle, mitral valve and left atrium.

**Figure 23.5** (a) True real-time biplane (apical four-chamber and two-chamber views), and (b) triplane (apical four-chamber, two-chamber and apical long-axis views). Note: images obtained without moving the probe.

### TRANSTHORACIC (TTE) AND TRANSOESOPHAGEAL ECHOCARDIOGRAPHY

TTE and TOE are complementary ultrasound techniques, each with its own strengths and weakness (Table 23.2). For example, a vegetation imaged on the mitral valve of a septic patient will usually require a TOE to evaluate complications of endocarditis.

#### TRANSTHORACIC ECHOCARDIOGRAPHY

Recent technological advances such as harmonic imaging have greatly improved transthoracic surface imaging. TTE images may be inadequate in some critically ill patients, especially in intubated mechanically ventilated patients, or patients with chronic lung disease, obesity, chest trauma or surgical wounds. Inability to position such patients appropriately is a further limiting factor.

#### TRANSOESOPHAGEAL ECHOCARDIOGRAPHY<sup>6,7</sup>

The transducer is mounted at the tip of a flexible gastro-scope-like probe which can be manoeuvred to various positions in the oesophagus and stomach close to the heart (Figure 23.6).

The modern multiplane probes allow rotation of the ultrasound scanning plane from 0 to 180°, which provides a mirror-image orientation. Multiple tomographic imaging planes can be obtained without the necessity for further probe manipulation. Compared to TTE, TOE provides additional information in 32–100% of intensive care examinations and unexpected new diagnoses in 38–59%, leading to significant changes in treatment.<sup>8</sup> Approximately 20% of patients with unexplained hypotension require surgery on the basis of new TOE findings.<sup>9,10</sup>

### INDICATIONS FOR ECHOCARDIOGRAPHY<sup>11,12</sup>

The indications for echocardiography broadly fall into three categories:

1. morphologic diagnosis of specific cardiac/great-vessel pathology (usually guided by clinical suspicion)
2. haemodynamic assessment and monitoring of cardiac function
3. others, such as evaluation of patients with atrial fibrillation for the presence of left atrial (LA) clot prior to cardioversion

Guidelines for the use of echocardiography are based on expert consensus and observational studies. There are no randomised trials that specifically test the impact of echocardiography on outcome. In intensive care practice, echocardiography is used to evaluate clinical syndromes that suggest a diagnosis or, more often, a number of possible diagnoses. For example, haemodynamic instability in a patient with major blunt chest trauma suggests cardiac contusion or pericardial effusion causing tamponade. Nevertheless, the echocardiographic examination might reveal hypovolaemia with hyperdynamic LV systolic function or valvular damage with severe regurgitation.

Some common syndromes in which echocardiography is especially useful are listed in Table 23.3.

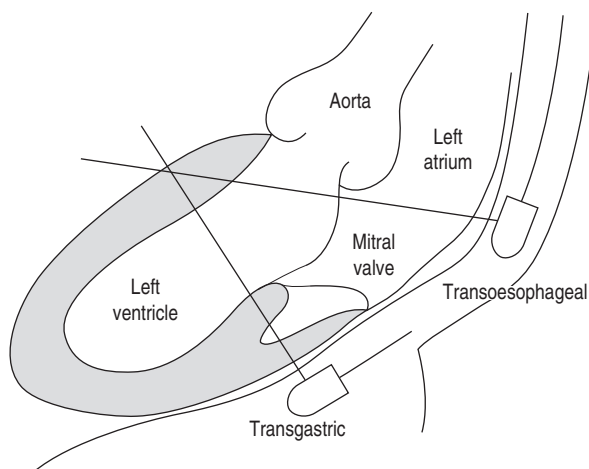

As a general rule, unless there is gross haemodynamic instability or some other overriding reason, the echocardiographic examination should be structured around a basic set of 2-D views. This applies to both TTE and TOE. The focus of the TOE examination should be on the most important specific clinical question. The second priority should be other potential pathology in the differential diagnosis. A printed report should be performed after each echocardiographic examination and should be stored and available for future reference.<sup>13</sup>

**Table 23.2** Transthoracic echocardiography (TTE) and transoesophageal echocardiography (TOE): advantages and disadvantages

	TTE	TOE	Comments
Echocardiographic windows	'Unlimited'	'Limited'	
Time lag to diagnosis	(virtually) Instantaneous	Short (min)	
Contraindications	None	Occasional	e.g. oesophageal stricture
Invasive	No	Minimal	
Morbidity	No	Minimal	Low but measurable complication rate with TOE
Mortality	No	Minimal	TOE mortality about 1/10 000
Image quality			
Non-ventilated	Good/excellent	Excellent (usually)	TTE: poor images postop cardiac surgery, chronic airways limitation, obese, etc.
Ventilated	Poor to excellent	Excellent (usually)	
<b>Specific pathology</b>			
<b>Endocarditis</b>			
Native valve	Useful if low index of suspicion	Sensitive and specific	TOE essential for diagnosis of complications, e.g. abscess, etc.
Prosthetic valve	Useful in conjunction with TOE	Essential	
Aortic dissection	?	Essential	TTE occasionally useful for diagnosis. Acute regurgitation can also be assessed
Aortic trauma	±	Essential	
Left atrial appendage clot	No	Essential	
Left ventricle clot	Yes	Yes	TTE more useful than TOE to image LV apical clot
Pericardial effusion	Yes	Yes	TTE essential for guiding needle pericardiocentesis
Localised tamponade (post cardiac surgery)	Occasionally useful	(Usually) essential	TOE especially useful for posterior collections

LV, left ventricular.

**Figure 23.6** Transducer position in transoesophageal echocardiography.

### VALVULAR HEART DISEASE<sup>14,15</sup>

Echocardiography is the 'gold standard' for evaluating valvular heart disease. 2-D echocardiography provides excellent imaging of all cardiac valves. Various Doppler techniques allow accurate haemodynamic evaluation of the valves.

#### VALVULAR STENOSIS

Narrowing or stenosis of any heart valve obstructs blood flow, increasing velocity and causing a pressure gradient across the valve. Evaluation of valvular stenosis requires: (1) imaging of the valve to define the morphology and mobility of the valve cusps; (2) some quantification of the degree of stenosis; and (3) the effect of pressure overload on relevant cardiac chambers. Transvalvular pressure gradients ( $\Delta P$ ) can be estimated by Doppler techniques (see above). Note that in conditions of low cardiac output, pressure gradients will be low, thereby underestimating the severity of stenosis.

#### Aortic stenosis

The most common aetiology of valvular aortic stenosis is degeneration and calcification of the valve apparatus, although bicuspid aortic valve and rheumatic heart disease may also cause aortic stenosis. Thickening/calcification of relatively immobile valve leaflets causes valvular obstruction and pressure overload, resulting in LV hypertrophy. Severe aortic stenosis may occasionally cause sudden collapse, cardiogenic shock or pulmonary oedema of unknown cause.

**Assessment of severity** Visual assessment of aortic valve cusp thickness, calcification, mobility and degree of LV hypertrophy will often indicate the physiological significance of the aortic stenosis. Doppler echocardiography

Table 23.3 Indications for echocardiography in the intensive care unit according to clinical syndrome

Clinical syndrome	Findings	Comments
<b>Hypotension</b>		
Acute myocardial infarct		
No murmur	LV RWMA(s) RV RWMA Hypovolaemia	Usually severe ↓ LV systolic function RV ↓ > LV ↓ 'Empty' LV cavity, systolic function largely preserved
New murmur	Acute MR Papillary muscle rupture (partial or complete) VSD	Often no murmur with normal LA size 'Good' LV function with severe MR RWMA. High-velocity left-to-right systolic jet
Rarely	Cardiac rupture/tamponade LV pseudoaneurysm	Acute pericardial tamponade, usually fatal Containment of rupture
Cardiothoracic surgery	Cardiac tamponade	Often localised. There may be no 'echo-free space' due to clot compressing the heart. Cardiac filling pressures may be normal
	(New) RWMA Hypovolaemia Global LV ↓ Valvular dysfunction	May be due to graft occlusion, air embolism 'Empty' LV with RWMA Stunning or long-standing cardiomyopathy Often long-standing but may be worsened by surgery, e.g. ischaemia to a papillary muscle of mitral valve
Dynamic LVOT obstruction	LVOT pressure gradient, SAM, MR	Inotropes/IABP/hypovolaemia worsen LVOT obstruction
Trauma	Hypovolaemia Cardiac contusion Valvular injury	'Empty' LV with vigorous contraction RWMA (RV > LV) Most common aortic valve (AR) or mitral valve (MR), occasionally tricuspid valve (TR)
	VSD/ASD Cardiac tamponade Ruptured thoracic aorta	Occasionally More common in penetrating chest injuries Widened mediastinum (90%) at isthmus of aorta. TOE required
Sepsis	Often normal LV systolic function with 'empty' LV Infective endocarditis – vegetations/abscess/regurgitation	Possible global/regional LV depression TOE more sensitive than TTE for imaging vegetations/abscess/fistula
'Isolated' hypotension ('hypotension ?cause')	Global LV ↓ or RWMA Valvular dysfunction	Cardiomyopathy or stunning Usually chronic, occasionally acute (e.g. ruptured papillary muscle of mitral valve)
	Dynamic LVOT obstruction Acute cor pulmonale	Pulmonary embolism – usually dilated right heart with depressed systolic function, sometimes with clot in a proximal pulmonary artery
Sepsis (source?)	Vegetations, regurgitation ± abscess Normal TOE examination	Infective endocarditis until proven otherwise Infective endocarditis unlikely. If clinically indicated serial TOE
Systemic emboli (source?)	LA/LAA clot	Usually enlarged LA and atrial fibrillation TOE usually required for diagnosis
	LV clot	Usually associated with RWMA or global LV depression. TTE for apical clot TOE essential for diagnosis plaques
	Aortic atherosclerotic Vegetations – aortic or abscess Clot – prosthetic aortic or mitral valve Patent foramen ovale with paradoxical embolism	Septic? Associated prosthetic valve dysfunction RA pressure > LA pressure (e.g. IPPV with high PEEP). TOE (bubble contrast) usually necessary for diagnosis
	Tumour (e.g. LA myxoma)	Uncommon

**Table 23.3** Indications for echocardiography in the intensive care unit according to clinical syndrome—*Continued*

Clinical syndrome	Findings	Comments
Pulmonary oedema (cause?)	↓ LV systolic/diastolic function Valvular dysfunction (MR, MS, AR, AS)	Isolated LV diastolic dysfunction not uncommon If flail leaflet/ruptured papillary muscle suspected then TOE indicated
Dyspnoea/hypoxia without pulmonary oedema (dyspnoea cause?)	Intracardiac shunt Normal	Suggests non-cardiac cause (e.g. ARDS)
	Pulmonary embolism (dilated right heart chambers ± clot in pulmonary artery) Cardiac tamponade Miscellaneous e.g. chronic cor pulmonale, RVH, constrictive pericarditis, diastolic dysfunction, intracardiac shunt, RV volume overload	Infers moderate to large clot burden i.e. submassive/massive PE  Usually other clinical signs of tamponade present
Chest pain of uncertain aetiology (chest pain cause?)	RWMA	Infers presence of coronary artery disease
	Dissecting aortic aneurysm (intimal flap, true/false lumen)	TOE more sensitive than TTE
	PE (dilated right heart chambers ± clot in pulmonary artery) Pericarditis	Moderate to large embolus  Effusion often too small to diagnose with echocardiography
	Aortic stenosis	Clinical signs of stenosis may be absent

AR, aortic regurgitation; ARDS, acute respiratory distress syndrome; AS, aortic stenosis; ASD, atrial septal defect; IABP, intra-aortic balloon pump; IPPV, intermittent positive-pressure ventilation; LA, left atrium; LAA, left atrial appendage; LV, left ventricle; LVOT, left ventricular outflow tract; MR, mitral regurgitation; MS, mitral stenosis; PE, pulmonary embolism. PEEP, positive end-expiratory pressure; RA, right atrium; RV, right ventricle; RVH, right ventricular haemorrhage; RWMA, regional wall motion abnormality; SAM, systolic anterior motion; TOE, transoesophageal echocardiography; TR, tricuspid regurgitation; VSD, ventricular septal defect.

is essential for assessment of severity: (1) peak aortic velocity; (2) mean transvalvular pressure gradient; (3) aortic valve area; and (4) ratio of LVOT velocity/aortic valve velocity ( $V_1/V_2$ ).

- *Peak aortic velocity* (normal = 1.7 m/s) (Figure 23.7). In the presence of thickened immobile aortic valve cusps, a peak velocity = 4.5 m/s (i.e. peak pressure gradient 81 mmHg) almost certainly indicates severe stenosis.

**Figure 23.7** Continuous-wave Doppler recording of an aortic stenosis jet in a patient with critical stenosis. The jet velocity is 589 cm/s (5.89 m/s). The calculated maximum pressure gradient is 139 mmHg. Mean pressure gradient is 94 mmHg.

- *Mean transvalvular pressure gradient.* Aortic valve velocity integrated over time is displayed on the monitor and the spectral display traced. A mean pressure gradient of 50 mmHg suggests severe aortic stenosis. From a practical point of view, a patient with normal LV systolic function, a peak aortic velocity gradient of 3.0 m/s and a mean pressure gradient of 30 mmHg is extremely unlikely to have critical aortic stenosis, whereas a patient with thickened aortic leaflets, restricted movement of cusps, aortic velocity > 4.5 m/s and a mean pressure gradient = 50 mmHg will almost certainly have critical aortic stenosis. Difficulties in assessment of aortic stenosis severity arise in patients with depressed LV function and a peak aortic velocity not greatly increased, typically about 3.0–3.5 m/s, and a transvalvular gradient of 25–30 mmHg. Such patients may have mild to moderate aortic stenosis and unrelated LV dysfunction or critical aortic stenosis with severe depression of LV function; dobutamine stress echocardiography is a useful test to distinguish one condition from another.
- *Aortic valve area* (normal 3–4 cm<sup>2</sup>). In severe aortic stenosis the aortic valve area is 0.75 cm<sup>2</sup>. The aortic valve area is estimated using the continuity equation, which is based on the principle that, if the volume of blood flow upstream from an orifice is known, then measuring the velocity of blood immediately downstream from the orifice allows calculation of its cross-sectional area. According to the formula:  $A_1 \times V_1 = A_2 \times V_2$ , where  $A_1$  = LVOT cross-sectional area,

$V_1$  = LVOT VTI,  $A_2$  = aortic valve cross-sectional area,  $V_2$  = aortic VTI. The equation can be rearranged:  $A_2 = A_1 \times V_1/V_2$ .

- **Ratio of LVOT velocity/aortic valve velocity ( $V_1/V_2$ )** provides a 'dimensionless' measurement of aortic stenosis severity which is independent of cardiac output. A velocity ratio ( $V_1/V_2$ ) of  $< 0.25$  implies an aortic valve area of  $0.75 \text{ cm}^2$  (i.e. severe aortic stenosis).

Accurate estimation of maximum aortic jet velocity is best obtained by TTE. However, TOE allows planimetry (tracing) of the aortic valve orifice in the short-axis view which correlates well with catheter-derived aortic valve area.<sup>16</sup> TOE planimetry may be useful in critically ill patients when other data are inconsistent or inconclusive.

### Mitral stenosis

Significant mitral stenosis can occasionally contribute to haemodynamic instability in critically ill patients. Dyspnoea has usually been present for many years, so that mitral stenosis has been diagnosed prior to admission to intensive care. Mitral stenosis secondary to rheumatic heart disease produces typical M-mode (see Figure 23.1) and 2-D images of thickened and fused mitral valve leaflets with diastolic doming, resulting in a 'hockeystick' appearance of the anterior leaflet, together with an enlarged LA (Figure 23.8). In the short-axis view the mitral valve appears as a 'fish mouth' orifice, the area of which can be estimated (normal  $4\text{--}6 \text{ cm}^2$ ) (Figure 23.9) using planimetry.

**Assessment of severity** In addition to visualisation and planimetry of the valve, accurate assessment of mitral valve stenosis requires Doppler echocardiography: (1) peak velocity ( $E$ ) across the mitral valve is increased (normal =

**Figure 23.8** Two-dimensional (2-D) echocardiogram of a patient with mitral stenosis. The left atrium (LA) is enlarged. There is doming of both anterior (AMVL) and posterior (PMVL) leaflets with the typical 'hockeystick' appearance of the anterior leaflet (transthoracic echocardiography parasternal long axis). LV, left ventricle.

**Figure 23.9** Two-dimensional (2-D) echocardiogram of a patient with mitral stenosis. There is diminished separation between the anterior and posterior leaflets, with a typical 'fish-mouth' appearance. The valve area by 2-D planimetry is  $0.99 \text{ cm}^2$  (transthoracic echocardiography parasternal short axis).

$1.3 \text{ m/s}$ ). In severe mitral stenosis, the  $E$  velocity is usually  $> 2 \text{ m/s}$ ; (2) transvalvular pressure gradient: the mean pressure gradient between the LA and LV is usually  $> 10 \text{ mmHg}$  in severe stenosis; (3) pressure half-time ( $P_t \frac{1}{2}$ ) is the time it takes for the peak pressure gradient to halve. The rate of pressure decline across a stenotic orifice is determined by its cross-sectional area (i.e. the smaller the orifice, the slower the rate of decline). Pressure half-time  $> 220 \text{ ms}$  indicates severe mitral stenosis (mitral valve area =  $1 \text{ cm}^2$ )<sup>17</sup> (Figure 23.10). Pulmonary artery pressure should also be estimated (see below).

### Tricuspid stenosis and pulmonary stenosis

These disorders can also be diagnosed and quantified using similar echocardiographic techniques.

**Figure 23.10** Pressure half-time ( $P_t \frac{1}{2}$ ) measurement in a patient with mitral stenosis. The  $P_t \frac{1}{2}$  corresponds to a valve area of  $0.94 \text{ cm}^2$ .

### VALVULAR REGURGITATION

Evaluation of valvular regurgitation requires: (1) assessment of the valve morphology; (2) estimation of severity of regurgitation; and (3) effects of volume overload on relevant cardiac chambers. Mild valvular regurgitation of the mitral, tricuspid and pulmonary valves is common (70–90%) and such findings have no clinical significance. Trivial aortic regurgitation is found in only about 5% of examinations.

#### Aortic regurgitation

2-D echocardiography may show the cause of the aortic regurgitation, for example, valve destruction caused by infective endocarditis or a dilated aortic root with aortic dissection or, most commonly, degenerative calcification disease of aortic valve.

**Assessment of severity<sup>18</sup>** CFD imaging allows some grading of severity of regurgitation by comparing the width of the regurgitant jet to the LVOT area (Figure 23.11). If the jet occupies more than 60% of the LVOT area, then severe aortic regurgitation is probably present.

The velocity of the regurgitant jet is directly related to the pressure gradient between the aortic valve and the left ventricle. In severe aortic regurgitation, especially acute, aortic diastolic pressure falls rapidly and LV end-diastolic pressure increases, resulting in a rapid decay of the pressure gradient: an aortic regurgitant pressure half-time (250 m/s) suggests severe regurgitation. Flow reversal downstream during diastole in the descending aorta indicates severe aortic regurgitation.

**Mitral regurgitation** As with aortic regurgitation, echocardiography is useful in detecting the aetiology and mechanism of mitral regurgitation, such as annular dilation (poor coaptation of leaflets), endocarditis (leaflet destruction/perforation) and chordal or papillary muscle rupture (inadequate leaflet support). In mitral regurgitation, the left ventricle ejects blood both into the aorta and

backwards into the LA. Early in the course of mitral regurgitation the increase in stroke volume is achieved by an increase in LV ejection fraction (EF). Thus, a hyperdynamic normal-sized left ventricle with normal-sized LA implies acute mitral regurgitation. Over time mitral regurgitation causes enlargement of the LA and eventually the left ventricle dilates and LV function becomes less hyperdynamic. This apparent normalisation of LV function suggests impaired contractility and increased LA pressure. Pulmonary artery pressure also increases over time.

**Assessment of severity<sup>18</sup>** Severity of mitral regurgitation is assessed by CFD imaging of the regurgitant jet. The severity of mitral regurgitation is directly proportional to the size of the regurgitant jet within the LA (Figure 23.12). Mitral valve colour flow jet reaching the posterior wall of the LA suggests severe mitral regurgitation, as does systolic flow reversal in the pulmonary veins. Colour flow mapping of the narrowest cross-sectional area of a regurgitant jet (vena contracta) can estimate the severity of the mitral regurgitation<sup>19</sup> and this can be done in < 1 min.<sup>20</sup> Combining 2-D imaging with spectral Doppler imaging can be used to quantify valvular regurgitation by measuring regurgitant volume (volume of blood that leaks through an incompetent valve) and regurgitant fraction (fraction or percentage of stroke volume that regurgitates).

Another approach for estimating the regurgitant volume is to examine the flow pattern on the LV side of the mitral valve. Proximal isovelocity surface area (PISA) calculations, regurgitant volumes and fractions can be estimated.

#### Tricuspid regurgitation and pulmonary regurgitation

These disorders can be diagnosed and evaluated using similar principles; for example, severe tricuspid regurgitation causes systolic flow reversal in the hepatic veins.

**Figure 23.11** Severe aortic regurgitation; aliased jet occupies entire left ventricular (LV) outflow tract (transoesophageal echocardiography long axis). LA, left atrial.

**Figure 23.12** Severe mitral regurgitation secondary to leaflet posterior mitral valve leaflet (transoesophageal echocardiography four-chamber).

### INFECTIVE ENDOCARDITIS

Infective endocarditis should be suspected in any critically ill patient with sepsis and no obvious source of infection. The echocardiographic hallmark of endocarditis is the presence of vegetation(s) which appear as an echogenic chaotically moving mass attached to a heart valve (Figure 23.13). The Duke criteria<sup>21–23</sup> integrate clinical, microbiological and echocardiographic information in suspected infective endocarditis. Echocardiographic findings consistent with vegetation or new endocardial infection (abscess, prosthetic valve dehiscence, etc.) are major diagnostic criteria. In some situations, clot, tumour or marantic vegetation may mimic endocarditis. In a patient with endocarditis, echocardiography will: (1) image the vegetation and assess its size; (2) diagnose complications such as paravalvular abscess and fistula; (3) examine underlying valve morphology (e.g. bicuspid aortic valve); (4) diagnose and assess severity of associated valvular regurgitation; (5) assess cardiac function; and (6) image other heart valves. Large vegetations (> 10 mm) increase the risk of embolic events.<sup>24</sup> Despite advances in imaging, TTE is still insensitive compared to TOE<sup>25</sup> for detection of native valve vegetations and fails to demonstrate about 50% of them. TOE accuracy is much better, with a sensitivity and specificity of about 90%. In one study the negative predictive value was 86%.<sup>26</sup> TTE may be adequate to exclude vegetations in patients when clinical suspicion for endocarditis is low<sup>27</sup> provided that image quality is adequate.

About 25% of patients with *Staphylococcus aureus* septicaemia have infective endocarditis, even in the absence of obvious clinical signs.<sup>28</sup> TOE is essential for the diagnosis and detection of associated complications.

### PROSTHETIC VALVES

Echocardiographic examination of prosthetic valves requires knowledge of the various types of valves (bioprosthesis, homograft, mechanical). Blood velocity is

**Figure 23.13** Large vegetation (Veg) on the anterior mitral valve leaflet. The patient presented with septic shock and 'meningitis' and no obvious cardiac murmur (transoesophageal echocardiography long axis). LV, left ventricle.

nearly always increased through normal prosthetic valves and trivial regurgitation is characteristic of most mechanical valves. Such jets are always small, may be multiple and occur within the sewing ring of the valve. Paravalvular leaks are always abnormal and associated with dehiscence; infective endocarditis should always be considered. Suspected prosthetic valve endocarditis mandates TOE and serial examinations are often necessary. A characteristic rocking motion of the valve is diagnostic of dehiscence. TOE is superior to TTE for assessing mitral regurgitation in patients with prosthetic mitral valves, as acoustic shadowing by the mechanical valve of the LA causes poor imaging. In most instances, adequate echocardiographic assessment of prosthetic valves requires combined trans-thoracic and transoesophageal imaging.

### VENTRICULAR FUNCTION AND HAEMODYNAMIC ASSESSMENT

In critically ill patients, echocardiography, especially TOE, has evolved as an independent approach in the assessment and monitoring of cardiovascular haemodynamics. Cardiac systolic function is directly visualised and other parameters can be measured.

#### LEFT VENTRICLE

2-D and M-mode echocardiography allow accurate measurements of LV dimensions and wall thickness.

#### Systolic function

Echocardiography provides global and regional estimates of LV performance.

#### Global LV function

In intensive care patients, the two parameters most frequently used to assess LV global systolic function are EF and cardiac output.

#### Ejection fraction

The EF is the percentage of the LV diastolic volume that is ejected with each heart beat (normal EF > 50%). It should be appreciated that EF is the result of complex interactions between ventricular loading conditions and contractile state, and may not always reflect true ventricular contractility. Nevertheless, EF is extremely useful and can be estimated using various techniques:

1. Visual inspection of 2-D images. Although widely used, this method is subjective.
2. The American Society of Echocardiography recommends the modified Simpson's rule, where LV volumes are measured in two orthogonal views (apical four-chamber and apical two-chamber) (Figure 23.14a–d). The LV endocardial border is traced at end-diastole and end-systole. The ventricle is considered to be a series of discs which are summated. Calculation of LV end-diastolic and end-systolic volumes, although complicated, is easily computed using modern echocardiographic machines.

**Figure 23.14** Left ventricular (LV) ejection fraction estimation using modified Simpson's rule. The long axis of the LV is divided into a series of discs from base to apex; the LV endocardial border is traced in end-diastole (LVED) and end-systole (LVES) in two orthogonal views: apical (a) LVED, (b) LVES; four-chamber (c) LVED, (d) LVES two-chamber.

$$EF = \frac{EDV - ESV}{EDV} \times 100$$

where EDV = LV end-diastolic volume and ESV = LV end-systolic volume.

Real-time 3-D echocardiography is more accurate than 2-D techniques for the quantification of LV volumes.<sup>29</sup>

**Regional left ventricular function<sup>30</sup>**

Assessment of LV regional wall motion analysis is based on grading the contractility of individual segments: 1 = normal or hyperkinesis; 2 = hypokinesis; 3 = akinesis; 4 = dyskinesis (paradoxical systolic motion); 5 = aneurysmal. The American Society of Echocardiography divides the LV into 16 segments (six at the base, six at the mid ventricular level and four at the apex) (Figure 23.15).

Real-time 3D echocardiographic imaging is more sensitive than 2-D techniques for the detection of regional LV wall motion abnormalities.<sup>29</sup>

Segment level	AS	Ant	Lat	Post	Inf	Sep
Basal	1	2	3	4	5	6
Mid	7	8	9	10	11	12
Apex	13	14	15	-	16	13

**Figure 23.15** Regional wall motion analysis. AS, Anteroseptum; Ant, anterior; Lat, lateral; post, posterior; Inf, inferior; Sep, septum.

### Stroke volume and cardiac output

Doppler-derived blood flow velocities can be used to quantify cardiac output. The technique is based on the principle that the VTI of blood flow multiplied by the cross-sectional area (CSA) of its orifice yields an estimate of stroke volume ( $SV = CSA \times VTI$ ) (Figure 23.16a, b). The LVOT is the most commonly used site for stroke volume and cardiac output estimation. In general, correlations between echocardiographic and thermodilution-derived cardiac output have been reasonable, although neither method is a 'gold standard'.

Real-time 3-D is more accurate than 2-D echocardiography for measurement of LV volumes. Studies comparing 3-D echocardiographic LV volumes with magnetic resonance imaging (MRI) confirm the accuracy of 3-D echocardiography.<sup>29</sup>

### Preload (left ventricular end-diastolic volume)

The assessment of LV end-diastolic volume (LVEDV) is often important in critically ill patients. Significant hypovolaemia is inferred by LV end-systolic cavity obliteration. Although a presumptive diagnosis of hypovolaemia can often be made with such echo signs, other causes of end-systolic cavity obliteration, such as decreased systemic vascular resistance, severe mitral or aortic regurgitation, or ventricular septal defect, must be considered. Integrating the clinical picture together with CFD and, if necessary, quantitative assessment of preload, differentiates between the various diagnoses.

Modified Simpson's rule technique is the most accurate echocardiographic method for measuring LVEDV/preload in clinical practice (Figure 23.14a, c).

### Afterload

End-systolic wall stress (where wall stress = (pressure  $\times$  radius)/2  $\times$  wall thickness), determined by echocardiography, provides an index of LV afterload. This is rarely used in clinical practice.

### Diastolic function<sup>31</sup>

The non-invasive assessment of LV diastolic dysfunction has seen major advances in recent years. Diastolic dysfunction is a disorder of LV filling, where the LV is unable to fill to a normal LVEDV without an abnormal increase in end-diastolic pressure. All patients with LV systolic dysfunction have some degree of LV diastolic dysfunction. Some patients with congestive cardiac failure have normal or near-normal LV systolic function with isolated diastolic heart failure. Gandhi *et al.*,<sup>32</sup> using echocardiography, demonstrated that pulmonary oedema in patients with marked systemic hypertension is commonly due to isolated diastolic dysfunction. Mitral and pulmonary inflow patterns are Doppler techniques routinely used to diagnose diastolic dysfunction and assess severity.

**E/E<sup>1</sup> ratio.** Early diastolic blood flow from LA to LV results in an E-wave. Doppler tissue imaging recordings from the lateral (or medial) mitral annulus during early diastole result in an E<sup>1</sup>. E<sup>1</sup> is a good index of LV relaxation. The E/E<sup>1</sup> ratio correlates well with LV filling pressures. An E/E<sup>1</sup> ratio > 15 is associated with LA pressures > 15 mmHg, whereas an E/E<sup>1</sup> < 8 is highly specific for normal LA pressure.<sup>31</sup>

### RIGHT VENTRICLE (RV)

Evaluation of right-sided heart function is important in critically ill patients.

### Chamber size

The normal shape of the RV is a crescent, curving in front of, and concave towards, the LV. A combination of image planes is necessary to assess RV size. Ventricular dilation may be due to right-sided volume overload secondary to conditions such as tricuspid regurgitation, pulmonary regurgitation or atrial septal defect. CFD and occasionally intravenous injection of a contrast agent such as agitated saline will help distinguish the aetiology.

**Figure 23.16** Calculation of stroke volume (SV) using the left ventricular outflow tract (LVOT). (a) LVOT diameter ( $LVOT_d$ ) is measured from parasternal long axis view.  $LVOT_{CSA} = 0.785 \times (LVOT_d)^2$ , where  $LVOT_{CSA}$  is the LVOT cross-sectional area. (b)  $LVOT_{VTI}$  measured using pulsed-wave Doppler (apical five-chamber or long-axis view), where  $LVOT_{VTI}$  is the velocity–time integral.  $SV = LVOT_{CSA} \times LVOT_{VTI}$ .

**Wall thickness**

RV hypertrophy (due to pressure overload) leads to increased thickness of the RV free wall.

**Systolic function.** Right ventricular end-diastolic volume assessment is difficult because the shape of the RV and the presence of prominent trabeculations make the endocardial border difficult to outline. TOE is essential for assessing RV dysfunction following cardiac transplantation.

Detection of regional wall motion abnormalities is a sensitive and specific marker of RV ischaemia or infarction.<sup>33</sup> The diagnosis of cardiac contusion, which occurs commonly after blunt chest trauma, is often unrecognised and can be readily made by TOE.<sup>34</sup>

**Pulmonary artery pressure**

This is an important and routine part of assessing RV function. Some tricuspid regurgitation is present in > 90% of the adult population. The simplified Bernoulli equation is used: RV systolic pressure is obtained by adding right atrial pressure (RAP) to the transtricuspid gradient derived from the peak tricuspid regurgitation velocity ( $V_{tr}$ ) measured by Doppler (Figure 23.17). In the absence of pulmonary stenosis, systolic RV pressure = systolic PA pressure.

**CARDIOMYOPATHIES**

A simple classification of the cardiomyopathies includes: (1) dilated; (2) hypertrophic; and (3) restrictive.

**DILATED CARDIOMYOPATHY**

All echocardiographic features of dilated cardiomyopathy are non-specific, but LV dilation and reduced global

**Figure 23.17** Estimation of right ventricular systolic pressure (RVSP) and systolic pulmonary artery pressure (SPAP) in the presence of tricuspid regurgitation (TR). Peak TR velocity ( $V_{TR}$ ) measured by continuous-wave Doppler is 396 cm/s (3.9 m/s). Right atrial pressure (from central venous pressure) = 15 mmHg. Difference in pressure between RA and RV (using Bernoulli equation) is  $4 \times (V_{TR}^2)$  (i.e.  $4 \times (3.9)^2 = 62$ ). Therefore  $RVSP = 15 + 62 = 77$  mmHg. In the absence of pulmonary stenosis,  $RVSP = SPAP$ .

systolic function are characteristic. Both LV end-diastolic and LV end-systolic volumes are increased, with EF and fractional area of change uniformly reduced. Mural thrombus may be present. The RV may also be affected. There may be atrial enlargement. Due to the increased LVEDV, stroke volume and cardiac output may be preserved at rest. Significant mitral regurgitation, secondary to annular dilation and poor coaptation of the mitral leaflets, may be present. Diastolic dysfunction is invariably present and is an important prognostic feature. Pulmonary hypertension estimated from tricuspid regurgitation velocity may predict a poor prognosis.

**HYPERTROPHIC CARDIOMYOPATHY**

In critically ill patients, the diagnosis cannot be made without the assistance of echocardiography, where asymmetrical septal hypertrophy, the most common feature, can be readily identified and quantified, as can a variety of other hypertrophic patterns. In the elderly, a normal proximal septal bulge ('sigmoid septum') should not be confused with true hypertrophic cardiomyopathy.

**Ventricular outflow tract obstruction**

During systole, the anterior leaflet of the mitral valve moves anteriorly toward the interventricular septum and may obstruct the LVOT. The LVOT obstruction is dependent on loading conditions and may be absent at rest. Indeed, the dynamic nature of the LVOT obstruction is one of the hallmarks of this condition. The systolic anterior motion (SAM) of the leaflet distorts the mitral valve, causing mitral regurgitation. CFD (and PW Doppler) not only localise the site of LVOT obstruction, but also quantify the degree of mitral regurgitation. The severity of LVOT obstruction can be estimated by CW Doppler. Although the degree of obstruction may vary, a peak gradient of 50 mmHg indicates significant LVOT obstruction.

**Dynamic LVOT obstruction without asymmetrical septal hypertrophy<sup>35</sup>**

Dynamic LVOT obstruction with SAM can occur whenever a hyperdynamic state exists, especially in elderly patients with hypovolaemia and a septal bulge ('sigmoid' septum). The haemodynamic effects of this condition are identical to the LVOT obstruction of hypertrophic cardiomyopathy and can cause cardiogenic shock. Dynamic LVOT obstruction may be precipitated or worsened by positive inotropic or vasodilator therapy and intra-aortic balloon pumping. In hypotensive patients, a paradoxical haemodynamic response to conventional inotropic therapy is an indication for TOE. The LVOT gradient can usually be abolished by ensuring adequate volume replacement, avoiding positive inotropic agents and increasing afterload by administration of an agent such as phenylephrine (a pure  $\alpha$ -agonist).

**RESTRICTIVE CARDIOMYOPATHY**

Primary restrictive cardiomyopathy is characterised by impaired LV filling secondary to idiopathic myocardial stiffening. Echocardiographic findings usually include marked biatrial enlargement with normal LV cavity size and wall thickness and normal or slightly reduced systolic function. A characteristic restrictive mitral inflow pattern is present.

Secondary restrictive cardiomyopathy has a similar abnormal diastolic filling pattern secondary to a known myocardial cause (e.g. amyloidosis).

**PERICARDIAL DISEASE****PERICARDIAL EFFUSION AND TAMPONADE**

Echocardiography is the accepted gold standard for both the diagnosis of pericardial effusion and its haemodynamic significance. Pericardial fluid or blood can be recognised on 2-D as an 'echo-free' space around the heart (Figure 23.18). Whenever a pericardial effusion is imaged, the possibility of tamponade should be considered. When the effusion within the pericardial sac is large enough, intrapericardial pressure exceeds RV diastolic pressure and cardiac tamponade occurs, causing impaired cardiac filling and low cardiac output. 2-D echocardiographic features of cardiac tamponade may include:

1. Moderate to large pericardial effusion (usually). However, it should be appreciated that a small rapidly accumulating effusion (50–100 ml) can increase intrapericardial pressure acutely and tamponade the heart. Conversely, a large, slowly increasing effusion, sometimes over 1 l in volume, may have little effect on intrapericardial pressure and cause no haemodynamic embarrassment.
2. The heart may swing excessively in the pericardial sac. Electrocardiographically this may manifest as electrical alternans.

**Figure 23.18** Massive (5 cm) pericardial effusion (PE) in a patient with tamponade (transthoracic echocardiography subcostal).

3. Early diastolic collapse of the RV free wall is more specific (85–100%) but less sensitive (60–90%) for cardiac tamponade than
4. Late diastolic atrial collapse. Sustained (30% of cardiac cycle) RA collapse is more likely to be significant than brief collapse.
5. Respiratory variation in diastolic filling is manifested clinically by pulsus paradoxus. Doppler echocardiography demonstrates a similar phenomenon, namely exaggerated increase in tricuspid and decrease in mitral valve diastolic inflow with inspiration. A tricuspid valve inflow variation > 25% and a mitral valve inflow variation > 15% with respiration is consistent with tamponade. The inferior vena cava is usually dilated and its diameter does not vary with respiration in patients with cardiac tamponade. Doppler examination of the hepatic veins is also very important.

Echocardiography may also be used to guide pericardiocentesis by locating the optimal site for puncture and monitoring the residual effusion after drainage.<sup>36</sup> As 2-D echocardiography is a tomographic imaging technique, the needle tip is often difficult to visualise.

**CARDIAC TAMPONADE OCCURRING AFTER CARDIAC SURGERY**

The tamponade may be localised with differential compression of the right- or left-sided chambers and the clot is usually 'echo-dense' with little or no 'echo-free' space around the heart (Figure 23.19). Localised tamponade (e.g. of the RA or LA) is not uncommon in such patients. Not surprisingly, standard echocardiographic criteria, such as intermittent chamber collapse, are unreliable in detecting tamponade after cardiac surgery. The presence of 1 cm of pericardial separation (fluid/clot) in a patient with unexplained clinical deterioration (hypotension, decreased cardiac output) appears to be sensitive in

**Figure 23.19** Localised clot compressing mainly the right heart in a patient after cardiac surgery (transoesophageal echocardiography four-chamber). LA, left atrium; RA, right atrium; RV, right ventricle.

detecting tamponade.<sup>37</sup> In the absence of tamponade, other causes of hypotension, such as unsuspected hypovolaemia, ventricular dysfunction or LVOT obstruction, may be diagnosed by echocardiography. Indeed, unnecessary reoperation may be prevented in some instances.

### CONSTRUCTIVE PERICARDITIS

Echocardiography is of value in the diagnosis of constrictive pericarditis. There is often thickening of the pericardium, which may be imaged with 2-D echocardiography. Doppler studies of the tricuspid, mitral and pulmonary veins may show typical findings.

### CARDIAC MASSES

Before any diagnosis is made of a cardiac mass, it is essential to rule out pseudomasses (i.e. artefacts or normal cardiac structures). TOE is usually more sensitive than TTE. Intracardiac masses include thrombi, tumours and vegetations.

### INTRACARDIAC THROMBUS

Thrombi can occur in any cardiac chamber but are most common in the LV (often at the apex) and the LA (usually in the LA appendage). Low-flow states manifest as spontaneous echocardiographic contrast or echocardiographic 'smoke' and are precursors of clot formation and thromboemboli. LV clot (Figure 23.20), when it occurs after myocardial infarction, is associated with the regional wall motion abnormality. Clot may also occur in patients with dilated cardiomyopathy and severe global depression of LV systolic function. TTE is more sensitive than TOE for detection of LV apical clot. LA clot is much more common than RA clot and usually occurs in the setting of atrial fibrillation or mitral stenosis. TOE provides vastly superior images compared to TTE as LA clot is usually located in or near the LA appendage, which is poorly visualised with TTE. Conventional management

for patients with AF = 48 h requires therapeutic anticoagulation for 3 weeks before planned cardioversion. Another approach necessitates LA clot exclusion by TOE. If there is no LA clot, then cardioversion may proceed immediately, otherwise cardioversion is delayed. This TOE-based strategy has been shown to be associated with low embolic rates and a shorter time to cardioversion compared to conventional strategy, but no difference in outcome.<sup>38</sup>

### CARDIAC TUMOURS

LA myxoma is by far the most common benign cardiac tumour and can often be imaged by TTE, although superb images can be obtained with TOE. The tumour is usually attached by a pedicle to the interatrial septum. During diastole, the tumour may obstruct the mitral valve orifice. Rarely, other tumours, primary or metastatic, may be visualised.

### AORTIC DISEASE

TOE is paramount for diagnosing aortic pathology in critically ill patients because of its accuracy, portability, real-time imaging and low complication rate.

### AORTIC DISSECTION<sup>39</sup>

TOE is very useful for diagnosing aortic dissection. The sensitivity and specificity of TOE in diagnosis of aortic dissection are equivalent to that of computed tomography (CT) or MRI.<sup>40</sup> 2-D echocardiography will reveal the intimal flap (Figure 23.21) which is the hallmark of aortic dissection. CFD is useful in differentiating true from false lumen: (1) the false lumen is usually larger with slower flow; (2) the intimal flap pulsates in systole towards the false lumen because of the higher pressure in the true lumen. The entry point of the tear and the presence and extent of aortic regurgitation can also be evaluated.

**Figure 23.20** (a) Left ventricular (LV) apical clot. There was an associated regional wall motion abnormality (transthoracic echocardiography apical four-chamber). (b) Clot in left atrial appendage. RV, right ventricle; RA, right atrium; LA, left atrium.

**Figure 23.21** Aortic dissection involving the ascending aorta – the intimal flap (arrows) impinges on the aortic valve (AV) cusps during diastole (transoesophageal echocardiography). LA, left atrium.

#### **INTRAMURAL HAEMATOMA (IMH)<sup>41</sup>**

IMH represents a variant of aortic dissection with virtually identical clinical presentation. Indeed, it may be an early finding in patients who develop classical aortic dissection or rupture. IMH cannot be diagnosed by angiography as there is no intimal flap. 2-D echocardiography identifies IMH as a (> 0.7 cm) circular or crescentic thickening of the aortic wall or an echolucent zone in the aortic wall. There may be a thrombus-like echo pattern of the aortic wall.

#### **TRAUMATIC AORTIC RUPTURE**

TOE is both sensitive and specific for the diagnosis of aortic trauma.<sup>42</sup> The echocardiographic signs of aortic injury may include an intimal flap, aortic wall haematoma, aortic occlusion and fusiform aneurysm. Echocardiographic assessment for aortic injury requires an experienced operator.

#### **AORTIC ATHEROSCLEROSIS**

TOE allows imaging of aortic plaques which may be layered and immobile or pedunculated/sessile and liable to embolise systemically. On occasions, the aetiology of stroke, renal failure or peripheral vascular ischaemia in critically ill patients may become apparent after echocardiographic examination of the aorta.

#### **PENETRATING ATHEROSCLEROTIC ULCER**

This is an ulceration of an atherosclerotic lesion which penetrates the elastic lamina, resulting in haematoma within the media of the aortic wall. It usually occurs in the descending aorta but may also occasionally occur in the ascending aorta. Aortic pseudoaneurysms or occasionally aortic rupture may be due to progressive penetration of the ulcer. TOE is usually necessary for the diagnosis.

#### **AORTIC ANEURYSM**

Aneurysms of the aorta can easily be evaluated with echocardiography. Long-term follow-up of thoracic aneurysms without dissection usually utilises CT or MRI.

#### **PULMONARY EMBOLISM**

CT pulmonary angiogram is probably the preferred method for diagnosing pulmonary embolism. Nevertheless, echocardiography is useful to exclude massive or submassive pulmonary embolism in patients with unexplained hypotension. Pulmonary embolism causes acute obstruction of the pulmonary vasculature and haemodynamic compromise. Massive or submassive pulmonary embolism invariably causes acute cor pulmonale. The RV is acutely overloaded, causing distension and ‘rounding’ of the RV (RV to LV ratio > 0.6 in four-chamber view).<sup>43</sup> The RV hypokinesis is characteristic with sparing of the apex (McConnell’s sign).<sup>44</sup> The interventricular septum bulges into the LV cavity, resulting in LV diastolic dysfunction. The LV cavity is usually small and appears ‘undervolumed’. Significant RV hypertrophy is absent. Pulmonary hypertension is moderate and its severity can be estimated from the tricuspid regurgitant jet. Clot can also on occasions be directly imaged with TOE in the right heart cavity or proximal pulmonary arteries (Figure 23.22).

It should be appreciated that echocardiography is insensitive for the diagnosis of smaller pulmonary emboli where haemodynamic compromise is usually absent. Echocardiography is useful in assessing the severity of pulmonary embolism, e.g. if there are no signs of RV overload and systolic dysfunction in a patient with pulmonary embolism, then thrombolytics are not indicated.

**Figure 23.22** Clot in right pulmonary artery (RPA) in a patient with massive pulmonary embolus (transoesophageal echocardiography).

**Figure 23.23** Large ventricular septal defect (VSD) in a shocked patient with a recent myocardial infarction (transesophageal echocardiography deep gastric). RV, right ventricle; LV, left ventricle.

### CONGENITAL HEART DISEASE

Echocardiography is essential for the evaluation of patients with known or suspected congenital heart disease. However, it is unusual for adult patients to present to intensive care with undiagnosed haemodynamically significant congenital heart disease. The transoesophageal approach is often necessary in critically ill adult patients with suspected congenital heart disease. Congenital heart abnormalities, such as patent foramen ovale, atrial septal defect, ventricular septal defect, patent ductus arteriosus and coarctation of the aorta, can be diagnosed.

Non-congenital ventricular septal defect (e.g. complicating acute myocardial infarction or trauma) is easily diagnosed using either TTE or TOE (Figure 23.23).

# Oxygen therapy

Adrian T J Wagstaff

In mammals energy is provided by both anaerobic and aerobic respiration, the former being inadequate to provide adequate energy alone, so oxygen is the key ingredient to survival. Aerobic respiration is the most efficient mechanism for adenosine triphosphate (ATP) production. Absence or lack of ATP results in failure of energy-hungry enzyme systems, loss of cell homeostasis, and initially cellular and later organism death. A substantial part of critical care is targeted at treating and/or preventing hypoxia. An understanding of the common pathways that lead to cellular hypoxia from whatever cause is vital to providing appropriate support and treatment to the acutely unwell patient. This chapter will review the pathophysiology of oxygen delivery from atmosphere to cell; methods of assessment; types of therapy that can be acutely administered; and the potential hazards of oxygen use.

## PATHOPHYSIOLOGY OF OXYGEN DELIVERY

The single-cell organism (e.g. amoeba) requires oxygen for its survival and obtains it from the environment from simple diffusion. This relies upon Fick's first law of diffusion:

$$O_2 \text{ diffusion} = K \times A/T \times \Delta P^1$$

where  $K$  is the diffusion constant for a particular gas,  $A$  is the surface of a membrane,  $T$  is the membrane's thickness and  $\Delta P$  the difference in partial pressure across the membrane. About 600 million years ago single-celled organisms evolved into multicellular organisms. As oxygen is poorly soluble in water, diffusion alone became insufficient to deliver oxygen to the cells, and novel methods of delivery evolved, most notably the cardiovascular system.<sup>2</sup> This provided the means to deliver oxygen around the body.

## OXYGEN DELIVERY

Transport of oxygen to the cells can thus be divided into six simple steps reliant only on the laws of physics:

1. convection of oxygen from the environment into the body (ventilation)
2. diffusion of oxygen into the blood (oxygen uptake)
3. reversible chemical bonding with haemoglobin
4. convective transport of oxygen to the tissues (cardiac output: CO)
5. diffusion into the cells and organelles
6. the redox state of the cell

This chain of events is oxygen delivery ( $\dot{D}O_2$ ).

### STEP 1: CONVECTION – VENTILATION

The first step occurs in the lung in the form of pulmonary ventilation. At sea level the partial pressure of oxygen in environmental air is approximately 160 mmHg. On inspiration the air is humidified and mixed with exhaled carbon dioxide (CO<sub>2</sub>) such that at the alveolus the  $P_{aO_2}$  is 100 mmHg. This will vary in different environments and different conditions (Table 24.1). Much of oxygen therapy is based on increasing oxygen delivery into the lungs, whether it be by masks or other devices.

### STEP 2: DIFFUSION – ALVEOLUS TO BLOOD

Oxygen within the alveolus diffuses across the alveolar-capillary membrane. The average thickness of the alveolar capillary membrane is 0.3  $\mu\text{m}$  and the surface area of the respiratory membrane is 50–100 m<sup>2</sup>. This leads to a  $P_{aO_2}$  in the pulmonary capillaries of approximately 90 mmHg. Herein lie many of the problems seen in the critically ill where two mechanisms predominate:

1. the thickness and barrier effect of the space between alveolus and capillary
2. the relationship between perfusion and ventilation at alveolar level ( $V/Q$  ratio)

Good ventilation and good perfusion is ideal while poor ventilation and poor perfusion is bad. Even in normal lungs the ratios vary across the lung. In disease states the situation is exaggerated. For example, in pneumonia ventilation may be impaired while in pulmonary embolus perfusion is disrupted. Positive-pressure ventilation may further alter the balance of ventilation and perfusion.

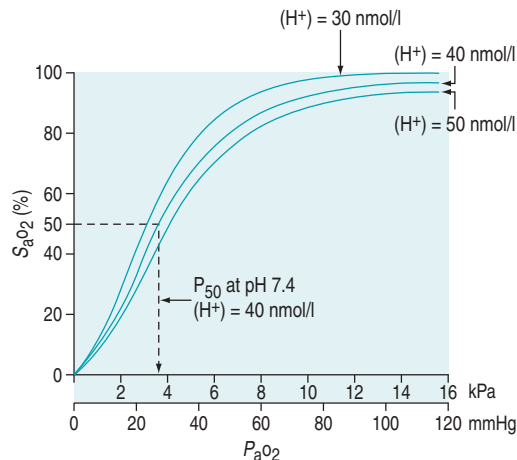

### STEP 3: HAEMOGLOBIN BINDING

Oxygen is poorly soluble in water, having a solubility of 0.003 082 g/100 g H<sub>2</sub>O. Having diffused across the alveolar capillary membrane, the oxygen binds rapidly to the respiratory pigment haemoglobin. The relationship between saturation of haemoglobin with oxygen ( $S_{aO_2}$ )

**Table 24.1** Clinical significance of some  $P_{aO_2}$  and  $S_{aO_2}$  values

$P_{aO_2}$		$S_{aO_2}$	Clinical significance
mmHg	kPa	%	
150	20.0	99	Inspired air at sea level
97	12.9	97	Young normal person
80	10.6	95	Young normal person asleep Old normal person awake Inspired air at 19 000 ft (5800 m)
70	9.3	93	Lower limit of normal
60	8.0	90	Respiratory failure (mild) Shoulder of $O_2$ dissociation curve
50	6.7	85	Respiratory failure (significant) Admit to hospital
40	5.3	75	Venous blood – normal Arterial blood – respiratory failure (severe) Acclimatised person at rest at 9000 ft (2750 m)
30	4.0	60	Unconscious if not acclimatised
26	3.5	50	P50 of haemoglobin
20	2.7	36	Acclimatised mountaineer exercising at 19 000 ft (5800 m) Hypoxic death

and  $P_{O_2}$  is not linear and forms a sigmoidal shape (Figure 24.1). The P50 is the  $P_{aO_2}$  at which 50% of the haemoglobin is saturated. Various factors are known to alter the affinity of haemoglobin for oxygen (Table 24.2). These have teleological advantages as, for example, a low pH or

**Figure 24.1** Haemoglobin oxygen dissociation curve. Normal curve at 40 nmol/l and shifts to left and right.**Table 24.2** Factors influencing the position of the oxygen dissociation curve

Factors increasing P50 (curve shifts to the right)	Factors decreasing P50 (curve shifts to the left)
Hyperthermia	Hypothermia
Decreased pH (acidaemia)	Increased pH (alkalaemia)
Increased $P_{CO_2}$ (Bohr effect)	Decreased $P_{CO_2}$
Increased 2,3-DPG	Decreased 2,3-DPG
	Fetal haemoglobin
	Carbon monoxide
	Methaemoglobin

2,3-DPG, 2,3-diphosphoglycerate.

high  $CO_2$  at tissue level could imply tissue hypoxia, and the reduction in oxygen-binding affinity, may increase oxygen availability. Similarly, hyperthermia (fever), hypercarbia and an increase in the concentration of 2,3-diphosphoglycerate (2,3-DPG) all move the curve to the right and increase oxygen availability. 2,3-DPG is a byproduct of glycolysis and therefore binds haemoglobin in predominantly hypoxic tissues, facilitating a release of oxygen. Conversely hypocarbia, alkalosis and low concentrations of 2,3-DPG result in a leftward shift of the curve and a higher affinity for binding for any given  $P_{O_2}$ . Systemic interventions such as alteration in  $P_{CO_2}$  or pH will influence the curve and therefore oxygen dissociation and availability.

#### STEP 4: CONVECTION – CARDIOVASCULAR

In humans the cardiovascular system is the solitary delivery system of oxygen to the cells. This is achieved by the convection (bulk flow) of oxygen – predominantly bound to haemoglobin (21 ml/100 ml) from the lungs via the heart and out into the systemic circulation by way of the arteries. These branch down to form the capillaries where the oxygen is offloaded to the tissues. Convection of oxygen by the cardiovascular system is influenced mainly centrally by CO and peripherally by local controls of the regional perfusion of the tissues.

The delivery of oxygen also relies on the concentration of oxygen in the blood ( $CaO_2$ ). This is calculated by the following formula:

$$CaO_2 = ([Hb](g/dl) \times 1.34 \times SaO_2) + (0.003 \times PaO_2)$$

1 g of haemoglobin binds 1.34 ml of oxygen. Thus changes in the  $S_{aO_2}$  and haemoglobin concentration are important in determining the oxygen concentration. Delivery of oxygen is therefore summarised by the formula:

$$\text{Delivery of oxygen } (\dot{D}O_2) \text{ ml/min} = 10 \times CO(1/\text{min}) \times CaO_2$$

The normal resting  $\dot{D}O_2$  is approximately 1000 ml/min. Oxygen consumption ( $\dot{V}O_2$ ) at rest is approximately 250 ml/min.

$$\text{Oxygen consumption } (\dot{V}_{O_2}) \text{ ml/min} = 10 \times \text{CO}(\text{l/min}) \times (C_{aO_2} - C_{\bar{v}O_2})$$

where  $C_{\bar{v}O_2}$  is calculated as  $(1.34 \times [\text{Hb}] \times S_{\bar{v}O_2}) + (0.003 \times P_{\bar{v}O_2})$

It can be seen that the amount of oxygen extracted is about 25% of that delivered at rest and that there is a large reserve. This obviously varies between organs. This ratio is referred to as the oxygen extraction ratio (OER).

$$\text{OER} = \dot{V}_{O_2} / \dot{D}_{O_2}$$

During exercise this can increase by up to 70–80% at maximum. Oxygen that is not removed by the tissues returns to the heart and lungs. Globally the difference between that delivered and that returning is the consumption. This model can also be used to look at regional consumption. Hence the saturation of mixed venous blood ( $S_{\bar{v}O_2}$ ), which is all the returning blood or central venous blood, can be used as an indicator of global  $\dot{V}_{O_2}$  and indirectly the adequacy of  $\dot{D}_{O_2}$ . If oxygen delivery by the microcirculation and cellular oxygen uptake are adequate, then a  $S_{\bar{v}O_2}$  value of 70% usually indicates that global  $\dot{D}_{O_2}$  is appropriate. Lower may indicate increased uptake but more often reduced or inadequate delivery. Mixed venous blood is useful for measurement of global  $\dot{D}_{O_2}$ , but it usually requires the presence of a pulmonary artery catheter. The use of central venous saturations has become an alternative surrogate which is usually adequate and considerably more practical.

The body cannot store large amounts of oxygen and is thus dependent on a continuous supply. The excess ability to increase  $\dot{D}_{O_2}$  to match changes in  $\dot{V}_{O_2}$  is an adaptation that permits sudden changes in demand such as exercise in which  $\dot{V}_{O_2}$  can exceed 1500 ml/min in some cases.

#### STEP 5: DIFFUSION – BLOOD TO MITOCHONDRION

Ninety per cent of cellular aerobic metabolism takes place in the mitochondria. The rate of diffusion of oxygen from bound oxyhaemoglobin to the mitochondria follows similar principles to the diffusion of oxygen into the blood from the alveoli. Namely:

1. Fick's law of diffusion, where the  $\Delta P$  is dependent on  $\dot{D}_{O_2}$  and the rate of cellular uptake and utilisation
2. the position of the oxygen haemoglobin dissociation curve

Once delivered to the cell, oxygen is utilised in the generation of ATP. This is achieved by the production of pyruvate from glucose via glycolysis. This produces only 2 ATP molecules per molecule of glucose. The pyruvate is converted to acetyl coenzyme A and in the mitochondrion enters the citric acid cycle (Krebs cycle), resulting in the production of reducing power to form NADH and FADH<sub>2</sub>. These molecules are transferred to the electron transport chain and oxidation to water releases the cellular energy currency ATP.<sup>3</sup>

Originally at approximately 160 mmHg, the partial pressure of oxygen at the mouth falls to a  $P_{O_2}$  in some mitochondria which can be as low as 1 mmHg. Below this value, cellular demands for oxygen outweigh its delivery, and ATP production may be reduced.

#### STEP 6: THE REDOX STATE OF THE CELL

Conventionally oxygen delivery from atmosphere to cell is considered a cascade, implying that a high concentration at one end will cascade down and increase oxygen in the cell. It will increase oxygen available to the cell potentially but the driving force for oxygen to enter the cell and the mitochondrion is the gradient between the partial pressure of oxygen in the cell and outside. Increased oxygen utilisation will reduce that tension and increase the gradient. Conversely, adequate oxygen in the cell will reduce the gradient between the cell and outside and oxygen will not diffuse. The cell determines how much oxygen it uses by creating the gradient that sucks oxygen in – it is not a cascade. Similarly, it is the ATP/adenosine diphosphate (ADP) ratio and probably hydrogen ion concentration that drive ATP production and modify oxygen requirement, i.e. the cell is largely autonomous and uses what it needs.<sup>4</sup> While ensuring adequate oxygen delivery is important, excess oxygen is at least theoretically of no benefit.

#### PATHOLOGY OF OXYGEN DELIVERY ( $\dot{D}_{O_2}$ )

Failure of oxygen delivery to the cells leads rapidly to cellular dysfunction, and can lead to cellular death and organ dysfunction, culminating in organism death. Failure of  $\dot{D}_{O_2}$  to match  $\dot{V}_{O_2}$  ( $\dot{V}_{O_2}$  drives the  $\dot{D}_{O_2}$  requirement) results in reduction in aerobic metabolism and energy production and necessitates production of ATP by the less efficient glycolytic pathway.

The level of  $\dot{D}_{O_2}$  at which  $\dot{V}_{O_2}$  begins to decline has been termed the 'critical  $\dot{D}_{O_2}$ ' and is approximately 300 ml/min in an adult (Figure 24.2).<sup>5</sup> 'Shock' is the usual term used in this situation, defined loosely as failure of delivery of oxygen to match the demand of tissue. Commonly this refers to failure of the circulation, but low  $\dot{D}_{O_2}$  can result from several pathological mechanisms which can occur as a single problem or in combination. Cellular hypoxia can result from each of the stages of oxygen delivery:

1. reduction in environmental oxygen, e.g. altitude: hypoxic hypoxia
2. failure to ventilate, whether from airway obstruction, loss of respiratory drive from the central nervous system, drugs or muscular failure – neuromuscular disease such as acute inflammatory demyelinating polyneuropathy (Guillain–Barré syndrome): hypoxic hypoxia
3. impaired gas exchange across the alveolar–capillary membrane, e.g. pneumonia, pulmonary embolus, acute asthma, pulmonary oedema: hypoxic hypoxia

**Figure 24.2** The normal relationship between  $\dot{V}_{O_2}$  and  $\dot{D}_{O_2}$ . Above the value of 'critical'  $\dot{D}_{O_2}$ ,  $\dot{V}_{O_2}$  is independent of oxygen delivery. Below this value,  $\dot{V}_{O_2}$  becomes supply-dependent and may be amenable to therapeutic interventions.

4. abnormal or reduced binding to haemoglobin so there is inadequate oxygen carriage, e.g. severe anaemia, carbon monoxide poisoning or methaemoglobinaemia: anaemic hypoxia
5. reduced CO, e.g. left ventricular failure. Failure of oxygen delivery: stagnant or ischaemic hypoxia
6. impaired diffusion at the blood–tissue interface, e.g. tissue oedema due to sepsis: hypoxic hypoxia
7. cytochrome or mitochondrial poisoning. Cyanide, arsenic and some antiretroviral drugs: histotoxic hypoxia

The above is summarised in Table 24.3 as the types of hypoxia.

The impact of a low  $\dot{D}_{O_2}$  can be made worse by an increase in oxygen demand. Metabolic rate increases with exercise, inflammation, sepsis, pyrexia, thyrotoxicosis, shivering, seizures, agitation, anxiety and pain.<sup>6</sup> Therapeutic interventions such as adrenergic drugs, e.g. adrenaline (epinephrine)<sup>7</sup> and certain feeding strategies can also lead to an increased  $\dot{V}_{O_2}$ .

In critical illness, where oxygen delivery is considered to be in jeopardy, there has been considerable interest in the relationship between  $\dot{D}_{O_2}$  and  $\dot{V}_{O_2}$  (see Figure 24.2). The presence of signs or markers of tissue hypoxia such as acidosis implies inadequate tissue oxygenation. This could either be from inadequate delivery failing to meet consumption requirements or due to a reduced ability of the tissues to extract oxygen. The former could be corrected by increasing delivery; the latter is more difficult. Historically this has led to the strategy for delivering 'supranormal'  $\dot{D}_{O_2}$  to ensure adequate supply.<sup>8,9</sup> There were some intrinsic problems in this approach. It is irrefutable that, if delivery is inadequate, it should be corrected to meet consumption, but much of the early work was based on the relationship between delivery and consumption trying to reach a point where delivery outstripped consumption. As both values are derived from the same root equation and same data, mathematical linkage was inevitable, so as one increased, so would the other.<sup>10,11</sup> Also the inotropes used to increase delivery also increased consumption.

Clinical studies clearly show that adequate resuscitation to meet oxygen requirements is sensible. In the critically ill going beyond this is not helpful,<sup>12,13</sup> although there may be a place for supraoptimal values in the high-risk surgical patient.<sup>8,9</sup> In the acute situation the combined use of markers of tissue hypoxia, such as acidosis and lactate, in conjunction with surrogates of oxygen delivery, such as  $ScvO_2$ , and standard haemodynamic measurements of an adequate circulation have proved beneficial.<sup>14,15</sup> So-called early goal-directed therapy is now included in published guidelines for the treatment of severe sepsis (Table 24.4).<sup>16</sup> The benefits of this new approach may well have as much to do with the prompt and aggressive improvements in haemodynamics and resuscitation as the values obtained. Timing is probably the significant difference when compared with other applications of the 'supranormal' technique. Targeted

**Table 24.3** Types of hypoxia

Type of hypoxia	Pathophysiology	Examples
Hypoxic hypoxia	Reduced supply of oxygen to the body leading to a low arterial oxygen tension	1. Low environmental oxygen (e.g. altitude) 2. Ventilatory failure (respiratory arrest, drug overdose, neuromuscular disease) 3. Pulmonary shunt: (a) Anatomical – ventricular septal defect with right-to-left flow (b) Physiological – pneumonia, pneumothorax, pulmonary oedema, asthma
Anaemic hypoxia	The arterial oxygen tension is normal, but the circulating haemoglobin is reduced or functionally impaired	Massive haemorrhage, severe anaemia, carbon monoxide poisoning, methaemoglobinaemia
Stagnant hypoxia	Failure of transport of sufficient oxygen due to inadequate circulation	Left ventricular failure, pulmonary embolism, hypovolaemia, hypothermia
Histotoxic hypoxia	Impairment of cellular metabolism of oxygen despite adequate delivery	Cyanide poisoning, arsenic poisoning, alcohol intoxication

**Table 24.4** Early goal-directed therapy. A summary of  $\dot{D}O_2$  parameters set to achieve in first 6 hours of the diagnosis of severe sepsis with associated hypotension and a plasma lactate concentration of  $\geq 4$  mmol/l

Variable	Parameters
Arterial oxygen saturation ( $SAO_2$ )	$\geq 93\%$
Central venous pressure (CVP)	8–12 mmHg
Mean arterial pressure (MAP)	65–90 mmHg
Urine output (UO)	$\geq 0.5$ ml/kg per hour
Mixed venous oxygen saturations ( $SV_{O_2}$ ) or central venous oxygen saturations ( $Scv_{O_2}$ )	$\geq 70\%$
Haematocrit	$\geq 30\%$

(After Rivers E *et al.* Early goal-directed therapy in the treatment of severe sepsis and septic shock. *N Engl J Med* 2001; **345**: 1368–77.)

**Table 24.5** Summary of targeted oxygen delivery

Goal-directed therapy
Supraoptimal values in the critically ill – not recommended
Perioperative optimisation with supranormal values – possibly useful but controversial
Resuscitation against markers of peripheral oxygen use such as $Scv_{O_2}$ and lactate (early goal-directed therapy) – currently advocated

oxygen delivery is a major debate that is still evolving (Table 24.5). Oxygen delivery can be improved in a variety of ways, from the ambient inspired oxygen through the lungs and cardiovascular system to the cell itself, but once at the cell the ability to manipulate delivery ceases.

### CELLULAR HYPOXIA

In environments where the  $\dot{D}O_2$  is reduced, the human cell can tolerate hypoxia to a certain extent by adapting ‘hibernation’ strategies to reduce metabolic rate, increased oxygen extraction from surrounding tissues and enzyme adaptations that allow continuing metabolism at low  $PO_2$ .<sup>17</sup> Anaerobic metabolism is actively utilised by some tissues. At times of low oxygen concentrations, both myocardial and vascular endothelium upregulate glycolytic enzymes and glucose transport proteins.<sup>18</sup> This is not sustainable.

Local failure of cellular energy production has feedback effects on the local circulation to improve oxygen delivery. This effect is replicated regionally and then systemically with effects on the lungs, heart and circulation to try to meet the oxygen needs. If this fails, the consequences of hypoxia are seen at cellular then regional and finally systemic levels.

### REGIONAL HYPOXIA

Much of what has been discussed describes effects of oxygen delivery and uptake for the body as a whole. The reality is far more complex, as not only can each organ system have its  $\dot{D}O_2$  manipulated to meet demand, but also within each organ regional demands may vary and can be varied. Few of the clinical methods commonly used for assessing  $\dot{D}O_2$  can identify changes in either organ or regional  $\dot{D}O_2$ . Thus it is possible in critical illness for tissue hypoxia to exist with associated organ dysfunction, despite normal global  $\dot{D}O_2$  and  $S\bar{v}O_2$  values.<sup>19</sup>

The effects of disordered or diverted regional blood flow can be important. For example, in shock splanchnic blood flow is often reduced with the potential for ischaemia. Clearly detection of gut ischaemia could be used to influence management of oxygen delivery and hopefully reduce the likelihood of multiorgan failure.<sup>20</sup> The control of regional blood flow is itself complex. Methods of increasing global  $\dot{D}O_2$  in the hope that it will optimise all tissues often necessitate the use of vasoactive drugs (vasopressors, inotropes and vasodilators). Paradoxically, although such therapy can influence regional flow, it may not necessarily be in the direction sought in individual regions.

### DIAGNOSIS AND MONITORING OF $\dot{D}O_2$

The last two decades have shown that the value of correcting markers of tissue hypoperfusion and hypoxia is far greater than that of targeting subjective predictive values for populations. It is important to recognise and treat these problems early so that organ  $\dot{D}O_2$  can be preserved.<sup>14</sup> Clinical assessment of  $\dot{D}O_2$  and  $\dot{V}O_2$ , e.g. heart rate, blood pressure or urine output, can be misleading. Particularly in the young patient, the ability of the OER to increase to as high as 70–80% can mean that such variables can change only late in the evolution of diminished  $\dot{D}O_2$ . However, the assessment of an effective CO (ECO) – normal heart rate, blood pressure and peripheral perfusion with signs of organ function and normal oxygen saturation – must not be excluded in favour of more technical quantitative methods. Rather the technical values must be considered in the clinical context. All assessments of  $\dot{D}O_2$ , clinical or technical, require continuous re-evaluation to ensure that the treatments being planned or administered are appropriate for the patient’s current condition.

### $SAO_2$ and $PAO_2$

Both these measures are included in the  $CaO_2$  equation (see above), and their importance is clear. However it can be difficult to define what is a ‘safe’  $SAO_2$  and/or  $PAO_2$ . Measured systemically, they do not alone reflect tissue oxygenation and oxygen extraction mechanisms vary between organs. In general, however, supplementary

oxygen is required when  $P_{aO_2}$  falls below 60 mmHg or the  $S_{aO_2}$  is below 90%. The clinical significance of common  $P_{aO_2}$  and  $S_{aO_2}$  values is listed in Table 24.1.

### ACID–BASE BALANCE

Many intensive care units use acid–base balance as a simple bedside indicator of global  $\dot{D}O_2$ . The presence of acidosis and a base deficit of less than  $-2$  may be used to detect evidence of inadequate  $\dot{D}O_2$ . They can only reflect global perfusion. The use of the plasma lactate concentration is an unreliable indicator of tissue hypoxia. It represents the balance between production and consumption so if used in isolation or as a single value to assess  $\dot{D}O_2$  it can easily mislead.<sup>21</sup> The use of lactate as a marker of  $\dot{D}O_2$  is best used as a trend using serial measurements.

### $S\bar{v}O_2/S_{cv}O_2$

In critical illness a falling  $\dot{D}O_2$  can be compensated for by an increase in oxygen extraction. This leads to a lower oxygen saturation of haemoglobin returning to the right side of the heart. Analysis of this saturation either in vivo (fibreoptic oximetry) or in vitro (oximetry) allows assessment of the OER. Classically, a low  $S\bar{v}O_2$  ( $<70\%$ ), in the face of a normal  $S_{aO_2}$ , implies tissue hypoperfusion secondary to a low CO, either hypovolaemia or pump failure. It could however indicate very high  $\dot{V}O_2$ , which may occur with hyperthermia. Conversely a raised  $S\bar{v}O_2$  ( $>75\%$ ) will imply low demand, e.g. hypothermia, or a cellular utilisation problem, easily explained in cyanide poisoning when the oxidative phosphorylation mechanism is inhibited, but much more difficult to rationalise when it is seen (commonly) in sepsis. In a very-low-output state it could indicate total failure of peripheral perfusion and therefore no oxygen usage.  $S_{cv}O_2$  is a reasonable surrogate for  $S\bar{v}O_2$  and reduces the need for the more complex pulmonary artery catheter.<sup>15,22</sup> Whichever method of venous oxygen saturation is used, it must be in conjunction with other markers of adequacy of oxygen delivery and clinical context, as outlined in Table 24.4.

### MEASUREMENT OF REGIONAL $\dot{D}O_2$

As outlined above, most assessments of  $\dot{D}O_2$  are global and do not reflect regional differences between organs or even within differing tissues of the same organ. Current methods of non-invasively assessing individual organ or tissue oxygenation are limited. The measurements are difficult, require specialised techniques and are not widely available. Currently only gastric tonometry and near-infrared spectroscopy (NIRS) have clinical applications in the detection of organ hypoxia.<sup>20</sup> In the future NMR spectroscopy or positron emission tomography may allow direct non-invasive measurement of  $\dot{D}O_2$  and tissue oxygenation, but at present the environment for such testing is not easily accessed by the critically ill.

## OXYGEN THERAPY APPARATUS AND DEVICES

### PRINCIPLES

In the hypoxic self-ventilating patient, delivery of oxygen to the alveoli is usually achieved by increasing the environmental oxygen fraction ( $F_{iO_2}$ ). Most commonly this involves the application of one of the many varieties of oxygen mask to the face, such that it covers the nose and mouth. There are also other methods, e.g. nasal cannulae, but each method needs to fulfil the same basic requirements.

Most of the simpler oxygen delivery devices, e.g. plastic masks, nasal cannulae, deliver oxygen at relatively low oxygen flow rates relative to peak inspiratory flows (25–100 l/min). The final  $F_{iO_2}$  delivered is heavily influenced by the entrainment of environmental air which dilutes the set  $F_{iO_2}$ . From a physics perspective the actual concentration of oxygen delivered is determined by the interaction between the delivery system and the patient's breathing pattern. The actual  $F_{iO_2}$  that reaches the alveolus is therefore unpredictable. Factors that influence this can broadly be divided into patient factors and device factors, which are summarised in Table 24.6.<sup>23</sup>

In the hypoxic patient it is common to find significant increases of inspiratory flow rates as well as an absence of the respiratory pause. This can result in the actual  $F_{iO_2}$  at the alveolus being significantly less than that believed to be being delivered. This is due to a greater proportion of the inhaled gas being entrained air when the patient's inspiratory flow rate increases. The normal peak inspiratory flow rate (PIFR) is between 25 and 35 l/min. In critical illness it can rise to eight times normal (Figure 24.3).<sup>24</sup> The greater the inspiratory flow rate, the lower the alveolar  $F_{iO_2}$ . This is particularly true for the variable performance-type masks, but is also seen even in the more 'reliable' Venturi-type masks, particularly when the higher  $F_{iO_2}$  Venturi inserts are used. The presence of a valve-controlled reservoir bag on a 'non-rebreather' semirigid plastic mask should compensate for high inspiratory flows, hence the belief that such masks can deliver 100% oxygen. This is not the case, and in models of human ventilation, such masks do not seem to confer significant extra oxygen

**Table 24.6** Factors that influence the  $F_{iO_2}$  delivered to a patient by oxygen delivery devices

Patient factors	Device factors
Inspiratory flow rate	Oxygen flow rate
Presence of a respiratory pause	Volume of mask
Tidal volume	Air vent size
	Tightness of fit

(After Leigh J. Variation in performance of oxygen therapy devices. *Anaesthesia* 1970; 25: 210–22.)

**Figure 24.3** Spirometric peak inspiratory flow rates (PIFR) taken from a group of 12 critical care patients with respiratory distress and hypoxia. Most of the patients have a PIFR below 150 l/min. However 2 patients exceed 200 l/min. This will have a negative effect on the concentration of oxygen delivered from a variable-performance system, e.g. Hudson.<sup>24</sup>

delivery ability above that of the semirigid plastic masks without the reservoir bag (Figures 24.4 and 24.5).<sup>25</sup>

The failure of oxygen masks to deliver the desired  $FiO_2$  can be improved by either having a high enough oxygen flow rate and reservoir to compensate for the high inspiratory flow rate, e.g. high-flow nasal cannulae such as the Vapotherm, or sealing the upper airway (nose and mouth)

**Figure 24.4** The performance of a Hudson mask on a model of human ventilation at a tidal volume of 500 ml and four oxygen flow rates (15 l/min (○), 10 l/min (△), 6 l/min (◇) and 2 l/min (□)). As the respiratory rate increases, so the effective inspired oxygen concentration (EIOC) deteriorates.<sup>25</sup>

**Figure 24.5** The performance of a Hudson non-rebreather mask on a model of human ventilation at a tidal volume of 500 mL and four oxygen flow rates (15 l/min (○), 10 l/min (△), 6 l/min (◇) and 2 l/min (□)). As the respiratory rate increases, so the effective inspired oxygen concentration (EIOC) deteriorates. Note also how the curves of the graph are similar to the Hudson mask without the reservoir bag, implying no superiority with its addition.<sup>25</sup>

from the environment, e.g. the continuous positive-airways pressure (CPAP) mask. Indeed, there are data to support the hypothesis that some of the improvement in oxygenation seen with CPAP ventilation may be due to the eradication of entrainment of environmental air, rather than the positive airway pressure exerted by the CPAP valve.<sup>24</sup>

In summary, the use of non-sealing oxygen masks and cannulae should be guided by the patient's requirements and response to therapy, rather than a belief that the concentration being delivered is what is reaching the alveolus. This can be particularly important in the treatment of patients whose ventilatory drive is sensitive to  $PO_2$  levels.

## OXYGEN DELIVERY DEVICES

Methods of delivering oxygen to conscious patients with no instrumentation to their airway can broadly be divided into four categories:

1. variable-performance systems
2. fixed-performance systems
3. high-flow systems
4. others

With the exception of the intravascular devices, they all consist of similar component parts, as follows.

#### **OXYGEN SUPPLY**

Delivery of oxygen can be from pressurised cylinders, hospital supply from cylinder banks, a vacuum-insulated evaporator (VIE) or an oxygen concentrator.

#### **OXYGEN FLOW CONTROL**

Oxygen delivery from the supply to the device is controlled by some sort of valve, often with an associated flow meter.

#### **CONNECTING TUBING**

The connecting tubing is both from the supply to the flow control and from the flow control to the device. The type and size of the tubing are important. Small-bore tubing can limit oxygen flow when high flow is intended. In some systems the connecting tubing can also act as a reservoir, e.g. Ayre's T-piece. Some devices require specialised tubing with appropriate end attachments, such as the Schröder valves required for connecting to the wall oxygen supply.

#### **RESERVOIR**

All oxygen delivery devices have some sort of reservoir. In the case of the simple oxygen mask it is the mask itself. Some low-flow CPAP circuits have a balloon reservoir. The nasal cannulae utilise the nasopharynx as a reservoir. An oxygen tent uses the volume of the tent as a large reservoir. The effectiveness of the reservoir in storing oxygen ready for the next inspiratory effort is one of the important factors in governing its ability to deliver the desired oxygen concentration. The oxygen tent is a good example of the effectiveness of a large reservoir, as it eliminates air entrainment whatever the patient's PIFR. Thus the oxygen flow rate does not have to be high, just enough to ensure that CO<sub>2</sub> rebreathing is abolished. Indeed it is the retention of CO<sub>2</sub> that can be the major problem if gas is expired into the reservoir.

#### **PATIENT ATTACHMENT**

The patient is connected to the oxygen supply and reservoir such that the device delivers oxygen to the airway, by directly covering the upper airway, e.g. plastic mask/head box, or intranasally, or by increasing the oxygen concentration in the wider environment as in an oxygen tent.

#### **EXPIRED-GAS FACILITY**

Expired gas from the patient needs to be allowed to dissipate into the environment, and not be retained in the system and be inspired at the next inspiratory effort. Most masks achieve this by having a small reservoir capacity and holes in the plastic to allow the gas to exit. One-way valves, as in the non-rebreather-type reservoir mask, aid in unidirectional flow of gas away from the patient.

High-flow T-piece systems like those used in a CPAP system utilise the high flow to remove the gas down an expiratory limb and into the environment.

#### **HUMIDIFICATION**

Most systems use the physiological humidification properties of the nasopharynx and trachea. However, high-flow systems may overcome this, leading to drying of the airway and secretions which can be uncomfortable and undesirable. Artificial humidification (and warming) should be employed using devices such as water bath or heat and moisture exchanger (HME).

#### **OXYGEN MONITOR**

Some systems have an oxygen monitor incorporated in the apparatus, e.g. a fuel cell. This allows the much more accurate monitoring of  $F_{iO_2}$ , but is dependent on where in the system it is placed, and also adds bulk and expense to the oxygen delivery method.

#### **VARIABLE-PERFORMANCE SYSTEMS**

Typically these are a non-sealed mask or nasal cannulae system which deliver oxygen at low gas flows (2–15 l/min). The reservoir is usually small, consisting of the volume of the mask in the case of the semirigid type, or the nasopharynx, as in the nasal cannulae. The entrainment of environmental air is important in their delivery capability and has to be considered when being used.

#### **NASAL CANNULAE**

The proximity of the reservoir – the nasopharynx – means that these systems are particularly sensitive to changes in inspiratory flow rate and particularly the loss of the respiratory pause. However, for mild hypoxia, they are tolerated well by patients who can eat and drink with them in situ. They can cause drying of the nasal mucosa when used at flow rates, and newer systems are available which can humidify and warm the inspired oxygen. They are cheap and easy to use with no risk of CO<sub>2</sub> retention.

#### **SIMPLE SEMIRIGID PLASTIC MASKS (E.G. HUDSON, MC)**

The most commonly used type of oxygen mask, these systems are cheap and easy to administer. The reservoir consists of the mask and rebreathing of CO<sub>2</sub> can therefore occur if they are used at oxygen flow rates below 4 l/min. A maximum  $F_{iO_2}$  of 0.6–0.7 can only be achieved, and this will be lower in the presence of respiratory distress.

#### **TRACHEOSTOMY MASKS**

These semirigid plastic masks act in the same way as their facial counterparts. However the delivery they achieve is very dependent on the presence of an endotracheal tube and the inflation status of its cuff. If absent or if the tube is deflated, then air from the nasopharynx will mix with that being delivered to the tracheostomy, and further dilute the  $F_{iO_2}$ .

**T-PIECE SYSTEM**

These simple systems, consisting of an inspiratory limb and expiratory limb forming the bar of the 'T', can be used with endotracheal tubes (oral, nasal or tracheostomy), or with a sealed CPAP-type mask. The oxygen flow rate needs to be high enough to match the patient's PIFR so as to prevent rebreathing of expired gas and thus potential entrainment of air from the expiratory limb. The seal of the mask or tube cuff is also important to prevent entrainment of air.

**FIXED-PERFORMANCE SYSTEMS**

These systems are so called because their delivery of oxygen is independent of the patient factors outlined above.

**VENTURI-TYPE MASKS**

Oxygen concentration is determined by the Venturi principle. Oxygen passing through a small orifice entrains air to a predictable dilution. The  $F_{iO_2}$  is adjusted by changing the Venturi 'valve' and setting the appropriate oxygen flow rate. Whilst the Venturi effect can deliver 40–60 l/min, this is only possible at the lower  $F_{iO_2}$  valves (e.g. at  $F_{iO_2}$  of 0.24 the flow rate is approximately 53 l/min at an inflow of 2 l/min), and oxygen flow rate falls as the  $F_{iO_2}$  increases. Thus in respiratory distress associated with hypoxia, the reduction in oxygen flow rate can lead to failure despite a higher  $F_{iO_2}$  setting. The larger orifice leads to the system behaving more like a simple mask.

**ANAESTHETIC BREATHING CIRCUITS**

Non-rebreathing systems have one-way valves (e.g. Ambu-bag) and usually closed mask systems so they deliver what is set. Non-rebreathing systems, Mapleson A, B, C, D and E or, in Accident and Emergency, a Waters bag, depend on the gas flows to ensure no rebreathing. No air entrainment is possible but rebreathing occurs readily at low flows (most require flows > 150 ml/kg).

**HIGH-FLOW SYSTEMS**

As alluded to above, the T-piece system can act as a fixed-performance system if the oxygen flow rate is sufficiently high. Other high-flow systems exist, e.g. Vapotherm, which use flow rates up to 30 l/min nasally. They require humidification and heating of the inspired gas to allow patient tolerance.

**POSITIVE-PRESSURE DEVICES**

For the purpose of this chapter, non-invasive positive-pressure ventilation (NIPPV) devices are described. NIPPV delivers oxygen with some element of positive pressure exerted during the respiratory cycle. It does not require instrumentation of the airway, and is delivered either by a tight-fitting mask to the face, nose or as a helmet. The simplest CPAP system is a T-piece with a

positive-pressure valve attached to the expiratory limb, as with a Mapleson E system. Other methods are also available; some utilise a balloon reservoir rather than a high-flow oxygen generator (Mapleson A). CPAP helps improve functional residual capacity and compliance.<sup>26</sup> There is no air entrainment and is probably why gas exchange initially improves rapidly. Theoretically the positive pressure inhibits alveolar closure which it may do but also to aid recruitment. A potential problem with the T-piece CPAP systems is that the oxygen flow rate has to be adjusted to the patient's PIFR so as to prevent closure of the valve and increasing the inspiratory work of breathing. Other methods of NIPPV such as bilevel positive airway pressure (BPAP) deliver oxygen at flows that should match the patient's demand.

**OTHER METHODS OF OXYGEN DELIVERY**

Intravascular oxygenation has been used, but not extensively, particularly in the self-ventilating patient population. Extracorporeal membrane oxygenation (ECMO) supporting both heart and lung may be superseded by relatively simple external oxygenators such as the Novolung interventional lung assist (ILA). In these, blood flow may be either 'pumped' or rely on the patient's circulation similar to the haemodiafiltration systems. Currently focused on CO<sub>2</sub> removal there is increasing interest in their oxygenation capabilities.

**HAZARDS OF OXYGEN THERAPY****SUPPLY**

Medical oxygen supply is a compressed gas. Pipeline supply to the 'wall' is usually at 4 bar of pressure (3040 mmHg). The cylinder supply when full is 137 bar (104 120 mmHg). As such, there are important risks when using oxygen, as explosion is a risk. Direct administration of oxygen at delivery pressures carries a real risk of barotrauma to the airway and alveoli, if not governed by an appropriate pressure-limiting valve, e.g. OHE flow meter.

Oxygen also supports combustion. The possibility of sparks in an oxygen-rich environment must be avoided. Patients must not smoke cigarettes when receiving oxygen therapy, even via nasal cannula. Another example is to ensure that oxygen supplies are removed or turned off when defibrillating, as a spark can occur in such situations.

**OXYGEN TOXICITY****CENTRAL NERVOUS SYSTEM TOXICITY (PAUL BERT EFFECT)**

Seen in diving, oxygen delivered at high pressure (> 3 atmospheres) can lead to acute central nervous system signs and seizures.

**LUNG TOXICITY (LORRIANE SMITH EFFECT)**

Exposure to a high  $F_{iO_2}$  results in pulmonary injury. It is known that a progressive reduction in compliance occurs, and is associated with interstitial oedema, leading to fibrosis. The mechanism remains unclear, but is believed to involve direct cellular damage to the lung tissue by highly reactive oxygen free radicals. High concentrations of oxygen produce a higher concentration of free radicals that overwhelm the normal scavenging mechanism lining the respiratory tract. This, possibly associated with loss of surfactant, and increase in sympathetic activity and airway collapse due to the lack of other non respiratory gases, leads to lung damage. Evidence for this mechanism is supported by the worsening of lung damage seen in paraquat poisoning. Paraquat produces large amounts of free oxygen radicals, and the administration of supplemental oxygen worsens its effects. Detecting this problem as the sole aetiology for pulmonary pathology can be difficult, especially as the usual indications for oxygen therapy usually imply some form of pulmonary pathology.

It is reasonable that the risk of oxygen-induced pulmonary toxicity is dependent on concentration and duration of exposure. However, what concentration/duration is likely to cause toxicity is not clear. In some subjects long exposure times and high concentrations do not lead to problems; however, in general, patients should remain below an  $F_{iO_2}$  of 0.5 where possible, and periods above this should be kept to the minimum required. 'Safe' periods of exposure above 0.5 vary from 16 to 30 hours. The clinical signs of oxygen toxicity are listed in Table 24.7. All are relatively non-descript and easily explained by other causes in a critically unwell patient.

**BRONCHOPULMONARY DYSPLASIA**

First described in 1967, this is a form of chronic lung disease that is associated with neonatal ventilation. Its pathophysiology includes the same factors as the adult form, but with the additional effect of immaturity. The advent of surfactant in the treatment of respiratory distress of the newborn and the addition of maternal steroid therapy

to promote pulmonary development have lowered the incidence and reduced the severity of the disease.

**RETINOPATHY OF PREMATURITY (ROP)**

Previously referred to as retrolental fibroplasia, ROP was first described in 1942. It is a vasoproliferative disorder of the eye affecting premature neonates. Similar to the lungs, the completion of development of the retinal vasculature is late in gestation (32–34 weeks).<sup>27</sup> In the 1950s an epidemic of ROP was described and a causal link to uncontrolled oxygen therapy was made.<sup>28</sup> Improved monitoring of oxygen therapy reduced the incidence of ROP, but was associated with an increase in perinatal mortality secondary to respiratory failure.<sup>29</sup> Subsequently, and despite good oxygen control, ROP continues to occur. This is now most likely due to the increased survival of increasingly premature low-birth-weight infants<sup>30</sup> rather than high  $P_{aO_2}$  alone. This suggests both oxygen and non-oxygen-related factors. ROP is a biphasic disease where the relatively hyperoxic environment following delivery initially leads to a slowing or even cessation of retinal vascular development of the premature infant. Additional oxygen may further contribute to this problem, by affecting the expression of vascular growth factors. The second phase of the disease is a hypoxic-induced neovascularisation, similar to that seen in diabetic retinopathy. This leads to fibrous scarring with risk of retinal detachment. How much oxygen is too much remains contentious and further research is required.<sup>31</sup>

**HYPERBARIC OXYGEN THERAPY**

Oxygen can be delivered to patients at higher than atmospheric pressure (2–3 atmospheres). This serves to increase the amount of oxygen carried in the plasma, rather than bound to haemoglobin. This follows Henry's law that states: 'At a constant temperature, the amount of a given gas dissolved in a given type and volume of liquid is proportional to the partial pressure of that gas in equilibrium with that liquid.' As the partial pressure of oxygen in the environment rises, so the amount of oxygen dissolved in the plasma also rises. Consequently, the contribution of the  $P_{aO_2}$  in the  $CaO_2$  formula (see above) increases. At rest the metabolic demands of an average person can be met by dissolved oxygen alone when breathing 100% at 3 atmospheres.

Hyperbaric oxygen therapy can be delivered either in a monoplace chamber designed for one individual, or in multiplace chambers for 2–10 people. The chambers encompass the whole body, and gas is piped from source, heated and humidified. The common indications for use are listed in Table 24.8.<sup>32,33</sup>

**CARBON MONOXIDE POISONING**

Carbon monoxide poisoning in particular attracts attention. A common consequence of house fires, it binds to

**Table 24.7** Symptoms and signs of oxygen toxicity

Central nervous system	Pulmonary
Nausea and vomiting	Dry cough
Anxiety	Substernal chest pain
Visual changes	Shortness of breath
Hallucinations	Pulmonary oedema
Tinnitus	Pulmonary fibrosis
Vertigo	
Hiccup	
Seizures	

**Table 24.8** Recognised indications for hyperbaric oxygen therapy

Primary therapy	Adjunctive therapy
Carbon monoxide poisoning	Radiation tissue damage
Air or gas embolism	Crush injuries
Decompression sickness (the 'bends')	Acute blood loss
Osteoradionecrosis	Compromised skin flaps or grafts
Clostridial myositis and myonecrosis	Refractory osteomyelitis
	Intracranial abscess
	Enhancement of healing of problem wounds

(After Tibbles PM, Edelsberg JS. Hyperbaric-oxygen therapy. *N Engl J Med* 1996; **334**: 1642–8; and Bennett M. Randomised controlled trials. In: Fledmeier J (ed.) *Hyperbaric Oxygen 2003 – Indications and Results. The UHMS Hyperbaric Oxygen Therapy Committee Report*. Undersea and Hyperbaric Medicine Society: 2003; 1212–37.)

haemoglobin with an affinity 210 times that of oxygen. Its half-life in air is 320 minutes, but this can be reduced to 90 minutes by giving the patient 100% oxygen, or 23 minutes with the addition of 3 atmospheres of hyperbaric therapy. Competitive dissociation of carbon monoxide from the haem-binding site and provision of dissolved oxygen to the tissues is believed to combine to reduce the sequelae of carbon monoxide poisoning, but the mechanisms are likely to be more complex.<sup>34</sup> Some studies have suggested both acute and longer-term benefit,<sup>35,36</sup> but others have been unable to conclude significant benefit.<sup>37,38</sup> Recent investigations have attempted to distinguish those patients more likely to benefit from hyperbaric oxygen therapy. Factors such as increasing age (> 35 years), an exposure time of > 24 hours, an associated loss of consciousness and carboxyhaemoglobin levels greater than 25% appear to result in an increased incidence of neurological sequelae, and probably benefit from hyperbaric oxygen.<sup>39</sup> Geographical distance to an appropriate centre often has a significant influence on hyperbaric usage in the acute setting, but mobile units and some evidence that late therapy may be of benefit should not necessarily preclude its usage.<sup>34,40</sup>

## COMPLICATIONS

Hyperbaric therapy is associated with the following complications:

1. barotrauma: middle ear and sinuses, rupture of the oval or round window, gastrointestinal distension, tooth displacement and pain, gas embolism on decompression

2. oxygen toxicity (as above). Especially a problem in the critically ill who may be on high concentrations for longer periods<sup>32</sup>
3. generalised seizures (Paul Bert effect)
4. visual problems: acute myopia, cataract formation

# Airway management and acute upper-airway obstruction

Gavin M Joynt

The primary objective of airway management is to secure unobstructed gas exchange and protect the lungs from soiling. Because of the critical importance of maintaining gas exchange, upper-airway obstruction is a life-threatening emergency. Upper-airway obstruction results from a wide range of pathophysiological processes, and therefore rapid assessment and establishment of a patent airway must take priority, even in the absence of a specific diagnosis. As no single airway management modality is universally applicable, the intensive care unit (ICU) physician must be capable of performing a variety of airway management techniques and instituting them in a logical and systematic way (Figure 25.1).

## AIRWAY MANAGEMENT TECHNIQUES

Airway management techniques are generally classified as non-invasive or invasive, depending on whether instrumentation occurs above or below the glottis, surgical or non-surgical, and definitive (Table 25.1). Definitive techniques secure the trachea and provide some protection from macroscopic aspiration and soiling. While bag-and-mask ventilation and direct laryngoscopic tracheal intubation remain the routine methods of airway management in ICU, the use of fiberoptic bronchoscopy is increasingly common, especially in special circumstances. Management of failed intubation and ventilation by various alternative techniques, particularly the use of the intubating laryngeal mask airway (iLMA) and cricothyroidotomy, is well described.<sup>1,2</sup>

The technique of choice will depend on each individual situation and is determined by the interaction of patient and clinical factors, which partially determine the appropriate technique (Table 25.2), and the clinician's experience in applying the chosen technique. Other factors include availability of help, levels of training and supervision and accessibility of equipment. A portable storage unit with a wide choice of equipment appropriate for difficult airway management should be available in every ICU (Table 25.3).

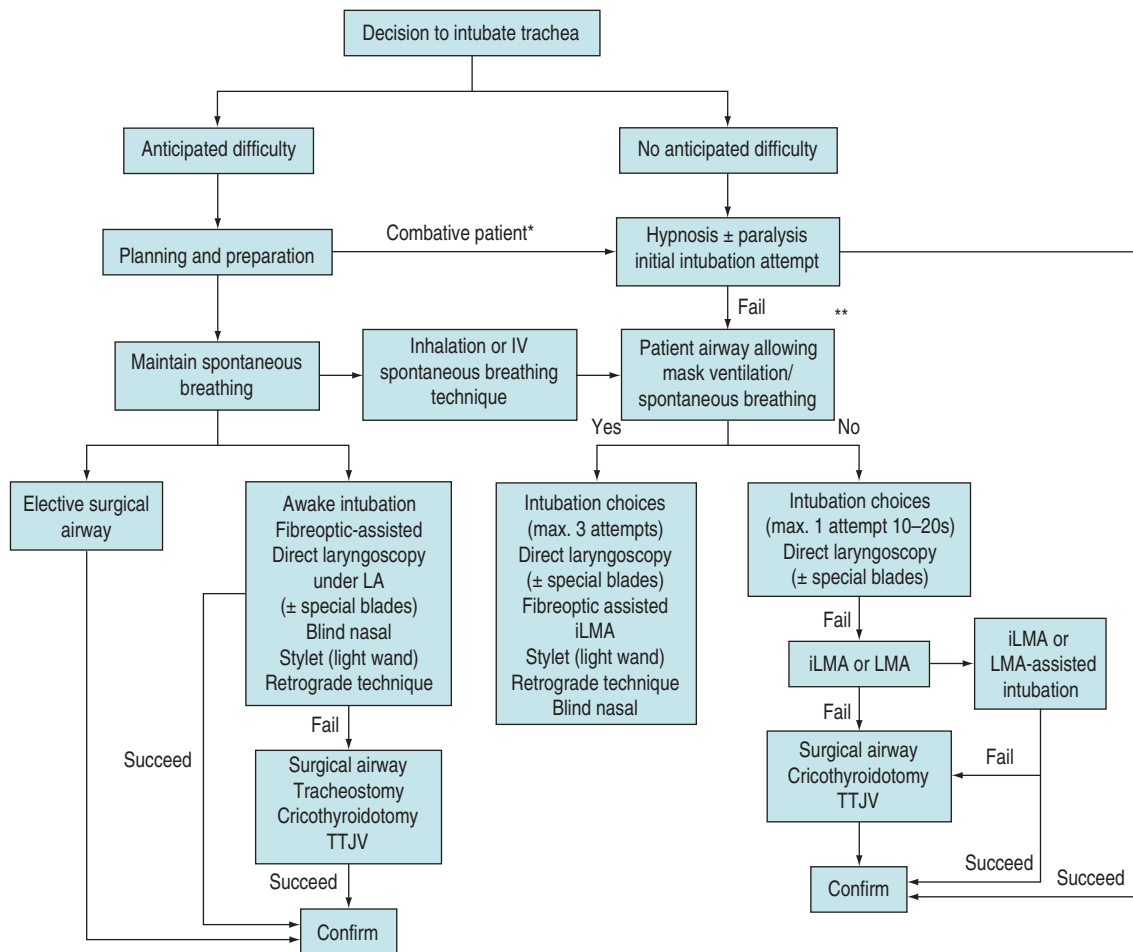

## NON-INVASIVE TECHNIQUES

### BAG-MASK VENTILATION

Mask ventilation, using a bag-mask resuscitator, is a basic skill that requires time and experience to master. It should be learned using mannekins, simulators and practice in the controlled environment of the operating theatre so that when used in the emergency setting in ICU the skill is already well established. The manually squeezed bag is self-inflating, usually with a simple reservoir bag in series, which, if kept inflated, ensures that a consistent high oxygen concentration can be delivered. The addition of a positive end-expiratory pressure (PEEP) valve may improve arterial oxygenation in patients with lung pathology and help overcome airway obstruction due to laryngospasm. Transparent face masks are recommended as they allow observation of misting during exhalation, assessment of the position of adjunct artificial airways and early observation of gross airway soiling.

Some considerations when performing mask ventilation include the following:

1. *Inadequate ventilation.* Good airway positioning by head tilt and chin lift, or if necessary the jaw thrust manoeuvre, is essential to maintain an open airway. The seal of the mask against the face is important and technically good hand positioning must be learned and practised. A beard may be covered with a large adhesive plastic dressing with a hole cut out for the mouth, or smeared with petroleum jelly or water-based lubricant. Ventilation of edentulous patients may be aided by improving hand position or special masks. Two operators are recommended if a mask face leak is excessive, one to hold the mask and the other to manipulate the bag-mask resuscitator.
2. *Gastric insufflation* is common if high tidal volumes are used and increases the risk of vomiting and aspiration (aim for 300–500 ml). Severe distension may occasionally cause cardiovascular compromise. Carefully applied cricoid may prevent gastric insufflation.
3. *Pulmonary aspiration.* In the emergency situation with a full stomach, mask ventilation with cricoid pressure is recommended until the airway can be secured. Passage

of a nasogastric tube to aspirate gastric contents can be attempted, but with caution as vomiting may be induced.

### ORO- AND NASOPHARYNGEAL AIRWAYS

In the unconscious patient, functional obstruction is primarily caused by loss of muscular tone and subsequent inspiratory airway narrowing at the soft palate, epiglottis and tongue base. An oropharyngeal airway can help establish an adequate airway for spontaneous or bag-mask ventilation when proper head positioning is insufficient. It is inserted with the concavity facing the palate and then

rotated 180° into the proper position as it is advanced. Complications include mucosal trauma, worsening the obstruction by pressing the epiglottis against the laryngeal outlet if the tongue displaces posteriorly, and occasionally laryngospasm. The following sizes (length from flange to tip) are recommended: large adult: 100 mm (Guedel size 5); medium-sized adult: 90 mm (Guedel size 4); small adult; 80 mm (Guedel size 3).

A nasopharyngeal airway is a soft rubber or plastic tube inserted into the nostril and advanced along the floor of the nose (in the direction of the occiput). Correctly

LMA, laryngeal mask airway; ILMA, intubating laryngeal mask airway. It is difficult to gain experience with rarely used techniques such as cricothyroidotomy, jet ventilation and retrograde intubation, but reasonable competence can be achieved using mannequins and simulators.

positioned, the tube traverses the posterior pharynx. It is better tolerated by semiconscious patients than the oropharyngeal airway. Complications include epistaxis, aspiration and, rarely, laryngospasm or oesophageal placement.

#### **LARYNGEAL MASK AIRWAY (LMA) AND INTUBATING LMA**

The LMA is a reusable device that consists of a silicone rubber tube connected to a distal elliptical spoon-shaped mask with an inflatable rim, which is positioned blindly into the pharynx to form a low-pressure seal against the laryngeal inlet.<sup>3</sup> LMAs are useful to achieve non-definitive airway patency in many emergency situations (see Figure 25.1), and can be used to provide positive-pressure ventilation.<sup>2</sup> Once positioned the LMA has been used to guide the passage of stylets, bougies, the bronchoscope and an endotracheal tube into the trachea, but with difficulty.<sup>2,4</sup> The iLMA or FasTrach is a modification of the LMA with several features to facilitate intubation once the iLMA is placed.<sup>5</sup> There is a guiding ramp and epiglottic elevating bar at the aperture to direct the endotracheal tube to the glottis. It also has an anatomically curved, rigid shaft and handle to allow easy and firm manipulation during placement and when the endotracheal tube is passed.<sup>6</sup> The iLMA is the laryngeal mask of choice if intubation is required, as is frequently the case in ICU patients.

Although preparation and patient positioning techniques for placement of a LMA and iLMA are similar, the insertion technique is quite different. The mask airway is prepared for insertion by deflating and

**Table 25.2** Commonly recommended applications of described airway management techniques. Examples of common alternatives are given in approximate order of choice

	Difficult direct laryngoscopic intubation	With difficult spontaneous/mask ventilation
Awake	Fibreoptic bronchoscopic intubation Direct laryngoscopic intubation* Blind nasal intubation Retrograde intubation	Percutaneous cricothyroidotomy* Surgical tracheostomy*
Anaesthetised or comatose (empty stomach)	Bag-and-mask ventilation Direct laryngoscopic intubation Different blade Fibreoptic bronchoscopic intubation Intubating LMA/LMA Lighted stylet Blind nasal intubation	Laryngeal mask airway (LMA) Transtracheal jet ventilation Rigid ventilating bronchoscope Percutaneous cricothyroidotomy Surgical tracheostomy
(full stomach)	Maintain cricoid pressure with all techniques Intubating LMA/Proseal LMA Combitube	Percutaneous cricothyroidotomy Surgical tracheostomy Combitube

The technique(s) chosen should also depend on the clinician's knowledge and ability. Cricoid pressure should be applied with a force of approximately 30 N, but applied force can be temporarily reduced to assist airway manoeuvres.

\*Under local anaesthesia.

Chemical indicators

smoothing out the cuffed rim to be wrinkle-free, and the posterior surface and patient hard palate are lubricated with water soluble jelly. The patient is positioned as for endotracheal intubation, with slight flexion of the neck and extension of the atlanto-occipital joint (sniffing-the-morning-air position). The LMA is inserted with the tip of the cuff continuously applied to the hard palate, and with the right index finger guiding the tube to the back of the tongue until a firm resistance is encountered. The cuff is then inflated with 20–40 ml of air (adult sizes) before attachment of the breathing circuit.

To begin insertion of an iLMA, ensure the curved metal tube is in close proximity to the chin (the metal handle points to the toes) and the mask tip flat against the palate prior to insertion. The mask is inserted and positioned with a circular motion, maintaining contact pressure between the posterior aspect of the mask and the palate and posterior pharynx, until some resistance in the hypopharynx is felt. A laryngoscope can be used to assist placement. Once gas exchange is established, an attempt at intubation can be made. The well-lubricated endotracheal tube is passed down the iLMA tube, rotating gently to distribute the lubricant until the 15-cm marker (or the transverse line on the proprietary LMA Fastrach endotracheal tube). The endotracheal tube tip is now positioned through the epiglottic elevating bar. Gently lift the iLMA about 2–5 cm with the metal handle while the endotracheal tube is advanced into the trachea. Inflate the endotracheal tube cuff and confirm tracheal intubation (see later). Remove the endotracheal tube connector, and position the stabiliser rod on the endotracheal tube opening – this is needed to maintain the tube position in the trachea as the mask is removed. Lastly, gently remove the iLMA over the endotracheal tube/stabiliser assembly. Remove the stabiliser rod, reconfirm tube position and secure.

The successful use of an iLMA requires some familiarity with the equipment and technique, and at least simulated exposure is strongly recommended. Contraindications for using an iLMA or LMA include inability to open the mouth, pharyngeal pathology, airway obstruction at or below the larynx, low pulmonary compliance or high airway resistance. Complications include aspiration, gastric insufflation, partial airway obstruction, coughing, laryngospasm, postextubation stridor and kinking of the shaft of the LMA.

#### **COMBITUBE (OESOPHAGEAL–TRACHEAL DOUBLE-LUMEN AIRWAY)**

The oesophageal–tracheal Combitube is a double-lumen tube that is blindly inserted into the oropharynx up to the indicated markings.<sup>7</sup> The oesophageal lumen is blocked at the distal end and has side perforations at the pharyngeal level whereas the tracheal lumen has a hole at the distal end. It has two balloon cuffs, a distal one and a proximal pharyngeal balloon. The patient is ventilated through the oesophageal lumen initially as the Combitube usually enters the oesophagus,<sup>7</sup> with the distal cuff sealing the oesophagus and the proximal balloon sealing the proximal pharynx. Gas exits the perforations and enters the pharynx and larynx. In the event of failure of ventilation, tracheal intubation may have occurred and then the tracheal lumen is ventilated while the distal cuff seals the trachea. Although demonstrated to be a useful airway management adjunct, its role in resuscitation and management of the difficult airway in the ICU environment is yet to be established. Barotrauma, especially oesophageal rupture, has been reported.

## INVASIVE TECHNIQUES

### ENDOTRACHEAL INTUBATION

Endotracheal intubation remains the 'gold standard' of definitive airway management, allowing for spontaneous and positive-pressure ventilation, with good macroscopic protection from aspiration. Indications include acute airway obstruction, facilitation of tracheal suctioning, protection of the airway in those without protective reflexes, and respiratory failure requiring ventilatory support with high inspired concentrations of oxygen and PEEP.

#### Preparation

Prior to proceeding with any attempts at intubation, regardless of the technique chosen, preparation and checking of all relevant equipment are essential. Tracheal intubation should be preceded by adequate preoxygenation, particularly in ICU patients who frequently have pulmonary or cardiac pathology. Difficult airway management equipment (see Table 25.3) should also be accessible within a few minutes. Food, vomitus, blood or sputum may obstruct the airway and therefore suction, able to generate at least 300 mmHg (40 kPa) and a flow rate of 30 l/min, should always be available. Excessively vigorous suctioning should be avoided as it can cause laryngospasm, vagal stimulation, mucosal injury and bleeding.

#### Direct laryngoscopy

Although an essential skill for all intensivists, direct laryngoscopy and intubation is difficult to master.<sup>8</sup> It can be learned by simulation, exposure to patients in a controlled environment such as the operating room and subsequently practised under supervision in the ICU setting. A detailed description of the technique is beyond the scope of this chapter; however certain problems and complications commonly encountered in ICU patients should be anticipated and prevented.

Cricoid pressure is usually required as few ICU patients can be adequately starved prior to intubation. ICU patients are at high risk for severe hypotension following the use of hypnotic or sedative agents used to facilitate intubation. Mechanisms include, but are not limited to, direct drug effects causing myocardial depression and decreases in peripheral vascular resistance, a reduction in venous return and preload following the increase in intrathoracic pressure with positive-pressure ventilation and the removal of sympathetic stimulation once anxiety disappears. It is therefore useful to ensure adequate hydration, availability of inotrope and vasopressor drugs, judicious use of positive ventilatory pressures and close haemodynamic monitoring before and during the intubation period.

Because intubation is often more difficult in ICU patients (see later), excellent technique is needed. All *first* attempts at intubation should incorporate proper head position, the use of techniques such as BURP (backward, upward, rightward pressure) that may be helpful to bring

the vocal cords into the field of vision, and, if necessary, the use of a gum elastic bougie or equivalent. A difficult-to-visualise 'anterior larynx' can often be more easily intubated if a gum elastic bougie is advanced in the midline and directed anteriorly into the trachea. The endotracheal tube is then advanced over the guide from an initial 90° anticlockwise-rotated position. Clinical signs of correct tracheal placement of the guide include coughing (in incompletely paralysed patients), a resistance felt before the guide is fully advanced (usually at 45 cm or less from the lips because of resistance at the carina or bronchus) and a sensation of clicks from the tracheal rings. A number of alternative intubating guides are available, including the hollow endotracheal tube changer, which can be attached to a side-stream capnometer, or to an oxygen source. The lighted stylet is less commonly used and has a light at the distal end that results in a characteristic midline transillumination appearance when the light enters the larynx.

If multiple intubation attempts are required, the maximum interruption to ventilation should be about 30 s and adequate ventilation and oxygenation must be provided between attempts. Minimum monitoring should consist of continuous-pulse oximetry, electrocardiogram (ECG) and blood pressure. In ICU patients the largest reasonable endotracheal tube should be chosen to facilitate optimal sputum clearance, access for fiberoptic bronchoscopy and to reduce airway resistance in difficult-to-ventilate patients. Sizes of 8.0–9.0 mm in adult males and 7.0–8.0 mm in adult females are generally used.

The route of intubation may be orotracheal or nasotracheal. The orotracheal route is preferred because it has fewer complications. Nasotracheal intubation is contraindicated in the presence of fracture of the base of skull. Other complications include epistaxis, turbinate cartilage and nasal septal damage, and in the long-term an increased risk of nosocomial pneumonia and sinusitis.<sup>9</sup>

#### Rigid indirect fiberoptic technique

The Bullard laryngoscope is a rigid, indirect fiberoptic instrument that is shaped to follow the hard palate. The learning curve appears reasonable and it has been shown to be a viable alternative for intubation in the difficult airway and reduces cervical spine movement during laryngoscopy compared with the Macintosh or Miller laryngoscope.<sup>10</sup>

#### Fiberoptic bronchoscopic technique

This technique offers advantages of direct visualisation, immediate diagnosis of upper-airway lesions and immobility of the neck during the procedure.<sup>11</sup> It also allows reasonably comfortable intubation of a cooperative, awake patient under local anaesthesia, and use of the sitting position. Experience and skill are necessary, especially for dealing with emergent situations, but success rates > 96% are expected.<sup>12</sup> Fiberoptic oral intubation may also be performed in anaesthetised patients, using

a modified face mask with diaphragm. Nasal intubation is usually performed through an endotracheal tube placed in the nasopharynx, with the tip just above the glottis. The fiberoptic bronchoscope tip is guided into the trachea and the tube is advanced over the bronchoscope. Correct placement is visually checked before the scope is removed. In ICU the fiberoptic bronchoscope can be used to improve the safety of airway procedures such as endotracheal tube changes and percutaneous tracheostomy.<sup>13,14</sup> A number of specially designed oral airways are available to assist oral fiberoptic intubation. The most common cause of failure is obstructed vision from blood or secretions.

#### **Less commonly used techniques of endotracheal intubation**

Blind nasal intubation is less common since the advent of fiberoptic bronchoscopy, but is sometimes considered in spontaneously breathing patients. Possible indications include inability to open the mouth (e.g. mandibular fracture or temporomandibular joint pathology), cervical spine injury and faciomaxillary injury when blood and secretions may obscure a fiberoptic view.

The retrograde intubation technique consists of the percutaneous introduction of a J-tip guidewire through the cricothyroid membrane, which is then advanced into the retropharynx. The tip is retrieved from the oral cavity, and the wire is used to guide an oral endotracheal tube past the obstruction and into the trachea.<sup>15</sup> The procedure is a relatively simple and safe alternative if other techniques fail or are not possible. Commercial kits are available.

#### **Confirmation of tracheal tube placement**

Confirming correct intratracheal tube placement is essential. Direct visualisation and measurement of expired CO<sub>2</sub> by capnography are the most reliable methods.<sup>16</sup> Capnography may produce false-positive results with the first few breaths after oesophageal intubation (i.e. detectable end-tidal P<sub>CO<sub>2</sub></sub>), if gastric insufflation from mask ventilation has occurred. A false-negative (decreased P<sub>CO<sub>2</sub></sub>, despite correct position) may occur with cardiac arrest and low-cardiac-output states. Position can also be reliably confirmed by fiberoptic confirmation and the use of oesophageal detectors or self-inflating bulbs.<sup>1</sup> Other clinical signs, such as auscultation of breath sounds over both sides of the chest and epigastrium, visualisation of condensed water vapour in the tube and chest wall movement, are less reliable.

#### **Complications of endotracheal intubation**

These may be classified into those occurring during intubation (e.g. incorrect tube placement, laryngeal trauma, deleterious cardiovascular response to laryngoscopy and intubation, increase in intracranial pressure, hypoxaemia and aspiration), while the tube is in place (e.g. blockage, dislodgment, tube deformation, damage to larynx and complications of mechanical ventilation), and following extubation (e.g. aspiration and postextubation airway obstruction, laryngeal and tracheal stenosis). Specific

techniques should be used to minimise side-effects such as cardiovascular responses and increases in intracranial pressure.

#### **TRANSTRACHEAL JET VENTILATION (TTJV)**

Percutaneous TTJV, using a large-bore intravenous (IV) catheter inserted through the cricothyroid membrane, can be used to provide temporary ventilation when other techniques have failed.<sup>17</sup> Ventilation through the cannula with a standard manual resuscitator bag is inadequate, and a jet ventilation system is necessary. A high-pressure (up to 50 psi or 344 kPa) oxygen source is required for adequate ventilation through a 14 FG IV cannula with a manually regulated jet injector. Expiratory gases must be able to escape via the glottis. Appropriate chest movements during expiration must be noted. The consequence of expiratory obstruction is severe and potentially fatal barotrauma.

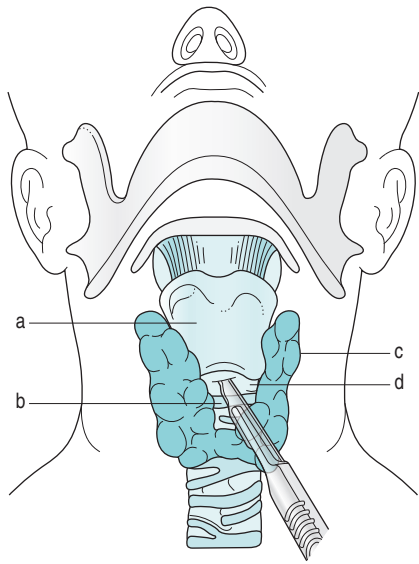

Complications may be caused by insertion of the IV cannula (e.g. bleeding and oesophageal perforation), use of high-pressure gases (e.g. hyperinflation, barotrauma), catheter kinking or displacement (the latter causing potentially catastrophic subcutaneous emphysema) and failure to protect the airway (i.e. aspiration).

#### **CRICOTHYROIDOTOMY**

Cricothyroidotomy, by surgery or percutaneously, is a reliable, relatively safe and easy way of providing an emergency airway.<sup>18</sup> It is the method of choice if severe or complete upper-airway obstruction exists. The simplest, fastest and most proven method uses a horizontal incision through the cricothyroid membrane with the space held wide open by the scalpel handle or forceps. This is followed by insertion of a small tracheostomy or endotracheal tube (Figure 25.2). If available, a small surgical hook is useful to hold down the inferior margin of the incision to facilitate cannulation. Commercial cricothyroidotomy sets, using the Seldinger technique, are available. A tube with internal diameter of 3.0 mm will allow adequate gas flow for self-inflating bag ventilation provided supplemental oxygen is used. Since the diameter of the cricothyroid space is 9 × 30 mm, tubes of 8.5 mm *outer* diameter or less should avoid laryngeal and vocal cord damage. Commercially available percutaneous tracheostomy sets that meet the above requirements are available. Complications such as subglottic stenosis (1.6%), thyroid fracture, haemorrhage and pneumothorax are acceptably low. Cricothyroidotomy is generally contraindicated in complete laryngotracheal disruption and age < 12 years.

#### **TRACHEOSTOMY**

There is little agreement on the indications, best technique or optimal timing of tracheostomy in ICU patients. Suggested indications for tracheostomy include bypass of glottic and supraglottic obstruction, access for tracheal toilet, provision of a more comfortable airway for prolonged ventilatory support and protection of the airways

**Figure 25.2** Cricothyroidotomy performed with a scalpel. (a) Thyroid cartilage; (b) cricoid cartilage; (c) thyroid gland; (d) cricoid membrane, usually easily palpable subcutaneously.

from aspiration.<sup>19</sup> In uncomplicated patients, percutaneous tracheostomy performed by an intensivist at the bedside is at least as safe as surgical tracheostomy performed in the operating room, and is probably associated with a lower incidence of infectious complications.<sup>20,21</sup> The added convenience and cost savings have made percutaneous tracheostomy the procedure of choice in many institutions. However, the percutaneous technique is best avoided in the presence of coagulopathy – an international normalised ratio (INR) > 2 or platelet count <  $40 \times 10^9/l$ ; significant anatomical abnormality in the anterior neck in the region of the trachea, vessels or thyroid gland; previous tracheostomy scar; or a cervical spinal injury that is considered unstable.

Ciaglia's percutaneous technique was described in 1985.<sup>22</sup> After making an adequate skin incision and using blunt dissection with forceps the trachea is gently exposed. The endotracheal tube is then withdrawn so that its cuff lies just above the vocal cords. The operator confirms tube position to be above the stoma site by palpation of the trachea. A J-wire is placed in the trachea through a needle inserted through the membrane above or below the second tracheal ring. A series of curved dilators is used to enlarge the stoma progressively. A tracheostomy tube is then inserted into the trachea and the endotracheal tube removed. Ciaglia later introduced a modified tapered dilator to avoid the use of multiple dilators. Although quicker, the single dilator may cause more tracheal wall injuries and ring fractures.<sup>22</sup> The Griggs technique utilises a Kelly forceps, modified to allow it to be guided by the J-wire, to dilate the tract before insertion of tracheostomy tube.<sup>23</sup> Although the Griggs

**Table 25.4** Complications of tracheostomy

#### Immediate

- Procedural complications
  - Haemorrhage
  - Surgical emphysema, pneumothorax, air embolism
  - Cricoid cartilage damage
- Misplacement in pretracheal tissues or right main bronchus
- Compression of tube lumen by cuff herniation
- Occlusion of the tip against the carina or tracheal wall

#### Delayed

- Blockage with secretions
- Infection of the tracheostomy site, tracheobronchial tree and larynx
- Pressure on tracheal wall from the tracheostomy tube or cuff
  - Mucosal ulceration and perforation
  - Deep erosion into the innominate artery
  - Tracheo-oesophageal fistula

#### Late

- Granulomata of the trachea
- Tracheal and laryngeal stenosis
- Persistent sinus at tracheostomy site
- Tracheomalacia and tracheal dilatation

technique is marginally faster (by 2–3 minutes) than the Ciaglia technique, most, but not all, prospective studies have suggested that the Griggs technique may cause marginally more bleeding and functional complications, and cannula insertion may be somewhat more difficult.<sup>24,25</sup> Fibreoptic bronchoscopy during percutaneous tracheostomy may help to prevent incorrect guidewire placement and tracheal ring rupture or herniation, but definitive evidence supporting its routine use is lacking. Definitive identification of the best technique still requires further investigation and long-term follow-up.

Minitracheostomy describes the percutaneous insertion of a small 4-mm non-cuffed tracheostomy tube through the cricothyroid membrane or trachea, mainly to facilitate suctioning in patients with poor cough ability.

Complications of tracheostomy are listed in Table 25.4.

#### LOCAL ANAESTHESIA

Instrumentation of the upper airway in awake patients requires good local anaesthesia to increase comfort, improve cooperation, attenuate cardiovascular responses and reduce the risk of laryngospasm. Rapid transcricoid injection and either sprayed or nebulised lidocaine to the nares, posterior pharynx and tongue are effective (Table 25.5).<sup>26</sup> Nerve block techniques may improve analgesia but are not essential. Cocaine has been a popular choice for its vasoconstrictor properties, but it is toxic and its supply is regulated. Systemic absorption of topically applied lidocaine (maximum dose 4 mg/kg) is variable, and the clinician should be alert for signs and symptoms of toxicity.

Table 25.5 Local anaesthesia of the upper airway in adults

Technique	Drug dosage
<b>Nerve block</b>	
Internal branch of superior laryngeal nerve	Lidocaine 1–2% (2 ml/side)
Glossopharyngeal nerve	Lidocaine 1–2% (3 ml/side)
<b>Topical anaesthesia of the tongue and oropharynx</b>	
Gargle	Lidocaine viscous 4% (5 ml)
Spray	Lidocaine 10% (5–10 sprays = 50–100 mg)
Nebulised	Lidocaine 4%
<b>Topical anaesthesia of the nasal mucosa</b>	
Cocaine spray or paste	Cocaine 4–5% (0.5–2 ml)
Gel	Lidocaine 2% gel (5 ml)
Lidocaine spray	Lidocaine 10% (10 sprays = 100 mg)
Lidocaine + phenylephrine spray	Lidocaine 3% + phenylephrine 0.25% (0.5 ml)
<b>Topical anaesthesia of glottis and trachea</b>	
Spray-as-you-go through bronchoscope	Lidocaine 1–4% (3 mg/kg)
Cricothyroid membrane puncture	Lidocaine 2% (5 ml)
Nebulised	Lidocaine 4% (4 ml) ± phenylephrine 1% (1 ml)

## THE DIFFICULT AIRWAY

The difficult airway has been described as one in which a conventionally trained anaesthesiologist experiences difficulty with mask ventilation, tracheal intubation or both. Difficult intubations may be expected in 1–3% of patients presenting for general anaesthesia, and the incidence is likely to be considerably higher in ICU patients.

More than 85% of difficult intubations can be managed successfully by experienced clinicians without resorting to a surgical solution. The experience of the operator is probably the most important factor determining success or failure. Experience implies greater manual skills, better anticipation of problems, use of pre-prepared strategies, and familiarity with multiple techniques. Thus, training of intensivists must specifically include a variety of airway management strategies and skills.

## ASSISTANCE AND ENVIRONMENT

Because the patient's condition may rapidly deteriorate as a consequence of a poorly managed airway emergency, the *most senior help available* should be immediately summoned. If the situation allows, the patient should be moved to the best location for emergency airway interventions, usually the operating theatre or ICU, and difficult airway equipment requested (see Table 25.3). A senior assistant can help in gaining IV access,

administering drugs, setting up equipment and managing the airway. A skilled intensivist or ear, nose and throat surgeon (gowned and standing by) can help to provide a surgical airway or perform rigid bronchoscopy to remove foreign bodies.

## ANTICIPATING AND GRADING A DIFFICULT AIRWAY

Intubation difficulty can be anticipated or predicted by the following (although the sensitivity and specificity of individual features and classifications tend to be low, a combination of features will significantly raise the risk of a difficult airway):

- Anatomical or pathological features of difficult intubation in subjects who otherwise appear normal:
  - short neck, especially if obese or muscular (a thyromental distance < 6 cm)
  - limited neck and jaw movements (e.g. as a result of trismus, osteoarthritis, ankylosing spondylitis, rheumatoid arthritis or perioral scarring)
  - protruding teeth, small mouth (interincisor distance < 3 cm), long high curved palate or receding lower jaw
  - space-occupying lesions of the oropharynx and larynx
  - congenital conditions with any of the above features (e.g. Marfan's syndrome)
- Mallampatti classification<sup>27</sup> of visualising the oropharyngeal structures (a cooperative sitting patient is required for this assessment, and class > 2 predicts possible difficulty):
  - class 1: visible soft palate, uvula, fauces and pillars
  - class 2: visible soft palate, uvula and fauces
  - class 3: visible soft palate and base of uvula
  - class 4: soft palate is not visible
- The degree of difficulty experienced visualising the larynx by direct laryngoscopy should be recorded and is commonly graded by the classification of Cormack and Lehane.<sup>28</sup> Recently grade III has been divided into IIIa (epiglottis is mobile) and IIIb (epiglottis is not mobile) subgrades:
  - grade I: complete glottis is visible
  - grade II: anterior glottis is not visible
  - grade III: epiglottis but not glottis is visible
  - grade IV: epiglottis is not visible

## FAILED INTUBATION AND VENTILATION ALGORITHMS

A pre-prepared plan in the event of failed intubation and/or ventilation is essential and a number have been described in the form of single or multiple algorithms.<sup>1,2</sup> The algorithm shown here is an example of a single algorithm applicable to some anticipated airway difficulty scenarios in ICU patients (see Figure 25.1). Although not comprehensive, the algorithm is complex and only

one or two pathways are applicable to an individual clinical scenario. The relevant pathway should be identified as early as possible in each individual case and then applied. Ultimately effective implementation depends on the skill of the operator and the appropriate use of the airway techniques described above.

If the initial attempt at intubation fails, *call for help immediately*. Repeated attempts at direct laryngoscopy should be avoided unless a more experienced operator intervenes, or a potentially helpful manoeuvre has been carried out (e.g. significant repositioning, externally applied laryngeal pressure or change of laryngoscope blade). Hypoxia will quickly result if the patient is inadequately ventilated between attempts (see above). In addition, oedema and bleeding caused by repeated laryngoscopy attempts may impair both mask ventilation and the use of alternative techniques such as fiberoptic intubation. When indicated to prevent hypoxia a surgical airway should not be delayed (see Figures 25.1 and 25.2).

## UPPER-AIRWAY OBSTRUCTION

### ANATOMY AND PATHOPHYSIOLOGY

The upper airway begins at the nose and mouth, and ends at the carina. Obstruction is likely to occur at sites of anatomical narrowing, such as the hypopharynx at the base of the tongue, and the false and true vocal cords at the laryngeal opening. Sites of airway obstruction are classified as supraglottic (above the true cords), glottic (involving the true vocal cords) or infraglottic (below the true cords and above the carina).

The upper airway can also be divided into intrathoracic and extrathoracic portions, which behave differently during inspiration and expiration. The intrathoracic airway dilates during inspiration because it is 'pulled outwards' by negative intrapleural pressure. Positive intrapleural pressure during expiration causes compression and narrowing. Conversely the compliant extrathoracic airway, unexposed to intrapleural pressure, collapses during inspiration and expands during expiration. Recalling this phenomenon helps the understanding of typical clinical signs, radiographs and flow–volume loops.

### AETIOLOGY

Acute upper-airway obstruction may result from functional or mechanical causes (Table 25.6). Functional causes include central nervous system and neuromuscular dysfunction. Mechanical causes may occur within the lumen, in the wall or extrinsic to the airway.

### CLINICAL PRESENTATION

The signs of partial airway obstruction are often progressive and begin with hoarseness, other voice changes or coughing, with more severe obstruction being marked

**Table 25.6** Clinical conditions associated with acute upper-airway obstruction

#### Functional causes

##### Central nervous system depression

Head injury, cerebrovascular accident, cardiorespiratory arrest, shock, hypoxia, drug overdose, metabolic encephalopathies

##### Peripheral nervous system and neuromuscular abnormalities

Recurrent laryngeal nerve palsy (postoperative, inflammatory or tumour infiltration), obstructive sleep apnoea, laryngospasm, myasthenia gravis, Guillain–Barré polyneuritis, hypocalcaemic vocal cord spasm

#### Mechanical causes

##### Foreign-body aspiration

##### Infections

Epiglottitis, retropharyngeal cellulitis or abscess, Ludwig's angina, diphtheria and tetanus, bacterial tracheitis, laryngotracheobronchitis

##### Laryngeal oedema

Allergic laryngeal oedema, angiotensin-converting enzyme inhibitor-associated, hereditary angioedema, acquired C1 esterase deficiency

##### Haemorrhage and haematoma

Postoperative, anticoagulation therapy, inherited or acquired coagulation factor deficiency

##### Trauma

##### Burns

Inhalational thermal injury, ingestion of toxic chemical and caustic agents

##### Neoplasm

Pharyngeal, laryngeal and tracheobronchial carcinoma, vocal cord polyposis

##### Congenital

Vascular rings, laryngeal webs, laryngocele

##### Miscellaneous

Cricoid arthritis, achalasia of the oesophagus, hysterical stridor, myxoedema

by drooling, gagging, choking, inspiratory stridor or noisy respiration. Paradoxical chest wall movements and intercostal and supraclavicular retractions may be marked in severe obstruction. Powerful respiratory efforts may produce dermal ecchymoses and subcutaneous emphysema. Respiratory decompensation may be rapid in onset, and progress to complete obstruction. Lethargy, diminishing respiratory efforts and loss of consciousness are late signs of hypoxaemia and hypercarbia. Bradycardia and hypotension herald impending cardiac arrest.

Signs of sudden complete upper-airway obstruction are characteristic and progress rapidly. The victim cannot breathe, speak or cough, and may hold the throat between the thumb and index finger – the universal choking sign.<sup>29</sup> Agitation, panic and vigorous breathing

efforts are rapidly followed by cyanosis. Respiratory efforts diminish as consciousness is lost, and death results within 2–5 min if obstruction is not relieved.

### SPECIAL EVALUATION OR INVESTIGATIONS

If the patient remains stable, specific diagnostic evaluation may be undertaken, provided advanced airway management facilities and skilled personnel are immediately available.

#### LARYNGOSCOPY AND BRONCHOSCOPY

*Indirect laryngoscopy* in a stable, cooperative patient is useful to diagnose foreign bodies, retropharyngeal or laryngeal masses and other glottic pathology.<sup>30</sup>

*Assessment with a flexible fiberoptic bronchoscope or laryngoscope* is the evaluation method of choice in ICU patients and enables direct visualisation of upper-airway anatomy and function. The procedure can be performed at most sites without transporting the patient and risking complete obstruction. It can be applied to an awake, spontaneously breathing patient and, with care, should not worsen the obstruction. If indicated, definitive airway control by intubation can usually be achieved, by advancing an endotracheal tube over the bronchoscope into the trachea. Disadvantages are the need for a skilled operator and a cooperative patient, and the poor visual field reduces effectiveness if blood and secretions are copious.

*Direct laryngoscopy* enables forceps removal of foreign bodies and high-volume suctioning of blood, vomitus and secretions. Endotracheal intubation can rapidly be achieved under direct vision. Disadvantages are the need for general anaesthesia or good local analgesia (often difficult in the emergency setting). Direct laryngoscopy can be traumatic, and may worsen soft-tissue bleeding and oedema.

#### RADIOGRAPHIC IMAGING

Patients with potentially unstable airways should not be transported from a 'safe' environment like the

emergency room, operating theatre or ICU for radiological investigation until the airway is secure. Anteroposterior and lateral plain neck X-rays are useful to detect radiopaque foreign bodies. The lateral view in the upright position in inspiration with the neck fully extended may reveal swelling of the epiglottis and supraglottic tissues. Ballooning of the hypopharynx is a classical sign of epiglottitis, but is not always present. Soft tissues and the extent of space-occupying lesions are best visualised by computed tomography (CT) scan, which can also assess the thyroid, cricoid and arytenoid cartilages and the airway lumen in stable patients, or in those in whom the airway has been secured.<sup>31</sup> Although magnetic resonance imaging (MRI) has been used to image the upper airway, its use in acute airway obstruction is unproven.

#### GAS FLOW MEASUREMENT

Flow–volume loop measurement reveals characteristic patterns corresponding to different types and position of pathological lesions (Figure 25.3).<sup>32</sup>

### MANAGEMENT

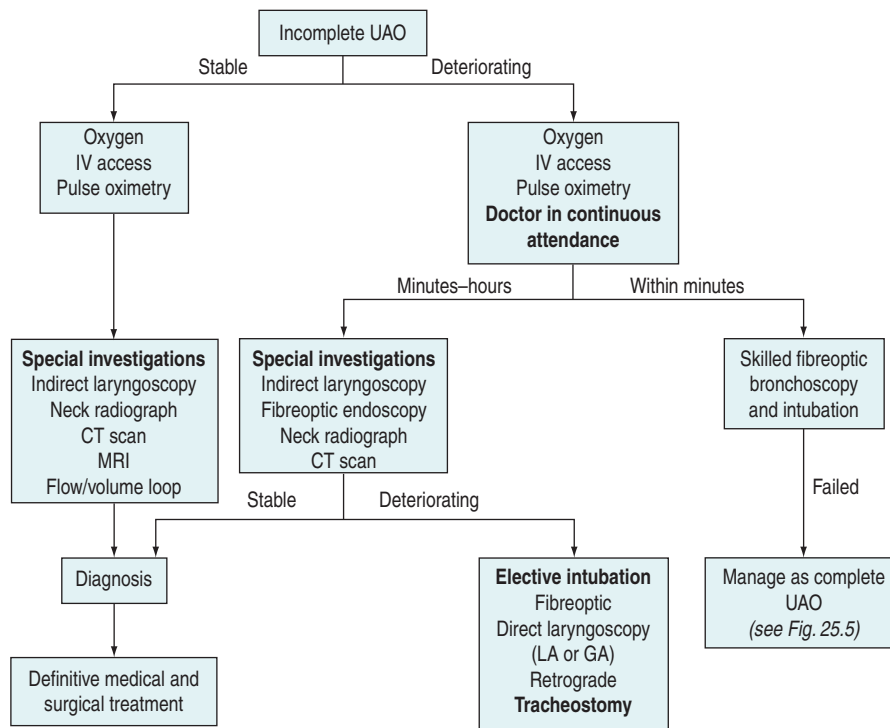

#### PREPARATION

Simplified algorithms to assist the management of partial and complete upper-airway obstruction are shown in Figures 25.4 and 25.5 and an appropriate management path should be chosen. Improvisation may be required for certain difficult problems. Special techniques in patients with suspected cervical spine instability are discussed elsewhere in this volume. Initial management follows:

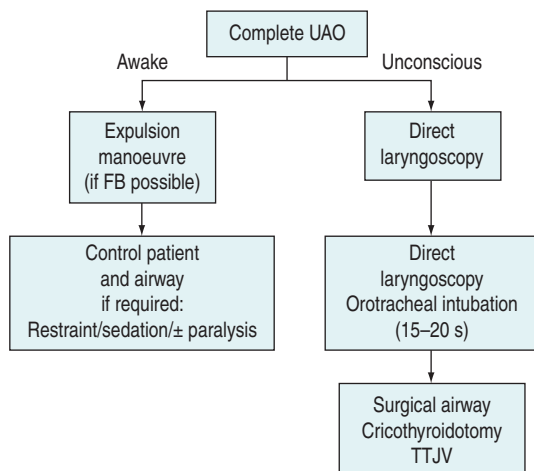

1. Supplemental oxygen (100%) is immediately administered.
2. A choice of equipment for definitive airway control must be available and ready for use (see Table 25.3).
3. In adults IV access should be secured.

**Figure 25.3** Flow–volume loops. Patterns resulting from different pathological lesions: (a) lower-airway obstruction (e.g. chronic obstructive pulmonary disease or asthma); (b) fixed, non-variable upper-airway obstruction (e.g. fibrous ring in trachea); (c) variable upper-airway obstruction, intrathoracic (e.g. tumour in the lower trachea); (d) variable upper-airway obstruction, extrathoracic (e.g. vocal cord tumour or paralysis).

**Figure 25.4** Management of partial upper-airway obstruction (UAO). i.v., intravenous; CT, computed tomography; MRI, magnetic resonance imaging; LA, local anaesthesia; GA, general anaesthesia.

**Figure 25.5** Management of complete upper-airway obstruction (UAO). Attempts at orotracheal intubation should not take longer than 10–20 s. FB, foreign body; TTJV, transtracheal jet ventilation.

4. Initiate continuous monitoring of vital signs and pulse oximetry.
5. Patient transport before securing the airway must be carefully considered as it is difficult to provide safe conditions during transport.<sup>30</sup>

## AIRWAY MANAGEMENT TECHNIQUES IN AIRWAY OBSTRUCTION

### THE UNCONSCIOUS PATIENT

If the upper airway is obstructed by the tongue and retropharyngeal tissues in an unconscious patient, airway patency is initially achieved by using standard airway manoeuvres<sup>33</sup> and oropharyngeal and nasopharyngeal airways. Definitive airway control should follow if consciousness does not immediately return.

### ENDOTRACHEAL INTUBATION

1. *Direct laryngoscopic intubation* is the method of choice for the unconscious, apnoeic patient as it allows rapid evaluation of any supraglottic problem and immediate airway security. It can also be attempted in an awake patient after careful application of local anaesthesia. Although there is some risk of loss of the airway after local anaesthesia, complete loss of the airway *under general anaesthesia* is common and may be catastrophic.
2. *Awake fiberoptic intubation* in a spontaneously breathing patient is usually safe, but requires a skilled operator. The procedure will take 2–10 minutes or longer,<sup>34</sup> and urgency of the case must be assessed beforehand with this time frame in mind. Alternatives should be initiated if the obstruction progresses or if intubation fails after a reasonable time. The following

points may assist visualisation in acute upper-airway obstruction:

- (a) The procedure is clearly explained to the patient.
  - (b) Good local anaesthesia and mucosal vasoconstrictors are important. Failure is most commonly due to excessive secretions and bleeding.
  - (c) If desired, the suction port of the fibroscope can be used to insufflate 100% oxygen or apply local anaesthetic. This also clears the fibroscope tip of secretions. Additional large-bore suction catheters may help.
3. *Blind nasotracheal intubation* provides a patent nasopharyngeal airway during the procedure, but is less useful when fiberoptic laryngoscopy is available.

Once endotracheal intubation is safely accomplished and confirmed, secure fixation of the endotracheal tube is mandatory. The patient's upper limbs may need to be restrained to avoid self-extubation.

### SURGICAL AIRWAYS

A surgical airway is indicated when endotracheal intubation is not possible, or when an unstable cervical spine is threatened by available airway techniques. It is the last line of defence against hypoxia. In airway obstruction options include the following:

1. *Cricothyroidotomy* is the method of choice if severe or complete upper-airway obstruction exists.
2. *Percutaneous transtracheal jet ventilation*. The technique must *not* be used in complete upper-airway obstruction because expiratory obstruction can cause severe and potentially fatal barotrauma.
3. *Tracheostomy* in the emergency setting is rarely required, although surgical tracheostomy under local anaesthesia may be reasonable under some controlled conditions (see Figure 25.4).

## COMMON CLINICAL CONDITIONS AND THEIR MANAGEMENT

### FOREIGN-BODY OBSTRUCTION

Foreign-body obstruction is the most common cause of acute airway obstruction. The elderly, especially those in institutions, are at risk. The use of dentures, alcohol and depressant drugs increases risk. Fatal food asphyxiation or 'café coronary' should be considered in any acute respiratory arrest where the victim cannot be ventilated.<sup>35</sup>

Patients who are still able to cough or speak clearly should be given the opportunity to expel the foreign body spontaneously. If not, expulsion of the foreign body can be attempted with one or a combination of chest thrusts, abdominal thrusts (Heimlich manoeuvre<sup>29</sup>) or back blows applied in rapid sequence in the most convenient order.<sup>35</sup> The abdominal thrust is performed from behind: the rescuer encircles his or her arms around the victim, placing the thumb of one fist between the umbilicus and xiphisternum. The fist is gripped by the other

hand, and an inward, upward thrust is applied. Chest thrusts are similar (rescuer's arms should encircle the chest, and a fist placed over midsternum) and are convenient for use in pregnancy and obesity. Unwanted effects, such as vomiting, aspiration, fractured ribs, barotrauma and ruptured organs, have been reported. Extract *visible* solid material with a finger sweep only in unconscious patients.<sup>33</sup> If these manoeuvres fail, management immediately proceeds as shown in Figures 25.4 and 25.5. If cardiac arrest occurs, proceed with cardiopulmonary resuscitation.

### EXTRINSIC AIRWAY COMPRESSION

Extrinsic space-occupying lesions can cause upper-airway obstruction. Compression from haematomas may be associated with trauma, neck surgery, central venous catheterisation, anticoagulants and congenital or acquired coagulopathies. Haematomas following surgery should immediately be evacuated by removing skin and subcutaneous sutures. If this fails, an artificial airway must be secured immediately. In patients with coagulation abnormalities, intubation is preferred over a surgical airway. Most haematomas secondary to coagulopathy do not require surgical intervention, and resolve with conservative therapy (i.e. vitamin K and blood component therapy).

Partial airway obstruction caused by retropharyngeal abscess is best managed by drainage under local anaesthesia. Gentle fiberoptic examination and intubation or direct laryngoscopy and intubation in the lateral, head-down position are favored by some.<sup>30</sup> Risks are related to inadvertent rupture of the abscess, with subsequent flooding of the airway.

Ludwig's angina is a mixed infection of the floor of the mouth resulting in an inflammatory mass in the space between the tongue and the muscles and anterior neck fascia. The supraglottic airway is compressed and becomes narrowed.<sup>36</sup> Direct laryngoscopy is difficult, as the tongue cannot be anteriorly displaced. Awake fiberoptic-guided intubation or a surgical airway, along with antibiotic therapy, is required.

### INTRINSIC AIRWAY COMPRESSION

#### *Burn inhalation and ingestion injury*

Patients with large burn area (more than 40%), or with severe facial burns or inhalation injury (soot in the nostrils, burns of the tongue and pharynx, stridor or hoarseness) are at risk of developing progressive supraglottic oedema, usually within 24–48 hours. Such patients usually require early prophylactic tracheal intubation. If not prophylactically intubated, subsequent need for tracheal intubation can best be decided by frequent (2–4-hourly), repeated awake fiberoptic laryngoscopy as well as regular charting of known signs and symptoms of obstruction.<sup>37</sup> Careful inspection by direct laryngoscopy is an alternative to fiberoptic laryngoscopy. Ingestion of hot fluids or corrosive agents can also cause delayed oedema and airway swelling and should be managed similarly.<sup>38</sup>

### Adult epiglottitis

Epiglottitis is an uncommon but increasingly recognised infectious disease in adults.<sup>39</sup> It involves the epiglottis and supraglottic larynx, causing swelling with consequent airway obstruction. *Haemophilus influenzae*, *H. parainfluenzae*, *Streptococcus pneumoniae*, haemolytic streptococci and *Staphylococcus aureus* are common causative organisms. Reported mortality varies in adults (0%–7%), due to difficult diagnosis and non-standardised treatment.<sup>40</sup> Clinical features are sudden onset of sore throat (pain often greater than suggested by clinical findings), muffled voice, dysphagia, stridor, dyspnoea and respiratory distress. Systemic toxæmia is common. Gentle indirect laryngoscopy, fiberoptic laryngoscopy or lateral neck X-ray confirms the diagnosis.

Airway management is controversial.<sup>39–41</sup> Some experts recommend securing a definitive airway on presentation while others suggest close observation in ICU. There are, however, reports of sudden obstruction and death with the latter approach.<sup>40</sup> Onset of dyspnoea is an important sign predicting the need for intubation. Both tracheal intubation and tracheostomy are acceptable, but tracheal intubation may result in better long-term outcome. Prior to securing the airway, patient positioning is important, and changing from a sitting to supine position may induce complete obstruction. In more stable patients, awake fiberoptic intubation is preferable if a skilled operator is available. Endotracheal intubation following gaseous induction is recommended by some authorities, but complete obstruction can occur, even when this procedure is undertaken by a skilled anaesthetist.<sup>41</sup> A skilled assistant, scrubbed and ready to secure a surgical airway, may prevent disaster. Rapid-sequence induction using muscle relaxants is dangerous and should be avoided. Tracheostomy under local anaesthesia is a safe alternative.

Antibiotics are administered as soon as the diagnosis is established. Cefotaxime 2 g IV 6-hourly or ampicillin 1–2 g IV 6-hourly plus chloramphenicol 50 mg/kg per day are empiric regimens; however, patient factors, local bacterial sensitivities and cultures of epiglottal swabs and blood may influence the antibiotic choice. Supportive care includes adequate sedation and tracheobronchial toilet. Abscesses should be surgically drained. There is no good evidence supporting the use of steroids.

### Angioedema

Allergic responses involving the upper airway may be localised or part of a systemic anaphylactic reaction. Angioedema is characterised by subepithelial swelling. Angioedema of the lips, supraglottis, glottis and infraglottis may result in airway obstruction. The systemic reaction consists of variable combinations of urticaria (79%), bronchospasm (70%), shock, cardiovascular collapse and abdominal pain.<sup>42</sup> Common causative agents are Hymenoptera stings, shellfish ingestion and drugs. Treatment consists of immediately ensuring an adequate airway (see Figures 25.4 and 25.5), and administration of oxygen, adrenaline (epinephrine) and steroids. As it is

likely to recur, the patient should be kept under close supervision and fully investigated.

Hereditary angioedema is a rare, inherited disorder of the complement system, caused by functionless or low levels of C1 esterase inhibitor.<sup>43</sup> Non-pruritic, non-painful angioedema involving skin and subcutaneous tissue occurs in various locations, including the upper airway.<sup>44</sup> Precipitating causes include stress, physical exertion and localised trauma (including dental or maxillofacial surgery and laryngoscopy). Acute attacks do not respond to adrenaline, antihistamines or corticosteroids. Management consists of establishing a secure airway and infusion of C1 esterase inhibitor concentrate (25 U/kg) which has an onset of action of 30–120 minutes.<sup>44,45</sup> If not available, fresh frozen plasma (2–4 units) may be considered. Stanazolol 1–4 mg daily or danazol 50–600 mg/day has been shown to be effective in decreasing frequency and severity of attacks.<sup>46</sup> Antifibrinolytic agents (e.g. tranexamic acid) are less effective. Danazol, C1 esterase inhibitor and fresh frozen plasma (2–4 units) can be used as preoperative prophylaxis.<sup>45</sup>

Angiotensin-converting enzyme inhibitor-related angioedema is increasingly seen and is possibly the result of reduced bradykinin metabolism.<sup>47</sup> Treatment focuses on airway support.

### Postextubation laryngeal oedema

Laryngeal oedema following extubation occurs in about 20% of adults, but is not usually severe enough to precipitate reintubation.<sup>48</sup> Risk of severe oedema is increased after excessive airway manipulation, traumatic or prolonged tracheal intubation and if high cuff pressures are used. Treatment in adults is conservative, with close observation and humidified oxygen therapy. Nebulised plain epinephrine (1–2 ml 1:1000 solution diluted with 2 ml saline or undiluted 1:1000 solution 4–5 ml) or racemic epinephrine (0.25–0.5 ml 2.25% solution in 2–4 ml saline) has been used. Nebulisation may need to be repeated every 30–60 minutes. The prophylactic use of steroids to reduce post extubation laryngeal oedema remains controversial. Optimal dose, duration and target groups for prophylaxis have not yet been clearly defined. A recent study demonstrated that methylprednisolone 20 mg IV four-hourly started 12 hours prior to extubation (80 mg total dose) reduced the incidence of early re-intubation in patients intubated for more than 36 hours.<sup>48</sup>

### POSTOBSTRUCTION PULMONARY OEDEMA

Postobstruction pulmonary oedema may occur in up to 11% of cases of airway obstruction.<sup>49</sup> Oedema appears to be caused by the markedly decreased intrathoracic and interstitial tissue pressure resulting from forced inspiration against a closed upper airway. The resulting increased hydrostatic gradient causes transudation of fluid from pulmonary capillaries to the interstitium. In addition, increased venous return may increase pulmonary blood flow and pressure, further worsening oedema. Hypoxia and the hyperadrenergic stress state may also affect

capillary hydrostatic pressure, although pulmonary capillary occlusion pressure is often normal. The oedema usually occurs within minutes after the relief of the obstruction, but may be delayed up to 2.5 hours.<sup>50</sup> Management includes maintenance of airway patency, oxygen therapy, diuretics, morphine and fluid restriction. Application of continuous positive airways pressure or ventilation with PEEP may be necessary in severe cases. Pulmonary artery catheterisation need only be used for complicated cases.

# Acute respiratory failure in chronic obstructive pulmonary disease

Matthew T Naughton and David V Tuxen

The terms 'chronic obstructive pulmonary or airways disease' (COPD or COAD) are applied to patients with chronic bronchitis and/or emphysema. COPD affects 5% of the adult population, is the fifth most common cause of death worldwide and is the only major cause of death that is increasing in prevalence.<sup>1</sup> Despite this, when an acute deterioration occurs, most precipitating factors are reversible and the outcome is usually good.<sup>2</sup> This justifies aggressive management in the majority of patients.

## AETIOLOGY

The causes of COPD can be divided into environmental and host factors. Environmental factors include tobacco smoke, air pollution, indoor fumes (e.g. indoor cooking with solid biomass fuel) and poor socioeconomic status. The biggest single factor in over 95% of patients with COPD is tobacco smoking (Figure 26.1). However, only approximately 15% of smokers develop COPD. Marijuana smoking may cause premature and quite advanced bullous emphysema compared with tobacco smokers due to extremely hot and toxic inhaled smoke held at peak inspiration for prolonged periods of time.<sup>3</sup> Host factors are the balance between circulating proteases and antiproteases (e.g. alpha-1 antitrypsin deficiency) and the intake of antioxidant vitamins (A, C, E).<sup>4</sup>

## PATHOPHYSIOLOGY

Reduced expiratory airflow in COPD is due to both increased airway resistance and reduced lung elastic recoil. Airway resistance is increased by mucosal oedema and hypertrophy, secretions, bronchospasm, airway tortuosity and airflow turbulence and loss of lung parenchymal elastic tissues that normally support the small airways. Loss of lung elastic recoil pressure is due both to loss of lung elastin and loss of alveolar surface tension from alveolar wall destruction.

Reduced lung elastic recoil decreases expiratory airflow by reducing the alveolar pressure driving expiratory

airflow and by reducing the intraluminal airway pressure, which normally distends small airways during expiration. Forced expiration increases alveolar driving pressure but also causes dynamic airway compression resulting in no improvement or sometimes reduction in expiratory airflow. These factors are present in varying proportions, depending on the degree of chronic bronchitis and emphysema and the individual patient.

Airflow limitation results in prolonged expiration, pulmonary hyperinflation, inspiratory muscle disadvantage, increased work of breathing and the sensation of dyspnoea. All these factors are worsened during an exacerbation of COPD.

Pulmonary hyperinflation has both static and dynamic components. The static component remains at the end of an expiratory period long enough for all expiratory airflow to cease (30–120 s), enabling the lungs and chest wall to reach their static functional residual capacity (FRC). This component of hyperinflation is due to loss of parenchymal elastic recoil, chest wall adaptation<sup>5</sup> and airway closure that occurs throughout expiration. Dynamic pulmonary hyperinflation is the further increase in hyperinflation due to slow expiratory airflow not allowing completion of expiration before the arrival of the next breath. The extent of dynamic hyperinflation depends on the severity of airflow obstruction, the amount inspired (tidal volume) and the expiratory time.<sup>6</sup> Thus, the degree of hyperinflation may vary in a patient with changes in minute ventilation due to changes in CO<sub>2</sub> production (depending on exercise, diet or the metabolic response to illness) or dead space, as well as with changes in airflow obstruction during an exacerbation.

Chest wall hyperinflation leads to suboptimal muscle length–tension relationships and mechanical disadvantage, thereby predisposing patients to respiratory muscle fatigue, as the work of breathing increases, particularly if associated with myopathic situations (steroids, electrolyte disturbances). Minor reductions in lung function due to infection, mild cardiac failure or atelectasis increase the work of breathing, due to both increases in respiratory impedance and increases in dead space. With acute changes in workload, rapid decompensation with ventilatory failure and acute hypercapnia may occur.

**Figure 26.1** Decline in lung function with age in different smoking categories. FEV<sub>1</sub>, forced expiratory volume in 1 second; COPD, chronic obstructive pulmonary disease.

Central respiratory drive may also be impaired, or poorly responsive to physiological triggers – hypoxaemia or hypercapnia – and lead to chronic hypercapnia. This may occur in the setting of sleep (i.e. obstructive sleep apnoea), obesity or drugs (sedatives, antiepileptics, alcohol).

Hypoxia and vascular wall changes lead to pulmonary vasoconstriction, pulmonary hypertension, cor pulmonale,  $V/Q$  mismatching and the development of shunts.

#### CHRONIC BRONCHITIS OR EMPHYSEMA?

The value of labelling patients as chronic bronchitis or emphysema is uncertain as the two disease processes usually coexist and the principles of management are similar. Five pathophysiologic processes may be present to varying degrees in each patient with COPD: (1) inflammatory airway narrowing (bronchiolitis); (2) loss of connective tissues tethering airways; (3) loss of alveoli and capillaries; (4) hyperinflation; and (5) increased pulmonary vascular resistance. Early/mild COPD tends to be dominated by bronchiolitis with a minimal component of emphysema (Figure 26.2), whereas when COPD becomes severe, the reverse is true. However, recognition that COPD is dominated by one of these patterns is helpful with regard to clinical pattern and prognosis.

#### CLINICAL FEATURES OF ACUTE RESPIRATORY FAILURE IN COPD

Acute respiratory failure (ARF) in COPD can present with two distinct clinical patterns<sup>7</sup> (Table 26.1).

#### PRECIPITANTS OF ACUTE RESPIRATORY FAILURE

In approximately 50% of patients, there is an infective cause, in 25% heart failure and in the remaining 25% retained secretions, air pollution, coexistent medical problems (e.g.

**Figure 26.2** Proportional contributions of bronchiolitis and emphysema at different levels of severity of lung disease.

**Table 26.1** Clinical differences between normocapnic and hypercapnic chronic obstructive pulmonary disease

Normocapnic ( $P_{aCO_2}$ 35–45 mmHg)	Hypercapnic ( $P_{aCO_2} > 45$ mmHg)
Emphysema > chronic bronchitis	Chronic bronchitis > emphysema
Thin	Obese
Pursed-lip breathing	Central nervous system depression: consider the role of oxygen therapy
Accessory muscle use	Alcohol, sedatives, analgesics
Hyperinflated	Sleep-related hypoventilation
Right heart failure late	Right heart failure early

pulmonary embolus, medication compliance or side-effects) or no cause can be identified<sup>8</sup> (Table 26.2).

The most common bacterial isolates are *Streptococcus pneumoniae* and *Haemophilus influenzae* in 80% of exacerbations.<sup>9</sup> *S. viridans*,<sup>10</sup> *Moraxella* (previously *Branhamella*) *catarrhalis*,<sup>11</sup> *Mycoplasma pneumoniae*<sup>12</sup> and *Pseudomonas aeruginosa* may also be found. Viruses can be isolated in 20–30% of exacerbations<sup>13</sup> and include rhinovirus, influenza and parainfluenza viruses, coronaviruses and occasionally adenovirus, and respiratory syncytial virus. Whether these organisms are pathogens or colonisers is often unclear.

#### PNEUMONIA

Pneumonia has been estimated to account for 20% of presentations requiring mechanical ventilation.<sup>13</sup> It is most commonly caused by *S. pneumoniae* and *H. influenzae* but *Mycoplasma*, *Legionella*, enteric Gram-negatives and viruses are occasional causes.

**Table 26.2** Precipitants of acute respiratory failure in chronic obstructive pulmonary disease

Infective (including aspiration)
Left ventricular failure (systolic and diastolic failure)
Sputum retention (postoperative, traumatic)
Pulmonary embolism
Pneumothoraces and bullae
Uncontrolled oxygen
Sedation
Medication – non-compliance or side-effects
Nutritional (K, PO <sub>4</sub> , Mg deficiency, CHO excess)
Sleep apnoea

### LEFT VENTRICULAR FAILURE

Left ventricular (LV) systolic failure may result from coexisting ischaemic heart disease, fluid overload, tachyarrhythmias or biventricular failure secondary to cor pulmonale. LV diastolic failure occurs commonly and is precipitated by hypoxaemia, tachycardia,<sup>14</sup> pericardial constraint due to intrinsic positive end-expiratory pressure (PEEP<sub>i</sub>) or right ventricular (RV) dilation. Increased work of breathing related to COPD will also increase by up to 10-fold the amount of blood flow to the respiratory pump muscles,<sup>15</sup> thereby causing an increased demand upon the overall cardiac output. In patients with borderline cardiac status, this may precipitate heart failure. The components of right and LV failure can be accurately distinguished by Doppler echocardiography. Pulmonary congestion can be difficult to diagnose because of the abnormal breath sounds and chest X-ray appearance which are commonly present in COPD. In a recent publication, 51% of patients with acute exacerbation of COPD had echocardiographic evidence of left heart failure (systolic 11%, diastolic 32%, systolic and diastolic 7%).<sup>16</sup>

### UNCONTROLLED OXYGEN ADMINISTRATION

This may precipitate acute hypercapnia in patients with more severe COPD, due to: (1) shunting blood to low- $V/Q$  lung units and increasing dead space; (2) loss of hypoxic drive; (3) dissociation of CO<sub>2</sub> from Hb molecule (Haldane effect); and (4) anxiety and reduction in tachypnoea.

## DIAGNOSIS AND ASSESSMENT

### DIAGNOSIS

The clinical examination findings of COPD depend upon severity.

In mild stable disease (e.g. forced expiratory volume in 1 second (FEV<sub>1</sub>) 50–70% predicted normal), an

expiratory wheeze on forced expiration and mild exertional dyspnoea may be the only symptoms.

In moderate-severity COPD (e.g. FEV<sub>1</sub> 30–50% predicted normal), modest to severe exertional dyspnoea is associated with clinical signs of hyperinflation (ptosed upper border of liver beyond the level of nipple and loss of cardiac percussion) and signs of increased work of breathing (use of accessory muscles and tracheal tug).

In severe stable COPD (e.g. FEV<sub>1</sub> < 30% predicted normal), marked accessory muscle use is associated with tachypnoea at rest, pursed-lip breathing, hypoxaemia and signs of pulmonary hypertension (RV heave, loud and palpable pulmonary second sound and elevated a-wave in jugular venous pressure (JVP)) and cor pulmonale (elevated JVP, hepatomegaly, ankle swelling).

In severe unstable COPD, there is marked tachypnoea at rest, hypoxaemia and tachycardia, and, in some, signs of hypercapnia (dilated cutaneous veins, blurred vision, headaches, obtunded mentation, confusion).

Clinical examination may also identify associated medical conditions that might have precipitated the exacerbation such as crackles and bronchial breathing due to infection, crackles and cardiomegaly related to heart failure or mediastinal shift related to a pneumothorax.

Basic investigations such as spirometry are very useful in confirming a clinical diagnosis and determining severity of disease. The severity of COPD may be best judged by the reduction in FEV<sub>1</sub> compared with predicted values. Vital capacity (VC) is initially normal and decreases later in the course of the disease, but to a lesser degree than the FEV<sub>1</sub>.

An FEV<sub>1</sub>/VC ratio < 70% with an FEV<sub>1</sub> of 50–80% predicted normal without a bronchodilator response usually indicates mild COPD. A significant bronchodilator response, which implies asthma, is regarded as a 12% or greater increase and 200 ml increase in either FEV<sub>1</sub> or VC. An FEV<sub>1</sub> 30–50% predicted normal indicates moderately severe COPD and FEV<sub>1</sub> < 30% predicted normal indicates severe COPD.

Although the diagnosis may be based on spirometry alone, further lung function testing may be useful to characterise the disease. Flow–volume curves demonstrate reduced expiratory flow rates at various lung volumes and show the characteristic concave expiratory flow pattern. Lung volumes measured by either helium dilution or plethysmography show elevated total lung capacity, FRC and residual volume. Characteristically, the residual volume/total lung capacity ratio is >40% in COPD and represents intrathoracic gas trapping. The total lung carbon monoxide (TLCO) uptake is a measurement of alveolar surface area and its reduction approximates the amount of emphysema present (usually <80% predicted normal).

A chest X-ray will commonly show hyperinflated lung fields, as suggested by 10 ribs visible posteriorly, six ribs visible anteriorly or large airspace anterior to heart (> 1/3 of the length of the sternum), flattened diaphragms (best seen on lateral chest X-ray) and a paucity

of lung markings. Pulmonary hypertension is manifest by enlarged proximal and attenuated distal vascular markings and by RV and atrial enlargement. Lung bullae may be evident.

A high-resolution computed tomographic (CT) scan of the chest (1–2-mm slices) can demonstrate characteristic appearance and regional distribution of emphysema. It can also assess for coexistent bronchiectasis, LV failure<sup>17</sup> and pulmonary fibrosis. Such scans are less sensitive than standard chest CT scans (1-cm slice) for detecting pulmonary lesions (e.g. neoplasms). Nuclear ventilation perfusion scans can also provide a characteristic appearance of COPD.

An electrocardiogram (ECG) is commonly normal but may show features of right atrial or RV hypertrophy and RV strain, including P pulmonale, right-axis deviation, dominant R-waves in V1–2, right bundle-branch block, ST depression and T-wave flattening or inversion in V1–3. These changes may be chronic or may develop acutely if there is significant increase in pulmonary vascular resistance during the illness. The ECG may also show coexistent ischaemic heart disease, tachycardia and atrial fibrillation. Occasionally, continuous ECG monitoring is required to identify transient arrhythmias, which may also precipitate acute deterioration. Plasma brain natriuretic peptide (BNP) levels may also assist in the diagnosis of heart failure (elevated BNP) from pulmonary causes (low BNP) in patients under 70 years free of renal impairment.

### DIFFERENTIAL DIAGNOSIS

The history of *chronic asthma* is one of long-term dyspnoea, wheeze and cough, usually at night or upon exercise, beginning in childhood with clear-cut precipitating agents (e.g. weather, dust, pets, drugs) and a favourable response to either steroids or inhaled  $\beta_2$ -agonists. Late-onset asthma (>40 years of age) is not uncommon and is often associated with recurrent gastro-oesophageal reflux. In both forms of asthma, TLCO is normal. There is usually a bronchodilator response in the FEV<sub>1</sub> if the patient has unstable asthma. In patients in whom asthma is considered but lung function tests are normal, the FEV<sub>1</sub> response to an inhalational challenge (e.g. methacholine or hypertonic saline) may assist in discriminating asthma from other causes of dyspnoea.

Bronchiolitis obliterans is a condition which presents as a fixed airflow obstruction following a viral illness, inhalation of toxic fumes, following bone marrow or heart/lung transplantation, or related to drugs (e.g. penicillamine). It generally begins as a cough some weeks after insult and insidious onset of dyspnoea. There is a broad spectrum of radiological appearances from normal to reticulonodular to diffuse nodular. Lung tissue via bronchoscopy or by thoracoscopy is required for diagnosis. Histologically, there is a characteristic chronic bronchiolar inflammation appearance, and if granulation tissue extends into the alveoli, it is referred to as

bronchiolitis obliterans or organising pneumonia. Removal of the offending agent and instigation of steroids are generally associated with a favourable prognosis.

Bronchiectasis is often associated with fixed mild to moderate airflow obstruction. A chronic productive cough (daily for 2 consecutive years) is characteristic. Clinical features such as clubbing, localised pulmonary crackles and a characteristic appearance on high-resolution CT, with dilated or plugged small airways at least twice the size of accompanying blood vessel, assist in the diagnosis.

Chronic heart failure (CHF) may be a differential diagnosis of COPD, or simply coexist, as both disorders are common in smokers.<sup>14,16</sup> Orthopnoea and paroxysmal nocturnal dyspnoea are features which correlate with heart failure severity. A past history of myocardial ischaemia or atrial fibrillation should alert one to the possibility of heart failure. An echocardiogram and high-resolution CT (looking for shift in interstitial oedema with changes in posture from supine to prone)<sup>17</sup> are sensitive markers of CHF.

### DIAGNOSIS OF RESPIRATORY FAILURE

An exacerbation of COPD is usually clinically obvious. However, it is important to diagnose the extent of deterioration. The following may be useful.

#### BLOOD GASES

Blood gases are mandatory to assess hypoxia, hypercapnia and acid–base status. Chronic hypercapnia may be recognised by a bicarbonate level >30 mmol/l and a base excess >4 mmol/l indicating renal compensation. However, other causes of a high serum bicarbonate need to be excluded (e.g. diuretic therapy, high-dose steroids or high-volume gastric fluid loss) or chronic hypercapnia may be incorrectly assumed and the severity of COPD overestimated. Renal compensation for chronic hypercapnia will increase the serum bicarbonate by approximately 4 mmol/l for each 10 mmHg (1.33 kPa) of chronic  $P_{aCO_2}$  rise above 40 mmHg (5.3 kPa), in order to return pH to the low-normal range. Irrespective of the COPD patient's usual  $P_{aCO_2}$  level, an acute increase in  $P_{aCO_2}$  leads to a decreased arterial pH. This indicates that compensatory mechanisms are exhausted and there is an increased risk of respiratory collapse.

### NON-VENTILATORY MANAGEMENT

#### OXYGEN THERAPY

Oxygen given by low-flow intranasal cannulae or 24–35% Venturi mask should be titrated to achieve a saturation ( $SpO_2$ ) of  $90 \pm 2\%$  as these levels will avoid significant increases in  $P_{aCO_2}$  in the majority of COPD patients with ARF. Increases in  $P_{aCO_2}$  are most common in patients with initial  $P_{aCO_2} > 50$  mmHg and pH <7.35.<sup>18</sup> If the rise in

$P_{aCO_2}$  is excessive ( $>10$  mmHg or 1.33 kPa), then  $F_{iO_2}$  should be reduced, titrating  $S_{pO_2}$  to 2–3% below the previous value, and arterial blood gases should be repeated. If no  $P_{aCO_2}$  rise occurs with oxygen therapy, then a higher  $S_{pO_2}$  may be targeted with repeat blood gases.

Inadequate reversal of hypoxia (e.g.  $S_{pO_2} < 85\%$ ) is suggestive of an additional problem such as pneumonia, pulmonary oedema or embolus, or a pneumothorax. Investigation of this should commence and a higher  $O_2$  delivery system should be used (see Chapter 24). Although high levels of  $O_2$  should be avoided, reversal of hypoxia is important and  $O_2$  should not be withheld in the presence of hypercapnia, or withdrawn if it worsens.

### BRONCHODILATORS

Bronchodilators are routinely given in all acute exacerbations of COPD because a small reversible component of airflow obstruction is common, and bronchodilators improve mucociliary clearance of secretions.<sup>19</sup> However, a large meta-analysis of 22 large randomised controlled long-term trials of ambulatory COPD patients involving either anticholinergics and/or  $\beta_2$  agonists (short- and long-acting) over 3–60 months indicates that anticholinergics are more favourable than placebo in terms of acute exacerbations, hospitalisations and respiratory deaths.<sup>20</sup> There were no favourable advantages with  $\beta_2$ -agonists compared with placebo for acute exacerbations or hospitalisations, and placebo was better than  $\beta_2$ -agonists in terms of respiratory death.<sup>20</sup>

#### ANTICHOLINERGIC AGENTS

Anticholinergic agents, such as ipratropium bromide, have been shown to have a similar or greater bronchodilator action than  $\beta$ -agonists in COPD,<sup>1,21,22</sup> and also to have fewer side-effects and no tachyphylaxis. Anticholinergic agents should be used routinely in COPD with ARF and many now believe them to be the agent of first choice.<sup>1</sup> An ipratropium bromide nebule of 0.5 mg in 2 ml should be nebulised initially 2-hourly, then every 4–6 hours. Long-term use of ipratropium bromide has been shown to reduce the incidence of exacerbations<sup>23</sup> and is therefore recommended for chronic use in ambulatory COPD. Long-acting anticholinergics (e.g. tiotropium) offer potential of once-daily dosing.

#### NEBULISED $\beta_2$ -AGONISTS

Nebulised  $\beta$ -agonists are also effective bronchodilators in COPD,<sup>21,22</sup> although they may cause tachycardia, tremor, mild reductions in potassium and  $P_{aCO_2}$  (due to pulmonary vasodilatation) and tachyphylaxis. Nebulised  $\beta$ -agonists (e.g. salbutamol, terbutaline or fenoterol) given 2–4-hourly should be used routinely in combination with ipratropium. This combination has been shown to be more effective than either agent alone.<sup>1</sup> Parenteral sympathomimetic agents are rarely indicated and not recommended for routine use. In stable patients, long-term use of  $\beta$ -agonists may improve

symptoms of dyspnoea, particularly in the subgroup of COPD with an objective bronchodilator response. Long-acting  $\beta$ -agonists may also have a beneficial effect on symptoms, quality of life and exercise capacity in COPD.<sup>24</sup>

#### AMINOPHYLLINE

Aminophylline is a weak bronchodilator in COPD. It improves diaphragm contractility,<sup>25</sup> stimulates respiratory drive,<sup>26</sup> improves mucociliary transport<sup>27</sup> and right heart function,<sup>28</sup> is anti-inflammatory<sup>29</sup> and is a weak diuretic. Some studies have shown no benefit and significant side-effects,<sup>30</sup> whereas others have shown small benefit<sup>31</sup> in stable COPD. Theophylline has a number of additional effects that may also be of benefit in COPD, although the clinical importance of these is not yet established. For an exacerbation, aminophylline (loading dose 5–6 mg/kg IV over 30 min, followed by an infusion of 0.5 mg/kg per h) is commonly also given, despite doubt about its overall benefit. Serum theophylline levels must be monitored regularly to reduce risk of toxicity. The low therapeutic range should be targeted (55–85 mmol/l) for the best ratio of effect to side-effect.<sup>32</sup> The high therapeutic range (85–110 mmol/l) has little additional benefit and a significant increase in side-effects,<sup>32</sup> but is thought necessary for diaphragm contractility and respiratory stimulation effects. There is some evidence in favour of theophylline use in the long-term management<sup>33</sup> of COPD but, due to its narrow therapeutic window, it should be used with caution.

#### STEROIDS

In acute exacerbations of COPD, short-term steroids have been shown to improve airflow obstruction,<sup>34</sup> including those patients requiring mechanical ventilation for COPD.<sup>35</sup> Doses similar to those for acute asthma should be used. Methylprednisolone 0.5 mg/kg, given 6-hourly for 72 h, was used in the study by Albert *et al.*,<sup>34</sup> demonstrating benefit in patients with an exacerbation of COPD. Current American Thoracic Society guidelines recommend the equivalent to oral prednisolone at 0.5 mg/kg body weight for up to 10 days, then ceasing; however, this will depend upon the response to treatment, and their pre-morbid use.<sup>1</sup> Steroids should be avoided if the deterioration is clearly due to bacterial pneumonia without bronchospasm.

Longer-term oral steroids in COPD are associated with a substantial increased risk of side-effects (osteoporosis, diabetes, peptic ulcer, myopathy, systemic hypertension, fluid retention, weight gain), which are likely to impair quality of life and precipitate readmission and are therefore not recommended.<sup>1</sup> A small group of patients (15%) may demonstrate a significant bronchodilator response; coexistent asthma is likely in these patients and longer-term high-dose (oral or inhaled) steroids may be necessary. In the majority of patients, long-term inhaled steroids do not improve lung function or survival; however, they do improve quality of life and reduce admissions and are therefore recommended as long-term treatment at low to medium dose.<sup>1</sup>

### ANTIBIOTICS

Antibiotics have an accepted role in the treatment of infection-induced exacerbations of COPD. Amoxicillin is a suitable first-line agent against *Haemophilus influenzae* and *Streptococcus pneumoniae* for outpatient exacerbations.<sup>36</sup> Serious exacerbations requiring hospital admission require newer agents such as ciprofloxacin or a third-generation cephalosporin.<sup>37</sup> Antibiotics for pneumonia are discussed elsewhere in this volume.

### SECRETION CLEARANCE TECHNIQUES

Clearance of lower respiratory secretions is of crucial importance.

#### CHEST PHYSIOTHERAPY

Chest physiotherapy should be initiated and regularly repeated as both a curative and preventive measure. Encouragement of coughing and deep breathing are the two most important factors. 'Bubble positive expiratory pressure (PEP)' is an inexpensive method of assisting sputum clearance in patients with retained secretions or those having difficulty expectorating.

#### NEBULISED MUCOLYTIC AGENTS

Nebulised mucolytic agents, such as acetylcysteine, continue to be proposed, although their benefit has never been established in acute exacerbations of COPD.<sup>38</sup> Oral mucolytics have been shown to reduce cough frequency and severity in stable COPD.<sup>39</sup>

#### OROPHARYNGEAL/NASOPHARYNGEAL SUCTIONING

Oropharyngeal/nasopharyngeal suctioning can be performed with or without a nasopharyngeal airway. It is desirable but uncommon for the suctioning catheter to enter the trachea; the technique is useful in clearing pharyngeal secretions, stimulating coughing and clearing lower respiratory secretions coughed only as far as the hypopharynx in patients with suppressed conscious states.

#### FIBROPTIC BRONCHOSCOPY

Fibreoptic bronchoscopy is occasionally used in COPD with ARF. Although effective in clearing sputum, it is labour-intensive and may be poorly tolerated by a patient with marginal respiratory function. Indications are lobar consolidation, where sputum plug obstruction is suspected, for bronchoalveolar lavage to diagnose pneumonia or to assist difficult secretion clearance.

### OTHER MEASURES

Other adjunctive measures are applicable to some patients.

#### HYDRATION, DIURETICS, DIGOXIN AND VASODILATORS

COPD patients are sensitive to changes in fluid status and intravenous hydration should be undertaken with care

and minimised. Diuretics and digoxin are of benefit if LV failure is present. Even if evidence of LV failure is minimal, a trial of diuresis is worthwhile in patients refractory to usual treatment. Digoxin has been shown to improve LV function in patients with cor pulmonale.<sup>40</sup>

Diuretics will reduce fluid overload in cor pulmonale; however, care should be taken with severe pulmonary hypertension where a decrease in RV filling pressure may result in a low-output state. Digoxin is of no established benefit to RV function in cor pulmonale, where the primary problem is increased afterload.<sup>41</sup> Pulmonary hypertension is commonly present in severe COPD and is associated with a poor prognosis. In stable COPD pulmonary vasodilators may have acutely beneficial effects<sup>42</sup> but have not yet been shown to improve outcome.<sup>43</sup> In ARF, pulmonary hypertension invariably increases and may precipitate acute cor pulmonale. Although not clinically proven, pulmonary vasodilators have a rational basis in this setting. Numerous agents have been or are undergoing trials to reduce pulmonary hypertension in COPD. These agents include calcium channel blockers (e.g. nifedipine), endothelin receptor antagonists (e.g. bosentan), phosphodiesterase inhibitors (e.g. sildenafil) and prostacycline analogues (e.g. epoprostenil, iloprost and trepostinil).<sup>42</sup> Side-effects include systemic hypotension, tachycardia, worsening of hypoxia and failure to improve haemodynamics. A trial of vasodilators appears reasonable if cor pulmonale is present with ARF, provided that response to therapy is carefully monitored. The diagnosis and response to treatment of pulmonary hypertension may require a right heart catheter.

#### ANTICOAGULANTS

Subcutaneous heparin (e.g. 5000 units b.d.) is recommended as a prophylactic measure against venous thromboembolism. There is no evidence for warfarinisation in COPD patients with pulmonary hypertension.

#### ELECTROLYTE CORRECTION

Electrolyte correction is important. Hypophosphataemia is common and may cause respiratory muscle weakness.<sup>44</sup> Hypomagnesaemia,<sup>45</sup> hypocalcaemia<sup>46</sup> and hypokalaemia may also be present and may impair respiratory muscle function. Hyponatraemia may occur with inappropriate antidiuretic hormone release or with excess use of diuretics and inappropriate intravenous fluids.

#### HYPOTHYROIDISM

Hypothyroidism is an important condition to be recognised, particularly in the hypercapnic patient group.

#### INTERCOSTAL DRAINAGE

Intercostal drainage is indicated for pneumothorax and pleural effusions of sufficient volume to compromise respiratory function. Formal intercostal catheter insertion may be required but mandates hospital admission and is associated with infection and discomfort. Simple aspiration of pneumothoraces has been shown to result in few complications, a reduced admission rate and reduced hospital stay.

### RESPIRATORY STIMULANTS

Many drugs have been shown to increase respiratory drive and lower  $P_{aCO_2}$ . These include acetazolamide, medroxyprogesterone, naloxone, doxapram and almitrine. Use of such agents presupposes that the limiting factor is reduced respiratory drive, whereas the majority of ARF is limited by a reduced capacity to deal with an increased load to breathing. Side-effects include increased dyspnoea and fatigue, impaired sleeping, with almitrine, and increased pulmonary hypertension. Respiratory stimulants have not been shown to improve either short-term or long-term outcome. As a result respiratory stimulants are not recommended or used in ARF. Narcotic- or benzodiazepine-induced respiratory depression is best managed with the appropriate antagonist – naloxone or flumazenil.

### NUTRITION

Nutrition is important, as patients with severe COPD are often undernourished and suffer a deterioration in nutritional status when hospitalised. This poor nutritional state is associated with decreased respiratory muscle mass and strength, increased risk of fatigue, ARF and death. Enteral feeding is preferred, but parenteral nutrition should be considered if enteral feeding is not tolerated. Excessive carbohydrate calories should be avoided as this increases  $CO_2$  production (by ~15%) and may worsen respiratory failure. Low-carbohydrate/high-fat combinations are preferred in ARF during spontaneous ventilation.

### NON-INVASIVE VENTILATION (NIV)

NIV is a technique in which ventilatory support is provided via a nasal or facial mask without endotracheal intubation. There have been several randomised controlled trials of NIV in COPD patients with acute hypercapnic respiratory failure which have demonstrated improved respiratory physiology, reduced mortality (up to 12 months), reduced iatrogenic complications, reduced need for intubation and mechanical ventilation and reduced length of stay in hospital.<sup>47–50</sup> All studies have shown good tolerance of the technique (~80% of patients), with few side-effects, improvements in both oxygenation and  $P_{aCO_2}$  compared with medically treated control patients.<sup>51,52</sup>

The goal of this technique is: (1) to unload respiratory muscles and augment ventilation and oxygenation, reduce  $CO_2$  and correct acidosis until the underlying problem can be reversed; (2) when applied intermittently, to offset the adverse effects of sleep or position-induced adverse changes to ventilation, increased upper airway resistance and lung volume.

Indications for NIV are a deterioration of COPD with: (1) acute dyspnoea; (2) respiratory rate > 28 breaths/min; (3)  $P_{aCO_2}$  > 45 mmHg with a pH < 7.35, despite optimal medical treatment and not related to excessive

supplemental oxygen. Although these indications are for mild exacerbations, most randomised studies have used these as entry guidelines.<sup>47–50</sup> Initial guidelines recommended NIV use to be limited to patients with pH in the range 7.25–7.35; however, recent evidence suggests that NIV is useful even in those patients with lower pH values (to as low as 7.0) and associated more severe hypercapnia (as high as 140 mmHg).<sup>53</sup> Included in the indications are recently extubated patients in whom NIV has been shown to reduce reintubation rates significantly.<sup>54</sup> Recently NIV has been advocated for use in patients with hypoxic respiratory failure,<sup>55</sup> but success is significantly less in the setting of hypoxaemia and either normocapnia or hypocapnia.<sup>56</sup> NIV may also have a role in some patients where mechanical ventilation is considered inappropriate.

Side-effects of NIV have included discomfort, intolerance, skin necrosis, gastric distension and aspiration. Pressure support has been reported as better tolerated than assist/control.<sup>51</sup>

### INVASIVE MECHANICAL VENTILATION

#### OUTCOME OF ARF AND THE DECISION TO VENTILATE INVASIVELY

When respiratory failure progresses or fails to resolve despite aggressive conservative management, including NIV, mechanical ventilatory support may be necessary. The decision to ventilate requires careful consideration in some patients who may have near-end-stage lung disease and whose quality of life may not justify aggressive treatment. This decision requires consideration of the outcome of ARF.

Patients with COPD have a reduced life expectancy compared with an age-matched general population group and this life expectancy decreases in proportion with severity of COPD as assessed by FEV<sub>1</sub> (Figure 26.3).

An episode of ARF further decreases survival (see Figure 26.3). ARF precipitated only by bronchitis has a better outcome,<sup>2</sup> whereas ARF due to more serious causes, such as pneumonia, LV failure and pulmonary embolus, has a worse outcome<sup>57</sup> and studies including all such outcomes have lower survival rates (see Figure 26.3).

If ARF requires invasive mechanical ventilation, survival decreases further still (see Figure 26.3). Although the majority of patients do not require mechanical ventilation, the short-term survival in this more severe subset is still good, with a hospital survival rate in some series as high as 80%,<sup>58</sup> but 2- and 3-year survival is significantly lower (see Figure 26.3).<sup>59,60</sup> The severity of ARF and the severity of underlying COPD based on FEV<sub>1</sub>, lifestyle score and dyspnoea score are also predictors of outcome.<sup>13,57</sup> Lifestyle<sup>13</sup> and dyspnoea<sup>61</sup> categories may be the most useful factors in the decision to withhold mechanical ventilation. Lifestyle categories 3 (house-bound and at least partly dependent) and 4 (bed- or chair-bound) indicate both a

**Figure 26.3** Survival curves for various patient groups with chronic obstructive pulmonary disease (COPD). Note: these are approximations only, based on other studies<sup>13,57</sup> with different patient numbers, criteria and study periods. FEV<sub>1</sub>, forced expiratory volume in 1 second; ARF, acute respiratory failure.

poor outcome (see Figure 26.3)<sup>13</sup> and quality of life that may not justify aggressive treatment.

Thus invasive mechanical ventilation may be withheld in end-stage lung disease, when low survival, poor quality of life or permanent ventilator dependence are likely. This decision should be based on the following criteria. In general, patients must fulfil all the following criteria for invasive mechanical ventilation to be withheld:

- known severe COPD, which has been assessed and failed to respond to adequate therapy
- severe limitation of lifestyle by dyspnoea with a poor prior quality of life
- no identifiable reversible factors (e.g. pneumonia, sputum retention, LV failure)

If end-stage lung disease is suspected but there is insufficient information, then a trial of aggressive therapy, including invasive mechanical ventilation, should be undertaken and subsequently withdrawn if unsuccessful. Despite this, most patients with COPD who present with ARF do not have end-stage disease and, although their immediate problems may be life-threatening, their short-term outcome is sufficiently good to justify full active treatment.

#### INDICATIONS FOR INVASIVE MECHANICAL SUPPORT

- The clinical appearance of fatigue and impending respiratory collapse despite non-invasive ventilatory support
- Deteriorating conscious state due to fatigue or hypercapnia or both

- Hypoxia refractory to high levels of inspired O<sub>2</sub>
- Deterioration due to failure of secretion clearance
- Respiratory arrest

#### MECHANICAL VENTILATION TECHNIQUE

The goals of mechanical ventilation in COPD are to support ventilation while reversible components improve, to allow respiratory muscle to rest and recover whilst preventing wasting from total inactivity and to minimise dynamic hyperinflation. This is usually best accomplished with low-level ventilatory support. Patients requiring low-level support may be commenced on 8–15 cmH<sub>2</sub>O pressure support, with 3–8 cmH<sub>2</sub>O PEEP. Patients who are completely exhausted, postarrest, comatose or not tolerating pressure support alone, should be commenced or transferred to synchronised intermittent mandatory ventilation mode.

Excessive dynamic hyperinflation must be avoided by using a low minute ventilation – 115/ml per kg is a guideline<sup>6</sup> – and allowing adequate time for expiration. This should be achieved by the use of a small tidal volume (8 ml/kg) and a ventilator rate <14 breaths/min.<sup>6,62</sup> Dynamic hyperinflation can be assessed clinically, by visualising the expiratory flow–time curve, and by measuring plateau airway pressure ( $P_{plat}$ ) or PEEP<sub>i</sub>.  $P_{plat}$  should be measured by applying an end-inspiratory pause of 0.5 s. This should only be applied following a single breath as it shortens expiratory time and, if it is applied to a series of breaths, it increases dynamic hyperinflation, resulting in an increased  $P_{plat}$  level and increased risk to the patient. If  $P_{plat}$  is >25 cmH<sub>2</sub>O, there is likely to be dynamic hyperinflation, and the ventilator rate should be reduced. However,  $P_{plat}$  may be high without dynamic hyperinflation if chest wall compliance is low. Intrinsic PEEP measured as a prolonged end-expiratory pause more directly assesses dynamic hyperinflation. Provided PEEP<sub>i</sub> is accurately measured, it is a useful tool to follow dynamic hyperinflation. In severe airflow limitation it may be necessary to accept low levels of PEEP<sub>i</sub>, but as PEEP<sub>i</sub> rises above 8–10 cmH<sub>2</sub>O, further prolongation of expiratory time must be considered. Although still controversial, the use of a high inspiratory flow rate is recommended,<sup>6,63</sup> as it results in a shorter inspiratory time and hence a longer expiratory time for a given ventilatory rate. It has been shown to reduce dynamic hyperinflation and alveolar pressure<sup>6</sup> further and to improve gas exchange.<sup>63</sup>

If dynamic hyperinflation is excessive and causing circulatory compromise or risk of barotrauma, then minute ventilation should be decreased, hypercapnic acidosis accepted and spontaneous ventilation, which will only increase dynamic hyperinflation, should be discouraged by sedation. Muscle relaxants should be avoided unless essential. When dynamic hyperinflation is critical during controlled mechanical ventilation, PEEP<sub>i</sub> increases pulmonary hyperinflation and should not be applied.<sup>64</sup>

If dynamic hyperinflation is not excessive then spontaneous ventilation should be encouraged to promote ongoing respiratory muscle activity and to minimise wasting. Flow-by, pressure support and low-level CPAP may all reduce the work of spontaneous breathing and promote a better ventilatory pattern. CPAP approximately equal to the level of PEEP<sub>i</sub> is most commonly recommended.<sup>65</sup> Care must be taken with all of these supports as each can increase dynamic hyperinflation by a different mechanism, leading to circulatory compromise or risk of barotrauma. Flow-by increases resistance through the expiratory valve, pressure support increases tidal volume and may increase inspiratory time and CPAP increases FRC.

#### WEANING FROM INVASIVE MECHANICAL VENTILATION

Weaning a patient with severe COPD from ventilatory support can be difficult and prolonged. Numerous criteria have been proposed to assess the capacity of the patient to wean;<sup>66</sup> however, the predictive value of any of these individual criteria is limited. The simple criterion of patient respiration rate/tidal volume < 100 breaths/min per litre had the best predictive value for weaning success, but the advantage of this overly simple clinical assessment during weaning is uncertain.<sup>66</sup> Weaning or withdrawal of ventilation is further discussed elsewhere in this volume.

#### TRACHEOSTOMY

In a small group of patients who have failed extubation despite NIV or who have required long-term ventilatory support, tracheostomy may be beneficial. After 10 days of endotracheal intubation, the risk of trauma and sepsis increases.

A tracheostomy allows long-term ventilatory support, sputum clearance, protection of the upper airway from oral secretions and, off mechanical ventilation, reduced dead space and upper-airway resistance. Compared with naso/orotracheal intubation, tracheostomy is much less intrusive and therefore less sedation is required. Also, it allows direct access to the large airways for the purpose of suctioning and bronchoscopy. However, patients are unable to generate sufficient upper-airway seal to cough, and as such may have ongoing atelectasis until tracheostomy removal and the development of an effective cough. Usually a nasogastric feeding tube is required. Consider percutaneous endoscopic gastrostomy (PEG) tube feeding if long-term tracheostomy is being considered to avoid nasal trauma and infection and to reduce oesophagitis. Minimal occlusion tracheostomy cuff pressures (usually < 20 cmH<sub>2</sub>O) should be checked 8-hourly. Use of double-lumen tracheostomies with adequate humidification is recommended to allow for inner-tube cleaning and the avoidance of occlusion due to dried secretions.

Consider removing the tracheostomy when:

1. there is an absence of upper-airway obstruction (e.g. no granulation tissue or tracheal stenosis)

2. suctioning is becoming less frequent (< 2–4-hourly)
3. the patient is cooperative and has a good capacity to cough, for example, good respiratory muscle strength
4. the patient is able to protect the upper airway from aspiration
5. the patient is less dependent on invasive ventilatory support (e.g. not continuous) and non-invasive ventilatory support is available
6. there is a decreasing oxygenation requirement (e.g.  $F_{iO_2} < 40\%$ )

#### FAILED WEANING

A small group of patients with end-stage lung disease will be unable to wean successfully from ventilator support despite optimisation of all reversible factors. A number of options now exist for such patients:

- long-term institutional or home ventilatory support
- withdrawal of support. Permanent institutional mechanical ventilation for a patient with low general health status represents a poor quality of life and withdrawal of support may be a preferable alternative

### POST INTENSIVE UNIT CARE

#### REHABILITATION

Rehabilitation should be considered for all patients with COPD, particularly those following ARF. There are numerous randomised controlled trials showing improvements in exercise physiology, lung function, quality of life and reduced hospitalisation rates.<sup>67,68</sup> Such programmes include extensive education and aerobic upper and lower-limb and respiratory muscle exercise, usually three times per week over a 6-week period. Patients are recommended to continue with exercises regularly and independently thereafter.

#### VACCINATION

Vaccination should be considered in all patients with COPD when stable. Annual influenza and 5-yearly pneumococcal vaccination is recommended.<sup>1</sup>

#### LUNG VOLUME REDUCTION SURGERY

Lung volume reduction surgery is a palliative surgical procedure for patients aged < 75 years, with advanced disabling emphysema. Poorly perfused and poorly ventilated areas of one or both lungs, thought to compress relatively preserved areas of well-functioning lung tissue, are excised by either midline sternotomy or endoscopically, with video assistance.<sup>69</sup> Such areas in the lung, usually apically placed, are determined by V/Q scans and high-resolution CT scans. Suitable patients must have undergone a pulmonary rehabilitation programme, be on optimal medical treatment and have disabling dyspnoea

and anatomically suitable (apical bullous) emphysema. Patients with profoundly severe emphysema (e.g. FEV<sub>1</sub> or TLCO < 20% predicted) are unlikely to benefit.<sup>69</sup> Group mean data suggest that the mean FEV<sub>1</sub> increases from 0.5 to 0.91 litres, and the mean 6-min walk distance increases from 205 to 290 metres, both associated with significant improvement in quality of life. The peak improvements in physiology occur at 1–2 years and thereafter decline to presurgical levels. Improvements in survival are yet to be determined.<sup>69</sup>

### LUNG TRANSPLANTATION

Lung transplantation is another palliative surgical procedure for patients with advanced disabling COPD who are aged < 65 years, are not ventilator-dependent, are on less than 10 mg prednisolone/day and are free of significant coexistent disease. It may be used following lung volume reduction surgery. The current 1-, 2- and 5-year international survival figures are 75, 66 and 50% respectively.<sup>70</sup> Common complications are systemic hypertension, bronchiolitis obliterans, acute rejection, viral infection with cytomegalovirus and neoplasms.<sup>66</sup> Its widespread application in COPD is in doubt because of the very limited supply of donor lungs.<sup>71</sup>

### PROGNOSIS

Patients with sufficiently severe COPD to warrant hospital admission incur an inpatient mortality of 7%, and 90-day mortality of 15% in the UK.<sup>72</sup> Predictors of mortality were performance status, age and admission urea, albumin, pH and SpO<sub>2</sub> plus the presence of respiratory physicians involved in the care.<sup>72</sup> Although in-hospital mortality for hypercapnic COPD patients may reach 62%,<sup>73</sup> in an Australian report, in-hospital mortality for hypercapnic COPD patients treated with NIV was 11% and all deaths

**Table 26.3** The body mass index, airflow obstruction, dyspnoea and exercise capacity (BODE) index (maximum is 10)

Score	0	1	2	3
FEV <sub>1</sub> (% predicted)	>65	50–64	36–49	<35
Six-minute walk distance	>350	250–350	150–250	<150
Modified MRC dyspnoea score	0–1	2	3	4
Body mass index	>21	<21		

The 4-year survival rates are 80% for a score of 2, 70% for 3–4, 60% for 5–6 and 20% for scores 7–10. Modified Medical Research Council (MRC) score is from zero (no dyspnoea) to 4 (extreme dyspnoea upon getting dressed or leaving the house).<sup>75</sup> FEV<sub>1</sub>, forced expiratory volume in 1 second.

were with palliative intent, which followed time to allow for patient and family discussions. In Hong Kong, acute hypercapnic COPD patients have a 12-month readmission rate of 80% and a 49% 1-year mortality.<sup>74</sup> The body mass index, airflow obstruction, dyspnoea and exercise capacity (BODE) index<sup>75</sup> is a 10-point scale made up from the following four variables: (1) body mass index; (2) airflow obstruction; (3) severity of dyspnoea; and (4) exercise capacity, and has been found to be very useful in predicting survival in ambulatory patients with COPD (Table 26.3).

# Mechanical ventilation

Andrew D Bersten

Mechanical ventilation for acute respiratory failure (ARF) is now a routine aspect of patient management in the intensive care unit (ICU). The 1952 Copenhagen polio epidemic introduced the notion of organised areas (ICU) for the provision of positive-pressure ventilation,<sup>1</sup> which was usually applied through a tracheostomy that had been inserted to allow suction of secretions. However, methods of ventilatory assistance without intubation had proliferated prior to the polio epidemic (both negative-pressure chest wall devices and positive-pressure face mask devices), and current trends are to an increased use of non-invasive ventilation (NIV) in patients with respiratory failure.<sup>2</sup>

Almost all of the ventilatory modes that are conventionally applied during *intubated* ventilation (IV) can be applied *non-invasively*; however, IV remains the primary mode of respiratory assistance in critically ill patients. There are also an increasing number of patients receiving chronic ventilatory assistance but, since the majority of these use chronic NIV, this chapter is primarily directed at intubated mechanical ventilation for both ARF and acute-on-chronic respiratory failure.

## A PHYSIOLOGICAL APPROACH

During normal spontaneous breathing, contraction of the respiratory muscles overcomes both the elastic recoil and resistance of the respiratory system (lung and chest wall). A fall in regional pleural pressure results in alveolar inflation as gas is forced in under the resultant pressure gradient. Expiration is usually passive but the expiratory muscles may assist the elastic recoil of the respiratory system.

The work ( $W$ ) performed by the respiratory muscles ( $W_{\text{mus}}$ ) can be measured from the relationship between pressure ( $P$ ) and volume ( $V$ ), and partitioned into elastic ( $W_{\text{el}}$ ) and resistive ( $W_{\text{res}}$ ) work:

$$W_{\text{mus}} = W_{\text{el}} + W_{\text{res}} \quad \text{Equation 1}$$

Inertial work is negligible, and usually ignored. Further, Equation (1) does not explicitly describe the elastic work required to initiate inspiration when intrinsic positive end-expiratory pressure (PEEP<sub>i</sub>) is present.

Because volume is constant in Equation (1), it can be simplified to:

$$P_{\text{mus}} = P_{\text{el}} + P_{\text{res}} \quad \text{Equation 2}$$

It follows that, during positive-pressure ventilatory assistance, where  $P_{\text{ao}}$  is the ventilatory pressure applied at the airway:

$$P_{\text{ao}} + P_{\text{mus}} = P_{\text{el}} + P_{\text{res}} \quad \text{Equation 3}$$

and that when the work is solely applied by the ventilator with no respiratory muscle contraction (controlled mechanical ventilation (CMV)):

$$P_{\text{ao}} = P_{\text{el}} + P_{\text{res}} \quad \text{Equation 4}$$

This nomenclature allows physiologic discussion of the different ventilatory modes, from controlled ventilation to spontaneous, unassisted ventilation, and introduces the equation of motion, which is used in the estimation of respiratory mechanics:

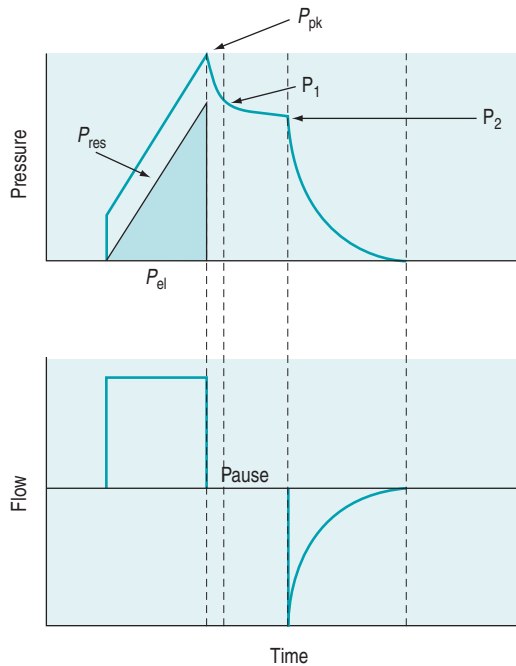

$$P_{\text{ao}} = E_{\text{rs}} \cdot V + R_{\text{rs}} \cdot \dot{V} + P_0 \quad \text{Equation 5}$$

where  $E_{\text{rs}}$  is the respiratory system (lung and chest wall) elastance (the inverse of compliance),  $R_{\text{rs}}$  is the respiratory system resistance,  $\dot{V}$  is the gas flow rate and  $P_0$  is the total PEEP (the sum of extrinsic PEEP [PEEP<sub>c</sub>] and PEEP<sub>i</sub>). PEEP<sub>i</sub> imposes a threshold load – additional elastic work – as inspiratory muscle contraction must occur without  $\dot{V}$  until  $P_{\text{ao}}$  falls below atmospheric pressure (see section on patient–ventilator interaction, below).

## MODES OF VENTILATION

### CONTROLLED MECHANICAL VENTILATION

The simplest form of positive-pressure breath occurs in a relaxed subject, and the ventilator provides a constant gas flow during inspiration. The volume delivered will depend upon the inspiratory time ( $T_i$ ), and  $P_{\text{ao}}$  during inspiration will reflect  $E_{\text{rs}}$  and  $R_{\text{rs}}$  (Figure 27.1). Expiration is a passive, and usually exponential, decline in volume to the relaxation volume of the respiratory system, equal to the functional residual capacity (FRC).

**Figure 27.1** Schematic diagram of a volume-controlled breath with constant inspiratory flow. A period of no inspiratory gas flow has been interposed before expiration (pause) to illustrate dissipation of lung resistance as airways resistance (fall from  $P_{pk}$  to  $P_1$ ) and tissue resistance (fall from  $P_1$  to  $P_2$ ). The inspiratory pressure due to the elastic properties of the respiratory system is illustrated as the filled area ( $P_{el}$ ), and the lung resistive pressure is labelled as  $P_{res}$ . See text for more detail.

CMV is the most basic form of mechanical ventilation; however, it is an extremely useful baseline, and is still commonly used. A preset minute ventilation is made up from a fixed respiratory rate ( $f$ ) and tidal volume ( $V_T$ ). Provided that there are not large variations in alveolar dead space, this maintains a preset alveolar ventilation ( $V_A$ ) and  $CO_2$  clearance. Consequently, CMV is useful in conditions where there is alveolar hypoventilation (e.g. respiratory muscle weakness), when  $P_{aCO_2}$  needs to be maintained in a fixed range (e.g. raised intracranial pressure) or when the work of breathing must be minimised (e.g. severe cardiorespiratory failure). Because CMV may not match respiratory drive, and spontaneous, supported or assisted breaths are not possible during CMV, sedation, and sometimes muscle paralysis, may be needed. CMV is usually combined with  $PEEP_c$ , which can recruit collapsed lung and reduce intrapulmonary shunt. The components are discussed below.

#### TIDAL VOLUME ( $v_T$ )

Although traditional CMV  $V_T$  has been 12–15 ml/kg, this may result in excessive lung stretch, particularly in

patients with acute lung injury (ALI), leading to ventilator-induced (VILI) – also described as ventilator-associated – lung injury (VALI).<sup>3</sup> The basis for this larger  $V_T$  can be traced back to progressive atelectasis and intrapulmonary shunt, when physiologic  $V_T$  was used during general anaesthesia. This could be reversed by larger  $V_T$  ventilation or intermittent sigh breaths.<sup>4</sup> In patients with ALI,  $V_T$  of 6 ml/kg versus 12 ml/kg predicted body weight (i.e. often 4–5 ml/kg versus 9–10 ml/kg true weight) reduced mortality from 40% to 31%.<sup>5</sup> Consequently, lower  $V_T$  should be strongly considered during CMV, and other forms of ventilatory assistance in patients with ALI. However, greater levels of PEEP are usually required; similar data are not available for other respiratory diseases. Indeed, although the reduction in  $V_T$  is particularly applicable to ALI, excessive lung stretch will be less likely in other patient cohorts that are able to ventilate a greater proportion of the lung (see Chapter 29).

#### RESPIRATORY RATE ( $f$ )

The desired minute ventilation can be selected from the product of  $V_T$  and  $f$ . Common CMV rates are 10–20 breaths/min in adults. Sufficient expiratory time ( $T_e$ ) must be allowed to minimise dynamic hyperinflation and  $PEEP_i$ . Although high  $f$  (up to 35 breaths/min) were allowed in the Acute Respiratory Distress Syndrome (ARDS) Network protocol, and the low- $V_T$ , low-mortality group had a mean  $f$  of ~30 breaths/min,<sup>5</sup> laboratory data suggest a possible additive role of high  $f$  in VILI.<sup>6</sup>

#### INSPIRATORY FLOW PATTERN

The simplest form of CMV uses a constant inspiratory flow ( $\dot{V}_I$ ), and in combination with  $T_i$ , a preset volume is delivered. This is also called volume-controlled ventilation (VCV), and some ventilators use  $V_T$  and  $T_i$  to set  $\dot{V}_I$ . Alternative  $\dot{V}_I$  patterns that are commonly available with VCV include a ramped descending flow pattern and a sine pattern. When a time-preset inspiratory pressure is delivered, this is termed pressure-controlled ventilation (PCV).

There are no convincing outcome data differentiating these different modes of CMV and PCV. Although the peak airway pressure ( $P_{pk}$ ) is lower with PCV than constant-flow CMV, the alveolar distending pressure, which is usually inferred from the plateau pressure ( $P_{plat}$ ), is no different provided that  $T_i$  and  $V_T$  are the same.<sup>7</sup> During PCV,  $P_{res}$  is dissipated during inspiration so  $P_{pk}$  and  $P_{plat}$  are equal, and during CMV,  $P_{res}$  accounts for the difference between  $P_{pk}$  and  $P_{plat}$  (Figure 27.2). Similarly, different CMV<sub>I</sub> patterns will alter  $P_{pk}$  without changing  $P_{plat}$  or mean airway pressure ( $P_{mean}$ ) when  $T_i$  and  $V_T$  are constant. In ARDS patients, comparing VCV and PCV, there is no difference in haemodynamics, oxygenation, recruited lung volume or distribution of regional ventilation;<sup>7,8</sup> however, PCV may dissipate viscoelastic strain earlier.<sup>8</sup> However, high  $\dot{V}_I$  may cause or exacerbate VILI,<sup>9</sup> which may explain why some animal models have found PCV to be injurious compared to VCV, as PCV inherently has a high early  $\dot{V}_I$ .

**Figure 27.2** Actual pressure–time data from a patient with acute lung injury ventilated with volume-controlled ventilation (panel A), and then with pressure-controlled ventilation (panel B); tidal volume, I:E ratio and respiratory rate are constant. The airway pressure ( $P_{aw}$ , bold line) has been broken down to its components,  $P_{el}$  and  $P_{res}$  (see Figure 27.1). Although there is no inspiratory pause, there is marked similarity between panel A and Figure 27.1, with the inspiratory difference between  $P_{aw}$  and  $P_{el}$  due to a constant  $P_{res}$ . In panel B, the decelerating inspiratory flow pattern seen with pressure-controlled ventilation results in dissipation of  $P_{res}$  by end-inspiration. Consequently, during pressure-controlled ventilation  $P_{aw} \approx P_{plat}$  obtained during volume-controlled ventilation. In other words, for the same ventilator settings there is no difference in the elastic distending pressure.

Pressure-regulated volume control (PRVC) is a form of CMV where the  $V_T$  is preset, and achieved at a minimum pressure using a decelerating flow pattern.

### INSPIRATORY PAUSE

An end-inspiratory pause allows examination of the decay in  $P_{pk}$ , and measurement of  $P_{plat}$ . If  $T_i$  and  $V$  are maintained constant there is no improvement in oxygenation, and a more rapid  $\dot{V}_I$  will be needed. This may alter the distribution of ventilation. Theoretically, an end-inspiratory pause will allow a 32% dissipation of the total energy loss within the respiratory system,<sup>10</sup> which may significantly reduce

the forces driving expiration, and this could exacerbate gas trapping in patients with severe airflow limitation.

### INSPIRATORY TIME, EXPIRATORY TIME, I:E RATIO

The combination of  $V_T$  and inspiratory  $\dot{V}$  will determine  $T_i$ , which in combination with  $f$  sets  $T_c$ . A typical  $T_i$  is 0.8–1.2 s; with a  $V_T$  of 500 ml and inspiratory  $\dot{V}$  of 0.5 l/s, the  $T_i$  is 1.0 s. During spontaneous ventilation, the distribution of ventilation at low  $\dot{V}_I$  is determined by regional  $E$ , and at high inspiratory  $\dot{V}$  by regional  $R$ , leading to greater ventilation of non-dependent lung. In patients with severe airflow limitation high inspiratory flow rates may be used in order to prolong  $T_c$  and minimise dynamic hyperinflation.<sup>11</sup>

The I:E ratio is usually set at or below 1:2 to allow an adequate  $T_c$  for passive expiration. During inverse-ratio ventilation (IRV), the I:E ratio is greater than 1:1. The putative benefits of a prolonged  $T_i$  include recruitment of long time-constant alveoli, and a short  $T_c$  results in gas trapping and PEEP<sub>i</sub>. Early reports of clinical benefit did not control for PEEP<sub>i</sub>, and when total PEEP,  $f$  and  $V_T$  are constant,<sup>7,8</sup> pressure control (PC) IRV tends to reduce  $P_{aCO_2}$  but does not improve oxygenation, may have deleterious haemodynamic effects and may exaggerate regional overinflation.<sup>8</sup>

### POSITIVE END-EXPIRATORY PRESSURE

PEEP is an elevation in the end-expiratory pressure upon which all forms of mechanical ventilation may be imposed. When PEEP is maintained throughout the respiratory cycle in a spontaneously breathing subject, the term ‘constant positive airway pressure’ (CPAP) is used. The primary role of PEEP is to maintain recruitment of collapsed lung, increase FRC and minimise intrapulmonary shunt. PEEP may also improve oxygenation by redistributing lung water from the alveolus to the interstitium, and although there is no direct effect of PEEP to reduce extravascular lung water, this may occur in patients with left ventricular failure due to a reduction in venous return and left ventricular afterload. Further, inadequate PEEP may contribute to VILI by promoting tidal opening and closing of alveoli.<sup>3</sup> PEEP levels of 5–15 cmH<sub>2</sub>O are commonly used, and levels up to 25 cmH<sub>2</sub>O may be required in patients with severe ARDS. Although a large multicentre study found no benefit of higher PEEP levels when  $V_T$  was 6 ml/kg,<sup>12</sup> individual titration may need to be considered.

PEEP titration in ARDS is complex (see Chapter 29), and should aim to improve oxygenation and minimise VILI. Since PEEP reduces venous return, cardiac output and O<sub>2</sub> delivery may fall despite an improvement in  $P_{aO_2}$ ; indeed, this concept has been used to optimise PEEP in ARF.<sup>13</sup> However, in addition to recruitment, increasing PEEP may lead to overinflation of non-dependent alveoli which are already aerated at end-expiration.<sup>14,15</sup> This will be less likely if alveolar distending pressure is kept < 30–35 cmH<sub>2</sub>O, or the change in driving pressure is < 2 cmH<sub>2</sub>O when  $V_T$  is constant.<sup>16</sup>

PEEP<sub>c</sub> is applied by placing a resistance in the expiratory circuit (Figure 27.3), with most ventilators using a solenoid valve. Independent of the technique, a threshold resistor is preferred since it offers minimal resistance to flow once its opening  $P$  is reached. This will minimise expiratory work, and avoid barotrauma during coughing or straining.

PEEP<sub>i</sub> is an elevation in the static recoil pressure of the respiratory system at end-expiration. PEEP<sub>i</sub> arises due to an inadequate  $T_c$ , usually in the setting of severe airflow obstruction. However, it may be a desired endpoint during IRV. The sum of PEEP<sub>c</sub> and PEEP<sub>i</sub> is the total PEEP (PEEP<sub>tot</sub>). The distribution of PEEP<sub>i</sub> is likely to be less uniform than an equivalent PEEP<sub>c</sub>, and this may not have the same physiological effects. When patients with severe airflow obstruction are triggering ventilation, PEEP<sub>c</sub> less than PEEP<sub>i</sub> may be applied to reduce elastic work (see section on patient–ventilator interaction, below).

Figure 27.3 Positive end-expiratory pressure values.

#### FRACTIONAL INSPIRED OXYGEN CONCENTRATION ( $F_{iO_2}$ )

Adequate arterial oxygen saturation is achieved through a combination of minute ventilation, PEEP and  $F_{iO_2}$  adjustment. Even patients with normal respiratory systems usually need an  $F_{iO_2} > 0.21$ , due to ventilation–perfusion mismatch secondary to positive-pressure ventilation. In patients with ARF it is common to start with an  $F_{iO_2}$  of 1 and titrate down as PEEP and minute ventilation are adjusted. Because high  $F_{iO_2}$ s are damaging to the lung, and nitrogen washout may exacerbate atelectasis, it is reasonable to aim at an  $F_{iO_2} \leq 0.6$ .

#### SIGH

Many ventilators have the ability to deliver a breath intermittently at least twice  $V_T$ . Sighs may reduce atelectasis, in part through release of pulmonary surfactant,<sup>17</sup> resulting in recruitment and improved oxygenation in ARDS.<sup>18</sup> However, if sighs or recruitment manoeuvres are used, care must be taken to avoid recurrent excessive lung stretch.

#### ASSIST-CONTROL VENTILATION (ACV)

During ACV, in addition to the set  $f$ , patient effort can trigger a standard CMV breath (Figure 27.4). This allows greater patient comfort; however, there may be little reduction in respiratory work compared to an unassisted breath at low  $V_i$ , because the respiratory muscles continue to contract through much of the breath.<sup>19</sup> The equivalent PCV breath is termed pressure assist-control ventilation (PACV). Differences between triggering modes will be discussed below, in the section on patient–ventilator interaction.

#### INTERMITTENT MANDATORY VENTILATION (IMV), SYNCHRONISED IMV (SIMV)

IMV was introduced over 20 years ago to aid weaning from CMV by allowing the patient to take unimpeded breaths while still receiving a background of controlled breaths. Proposed advantages include a reduction in sedation, lower mean intrathoracic pressure with less barotrauma and adverse haemodynamic consequences, improved intrapulmonary gas distribution, continued use of respiratory muscles and faster weaning. During SIMV  $T_i$  is partitioned into patient-initiated and true spontaneous breaths to avoid breath-stacking. However, during spontaneous breaths the work of breathing imposed by the endotracheal tube, circuit and ventilator must be overcome.<sup>20</sup> In weaning studies comparing SIMV with T-piece trials and pressure support ventilation (PSV), SIMV is the slowest.<sup>21</sup> Many clinicians add PSV during gradual reduction in respiratory rate with SIMV to overcome the added respiratory work imposed by the circuit and endotracheal tube; however, this approach has not been formally compared with other weaning techniques.

**Figure 27.4** Schematic representation of airway pressure versus time for a variety of forms of ventilatory assistance. SV, spontaneous ventilation; CPAP, continuous positive airway pressure; PEEP, positive end-expiratory pressure; CMV, controlled mechanical ventilation; IMV, intermittent mandatory ventilation; PSV, pressure support ventilation; IRV, inverse-ratio ventilation; APRV, airway pressure release ventilation.

**PRESSURE SUPPORT VENTILATION**

During PSV, each patient-triggered breath is supported by gas flow to achieve a preset pressure, usually designated to be above the  $PEEP_c$ . This can be explained by referring to the equation of motion where:

$$P_{mus} + P_{ao} = E_{rs} V + R_{rs} \dot{V} + P_o \quad \text{Equation 6}$$

During PSV,  $P_{ao}$  is the targeted variable by the ventilator, which leads to a significant and important reduction in  $P_{mus}$  and work of breathing.<sup>22</sup> The detection of neural expiration varies between ventilators, but commonly relies upon a fall in the inspiratory  $\dot{V}$  to either 25% of the initial flow rate or to less than 5 l/min: some ventilators allow titration of the percentage reduction in initial flow to allow improved patient-ventilator synchrony. PSV may also be titrated to offset the work imposed by

the circuit and endotracheal tube. The absolute level required to offset this will vary with endotracheal tube size and inspiratory  $\dot{V}$ ,<sup>23</sup> but is commonly 5–10 cmH<sub>2</sub>O.<sup>24</sup> PSV can be used during weaning, or as a form of variable ventilatory support, with pressures of 15–20 cmH<sub>2</sub>O commonly used. Disadvantages include variable  $V_T$ , and hence minute ventilation, the potential to deliver an excessive  $V_T$  (common in patients recovering from ARDS), and patient-ventilator dyssynchrony (see below).

Volume-assured pressure support (VAPS) is a mode of adaptive PSV where breath-to-breath logic achieves a preset  $V_T$ .

**PROPORTIONAL ASSIST VENTILATION (PAV)**

PAV is a form of partial ventilatory support where inspiratory  $P$  is applied in proportion to patient effort. Because this allows the breathing pattern and minute ventilation to be matched to patient effort, it is only suitable if respiratory drive is normal or elevated. In concept this should optimise the patient-ventilator interaction; however, the prescription of PAV requires a greater level of physiological understanding than similar forms of partial ventilatory support such as PSV, since there is no target  $P$ ,  $V$  or  $\dot{V}$ . PAV is usually prescribed using volume assist (VA) and flow assist (FA), with  $V$  and  $\dot{V}$  measured continuously. VA generates greater  $P$  as  $V$  increases, leading to elastic unloading, and FA generates greater  $P$  as  $\dot{V}$  increases, leading to resistive unloading. Not surprisingly, the units of VA are cmH<sub>2</sub>O/L (i.e. an elastance term) and those for FA are cmH<sub>2</sub>O/l per second (i.e. a resistance term). This can be illustrated by referring to Equation (6):

$$P_{mus} + P_{ao} = E_{rs} V + R_{rs} \dot{V} = P_o$$

where  $P_{ao}$  is determined by PAV, where  $PAV = VA + FA$ , so:

$$P_{mus} + VA \times V + FA \times \dot{V} = E_{rs} V + R_{rs} \dot{V} + P_o \quad \text{Equation 7}$$

consequently

$$P_{mus} = (E_{rs} - VA)V + (R_{rs} - FA)\dot{V} + P_o \quad \text{Equation 8}$$

If  $E_{rs}$  and  $R_{rs}$  are known, PAV can, at least in principle, be targeted to reduce a specified proportion of either, or both, elastic and resistive respiratory work. For example, when VA and FA are adjusted to counterbalance  $E_{rs}$  and  $R_{rs}$  so as to achieve normal values, minute ventilation increases, and respiratory drive and work decrease; if  $PEEP_i$  is present, work can be further reduced by applying  $PEEP_c$ .<sup>25</sup> Estimates of respiratory mechanics are relatively hard to measure in spontaneously breathing patients; however, they are now offered on some ventilators. Consequently, PAV is often titrated to patient comfort. Despite a growing body of data demonstrating reduced work of breathing and improved patient-ventilator synchrony with PAV, it is a more difficult technique to use,

and definitive studies showing a clinically important outcome difference are awaited.

### BILEVEL VENTILATION

Also described as biphasic positive airway pressure (BIPAP), this is a ventilatory mode where two levels of airway pressure are provided. The patient may cycle between these two levels as triggered by their ventilatory effort, in which case inspiratory positive airway pressure (IPAP) and expiratory positive airway pressure (EPAP) are set; however, this is no different to equivalent support with PSV and PEEP. Another use of bilevel ventilation is to allow spontaneous breathing at both levels of airway pressure, with time cycling between both pressure levels (high and low CPAP). An example of this is airway pressure release ventilation (APRV), where minute ventilation and CO<sub>2</sub> excretion are augmented by brief (1–1.5 s) periodic cycling to the lower level of CPAP. As the augmented  $V_T$  is dependent upon elastance of the respiratory system, it will be smaller in patients with ‘stiff’ respiratory systems. APRV without spontaneous breathing has a similar pressure profile to PCIRV.

Adequate ventilatory support can be supplied by both of these forms of bilevel ventilation. Patient-triggered bilevel ventilation is most commonly used during NIV; APRV offers a number of benefits and is usually applied during IV. Spontaneous respiratory efforts may: (1) improve matching of ventilation and perfusion due to increased dependent aeration; (2) increase venous return and hence cardiac output; and (3) promote reduced sedation. However, oxygenation does not immediately improve, and unsupported spontaneous breaths may increase left ventricular afterload and promote ventilator–patient dyssynchrony. APRV is contraindicated in chronic obstructive pulmonary disease, asthma and when deep sedation is required.

### HIGH-FREQUENCY VENTILATION (HFV)

HFV encompasses techniques where small  $V_T$  (1–3 ml/kg) are delivered at high  $f$  (100–300/min). Hazards include inadequate humidification and gas trapping in patients with severe airflow limitation. High-frequency jet ventilation (HFJV) utilises dry gas from a high-pressure source delivered into an intratracheal catheter or specifically manufactured endotracheal tube. High-frequency oscillation (HFO) uses oscillatory flow within the airway to provide active inspiration and expiration at rates of 3–20 Hz. HFO offers benefit over conventional ventilation in neonates and children with respective infant and acute respiratory distress syndrome; data in adults are inconclusive.<sup>26</sup> HFJV has been used with improvement in gas exchange in adults with ARDS.<sup>27</sup>

### LIQUID VENTILATION

Perfluorocarbons have a high solubility for both O<sub>2</sub> and CO<sub>2</sub>, and reduce surface tension, somewhat analogous

to pulmonary surfactant. Partial liquid ventilation is now the most common method of administration, with perfluorocarbon equal to the FRC administered via the endotracheal tube. The non-dependent lung is still ventilated, and may have increased blood flow due to compression of the pulmonary circulation in the dependent lung by the perfluorocarbon. Together with the perfluorocarbon-mediated reduction in surface tension, alveoli are recruited and oxygenation improved. However, when PEEP is applied the perfluorocarbon may be pushed distally and overdistend dependent alveoli.

Small clinical studies have reported improved gas exchange and respiratory mechanics after administration of perfluorocarbons;<sup>28</sup> however, a moderately large clinical study ( $n = 311$ ) found that patients receiving conventional ventilation compared to both low- and high-dose perfluorocarbons had more ventilator-free days and tended to reduce mortality.<sup>29</sup> Consequently, liquid ventilation cannot be recommended.

### INDICATIONS AND OBJECTIVES OF MECHANICAL VENTILATION<sup>30</sup>

Institution of mechanical ventilation is a clinical decision; it can only be supported by parameters such as blood gases or measures of respiratory muscle function. Even then, the decision to choose IV over NIV will be influenced by numerous factors, including the likely course of the ARF and its response to treatment. Often there will be an indication for intubation (Table 27.1) and mechanical ventilation; however, if intubation is required to overcome upper-airway obstruction, no ventilatory assistance may be needed despite the increase in respiratory work imposed by the endotracheal or tracheostomy tube.<sup>18</sup>

**Table 27.1** Indications and objectives of intubated mechanical ventilation

#### Endotracheal intubation or tracheostomy

- For airway protection (e.g. coma)
- For suction of secretions
- To assist sedation and neuromuscular paralysis (e.g. to ↓  $V_{O_2}$ , ↓ respiratory distress)
- To overcome upper-airway obstruction.

#### Mechanical ventilation

- To manipulate alveolar ventilation ( $V_A$ ) and  $P_{aCO_2}$  (e.g. reverse respiratory acidosis, ↓ cerebral blood flow and intracranial pressure)
- To ↑  $S_{aO_2}$  and  $P_{aO_2}$  (by ↑ functional residual capacity, ↑ end-inspiratory lung volume, ↑  $V_A$ , ↑  $F_{iO_2}$ )
- To ↓ work of breathing (e.g. to overcome respiratory muscle fatigue)
- To ↑ functional residual capacity (e.g. ↑  $P_{aO_2}$ , ↓ ventilator-induced injury)
- To stabilise the chest wall in severe chest injury

Once the decision has been made to proceed to ventilatory support the choice of mode should be based on a physiological approach, local expertise and simplicity.

Patients who are likely to need ventilatory assistance (e.g. acute severe asthma) should be considered for early ICU admission since this will allow faster responses and avoid cardiorespiratory arrest. Specific issues and methods of ventilatory assistance are dealt with in Chapters 29, 31 and 33. In patients with traumatic brain injury IV is commonly required to protect the airway and control ICP; similarly, patients with severe pancreatitis or serious abdominal infection may need prolonged IV to maintain an adequate FRC, reduce work of breathing, protect their airway and allow suctioning of secretions.

### INITIATION OF INTUBATED MECHANICAL VENTILATION

A manual resuscitation circuit, mechanical ventilator and equipment for safe endotracheal intubation (see Chapter 25) should be available. Initial ventilator settings are commonly set to achieve adequate oxygenation and  $V_A$ ; however, this will depend upon the patient's condition. Common settings are:  $V_T$  6–10 ml/kg,  $f$  10–20 breaths/min, PEEP 5 cmH<sub>2</sub>O and  $F_{iO_2}$  of 1.0, and these will need to be adjusted according to a specific patient's pathophysiology and response.

### MANUAL RESUSCITATION CIRCUITS

Manual resuscitation circuits are primarily used to provide emergency ventilation when spontaneous effort is absent or inadequate. They may be used with a face or laryngeal mask, or an endotracheal tube. Occasionally they are used to provide a high inspired O<sub>2</sub> concentration during spontaneous breathing; however, this may impose significant additional respiratory work.<sup>31</sup> In the ICU they are commonly used for preoxygenation and manual lung inflation.

Their basic design includes a fresh gas flow of O<sub>2</sub>, a reservoir bag and valves to allow spontaneous or positive-pressure breathing. Most manual resuscitation circuits use a self-inflating reservoir bag since this allows the circuit to be used by unskilled personnel and does not require a fresh gas flow. However, circuits using reservoir bags that are not self-inflating are still used in some institutions since they allow a better manual assessment of the respiratory mechanics – the 'educated hand' – and it is clear when there is an inadequate seal with a mask. Oxygen-powered manually triggered devices have been used for many years; however, this has declined markedly since high  $\dot{V}$  and P may lead to barotrauma or gastric inflation.

Self-inflating reservoir bags use a series of one-way valves to allow fresh gas flow oxygen and entrained air to fill the bag. Inspired oxygen fractions as high as 0.8 may be achieved with neonatal or paediatric bags when an additional reservoir bag is used to allow fresh gas flow filling during expiration, after the bag has refilled.<sup>32</sup>

However, lower  $F_{iO_2}$ s (~0.6) will be obtained with both conventional O<sub>2</sub> flow rates of 8–15 l/min, and usual  $V_T$  and  $f$ , with an adult bag. Generally the valves are simple flap or duck-bill in nature, and both positive-pressure and spontaneous ventilation are possible. The reservoir bag volume in adults is typically 1600 ml, and  $V_T$  can be judged from chest wall movement. It is essential that these devices use standard 15/22-mm connectors to allow rapid connection to standard endotracheal tubes and ventilator circuits.

### COMPLICATIONS OF MECHANICAL VENTILATION (TABLE 27.2)<sup>26</sup>

Although mechanical ventilation may be vital, it also introduces numerous potential complications. Monitoring includes a high nurse-to-patient ratio (usually 1:1), ventilator alarms and pulse oximetry. Capnography is recommended to confirm endotracheal tube placement, and may be used to monitor the adequacy of  $V_A$ ;

**Table 27.2** Complications of intubation and mechanical ventilation

<b>Equipment</b>
<ul style="list-style-type: none"> <li>● Malfunction or disconnection</li> <li>● Incorrectly set or prescribed</li> <li>● Contamination</li> </ul>
<b>Pulmonary</b>

<b>Circulation</b>
<ul style="list-style-type: none"> <li>● ↓ Right ventricular preload → ↓ cardiac output</li> <li>● ↑ Right ventricular afterload (if the lung is overdistended)</li> <li>● ↓ Splanchnic blood flow with high levels of positive end-expiratory pressure (PEEP) or mean <math>P_{aw}</math></li> <li>● ↑ Intracranial pressure with high levels of PEEP or mean <math>P_{aw}</math></li> <li>● Fluid retention due to ↓ cardiac output → ↓ renal blood flow</li> </ul>
<b>Other</b>
<ul style="list-style-type: none"> <li>● Gut distension (air swallowing, hyomotility)</li> <li>● Mucosal ulceration and bleeding</li> <li>● Peripheral and respiratory muscle weakness (see Chapter 49)</li> <li>● Sleep disturbance, agitation and fear (which may be prolonged after recovery)</li> <li>● Neuropsychiatric complications</li> </ul>

however, expired  $\text{CO}_2$  is strongly influenced by factors that alter alveolar dead space, such as cardiac output. Intermittent blood gases, PEEP<sub>i</sub>, airway pressures in volume-preset modes and  $V_T$  in pressure-preset modes should be recorded. Individual patients may benefit from more extensive monitoring of their respiratory mechanics or tissue oxygenation.

The patient's airway (i.e. patency, presence of leaks and nature and amount of secretions), breathing (i.e. rate, volume, oxygenation) and circulation (i.e. pulse, blood pressure and urine output) must be monitored. Ventilatory and circuit alarms should be adjusted to monitor an appropriate range of  $V$ ,  $P$  and temperature. This should alert adjacent staff to changes in  $P$  and/or  $V$  that may be caused by an occluded endotracheal tube, tension pneumothorax or circuit disconnection. These alarms may be temporarily disabled while the cause is detected, but never permanently disabled. Sudden difficulties with high  $P$  during volume-preset ventilation or oxygenation must initiate an immediate search for the cause. This should start with the patency of the airway, followed by a structured approach to both the circuit and ventilator, and to factors altering the  $E$  and  $R$  of the lung and chest wall such as bronchospasm, secretions, pneumothorax and asynchronous breathing. In addition to careful clinical examination an urgent chest radiograph and bronchoscopy may be required.

Mechanical ventilation is also associated with a marked increase in the incidence of nosocomial pneumonia due to a reduction in the natural defence of the respiratory tract, and this represents an important advantage offered by NIV. In patients successfully managed with NIV, Girou and colleagues reported a reduction in the incidence of nosocomial pneumonia, associated with improved survival, compared to IV.<sup>33</sup> Erect versus semirecumbent posture<sup>34</sup> also reduces the incidence of ventilator-associated pneumonia.

Although lung overdistension may result in alveolar rupture leading to pulmonary interstitial air, pneumomediastinum or pneumothorax, it may also lead to diffuse alveolar damage similar to that found in ALI and ARDS. Both are termed VILI, and  $V_T$  reduction leads to a marked decrease in ALI mortality, due to a reduction in multiple-organ dysfunction.<sup>5</sup> There are also laboratory data suggesting that inadequate PEEP with tidal recruitment and derecruitment of alveoli leads to VILI; however, this has not been proven in a clinical trial. Finally, patient-ventilator asynchrony may result in wasted respiratory work, impaired gas exchange and respiratory distress (see below).

Positive-pressure ventilation elevates intrathoracic pressure, which reduces venous return, right ventricular preload and cardiac output. The impact is reduced by hypervolaemia and partial ventilatory support, where patient effort and a reduction in pleural pressure augment venous return. Secondary effects include a reduction in regional organ blood flow leading to fluid retention by the kidney, and possibly impaired hepatic function. This

latter effect is only seen at high levels of PEEP where an increase in resistance to venous return and a reduction in cardiac output may combine to reduce hepatic blood flow.

Sleep disturbance, and agitation and discomfort are common in mechanically ventilated patients. These effects may be reduced with sedation until weaning is planned; however, it is important not to prolong mechanical ventilation due to excessive use of sedatives, which may also depress blood pressure and spontaneous respiratory effort. Finally, complex neuropsychological sequelae have been described in recovering ARDS patients.<sup>35,36</sup> These do not appear to reflect the severity of the acute illness since ARDS patients have a poorer quality of life than patients with a similar severity of illness without ARDS.<sup>37</sup> However, they do correlate with their duration of hypoxaemia. Clearly, this is an important issue that needs further research.

#### WITHDRAWAL (WEANING) FROM MECHANICAL VENTILATION

Once the underlying process necessitating mechanical ventilation has started to resolve, withdrawal of ventilatory support should be considered; increased duration of ventilation leads to a progressive rise in complications such as ventilator-associated pneumonia. However, other important parameters that must be considered include the neuromuscular state of the patient (ability to initiate a spontaneous breath), adequacy of oxygenation (typically low requirements for PEEP (5–8 cmH<sub>2</sub>O) and  $F_{iO_2} < 0.4$ –0.5) and cardiovascular stability.<sup>38</sup> Once a patient is considered suitable to wean, a secondary question is whether an artificial airway is still required for airway protection or suction of secretions. Many patients can rapidly make the transition from mechanical ventilation to extubation, but ~20% of patients fail weaning despite meeting clinical criteria.<sup>21</sup> Advanced age, prolonged mechanical ventilation and chronic obstructive pulmonary disease all increase the likelihood that weaning will be difficult.<sup>21</sup>

Weaning failure is usually associated with an increase in respiratory drive and respiratory rate and a fall in  $V_T$  which contributes to hypercapnoea;<sup>39</sup> about 10% of patients fail due to central respiratory depression. Various indices such as maximal inspiratory pressure (MIP), minute ventilation ( $V_E$ ),  $f V_T / V_T$  ratio and the compliance, respiratory rate, oxygenation, maximum inspiratory pressure (CROP) index have been investigated as predictors of weaning failure (Table 27.3). They are rarely used alone and careful clinical assessment is often adequate, yielding a reintubation rate as low as 3%,<sup>40</sup> and none of these indices assess airway function following extubation. Although the typical threshold value for the rapid shallow-breathing index ( $f/V_T$  ratio) is  $> 105$ , a large recent multicentre study reported progressive increase in risk as this increased with a threshold of 57; in addition a

**Table 27.3** Sample of measurements that have been used to predict successful outcome from weaning in critically ill patients\*

Parameter	Typical threshold value <sup>†</sup>	Comment
$V_E$	$\leq 15$ l/min	Moderate to high sensitivity, low specificity
MIP	$\leq -15$ cmH <sub>2</sub> O	High sensitivity, low specificity
CROP index <sup>#</sup>	$\geq 13$	Moderate to high sensitivity, modest specificity
<b>During a spontaneous breathing trial</b>		
$f$	$\leq 38$ breaths/min	High sensitivity, low specificity
$V_T$	$\geq 325$ ml (4 ml/kg)	High sensitivity, low specificity
$f/V_T$	$\leq 105$	High sensitivity, moderate specificity

\*See reference 38 for further detail.

<sup>†</sup>Although threshold values are often used, the data are not dichotomous. For example, as the  $f/V_T$  ratio increases, so does the rate of reintubation.<sup>41</sup>

<sup>#</sup>CROP index =  $(C_{dyn} \times MIP \times [PaO_2/PAO_2]/f)$ .<sup>21</sup>

MIP, maximal inspiratory pressure; CROP, compliance, respiratory rate, oxygenation, maximum inspiratory pressure.

positive fluid balance immediately prior to extubation was a significant risk factor for reintubation.<sup>41</sup> Consequently, weaning indices should not necessarily delay extubation or a weaning trial. However, they may quantitate important issues in the general clinical assessment, and may be directly relevant for a given patient. For example, frequent small  $V_T$ , an inadequate vital capacity (less than 8–12 ml/kg), large minute ventilation ( $= 15$  l/min), depressed respiratory drive and reduced respiratory muscle strength (MIP  $= -15$  cmH<sub>2</sub>O) or drive should be strongly factored into deciding whether a patient is ready to undergo a trial of weaning safely.

Direct comparisons between T-piece trials, PSV and SIMV as weaning techniques have been performed in patients previously failing a 2-hour trial of spontaneous breathing. In the study by Brochard and colleagues,<sup>42</sup> PSV led to fewer failures and a shorter weaning period. In contrast, Esteban and coworkers<sup>43</sup> found that a once-daily trial of spontaneous breathing resulted in the shortest duration of mechanical ventilation; however, a relatively high proportion of patients required reintubation (22.6%). Viewed together these studies suggest that weaning was slower with SIMV,<sup>19</sup> although SIMV with PSV was not studied, and that either PSV or a T-piece trial is the preferred method for weaning. Since low levels of PSV can help compensate for the additional work of

breathing attributable to the endotracheal tube and circuit, some clinicians use low levels of PSV (5–7 cmH<sub>2</sub>O) during weaning or during a spontaneous breathing trial. However, the work of breathing following extubation is usually higher than expected, probably due to upper-airway oedema and dysfunction, so that work is similar to that during a T-piece trial.<sup>21</sup>

Reintubation is associated with a 7–11-fold increased risk of hospital death.<sup>19</sup> A number of factors may account for this, including selection of previously unaccounted-for severity of illness as the mortality rate associated with reintubation is much higher in patients whose primary diagnosis was respiratory failure. In addition, complications which may (pneumonia, heart failure) or may not be attributable to extubation contribute to this poor outcome. Hence, an important goal during mechanical ventilation will be to proceed to early and expeditious extubation with a low reintubation rate.

### PATIENT-VENTILATOR INTERACTION

This is an extremely important issue in patients with either partial ventilatory support, or those breathing spontaneously through the ventilator. Dyssynchrony can lead to agitation, diaphoresis, tachycardia, hypertension and weaning failure or a failure of NIV. Once this pattern is identified it is crucial that airway complications (partial obstruction, displacement) or a major change in the clinical state (e.g. pneumothorax, acute pulmonary oedema) are excluded before considering problems with patient-ventilator interaction. For simplicity this will be subdivided into: (1) triggering of inspiration; (2) inspiration; and (3) cessation of inspiration; however, difficulties at each of these phases will lead to changes in respiratory drive and effort that may be expressed throughout the respiratory cycle. Importantly, major problems with patient-ventilator dyssynchrony can be identified by carefully observing respiratory effort and ventilator cycling at the bedside and this may be assisted by observing  $P$ ,  $V$  and  $\dot{V}$  waveforms displayed by the ventilator.

### TRIGGERING OF INSPIRATION

1. PEEP<sub>i</sub> is an important hindrance to the triggering of inspiration in patients with severe airflow limitation, since their inspiratory muscles must first reduce  $P_{ao}$  below ambient pressure.<sup>44</sup> Consequently  $P_{mus}$  must exceed PEEP<sub>i</sub> prior to triggering an assisted breath either by reducing airway pressure (pressure trigger) or by reducing circuit flow (flow trigger). This inspiratory threshold load may be up to 40% of the total inspiratory work in ARF with dynamic hyperinflation, and commonly results in ineffective triggering. Triggering can be markedly improved and respiratory work reduced by low levels of CPAP<sup>37,45</sup> – commonly 80–90% of dynamic PEEP<sub>i</sub>.<sup>46</sup>
2. A fall in  $P_{ao}$  has been the most common form of triggering. Pressure is usually sensed at the expiratory block of the ventilator. Sensing at the Y-piece is not superior

since there is a similar delay in sensing as the transducer is usually sited in the ventilator. Flow triggering senses a fall in continuous circuit flow, and was introduced as a method of reducing inspiratory work. However, there has been a marked improvement of both pressure and flow triggering in modern ventilators, with the trigger time delay falling from  $\sim 400$  to  $\sim 100$  ms, and a similar improvement in the maximum fall in airway pressure.<sup>47</sup>

Attempts to improve the trigger function by oversetting the pressure sensitivity ( $> -0.5$  cmH<sub>2</sub>O) may lead to autocycling, which may also occur with overset flow triggering. This is due to the  $P$  and  $\dot{V}_I$  effects of cardiac oscillations, hiccups, circuit rainout or mask leak with NIV, and has been reported as a cause of apparent respiratory effort in brain-dead patients.<sup>48</sup> Flow triggering reduces the risk of autocycling at a given trigger sensitivity, and reduces respiratory effort a small amount compared to pressure triggering; however, it does not alter the frequency of ineffective efforts,<sup>49</sup> or patient effort following triggering.<sup>40</sup>

### INSPIRATION

Once inspiration is triggered or sensed by the ventilator,  $\dot{V}$  is determined by  $P, T_i$  or  $V$ . For example, during PSV ventilation a target  $P$  is held until expiration is sensed, and during ACV  $\dot{V}$  is held for a set  $T_i$ . During ACV there may be continued inspiratory effort, and since inspiratory  $\dot{V}$  is fixed, this will be reflected by a scalloping of the  $P_{ao}-T$  graph if  $\dot{V}$  is inadequate. Again this may be illustrated using the equation of motion:

$$P_{\text{mus}} + P_{\text{ao}} = E_{\text{rs}} V + R_{\text{rs}} \dot{V} + P_o \quad \text{Equation 6}$$

$P_{\text{mus}}$  will reflect the difference between  $P_{\text{ao}}$  due to  $E, R$  and  $P_o$  and the observed  $P_{\text{ao}}$ . In contrast, during  $P$ -cycled ventilation (PACV), greater patient effort is rewarded, and inspiratory work is lower than during equivalent ACV.<sup>50</sup>

Modern ventilators allow adjustment of inspiratory  $\dot{V}$  and  $\dot{V}$  pattern, and the rate of rise of  $P_{\text{ao}}$ . Low inspiratory rates during ACV result in significant inspiratory work, but this may be markedly reduced by increasing inspiratory  $\dot{V}$  to 65 l/min.<sup>51</sup> However, these issues are quite complex, and  $f$  increases (probably due to a lower respiratory tract reflex) as  $\dot{V}_I$  increases,<sup>52</sup> reducing  $T_c$ , which may contribute to dynamic hyperinflation in patients with severe airflow obstruction. During PSV and PACV, many ventilators allow adjustment of the rate of rise of  $P$  to its target. A steeper  $P$  ramp leads to earlier attainment of the  $P$  target, greater early rates and reduction of inspiratory drive and work.<sup>53,54</sup>

### CESSATION OF INSPIRATION

During PSV, an increase in airways resistance will result in a delayed fall in  $\dot{V}_I$ . Since this is the trigger for cycling to expiration, the ventilator may continue to provide  $\dot{V}_I$  while the patient desires to exhale. This commonly leads to recruitment of expiratory muscles, detected both clinically and as a transient rise in the end-inspiratory  $P_{\text{ao}}$ .<sup>55</sup>

Some modern ventilators allow control of the fall in  $\dot{V}_I$  that is sensed as end-inspiration. High levels of PSV ( $\geq 20$  cmH<sub>2</sub>O), weak respiratory muscles and mask leak with NIV are other common causes of dyssynchrony at the termination of inspiration. In this last group, PACV, which is time-cycled, allows improved patient-ventilator synchrony at end-inspiration compared to PSV.<sup>56</sup>

# Humidification and inhalation therapy

Andrew D Bersten

The upper airway normally warms, moistens and filters inspired gas. When these functions are impaired by disease, or when the nasopharynx is bypassed by endotracheal intubation, artificial humidification of inspired gases must be provided.

## PHYSICAL PRINCIPLES

Humidity, the amount of water vapour in a gas, may be expressed as:

1. *absolute humidity* (AH) – the total mass of water vapour in a given volume of gas at a given temperature ( $\text{g}/\text{m}^3$ )
2. *relative humidity* (RH) – the actual mass of water vapour (per volume of gas) as a percentage of the mass of saturated water vapour, at a given temperature. Saturated water vapour exerts a saturated vapour pressure (SVP). As the SVP has an exponential relation with temperature (Table 28.1), addition of further water vapour to the gas can only occur with a rise in temperature
3. *partial pressure*

## PHYSIOLOGY

Clearance of surface liquids and particles from the lung depends on beating cilia, airway mucus and transepithelial water flux. Airway mucus is derived from secretions from goblet cells, submucosal glands and Clara cells, and from capillary transudate. Conducting airways are lined with pseudostratified, ciliated columnar epithelium and numerous fluid-secreting glands. As the airway descends, the epithelium becomes stratified, and then cuboidal and partially ciliated, with very few secretory glands at the terminal airways. The cilia beat in a watery (sol) layer over which is a viscous mucous layer (gel), and move a superficial layer of mucus from deep within the lung toward the glottis (at a rate of 10 mm/min at 37°C and 100% RH). Both cilia function and mucus composition are influenced by temperature and adequate humidification.

The nasal mucosa has a large surface area with an extensive vascular network which humidifies and warms

inhaled gas more effectively than during mouth-breathing. Heating and humidification of dry gas are progressive down the airway, with an isothermic saturation boundary (i.e. 100% RH at 37°C or AH of 43  $\text{g}/\text{m}^3$ ) just below the carina.<sup>1</sup> Under resting conditions, approximately 250 ml of water and 1.5 kJ (350 kcal) of energy is lost from the respiratory tract in a day. A proportion (10–25%) is returned to the mucosa during expiration due to condensation.

The minimal moisture level to maintain ciliary function and mucus clearance is uncertain. Although reproducing an isothermic saturation boundary at the carina may be ideal, it does not seem essential in all situations. Mucus flow is markedly reduced when RH at 37°C falls below 75% (AH of 32  $\text{g}/\text{m}^3$ ), and ceases when RH is 50% (AH of 22  $\text{g}/\text{m}^3$ ).<sup>2</sup> This suggests that an AH exceeding 33  $\text{g}/\text{m}^3$  is needed to maintain normal function. At this AH level, inspired gas temperature does not appear to be important unless excessive.<sup>3</sup> Mucociliary function is also impaired by upper respiratory tract infection, chronic bronchitis, cystic fibrosis, bronchiectasis, immotile cilia syndrome (including Kartagener's syndrome), dehydration, hyperventilation, general anaesthetics, opioids, atropine and exposure to noxious gases. High fractional inspired oxygen concentrations ( $F_{iO_2}$ ) may lead to acute tracheobronchitis, with depressed tracheal mucus velocity within 3 h.<sup>4</sup> Inhaled  $\beta_2$ -adrenergic agonists increase mucociliary clearance by augmenting ciliary beat frequency, and mucus and water secretion.<sup>5</sup>

## CLINICAL APPLICATIONS OF HUMIDIFICATION

### TRACHEAL INTUBATION

The need for humidification during endotracheal intubation and tracheostomy is unquestioned. As the upper airway is bypassed, RH of inspired gas falls below 50% with adverse effects, including:<sup>6</sup>

1. increased mucus viscosity
2. depressed ciliary function
3. cytological damage to the tracheobronchial epithelium, including mucosal ulceration, tracheal inflammation and necrotising tracheobronchitis<sup>7</sup>

**Table 28.1** Relationship of temperature and saturated vapour pressure

Temperature (°C)	Saturated vapour pressure		Absolute humidity (g/m <sup>3</sup> )
	(mmHg)	(kPa)	
0	4.6	0.6	4.8
10	9.2	1.2	9.3
20	17.5	2.3	17.1
30	31.3	4.2	30.4
34	39.9	5.3	37.5
37	47.1	6.3	43.4
40	55.3	7.4	51.7
46	78.0	10.4	68.7

4. microatelectasis from obstruction of small airways, and reduced surfactant leading to reduced lung compliance
5. airway obstruction due to tenacious or inspissated sputum with increased airway resistance

Metaplasia of the tracheal epithelium occurs over weeks to months in patients with a permanent tracheostomy. These patients do not usually require humidified gas, suggesting that humidification occurs lower down the respiratory tree. Nonetheless, humidification of inspired gas may be needed during an acute respiratory tract infection.

### HEAT EXCHANGE

The respiratory tract is an important avenue to adjust body temperature by heat exchange. Humidification of gases reduces the fall in body temperature associated with anaesthesia and surgery.<sup>6</sup> In this setting, active humidifiers are of no benefit over heat and moisture exchangers (HMEs).<sup>8</sup> Excessive heat from humidification may produce mucosal damage, hyperthermia and overhumidification.<sup>9</sup> However, if water content is not excessive, mucociliary clearance is unaffected up to temperatures of 42°C.<sup>3</sup> Overhumidification may increase secretions and impair mucociliary clearance and surfactant activity, resulting in atelectasis.<sup>9</sup>

### IDEAL HUMIDIFICATION

The basic requirements of a humidifier should include the following features:<sup>10</sup>

1. The inspired gas is delivered into the trachea at 32–36°C with a water content of 30–43 g/m<sup>3</sup>.
2. The set temperature remains constant and does not fluctuate.
3. Humidification and temperature remain unaffected by a large range of fresh gas flows, especially high flows.
4. The device is simple to use and to service.
5. Humidification can be provided for air, oxygen or any mixture of inspired gas, including anaesthetic agents.

6. The humidifier can be used with spontaneous or controlled ventilation.
7. There are safety mechanisms, with alarms, against overheating, overhydration and electrocution.
8. The resistance, compliance and dead-space characteristics do not adversely affect spontaneous breathing modes.
9. The sterility of the inspired gas is not compromised.

## METHODS AND DEVICES

### WATER BATH HUMIDIFIERS

Inspired gas is passed over or through a water reservoir to achieve humidification. Their efficiency is dependent on ambient temperature and the surface area available for gas vaporisation.

#### COLD-WATER HUMIDIFIERS

These units are simple and inexpensive, but are inefficient, with a water content of around 9 g/m<sup>3</sup> (i.e. about 50% RH at ambient temperatures). They are also a potential source of microbiological contamination. Routine use of cold-water humidifiers to deliver oxygen with simple facemasks is unnecessary.

#### HOT-WATER HUMIDIFIERS (FIGURES 28.1 AND 28.2)

Inspired gas is passed over (i.e. blow-by humidifier, e.g. Fisher–Paykel, Fisher and Paykel Medical, New Zealand) or through (i.e. bubble or cascade humidifier, e.g. Bennett Cascade, Bennett Medical Equipment, USA) a heated-water reservoir. Gas leaving the reservoir theoretically contains high water content. The water bath temperature is thermostatically controlled (e.g. at 45–60°C) to compensate for cooling along the inspiratory tubing targeting an inspired RH of 100% at 37°C. A heated wire may be sited in the inspiratory tubing to maintain preset gas

**Figure 28.1** Hot-water 'blow-by' humidifier.

Figure 28.2 Hot-water 'cascade' or 'bubble' humidifier.

temperature and humidity (e.g. Fisher–Paykel humidifier). It is commonly believed that hot-water humidifiers do not produce aerosols, but microdroplets (mostly less than 5  $\mu\text{m}$  diameter) have been reported with bubble humidifiers,<sup>11</sup> and this may be a potential source of infection.

#### Fisher–Paykel humidifier

This is a commonly used blow-by humidifier. The delivery hose is heated by an insulated heating wire to achieve a manual preset inspired temperature. An additional servo-control unit is available, while more recent models have a dual servo unit which combines this function in the heater base. Audible alarms indicate disconnection and variations over 2°C from the set delivery temperature. The heater base is protected from overheating by a thermostat set at 47°C. If this fails, another safety thermostat operates at 70°C. A disposable humidification chamber is filled manually with water or by a gravity-feed set. To minimise rain-out, the chamber outlet can be set at a temperature below the delivery hose outlet temperature – 2–3°C is usually adequate and does not compromise RH. Temperature alarms are fixed at 41°C and 29.5°C, with a back-up safety set at 66°C for the delivery chamber.

Although these humidifiers are often regarded as providing optimal humidification in ventilated patients, their performance is lower than expected (36 mg/l with MR 850 with the outlet temperature set to 37°C and the delivery hose set at 40°C, and optimal conditions in bench studies, and up to 41.9 mg/l in practice).<sup>12</sup> However, under conditions of high ambient temperature and/or high ventilator output temperature the inlet temperature to the humidification chamber can be high enough that the heater base operates at a low enough temperature that humidification is impaired, with reduction in inspired water content as low as 19 mg/l in bench studies, and 23.4 mg/l in practice.<sup>12</sup> The automatic compensation now available on this humidifier helps compensate for poor performance, which can also be prevented by setting the chamber outlet and hose to 40°C. High minute ventilation is well tolerated, but a small decrease in

water content output has also been found with higher respiratory rates.<sup>13</sup>

#### Counter flow-heated humidifiers

Using the countercurrent principle for gas and heated water, newer designs may further improve performance so that performance is independent of gas flow and respiratory rate, with lower imposed work of breathing.<sup>13</sup>

### HEAT AND MOISTURE EXCHANGERS

Modern HMEs are popular intensive care unit (ICU) humidifiers due to their simplicity and increased efficiency. They all work on the basic principle of heat and moisture conservation during expiration, allowing inspired gas to be heated and humidified. HMEs may be hydrophobic or hygroscopic, and may also act as a microbial filter (HMEF). However, since nosocomial pneumonia is primarily due to aspiration of oropharyngeal secretions followed by secondary ventilator tubing colonisation, HMEFs have not been shown to reduce the frequency of nosocomial pneumonia, and the incidence is similar when HMEs and hot-water humidifiers are compared during prolonged ventilation.<sup>14,15</sup>

Modern HMEs are light with a small dead space (30–95 ml), but are varied in their level of humidification. Hygroscopic HMEs adsorb moisture on to a foam or paper-like material that is chemically coated (often calcium chloride or lithium chloride), and this tends to increase their efficiency (i.e. AH around 30 g/m<sup>3</sup>) compared to hydrophobic HMEs (i.e. AH 20–25 g/m<sup>3</sup>).<sup>16–21</sup> The efficiency of older HMEs decreases with time;<sup>13</sup> however, modern HMEs may retain their ability to humidify for at least 4 days with minimal change in resistance.<sup>22</sup> Consequently, HMEs that achieve relatively high AH may be suitable for long-term mechanical ventilation in selected patients, particularly as the majority of reported HME complications (e.g. thick secretions and endotracheal tube occlusion) occurred with units of lower humidification levels.<sup>23–25</sup> Nevertheless, HMEs increase dead space and imposed work of breathing, and cannot match the humidification offered by hot-water humidifiers, which remain the 'gold standard', particularly if secretions are thick or bloody, minute ventilation is high,<sup>15,19</sup> humidification is necessary for more than 4 days<sup>26</sup> or if used in children and neonates.

### COMPLICATIONS OF HUMIDIFICATION

#### INADEQUATE HUMIDIFICATION

An AH exceeding 30 g/m<sup>3</sup> is recommended in respiratory care.<sup>24</sup> Inadequate humidification is usually only a problem with HMEs. With hot-water humidifiers, however, efficiency is reduced by increasing gas flow rates and rainout. A decrease of about 1°C occurs for each 10 cm of tubing beyond the end of the delivery hose (i.e. the

Y-connector and right-angled connector), and should be catered for. Inadequate humidification in high-frequency ventilation can be overcome by using superheated humidification of the entrained gas with a temperature thermistor built into the endotracheal tube.<sup>23,27</sup>

### OVERHUMIDIFICATION

Overheating malfunction of hot-water humidifiers may cause a rise in core temperature, water intoxication, impaired mucociliary clearance and airway burns.<sup>9</sup>

### IMPOSED WORK OF BREATHING

The work of breathing imposed by a humidifier, primarily resistive work, is an important additional respiratory load in ICU patients. Consequently their imposed work increases with inspiratory flow rate, and the progressive increase in water content of HMEs is also associated with increased resistance.<sup>28</sup> The Fisher–Paykel humidifier imposes relatively low work compared to the Bennett cascade,<sup>29</sup> and HMEs typically have a resistance of 2.5 cmH<sub>2</sub>O/l per second.<sup>19</sup>

### INFECTION

Current evidence argues against humidifiers as important factors in nosocomial respiratory tract infection. Although water reservoirs represent a good culture medium for bacteria such as *Pseudomonas* species, it is rare to culture bacteria from humidifiers. Any such positive finding is usually preceded by colonisation of the circuit by the patient's own flora within the first 24 h of use.<sup>30,31</sup> Indeed, the incidence of nosocomial pneumonia is reported to be higher (due to outside contamination) if the circuit is changed too frequently (every 24 h<sup>32</sup> or 48 h<sup>29</sup>).

Many HMEs are also effective bacterial filters, with efficiencies usually greater than 99.9 977%,<sup>15</sup> i.e. less than 23 out of 1 million bacteria will pass through – filters that can exclude all virus particles are not currently available. However, provided that fresh circuits are used for each new patient, filtration does not alter the incidence of ventilator-associated pneumonia or mortality.<sup>33</sup>

### ELECTRICAL HAZARDS

See Chapter 75.

### INHALATION THERAPY

Therapeutic aerosols are particles suspended in gas that are inhaled and deposited within the respiratory tract. Numerous factors, including particle size, inertia and physical nature, gravity, volume and pattern of ventilation, temperature and humidity, airway geometry, lung disease and the delivery system, alter aerosol deposition. In general, particles of diameter 40 µm deposit in the

upper airway, 8–15 µm deposit in bronchi and bronchioles, 3–5 µm deposit in peripheral conducting airways and 0.8–3.0 µm settle in lung parenchyma. Optimal particle size will depend on the clinical indication and agent used (e.g. β<sub>2</sub>-adrenergic agonists, anticholinergics, corticosteroids, antibiotics, antivirals, surfactant therapy, sputum induction and water). Obviously, if an HME with filtration characteristics is being used, the aerosol needs to be delivered proximal to the filter.

### AEROSOL DELIVERY

Therapeutic aerosols may be delivered by nebuliser (jet or ultrasonic), metered-dose inhaler (MDI) or dry-particle inhaler (DPI). Although each of these methods tends to be less efficient in ventilated patients, provided that care is taken to optimise their performance, each can provide equivalent clinical effect.

### NEBULISERS<sup>34</sup>

The most common jet nebulisers are sidestream nebulisers. These use an extrinsic gas flow through a narrow orifice, to create a pressure gradient that draws the drug mixture from a liquid reservoir (i.e. Bernoulli's principle; Figure 28.3). The gas is then directed at a baffle to reduce the mean particle size. This extrinsic gas flow (usually 3–10 l/min) adds to the inspiratory flow, and may increase patient tidal volume unless the ventilator automatically compensates, or the preset tidal volume is adjusted. Further, this additional gas flow may impair ventilator triggering since it may prevent the development of a negative pressure or necessary reduction in continuous flow needed. Mainstream nebulisers employ inspiratory gas flow to actuate nebulisation. These are commonly large-volume water nebulisers that entrain air to achieve fresh gas flow rates of 20–30 l/min.

Ultrasonic nebulisers use high-frequency sound waves (typically 1 MHz) to create an aerosol above a liquid reservoir, to produce small uniform droplets (< 5 µm) and a high mist density (i.e. 100–200 g/m<sup>3</sup>). Tidal volume is not altered; however, ultrasonic nebulisers may cause overhydration and increased airway resistance.

Nebuliser aerosol deposition is highly variable, with significant rainout in the ventilatory circuit, endotracheal tube and large conducting airways. In a bench study delivery ranged from 6% of nebuliser charge to 37% depending upon humidification and breath activation; parallel in-vivo data were similar but found a 20-fold difference in drug delivery.<sup>35</sup> Numerous factors have been shown to improve aerosol deposition, but only some of these are commonly practised. For example, although heating and humidification reduce aerosol deposition by ~50% due to increase in both droplet size and rainout, regular circuit disconnection and exclusion of humidification prior to nebulisation are not practical. However, placement of the nebuliser in the inspiratory limb of the

Figure 28.3 Sidestream nebuliser.

circuit less than 30 cm from the endotracheal tube allows this tubing to act as a spacer or aerosol-holding chamber. This reduces aerosol velocity and losses due to impaction. Inspiratory activation of the nebuliser increases deposition by two- and threefold under dry and humidified conditions respectively;<sup>35</sup> use of a large chamber fill, tidal volume of 500 ml or more and minimisation of turbulent inspiratory flow (low flow rate, prolonged inspiratory time) also augment aerosol delivery.<sup>31,36</sup>

#### METERED-DOSE INHALERS

MDIs suspend micronised crystals of drug in a propellant gas under high pressure, allowing a relatively fixed volume (i.e. dose) to be delivered with each actuation (e.g. 90 µg for salbutamol and 18 µg for ipratropium).<sup>37</sup> Aerosol delivery is approximately 4–6% in ventilated adults,<sup>32</sup> but increases to 11% when a spacer chamber is used, which is similar to optimal no-spacer values reported in the ambulant population.<sup>38</sup> Similar to nebulisers, absence of humidification, inspiratory limb position, inspiratory activation and minimisation of turbulence by lowering inspiratory flow rate and prolonging inspiratory time will increase aerosol delivery. It is important to avoid use of an elbow adapter, because this has been associated with dramatic reductions in aerosol delivery and efficacy. Further hazards of MDIs include a low risk of reaction to chlorofluorocarbons, and the risk of necrotising inflammation of the airway mucosa when large doses of drug are administered with an MDI and catheter system due to oleic acid which is present in some MDI formulations.<sup>39</sup>

#### DRY-POWDERED INHALERS

DPIs are now in common use in ambulant practice but there is little experience with them in ventilated patients. They could be used in-line with ventilation, but the efficacy of a dry powder in combination with humid gases is unknown.

### CLINICAL APPLICATIONS OF INHALATION THERAPY

#### HUMIDIFICATION

Humidifiers produce gas with a water content dictated by temperature and water vapour pressure, whereas nebulisers produce gas with a water content determined by the aerosol content. The latter can provide water to the respiratory tract, particularly if the water reservoir is heated to increase mist density. However, the risk of infection is increased, as droplets can carry bacteria to the alveoli. Consequently, only sterile water should be used to fill the reservoir, and all units should be regularly changed and sterilised.

#### MUCOLYTICS

The role of mucolytics to reduce viscosity of secretions in critically ill patients is unknown. Oral mucolytics such as acetylcysteine reduce exacerbations of chronic bronchitis and chronic obstructive pulmonary disease (COPD), although this appears to be isolated to subjects not receiving inhaled steroids.<sup>40</sup> Aerosolised acetylcysteine has also been used as a mucolytic, but may cause bronchospasm. Case reports of recombinant human DNase appear promising when standard regimens fail to clear thick secretions.<sup>36</sup>

#### BRONCHODILATOR THERAPY

Optimal aerosol delivery and bronchodilator response are extremely important in critically ill patients with severe airflow limitation, and this can be achieved using either a nebuliser or MDI technique provided that care is taken to optimise performance. The response can be judged clinically, and in ventilated patients monitored by changes in peak-to-plateau airway pressure gradient, calculated airways resistance and intrinsic PEEP. Numerous studies

show effective bronchodilatation with  $\beta_2$ -agonists and anticholinergic agents such as ipratropium in ventilated patients,<sup>31</sup> and their combination is more effective than a single agent alone.<sup>36</sup> When compared with systemic corticosteroids, inhaled steroids are effective in severe asthma<sup>41</sup> and in exacerbations of COPD.<sup>42</sup>

#### BRONCHODILATOR DOSING

Standard doses of salbutamol are 2.5 mg administered by a nebuliser or four puffs of an MDI (360  $\mu$ g), and this can be expected to elicit a bronchodilator response that is slightly shorter-lasting than is usual in ambulatory subjects. Consequently, dosing should be 3–4-hourly. Ipratropium is usually administered as 0.5 mg by a nebuliser or 4 puffs of an MDI. Higher or more frequent drug dosing is often effective when there is severe, reversible airflow obstruction, and continuous nebulisation of a  $\beta_2$ -agonist may be used in acute severe asthma until there has been a clinical response. If the patient is moribund with minimal ventilation or unable to tolerate nebulisation, parenteral administration should be considered; however, under most circumstances there is no particular benefit with this route.<sup>43</sup>

#### NON-INVASIVE POSITIVE-PRESSURE VENTILATION (NIPPV)

Optimal bronchodilator therapy for patients requiring NIPPV, particularly for acute exacerbations of COPD, is unknown. It is preferable not to interrupt NIPPV for this purpose and both nebulisers and MDIs appear effective during NIPPV.<sup>36</sup> Despite the potential for increased loss of nebulised drug in a high-gas-flow continuous positive-airways pressure circuit, good bronchodilator response with salbutamol has been reported in this setting.<sup>44</sup>

#### DELIVERY OF ANTIBIOTICS AND ANTIVIRAL AGENTS

Aerosolised antibiotics have been contentious for many years; however, the potential to achieve high concentrations of antibiotics at the site of infection while minimising adverse effects remains appealing. Numerous studies in patients with cystic fibrosis have shown a reduction in sputum volume and density of bacteria, and improved lung function with reduced risk of hospitalisation when inhaled aminoglycosides are used.<sup>45,46</sup> Similar results, including a reduction of markers of airway inflammation, have been reported with bronchiectasis,<sup>47,48</sup> and in mechanically ventilated patients with chronic respiratory failure.<sup>49</sup> Although there has been concern that aerosolised antibiotics will promote the development of resistant organisms,<sup>50</sup> this study examined whole ICU prophylaxis with polymyxin, rather than treatment, and other studies using aminoglycosides have not reported the development of resistance.<sup>39,51</sup> Other antimicrobials that have been safely nebulised include vancomycin, amphotericin B and pentamidine for *Pneumocystis carinii* pneumonia. However, inhaled amphotericin may result in bronchospasm.

In animal models of bronchopneumonia inhaled amikacin<sup>52</sup> and ceftazidime<sup>53</sup> achieved 3–30 times increases in lung tissue concentrations, and better sterilisation of lung when compared to intravenous administration. Using either inhaled gentamicin or vancomycin there appears to be clinical benefit when inhaled antibiotics are added to systemic therapy in ventilator-associated pneumonia.<sup>54</sup> Aerosolised ribavarin is effective for respiratory syncytial virus infection, resulting in a shorter period of ventilation and hospitalisation.<sup>55</sup> However, ribavarin deposition in the circuit may cause valve malfunction, and concerns of teratogenicity in health care personnel have dictated its use with care.<sup>43</sup>

#### SPUTUM INDUCTION

Nebulised 3% saline is effective in sputum induction for diagnosing *P. carinii* pneumonia in patients with the acquired immunodeficiency syndrome (AIDS), thereby often obviating the need for bronchoscopy.<sup>56</sup> Sputum induction has been used to diagnose a number of other infections, and appears to be safe in patients with severe airflow limitation.<sup>57</sup>

#### SURFACTANT THERAPY

Surfactant preparations have been delivered by instillation and as an aerosol in neonates with respiratory distress syndrome, and in adults with the acute respiratory distress syndrome. Aerosolised surfactant achieves a more uniform distribution and avoids problems of instilling liquid into injured lungs. However, large amounts are needed for lung deposition, and preferential distribution occurs to less damaged lung areas that receive better ventilation.<sup>58</sup>

#### PROSTANOIDS<sup>38</sup>

Inhaled prostanoids target selective pulmonary vasodilatation to well-aerated areas, leading to similar improvements in oxygenation as inducible nitrous oxide in patients with the acute respiratory distress syndrome. When delivered systemically these agents lead to impaired oxygenation and to hypotension due to non-selective pulmonary and systemic vasodilatation respectively. Iloprost has a longer half-life (about 20–30 min compared with 3 min for prostacyclin), and is sometimes used for chronic pulmonary hypertension (2.5–5 mg 6–9 times per day), and similar doses can be used in mechanically ventilated patients.

# The acute respiratory distress syndrome (ARDS)

Andrew D Bersten

The acute respiratory distress syndrome (ARDS) was first described in 1967 by Ashbaugh and colleagues as the 'acute onset of tachypnea, hypoxemia and loss of compliance after a variety of stimuli'.<sup>1</sup> Continued research examining the underlying mechanisms and management strategies is now translating into improved outcome.

## DEFINITIONS

Acute lung injury (ALI) and its more severe subset ARDS describe acute hypoxaemic respiratory failure due to bilateral and diffuse alveolar damage. The most common criteria are the 1994 American–European Consensus Conference definitions<sup>2</sup> (Table 29.1), which are broad and inclusive. However, these fail to specify an acute cause, use a  $P_{aO_2}/F_{iO_2}$  ratio independent of respiratory support and are not specific about the radiographic criteria. The lung injury score (LIS),<sup>3</sup> which uses a four-point score attributed to ranges of  $P_{aO_2}/F_{iO_2}$  ratio, positive end-expiratory pressure (PEEP), respiratory system compliance and the number of quadrants involved on chest radiograph, and the Delphi definition, which demands a  $P_{aO_2}/F_{iO_2}$  ratio  $\leq 200$  with 10 cmH<sub>2</sub>O PEEP, have a greater sensitivity when matched against autopsy evidence of diffuse alveolar damage.<sup>4</sup>

## CHEST RADIOGRAPH AND CHEST COMPUTED TOMOGRAPHY IN ACUTE LUNG INJURY

The interpretation of the chest radiograph is central to these definitions of ALI and ARDS. However, there is considerable interobserver variability in both chest radiograph interpretation and in the definition of an infiltrate. In the American–European Consensus Conference definition the infiltrate must be bilateral and consistent with pulmonary oedema,<sup>2</sup> whereas the LIS rates the number of quadrants with alveolar consolidation<sup>3</sup> and the Delphi definition requires bilateral airspace disease. The intention of these descriptions is fairly clear and excludes opacity due to pleural effusion, nodules, masses, collapse and pleural thickening. However, it is desirable to improve

interobserver agreement and this will require training and more specific definitions.

Chest computed tomography (CT)<sup>5</sup> has proved extremely helpful in pathophysiological studies of ALI, has demonstrated the heterogeneity of lung inflation and is commonly used to assist clinical management. Autopsy and chest radiographs of ALI show a uniform process affecting both lungs; however, chest CT early in the course of ALI in supine patients demonstrated that there was a dorsal dependent increase in lung density, and that the ventral lung was relatively normal. In addition, CT frequently showed previously undiagnosed pneumothorax, pneumomediastinum and pleural effusion. After the second week of mechanical ventilation CT scans may demonstrate altered lung architecture and emphysematous cysts or pneumatoceles.

CT numbers or Hounsfield units can be assigned to each voxel (~2000 alveoli in a standard 10-mm slice).<sup>5</sup> These data can then be used to assess what proportion of a region of interest is non-aerated, poorly aerated, normally aerated or hyperinflated. Initially a single basal lung slice was studied, but it is clear that far more information can be obtained by studying the whole lung, and by using thinner slices. This allows: (1) reconstruction of the upper and lower lobes (the middle lobe is difficult to separate); (2) the same section of lung to be studied at different levels of inflation or PEEP (the lung also moves in a cephalocaudal direction with respiration); and (3) a broader picture of the lung to be obtained (lung damage is heterogeneous in ALI). However, whole-lung CT demands considerable exposure to ionising radiation, and different information, perhaps more pertinent to mechanical ventilation, is obtained from dynamic CT.

Clinical assessment of chest CT is discussed in Chapter 35, and CT findings in ALI are discussed below, in the section on clinical management.

## EPIDEMIOLOGY

Estimates of the incidence and outcome from ALI and ARDS vary widely. In part this has been due to differences

**Table 29.1** Definition of acute lung injury (ALI) and acute respiratory distress syndrome (ARDS)<sup>2</sup>

Condition	Timing	$Pao_2/Fio_2$	Chest radiograph	PAOP
ALI	Acute	$\leq 300$ mmHg	Bilateral infiltrates	$\leq 18$ mmHg or no clinical evidence of elevated LAP
ARDS	Acute	$\leq 200$ mmHg	Bilateral infiltrates	$\leq 18$ mmHg or no clinical evidence of elevated LAP

PAOP, pulmonary artery occlusion pressure; LAP, left atrial pressure.

in the definitions used, but it also appears likely that case-mix and local factors influence outcome and incidence. Using the 1994 consensus definition the Australian incidence is 34 per 100 000 for ALI and 28 per 100 000 for ARDS;<sup>6</sup> recent US estimates are 79 and 59 per 100 000 respectively<sup>7</sup> – both much greater than many previous estimates. The Australian data equate to 1 in 10 non-cardiothoracic intensive care unit (ICU) patients developing ARDS, which reflects the tendency for clinicians to underestimate the incidence of ALI and ARDS.

Reported mortality rates are also influenced by the definitions used. For many years the mortality for ARDS was reported to be ~60%; the Australian multicentre data reported mortality rates of 32% for ALI and 34% for ARDS,<sup>6</sup> with US mortality rates a little higher at 38.5% and 41%.<sup>7</sup> However, particular diagnostic groups such as multiple trauma have a lower mortality rate than other causes of ARDS, and patients with ALI who have chronic liver disease, non-pulmonary organ dysfunction, sepsis or age greater than 70 years (hazard ratio 2.5)<sup>8</sup> have a higher risk of death. Consequently many factors need to be considered when assessing outcome prediction.

### PULMONARY FUNCTION IN SURVIVORS

Respiratory function is most abnormal soon after discontinuation of mechanical ventilation, but usually returns towards normal by 6–12 months. Although a variety of abnormal pulmonary function tests may be found, impaired diffusing capacity is the most common. This is rarely symptomatic, but occasional patients have severe restrictive disease, and this is correlated with their cumulative LIS.<sup>9</sup>

### QUALITY OF LIFE IN SURVIVORS

Compared with disease-matched ICU patients who do not develop ARDS, patients with ARDS have a more severe reduction in both pulmonary and general health-related quality of life.<sup>10</sup> Many patients have reduction in exercise tolerance that may be attributable to associated

critical-illness neuropathy and myopathy; nerve entrapment syndromes and heterotopic calcification play a role in a minority.<sup>7</sup> Depression, anxiety and posttraumatic stress disorder are also common (20–50% of survivors).<sup>7</sup> However, it is unclear whether neuropsychological disability is a direct consequence of the illness, or related to the associated stress. Finally, most survivors have cognitive impairments such as slowed mental processing, or impaired memory or concentration, and these correlate with the period and severity of desaturation  $< 90\%$ .<sup>11</sup> Although these data suggest that ARDS confers a specific risk of impaired quality of life, the mechanism is unclear. However, they do caution against permissive hypoxaemia as a strategy to reduce ventilator-induced lung injury (VILI).

### PATIENTS AT-RISK FOR ALI AND ARDS

Clinical risk factors for the development of ALI and ARDS can be classified as either direct or indirect (Table 29.2). These identify over 80% of patients who develop ARDS; the most common risk factors are sepsis, pneumonia and aspiration of gastric contents. Multiple risk factors, low pH, chronic alcohol abuse or chronic lung disease substantially increases the incidence of ALI in at-risk patients.

### BIOLOGICAL MARKERS AS PREDICTORS OF ALI

In addition to identifying these clinical risk groups, there has been considerable interest in identifying possible biological markers that could be used to predict the development of ALI. Although greater specificity may be gained from sampling the epithelial lining fluid (e.g. using bronchoalveolar lavage fluid), an ideal biological marker would be more simply sampled, such as plasma. Numerous proteins, such as the cytokines interleukin (IL)-1, tumour necrosis factor- $\alpha$  (TNF- $\alpha$ ) and IL-10, and von Willebrand's factor antigen are elevated in at-risk

**Table 29.2** Clinical risk factors for acute lung injury (ALI) and acute respiratory distress syndrome (ARDS)

Direct	Indirect
Pneumonia (46%)*	Non-pulmonary sepsis (25%)
Aspiration of gastric contents (29%)	Multiple trauma (41%)
Lung contusion (34%)	Massive transfusion (34%)
Fat embolism	Pancreatitis (25%)
Near-drowning	Cardiopulmonary bypass
Inhalational injury	
Reperfusion injury	

\*Denotes the approximate percentage of intensive care unit at-risk cases that developed ALI (data from Bersten AD, Hunt T, Nicholas TE et al. Plasma surfactant proteins (SP) as predictors of ARDS: patient demographics from an Australian multicentre study. *Am J Respir Crit Care Med* 2002; **165**: A476)

patients and patients with ALI and ARDS; however, they are not predictive. In relatively small studies both ferritin<sup>12</sup> and surfactant protein B<sup>13</sup> have been shown to be predictive of ARDS. Although ferritin likely represents a non-specific oxygen free-radical response, the leakage of surfactant protein B from the alveolus into the blood is lung-specific.

## **PATHOGENESIS**

Although it is well accepted that diffuse alveolar damage with: (1) pulmonary oedema due to damage of the alveolocapillary barrier; (2) a complex inflammatory infiltrate; and (3) surfactant dysfunction are essential components of ALI, the sequence of events is uncertain and probably depends upon the precipitating insult and host response. For example, in endotoxin-induced lung injury, hypoxaemia and reduced lung compliance occur well before recruitment of neutrophils or an increase in lung weight due to an increase in permeability.<sup>14</sup> In addition, surfactant turnover is dramatically increased prior to these changes often thought to be typical of early ALI. Further, epithelial lining fluid sampled immediately following intubation in patients with ALI has markedly increased concentrations of type III procollagen peptide, suggestive of fibrosing alveolitis extremely early in the course of lung damage.

## **THE ALVEOLOCAPILLARY BARRIER**

The normal lung consists of 300 million alveoli with alveolar gas separated from the pulmonary microcirculation by the extremely thin alveolocapillary barrier (0.1–0.2 µm thick). Since the endothelial pore size is 6.5–7.5 nm, and the epithelial pore size is almost one-tenth that, at 0.5–0.9 nm, the epithelium is the major barrier to protein flux.<sup>15</sup> The surface area of the alveoli is estimated to be 50–100 m<sup>2</sup>, which is made up predominantly of alveolar type I cells, with the metabolically active type II cells accounting for ~10% of the surface area. In turn, these cells are covered by the epithelial lining fluid, with an estimated volume of 20 ml, ~10% of which is surfactant with the remainder filtered plasma water and low-molecular-weight proteins, and a small number of cells, mainly alveolar macrophages and lymphocytes.

In ALI the alveolocapillary barrier is damaged with bidirectional leakage of fluid and protein into the alveolus and leakage of surfactant proteins and alveolar cytokines into the plasma. There is also disruption of the epithelial barrier, surfactant dysfunction and proliferation of alveolar type II cells as the progenitor of type I cells. The outcome of this process must reflect a balance between repair and fibrosing alveolitis. As discussed above, the precise sequence of events causing and maintaining damage of the alveolocapillary barrier is complex and uncertain and likely varies depending on the underlying cause. For example, indirect causes of ALI may initially cause

pulmonary endothelial injury followed by recruitment of inflammatory cells and epithelial damage, while direct causes of ALI may initially cause epithelial injury and secondary recruitment of inflammatory cells.

## **NEUTROPHILS IN ACUTE LUNG INJURY**

Neutrophils are the most abundant cell type found in both the epithelial lining fluid (e.g. bronchoalveolar lavage fluid) and alveoli in histological specimens from early in the course of ALI. Although neutrophil migration across the endothelium or epithelium does not cause injury, when activated they release reactive oxygen species, cytokines, eicosanoids and a variety of proteases that may make an important contribution to tissue damage in ALI. Following bone marrow demargination, activated neutrophils adhere to the endothelium on their passage to the alveolus, and this may be accompanied by an early, transient leukopenia. Although neutrophils have an important role in host defence due to their bactericidal activity, there is a marked (50–1000-fold) increase in the release of cytotoxic compounds when they are activated by adherence to the endothelium, epithelium or contact with interstitial extracellular matrix proteins.<sup>16</sup> The factors involved in adhesion of neutrophils are complex and involve the integrin family of proteins, selectins and a number of adhesion molecules.

In models of ALI, antibodies to adhesion molecules (e.g. CD11b/CD18 antibodies) ameliorate lung injury, suggesting a crucial and central role of this cell type. However, ALI occurs in neutropenic patients, and was not more common when granulocyte colony-stimulating factor was administered to patients with pneumonia.<sup>17</sup> Clearly, other cell types play an important role, and neutrophil chemoattractants such as IL-8 must be present in the lung prior to neutrophil accumulation.

## **OTHER CELL TYPES INVOLVED IN ACUTE LUNG INJURY**

Pulmonary endothelial cells, platelets, interstitial and alveolar macrophages and alveolar type II cells also play important roles in alveolar inflammation. Pulmonary endothelial cells express a variety of adhesion molecules and cyclooxygenase-2 (COX-2); secrete endothelin and cytokines, including IL-8;<sup>18</sup> stimulate procoagulant activity; and 'cross-talk' with the alveolar macrophages and type II cells. They will be involved in generalised endothelial activation, and are subject to mechanical stress, secondary to both vascular pressure and to their close association with the alveolus. Von Willebrand's factor antigen is synthesised by vascular endothelial cells, and although this may explain its lack of specificity for ALI, its plasma levels are a good marker of endothelial injury.<sup>19</sup>

Microvascular thrombosis is common in ALI, and contributes to pulmonary hypertension and wasted ventilation. Although platelet aggregation may contribute to ALI through release of thromboxane A<sub>2</sub>, serotonin,

lysosomal enzymes and platelet-activating factor, they are less important than the other cell types.

Alveolar macrophages are the most common cell type normally found in bronchoalveolar lavage fluid, and, together with interstitial macrophages, play an important role in host defence and modulation of fibrosis. They are capable of releasing IL-6 and a host of mediators, similar to the activated neutrophil, including TNF- $\alpha$  and IL-8 in response to stretch,<sup>20</sup> and may amplify lung injury. However, depletion of alveolar macrophages does not reduce neutrophil recruitment or outcome from tracheal instillation of *Pseudomonas aeruginosa*,<sup>21</sup> questioning the central role of this cell type. Macrophages also release a number of factors such as transforming growth factor- $\alpha$  and platelet-derived growth factor that stimulate fibroblast proliferation, deposition of collagen and glycosaminoglycans, angiogenesis and lung fibrosis.

Alveolar epithelial type II cells are extremely metabolically active; they manufacture and release surfactant, control alveolar water clearance using ion pumps, express cytokines which in turn interact with surfactant production and are the progenitor of type I cells following injury. In response to both stretch and endotoxin, type II cells express IL-8 and TNF- $\alpha$ , with the latter cytokine augmenting Na<sup>+</sup>, and hence water, egress from the alveolus.<sup>22</sup>

### CHEMOKINES IN ACUTE LUNG INJURY

The expression and secretion of chemokines (chemoattractant cytokines) at sites of inflammation are probably key proximal steps in initiating the inflammatory cascade. IL-8 appears particularly important in initiating ALI because of its ability to induce chemotaxis and activation of neutrophils. IL-8 is elevated in ALI bronchoalveolar lavage fluid within hours of the initiating insult and before recruitment of neutrophils, and in a manner that reflects subsequent morbidity and mortality. In animal models of sepsis and acid aspiration, instillation of antibodies against IL-8 prevents the recruitment of neutrophils and protects the lung. Indeed, the recruitment and retention of neutrophils require the generation and maintenance of a localised chemotactic/haptotactic gradient.<sup>23</sup>

### MEDIATORS IN ACUTE LUNG INJURY

From the discussion above it is clear that numerous mediators, derived from a number of different cell types, play important roles in the pathophysiology of ALI. These include cytokines, chemokines, complement, reactive oxygen species, eicosanoids, platelet-activating factor, nitric oxide, proteases, growth factors and lysosomal enzymes. As the alveolocapillary barrier becomes injured, these are no longer compartmentalised in the alveolus, and many of these proteins have been measured in blood as well as in the epithelial lining fluid. Care must be taken when interpreting these data as immunologic levels may not reflect biologic activity; inhibitors or binding proteins may

complex with the active protein or epitope and interfere with immunologic detection; and the ultimate biological effect will depend upon a balance of proinflammatory and anti-inflammatory effects.

Although many of the over 40 biologically active cytokines are implicated in ALI, TNF- $\alpha$ , IL-1 $\beta$ , IL-6 and IL-8 are the most important. However, even greater increases are found in their cognate receptors or antagonists, such as the counterregulatory cytokine IL-10, so that their biological impact is markedly reduced.<sup>24</sup> Despite numerous studies, measurement of cytokines in blood or epithelial lining fluid has not proven predictive of the development of ALI or of mortality.

### RESOLUTION OF ACUTE LUNG INJURY AND THE DEVELOPMENT OF FIBROSING ALVEOLITIS

Although elevated levels of type III procollagen peptide are found in the epithelial lining fluid soon after diagnosis, histological evidence of fibrosing alveolitis (mesenchymal cells and new vessels in alveoli) is not usually found until at least 5 days following the onset of ALI. In the majority of patients there is clinical resolution of ALI provided that the underlying cause is promptly and effectively treated. Alveolar oedema resolves with active transport of Na<sup>+</sup> by the type II cells followed by passive clearance of water through transcellular aquaporin channels, and repair of the alveolocapillary barrier is associated with improved outcome. Type II cells proliferate and cover the denuded epithelium before differentiating into type I cells. Both proapoptotic and antiapoptotic (granulocyte colony-stimulating factor (G-CSF) and granulocyte-macrophage colony-stimulating factor (GM-CSF)) factors are found in the alveolus during this phase; however, little is known regarding control over the delicate balance between repair and fibrosis.

### CLINICAL MANAGEMENT

The factors leading to ALI must be promptly and appropriately treated. This includes diagnosis and appropriate treatment of infection with drainage of collections and appropriate antimicrobial agents, recognition and rapid resuscitation from shock, splinting of fractures and careful supportive care. Prevention of deep venous thrombosis, stress ulceration and nosocomial infection is important in all critically ill patients. Adequacy of nutrition, often enteral nutrition, must also be considered.

### MECHANICAL VENTILATION

Patients present with acute hypoxaemic respiratory failure, and an increase in the work of breathing, usually requiring mechanical ventilation (Table 29.3). The role of non-invasive ventilation in ALI is uncertain as there appears to be a greater complication rate, perhaps due to delayed intubation.<sup>25</sup> However, non-invasive ventilation is worth considering in particular circumstances (see Chapter 33).

**Table 29.3** Pathophysiology of acute lung injury (ALI) and adult respiratory distress syndrome (ARDS)

Feature	Cause(s)
Hypoxaemia	True shunt (perfusion of non-ventilated airspaces) Impaired hypoxic pulmonary vasoconstriction V/Q mismatch is a minor component
↑ Dependent densities (CT) (Collapse/consolidation)	Surfactant dysfunction alveolar instability Exaggeration of normal compression of dependent lung due to ↑ weight (↑ lung water, inflammation)
↑ Elastance (↓ compliance)	Surfactant dysfunction (↑ specific elastance) ↓ Lung volume ('baby lung') ↑ Chest wall elastance Fibrosing alveolitis (late)
↑ Minute volume requirement	↑ Alveolar dead space ( $V_{Dphys}/V_t$ often 0.4–0.7) ↑ $V_{CO_2}$
↑ Work of breathing	↑ Elastance ↑ Minute volume requirement
Pulmonary hypertension	Pulmonary vasoconstriction (thromboxane $A_2$ , endothelin) Pulmonary microvascular thrombosis Fibrosing alveolitis Positive end-expiratory pressure

The method and delivery of ventilatory support must take into account the pathophysiology of ALI and ARDS. For many years laboratory studies have described VILI, and the most important clinical study was the ARDS Network study where 861 ALI patients from 75 ICUs were randomised to receive a tidal volume ( $V_T$ ) of either 12 or 6 ml/kg predicted body weight.<sup>26</sup> Mortality was reduced by 22% from 40% to 31% in the lower- $V_T$  group. There was a strict PEEP and  $F_{iO_2}$  protocol, and patients were ventilated with assist-control ventilation to avoid excessive spontaneous  $V_T$ . Meta-regression of five clinical studies trialling different  $V_T$  strategies found that a  $V_T < 7.7$  ml/kg predicted body weight (pbw) was protective, and that above 11.2 ml/kg pbw was borderline detrimental.<sup>27</sup> Whether this protective effect of lower  $V_T$  is due to lower static distending pressure of the respiratory system is contentious; however, Hager and colleagues<sup>28</sup> found that lower  $V_T$  ventilation was protective across all quartiles of plateau pressure ( $P_{plat}$ ) in the ARDS Network trial, and that no safe upper limit of  $P_{plat}$  could be identified.

#### AVOIDANCE OF OVERSTRETCH AND INADEQUATE RECRUITMENT

The increase in dependent lung density found on chest CT, due to non-aerated and poorly aerated lung, reduces the volume of aerated lung available for tidal inflation. Both PEEP and tidal recruitment will increase aeration of some of these airspaces, but a  $V_T$  that is not reduced in proportion to the reduction in aerated lung may lead to overstretch of aerated lung parenchyma, which may lead to further diffuse alveolar damage. Studies where increased chest wall

compliance led to increase airway pressure ( $P_{aw}$ ) have clearly shown that it is lung stretch, not increased  $P_{aw}$ , that causes injury;<sup>29</sup> consequently this has been termed volutrauma. In addition, laboratory studies have shown that repeated opening and closing of airspaces by tidal recruitment result in diffuse alveolar damage (atelectrauma). Although data from animal models support both as important mechanisms of VILI, with both resulting in alveolar inflammation and elevated alveolar cytokines (biotrauma),<sup>31</sup> which may 'spill' into the systemic circulation,<sup>30</sup> only VILI due to overstretch is supported by clinical data. CT scans performed during ARDS Network protective ventilation show that tidal inflation occurs primarily in either normally aerated or overinflated compartments, with little tidal recruitment.<sup>31</sup> The pulmonary inflammatory response was associated with tidal overinflation.

#### OVERSTRETCH

The normal lung is fully inflated at a transpulmonary pressure of ~30 cmH<sub>2</sub>O. Consequently, a maximum  $P_{plat}$ , the elastic distending pressure, of 30–35 cmH<sub>2</sub>O has been recommended to avoid overstretch, and the ARDS Network study targeted  $P_{plat} \leq 30$  cmH<sub>2</sub>O.<sup>28</sup> The transpulmonary pressure may be lower than expected for a given  $P_{plat}$  in patients with a high chest wall elastance (e.g. obesity, abdominal compartment syndrome, postabdominal or thoracic surgery). It is also common for individual patients to show evidence of overinflation at much lower elastic distending pressures (18–26 cmH<sub>2</sub>O).<sup>32,33</sup> Finally, inspiratory muscle effort will lower  $P_{plat}$  by reducing intrapleural pressure, potentially avoiding detection of an excessive transpulmonary pressure.

This is particularly common when pressure support ventilation is used as a primary mode of ventilatory support:  $V_T$  that would produce an unacceptably high  $P_{\text{plat}}$  during mechanical ventilation will produce the same volutrauma during a spontaneous or supported mode of ventilation, and should be avoided. None of these issues is easily overcome. Although placement of an oesophageal balloon (see Chapter 34) allows measurement of the transpulmonary pressure, it must be correctly placed, have an adequate occlusion pressure ratio, and measurements are preferably performed in a semisitting position in order to lift the mediastinum off the oesophagus. Similarly, static or dynamic volume–pressure curves or quantitative chest CT can be used to determine overinflation, though chest CT cannot determine overstretch.<sup>5</sup> Consequently, unless particular expertise is available,  $V_T$  limitation is currently the most practical approach.

#### ADEQUATE PEEP

PEEP improves  $P_{\text{aO}_2}$  by increasing functional residual capacity, and recruiting alveoli. Because PEEP may reduce cardiac output by impairing venous return, Suter and coworkers suggested that maximum oxygen delivery (oxygen content  $\times$  flow) should be used to optimise PEEP.<sup>33</sup> Other end-points such as either titrating PEEP to a particular  $P_{\text{aO}_2}/F_{\text{iO}_2}$  ratio or to prevent repeated opening and closing of alveoli have been suggested. The ARDS Network Study protocol<sup>28</sup> titrates PEEP to the  $P_{\text{aO}_2}/F_{\text{iO}_2}$  ratio, but this results in tidal overinflation in about one-third of patients.<sup>33</sup> Concurrently there is little evidence of tidal recruitment, which may explain why a higher PEEP protocol<sup>34</sup> did not prove beneficial. In patients at risk for ARDS prophylactic PEEP (8 cmH<sub>2</sub>O) was not protective.<sup>35</sup>

The lower inflection point of a volume–pressure curve has been used to set PEEP, because early studies suggested that this reflected recruitment of collapsed alveoli. However, in patients with ALI, recruitment occurs well above the lower inflection point, along the entire volume–pressure curve and above the upper inflection point.<sup>36,37</sup> Concurrently, there is frequently evidence of overstretching and hyperinflation on CT scans<sup>33,38</sup> or dynamic volume–pressure analysis.<sup>33</sup> The amount of lung available for recruitment in ARDS is also extremely variable,<sup>39</sup> and does not appear to differ comparing pulmonary with extrapulmonary causes.<sup>40</sup> Although routine CT analysis has been advocated by some, it is cumbersome and has not been shown to influence outcome; non-invasive bedside alternatives are under investigation. Consequently, PEEP titration is often a compromise aiming to minimise both atelectrauma and volutrauma.<sup>41</sup>

Although a protective ventilation strategy using the ‘open-lung’ approach with PEEP levels above the lower inflection point and frequent recruitment manoeuvres did report a reduction in mortality, the treatment arm also included low  $V_T$  and recruitment manoeuvres.<sup>42</sup> Reasonable approaches to PEEP titration include: (1) the use

of a scale similar to the ARDS Network protocol; (2) titration of PEEP to  $P_{\text{aO}_2}$ , aiming for a PEEP of  $\sim 15$  cmH<sub>2</sub>O; or (3) measuring elastic mechanics at the bedside. The delta-PEEP technique is a simple technique that indirectly assesses excessive stress as PEEP is changed at a constant  $V_T$ <sup>33</sup> (see Chapter 34).

#### Recruitment manoeuvres

It is unclear whether additional recruitment manoeuvres are of additional benefit once an adequate level of PEEP is applied. Typically a high level of continuous positive airways pressure (30–40 cmH<sub>2</sub>O) is applied for 30–40 seconds in an apnoeic patient, followed by return to a lower level of PEEP and controlled ventilation. This may be followed by a marked improvement in oxygenation. However, this is not a consistent finding, and hypotension may occur due to reduced venous return if there is inadequate fluid loading. Although a recruitment manoeuvre was applied by Amato and colleagues and associated with an improvement in outcome, they also applied a higher level of PEEP and lower  $V_T$  in the protective lung strategy group.<sup>42</sup> A number of small trials have shown improvement in oxygenation following recruitment manoeuvres; however, the largest clinical trial<sup>43</sup> failed to show an effect. Grasso and colleagues<sup>44</sup> found that recruitment manoeuvres were only effective early in ARDS and with lower levels of baseline PEEP, probably explaining the variable responses reported.

In addition to physical recruitment of alveoli, lung stretch above resting  $V_T$  is the most powerful physiological stimulus for release of pulmonary surfactant from type II cells. This is associated with an increase in lung elastance and improved  $P_{\text{aO}_2}$  in the isolated perfused lung,<sup>45</sup> and is a possible explanation for the improvement in oxygenation, recruited lung volume and elastance reported with the addition of three sigh breaths in patients with ARDS.<sup>46</sup> Similarly, in models of lung injury biologically variable or fractal  $V_T$  is associated with less lung damage with lower alveolar levels of IL-8,<sup>47</sup> improved oxygenation and lung elastance with greater surfactant release.<sup>48</sup> Again, these data caution against monotonous low  $V_T$  ventilation, and suggest that intermittent or variable lung stretch may reduce lung injury.

#### MODE OF VENTILATION

Non-invasive ventilation should not be routinely used in ALI and ARDS (see Chapter 33) and most patients require intubated mechanical ventilation. Following intubation controlled ventilation allows immediate reduction in the work of breathing and application of PEEP and a high  $F_{\text{iO}_2}$ . Later in the clinical course assisted or supported modes of ventilation may allow better patient–ventilator interaction (see Chapter 27), and possibly improved oxygenation through better mismatch as a result of diaphragmatic contraction.<sup>49</sup> Withdrawal or weaning from mechanical ventilation is discussed in Chapter 27.

An advantage of assist-control ventilation (as used in the ARDS Network study) is that spontaneous effort

cannot generate a greater volume than  $V_T$ . Care should be taken with synchronised intermittent mandatory ventilation (SIMV), particularly if pressure support is added to SIMV, as excessive  $V_T$  may occur during supported breaths. There is an increasing tendency to use pressure-controlled (PC) ventilation or pressure-regulated volume control (PRVC) as  $P_{pk}$  is lower than volume-controlled (VC) ventilation with a constant inspiratory flow pattern. However, the decelerating flow pattern of PC or PRVC means that most of the resistive pressure ( $P_{res}$ ) during inspiration is dissipated by end-inspiration, which is in contrast to VC with a constant inspiratory flow pattern where  $P_{res}$  is dissipated at end-inspiration (see Chapter 27, Figure 27.2). Consequently, with PC and PRVC  $P_{pk} \approx P_{plat}$  which is the same as  $P_{plat}$  during VC.<sup>50</sup> In addition oxygenation, haemodynamic stability and mean airway pressure are no different between PC and VC, and a moderately sized randomised study found no difference in outcome.<sup>51</sup> However, there may be differences in lung stress due to greater viscoelastic build up with VC.

Inverse-ratio ventilation, often together with PC, has been used in ARDS. However, when PEEP<sub>i</sub> and total PEEP are taken into account, apart from a small decrease in  $P_{aCO_2}$ , there are no advantages with inverse-ratio ventilation. Mean airway pressure is higher, with a greater risk of both haemodynamic consequences<sup>50</sup> and regional hyperinflation.<sup>52</sup> Consequently, an inspiratory to expiratory ratio less than 1:1 is recommended.

A number of other modes of ventilation (see Chapter 27), including airway pressure release ventilation and high-frequency oscillation, have been proposed for use in ARDS, but without new data there do not appear to be any major advantages over the optimal conventional ventilation.

### TARGET BLOOD GASES

As discussed above, there are many variables that need to be considered when choosing target blood gases in ARDS. For example, if a patient also has a traumatic brain injury, it may be inappropriate to accept hypercapnia.

### Oxygenation targets and $F_{iO_2}$

There must be a compromise between the major determinants of oxygenation, including the extent of poorly or non-aerated lung, hypoxic pulmonary vasoconstriction and mixed venous oxygen saturation, and the target  $P_{aO_2}$ . The association between cognitive impairment and arterial saturation ( $S_{aO_2}$ ) < 90%<sup>11</sup> suggests that  $S_{aO_2} \geq 90\%$  and usually  $P_{aO_2} > 60$  mmHg is a reasonable target. Because positive-pressure ventilation may reduce cardiac output it is also important to consider tissue oxygenation.

In addition to PEEP, increased  $F_{iO_2}$  is used to improve  $S_{aO_2}$ . However, high  $F_{iO_2}$  may also cause tissue injury, including diffuse alveolar damage. The balance between increased airway pressure and  $F_{iO_2}$  is unknown, but high  $F_{iO_2}$  is generally regarded as being less damaging.<sup>53</sup> In part this is because diffuse alveolar damage itself protects

the lung against hyperoxia, perhaps through prior induction of scavengers for reactive oxygen species.<sup>54</sup> A reasonable compromise is to start ventilation at a  $F_{iO_2}$  of 1 and to titrate down, aiming for an  $F_{iO_2} \leq 0.6$ . In patients with extreme hypoxaemia, additional measures such as inhaled nitric oxide (iNO) and prone positioning may be tried, along with a lower  $S_{aO_2}$  target.

### Carbon dioxide target

Low  $V_T$  strategies will result in elevations in  $P_{aCO_2}$  unless minute ventilation is augmented by an increase in respiratory rate. The ARDS Network protocol aimed at normocapnia, with a maximum respiratory rate of 35 breaths/min, to minimise respiratory acidosis.<sup>28</sup> This exposes the lung to more repeated tidal stretch, and may result in dynamic hyperinflation due to a shortened expiratory time.<sup>55</sup> In addition, allowing the  $P_{aCO_2}$  to rise above normal may not be harmful in many patients.

If hypercapnic acidosis occurs slowly, intracellular acidosis is well compensated, and the associated increase in sympathetic tone may augment cardiac output and blood pressure. Although the respiratory acidosis may worsen pulmonary hypertension and induce myocardial arrhythmias, these effects are often small, particularly if there has been time for metabolic compensation. In addition, in an ischaemia–reperfusion model of ALI, therapeutic hypercapnia reduced lung injury and apoptosis.<sup>56</sup> However, clinical studies of permissive hypercapnia must be undertaken before therapeutic hypercapnia is considered. Hypercapnia should be avoided in patients with or at risk from raised intracranial pressure.

## ADDITIONAL MEASURES TO IMPROVE OXYGENATION

### PRONE POSTURE

In ~ 70% of patients with ARDS, prone positioning will result in a significant increase in  $P_{aO_2}$ , with a modest increase in  $P_{aO_2}$  sustained in the supine position.<sup>57</sup> The mechanisms involved include recruitment of dorsal lung, with concurrent collapse of ventral lung; however, perfusion is more evenly distributed, leading to better matching. Although three large clinical studies<sup>58,59</sup> did not show an improvement in mortality, post-hoc analysis suggests that mortality may be reduced in the most hypoxaemic patients.<sup>57</sup> Although further data are awaited, prone positioning may be used as rescue therapy in life-threatening hypoxaemia.

### MANIPULATION OF THE PULMONARY CIRCULATION

iNO and prostacyclin (PGI<sub>2</sub>) may be used to reduce pulmonary shunt and right ventricular afterload by reducing pulmonary artery impedance. When hypoxic pulmonary vasoconstriction is active, there is redistribution of pulmonary blood flow away from the poorly ventilated dependent areas to more normally ventilated lung, leading to an increase in  $P_{aO_2}$ . Both iNO and PGI<sub>2</sub> are potent vasodilators, and since they are delivered as part

of the gas mix (iNO) or inhaled (PGI<sub>2</sub>), they are delivered to well-ventilated lung. Both act to vasodilate the local pulmonary circulation and increase the redistribution of pulmonary blood flow away from poorly ventilated lung, reducing pulmonary shunt and improving oxygenation. Intravenous almitrine is a selective pulmonary vasoconstrictor that reinforces hypoxic pulmonary vasoconstriction, and although this may improve oxygenation alone, there is a synergistic effect with iNO.

Inhaled NO or PGI<sub>2</sub> may also be used to reduce right ventricular afterload; however a consequent increase in cardiac output is rare in ARDS. Intravenous PGI<sub>2</sub> will improve cardiac output in ARDS; however, there is non-specific pulmonary vasodilation with increased blood flow through poorly ventilated lung zones, resulting in a deterioration in oxygenation.

#### **Inhaled nitric oxide**

Nitric oxide is an endothelium-derived smooth-muscle relaxant. It also has other important physiological roles, including neurotransmission, host defence, platelet aggregation, leukocyte adhesion and bronchodilation. Doses as low as 60 parts per billion iNO may improve oxygenation; however, commonly used doses in ARDS are 1–60 parts per million, with the higher doses required for reduction in pulmonary artery pressure. A rise in  $P_{aO_2}$  exceeding 20% is generally regarded as a positive response, and iNO should be continued at the minimum effective dose.

Inhaled NO may be delivered continuously or using intermittent inspiratory injection. Delivery is usually in the form of medical-grade NO/N<sub>2</sub>, and this should be adequately mixed to avoid delivery of variable NO concentrations. It is recommended that inspiratory NO and NO<sub>2</sub> concentrations are measured, either by an electrochemical method or by chemiluminescence. The electrochemical method is accurate to 1 ppm, which is adequate for clinical use, and is less expensive. Local environmental levels of NO and NO<sub>2</sub> are low and predominantly influenced by atmospheric concentrations; however, it is still common practice to scavenge expired gas. Binding to haemoglobin in the pulmonary circulation rapidly inactivates NO, and systemic effects are only reported following high concentrations of iNO. Systemic methaemoglobin levels may be monitored, and are generally less than 5% during clinical use of iNO, but they should be compared to a baseline level. NO may cause lung toxicity through combination with oxygen free radicals, and through metabolism of NO to NO<sub>2</sub>, although these do not appear to be major clinical problems.

Only 40–70% of patients with ARDS have improved oxygenation with iNO (responders), and this is likely due to active hypoxic pulmonary vasoconstriction in the remainder. Addition of intravenous almitrine can have an additive effect on oxygenation, and may improve the number of responders. Although clinical trials have shown no improvement in mortality or reversal of ALI,

iNO was safe and did significantly improve oxygenation initially (as compared to placebo or no iNO), but this was not sustained beyond 12–24 hours. Consequently iNO cannot be recommended for routine use in ARDS, although in some patients with severe hypoxaemia, perhaps in combination with almitrine, iNO will provide temporary rescue.

#### **Inhaled prostacyclin**

PGI<sub>2</sub> (up to 50 ng/kg per min) improves oxygenation as effectively as iNO in ARDS patients. It is continuously jet-nebulised due to its short half-life (2–3 min). Potential advantages include increased surfactant release from stretched type II cells, avoidance of the potential complications of iNO and minimal toxicity. However, PGI<sub>2</sub> is dissolved in an alkaline glycine buffer which alone can result in airway inflammation. Iloprost is a derivative of PGI<sub>2</sub> with similar activity, a longer duration of action, and without an alkaline buffer. However, neither agent has been shown to improve outcome in ARDS patients.

### **PHARMACOLOGICAL THERAPY**

Apart from improved mortality in sepsis following activated protein C,<sup>60</sup> there are no proven pharmacological therapies for ALI or ARDS despite numerous studies. However, the lack of a protective ventilation strategy in many of these studies may have masked a drug effect.

#### **SURFACTANT REPLACEMENT THERAPY**

Surfactant dysfunction is an important and early abnormality contributing to lung damage in ALI.<sup>38,61</sup> Pulmonary surfactant reduces surface tension, promoting alveolar stability, reducing work of breathing and lung water. In addition surfactant has important roles in lung host defence. Reactive oxygen species, phospholipases and increased protein permeability lead to inhibition of surfactant function, composition is abnormal and turnover is markedly increased. VILI is difficult to demonstrate without surfactant dysfunction.<sup>56</sup> Consequently, there has been considerable interest in exogenous surfactant replacement therapy.

Recombinant surfactant protein C-based surfactant administered intratracheally improves oxygenation in ARDS without an improvement in mortality.<sup>62</sup> However, as subgroup analysis appeared promising, further clinical trials are under way in direct or pulmonary causes of ARDS.

#### **GLUCOCORTICOIDS**

Glucocorticoids may have a role in ARDS through reduction of the intense inflammatory response and their potential to reduce fibroproliferation and collagen deposition, by faster degradation of fibroblast procollagen mRNA. Although a small study, with cross-over, showed a reduction in mortality,<sup>63</sup> a study of 180 patients with persistent ARDS (of at least 7 days' duration) found no

improvement in mortality up to 180 days later, but did show an improvement in ventilator-free days and shock-free days.<sup>64</sup> However, this was offset by neuromuscular complications, and patients enrolled at least 14 days after the onset of ARDS had increased 60- and 180-day mortality rates. These data do not support the routine use of steroids in ARDS.

#### KETOCONAZOLE

Ketoconazole is an antifungal drug that also inhibits thromboxane synthase and 5-lipoxygenase. However, promising results from small studies in at-risk patients have not been confirmed in a larger treatment trial.<sup>65</sup>

#### OTHER PHARMACOLOGIC THERAPIES

Numerous other therapies, including cytokine antagonism, non-steroidal anti-inflammatory drugs, scavengers of reactive oxygen species and lisofylline<sup>66</sup> have been trialed without success. The complex balance of inflammation and repair in ALI, and the critical additional damage secondary to VILI, may explain these results. However, studies in less heterogeneous groups with minimisation of VILI using standardised ventilation protocols, together with a growing understanding of ALI and ARDS, offer potential pharmacological therapies.

# Pulmonary embolism

Andrew R Davies and David V Pilcher

Pulmonary embolism (PE) is a commonly considered, but relatively uncommonly diagnosed, condition. It is important to have an adequate understanding of the pathophysiology, as well as a rapid and reliable strategy of investigation and management. This is particularly important in critically ill patients where diagnosis can be difficult and PE may be life-threatening.

## AETIOLOGY

Deep venous thrombosis (DVT) and PE are components of a single disease termed venous thromboembolism (VTE). Embolisation of DVT to the pulmonary arteries leads to PE, which is the most severe and life-threatening manifestation. VTE occurs in the population at a rate of about 1 in 1000 per year and is more common both with advancing age and in males.

Most PE results from DVT of the lower limbs, pelvic veins or inferior vena cava (IVC), although DVT of the upper limbs, right atrium or ventricle does also occur. Up to 40% of patients with DVT develop PE, although if the DVT is isolated to below the knee, clinically obvious PE is rare.

Predisposing risk factors for VTE involve one or more components of Virchow's triad: (1) venous stasis; (2) vein wall injury; and (3) hypercoagulability of blood. The main factors are immobility (from any cause), surgery, trauma, malignancy, pregnancy and thrombophilia (Table 30.1).

VTE can be recurrent, which should prompt investigation for thrombophilia, which describes a group of conditions which are inherited and associated with a high incidence of VTE. The most important of these is activated protein C resistance, which is mediated by the factor V Leiden mutation. Up to 50% of patients with recurrent VTE episodes (as well as 20% of patients with a single episode) have this condition; however, its association appears to be greater with DVT than with PE.<sup>1</sup> Up to 5% of patients with VTE develop chronic pulmonary hypertension.<sup>2</sup>

## PATHOPHYSIOLOGY

The effects of PE range from being incidental and clinically irrelevant to causing severe obstruction to the pulmonary

circulation and sudden death. Pulmonary arterial obstruction and the subsequent release of vasoactive agents such as serotonin and thromboxane A<sub>2</sub> from platelets lead to elevated pulmonary vascular resistance and acute pulmonary hypertension.

Acute pulmonary hypertension increases right ventricular (RV) afterload and RV wall tension, which leads to RV dilatation and dysfunction, with coronary ischaemia being a major contributing mechanism.<sup>3</sup> In massive PE, the combination of coronary ischaemia, RV systolic failure, paradoxical interventricular septal shift and pericardial constraint leads to left ventricular (LV) dysfunction and a 'low-cardiac-output' shock state. In patients with underlying cardiorespiratory disease, a small PE can have profound consequences.

Pulmonary arterial obstruction causes a mismatch between lung ventilation and perfusion, which leads to hypoxaemia. The ventilation of lung units which are no longer perfused causes increased dead-space ventilation and a widening of the end-tidal to arterial CO<sub>2</sub> gradient. Alveolar hyperventilation also occurs, leading to hypocapnia. Increased right atrial pressure can open a patent foramen ovale, which often results in right-to-left shunting manifested as either profound hypoxaemia or paradoxical (arterial) embolisation, which commonly presents as a cerebral infarct.

## CLINICAL PRESENTATION

PE is relatively uncommon in critically ill patients despite the frequent presence of risk factors for VTE. However, when PE does occur, the diagnosis is frequently overlooked or is difficult to confirm because of the presence of coexistent cardiorespiratory disease. Clinical assessment raises the suspicion of PE but is neither sensitive nor specific. A number of clinical prediction systems have been developed, the most widely reported of which are the Wells' score and the Geneva score.<sup>4</sup> The differential diagnosis is listed in Table 30.2.

## SYMPTOMS

Dyspnoea, pleuritic chest pain, and haemoptysis are the classic symptoms of PE. Most patients will have at least

**Table 30.1** Risk factors for venous thromboembolism

<b>Primary hypercoagulable states (thrombophilia)</b>
Antithrombin III deficiency
Protein C deficiency
Protein S deficiency
Resistance to activated protein C resistance (inherited factor V Leiden mutation)
Hyperhomocysteinaemia
Lupus anticoagulant (antiphospholipid antibody)
<b>Secondary hypercoagulable states</b>
Immobility
Surgery
Trauma
Malignancy
Pregnancy and the puerperium
Obesity
Smoking
Oestrogen-containing oral contraception or hormone replacement therapy
Indwelling catheters in great veins and the right heart
Burns
Patients with limb paralysis (e.g. spinal injuries)
Heart failure
Increasing age

**Table 30.2** Differential diagnosis of pulmonary embolism

Acute myocardial infarction
Acute pulmonary oedema
Pneumonia
Asthma or exacerbation of chronic obstructive pulmonary disease
Pericardial tamponade
Pleural effusion
Fat embolism
Pneumothorax
Aortic dissection
Rib fracture
Musculoskeletal pain
Anxiety

one of these symptoms, with dyspnoea being the most common. The combination of pleuritic chest pain and haemoptysis reflects a late presentation where pulmonary infarction has occurred. If syncope occurs there is a high likelihood that there has been a massive PE. A family history of venous thrombosis raises the possibility of inherited thrombophilia.

### PHYSICAL SIGNS

Physical signs can be absent, but the most frequent sign is tachypnoea. Others include tachycardia, fever and signs of RV dysfunction (raised jugular venous pressure, parasternal heave and loud pulmonary component of the second

heart sound). If massive PE is present, signs may include hypotension, pale mottled skin and peripheral or even central cyanosis. It is important also to examine for signs of DVT in the legs and arms.

### INVESTIGATIONS

The diagnosis of PE requires a high level of clinical suspicion and the appropriate use of investigations. The aim of these investigations is to confirm or exclude the presence of PE and then to stratify treatment accordingly. The optimal investigation strategy depends upon the individual patient and institution as a number of investigations are available. Pulmonary angiography has traditionally been considered the 'gold standard' for the diagnosis of PE. The advent of multidetector row computed tomography (CT) scanning (which compares well with standard pulmonary angiography<sup>5</sup>) has led to the emergence of this as the 'first-line' test in many centres. A suggested investigation algorithm is shown in Figure 30.1.

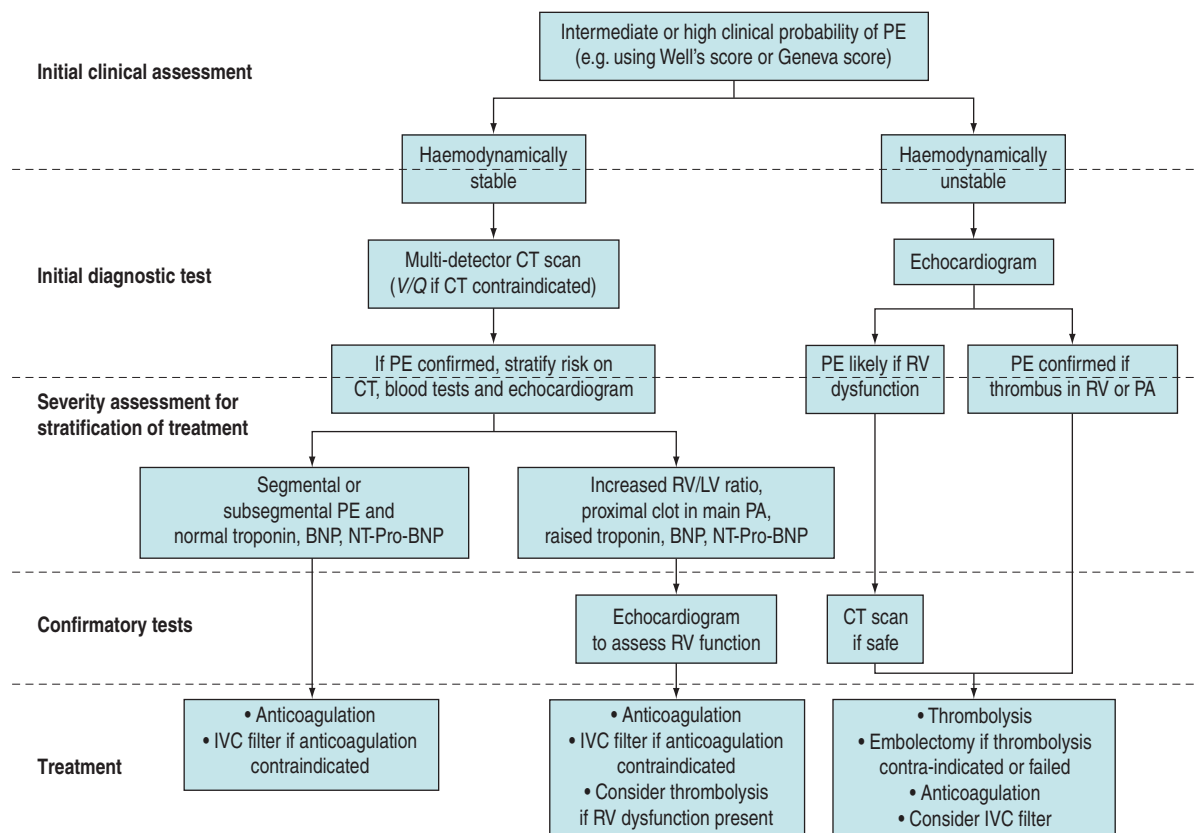

### D-DIMER

The serum D-dimer level is useful for exclusion of VTE, particularly when it is normal and combined with a low-risk clinical assessment.<sup>6</sup> A variety of different assays are available. Negative tests, particularly from enzyme-linked immunosorbent assays (ELISA), are highly predictive of the absence of both DVT and PE.<sup>7</sup> A high D-dimer concentration is also an independent predictive factor associated with mortality.<sup>8</sup>

Unfortunately, positive D-dimer tests are common in intensive care unit (ICU) patients who often suffer from one of the variety of conditions (such as trauma, surgery, diffuse intravascular coagulation, malignancy, acute myocardial infarction, pneumonia and heart failure) which also lead to a raised D-dimer, meaning that other tests are required to confirm or refute the diagnosis of VTE.

### TROPONIN, BRAIN NATRIURETIC PEPTIDE (BNP) AND NT-TERMINAL PRO-BNP

Although of little use for diagnosis, measurement of troponin, BNP or NT-terminal Pro-BNP can add to the risk stratification of patients with known PE. The presence of a raised troponin is associated with haemodynamic instability in patients with non-massive PE independently of clinical, echocardiographic and laboratory findings.<sup>9</sup> Raised troponin also predicts a higher mortality.<sup>10</sup> Low levels of BNP and NT-terminal Pro-BNP have been shown to correlate with an uneventful course in patients with known PE.<sup>11</sup> NT-terminal Pro-BNP appears to be a better predictor of outcome than troponin.<sup>12</sup>

**Figure 30.1** Suggested investigation and treatment algorithm for pulmonary embolism (PE). CT, computed tomography; V/Q, ventilation/perfusion scan; RV, right ventricular; PA, pulmonary artery; BNP, brain natriuretic peptide; RV/LV, right ventricle/left ventricle; IVC, inferior vena cava.

### ARTERIAL BLOOD GASES

A normal arterial blood gas profile does not rule out the diagnosis; however hypoxaemia (with a widened alveolar-arterial oxygen gradient), hypocapnia and an increased end-tidal CO<sub>2</sub> gradient<sup>13</sup> should raise the suspicion of PE, even though there are many other causes of these findings in critically ill patients.<sup>14</sup> Metabolic acidosis may be present if shock from a large PE occurs.

### ELECTROCARDIOGRAPH

A normal electrocardiograph (ECG) is found in about one-third of patients. Apart from sinus tachycardia (which is non-specific), the most frequent ECG abnormalities are non-specific S-T depression and T-wave inversion in the anterior leads, reflecting right heart strain. The pattern of a deep S-wave in lead I, and a Q-wave and inverted T-wave in lead III (S1Q3T3) is classical but is infrequently present. Other possible abnormalities include left- or right-axis deviation, P pulmonale, right bundle-branch block and atrial arrhythmias. The ECG is also useful in excluding acute myocardial infarction and pericarditis.

### CHEST X-RAY

The chest X-ray is often normal or only slightly abnormal, with non-specific signs such as cardiac enlargement, pleural effusion, elevated hemidiaphragm, atelectasis and localised infiltrates. More specific findings, including focal oligoemia, a peripheral wedge-shaped density above the diaphragm or an enlarged right descending pulmonary artery,<sup>15</sup> are uncommon and difficult for non-radiologists to identify. The chest X-ray is also useful in identifying an alternative diagnosis such as pneumothorax, pneumonia, acute pulmonary oedema, rib fracture and pleural effusion.

### COMPUTED TOMOGRAPHY

As CT technology has improved, CT angiography (CTA) has emerged as a cost-effective and clinically reliable alternative to the V/Q scan.<sup>16</sup> The single-detector row CT has been superseded by multidetector row CT, which allows imaging of the entire chest with high-resolution images in 'in-plane' and 'through-plane' resolution. High-resolution images to the level of segmental and in some cases

subsegmental pulmonary arteries can be obtained in a short time period (often a single breath-hold).

When CTA is compared to conventional angiography it appears reliable, with sensitivity, specificity and accuracy of 100%, 89% and 91% respectively.<sup>5</sup> Adding venography of the leg veins to the CTA (CTA-CTV) further increases the diagnostic certainty.<sup>17</sup> It is therefore recommended that CTA or CTA-CTV should be the principal radiological test for patients with high and moderate probability of PE.<sup>18</sup>

Although the ability of many CT scanners to detect PE at the subsegmental level is limited, it is debatable whether this is of clinical significance. Patients who have negative or indeterminate CT scans and in whom anticoagulation is withheld have low subsequent rates of thromboembolic events.<sup>19</sup>

The advantage of CT is that it can not only diagnose PE but can also be used to assess severity of the condition. Increased RV/LV ratio (> 0.9)<sup>20</sup> and clot in the

proximal branches of the pulmonary artery<sup>21</sup> correlate with the clinical severity of PE. Severity stratification is further increased by combining CT with other tests such as troponin<sup>9</sup> and BNP or NT-terminal ProBNP.<sup>11</sup> CT scanning may also identify the causative DVT in the veins of the legs, pelvis and abdomen or detect alternative or additional diagnoses such as a pulmonary mass, pneumonia, emphysema, pneumothorax, pleural effusion or mediastinal adenopathy (Figure 30.2).

### ECHOCARDIOGRAPHY

Because of its portability, echocardiography has become increasingly useful in critically ill patients with possible PE. Many patients with PE have an echocardiographic abnormality, the most common being RV dilatation, RV hypokinesis, paradoxical interventricular septal motion toward the LV, tricuspid regurgitation and pulmonary hypertension.<sup>22</sup> The pattern of RV hypokinesis with

**Figure 30.2** Computed tomography (CT) scanning and pulmonary embolism (PE). Three CT images from the same patient demonstrating the ability of CT to detect pulmonary emboli, assess severity and confirm additional diagnoses. Image 1 (mediastinal window): filling defects in the right pulmonary artery and inferior branch of the left pulmonary artery. A pulmonary artery catheter is also in situ. Image 2 (lung window): a left pneumothorax with pleural adhesions, and a small area of left-sided posterior consolidation. Image 3 (mediastinal window): dilatation of the right ventricle relative to the left ventricle.

apical sparing is considered pathognomonic for PE.<sup>23</sup> The presence of RV dysfunction correlates with mortality.<sup>24</sup> Echocardiography is poor at excluding PE, as a negative echocardiogram can miss up to 50% of PEs.<sup>25</sup>

Transthoracic echocardiography will also allow estimation of pulmonary arterial pressure, identification of intracardiac thrombi (which usually requires surgical embolectomy) and aids in differential diagnosis by excluding aortic dissection and pericardial tamponade. Transoesophageal echocardiography has the additional benefit of directly identifying embolus in the proximal pulmonary arteries, which is common in patients with haemodynamically significant PE.<sup>26</sup>

Echocardiography has its best application in haemodynamically unstable patients, where it can be rapidly brought to the patient. If the patient has RV dilatation and hypokinesis in the right clinical setting, PE is extremely likely.

### VENTILATION/PERFUSION SCANNING

The lung ventilation/perfusion ( $V/Q$ ) scan is becoming less commonly used with the advent of multidetector row CT. The perfusion scan identifies defects in perfusion which may be classified as single or multiple, and as sub-segmental, segmental or lobar. By combining this with ventilation scanning, these perfusion defects can then be labelled as mismatched (normal ventilation in a zone of perfusion defect) or matched defects (ventilation defect corresponds to perfusion defect). The probability of PE is then classified as high, intermediate or low probability for PE, or normal.<sup>27</sup>

A normal lung scan effectively excludes PE and treatment can be safely withheld. A high-probability scan is considered diagnostic for PE. The majority of patients do not have such clear-cut scan results, and even a low-probability scan cannot satisfactorily exclude PE, as a patient with a low-probability scan but with a high level of clinical suspicion has a 40% chance of having a PE.

Despite the increased use of CT, the  $V/Q$  scan retains a role when CT is either unavailable or contraindicated (e.g. significant renal impairment, anaphylaxis to intravenous contrast or pregnancy).<sup>15</sup>  $V/Q$  scanning also allows quantification of regional blood flow within the lungs, which may be required in the assessment of chronic pulmonary venous embolism.

### MAGNETIC RESONANCE IMAGING

PE may also be diagnosed by gadolinium-enhanced magnetic resonance pulmonary angiography. So far, this has proven more useful in the assessment of chronic VTE.

### PULMONARY ANGIOGRAPHY

The pulmonary angiogram is regarded as the only test which can exclude PE with relative certainty. It will detect most PEs even at the subsegmental level. However, it is unavailable in many centres.

### SEARCH FOR DEEP VENOUS THROMBOSIS

Doppler ultrasound has been recommended to search for DVT in the leg veins, from where over 90% of emboli originate. If a leg DVT is confirmed, anticoagulation is required unless the DVT is entirely below the knee, where the associated morbidity is low. Ultrasound is highly accurate in symptomatic or proximal DVT, although in asymptomatic patients, ultrasound is much less likely to find DVT, meaning the absence of a DVT does not exclude PE.

Leg venography is a more sensitive test; however, it is invasive and now uncommonly performed.

### INVESTIGATION STRATEGY IN HAEMODYNAMICALLY STABLE PATIENTS

- CTA is the preferred initial test and, if positive, the patient should be stratified into high- or low-risk. The presence of clot within pulmonary arteries confirms the diagnosis of PE.
- Echocardiography should then be considered to assess for RV dysfunction for high-risk patients who have:
  - clot within proximal pulmonary arteries
  - raised RV/LV ratio ( $> 0.9$ )
  - raised troponin, BNP or NT-terminal Pro-BNP
- If there is a high clinical suspicion of PE and the CT is negative (or the  $V/Q$  scan is low or intermediate probability), then a pulmonary angiogram is required to exclude PE.

### INVESTIGATION STRATEGY IN HAEMODYNAMICALLY UNSTABLE PATIENTS

- Echocardiography (preferably transoesophageal) should be the first test performed.
- If the patient has acute RV dilatation and visible embolus, PE is confirmed.
- If there is RV dilatation but no visible embolus, then a CTA is required depending on how unstable the patient is.
- If there is no RV dilatation, it is unlikely that the haemodynamic instability is caused by PE (although this cannot be excluded completely). Efforts towards finding an alternative diagnosis are the priority.
- If echocardiography is not readily available, a CTA should be performed.

## MANAGEMENT

### MANAGEMENT PRINCIPLES

Unless there is a serious contraindication, nearly all patients should receive anticoagulation with either unfractionated or low-molecular-weight heparin (LMWH)

to prevent VTE recurrence. However removal or destruction of the embolus is a key principle in treatment of the more severe cases of PE based on the importance of RV dysfunction to both the pathophysiology and the outcome of PE.

To assist in planning management, it is worth grading the severity of PE as follows:

#### **MASSIVE PULMONARY EMBOLISM (HAEMODYNAMICALLY UNSTABLE)**

Patients with PE and hypotension have a 25–30% mortality rate despite treatment. If cardiopulmonary resuscitation is required, this increases to 65%. These patients have the most to benefit from a strategy that includes attempts at urgent removal of embolus (by administering a thrombolytic agent or performing embolectomy), concurrent haemodynamic support and prevention of further embolisation.

#### **SUBMASSIVE PULMONARY EMBOLISM (HAEMODYNAMICALLY STABLE WITH EVIDENCE OF RIGHT VENTRICULAR DYSFUNCTION)**

Patients with PE and evidence of RV dysfunction have higher mortality and recurrence rates than those with normal RV function.<sup>24</sup> They also develop shock and RV thrombi more frequently. These patients require prevention of further embolisation but also warrant strong consideration of removal of embolus using a thrombolytic agent. Thrombolysis appears to improve outcomes,<sup>28</sup> although this appears to be at the expense of a higher bleeding risk.<sup>29</sup> Echocardiogram is not always required to diagnose RV dysfunction as CT-diagnosed RV dilatation has also been shown to predict poor outcomes.<sup>30</sup>

#### **MILD PULMONARY EMBOLISM (HAEMODYNAMICALLY STABLE WITH NO RIGHT VENTRICULAR DYSFUNCTION)**

Patients with PE who have normal blood pressure and normal RV function have a low risk of death or recurrence. Methods to remove embolus will therefore be unlikely to confer benefit. Prevention of further embolisation is the major goal.

The major principles of management are therefore:

- prevention of further embolisation (massive, submassive or mild PE)
- removal of emboli (massive or submassive PE)
- concurrent haemodynamic support (massive PE)

A suggested management strategy is outlined in Figure 30.1.

### **PREVENTION OF FURTHER EMBOLISATION**

#### **ANTICOAGULATION**

Heparin has been known to prevent recurrence and reduce the mortality from PE for over 35 years. LMWHs are as effective and safe as unfractionated heparin<sup>31</sup> and

**Table 30.3** Weight-based dosing of intravenous heparin (adapted from Raschke *et al.*<sup>33</sup>)

<b>Initial dosing</b>			
Loading 80 u/kg			
Maintenance infusion 18 u/kg per h			
Perform APTT in 6 h			
<b>Subsequent dose adjustments</b>			
APTT	Dose change (u/kg per h)	Additional action	Next APTT
< 35	+4	Rebolus of 80 u/kg	6 h
35–45	+2	Rebolus of 40 u/kg	6 h
46–70	0	Nothing	6 h
71–90	–2	Nothing	6 h
> 90	–3	Stop infusion for 1 h	6 h

APTT, activated partial thromboplastin time.

may even be better.<sup>32</sup> LMWHs offer several advantages over unfractionated heparin, including a longer half-life, increased bioavailability, a more predictable dose–response and less requirement for monitoring and dose adjustments, and can be readily used in the stable patient with PE.

Unfractionated heparin should be used for those patients who have recently had a thrombolytic agent or embolectomy as it can be easily and rapidly reversed. Heparin should be administered by intravenous infusion with a bolus and initial monitoring should be with 6-hourly activated partial thromboplastin time (APTT) testing. Since subtherapeutic levels of anticoagulation increase the risk of recurrence, it is important to achieve therapeutic heparinisation rapidly. Weight-based dosing of heparin should be used as target anticoagulation levels are reached sooner<sup>33</sup> (Table 30.3).

The predominant complications of both unfractionated heparin and LMWHs are haemorrhagic. These include bleeding peptic ulcer, stroke, retroperitoneal haematoma and post surgical wound haemorrhage. Heparin-induced thrombotic thrombocytopenia syndrome (HITTS) can also occur. Bleeding complications and HITTS appear to be less common when LMWHs are being used.

Oral anticoagulants should be started as soon as possible so that heparin can be ceased when the international normalised ratio is > 2.0.

A number of conditions are considered to be relative contraindications to anticoagulant therapy, the major ones are active peptic ulceration, recent surgery, recent trauma and recent cerebral haemorrhage. In each individual patient the risk-to-benefit ratio (taking into account the severity of the PE) should be considered before anticoagulation is withheld from the patient.

#### **INFERIOR VENA CAVA FILTER**

IVC filters are another method used to prevent further embolisation. They are indicated for patients in whom anticoagulation is contraindicated, those who experience

recurrent PE despite adequate anticoagulation and those undergoing open surgical embolectomy.<sup>34</sup> Insertion is usually performed percutaneously in a radiology department, but it can be done at the bedside.<sup>35</sup> They lower early recurrence rates but increase long-term DVT recurrence rates,<sup>36</sup> although newer retrievable designs may be better.<sup>37</sup> A recent analysis of a multicentre register analysis demonstrated a significant reduction in 90-day mortality associated with IVC filters.<sup>38</sup>

Absolute indications include:

- new or recurrent PE despite anticoagulation
- contraindications to anticoagulation
- complications resulting from anticoagulation

Other recommended indications include:

- patients with extensive DVT
- patients following a surgical embolectomy
- patients with massive PE

## REMOVAL OF EMBOLI

### THROMBOLYTIC AGENTS

Thrombolytic agents result in dramatic and immediate haemodynamic improvement in some patients by dissolving the embolus and reducing pulmonary arterial obstruction. Experimental studies, clinical observations and randomised trials have consistently demonstrated the favourable effects of thrombolysis on angiographic, haemodynamic and scintigraphic parameters of patients with acute PE. All of the commonly used agents (including streptokinase, urokinase, alteplase and reteplase) can be rapidly effective, although comparisons with patients who received heparin most commonly reveal similar degrees of embolus resolution after a few days to a week.

A large multicentre patient registry found that patients receiving thrombolytic agents (clearly on an ad-hoc basis) had lower rates of mortality and recurrence than patients receiving heparin.<sup>39</sup> Despite this, there has been no randomised study comparing a thrombolytic agent with standard anticoagulation which has found a mortality difference, although the studies have likely been underpowered to detect this.

A meta-analysis found that thrombolytic therapy was associated with a non-significant reduction in recurrent PE or death when compared to heparin in patients with PE. However, when only studies that included massive PE were aggregated, there was indeed a significant reduction in mortality in favour of thrombolysis.<sup>29</sup>

Thrombolytics in patients with submassive PE do not reduce mortality but do significantly reduce clinical deterioration, requiring an escalation of treatment in the ICU.<sup>28</sup>

There is therefore adequate justification for the use of a thrombolytic agent in patients with massive PE unless there is a clear contraindication. There is also strong justification for the use of a thrombolytic in patients with submassive PE (identified by RV dysfunction).

**Table 30.4** Recommended doses of thrombolytic agents for pulmonary embolism

Urokinase	4400 u/kg bolus (over 10 min) followed by 4400 u/kg per h for 12 h
Streptokinase	250 000 unit bolus (over 15 min) followed by 100 000 u/h for 24 h
Alteplase	10 mg bolus followed by 90 mg over 2 h
Reteplase	10 unit boluses 30 min apart

Comparative studies between the various thrombolytic agents have been too few to make rational comparison and, although there may be slight differences between thrombolytic agents, the choice of drug is less important than the choice to give a thrombolytic at all. One should be given in the doses recommended in Table 30.4, and this can be administered through either a peripheral or a central venous catheter. In contrast to the use of thrombolytics in acute myocardial infarction, thrombolytics are useful in PE when given up to 14 days after symptoms begin. Once the thrombolytic agent has been ceased, heparin should be commenced.

Haemorrhagic complications are not uncommon and can significantly affect patient morbidity; however it is difficult to predict those patients who are at the highest risk for bleeding. Major clinically significant bleeding can occur in up to 10% of patients, although cerebral haemorrhage is fortunately uncommon (0.5%).<sup>29</sup> Whilst recent surgery is often considered a contraindication, acceptable safety has been demonstrated in these patients. Clearly individual patients should have the risks and the benefits weighed up: in shocked patients with PE the balance appears to be in favour of thrombolytic agents for most patients.

If bleeding occurs, the thrombolytic agent should be ceased, fresh frozen plasma should be given to replace coagulation factors and an antifibrinolytic agent (such as aprotinin) should be commenced.

### SURGICAL EMBOLECTOMY

The merit of surgical embolectomy, which has traditionally been seen as a life-saving option for moribund patients with massive PE, has been questioned in the era of increasingly effective thrombolytics. Results of embolectomy surgery vary widely and there has traditionally been an associated perioperative mortality of 25–50%. There is little evidence to compare embolectomy and thrombolytics reliably.

A recent study in an academic centre has documented a perioperative mortality of 6% and a total mortality of 18% when a surgical approach that included rapid diagnosis, prompt frozen plasma intervention and a high frequency of concurrent IVC filter placement was used.<sup>40</sup> Embolectomy was performed in more than half of these patients because either there were contraindications to thrombolytics or the thrombolytic treatment had failed.

Therefore, whilst patients with massive PE who have no contraindications to thrombolysis should receive a thrombolytic agent, surgical embolectomy should be strongly considered in centres with access to cardiothoracic surgeons when a contraindication to thrombolysis exists or the therapy fails.

Indications for embolectomy in patients with PE include:

- massive PE with shock
- patients where thrombolytic agents are contraindicated
- patients who appear to fail thrombolytic agent
- patients with free-floating cardiac thrombus

### PERCUTANEOUS EMBOLECTOMY

Percutaneous methods include either embolus extraction techniques (pure percutaneous embolectomy) or embolus disruption techniques (including catheter-directed thrombolysis and percutaneous thrombus fragmentation techniques).<sup>41</sup> Successful embolectomy does not always occur and mortality is still about 20–30%. Rheolytic thrombectomy<sup>42</sup> and methods combining mechanical disruption and thrombolytic therapy<sup>43</sup> have emerged as promising interventions. Whilst awaiting well-designed studies of these interventions, they remain limited to specialised centres.

### CONCURRENT HAEMODYNAMIC SUPPORT

Shocked patients with PE need urgent haemodynamic support in addition to the definitive measures mentioned above.

### INTRAVENOUS FLUIDS

In patients with moderate or massive PE, volume loading can improve haemodynamic status,<sup>44</sup> although if excessive, fluid therapy worsens RV function which can in turn affect LV function and become detrimental.<sup>45</sup> For this reason cautious amounts of intravenous fluid should be given.

### INTRAVENOUS VASOACTIVE AGENTS

Coronary ischaemia is an important component of the pathogenesis of haemodynamic instability in massive PE. A focus on reducing this ischaemia requires elevation of the blood pressure whilst attempts are being made to lower the pulmonary and RV pressures by removal of the embolus (with thrombolytic agent or embolectomy).

An important concept to consider is the RV coronary perfusion pressure (RVCPP), which is estimated by the formula:

$$\text{RVCPP} = \text{MAP} - \text{RVP}_m$$

where

$$\text{RVP}_m = \text{CVP} + 1/3(\text{PAP}_s - \text{CVP})$$

where MAP is the mean arterial pressure,  $\text{RVP}_m$  is the mean RV pressure, CVP is the central venous pressure and  $\text{PAP}_s$  is the systolic pulmonary arterial pressure, all in mmHg.

When the RVCPP falls as low as 30 mmHg, RV myocardial blood flow falls substantially, leading to severe RV failure and shock. Efforts to elevate the MAP and reduce the  $\text{PAP}_s$  will clearly increase the RVCPP and improve coronary blood flow and ischaemia. Vasopressor agents are therefore the most important initial therapy in the shock state due to massive PE as they will predominantly increase MAP, and therefore RVCPP.

Noradrenaline (norepinephrine) is the most appropriate vasopressor, because of its  $\alpha$ -adrenoceptor agonist activity. Noradrenaline is preferred to a pure  $\alpha$ -agonist, such as phenylephrine, as cardiac output and RV myocardial blood flow effects are greater due to the added  $\beta$ -adrenoceptor agonist action. Dopamine, adrenaline (epinephrine) and vasopressin are appropriate alternatives to noradrenaline.

Although some have suggested using a systemic vasodilator to improve the cardiac output in massive PE, vasodilators can be harmful, as even though cardiac output might improve, the MAP either remains constant or falls and therefore RVCPP is not necessarily improved. Therefore isoprenaline, dobutamine, nitroglycerine, nitropruside or milrinone should only be considered if MAP is adequate and treatment is focused on cardiac output or pulmonary artery pressure.

Beneficial effects have been shown with intra-aortic balloon counterpulsation in animal studies. In patients apparently dying of PE despite thrombolytics and ongoing resuscitative efforts, this appears a reasonable approach as a method of augmenting RVCPP, as long as it is in association with the use of pressor agents. Extracorporeal membrane oxygenation (ECMO) is an extreme but alternative form of mechanical assistance which may be available in more specialised institutions.<sup>46</sup> Technological advances appear to have reduced the number of procedure-related complications attributed to ECMO.<sup>47</sup>

### SELECTIVE PULMONARY VASODILATORS

Inhaled nitric oxide has been used in patients with massive PE based on animal studies and case series,<sup>48</sup> because it selectively decreases pulmonary arterial pressure without influencing systemic haemodynamics. It may have dramatic haemodynamic effects but should be adjunctive to other resuscitative efforts, including elevation of the systemic blood pressure. Inhaled prostacyclin is an alternative, but has limited supporting evidence.<sup>49</sup>

### OTHER MANAGEMENT ISSUES

Oxygen should be given to keep an adequate oxygen saturation. High flows may be required because of hyperventilation and the increased dead space. Intubation and mechanical ventilation are often necessary in patients with massive PE.

If chest pain is prominent, morphine should be given. To guide resuscitation, it is useful to have at least a central venous catheter, particularly before a thrombolytic agent is given. Although not essential, if a patient is severely shocked, a pulmonary artery catheter is recommended to assist in the titration of vasoactive agents and measure the pulmonary artery pressure. The pulmonary artery catheter also assists in the estimation of the RVCPP, either through direct measurement of the mean RV pressure using the 20-cm lumen of a pacing pulmonary artery catheter, or by calculation using the formula above. While there is increased risk of bleeding due to the concurrent

administration of thrombolytic agents and/or anticoagulants in these patients, this is probably outweighed by the importance of secure venous access and monitoring of the circulation in patients with haemodynamic compromise due to PE.

### PREVENTION

Prophylaxis is the most important management aspect of VTE. All ICU patients should have an adequate assessment as to whether prophylaxis is warranted, although

**Table 30.5** Prophylaxis of venous thromboembolism

Category of patient	Recommendation
All patients with high bleeding risk	IPC or GCS
<b>General (and other) surgery</b>	
Low-risk	Early mobilisation
Moderate-risk	Heparin bd or LMWH
High-risk	Heparin tds or LMWH
<b>Vascular surgery</b>	
No risk factors	Early mobilisation
Risk factors	Heparin bd or LMWH
<b>Orthopaedic surgery</b>	
Hip replacement	LMWH or fondaparinux or warfarin
Knee arthroplasty	LMWH or fondaparinux or warfarin or IPC
Hip fracture surgery	LMWH or fondaparinux or warfarin or heparin bd
<b>Neurosurgery</b>	
Intracranial surgery	IPC ± GCS or heparin bd or LMWH
High-risk	GCS/IPC + heparin/LMWH
<b>Trauma patients</b>	
No anticoagulation contraindication	LMWH
Anticoagulation contraindication	IPC ± GCS
Spinal cord injury	LMWH or IPC + heparin or IPC + LMWH
Burns	Heparin or LMWH
<b>Medical patients</b>	
Risk factors	Heparin or LMWH
Anticoagulation contraindication	GCS or IPC
<b>Risk definitions</b>	
<b>Low-risk surgery</b>	
Minor surgery in patients < 40 years old with no risk factors	
<b>Moderate-risk surgery</b>	
Non-major surgery in patients who are 40–60 years old with no risk factors	
Non-major surgery in patients < 60 years old with risk factors	
Major surgery in patients < 40 years old with no risk factors	
<b>High-risk surgery</b>	
Non-major surgery in patients > 60 years old with or without risk factors	
Major surgery in patients > 40 years old with no risk factors	
Major surgery in patients < 40 years old with risk factors	

IPC, intermittent pneumatic compression device; GCS, graduated compression stockings; heparin bd, 5000 units subcutaneously twice daily; LMWH, low-molecular-weight heparin; heparin tds, 5000 units subcutaneously three times daily. (Information from Geerts *et al.*<sup>50</sup>)

most should receive it.<sup>50</sup> Careful attention to the intervention and dose is required, as omission of prophylaxis<sup>51</sup> and failure of prophylaxis<sup>52</sup> are common. Some groups of surgical patients also appear to benefit from extended out-of-hospital prophylaxis.<sup>53</sup>

Traditional prophylaxis with fixed low-dose subcutaneous unfractionated heparin (i.e. 5000 units twice or three times daily) is now being challenged by both LMWHs and fondaparinux (a factor Xa inhibitor).<sup>50</sup> Both have been shown to be as efficacious as unfractionated heparin in many patient groups and they are associated with less bleeding and less HITTS. Although questions remain about the cost-effectiveness of LMWHs<sup>54</sup> and about comparisons between the various LMWH agents and fondaparinux, LMWHs require less monitoring than unfractionated heparin and are being more commonly recommended.<sup>50</sup>

Aspirin has also been shown to reduce VTE rate and mortality in high-risk patients,<sup>55</sup> although it seems less efficacious than other anticoagulants and is not currently recommended.<sup>50</sup>

Mechanical approaches (including graduated-compression stockings and intermittent pneumatic compression devices<sup>56</sup>) seem best utilised in low-risk patients, patients with contraindications to anticoagulation, or when used in addition to anticoagulation in high-risk patients.

A recommended approach to prophylaxis is included in Table 30.5.<sup>50</sup>

# Acute severe asthma

David V Tuxen and Matthew T Naughton

Acute severe asthma is a medical emergency associated with significant morbidity and mortality. The majority of adverse outcomes are attributed to underestimation of severity with delayed and/or inadequate treatment<sup>1–3</sup> and are potentially preventable.

The worldwide prevalence of asthma varies widely (2–37% in children),<sup>4</sup> but it is now clear that the overall prevalence has increased worldwide,<sup>5,6</sup> with life-threatening episodes affecting an estimated 0.5% of asthmatics per year.<sup>7</sup> Australia, New Zealand and the UK have amongst the highest incidences.<sup>7</sup> In Australia, 9% have asthma as a long-term condition<sup>8</sup> and up to 40% of children have asthma symptoms at some time.<sup>5</sup>

Although the prevalence of asthma is increasing, many countries have achieved reductions in hospital presentations and admissions,<sup>9,10</sup> reduced intensive care admissions and reduced overall asthma mortality.<sup>9,10</sup> Improved community management of asthma,<sup>1,2</sup> more widespread use of inhaled corticosteroids<sup>3</sup> and other preventive measures have been given the credit for these improvements.

Despite reducing admissions, significant and potentially preventable mortality continues to occur in those patients who do require intensive care or mechanical ventilation.<sup>11,12</sup>

## CLINICAL DEFINITION

Asthma has been defined as a lung disease with the following characteristics:<sup>13</sup>

- airway obstruction that is reversible (completely or partially), either spontaneously or with treatment
- airway inflammation
- increased airway responsiveness to a variety of stimuli

Exacerbations of asthma are characterised by increasing dyspnoea, cough, wheeze, chest tightness and decreased expiratory airflow. Status asthmaticus has had varying definitions. However, for practical purposes, any patient not responding to initial doses of nebulised bronchodilators should be considered to have status asthmaticus.<sup>14</sup>

## AETIOLOGY

The pathogenesis of asthma is complex, with both genetic and environmental influences. The increase in asthma prevalence has been attributed to the ‘hygiene hypothesis’<sup>15</sup> which suggests that reduced exposure to childhood infections as a result of antibiotics and hygienic lifestyle promotes an imbalance in T-cell phenotype leading to inflammatory cytokine overproduction. Immunoglobulin (Ig) E-dependent mechanisms appear to be particularly important in generating the characteristic state of airway inflammation and bronchial hyperreactivity with the allergens in the local environment dictating the specificity of the antibody response.<sup>16</sup> Triggers of acute asthma can be non-specific (cold air, exercise, atmospheric pollutants), specific allergens (housemite, pollen, animal danders), modifiers of airway control (aspirin,  $\beta$ -blockers) or stress and emotion. No precipitant can be identified in over 30% of patients.

## PATHOPHYSIOLOGY

The postmortem airway pathology of patients who die from acute asthma includes bronchial wall thickening from oedema and inflammatory cell infiltrate, hypertrophy and hyperplasia of bronchial smooth muscle and submucosal glands, deposition of collagen beneath the epithelial basement membrane and prominent intraluminal secretions. These secretions may narrow or occlude the small airways and postmortem studies frequently report extensive plugging and atelectasis.<sup>17,18</sup> When interpreting the latter findings it is important to remember that during life in very severe asthma, the lungs are hyperinflated close to total lung capacity (TLC) by maximal inspiratory effort and to beyond TLC during mechanical ventilation. At this time radiological atelectasis is rare, suggesting that most airways are communicating at these high lung volumes, even if airways are very narrowed. Only at death does the prolonged apnoea allow lung deflation, widespread airway closure and alveolar gas absorption to give the postmortem appearance of extensive complete occlusion that was not present to the same degree during life.

In some deaths bronchial mucus is absent; in these cases airway obstruction may be mainly due to intense smooth bronchoconstriction.

This observation may account for two patterns of progression of asthma:

1. Acute severe asthma is the more common group (80–90%), with progression of symptoms over many hours or days, often with a background of poor control and recurrent presentations. The majority of patients in this group are female. Upper respiratory infections are frequent triggers. It responds more slowly to treatment; this may reflect greater contribution from mucous inspissation and chronic bronchial wall inflammation with eosinophilia.<sup>19</sup>
2. Hyperacute, fulminating or asphyxic asthma is where the interval between onset of symptoms and intubation is less than 3 hours.<sup>19–21</sup> This presentation is less common (approximately 10–20% of life-threatening presentations) and tends to occur in younger patients with relatively normal lung function but high bronchial reactivity, and the majority of patients are male. Respiratory allergens, cold air or exercise and psychosocial stress are the most frequent triggers. This pattern typically responds quickly to bronchodilators and is thought to be mainly due to bronchial smooth-muscle contraction.

The characteristic pathology of asthma leads to increased airway resistance and dynamic pulmonary hyperinflation. This has a number of consequences:

- *Increased work of breathing* results from increased airway resistance and reduced pulmonary compliance as a result of high lung volumes. When asthma is severe, dynamic hyperinflation may bring the lung volume close to TLC.<sup>22</sup> This causes a severe mechanical disadvantage of inspiratory muscles with diaphragm flattening and results in a large inspiratory muscle effort affecting a small change in inspiratory pressure. The final outcome can be respiratory muscle failure with insufficient alveolar ventilation and consequent hypercapnia.<sup>23</sup>
- *Ventilation–perfusion mismatch* is the result of airway narrowing and closure. This leads to impaired gas exchange and increases the minute ventilation requirement, further adding to the work of breathing.<sup>23</sup>
- *Adverse cardiopulmonary interactions* are seen when the marked changes in lung volume and pleural pressure impact on the function of both left and right ventricles.<sup>24,25</sup> Spontaneous breathing during acute asthma can generate inspiratory pleural pressures as low as  $-35$  cmH<sub>2</sub>O.<sup>24,25</sup> This increases venous return to the right ventricle (RV) and increases RV volume during inspiration. However, increased RV afterload as a result of hypoxic pulmonary vasoconstriction, acidosis, increased lung volume<sup>24,25</sup> and increased pulmonary capacitance decrease return to the left ventricle (LV). These negative intrapleural pressures also cause increased LV afterload<sup>24,25</sup> and increased RV volume with

septal shift reduces LV volume,<sup>24,25</sup> further reducing LV output during inspiration. Pulsus paradoxus is the most direct result of these cardiopulmonary interactions in severe asthma. This is a decrease in systolic blood pressure during inspiration of  $> 10$  mmHg (typically 15–25 mmHg, normal = 5 mmHg). The degree of pulsus paradoxus may not correlate with the severity of asthma as it may be reduced by inspiratory muscle weakness or fatigue.

## CLINICAL FEATURES AND ASSESSMENT OF SEVERITY

The symptoms of asthma are well known and include wheeze, cough, dyspnoea and chest discomfort or tightness.

Triage and assessment of severity of the acute asthma attack are crucial. Underestimation or non-measurement of asthma severity is associated with increased mortality.<sup>26,27</sup> Assessment has two key features: assessment of initial severity and ongoing assessment of response to treatment.

## HISTORY

Any history of prior intubation and mechanical ventilation for asthma is a predictor for life-threatening asthma.<sup>26,27</sup> A history of poor asthma control and multiple recent medical presentations for asthma are recognised risk factors. Other risk factors include a poor response to prior treatments and poor psychosocial circumstances.

## PHYSICAL EXAMINATION

The general appearance and level of distress can be an important indicator of severity (Table 31.1). Use of accessory muscles, suprasternal retraction, markedly diminished breath sounds or a silent chest, central cyanosis, inability to speak (sentences, phrases, single words), a disturbance in the level of consciousness, upright posture and diaphoresis all suggest a severe attack.<sup>28</sup> A respiratory rate  $> 30$  breaths/min, pulse rate  $> 120$  beats/min and pulsus paradoxus of  $> 15$  mmHg are associated with severe asthma, though their absence does not preclude life-threatening asthma.

## VENTILATORY FUNCTION TESTS

The patient may not be able to perform these due to breathlessness. However, forced expiratory volume in 1 second (FEV<sub>1</sub>) and peak expiratory flow rate (PEFR) are useful indicators of severity and response to treatment when done serially. An FEV<sub>1</sub>  $< 1.0$  litre or PEFR  $< 100$  l/min indicates very severe asthma at significant risk of requiring mechanical ventilation. In some patients forced expiration may worsen symptoms; these measurements should cease if this occurs.<sup>29</sup>

**Table 31.1** Assessment of asthma severity

	Mild	Moderate	Severe
Conscious state	Alert and relaxed	Anxious, difficulty sleeping	Agitated, delirious
Speech	Sentences	Phrases	Words
Accessory muscles	Nil	Mild	Significant sitting upright
Wheeze	Moderate	Loud	Loud or silent
Pulse rate (beats/min)	< 100	100–120	> 120
Peak expiratory flow (% predicted)	> 80%	60–80%	< 60%
$P_{aCO_2}$ (mmHg)	< 45	< 45	> 45

Pulsus paradoxus, when present, indicates severe asthma; however it is an unreliable test.

### PULSE OXIMETRY

Pulse oximetry ( $SpO_2$ ) is usually readily available and provides a rapid assessment of oxygenation. It is also very valuable in regulation oxygen therapy, both for avoiding hypoxia ( $SpO_2 > 90\%$ )<sup>30</sup> and avoiding potential side-effects of hyperoxia ( $SpO_2 < 95\%$ ).<sup>31</sup> Of course, pulse oximetry cannot assess arterial  $P_{CO_2}$  or acid–base state or lactate and hence does not replace the need for blood gases

### ARTERIAL BLOOD GASES

Arterial hypoxaemia is almost invariably present in a patient with severe asthma breathing room air, though it usually responds well to low-level oxygen supplementation (28–35%).<sup>30</sup> Blood gases should not delay initiation of treatment, and are not required in mild asthma or moderate asthma that is responding well to treatment. They are very important in severe asthma, or moderate asthma with inadequate treatment response. The arterial  $P_{aCO_2}$  is an important measure of severity and, if hypercapnia is present, an important guide to treatment response.

Ventilation is initially increased in an acute attack, leading to hypocapnia and a respiratory alkalosis.<sup>30</sup> As the asthmatic attack worsens, the work of breathing,  $V/Q$  mismatch and adverse cardiopulmonary interactions all increase, and the minute ventilation required to maintain the same alveolar ventilation and  $P_{aCO_2}$  increases. Eventually the patient is incapable of meeting this demand and the  $P_{aCO_2}$  rises. The presence of hypercapnic acidosis is associated with an  $FEV_1$  of < 20% predicted

and reliably indicates that asthma is severe. A metabolic acidosis may also be present, and this is most commonly due to lactic acidosis<sup>32</sup> associated with intravenous or continuous nebulised  $\beta$ -agonists.<sup>33,34</sup>

### CHEST X-RAY

Although not generally helpful in assessing severity,<sup>35</sup> a chest X-ray should be performed when asthma is severe or refractory to treatment, when barotrauma or lower respiratory tract infection is suspected or when the diagnosis is in doubt. It is not required in milder attacks that respond well to treatment.

### ASSESSMENT OF TREATMENT RESPONSE

Repeated evaluation of the patient's response to treatment is a valuable tool in assessing severity of acute asthma. The response to the first 2 hours of treatment is an important predictor of outcome.<sup>36</sup> Adverse events are associated with underestimation of severity, inadequate observation after initial assessment and under treatment. Ongoing evaluation of response to therapy is critical. This evaluation should include repeated assessments of:

1. appearance and physical indicators of severity
2. objective measurements:  $FEV_1$  or PEF, heart rate, respiratory rate, pulsus paradoxus
3.  $SpO_2$  and oxygen requirements
4. progress of  $P_{aCO_2}$  or metabolic acidosis if present on blood gases

Admission to intensive care is preferred if the patient fulfils the above criteria for severe asthma. Indications for immediate admission to intensive care include respiratory arrest, altered mental status, arrhythmias or associated myocardial ischaemia.

### DIFFERENTIAL DIAGNOSIS

The diagnosis of asthma is usually obvious. However wheeze and dyspnoea may be caused by other illnesses such as left ventricular failure, aspiration, upper-airway obstruction, inhaled foreign body, pulmonary embolism or hyperventilation syndromes. Wheeze and dyspnoea arising in hospitalised patients who were not admitted with asthma are less likely to be due to asthma. Difficult asthma, as opposed to severe asthma, can present acutely and is a diagnostic dilemma. Such patients are well medicated (often self-medicating with high-dose steroids and may appear cushingoid or with high-dose  $\beta$ -agonists with lactic acidosis) and have seen many doctors and attended many hospitals. Lung function may be normal or indicate upper-airway dysfunction, indicative of an underlying vocal cord dysfunction or psychiatric condition, and upon intubation the patient is very easy to ventilate. Clues to another or additional diagnosis include:

1. no past history of asthma
2. sudden onset following vomiting or food intake
3. focal or asymmetrical chest auscultation findings
4. risk factors for thromboembolism
5. onset during hospitalisation when admitted with another condition

## MANAGEMENT

### ESTABLISHED TREATMENTS

Initial therapy of acute severe asthma should include the following.

#### OXYGEN

Hypoxaemia contributes to life-threatening events that complicate acute severe asthma.<sup>37</sup> Humidified supplemental oxygen should be titrated to achieve a  $SpO_2 > 90\%$ . The risk of oxygen-induced increasing hypercapnia with coexisting chronic obstructive pulmonary disease or pre-existing chronic hypercapnia is a well-known reason to maintain a lower  $SpO_2$  (e.g. 90–92%). This phenomenon was not believed to be relevant to the majority of patients with acute asthma; however, there is now emerging evidence that hyperoxia may be harmful to a more widespread group<sup>38</sup> by releasing pulmonary hypoxic vasoconstriction, worsening  $V/Q$  matching and increasing hypercapnia. A recent randomised controlled trial<sup>31</sup> showed a decrease in  $Paco_2$  in a group receiving 28%  $O_2$  and an increase in  $Paco_2$  in a group receiving 100%  $O_2$ .

#### $\beta$ -AGONISTS

Short-acting  $\beta$ -agonists remain the first-line bronchodilator therapy of choice.<sup>6,39–41</sup> Agents include salbutamol (albuterol), terbutaline, isoprenaline and epinephrine. Salbutamol is generally the agent of first choice as it has relative  $\beta_2$ -selectivity, with decreased  $\beta_1$ -mediated cardiac toxicity. Long-acting  $\beta$ -agonists such as salmeterol have no role in status asthmaticus due to slow onset of action and association with fatalities in this setting.<sup>14</sup> Eformotarol is a combined long- and short-acting  $\beta$ -agonist which could theoretically be used for acute asthma; however it is in dry powder form and unlikely to be helpful in intubated and mechanically ventilated patients.  $\beta$ -agonists cause bronchodilatation by stimulation of  $\beta_2$ -receptors on airway smooth muscle and may reduce bronchial mucosal oedema.<sup>42</sup>

$\beta$ -agonists are best given by metered-dose inhaler (MDI) and a spacer device. There are data to suggest that, in non-intubated patients, MDIs combined with a spacer device are more effective than nebulisers and are cheaper to use.<sup>43,44</sup> In intubated patients both nebulisers and MDIs have been used effectively.<sup>45</sup> The dose per MDI inhalation is 100  $\mu$ g and this can be given, in severe asthma, in repeated doses at 1–5-minute intervals.

Alternatively,  $\beta$ -agonists can be given by nebuliser in high and repeated doses.<sup>46</sup> The typical adult dose of

salbutamol is 5–10 mg (in 2.5–5.0 ml diluent volume) every 2–4 hours but more frequent doses with a higher total dose are often required in severe asthma. It should be noted that less than 10% of the nebulised drug reaches the lung even under ideal conditions.<sup>47</sup> Continuous nebulisation appears to be superior to intermittent doses and is commonly used at the beginning of treatment in severe asthma.<sup>14,48</sup> The nebuliser should be driven by oxygen with the flow at 10–12 l/min and a reservoir volume of 2–4 ml so as to produce particles in the desired 1–3  $\mu$ m range.<sup>49</sup> The total dose should be modulated by response to treatment and the level of toxic side-effects.

Two-thirds of patients presenting acutely will respond well to inhaled  $\beta$ -agonists,<sup>50</sup> irrespective of the method of administration. The remaining one-third are refractory even to high doses and usually require longer periods of intense treatment, including multiple other agents.

Intravenous  $\beta$ -agonists remain controversial. There is no clear evidence of benefit<sup>51</sup> and significant side-effects. Despite this, intravenous  $\beta$ -agonists have a theoretical benefit of additional access to lung units with severe airflow obstruction and poor nebulised drug delivery, and some studies have demonstrated improved response when intravenous  $\beta$ -agonist is used.<sup>52</sup> Intravenous  $\beta$ -agonists continue to be considered if the patient is not responding to continuous nebulisation.<sup>53</sup> The typical dose is 5–20  $\mu$ g/min but doses  $> 10$   $\mu$ g/min should be used with caution because of side-effects, which should be monitored closely. Salbutamol 100–300  $\mu$ g may also be given intravenously to non-intubated patients in extremis or delivered down an endotracheal tube if there is not time to gain intravenous access.

Side-effects of  $\beta$ -agonists include tachycardia, arrhythmias, hypertension, hypotension, tremor, hypokalaemia, worsening of ventilation–perfusion mismatch and hyperglycaemia,<sup>54</sup> but the most common side-effect of parenteral  $\beta$ -agonist – also occasionally seen with continuous nebulised  $\beta$ -agonists – is lactic acidosis. This occurs in over 70% of patients, has an onset within 2–4 hours of commencing an infusion or following an intravenous statim dose, levels may reach 4–12 mmol/l and may significantly add to respiratory acidosis and respiratory distress.<sup>34,55,56</sup> Parenteral infusions should be initially limited to 10  $\mu$ g/min and statim doses should not exceed 250  $\mu$ g. Serum bicarbonate and lactate should be regularly monitored. If lactic acidosis becomes significant, the salbutamol infusion should be reduced or ceased. Lactic acidosis will generally resolve within 4–6 hours of infusion cessation and is seldom a problem with infusions in place for more than 24 hours.

Long-term high-dose  $\beta$ -agonist use has been associated with increased mortality,<sup>57</sup> but whether high-dose  $\beta$ -agonists are a marker of disease severity, an indicator of suboptimal inhaled steroids or a direct cause of death is unclear. These concerns do not apply in the treatment of the acute asthma attack.

#### ANTICHOLINERGICS

Anticholinergics cause bronchodilatation by decreasing parasympathetic-mediated cholinergic bronchomotor

tone.<sup>58</sup> Ipratropium bromide is the most commonly used anticholinergic for asthma and is a quaternary derivative of atropine. A number of studies and meta-analyses now suggest clear additional benefit and few side-effects when ipratropium bromide is added to the  $\beta$ -agonist regimen<sup>59,60</sup> and ipratropium is now considered accepted first-line therapy for acute severe asthma in conjunction with  $\beta$ -agonist therapy. Preservative-induced bronchoconstriction has been reported in a few patients and can be prevented by using preservative-free solutions.<sup>61</sup> The bronchodilatation effect of ipratropium bromide appeared to be maximal with a dose of 250  $\mu\text{g}$  when studied in children between 9 and 17 years of age. The optimal dose is not known in adults; a reasonable regimen would be to add 500  $\mu\text{g}$  ipratropium bromide to the salbutamol nebuliser every 2–6 hours; however, initial dose intervals as low as 10–20 minutes have been recommended.<sup>62</sup>

### CORTICOSTEROIDS

The role of corticosteroids in the acute asthma attack has been well established. Systemic steroids should be considered in all but mild exacerbations of asthma.<sup>41</sup> Their benefits include increased  $\beta$ -responsiveness of airway smooth muscle, decreased inflammatory cell response and decreased mucus secretion. Early treatment with corticosteroids has been shown to decrease the likelihood of hospitalisation and decrease the mortality rate from acute asthma. Systematic reviews<sup>41,63</sup> suggest that effects commence within 6–12 hours, that oral administration is as effective as intravenous and that there is little evidence of benefit for initial daily doses exceeding 800 mg/day hydrocortisone (160 mg/day methylprednisolone) given in four divided doses.

Inhaled steroids have established long-term benefit and are believed to be a major factor in asthma mortality reduction.<sup>1–3</sup> There is now emerging evidence that inhaled steroids may also have a role during an acute attack<sup>64,65</sup> and it appears reasonable to use them routinely from day 1 as they may also enable more rapid dose reduction of parenteral steroids, potentially reducing side-effects.

Parenteral corticosteroid dose reductions should commence after 1–3 days according to the severity of the attack, the degree of chronic inflammation and the response to treatment, and should be converted to a reducing dose of oral steroids within 4–7 days (e.g. oral prednisolone starting at 0.5 mg/kg body weight or 40–60 mg/day).

Side-effects of corticosteroids include hyperglycaemia, hypokalaemia, hypertension, acute psychosis and myopathy,<sup>66,67</sup> though they are usually well tolerated acutely. The immunosuppressive effects can increase the risk of infections, including *Legionella*, *Pneumocystis carinii* and varicella,<sup>68,69</sup> especially when the patient is on long-term corticosteroids. Allergic reactions including anaphylaxis have been reported with the use of most corticosteroid preparations.

### AMINOPHYLLINE

There have been conflicting reports regarding the efficacy of aminophylline in acute asthma ranging from no benefit<sup>70</sup> to improved lung function and improved outcome.<sup>71</sup> However it is accepted that aminophylline is an inferior bronchodilator, with a narrow therapeutic range and frequent side-effects,<sup>72</sup> including headache, nausea, vomiting and restlessness; cardiac arrhythmias and convulsions can occur at serum levels above 200  $\mu\text{mol/l}$  (40 mg/l).

As a result, aminophylline is not a first-line treatment.<sup>40,41,53</sup> Aminophylline may be given to patients with acute asthma who are not showing a favourable response to full treatment with first-line agents. Careful administration and monitoring are required with an initial loading dose of 3 mg/kg (maximum 6 mg/kg, omitted if the patient is already taking oral theophylline) and an infusion of 0.5 mg/kg per hour. This should be reduced in patients with cirrhosis, cardiac failure or chronic obstructive pulmonary disease and in patients taking cimetidine, erythromycin or antiviral vaccines. Drug levels should be taken after a loading dose (if given), and then 24 hours later, aiming for a level of 30–80  $\mu\text{mol/l}$  (5–12 mg/l). Levels should be repeated daily thereafter until stability has been achieved. The duration should be based on the response to treatment.

### NON-ESTABLISHED TREATMENTS

A number of other therapies have reported benefit in acute severe asthma but their role in addition to full standard therapy has not been clearly established and they are not advocated for routine use. However these modes of therapy can be considered in the patient who is in extremis or who remains severe despite conventional treatment.

### EPINEPHRINE

Epinephrine has some theoretical advantages over pure  $\beta_2$ -agonists in that its additional  $\alpha$ -agonist actions of vasoconstriction and mucosal shrinkage may improve airway calibre. However, in practice, nebulised or subcutaneous epinephrine has not been shown to confer any advantage over nebulised  $\beta_2$ -agonists and is not recommended because of its cardiac side-effects.<sup>62</sup> Epinephrine may be tried in the patient who is failing to respond to conventional treatment. The nebulised dose is 2–4 mg in 2–4 ml (1% solution, 0.05 ml/kg) 1–4-hourly. The subcutaneous dose is 0.2–0.5 mg (0.2–0.5 ml of 1:1000 epinephrine) repeated if necessary 2–3 times at 30-minute intervals. Epinephrine by infusion may avert mechanical ventilation in very severe cases but should be used with caution with electrocardiogram monitoring and preferably with central venous access. An initial intravenous dose of 0.2–1.0 mg (2–10 ml of 1:10 000 epinephrine) is given slowly over 3–5 minutes. This may be followed by a continuous infusion of 1–20  $\mu\text{g}/\text{min}$ , which is weaned when the acute attack subsides.<sup>73</sup>

**MAGNESIUM SULPHATE**

Magnesium sulphate is postulated to block calcium channels, and possibly acetylcholine release at the neuromuscular junction, leading to smooth-muscle relaxation and bronchodilatation. It appeared to be well tolerated in early studies, and a number of randomised, double-blind, prospective trials were performed adding intravenous or nebulised magnesium sulphate to conventional therapy in adults with acute asthma. Some showed benefit whereas others showed no benefit.

Three meta-analyses<sup>74–76</sup> did not support routine use of magnesium and it is not recommended for acute asthma. If given, recommended doses are 5–10 mmol (1.25–2.5 g, 2.5–5.0 ml of 50% solution) given slowly over 20 minutes but doses up to 40–80 mmol (10–20 g) have been given.<sup>77</sup> Side-effects include hypotension, flushing, sedation, weakness, areflexia, respiratory depression and cardiac arrhythmias seen at higher serum levels (> 5 mmol/dl or 12 mg/dl). Serum concentrations should be measured if repeated or high doses are used.

**HELIOX**

Inhalation of a helium:oxygen mixture reduces gas density and turbulence with reduced airflow resistance. The most effective gas mixture is 70% helium (30% oxygen) and the minimum concentration likely to provide benefit is 60% helium. Work of breathing is decreased and pulmonary access of inhaled bronchodilators may be improved.<sup>78,79</sup> Small case-series and reports have suggested benefit from Heliox, randomised prospective trials have both positive and negative results<sup>80,81</sup> and a recent meta-analysis<sup>82</sup> shows a trend towards improved lung function, but insufficient evidence to recommend use of Heliox in severe asthma. However, it otherwise appears safe and may be tried in critical asthma to avert intubation or during difficult mechanical ventilation providing the patient can tolerate 30–40% O<sub>2</sub>.

**ANAESTHETIC AGENTS**

Ketamine, a dissociative anaesthetic agent, has been used in severe asthma.<sup>83</sup> It may cause bronchodilatation by both sympathomimetic potentiation and a direct effect on airway smooth muscle.<sup>84</sup> Small case-series have suggested some benefit, although a small randomised controlled trial found no benefit with ketamine in the treatment of acute severe asthma.<sup>85</sup> Ketamine may be a useful induction agent for endotracheal intubation (dose 1–2 mg/kg) as it may ameliorate the bronchoconstrictor response to intubation. It has been used as a continuous infusion in the dose range of 0.5–2 mg/kg per hour.<sup>85,86</sup> to treat refractory asthma. Side-effects include increased bronchial secretions, a hyperdynamic cardiovascular response and hallucinations; the hallucinations can be reduced with concomitant benzodiazepines.

The volatile inhalational agents, including halothane, isoflurane and enflurane, have been used in mechanically ventilated patients with severe asthma. Clinical data are

limited to small case-series and side-effects include direct myocardial depression, arrhythmias and hypotension.<sup>87</sup> The volatile anaesthetic agents should be used with great care and usually only as a prelude to or during invasive ventilation. An anaesthetic machine or custom-fitted ventilator is required for safe administration.

**LEUKOTRIENE ANTAGONISTS**

Leukotriene antagonists have shown benefit in chronic asthma<sup>88</sup> and there is some evidence of benefit in acute asthma.<sup>89,90</sup> However there is insufficient evidence and these benefits were of insufficient magnitude to recommend these agents for acute severe asthma.

**BRONCHOALVEOLAR LAVAGE**

Bronchoalveolar lavage has been used in severe refractory asthma to clear mucous plugging during mechanical ventilation.<sup>91</sup> It can transiently worsen bronchospasm and hypoxaemia and should be used when airflow obstruction has stabilised. It may have a role in ventilated patients with resistant mucus impaction, but is rarely used.

**THERAPIES NOT RECOMMENDED**

Antibiotics are not indicated<sup>92</sup> unless there is evidence of infection. Antihistamines are not effective. Inhaled mucolytics have been shown to have no benefit and may worsen airflow obstruction. Sedation is unsafe in acute asthma. There is a clear association between their use and avoidable deaths.<sup>93</sup> Patients with severe asthma should not be sedated unless being intubated and ventilated or in carefully monitored circumstances.

**VENTILATION IN ASTHMA****DYNAMIC HYPERINFLATION**

In all degrees of airflow obstruction, slow expiratory airflow results in incomplete exhalation of gas during normal expiratory times. Gas is trapped in the lungs by the arrival of the next breath and the lungs are unable to return their normal passive relaxation volume (functional residual capacity, FRC). Incomplete exhalation of each successive breath causes progressive accumulation of trapped gas, called dynamic hyperinflation (DH; Figure 31.1).<sup>94</sup> This continues until an equilibrium point is reached, where the exhaled volume increases to match the inspired volume (see Figure 31.1).<sup>94</sup> This equilibrium occurs because increasing lung volume increases small-airway calibre and lung elastic recoil pressure, both of which improve expiratory airflow and allow the inspired tidal volume to be exhaled in the expiratory time available. There are three primary determinants of this equilibrium point. Gas trapped at the end of expiration exerts a positive pressure on the alveoli; this pressure is intrinsic positive end-expiratory pressure (PEEP<sub>i</sub>) or auto-PEEP.<sup>94,95</sup> During expiration, sequential closure of the most severely obstructed

**Figure 31.1** Dynamic hyperinflation. The volume history of normal or acutely injured lungs compared with that of obstructed lungs when commenced on controlled mechanical ventilation. This shows initial lung volume to be at the passive relaxation volume of the respiratory system or functional residual capacity (FRC).  $V_t$ , tidal volume;  $V_{trap}$ , dynamically trapped gas volume above FRC;  $V_{ei}$ , end-inspiratory lung volume above FRC.

airways occurs, with only the less obstructed airways remaining in communication with the central airway at the end of tidal expiration.<sup>96</sup> As a consequence, measured PEEP<sub>i</sub> underestimates the true magnitude of PEEP; and is recognised as being insensitive to changes in severity.<sup>96</sup>

In mild airflow obstruction, this process is adaptive as it allows the desired minute ventilation, which could not be achieved at FRC, to be achieved at a higher lung volume (Figure 31.2: ‘mild AO’). In mild AO, a normal FRC can still be reached with prolonged passive expiratory period but the mildly narrowed airways undergo airway closure at lower lung volumes, reducing the expiratory reserve capacity (ER Cap) and increasing residual volume (RV; see Figure 31.2). This is in contrast to acute lung injury (ALI), where lung collapse reduces all lung volumes (see Figure 31.2:  $V_t$ , ER Cap and RV).

As asthma becomes more severe (see Figure 31.2: ‘mod AO’), the static FRC that would be reached with a long expiratory time is elevated above the normal FRC by airway closure (static hyperinflation), there is no ER Cap, DHI further increases lung volume to a level where work of breathing is increased by lower lung compliance and respiratory muscles become less efficient from shortening and mechanical disadvantage. At this level some degree of dyspnoea is expected.

When asthma is severe enough to risk requiring mechanical ventilation, static hyperinflation may increase FRC by 50%<sup>97</sup> and very little DHI is required to reach total lung capacity (see Figure 31.2: ‘severe AO’). In this circumstance, the minute ventilation required to maintain normocapnia would cause hyperinflation beyond normal total lung capacity. During spontaneous ventilation, the patient with severe asthma is unable to exceed total lung capacity (see Figure 31.2), has a much lower maximum minute ventilation capacity and as a result must become hypercapnic even at maximum respiratory effort with no fatigue.<sup>14</sup> When mechanical ventilation is commenced, increased tidal volume and rate delivery are easily able to increase minute ventilation and DHI well beyond normal total lung capacity (see Figure 31.2).<sup>94</sup> The consequences of this are commonly hypotension (due to increased intrathoracic pressure and decreased venous return) and barotrauma (Table 31.2).<sup>22,94,97,98</sup>

**NON-INVASIVE VENTILATION (NIV)**

NIV has been widely used for a variety of respiratory problems.<sup>99</sup> In severe asthma there are a number of potential benefits. Externally applied PEEP may help overcome PEEP<sub>i</sub> due to gas trapping and thus reduce the inspiratory threshold work of breathing. Augmentation of inspiration with NIV may further decrease the work of

**Figure 31.2** Comparison of lung volumes in patients with normal lungs, acute lung injury (ALI), and mild, moderate and severe airflow obstruction (AO). Severe AO is shown during both spontaneous ventilation (Spont) and mechanical ventilation (Mech V). TLC, total lung capacity. Functional residual capacity (FRC) is the static lung volume at the end of expiratory flow (60–90 seconds in severe AO). Expiratory reserve capacity (ER Cap) is the additional gas expired with expiratory effort after FRC has been reached. Residual volume (RV) is the minimum lung volume possible after prolonged expiration and maximum expiratory effort.  $V_t$ , tidal volume;  $V_{trap}$  is the gas trapped by dynamic hyperinflation during tidal ventilation.

**Table 31.2** Comparison of reported mortality associated with the mechanical ventilation of patients with severe asthma over the last five decades

Decade	No. of papers	No. of episodes	No. dead	Mortality		
				Mean	Minimum	Maximum
1960s	8	125	18	14.4%	0%	27%
1970s	7	183	31	16.9%	6%	38%
1980s	10	382	46	12.0%	0%	36%
1990s	12	571	61	10.7%	0%	26%
2000s	3	790	54	6.8%	4%	21%

inspiration and increase tidal volume and minute ventilation. If tidal volume is increased with a shorter inspiratory time, then increased minute ventilation can occur without a proportional increase in dynamic hyperinflation. Both inspiratory augmentation and PEEP may facilitate airspace opening, thus reducing  $V/Q$  mismatch.<sup>100,101</sup>

The role of NIV is well established in chronic obstructive pulmonary disease where a number of randomised trials have shown benefit.<sup>102,103</sup> Although there have been no large randomised trials in acute asthma, there is increasing evidence of benefit from NIV for this indication, with all studies reporting positive outcome.<sup>104,105</sup> Non-randomised studies have reported improvements in respiratory acidosis and respiratory rate following the introduction of NIV, and low requirements for invasive ventilation. In a small prospectively randomised study of acute asthma, Soroksky *et al.*<sup>105</sup> showed better lung function and decreased hospitalisation rate with NIV.

A trial of NIV in patients with acute severe asthma and risk of respiratory decompensation is now warranted in patients who are cooperative and can tolerate the face mask. Indications for use are:

1. moderate to severe dyspnoea or respiratory distress
2. hypercapnic acidosis
3. respiratory rate > 25 breaths/min, accessory muscle use or paradoxical breathing<sup>101</sup>

Contraindications to NIV include cardiac or respiratory arrest, a decreased conscious state, severe upper gastrointestinal bleeding, haemodynamic instability, facial trauma or surgery, inability to protect the airway and clear secretions and high risk of aspiration.<sup>100</sup>

Full face masks are used in the acute setting, and with stabilisation nasal masks. All masks must be carefully fitted to achieve comfort and a reliable seal and no leak, without causing redness or breaks to the skin particularly over the nose.

NIV should be commenced with 5 cmH<sub>2</sub>O continuous positive airway pressure (CPAP: expiratory positive airway pressure (EPAP) 5 cmH<sub>2</sub>O) and 8–10 cmH<sub>2</sub>O pressure support (inspiratory positive airway pressure (IPAP) 13–15 cmH<sub>2</sub>O). The aim is a respiratory rate

< 25 breaths/min and an exhaled tidal volume of 7 ml/kg. CPAP may be increased to 7 or 10 cmH<sub>2</sub>O if there is difficulty initiating inspiration or pressure support may be increased if tidal volume is low or respiratory rate remains high. It is not possible to achieve total pressures reliably (IPAP) > 20 cmH<sub>2</sub>O. NIV should be undertaken in an area familiar with its use and where close observation is available.

Complications of NIV include nasal bridge ulceration, mask discomfort, nasal congestion, gastric insufflation, aspiration, hypotension and pneumothorax;<sup>101</sup> however hypotension and pneumothorax are uncommon compared with their risk during mechanical ventilation.

## INVASIVE VENTILATION

Invasive mechanical ventilation in acute severe asthma may be life-saving, but can be associated with significant morbidity and mortality.<sup>97</sup> Institution of invasive ventilation with endotracheal intubation carries the risk of inadvertent pulmonary hyperinflation<sup>94,95,97</sup> and potential aggravation of bronchospasm, and a significant part of the morbidity and mortality has been attributed to pulmonary hyperinflation.<sup>94,95,97</sup> Despite these risks, the incidence of mechanical ventilation for asthma is decreasing and mortality of patients ventilated for asthma is also decreasing in some series.<sup>9,10</sup>

The decision to intubate depends both on the clinical status of the patient and the natural history of the type of asthma present. Hyperacute asthma may present with marked hypercapnia ( $P_{aCO_2}$  > 60 mmHg) due to mechanical limitations to ventilation as a result of dynamic hyperinflation. Such patients may not initially be fatigued and may respond rapidly to treatment, thereby avoiding mechanical ventilation. Acute severe asthma that has been progressing for days may have less hypercapnia but will often respond poorly to treatment. The  $P_{aCO_2}$  may rise despite maximal treatment due to fatigue and the patient may require intubation at a lower  $P_{aCO_2}$ . The general principles are to use NIV early but to avoid mechanical ventilation if safe to do so.

The decision to intubate is based primarily on the degree of respiratory distress as assessed by an experienced clinician and patients themselves. A patient with a high  $P_{aCO_2}$  (e.g. > 70 mmHg) who is dyspnoeic but not distressed and who may respond to full treatment over a few hours needs close observation but not immediate intubation. Patients are often able to tolerate hypercapnia without requiring invasive ventilation.<sup>106</sup> A patient with a lower  $P_{aCO_2}$  (e.g. 50–60 mmHg) who has been unwell for days and who has a deteriorating status despite treatment is likely to need intubation. A patient who complains of respiratory exhaustion is likely to need intubation. Absolute indications for intubation include cardiac or respiratory arrest, severe hypoxia or rapid deterioration of conscious state.<sup>14,54</sup>

Once the decision to intubate has been made, a safe option is to perform rapid-sequence intubation using the orotracheal approach. The largest possible endotracheal tube should be used to reduce the work of

breathing and to reduce the risk of occlusion by the tenacious secretions that often occur with asthma. Once the endotracheal tube is in place, slow hand ventilation (8–10 breaths/min) should maintain oxygenation until the ventilator can be connected.

### INITIAL VENTILATOR SETTINGS

The principles of initial mechanical ventilation are to avoid excessive DHI<sup>107</sup> and hypoventilation (Figure 31.3) by commencing with a minute ventilation < 115 ml/kg per min (< 8 l/min in a 70-kg patient) best achieved with a tidal volume of 5–7 ml/kg, a respiratory rate of 10–12 breaths/min and a short inspiratory time to ensure an expiratory time of  $\geq 4$  seconds.<sup>22,94,97,98,107</sup> This degree of hypoventilation will usually result in hypercapnic acidosis and continued respiratory distress necessitating heavy sedation, and sometimes requiring 1–2 bolus doses of a neuromuscular-blocking agent (NMBA). During initial controlled hypoventilation, PEEP will further increase lung volume and should not be used.<sup>98</sup>

This use of volume-controlled ventilation is most established for this ventilatory pattern. In volume control, a high inspiratory flow rate (70–100 l/min) is required to achieve a short inspiratory time. This will result in a high peak airway pressure but this will lower DHI and plateau airway pressure ( $P_{plat}$ ) and reduce barotrauma compared with lower inspiratory flow rates.<sup>94,97</sup> Pressure-controlled or assisted modes have been used<sup>108</sup> without adverse consequences. The theoretical advantage of a safe pressure limit in pressure modes is offset by the fact that equilibrium with the set safe pressure cannot be reached during the short inspiratory times required and thus either a higher pressure must be set or more than necessary hypoventilation may occur. It is not clear if one mode is superior to the other.

If significant hypotension occurs this should be treated by reducing the respiratory rate (thereby reducing dynamic hyperinflation) and intravascular volume loading.

### ASSESSMENT OF DYNAMIC HYPERINFLATION

Once mechanical ventilation has started, the degree of DHI should be assessed by measurement of the *plateau airway pressure* ( $P_{plat}$ ). This is the airway pressure after transient expiratory occlusion at the end of *inspiration*. This may be achieved by an end-inspiratory hold function on most current ventilators, which delays the commencement of the next breath (Figure 31.4a) or by applying a 0.5-second ‘plateau’ which does not delay the onset of the next breath. The latter should be applied for a single breath only, as application for several breaths in a row will decrease expiratory time and progressively increase DHI. This is the most easily measured estimate of average alveolar pressure at the end of inspiration and is directly proportional to the degree of hyperinflation and should be maintained at < 25 cmH<sub>2</sub>O.<sup>94,97</sup>

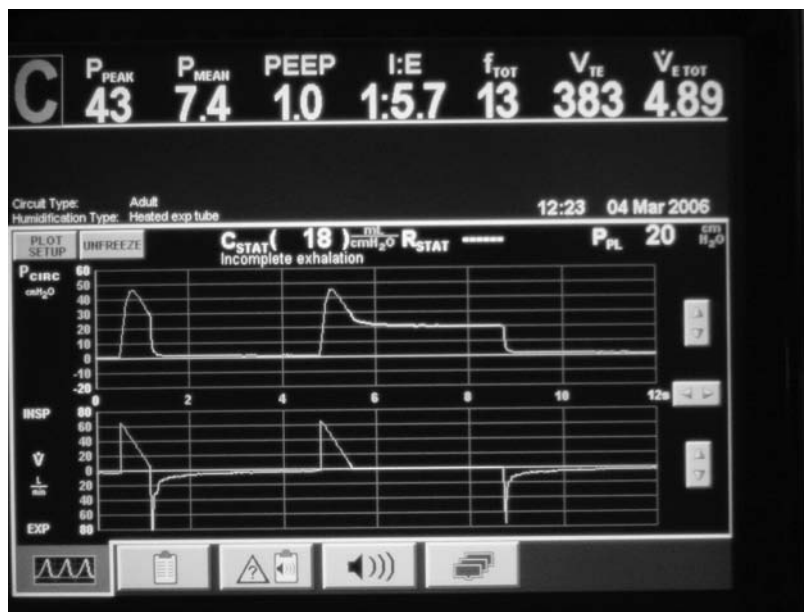

*Intrinsic PEEP* is the airway pressure during occlusion of expiratory flow at the end of *expiration* (Figure 31.4b). This also is an automated end-expiratory hold function on most current ventilators. However this measurement is known to underestimate true PEEP<sub>i</sub>, as a consequence of small-airway closure during expiration, resulting in many higher-pressure alveoli not communicating with the central airway at the end of expiration.<sup>96</sup> Because of this, PEEP<sub>i</sub> can be used to show the presence of DHI but is not recommended to regulate the mechanical ventilation. Ideally PEEP<sub>i</sub> should be < 12 cmH<sub>2</sub>O, though the exact safe level is unknown.

*End-inspiratory lung volume* ( $V_{EI}$ ) (see Figures 31.1 and 31.2) < 20 ml/kg (1.4 litres in a 70-kg patient) has been shown to be a good predictor of complications during mechanical ventilation<sup>97</sup> and to correlate with total lung volume.<sup>22</sup> It is the total exhaled volume during a period of apnoea (30–90 seconds) in a paralysed patient. Although valuable, it is not routinely used as it requires neuromuscular blockade and a volumetric measuring device.

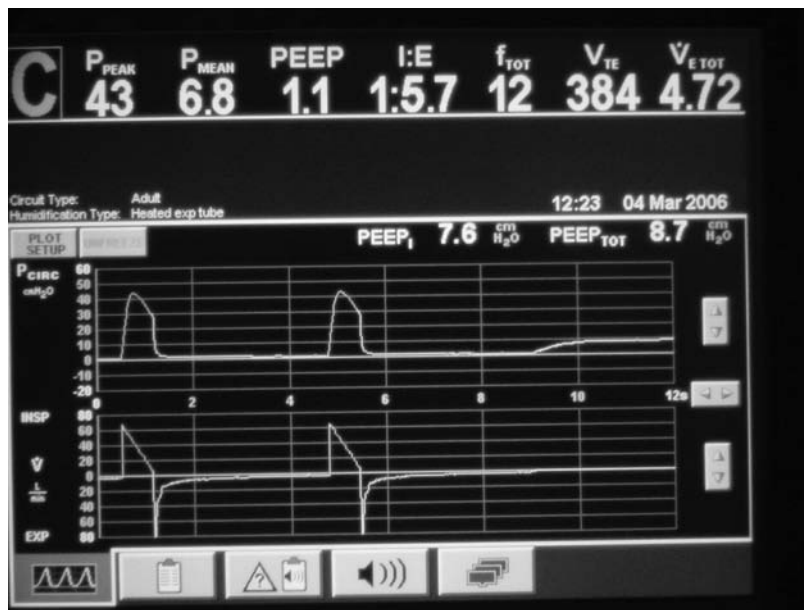

*Assessment of the change in blood pressure and central venous pressure* during a period of transient ventilator

**Figure 31.3** The effects of minute ventilation on  $P_{aCO_2}$  and end-inspiratory lung volume above functional residual capacity (FRC) in a typical patient with severe asthma. The minute ventilation required for (1) normocapnia; (2) profound hypoventilation; and (3) optimal hypoventilation.

(a)

(b)

**Figure 31.4** (a) The ventilator circuit pressure and flow traces versus time during controlled ventilation of a patient with severe airflow obstruction. Note the use of a low rate, low tidal volume ( $V_T$ ), a high inspiratory flow rate ( $V_i$  80 l/min) and hence a short inspiratory time ( $t_i < 1$  second). This causes a high peak airway pressure but allows a long expiratory time ( $> 4$  seconds). Expiratory flow is low throughout expiration and appears close to baseline at the onset of the next breath (second on screen), suggesting minimal gas trapping, but when an intrinsic positive end-expiratory pressure (PEEP<sub>I</sub>) manoeuvre is done (end-expiratory pause) there is a surprising degree of PEEP<sub>I</sub> present (7.6 cmH<sub>2</sub>O). (b) The ventilator circuit pressure and flow traces versus time during controlled ventilation of the same patient as in Figure 31.4a. When a  $P_{plat}$  manoeuvre is done (end-inspiratory pause) the  $P_{plat}$  is safe (20 cmH<sub>2</sub>O) with this ventilator pattern (despite the degree of PEEP<sub>I</sub> present in Figure 31.4a). Note the low  $P_{plat}$  despite the high peak airway pressure.

disconnection (1–2 min) or transient ventilator rate reduction (4–6 breaths/min for 2–4 min): if DHI has been suppressing circulation then a significant increase in blood pressure and reduction in central venous pressure will occur.

### ADJUSTMENT OF VENTILATION

Ventilatory patterns with an excessive minute ventilation risk hypotension and barotrauma and are associated with a high mortality. Using profound hypoventilation will guarantee avoidance of these complications but usually necessitates heavy sedation and neuromuscular blockade (see Figure 31.3). This, in association with parenteral steroids, has a high probability of myopathy,<sup>66,109,110</sup> which may cause severe prolonged disability. To minimise the risk of both these complications, DHI should be carefully assessed and the minimum amount of hypoventilation used to achieve a safe level of DHI (see Figure 31.3) in association with less sedation and minimal or no use of NMBAs.

Ventilation should be adjusted based on assessment of DHI, not on  $P_{aCO_2}$  or pH. If  $P_{plat}$  is  $> 25$  cmH<sub>2</sub>O or circulatory suppression is present, then the ventilator rate should be reduced. If  $P_{plat}$  is low, then ventilation can be liberalised by increasing the ventilator rate or reducing sedation and allowing spontaneous ventilation.

Hypercapnia is usually present but is well tolerated<sup>111</sup> and does not appear to depress cardiac function. There is no evidence of benefit from sodium bicarbonate but it may reduce acidaemia-induced respiratory distress and may be given if the pH is less than 7.1.

When airflow obstruction improves (decreasing  $P_{plat}$  and PEEPi), sedation may be decreased, ventilator rate reduced and spontaneous ventilation assisted with pressure support ventilation. Pressure support of 10–16 cmH<sub>2</sub>O may be used. Once spontaneous ventilation has commenced and when DHI is no longer critical, 3–7 cmH<sub>2</sub>O CPAP may be introduced to assist ventilator triggering and reduce the work of breathing.

### COMPLICATIONS OF INVASIVE VENTILATION IN ASTHMA

*Hypotension* may be caused by sedation, DHI, pneumothoraces or arrhythmias.<sup>94,97</sup> Hypovolaemia may be a contributory factor but is rarely a cause. Hypotension may be mild or life-threatening.<sup>112</sup> Hypotension due to DHI may be diagnosed by recovery of blood pressure during apnoea of 60 seconds (the ‘apnoea test’)<sup>112</sup> or by a longer period of low ventilator rate (4–6 breaths/min for 2–4 min). If this occurs, ventilation should be continued at a lower rate.

*Circulatory arrest with apparent electromechanical dissociation* is a recognised complication that may occur within 10 minutes of intubation and can lead to death or severe cerebral ischaemic injury if not managed correctly.<sup>112–114</sup> Standard mechanical ventilation recommendations (minute ventilation 115 ml/kg per min) have been estimated to be safe for 80% of patients requiring mechanical ventilation for acute severe asthma, with the

remaining 20% requiring a small to moderate reduction in minute ventilation to return DHI to a safe level.<sup>97</sup> A small percentage of patients with unusually severe asthma can rapidly develop excessive DHI during initial uncontrolled mechanical ventilation, leading to electro-mechanical dissociation, sometimes despite ‘safe’ levels of minute ventilation. If the cause of this is not immediately recognised, it can lead to prolonged and unnecessary cardiopulmonary resuscitation, unsafe procedures such as intercostal vascular access needles or pericardial taps and risk cerebral injury and death.<sup>112–114</sup> When this occurs, immediate disconnection from the ventilator for 60–90 seconds (the ‘apnoea test’; see above) or profound hypoventilation (2–3 breaths/min)<sup>54</sup> will diagnose and improve this situation. An even smaller percentage of patients may remain hypotensive despite profound hypoventilation with marked hypercapnia, fluid loading and inotropes. These patients may require Heliox delivered by the mechanical ventilator<sup>115</sup> or extracorporeal membrane oxygenation.<sup>114,116,117</sup>

*Pneumothoraces* were common before the advent of protective ventilatory strategies. DHI during mechanical ventilation was probably the major causative factor involved,<sup>94,97</sup> but pneumothorax may also occur in association with subclavian central venous catheter insertion and as a consequence of intercostal needle insertion for suspected tension pneumothorax during circulatory arrest (see above). The presence of severe airflow obstruction prevents lung collapse and favours gas loss through the ruptured alveoli, with the result that tension is almost always present in the pneumothorax. Once a unilateral tension pneumothorax is present, this will necessarily reduce ventilation to that lung and redistribute ventilation to the contralateral lung, thereby further increasing DHI in the second lung, and bilateral tension pneumothoraces may result with severely adverse consequences.

As soon as a tension pneumothorax is suspected, the ventilator rate should be immediately reduced to decrease the risk to the second lung. Clinical diagnosis of a tension pneumothorax can be difficult as the lungs in severe asthma are already overexpanded and hyperresonant with poor air entry. An urgent chest X-ray is always advisable for confirmation prior to intercostal catheter insertion unless severe hypotension is present. Intercostal catheters should always be inserted by blunt dissection. If intercostal needles are inserted for suspected pneumothorax, an intercostal catheter should always be inserted soon thereafter because if a tension pneumothorax was not present it is highly likely after an intercostal needle.

*Acute necrotising myopathy* is a serious complication that may occur in patients who are invasively ventilated for asthma and receive NMBAs or very deep sedation.<sup>66,109,110,118,119</sup> It is characterised by weakness with electromyographic evidence of myopathy and increased serum creatine kinase levels. Muscle biopsy reveals two patterns: myonecrosis with muscle cell vacuolisation or predominant type II fibre atrophy.<sup>66,118</sup> Recovery can

be slow with prolonged weaning from mechanical ventilation and the need for rehabilitation. Incomplete recovery after 12 months has been reported in a few patients.<sup>119,120</sup> The aetiology of the myopathy appears to be a combination of the effects of corticosteroids and NMBA with the duration of paralysis a strong predictor of myopathy.<sup>119,120</sup> The type of NMBA used seems to make no difference to the incidence of myopathy.<sup>118</sup> The relative contribution of corticosteroids versus NMBA in the causation of myopathy is unclear; it seems wise to minimise the dose of parenteral corticosteroids with early introduction of nebulised agents and to minimise or avoid NMBA if possible.

#### MORTALITY, LONG-TERM OUTCOME AND FOLLOW-UP

In a summary of 37 papers reporting the outcomes of 1260 patients requiring mechanical ventilation for asthma in the four decades prior to the year 2000<sup>55</sup> there was an overall mortality of 12.4% with a progressive reduction in reported mortality during that period (see Table 31.2). A selection of reports<sup>9,11,12</sup> published since 2000 have shown continued reduction in overall mortality (see Table 31.2) but with mortalities as high as 21% still occurring in one series.<sup>11</sup>

The largest and most comprehensive recent series<sup>9</sup> reported 1899 patients admitted to 22 Australian intensive care units over an 8-year period (1996–2003). This series reported a requirement for mechanical ventilation for 36% of patients admitted with severe asthma and a progressive reduction in annual mortality of the ventilated patients from 10% to 3% over the 8-year period.

The need for invasive ventilation is associated with an increased risk of death<sup>9,11,121</sup> and survivors of these near-fatal episodes of asthma have an increased risk of intensive care readmission and an increased risk of death after hospital discharge.<sup>27</sup>

For these reasons, patients who have an episode of asthma severe enough to require hospitalisation, particularly intensive care admission, need careful follow-up. This should include active identification and avoidance of precipitants, aggressive bronchodilator therapy including inhaled steroids, regular medical review, regular measurement of lung function, management plans for a deteriorating status and ready access to emergency services.<sup>9</sup>

# Pneumonia

Charles D Gomersall

The management of pneumonia is based on four findings and premises:

1. Pneumonia is associated with a wide range of largely non-specific clinical features.<sup>1</sup>
2. Pneumonia can be caused by over 100 organisms.<sup>2</sup>
3. The relationship between specific clinical features and aetiological organism is insufficiently strong to allow a clinical diagnosis of the causative organism.<sup>3,4</sup>
4. Early administration of appropriate antibiotics is important.<sup>3,5</sup>

The net result is that the differential diagnosis is wide and treatment should be started before the aetiological agent is known. The differential diagnosis and the likely causative organisms can be narrowed by using epidemiological clues, the most important of which are whether the pneumonia is community-acquired or health care-associated and whether the patient is immunocompromised. Note that the flora and antibiotic resistance patterns vary from country to country, hospital to hospital and even intensive care unit (ICU) to ICU within a hospital<sup>6</sup> and this must be taken into account.

## COMMUNITY-ACQUIRED PNEUMONIA

Recent evidence-based guidelines have been issued by the Infectious Diseases Society of America (IDSA) and American Thoracic Society (ATS)<sup>7</sup> and the European Respiratory Society.<sup>8</sup> Links to these and other pneumonia-related guidelines can be found at the following link page: [http://www.aic.cuhk.edu.hk/web8/Pneumonia\\_guidelines.htm](http://www.aic.cuhk.edu.hk/web8/Pneumonia_guidelines.htm).

## DEFINITION

Community-acquired pneumonia is an acute infection of the pulmonary parenchyma that is associated with at least some symptoms of acute infection, accompanied by an acute infiltrate on a chest X-ray (CXR) or auscultatory findings consistent with pneumonia (e.g. altered breath sounds, localised crackles) in a patient not hospitalised or residing in a long-term care facility for  $\geq 14$  days prior to the onset of symptoms.<sup>9</sup>

## AETIOLOGY

Table 32.1 gives possible aetiological agents based on epidemiological clues. *Streptococcus pneumoniae* is the most

commonly isolated organism. The next most common pathogens in patients admitted to ICU are: *Legionella* species, *Haemophilus influenzae*, Enterobacteriaceae species, *Staphylococcus aureus* and *Pseudomonas* species.<sup>10</sup>

## CLINICAL PRESENTATION

Pneumonia produces both systemic and respiratory manifestations. Common clinical findings include fever, sweats, rigors, cough, sputum production, pleuritic chest pain, dyspnoea, tachypnoea, pleural rub and inspiratory crackles. Classic signs of consolidation occur in fewer than 25% of cases. Multiorgan dysfunction or failure may occur depending on the type and severity of pneumonia.

The diagnosis of pneumonia may be more difficult in the elderly. Although the vast majority of elderly patients with pneumonia have respiratory symptoms and signs, over 50% may also have non-respiratory symptoms and over one-third may have no systemic signs of infection.

## INVESTIGATIONS<sup>7,8</sup>

Investigations should not delay administration of antibiotics as delays are associated with an increase in mortality.<sup>3</sup> Important investigations include:

1. CXR
2. Arterial blood gases or oximetry
3. Full blood count
4. Serum creatinine, urea and electrolytes
5. Liver function tests
6. Blood cultures ( $\times 2$ ) prior to the administration of antimicrobials
7. Sputum (if immediately available) for urgent Gram stain and culture. The usefulness of sputum tests remains debatable because of contamination by upper respiratory tract commensals. However, a single or predominant organism on a Gram stain of a fresh sample or a heavy growth on culture of purulent sputum is likely to be the organism responsible. The finding of many polymorphonuclear cells (PMN) with no bacteria in a patient who has not already received antibiotics can reliably exclude infection by most ordinary bacterial pathogens. Specimens should be obtained by deep cough and be grossly purulent. Ideally the specimen

**Table 32.1** Possible aetiological agents based on epidemiological clues<sup>2,3,7,9</sup>

Exposure	Organism
<b>Exposure to animals</b>	
Handling turkeys, chickens, ducks or psittacine birds or their excreta	<i>Chlamydia psittaci</i>
Exposure to birds in countries in which avian flu has been identified in birds	Influenza A H5N1
Handling infected parturient cats, cattle, goats or sheep or their hides	<i>Coxiella burnetii</i>
Handling infected wool	<i>Bacillus anthracis</i>
Handling infected cattle, pigs, goats or sheep or their milk	<i>Brucella</i> spp.
Insect bite. Transmission from rodents and wild animals (e.g. rabbits) to laboratory workers, farmers and hunters	<i>Francisella tularensis</i>
Insect bites or scratches. Transmission from infected rodents or cats to laboratory workers and hunters	<i>Yersinia pestis</i>
Contact with infected horses (very rare)	<i>Pseudomonas mallei</i>
Exposure to mice or mice droppings	Hantavirus
<b>Geographical factors</b>	
Immigration from or residence in countries with high prevalence of tuberculosis	<i>Mycobacterium tuberculosis</i>
North America. Contact with infected bats or birds or their excreta. Excavation in endemic areas	<i>Histoplasma capsulatum</i>
South-west USA	<i>Coccidioides</i> species, Hantavirus
USA. Inhalation of spores from soil	<i>Blastomyces dermatitidis</i>
Asia, Pacific, Caribbean, north Australia. Contact with local animals or contaminated skin abrasions	<i>Burkholderia pseudomallei</i>
<b>Host factors</b>	
Diabetic ketoacidosis	<i>Streptococcus pneumoniae</i> , <i>Staphylococcus aureus</i>
Alcoholism	<i>Streptococcus pneumoniae</i> , <i>Staphylococcus aureus</i> , <i>Klebsiella pneumoniae</i> , oral anaerobes, <i>Mycobacterium tuberculosis</i> , <i>Acinetobacter</i> spp.
Chronic obstructive pulmonary disease or smoking	<i>Streptococcus pneumoniae</i> , <i>Haemophilus influenzae</i> , <i>Moraxella catarrhalis</i> , <i>Chlamydia pneumoniae</i> , <i>Legionella</i> spp., <i>Pseudomonas aeruginosa</i>
Sickle-cell disease	<i>Streptococcus pneumoniae</i>
Pneumonia complicating whooping cough	<i>Bordetella pertussis</i>
Pneumonia complicating influenza	<i>Streptococcus pneumoniae</i> , <i>Staphylococcus aureus</i>
Pneumonia severe enough to necessitate artificial ventilation	<i>Streptococcus pneumoniae</i> , <i>Legionella</i> spp., <i>Staphylococcus aureus</i> , <i>Haemophilus influenzae</i> , <i>Mycoplasma pneumoniae</i> , enteric Gram-negative bacilli, <i>Chlamydia pneumoniae</i> , <i>Mycobacterium tuberculosis</i> , viral infection, endemic fungi
Nursing-home residency	Treat as health care-associated pneumonia
Poor dental hygiene	Anaerobes
Suspected large-volume aspiration	Oral anaerobes, Gram-negative enteric bacteria
Structural disease of lung (e.g. bronchiectasis, cystic fibrosis)	<i>Pseudomonas aeruginosa</i> , <i>Burkholderia cepacia</i> , <i>Staphylococcus aureus</i>
Lung abscess	Community-acquired methicillin-resistant <i>Staphylococcus aureus</i> , oral anaerobes, endemic fungi, <i>Mycobacterium tuberculosis</i> , atypical mycobacteria
Endobronchial obstruction	Anaerobes, <i>Streptococcus pneumoniae</i> , <i>Haemophilus influenzae</i> , <i>Staphylococcus aureus</i>
Intravenous drug addict	<i>Staphylococcus aureus</i> , anaerobes, <i>Mycobacterium tuberculosis</i> , <i>Streptococcus pneumoniae</i>
<b>Others</b>	
Epidemic	<i>Mycoplasma pneumoniae</i> , influenza virus
Air-conditioning cooling towers, hot tubs or hotel or cruise ship stay in previous 2 weeks	<i>Legionella pneumophila</i>
Presentation of a cluster of cases over a very short period of time	Bioterrorist agents: <i>Bacillus anthracis</i> , <i>Francisella tularensis</i> , <i>Yersinia pestis</i>

should be obtained before treatment with antimicrobials, if this does not delay administration of antibiotics, and be transported to the laboratory immediately for prompt processing to minimise the chance of missing fastidious organisms (e.g. *Streptococcus pneumoniae*). Acceptable specimens (in patients with normal or raised white blood cell (WBC) counts) should contain > 25 PMN per low-power field (LPF) and < 10–25 squamous epithelial cells (SEC)/LPF or > 10 PMN per SEC. These criteria should not be used for *Mycobacterium* and *Legionella* infection. Certain organisms are virtually always pathogens when recovered from respiratory secretions (Table 32.2). Patients with risk factors for tuberculosis (TB) (Table 32.3) and particularly those with cough for more than a month, other common symptoms of TB and suggestive radiographic changes should have sputum examined for acid-fast bacilli (AFB). Sputum cannot be processed for culture for anaerobes due to contamination by the endogenous anaerobic flora of the upper respiratory tract. In addition to the factors listed in Table 32.1, foul-smelling sputum, lung abscess and empyema should raise suspicion of anaerobic infection.

8. Aspiration of pleural fluid for Gram stain, culture, pH and leukocyte count – all patients with a pleural effusion > 1 cm thick on a lateral decubitus CXR.

**Table 32.2** Organisms which are virtually always pathogens when recovered from respiratory secretions<sup>9</sup>

<i>Legionella</i>
<i>Chlamydia</i>
Tuberculosis
Influenza, para-influenza virus, respiratory syncytial virus, adenovirus, Hantavirus, severe acute respiratory syndrome (SARS), coronavirus
<i>Strongyloides stercoralis</i>
<i>Toxoplasma gondii</i>
<i>Pneumocystis carinii</i>
<i>Histoplasma capsulatum</i>
<i>Coccidioides immitis</i>
<i>Blastomycoses dermatitidis</i>
<i>Cryptococcus neoformans</i>

**Table 32.3** Risk factors for pulmonary tuberculosis

Living in or originating from a developing country
Age (< 5 years, middle-aged and elderly men)
Alcoholism and/or drug addiction
Human immunodeficiency virus (HIV) infection
Diabetes mellitus
Lodging-house dwellers
Immunosuppression
Close contact with smear-positive patients
Silicosis
Poverty and/or malnutrition
Previous gastrectomy
Smoking

9. Urinary *Legionella* antigen. This test is specific (> 95%). In patients with severe legionnaire's disease sensitivity is 88–100% for *L. pneumophila* serogroup 1 (the most commonly reported cause of *Legionella* infection). Thus a positive result is virtually diagnostic of *Legionella* infection but a negative result does not exclude it. In areas where other *Legionella* species are more common, this test is less helpful.
10. Urinary pneumococcal antigen has moderate sensitivity (50–80%) and high specificity (> 90%).
11. Microimmunofluorescence serology for *Chlamydia pneumoniae* immunoglobulin (Ig) M. A titre of 1:16 is significant.
12. Human immunodeficiency virus (HIV) serological status.

Other investigations should be considered in patients with risk factors for infection with unusual organisms. Bronchoalveolar lavage may be useful in immunocompromised patients, those who fail to respond to antibiotics or those in whom sputum samples cannot be obtained.<sup>11</sup>

## MANAGEMENT

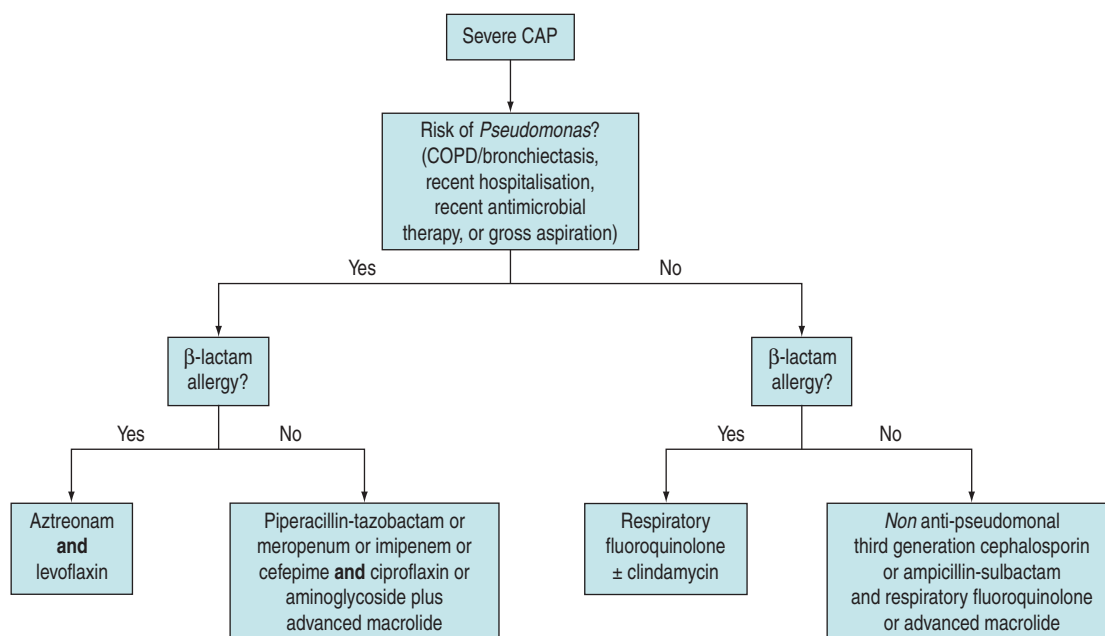

### GENERAL SUPPORTIVE MEASURES

Intravenous fluids may be required to correct dehydration and provide maintenance fluid. A general approach should be made to organ support with an emphasis on correcting hypoxia.

### ANTIMICROBIAL REGIMES

Each unit should have its own regimens tailored to the local flora and antibiotic resistance patterns. In the absence of such regimens the regimen outlined in Figure 32.1 may be helpful. This should be modified in the light of risk factors (see Table 32.1). Quinolones may be less appropriate in areas with a high prevalence of TB as their use may mask concurrent TB infection. Appropriate antimicrobial therapy should be administered within 1 hour of diagnosis.<sup>8,14</sup> There is controversy regarding the appropriate change to empiric therapy based on microbiological findings.<sup>7,8</sup> Changing to narrower-spectrum antimicrobial cover may result in inadequate treatment of the 5–38% of patients with polymicrobial infection. Furthermore, dual therapy may be more effective than monotherapy, even when the identified pathogen is sensitive to the agent chosen, particularly in severely ill patients with bacteraemic pneumococcal pneumonia.<sup>15</sup> For the treatment of drug-resistant *Streptococcus pneumoniae*, the regimens in Figure 32.1 are probably suitable for isolates with a penicillin minimum inhibitory concentration (MIC) < 4 mg/l.<sup>7</sup> If the MIC is ≥ 4 mg/l an antipneumococcal fluoroquinolone, vancomycin, teicoplanin or linezolid should be given.<sup>8</sup>

The role of zanamivir and oseltamivir in severe influenza pneumonia is not clear but early treatment of patients with less severe symptoms results in a reduction of the duration of symptoms if treatment is started early (< 48 hours from onset).<sup>16</sup> Oseltamivir is recommended as first-line therapy for patients with suspected avian influenza A/H5N1.<sup>17</sup>

**Figure 32.1** Antibiotic regimes for treatment of severe community-acquired pneumonia in critically ill patients.<sup>7,8</sup> Respiratory fluoroquinolones include moxifloxacin and levofloxacin. Advanced macrolides include azithromycin and clarithromycin. Cefotaxime is a suitable non-antipseudomonal third-generation cephalosporin.

Recommended treatment for other pathogens can be found at <http://www.journals.uchicago.edu/CID/journal/issues/v44nS2/41620/41620.tb9.html>.

### DURATION OF THERAPY

There are no clinical trials that have specifically addressed this issue. Courses as short as 5 days may be sufficient<sup>18</sup> but antibiotics should be continued until the patient has been afebrile for 48–72 hours and organ dysfunction has largely resolved.<sup>7</sup> Short courses may be suboptimal for patients with bacteraemic *Staphylococcus aureus* pneumonia, meningitis or endocarditis complicating pneumonia or infection with less common organisms (e.g. *Burkholderia pseudomallei* or fungi) or *Pseudomonas aeruginosa*.

### RESPONSE TO THERAPY<sup>7,9,19</sup>

This can be assessed subjectively (a response is usually seen within 1–3 days of starting therapy) or objectively on the basis of respiratory symptoms, fever, oxygenation, WBC count, bacteriology and CXR changes. The average time to defevescence varies with organism, severity and patient age (7 days in elderly patients, 2.5 days in young patients with pneumococcal pneumonia, 6–7 days in bacteraemic patients with pneumococcal pneumonia, 1–2 days in patients with *M. pneumoniae* pneumonia and 5 days in patients with *Legionella* pneumonia). Both blood and sputum cultures are usually negative within 24–48 hours of treatment, although *P. aeruginosa* and *M. pneumoniae* may persist in the sputum despite effective therapy. CXR changes lag

behind clinical changes with the speed of change depending on the organism, the age of the patient and the presence and absence of comorbid illnesses. The CXR of most young or middle-aged patients with bacteraemic pneumococcal pneumonia is clear by 4 weeks but resolution is slower in elderly patients and patients with underlying illness, extensive pneumonia on presentation or *L. pneumophila* pneumonia.

If the patient fails to respond, consider the following questions:

- Does the patient have pneumonia?
- Are there host factors which explain the failure (e.g. obstruction of bronchus by a foreign body or tumour, inadequate host response)?
- Has a complication developed (e.g. empyema, superinfection, bronchiolitis obliterans organising pneumonia)?
- Is the right drug being given in an adequate dose by the right route?
- Is the organism resistant to the drug being given?
- Are there other organisms?
- Is the fever a drug fever?

Useful investigations include computed tomography of the chest, bronchoalveolar lavage (Table 32.4) and trans-bronchial or open-lung biopsy.

### ADMISSION TO ICU

This will largely be determined by the need for organ support and the availability of beds. However the

**Table 32.4** Procedure for obtaining microbiological samples using bronchoscopy and protected specimen brushing (PSB) and/or bronchoalveolar lavage (BAL)<sup>12,13</sup>

Infection control	In patients suspected of having a disease which is transmitted by the airborne route (e.g. tuberculosis): <ul style="list-style-type: none"> <li>the risk of transmission should be carefully weighed against the benefits of bronchoscopy, which may generate large numbers of airborne particles</li> <li>perform bronchoscopy in a negative-pressure isolation room</li> <li>consider the use of a muscle relaxant in ventilated patients, to prevent coughing</li> <li>staff should wear personal protective equipment which should include a fit-tested negative-pressure respirator (N95, FFP2 or above) as a minimum. Use of a powered air-purifying respirator should be considered</li> </ul>
General recommendations	Suction through the endotracheal tube should be performed before bronchoscopy Avoid suction or injection through the working channel of the bronchoscope Perform protected specimen brushing before bronchoalveolar lavage
Ventilated patients	Set $F_{iO_2}$ at 1.0 Set peak pressure alarm at a level that allows adequate ventilation Titrate ventilator settings against exhaled tidal volume Consider neuromuscular blockade in addition to sedation in patients at high risk of complications who are undergoing prolonged bronchoscopy
Protected specimen brushing	Sample the consolidated segment of lung at subsegmental level If purulent secretions are not seen, advance the brush until it can no longer be seen but avoid wedging it in a peripheral position Move brush back and forth and rotate it several times
Bronchoalveolar lavage	Wedge tip of bronchoscope into a subsegment of the consolidated segment of lung Inject, aspirate and collect 20 ml of sterile isotonic saline. Do not use this sample for quantitative microbiology or identification of intracellular organisms. It can be used for other microbiological analysis Inject, aspirate and collect additional aliquots of 20–60 ml The total volume of saline injected should be 60–200 ml
Complications	Hypoxaemia (possibly less with smaller BAL volumes) Arrhythmia Transient worsening in pulmonary infiltrates Bleeding (particularly following PSB) Fever (more common after BAL)
Positive results	>5% of cells in cytocentrifuge preparations of BAL fluid contain intracellular bacteria <i>or</i> $\geq 10^3$ colony-forming units/ml in PSB specimen <i>or</i> $\geq 10^4$ colony-forming units/ml in BAL fluid

presence of three of the following should prompt referral for admission: systolic blood pressure  $\leq 90$  mmHg, multilobar disease,  $P_{aO_2}/F_{iO_2}$  ratio  $\leq 250$  ( $P_{aO_2}$  in mmHg) or  $\leq 33$  ( $P_{aO_2}$  in kPa), multilobar infiltrates, confusion, urea  $> 7$  mmol/l (20 mg/dl), leukopenia, thrombocytopenia, hypothermia and need for aggressive fluid resuscitation.<sup>7</sup>

## HOSPITAL-ACQUIRED PNEUMONIA

Hospital-acquired pneumonia occurs in 0.5–5% of hospital patients, with a higher incidence in certain groups, e.g. postoperative patients and patients in ICU. Diagnosis may be difficult: the clinical features of pneumonia are non-specific and many non-infectious conditions (e.g. atelectasis, pulmonary embolus, aspiration, heart failure

and cancer) can cause infiltrates on a CXR. Identification of the organism responsible is even more difficult than in patients with community-acquired pneumonia due to the high incidence of oropharyngeal colonisation by Gram-negative bacteria. Blood cultures are only positive in about 6% of cases of nosocomial pneumonia. Ventilator-associated pneumonia is nosocomial pneumonia arising  $> 48$ –72 hours after intubation. It is associated with a higher incidence of multidrug-resistant organisms.<sup>1</sup>

## PATHOGENESIS

Nosocomial pneumonia is thought to result from microaspiration of bacteria colonising the upper respiratory tract. Other routes of infection include macroaspiration of gastric contents, inhaled aerosols, haematogenous spread, spread from pleural space and direct inoculation from ICU personnel.

### CLINICAL DIAGNOSIS

Health care-associated pneumonia is defined on the basis of time of onset (developing more than 48 hours after admission to a health care facility<sup>1</sup>), CXR changes (new or progressive infiltrates) and either clinical features and simple laboratory investigations or the results of quantitative microbiology. Using a clinical approach, pneumonia is diagnosed by the finding of a new infiltrate or a change in an infiltrate on CXR and growth of pathogenic organisms from sputum plus one of the following: WBC count greater than  $12 \times 10^5$ /litre, core temperature  $\geq 38.3^\circ\text{C}$ , sputum Gram stain with scores of more than two on a scale of four of polymorphonuclear leukocytes and bacteria.

### INVESTIGATIONS

These are broadly similar to those required in community-acquired pneumonia:

- **CXR:** although studies using a histological diagnosis as the gold standard have demonstrated that pneumonia may be present despite a normal CXR, most definitions of nosocomial pneumonia require the presence of new persistent infiltrates on a CXR.
- **Respiratory secretions:** considerable controversy surrounds the issue of whether invasive bronchoscopic sampling (see Table 32.4) of respiratory secretions is necessary. A randomised controlled trial has demonstrated a reduced 14-day mortality amongst patients with ventilator-associated pneumonia who underwent invasive bronchoscopic sampling compared to those who were treated using a non-invasive management strategy.<sup>20</sup> However the important difference between the two groups may have been the use of quantitative microbiological techniques in the former rather than the use of invasive sampling.<sup>21</sup> Previous data have demonstrated a high correlation between the results of quantitative culture of invasive samples and quantitative culture of tracheal aspirates.<sup>22</sup> A more recent trial of non-quantitative culture of bronchoalveolar lavage specimens versus non-quantitative culture of tracheal aspirates revealed no difference in any outcome measures.<sup>23</sup> Although tracheal aspirates may predominantly reflect the organisms colonising the upper airway they may be useful in indicating which organisms are not responsible for the pneumonia, thus allowing the antimicrobial cover to be narrowed.<sup>1</sup> This interpretation is based on the premise that the predominant route of infection is via the upper respiratory tract. From this it can be assumed that if the organism is not present in the upper respiratory tract the probability of it being present in the lung parenchyma is low. Certain organisms are virtually always pathogens when recovered from respiratory secretions (see Table 32.2).
- **Blood cultures** identify the aetiological agent in 8–20% of patients. Bacteraemia is associated with a worse

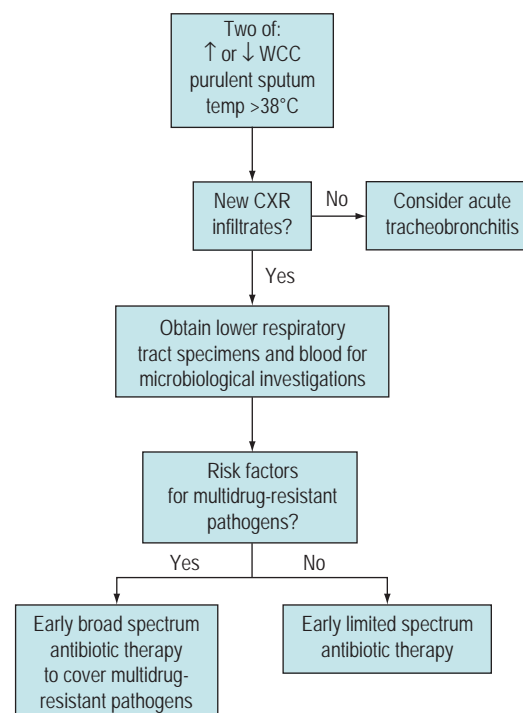

prognosis. In 50% of patients with severe hospital-acquired pneumonia and positive blood cultures there is another source of sepsis.

### MANAGEMENT

Management is based on the finding that early treatment with antimicrobials that cover all likely pathogens results in a reduction in morbidity and mortality.<sup>5</sup> If quantitative microbiology is not used the initial selection of antimicrobials is made on the basis of epidemiological clues (Figure 32.2; Table 32.5). Antimicrobials should be administered within 1 hour of diagnosis.<sup>14</sup> The results of microbiological investigations are used to narrow antimicrobial cover later. Treatment should be reassessed after 2–3 days or sooner if the patient deteriorates (Figure 32.3). An outline of management based on an invasive approach is given in Figure 32.4.

### DURATION OF THERAPY

Current ATS guidelines recommend 7 days' treatment provided the aetiological agent is not *P. aeruginosa* and the patient has a good clinical response with resolution of clinical features of infection.<sup>1</sup> The outcome of patients who receive appropriate initial empiric therapy for ventilator-associated pneumonia for 8 days is similar to those who receive treatment for 14 days.<sup>24</sup>

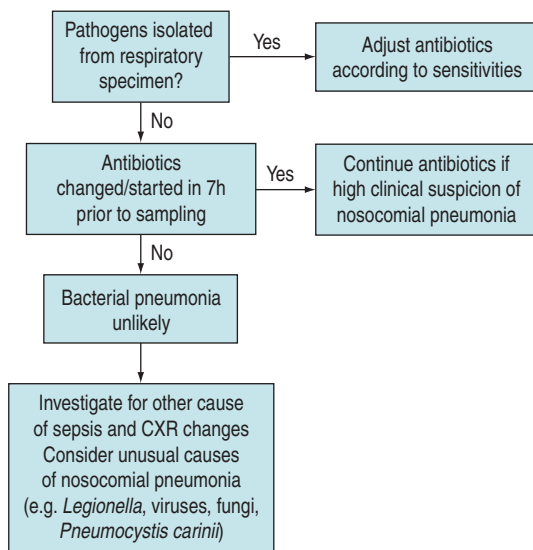

**Figure 32.2** An outline of initial management of nosocomial pneumonia based on a non-invasive clinical approach.<sup>1</sup>

**Table 32.5** Recommended initial empiric treatment for nosocomial pneumonia<sup>1\*</sup>

Situation	Antibiotics
No risk factors for multidrug-resistant pathogens	Cefotaxime <i>or</i> Levofloxacin, moxifloxacin or ciprofloxacin <i>or</i> Ampicillin/sulbactam <i>or</i> Ertapenem
Antimicrobial therapy in previous 90 days <i>or</i> Current hospitalisation for $\geq 5$ days <i>or</i> High frequency of antibiotic resistance in the specific hospital unit <i>or</i> Hospitalisation for 2 days or more in previous 90 days <i>or</i> Residence in nursing home or extended-care facility <i>or</i> Home infusion therapy (including antibiotics) <i>or</i> Chronic dialysis within 30 days <i>or</i> Home wound care <i>or</i> Family member with multidrug-resistant pathogen <i>or</i> Immunosuppression <i>or</i> Bronchiectasis	One of: Antipseudomonal cephalosporin (cefepime or ceftazidime) <i>or</i> Antipseudomonal carbapenem (meropenem or imipenem-cilastin) <i>or</i> $\beta$ -lactam/ $\beta$ -lactamase inhibitor (e.g. piperacillin-tazobactam or cefaperazone-sulbactam) <i>plus</i> one of: Aminoglycoside <i>or</i> Antipseudomonal quinolone (levofloxacin or ciprofloxacin) <i>plus</i> one of the following for patients at high risk of methicillin-resistant <i>Staphylococcus aureus</i> (MRSA) infection: Linezolid or vancomycin or teicoplanin

\*The use of dual therapy is not well supported by evidence but it does reduce the probability that the pathogen is resistant to the drugs being given. If an extended-spectrum  $\beta$ -lactamase-producing strain or an *Acinetobacter* sp. is suspected, a carbapenem should be given. If *Legionella pneumophila* is suspected, use a quinolone. Risk factors for MRSA infection in areas with a high incidence of MRSA include diabetes mellitus, head trauma, coma and renal failure.

**Figure 32.3** Subsequent management of nosocomial pneumonia based on a non-invasive clinical approach.<sup>1</sup>

### RESPONSE TO THERAPY

Clinical improvement is usually not apparent for 48–72 hours and therapy should not be changed in this time. The CXR is of limited value for assessing response: initial deterioration is common and improvement often lags behind clinical response. However a rapidly deteriorating CXR pattern with a  $> 50\%$  increase in size of infiltrate in

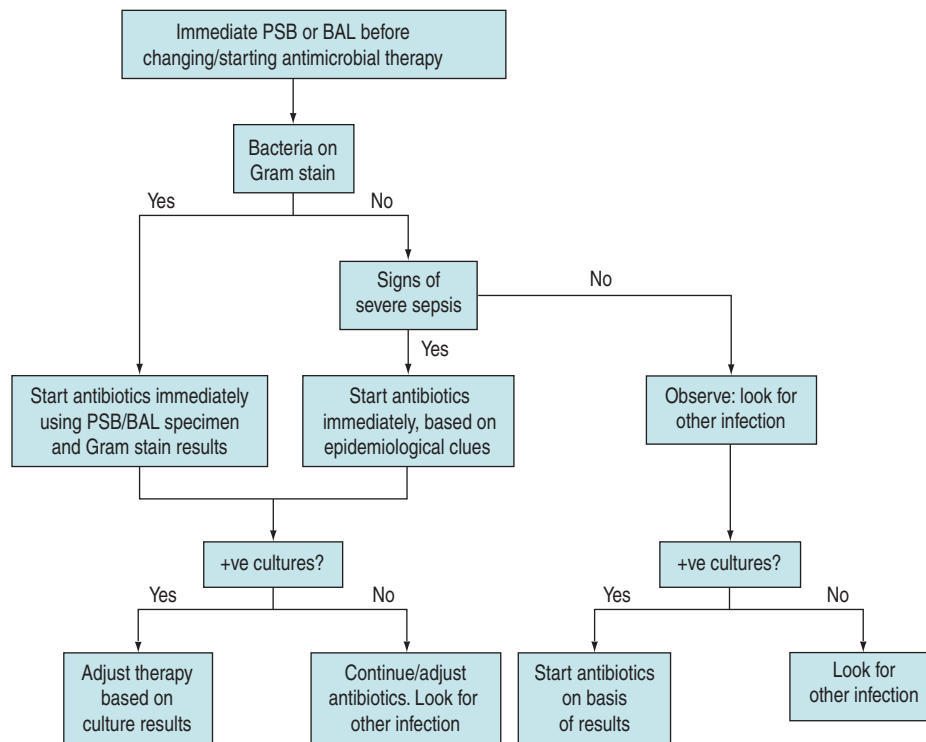

48 hours, new cavitation or a significant new pleural effusion should raise concern. If the patient fails to respond consider the diagnosis, host factors (e.g. immunosuppressed, debilitated), bacterial factors (e.g. virulent organism) and therapeutic factors (e.g. wrong drug, inadequate dose). Review the antibiotics and repeat cultures. It may be useful to broaden the antimicrobial cover while waiting for the results of investigations. Consider invasive sampling of respiratory secretions, computed tomography or ultrasound of the chest (to look for an empyema or abscess), another source of infection, open-lung biopsy to establish diagnosis and aetiology, or administration of steroids.

### PREVENTION

A number of measures have been shown to reduce the incidence of ventilator-associated pneumonia.<sup>25–31</sup> Measures recommended by the Centers for Disease Control (CDC) include hand-washing, nursing patients in a 30° head-up position, subglottic aspiration of secretions, orotracheal rather than nasotracheal intubation, changing the breathing circuit only when visibly soiled or mechanically malfunctioning and preferential use of non-invasive ventilation. CDC guidelines can be accessed via the link page: [http://www.aic.cuhk.edu.hk/web8/Pneumonia\\_guidelines.htm](http://www.aic.cuhk.edu.hk/web8/Pneumonia_guidelines.htm).

### TUBERCULOSIS

The main risk factors are listed in Table 32.3. Typical clinical features include fever, sweating, weight loss, lassitude, anorexia, cough productive of mucoid or purulent sputum,

**Figure 32.4** Management of suspected nosocomial pneumonia based on invasive sampling of respiratory secretions.

haemoptysis, chest wall pain, dyspnoea, localised wheeze and apical crackles. Patients may also present with unresolved pneumonia, pleural effusions, spontaneous pneumothorax and hoarseness or with enlarged cervical nodes or other manifestations of extrapulmonary disease. Clinical disease is seldom found in asymptomatic individuals, even those with strongly positive tuberculin test (Heaf grade III or IV). Older patients, who may have coexistent chronic bronchitis, can be missed unless a CXR is taken. The outlook for patients with TB who require ICU admission is poor. In one retrospective study the in-hospital mortality for all patients with TB requiring ICU admission was 67% but in those with acute respiratory failure it rose to 81%.<sup>32</sup> The presentation and management of TB in HIV-positive patients is different (see below).

## INVESTIGATION OF PULMONARY TUBERCULOSIS

### IDENTIFICATION OF MYCOBACTERIA<sup>33</sup>

Multiple (3–6) sputum samples should be collected, preferably on different days, for microscopy for AFB and culture. If sputum is not available bronchial washings taken at bronchoscopy and gastric lavage or aspirate samples should be obtained. Gastric aspirates need to be neutralised immediately on collection. Bronchoscopy and transbronchial biopsy may be useful in patients with suspected TB but negative sputum smear. Pleural biopsy is often helpful and mediastinoscopy is occasionally needed in

patients with mediastinal lymphadenopathy. Part of any biopsy specimen should always be sent for culture. Nucleic acid amplification tests on sputum have a sensitivity similar to culture in smear-negative patients with pulmonary TB but have the advantage of a much more rapid result. There is, however, a significant false-negative rate.<sup>34</sup>

### CHEST X-RAY

A normal CXR almost excludes TB (except in HIV-infected patients) but endobronchial lesions may not be apparent and early apical lesions can be missed. Common appearances include patchy/nodular shadowing in the upper zones (often bilateral), cavitation, calcification, hilar or mediastinal lymphadenopathy (may cause segmental or lobar collapse), pleural effusion, tuberculomas (dense round or oval shadows) and diffuse fine nodular shadowing throughout the lung fields in miliary TB. Inactivity of disease cannot be inferred from the CXR alone. This requires three negative sputum samples *and* failure of any lesion seen on CXR to progress. CXR appearances in HIV-positive patients with TB differ from non-HIV-infected patients.

### TREATMENT OF PULMONARY TUBERCULOSIS<sup>34,35</sup>

The most commonly used regimen consists of a 6-month course of rifampicin 600 mg/day (450 mg for patients < 50 kg) and isoniazid 300 mg/day plus a 2-month course

of pyrazinamide 2 g/day (1.5 g for patients < 50 kg) and ethambutol 15 mg/kg daily (streptomycin can be substituted for ethambutol). Ethambutol should only be used in patients who have reasonable visual acuity and who are able to appreciate and report visual disturbances. Visual acuity and colour perception must be assessed (if ethambutol is to be used) and liver and renal function checked before treatment is started. Steroids are recommended for children with endobronchial disease and, possibly, for patients with tuberculous pleural effusions. Pyrazinamide 10 mg/day should be given to prevent isoniazid-induced neuropathy to those at increased risk (e.g. patients with diabetes mellitus, chronic renal failure or malnutrition or alcoholic or HIV-positive patients).

### INFECTION CONTROL

Patients admitted to an ICU with infectious TB or suspected of having active pulmonary TB should be managed in an isolation room with special ventilation characteristics, including negative pressure. Patients should be considered infectious if they are coughing or undergoing cough-inducing procedures or if they have positive AFB smears and they are not on or have just started chemotherapy or have a poor clinical or bacteriologic response to chemotherapy.<sup>13,34</sup> Patients with non-drug-resistant TB should be non-infectious after 2 weeks of treatment, which includes rifampicin and isoniazid.<sup>34</sup> As TB is spread through aerosols it is probably appropriate to isolate patients who are intubated even if only their bronchial

washings are smear-positive. Staff caring for patients who are smear-positive should wear personal protective equipment including a fit-tested negative-pressure respirator (N95, FFP2 or higher). Use of a powered air-purifying respirator should be considered when bronchoscopy is being performed.<sup>13</sup> Detailed infection control advice can be obtained via the link page [http://www.aic.cuhk.edu.hk/web8/Pneumonia\\_guidelines.htm](http://www.aic.cuhk.edu.hk/web8/Pneumonia_guidelines.htm).

### PNEUMONIA IN THE IMMUNOCOMPROMISED

The lungs are amongst the most frequent target organs for infectious complications in the immunocompromised. The incidence of pneumonia is highest amongst patients with haematological malignancies, bone marrow transplant recipients and patients with acquired immunodeficiency syndrome (AIDS).

The speed of progression of pneumonia, the CXR changes (Table 32.6) and the type of immune defect provide clues to the aetiology. Bacterial pneumonias progress rapidly (1–2 days) whereas fungal and protozoal pneumonias are less fulminant (several days to a week or more). Viral pneumonias are not usually fulminant but on occasions may develop quite rapidly. Bronchoscopy is a major component of the investigation of these patients. Empiric management based on CXR appearances is outlined in Table 32.6. There is some evidence that early non-invasive ventilation may improve outcome amongst immunocompromised patients with fever and bilateral infiltrates.<sup>36</sup>

**Table 32.6** Causes of chest X-ray changes and empiric treatment of pneumonia in the immunocompromised

Chest X-ray appearance	Causes	Empiric treatment for suspected pneumonia
Diffuse infiltrate	Cytomegalovirus and other herpesviruses <i>Pneumocystis carinii</i> Bacteria <i>Aspergillus</i> (advanced) <i>Cryptococcus</i> (uncommon) Non-infectious causes, e.g. drug reaction, non-specific interstitial pneumonitis, radiation pneumonitis (uncommon), malignancy, leucoagglutinin reaction	Broad-spectrum antibiotics for at least 48 hours (e.g. third-generation cephalosporin and aminoglycoside) Co-trimoxazole Lung biopsy or lavage within 48 hours or full 2-week course of co-trimoxazole (depends on patient tolerance of invasive procedure)
Focal infiltrate	Gram-negative rods <i>Staphylococcus aureus</i> <i>Aspergillus</i> <i>Cryptococcus</i> <i>Nocardia</i> <i>Mucor</i> <i>Pneumocystis carinii</i> (uncommon) Tuberculosis <i>Legionella</i> Non-infectious causes (e.g. malignancy, non-specific interstitial pneumonitis, radiation pneumonitis)	Broad-spectrum antibiotics If response seen, continue treatment for 2 weeks If disease progresses, lung biopsy/aspirate within 48–72 hours or empiric trial of antifungal ± macrolide

### ***PNEUMOCYSTIS JIROVECI* PNEUMONIA (PCP)<sup>37</sup>**

The incidence of this common opportunistic infection has fallen substantially in patients with AIDS who are receiving prophylaxis and effective antiretroviral therapy, with most cases occurring in patients who are not receiving HIV care or among patients with advanced immunosuppression. The onset is usually insidious with dry cough, dyspnoea and fever on a background of fatigue and weight loss. Crackles in the chest are rare. Approximately 15% of patients have a concurrent cause for respiratory failure (e.g. Kaposi sarcoma, TB, bacterial pneumonia). Useful investigations are:

1. **CXR:** classical appearance is diffuse bilateral perihilar interstitial shadowing but in the early stages this is very subtle and easily missed. The initial CXR is normal in 10%. In a further 10% the changes are atypical with focal consolidation or coarse patchy shadowing. None of the changes are specific for PCP and may be seen in other lung diseases associated with AIDS. Pleural effusions, hilar or mediastinal lymphadenopathy are unusual in PCP but common in mycobacterial infection or Kaposi's sarcoma or lymphoma.
2. **Induced sputum:** in this technique the patient inhales nebulised hypertonic saline from an ultrasonic nebuliser. This provokes bronchorrhoea and the patient coughs up material containing cysts and trophozoites. The technique is time-consuming, requires meticulous technique and is less sensitive than bronchoscopy but less invasive. The possibility of concurrent TB should be considered and steps taken to minimise the risk of spread of infection.
3. **Bronchoscopy with bronchoalveolar lavage** leads to the diagnosis in over 90% of cases. Specimens should be sent for cytology. Transbronchial biopsy is not necessary in most cases.

Treatment should be started as soon as the diagnosis is suspected. Although there is some suggestion of potential benefit for early retroviral therapy for patients with HIV and PCP, some centres delay initiation of antiretrovirals until completion of PCP treatment in order to reduce the risk of an immune reconstitution syndrome. Treatment of choice is trimethoprim plus sulphamethoxazole (co-trimoxazole) 20 mg/kg per day + 100 mg/kg per day for 3 weeks plus prednisolone 40 mg orally twice daily for 5 days followed by 20 mg twice daily for 5 days and then 20 mg/day until the end of PCP treatment. Side-effects of co-trimoxazole are common in HIV patients (nausea, vomiting, skin rash, myelotoxicity). The dose should be reduced by 25% if the WBC count falls. Patients who are intolerant of co-trimoxazole should be treated with:

- pentamidine 4 mg/kg per day IV *or*
- primaquine with clindamycin *or*
- trimetrexate with leucovorin ( $\pm$  oral dapsone)

Response to treatment is usually excellent, with a response time of 4–7 days. If the patient deteriorates or

fails to improve: consider (re-) bronchoscopy (is the diagnosis correct?), treat co-pathogens and consider a short course of high-dose intravenous methylprednisolone and/or diuretics (patients are often fluid-overloaded). Approximately 40% of patients with HIV-related PCP who require mechanical ventilation survive to hospital discharge.<sup>38</sup>

### **BACTERIAL PNEUMONIA<sup>37</sup>**

This is the most common cause of acute respiratory failure in HIV-positive patients. Bacterial pneumonia is more common in HIV-infected patients than in the general population and tends to be more severe. *Streptococcus pneumoniae*, *Haemophilus influenzae*, *Pseudomonas aeruginosa* and *Staphylococcus aureus* are the commonest organisms. *Nocardia* and Gram-negatives should also be considered. Atypical pathogens (e.g. *Legionella*) are rare. Response to appropriate antibiotics is usually good but may require protracted courses of antibiotics because of high tendency to relapse. Patients with severe immunodeficiency (CD4<sup>+</sup> T-lymphocyte count < 100/ $\mu$ l) and a history of *Pseudomonas* infection or bronchiectasis or neutropenia should receive antibiotics that cover *P. aeruginosa* as well as other Gram-negatives. The possibility of concurrent PCP or TB should be excluded.

### **TUBERCULOSIS**

TB may be the initial presentation of AIDS, particularly in sub-Saharan Africa. The pattern of TB in HIV patients depends on the degree of immunosuppression. In patients with CD4<sup>+</sup> T lymphocytes > 350 cells/ $\mu$ l the clinical presentation is similar to TB in non-HIV-infected patients, although extrapulmonary disease is more common. In patients with CD4<sup>+</sup> T lymphocytes < 350 cells/ $\mu$ l extrapulmonary disease (pleuritis, pericarditis, meningitis) is common. Severely immunocompromised patients (CD4<sup>+</sup> T lymphocytes < 100 cells/ $\mu$ l) may present with severe systemic disease with high fever, rapid progression and systemic sepsis. In these patients lower and middle-lobe disease is more common, miliary disease is common and cavitation is less common. Sputum smears and culture may be positive even with a normal CXR.

Response to treatment is usually rapid. Complex interactions occur between rifamycins (e.g. rifampicin and rifabutin) and protease inhibitors and non-nucleosidase reverse transcriptase inhibitors used to treat patients infected with HIV. The choice of rifampicin or rifabutin depends on a number of factors, including the unique and synergistic adverse effects for each individual combination of rifampicin and anti-HIV drugs and consultation with a physician with experience in treating both TB and HIV is advised.<sup>39</sup> Infectious Diseases Society of America-recommended dosage adjustment for patients receiving antiretrovirals and rifabutin<sup>37</sup> can be obtained via the link page: <http://www.aic.cuhk.edu.hk/web8/Pneumonia>

guidelines.htm. The optimal time for initiating antiretroviral therapy in patients with TB is controversial. Early therapy may decrease HIV disease progression but may be associated with a high incidence of adverse effects and an immune reconstitution reaction.<sup>37</sup>

### CYTOMEGALOVIRUS (CMV) PNEUMONITIS<sup>40,41</sup>

Risk of infection is highest following allogeneic stem cell transplantation, followed by lung transplantation, pancreas transplantation and then liver, heart and renal transplantation and advanced AIDS. If both the recipient and the donor are seronegative then the risk of both infection and disease is negligible. If the recipient is seropositive the risk of infection is approximately 70% but the risk of disease is only 20%, regardless of the serostatus of the donor. However, if the recipient is seronegative and the donor is seropositive, the risk of disease is 70%. If steroid pulses and antilymphocyte globulin are given for treatment of acute rejection the risk of developing disease is markedly increased. Infection may be the result of primary infection or reactivation of latent infection. It is clinically important, but often difficult, to distinguish between CMV infection and CMV disease and a definitive diagnosis can only be made histologically. Detection of CMV-pp65 antigen in peripheral WBCs and detection of CMV DNA or RNA in the blood by quantitative polymerase chain reaction are the most useful tests for demonstrating CMV disease. Using thresholds of 10/300 000–50/200 000 positive circulating peripheral WBC, the positive predictive value for CMV-pp65 ranges from 64% to 82% and the negative predictive value from 70% to 95%.<sup>42–44</sup> Treatment consists of intravenous ganciclovir for at least 14 days. Foscarnet can be used if ganciclovir fails.

### FUNGAL PNEUMONIA

Fungi are rare but important causes of pneumonia. They can be divided into two main groups based on the immune response required to combat infection with these organisms. *Histoplasma*, blastomycosis, coccidioidomycosis, paracoccidioidomycosis and *Cryptococcus* require specific cell-mediated immunity for their control and thus, in contrast to infections which are controlled by phagocytic activity, the diseases caused by these organisms can occur in otherwise healthy individuals, although they cause much more severe illness in patients with impaired cell-mediated immunity (e.g. patients infected with HIV and organ transplant recipients). With the exception of *Cryptococcus*, these organisms are rarely seen outside North America. *Aspergillus* and *Mucor* spores are killed by non-immune phagocytes and as a result these fungi rarely result in clinical illness in patients with normal neutrophil numbers and function.

### CANDIDIASIS

This is effectively a combination of the two types of fungal infection in that impaired cell-mediated immunity

predisposes to mucosal overgrowth with *Candida* but impaired phagocytic function or numbers is usually required before deep invasion of tissues occurs. Primary *Candida* pneumonia (i.e. isolated lung infection) is uncommon<sup>40,45,46</sup> and more commonly pulmonary lesions are only one manifestation of disseminated candidiasis. Even more common is benign colonisation of the airway with *Candida*. In most reported cases of primary *Candida* pneumonia amphotericin B has been used. In disseminated candidiasis treatment should be directed to treatment of disseminated disease rather than *Candida* pneumonia per se.<sup>46</sup>

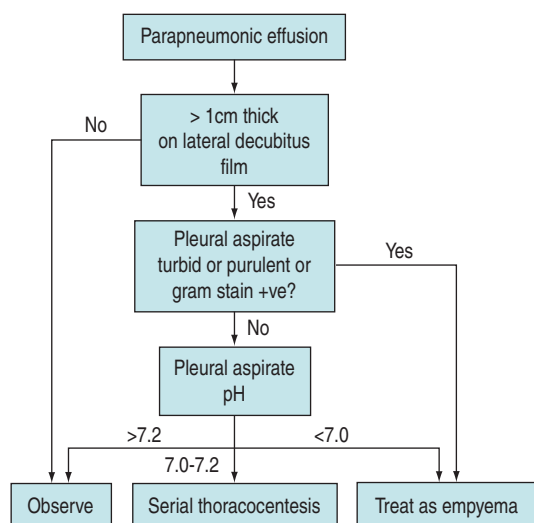

### INVASIVE ASPERGILLOSIS<sup>47</sup>

This is a highly lethal condition in the immunocompromised despite treatment and therefore investigation and treatment should be prompt and aggressive. Definitive diagnosis requires both histological evidence of acute-angle branching, septated nonpigmented hyphae measuring 2–4 µm in width and cultures yielding *Aspergillus* species from biopsy specimens of involved organs. Recovery of *Aspergillus* species from respiratory secretions in immunocompromised, but not immunocompetent, patients may indicate invasive disease with a positive predictive value as high as 80–90% in patients with leukaemia or bone marrow transplant recipients. Bronchoalveolar lavage with smear, culture and antigen detection has excellent specificity and reasonably good positive predictive value for invasive aspergillosis in immunocompromised patients. Although radiological features may give a clue to the diagnosis they are not sufficiently specific to be diagnostic. Characteristic CXR features (wedge-shaped pleural-based densities or cavities) occur late. The ‘halo sign’ (area of low attenuation surrounding a nodular lung lesion) is an early computed tomography finding whereas the ‘crescent sign’ (an air crescent near the periphery of a lung nodule) is a late feature.

In acutely ill immunocompromised patients intravenous therapy should be initiated if there is suggestive evidence of invasive aspergillosis while further investigations to confirm or refute the diagnosis are carried out. First-line therapy is voriconazole.<sup>48</sup> Caspofungin and amphotericin are alternatives.

### PARAPNEUMONIC EFFUSION

This may be an uncomplicated effusion which resolves with appropriate treatment of the underlying pneumonia or a complicated effusion which develops into an empyema unless drained. Complicated effusions tend to develop 7–14 days after initial fluid formation. They are characterised by increasing pleural fluid volume, continued fever and pleural fluid of low pH (< 7.3) which contains a large number of neutrophils and may reveal organisms on Gram staining or culture. An outline of management is given in Figure 32.5.

**Figure 32.5** An approach to the management of parapneumonic effusions.

## EMPYEMA<sup>49</sup>

### DEFINITION

An empyema is a collection of pus in the pleural space.

### AETIOLOGY

An empyema arises following infection of the structures surrounding the pleural space, including subdiaphragmatic structures, and chest trauma or may be associated with malignancy. Anaerobic bacteria, usually streptococci or Gram-negative rods, are responsible for 76% of cases.

### DIAGNOSIS

The diagnosis is simple. The patient is usually septic and may have a productive cough and chest pain. The CXR may show features suggestive of a pleural effusion and underlying consolidation but may also show an abscess cavity with a fluid level, in which case computed tomography scanning will be required to distinguish between an abscess and an empyema. Ultrasound can be useful to confirm the presence of fluid in the pleural space and to determine whether it can be drained by needle aspiration or, if there is debris within the fluid, drainage using an intercostal drain. The diagnosis is confirmed by aspiration of pus.

### TREATMENT

The mainstay of treatment is drainage either by intercostal drain or by surgical intervention. Patients who present before the pus is loculated and a fibrinous peel has formed on the lung can usually be treated by simple drainage. The combination with intrapleural fibrinolysis may be beneficial.<sup>50</sup> Optimal surgical management, which consists of decortication (open or thoracoscopic), is indicated if the empyema is more advanced or if simple

drainage fails. This is a major procedure and many patients with cardiac or chronic respiratory disease will not tolerate it. Alternatives for these patients are instillation of thrombolytics into the pleural space or thoracostomy. Antibiotics have only an adjunctive role. Broad-spectrum antibiotic regimes with anaerobic cover should be used until the results of microbiological analysis of the aspirated pus are available.

# Non-invasive ventilation

Graeme Duke and Andrew D Bersten

Non-invasive ventilation (NIV) is a valuable therapeutic option in the management of acute and chronic respiratory failure – for some diagnoses it is the preferred option. Successful use of NIV in acute respiratory failure (ARF) was first published in 1936,<sup>1</sup> and the use of NIV predates the introduction of laryngoscopy (early 1900s) and the widespread use of positive-pressure mechanical ventilation (MV) via an endotracheal tube (1950s).<sup>2</sup>

NIV is defined as ventilatory support without an (invasive) endotracheal airway. It has an increasingly important role in the short-term management of readily reversible ARF,<sup>3,4</sup> and in chronic respiratory failure due to obstructive sleep apnoea (OSA) and neuromuscular disease.

NIV may be achieved either through the delivery of positive airway pressure ( $P_{ao}$ ) or the application of a negative-pressure generator to the chest ('chest box' or cuirass) or body ('iron lung'). A conceptual framework is shown in Figure 33.1. This chapter deals primarily with the use of positive-pressure NIV to treat ARF.

Negative-pressure generators may be used for the management of acute or chronic respiratory disease.<sup>5</sup> Major limitations to the use of negative-pressure generators include the induction of OSA, lack of fractional inspired oxygen ( $FiO_2$ ) control, equipment bulk and size.<sup>6</sup> However, external negative-pressure generators suit some patients with chronic respiratory failure, particularly as there is no oral or nasal prosthesis.

The clinical efficacy of NIV depends upon: (1) the mode used; and (2) the nature and severity of the underlying respiratory disorder. Correctly applied, NIV can reduce morbidity and mortality, whereas inappropriate application may delay definitive therapy and adversely affect outcome. An understanding of the physiologic rationale for NIV will assist the clinician in understanding the indications and benefits, and predict the side-effects of the various NIV modes.<sup>7,8</sup> Many of the general issues regarding ventilation are discussed in Chapter 27, and this chapter will focus on those issues specific to NIV.

## PHYSIOLOGY OF NIV

The physiological benefits of NIV are similar to those of invasive ventilatory support. The application of NIV can reverse many of the physiologic and mechanical derangements associated with respiratory failure through:

- augmentation of alveolar ventilation ( $\dot{V}_A$ ) to reverse respiratory acidosis and hypercarbia
- alveolar recruitment and increased  $FiO_2$  to reverse hypoxia
- reduction in work of breathing ( $W_{mus}$ ) to reduce or prevent respiratory muscle insufficiency
- stabilisation of the chest wall in the presence of chest trauma or surgery
- reduction in left ventricular (LV) afterload that may lead to an improved cardiac function

The respiratory effort (pressure–volume work) required to achieve a desired minute volume ( $\dot{V}_E$ ) may be viewed as the summation of the individual forces that must be overcome to generate inspiratory flow, namely: elastic work (or 'stretch';  $W_{el}$ ), flow-resistive work (airflow obstruction;  $W_{res}$ ), and threshold work ( $W_{thres}$ ). Since the volume component is constant the equation of motion can be written as:

$$P_{mus} = P_{el} + P_{res} + P_{thres}$$

See Chapter 27 for a more detailed explanation.

With the addition of a device for ventilatory support, the respiratory muscle effort ( $P_{mus}$ ) required by the patient is equivalent to the difference between the applied  $P_{ao}$  and the total work required to maintain  $\dot{V}_E$ .

$$P_{mus} = (P_{el} + P_{res} + P_{thres}) - P_{ao}$$

This relationship may be rearranged into its individual components, as follows:

$$P_{mus} + P_{ao} = EV + R\dot{V} + PEEP$$

where  $E$  is the respiratory elastance (inverse of compliance),  $V$  is the volume of gas,  $R$  is the respiratory and circuit

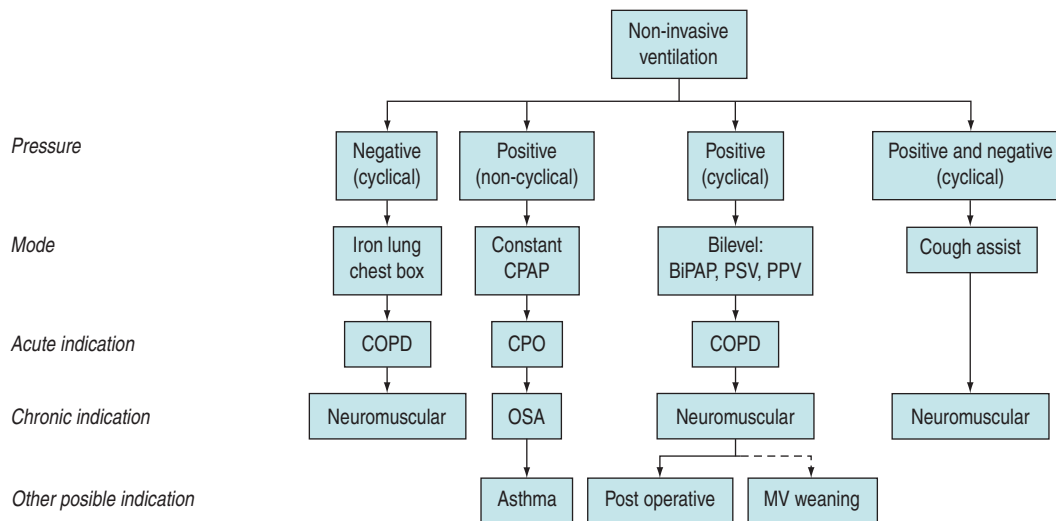

Figure 33.1 Conceptual non-invasive ventilation paradigm. See text for definitions.

flow-resistance,  $\dot{V}$  is the inspiratory flow rate and  $PEEP_i$  is the sum of the extrinsic and intrinsic PEEP ( $\approx P_{thres}$ ).

It is important to remember that breathing via a circuit will create additional airflow resistance ( $R$ ) adding to breathing work ( $P_{mus}$ ), and thus attention to circuit design is important (see below).

$PEEP_i$  is absent in the healthy lung, but common in the presence of tachypnoea, airflow obstruction and dynamic hyperinflation. This threshold load must be counterbalanced by an equivalent amount of inspiratory effort before inspiratory flow can commence. Since threshold load impedes inspiration it will also impede the onset (triggering) of inspiratory support modes (inspiratory positive airway pressure (IPAP) and pressure support ventilation (PSV)).

Respiratory failure occurs when the forces opposing inspiration – namely elastic ( $P_{el}$ ), resistive ( $P_{res}$ ) and threshold ( $PEEP_i$ ) work – exceed the respiratory muscle effort ( $P_{mus}$ ) required to maintain  $\dot{V}_E$ . Hypermetabolic states (e.g. trauma, sepsis) increase basal  $\dot{V}_E$ , whereas pulmonary and chest wall diseases increase respiratory workload, and neuromuscular disease impairs respiratory muscle effort. NIV may prevent respiratory failure by counterbalancing the respiratory workload and/or reducing respiratory muscle effort, and thus maintain  $\dot{V}_A$ .

Although all invasive MV modes may be delivered non-invasively, four are commonly described: continuous positive airway pressure (CPAP); PSV; bilevel or biphasic positive airway pressure (BiPAP); and pressure- or volume-limited intermittent positive-pressure ventilation. Other modes under investigation include high-frequency and proportional assist ventilation.

All NIV modalities utilise closed (or semiclosed) circuits and are thus capable of controlling and delivering high  $FiO_2$ . This is an important mechanism by which NIV improves oxygenation, independently of other mechanisms discussed below.

### CONTINUOUS POSITIVE AIRWAYS PRESSURE

CPAP is a form of NIV because it provides respiratory support even though the  $P_{ao}$  applied is constant throughout the respiratory cycle. This mode can address a number of objectives of ventilatory support, namely:

1. reduction in the work of breathing by:
  - alveolar recruitment leading to reduction in elastic work
  - reducing threshold load created in the presence of  $PEEP_i$
2. reversing hypoxia through alveolar recruitment and reduction of intrapulmonary shunt
3. reduction of LV transmural pressure (afterload)<sup>9,10</sup>

### INSPIRATORY POSITIVE AIRWAY PRESSURE AND PSV

Positive inspiratory airway pressure, without expiratory pressure (e.g. PSV or IPAP), provides respiratory support by reducing both the elastic and resistive components of respiratory work. This may result in:

- augmentation of tidal volume ( $V_T$ ) and reduction in  $P_{aCO_2}$
- reduction in  $P_{mus}$  with reduction or prevention of respiratory muscle insufficiency
- induction of pulmonary surfactant release through alveolar inflation above resting tidal volume<sup>11</sup>

### BILEVEL POSITIVE AIRWAY PRESSURE (BPAP)

BPAP allows separate settings for inspiratory (IPAP) and expiratory (EPAP) airway pressure levels, and is conceptually similar to PSV plus CPAP. Respiratory frequency is usually determined by the spontaneous rate but may be

time-cycled and independent of patient effort. In some patients BPAP may not be as effective in reducing  $P_{\text{mus}}$  as the combination of PSV plus CPAP.<sup>2,12</sup>

### CONTROLLED VENTILATION

NIV may also be administered as volume- or pressure-limited MV applied via a mask (instead of an endotracheal airway).

### PATIENT-VENTILATOR INTERACTION

This is discussed in Chapter 27, and subdivided into: (1) triggering of inspiration; (2) inspiration; and (3) cessation of inspiration. The only aspect that is specific to NIV arises from mask leaks that may interfere with the ability to sense the end of expiration because there is continued 'expiratory' gas flow.

### NON-INVASIVE VENTILATION EQUIPMENT

Equipment design varies according to NIV mode and purpose (e.g. critical care or domiciliary setting), and significant variation in performance characteristics have been documented.<sup>12,13</sup> The important characteristics of an efficient NIV circuit include:

- High gas flow that can match the peak inspiratory air-flow. Mechanisms to generate high flows include a pressurised gas supply, a gas turbine or a jet Venturi mechanism. A continuous-flow device often imposes less circuit work than a demand flow device.
- An expiratory resistor capable of maintaining the desired PEEP, yet offering a low resistance to expiratory flow to reduce fluctuations in the desired  $P_{\text{ao}}$ . This may be a threshold resistor or flow resistor. The optimal position for the expiratory valve is as close to the patient's airway as possible.
- Minimal-length, wide-bore tubing to reduce turbulence and flow resistance.
- A flow or pressure sensor for identifying inspiratory effort, and triggering positive inspiratory pressure support (e.g. PSV or IPAP).
- Ability to control and deliver a wide range of  $F_{\text{IO}_2}$ .
- Other desirable features include the facility to humidify inspired gases and nebulise drugs, and the provision for pressure relief safety valves, battery back-up, apnoea back-up support, acoustic suppression and monitoring of volume and  $P_{\text{ao}}$ . These features are less important for domiciliary (long-term) NIV equipment.

Many mask designs are also available and the optimal design depends upon the purpose and mode of NIV and patient anatomy and preference. These include intranasal, nasal, oronasal, full-face and helmet (full-head) masks. Desirable features of a mask include light-weight and transparent materials providing a comfortable air-tight seal with minimal dead space and separate inspiratory and expiratory ports to minimise airflow turbulence and

rebreathing.<sup>13,14</sup> In lung model studies, expiratory ports over the nasal bridge reduce dead space,<sup>15</sup> which may prove to be clinically advantageous.

Mask discomfort, arising from the mask seal, air leaks, humidification or claustrophobia, is a common cause of poor compliance with NIV. Masks that cover nose and mouth tend to produce more reliable and constant  $P_{\text{ao}}$  because they are unaffected by mouth breathing, a common problem in the critically ill patient. Nasal masks are less restrictive on the patient's ability to talk, eat/drink and expectorate and have a higher compliance in longer-term and domiciliary applications. To compensate for air leaks effectively, nasal masks should be used with circuits capable of rapidly augmenting and delivering high flows > 100 l/min.

Fibreoptic bronchoscopy can be easily, and often safely, performed during NIV. In addition to the usual precautions regarding fibreoptic bronchoscopy, an orofacial mask with at least two ports is required. One of these can be modified to allow a simple valve for insertion of the bronchoscope, and the other used for NIV. Provided there is adequate NIV flow reserve during suction, this can be performed during all modes of NIV. This technique may allow both diagnostic and therapeutic bronchoscopy without intubation in critically ill patients.

### COMPLICATIONS AND ASSESSMENT OF EFFICACY

Contraindications and complications specific to NIV are listed in Table 33.1. Most patients requiring NIV should be managed in a critical care ward with appropriately trained medical and nursing staff. Although the development of sophisticated, portable, non-invasive ventilators makes it

**Table 33.1** Contraindications and complications of non-invasive ventilation

#### Contraindications

- Respiratory arrest
- Unprotected airway (coma, sedation)
- Upper-airway obstruction
- Inability to clear secretions
- Untreated pneumothorax
- Marked haemodynamic instability

#### Complications

- Mask discomfort, patient intolerance
- Facial or ocular abrasions
- Nasal congestion, sinus pain
- Oronasal dryness
- ↑ Intraocular pressure (particularly in patients with glaucoma)
- ↑ Intracranial pressure (particularly in patients with neurotrauma)
- ↓ Blood pressure (if hypovolaemic)
- Aspiration pneumonia (rare)
- Aerophagy and gastric distension (uncommon; routine gastric decompression is unnecessary)

easy to provide NIV in any environment, its benefits may diminish outside the critical care environment.<sup>16,17</sup>

Following the application of NIV reversal of hypoxia, and transient reduction in respiratory rate and effort are commonly observed irrespective of the underlying disease. Although these are important goals of respiratory support, they are a poor guide to the true efficacy of NIV. More reliable clinical measures of NIV efficacy include reversal of hypercarbia and sustained improvement in respiratory function. Efficacy of NIV should be assessed using outcomes such as rates of compliance, intubation, nosocomial pneumonia and mortality.

### NON-INVASIVE VENTILATION AND ACUTE RESPIRATORY FAILURE<sup>2,16,18</sup>

#### CARDIOGENIC PULMONARY OEDEMA (CPO)<sup>2,8,19</sup>

CPO is a common cause of severe reversible ARF. Since the 1930s, a number of investigators have documented the therapeutic benefits of all modes of NIV – particularly CPAP – in the treatment of CPO. CPO leads to an increase in elastic workload ( $P_{ei}$ ) and, to a less extent, resistive workload ( $P_{res}$ ) as a consequence of diastolic LV dysfunction, an increase in lung water and impaired surfactant function. CPAP reverses hypoxia, recruits alveoli and reduces intrapulmonary shunt and LV afterload. Redistribution of extravascular lung water from alveoli to the interstitial space is aided by recruitment of alveoli and surfactant production.

Over 20 prospective randomised controlled trials of NIV in CPO have consistently demonstrated physiologic improvements in hypoxic and hypercapnic respiratory failure, and a significant reduction in the need for intubation, hospital length of stay and improved survival (95% confidence interval (CI) relative risk (RR) = 0.38–0.90).<sup>19</sup> Even though the majority of these patients were managed in a critical care setting the average duration of respiratory support was much shorter for NIV ( $9 \pm 11$  hours) than those who required MV.<sup>20</sup>

The optimal mode of NIV in CPO appears to be CPAP alone. The optimal  $P_{ao}$  level remains to be resolved, although 10 cmH<sub>2</sub>O appeared to be safe and effective in the majority of subjects. Whilst the addition of a differential inspiratory pressure (e.g. bilevel<sup>21</sup> and PSV<sup>22,23</sup>) appears to be as effective as CPAP, it does not appear to provide an additional outcome benefit<sup>19</sup> and may increase the rate of myocardial infarction<sup>24,25</sup> (95% CI RR 0.92–2.42).<sup>19</sup> Bilevel NIV and CPAP have equivalent impact on respiratory parameters, but may have different effects on myocardial function.<sup>24,25</sup> CPAP reduces preload and afterload<sup>9,10</sup> and myocardial catecholamine release<sup>26</sup> but the cyclical  $P_{ao}$  (of bilevel NIV) may cause preload and afterload to rise and fall during respiration.<sup>2,27</sup>

Current evidence supports the routine use of mask CPAP in moderate or severe CPO as standard therapy and as the first-line option for respiratory support.<sup>16,28</sup>

#### ACUTE RESPIRATORY FAILURE IN CHRONIC OBSTRUCTIVE PULMONARY DISEASE (COPD)

COPD patients have an elevated resistive work ( $P_{res}$ ), often coupled with an elevated basal  $\dot{V}_E$  and elastic work ( $P_{ei}$ ) as a result of the pre-existing parenchymal damage. Threshold load (PEEP<sub>i</sub>) is frequently present as a result of airflow obstruction, and is exacerbated during ARF by further increased  $W_{res}$  and respiratory rate. Reversible ARF is a common complication of COPD.

Both CPAP and PSV reduce  $P_{mus}$  in intubated COPD patients weaning from MV. The importance of NIV in hypercapnic ARF is now supported by at least 14 well-performed prospective randomised controlled studies<sup>18,29–31</sup> in over 600 patients. Most investigators have demonstrated a low incidence of side-effects and a significant decrease in intubation rates and in-hospital mortality.<sup>31</sup> The meta-analysis of NIV trials reveals significant reductions in mortality (95% CI RR = 0.35–0.76) and the need for intubation (95% CI RR = 0.33–0.53) – the number of patients needed to avoid intubation or death were as few as 4 and 10 respectively.<sup>32</sup> Risk reduction appears to be proportional to the severity of respiratory acidosis.<sup>33</sup> The incidence of nosocomial pneumonia is lower with NIV<sup>34–36</sup> and this may explain some of the mortality reduction associated with NIV.<sup>36</sup> Nevertheless, mask intolerance, nursing workload and failure rates are greater than those reported with NIV in CPO.<sup>2</sup>

Current evidence supports the use of NIV in hypercapnic ARF as a component of standard therapy in COPD subjects. This is supported by many respiratory medicine societies throughout the world,<sup>16,28,37</sup> that ‘patients hospitalised for exacerbations of COPD with rapid clinical deterioration should be considered for noninvasive positive pressure [ventilatory support] to prevent further deterioration in gas exchange, respiratory workload and the need for endotracheal intubation’.<sup>16</sup>

All modes of NIV have been shown to be effective but there are no comparative trials that address the question of optimal mode or pressure level.<sup>16</sup> Patients with ARF arising predominantly from airflow obstruction ( $P_{res}$ ) and/or threshold load are likely to respond to CPAP. Most patients also have reduced alveolar ventilation, marked hypercapnia or respiratory muscle insufficiency and are therefore likely to benefit from the addition of inspiratory support, i.e. PSV, IPAP or non-invasive positive-pressure ventilation (NIPPV).

NIV is indicated in the presence of respiratory acidosis (pH < 7.37) or persistent breathlessness.<sup>32,38</sup> These patients should be managed in a critical care setting where appropriate equipment and skill are available<sup>2</sup> and reported outcomes appear better.<sup>17,32</sup> The level of inspiratory support (usually 5–15 cmH<sub>2</sub>O) should be titrated to improve  $\dot{V}_E$ , as indicated by improvement in tidal volume and pH, and reductions in respiratory rate and  $P_{aco_2}$ . Low levels of CPAP (4–8 cmH<sub>2</sub>O) should be titrated to minimise the patient effort required to trigger inspiratory assistance and the  $F_{iO_2}$  titrated to reverse hypoxia.

Early predictors of NIV success in COPD patients include the pH and  $P_{aCO_2}$ , but not the  $P_{aO_2}$ , response within the first 2 hours of therapy.<sup>32,39</sup> Predictors of NIV failure include mask intolerance, severe acidosis (pH < 7.25), tachypnoea (> 35/min), impaired conscious state and poor clinical response to initial therapy.<sup>39</sup> Prior to the commencement of NIV the clinician should develop a clear management strategy for those patients who fail a trial of NIV.

Although reported success rates are high (70–90%), NIV failure (i.e. intubation) appears to increase with the severity of respiratory acidosis.<sup>32,38</sup> For the poorly compliant patient, reassurance and explanation together with a trial of different size and/or type of mask, or initiation with lower pressure settings, and brief periods off NIV will sometimes assist. Low-dose anxiolytic drugs may be beneficial where anxiety is a recurrent precipitant of tachypnoea, but should be used with extreme caution because of their respiratory-depressant side-effects.

Late failure (> 48 hours) occurs in 10–20% of patients<sup>18,30,39</sup> despite an initial improvement with NIV. This group of patients has a high mortality risk.<sup>40</sup> Whether their worse outcome is related to the severity of their underlying disease, or from delayed initiation of MV, remains unclear.

### ASTHMA

Asthma is an acute inflammatory lung disease that increases resistive ( $P_{res}$ ) and threshold ( $PEEP_i$ ) respiratory work. Physiological and clinical improvement has been demonstrated in acute asthmatics with the application of CPAP<sup>41–43</sup> and bilevel NIV.<sup>43–45</sup> One randomised controlled trial of bilevel NIV titrated over 30 minutes resulted in significant improvement in forced expiratory volume in 1 second ( $FEV_1$ ) and a lower hospital admission rate.<sup>46</sup>

The clinical role of NIV in the management of acute asthma and the benefit of differential inspiratory pressure, if any, remains to be clarified. We have found 5 cmH<sub>2</sub>O CPAP to be effective in moderate to severe asthma not responding to continuous inhaled bronchodilators. Nebulised drugs can be effectively delivered even in the presence of a high-flow NIV circuit.<sup>47</sup> Controlled clinical studies with robust end-points are awaited.

### ACUTE LUNG INJURY (ALI) AND ACUTE RESPIRATORY DISTRESS SYNDROME (ARDS)

Like CPO, ALI leads to increase in elastic workload ( $P_{el}$ ) and, to a lesser extent, resistive workload ( $P_{res}$ ) arising from an increase in alveolar–capillary permeability, the release of inflammatory mediators and impaired surfactant function. In contrast to CPO there is little supportive evidence for NIV in ALI and ARDS. Even though the addition of PEEP is important during MV for ALI or ARDS and NIV has a lower prevalence of nosocomial pneumonia,<sup>34–36</sup> current data do not support the routine use of NIV in undifferentiated hypoxaemic ARF.<sup>48,49</sup>

Despite numerous clinical reports of successful use of NIV in the setting of community-acquired pneumonia (without COPD) and other forms of ALI, the failure rate remains high.<sup>31,48,50–53</sup> This may reflect the differences in duration, severity and the pathophysiology of pneumonia, ALI and ARDS compared to CPO. Some studies showing apparent benefit have failed to exclude patients with CPO<sup>54</sup> or COPD<sup>55,56</sup> – specific subgroups known to benefit from NIV.

### PNEUMONIA IN THE IMMUNOCOMPROMISED PATIENT

MV is associated with high morbidity and mortality risks in immunocompromised patients.<sup>56–58</sup> These patients may benefit from NIV<sup>2</sup> through a reduction in intubation and MV,<sup>56,57</sup> but it is unclear whether this translates into improved hospital survival<sup>56,58</sup> or not.<sup>36,57</sup> Whether NIV simply avoids a high-morbidity therapy (i.e. MV)<sup>34</sup> or selects those with a more readily reversible form of ARF and those more likely to survive is unclear. Nevertheless it seems reasonable, based on the current data, to offer NIV to these patients.<sup>16</sup> Once again, clear guidelines need to be established for the management of those patients who fail a trial of NIV and those in whom MV is deemed inappropriate or futile.

### POSTOPERATIVE AND POSTTRAUMATIC ARF

ARF in postoperative and trauma patients may arise from a number of reversible pathological processes associated with increases in elastic workload ( $P_{el}$ ) and impaired respiratory muscle function, including dependent atelectasis, impaired chest wall mechanics, poor cough, nosocomial infection, aspiration pneumonitis and non-respiratory trauma or sepsis.

Mask CPAP consistently improves physiological parameters (e.g. oxygenation and respiratory rate) and reduces the risk of intubation in general surgical<sup>59</sup> and cardiothoracic patients<sup>60</sup> with mild postoperative hypoxic respiratory failure, but evidence for an outcome benefit is lacking. It is possible that the addition of inspiratory support (PSV or BiPAP) may improve survival in certain subgroups, such as postoperative lung resection.<sup>61</sup> Many of these patients have underlying COPD, and extrapolation of these results to non-COPD patients awaits further study.

Mask CPAP has been shown to be superior to MV in patients with isolated severe chest trauma,<sup>62,63</sup> but the exact role of NIV is unclear. NIV is contraindicated in the presence of other significant injuries such as neurotrauma and intracranial hypertension and in the presence of an untreated pneumothorax.

### NIV-ASSISTED WEANING

As a result of the demonstrable benefits of NIV in COPD and the widespread use of invasive PSV to assist weaning from MV, NIV has also been recommended to expedite

weaning from MV by allowing early extubation,<sup>63</sup> and to treat failed or accidental extubation. The putative advantages relate to reduction in the duration and the risks of MV (e.g. nosocomial pneumonia).

For COPD patients, once again, there appears to be a survival benefit,<sup>64</sup> but this is less clear in other groups,<sup>65</sup> where controlled studies do not support an overall benefit.<sup>16</sup> Although NIV is an option for early weaning it is not a substitute for strategies to improve early access to NIV (to reduce the need for MV) and improve weaning success (to reduce the risk of premature extubation).

### NIV AND CHRONIC RESPIRATORY DISEASE

NIV is an important modality for short-term assistance and long-term treatment of severe chronic respiratory failure associated with obstructive and central sleep apnoea syndromes,<sup>16,66</sup> and chronic hypoventilation syndromes associated with extrapulmonary disease such as neuromuscular disease,<sup>67</sup> and thoracic deformities.<sup>68</sup> There appears to be less benefit in chronic parenchymal lung disease, such as (stable) COPD and cystic fibrosis.<sup>69</sup>

These patients may require short-term MV or NIV in a critical care environment for respiratory support during an acute illness or as an aid to perioperative care. NIV (plus minitracheostomy for secretion removal) may improve outcome compared to intubation and MV<sup>70</sup> but failure rates appear to be higher than in acute hypercapnic COPD.<sup>71</sup> Alternatively these conditions may be first diagnosed during admission for treatment of severe ARF and, following recovery, will require assessment for long-term NIV.

### NIV AND SLEEP APNOEA SYNDROMES<sup>72,73</sup>

Moderate or severe OSA results in nocturnal hypoventilation and episodic hypoxia that can lead to pulmonary and systemic hypertension, cardiac failure, and daytime hypercapnia and somnolence. Many of these complications can be arrested or reversed through the appropriate use of nocturnal CPAP.<sup>16,66,74</sup> Patients with suspected sleep apnoea require accurate assessment by a respiratory physician, including sleep studies, prior to the routine use of domiciliary CPAP. Occasionally bilevel or controlled ventilation will be needed when there is inadequate central respiratory drive. In many patients respiratory drive will improve, and they can then be managed with CPAP after a period of bilevel or controlled ventilation.

Intercurrent illness, surgery or the use of sedatives and opioid analgesics will increase the frequency and duration of hypopnoea, apnoea and hypoxia. CPAP should be available even for those patients who do not require admission to a critical care ward.

### NIV AND CHRONIC HYPOVENTILATION SYNDROMES

Domiciliary NIV (predominantly using inspiratory support modes or NIPPV) should be considered in all patients presenting with severe chronic respiratory failure due to neuromuscular disease.<sup>67,69,75</sup> Early referral and consideration of domiciliary NIV are recommended because of improved outcomes<sup>67,76</sup> and quality of life. In cystic fibrosis patients it may have a role simply as a bridge to organ transplant.<sup>57,68</sup> In direct contrast to the role of NIV in acute exacerbations of COPD, there is little or no benefit of domiciliary NIV in the presence of stable COPD,<sup>16,37,71,77</sup> unless one of the former conditions coexists.

Assessment of these patients for domiciliary NIV includes respiratory function tests, blood gas analysis, sleep studies, together with trials of NIV modes and pressure settings. In general, indications for long-term NIV include the demonstration of symptomatic respiratory failure, daytime hypercapnia and a significantly reduced (< 20% predicted) vital capacity. The use of nocturnal or intermittent NIV has been shown to improve daytime respiratory and cardiac function, to improve exercise endurance, to slow the progression of respiratory dysfunction and to reduce the frequency of hospitalisation.<sup>67,76</sup>

# Respiratory monitoring

Andrew D Bersten

Clinical examination and the trend of vital signs such as respiratory rate ( $f$ ), and quantity and nature of sputum are extremely important in managing patients with respiratory disease. In particular, clinical examination should look for evidence of excessive inspiratory and/or expiratory pleural pressure changes and effort such as accessory muscle use, tracheal tug, supraclavicular and intercostal indrawing, paradoxical abdominal movement (which is suggestive of diaphragmatic fatigue<sup>1</sup>) and pulsus paradoxus. During spontaneous ventilation an excessive fall in blood pressure during inspiration ( $>10$  mmHg) is found in a number of conditions such as cardiac tamponade, cardiogenic shock, pulmonary embolism, hypovolaemic shock and acute respiratory failure. A curvilinear relationship exists between the fall in blood pressure and the change in pleural pressure during inspiration; however, there is marked variation between individuals.<sup>2</sup> Consequently, pulsus paradoxus is most useful in following trends; a reduction in the degree of paradox may be due to improvement and a fall in the negative pleural pressure needed for ventilation, or due to respiratory muscle insufficiency, and an inability to generate the same negative pleural pressure.

Additional information can be gained from blood gases and pulse oximetry (Chapter 14), and capnography, ventilatory pressures and waveform analysis in patients receiving respiratory assistance. This chapter will focus on tests of respiratory function that are directly relevant to critically ill patients.

## MONITORING GAS EXCHANGE

### OXYGENATION

This is reviewed in Chapter 14, and is only briefly discussed here. Hypoxaemia may be due to a low partial pressure of inspired  $O_2$  (rare), hypoventilation, diffusion impairment (rare), ventilation–perfusion ( $\dot{V}/\dot{Q}$ ) mismatch and shunt. Inert gas analysis has been used to quantitate ( $\dot{V}/\dot{Q}$ ) mismatch, and has demonstrated that hypoxaemia in acute respiratory distress syndrome (ARDS) is predominantly due to alveoli that are perfused but not ventilated (shunt),<sup>3</sup> consistent with computed tomography (CT) scan evidence of increased dependent lung density. However, inert gas analysis remains a

research tool, and less direct methods, such as the alveolar gas equation, are used to assess hypoxaemia:

$$PAO_2 = \text{inspired } PO_2 - PaCO_2 / \text{respiratory quotient}$$

where  $PAO_2$  is the alveolar  $PO_2$ , and this is usually simplified to:

$$PAO_2 = (760 - 47) \times F_{iO_2} - PaCO_2 / 0.8$$

where 760 is atmospheric pressure in mmHg, and 47 is the saturated vapour pressure of water at 37 °C since gas at the alveolus is fully humidified. The normal  $PAO_2$  to  $PaO_2$  gradient is less than 7 mmHg, but increases to 14 mmHg in the elderly. This normal A–a gradient is due to some venous admixture through the lungs, and a small right-to-left shunt through both the bronchial veins and the thebesian veins of the coronary circulation. This equation removes hypercarbia as a direct cause of hypoxaemia, and an increase in the A–a gradient will usually be due to ( $\dot{V}/\dot{Q}$ ) mismatch or right-to-left shunt. A commonly used alternative measure of hypoxaemia is the  $PaO_2/F_{iO_2}$  ratio. However, this does not account for the effect of a raised  $PaCO_2$ , and both measures are influenced by a number of factors (e.g. cardiac output, haemoglobin (Hb),  $F_{iO_2}$ ) in addition to the extent of venous admixture, which may be estimated from the intrapulmonary shunt equation:

$$\frac{\dot{Q}_s}{\dot{Q}_t} = \frac{C'_{lO_2} - C_{aO_2}}{C'_{lO_2} - C_{vO_2}}$$

where  $\dot{Q}_s$  is the intrapulmonary shunt blood flow,  $\dot{Q}_t$  is the total pulmonary blood flow,  $C'_{lO_2}$  is the end-capillary  $O_2$  content calculated from the  $PAO_2$ , and  $C_{aO_2}$  and  $C_{vO_2}$  are the  $O_2$  contents of arterial and mixed venous blood respectively.

### CARBON DIOXIDE

$PaCO_2$  is determined by alveolar ventilation ( $\dot{V}_A$ ), and  $CO_2$  production ( $\dot{V}_{CO_2}$ ):

$$PaCO_2(\text{mmHg}) = \dot{V}_{CO_2}(\text{ml/min STPD}) \times 0.863 / \dot{V}_A(1/\text{min BTPS})$$

where  $\dot{V}_A$  is the minute ventilation ( $\dot{V}_E$ ) minus the wasted or dead-space ventilation ( $\dot{V}_D$ ). The modified

Bohr equation (assuming  $P_{ACO_2} = P_{aCO_2}$ ) calculates the proportion of the  $V_T$  which is wasted ventilation (i.e. physiological dead space:  $V_{Dphys}$ ):

$$V_{Dphys}/V_T = P_{aCO_2} - P_{\bar{e}CO_2}/P_{aCO_2}$$

where  $P_{\bar{e}CO_2}$  is the mixed expired  $P_{\bar{e}CO_2}$ , and  $V_{Dphys}$  is composed of anatomical dead space ( $V_{Danat}$ ) and alveolar dead space ( $V_{D_{alv}}$ ) – notionally due to alveoli that are ventilated but not perfused. Normally  $V_{D_{alv}}$  is minimal and  $V_{Danat}$  comprises 30% of  $V_T$ . Since the volume of an endotracheal tube is less than the mouth or nose, and pharynx, intubation may reduce  $V_{Danat}$ ; however, when the connection from the endotracheal tube is taken into account there is little change in dead space. Positive-pressure ventilation increases dead space by distension of the airways increasing  $V_{Danat}$ , and through a tendency to increase alveoli that are ventilated but not perfused. In patients with ARDS, marked increases in  $V_{D_{alv}}$  lead to marked increases in the  $V_{Dphys}/V_T$  ratio (exceeding 0.6), which is an independent prognostic factor.<sup>4</sup>

### CAPNOGRAPHY

Capnography measures and displays exhaled  $CO_2$  throughout the respiratory cycle, with sampling usually by a mainstream sensor since sidestream systems tend to become blocked by secretions. However, when capnography is used in non-intubated patients, sidestream sampling is commonly used (e.g. modified nasal cannulae). Infrared spectroscopy measures the fraction of energy absorbed and converts this to a percentage of  $CO_2$  exhaled. During expiration the capnogram initially reads no  $CO_2$ , but as anatomical dead space is exhaled there is a rise in the exhaled  $CO_2$  to a plateau which falls to 0%  $CO_2$  with the onset of inspiration. In patients with significant respiratory disease a plateau may never be achieved. The end-tidal  $CO_2$  ( $P_{etCO_2}$ ) is the value at the end of the plateau, and is normally only slightly less than the  $P_{aCO_2}$ . However, this gradient will increase when alveolar dead space ( $V_{D_{alv}}$ ) increases, such as low cardiac output, pulmonary embolism and elevated alveolar pressure. Consequently the  $P_{etCO_2}$  may not reflect  $P_{aCO_2}$  in critically ill patients. Nevertheless, in a stable patient the gradient will be fairly constant, and can be used to guide  $\dot{V}_E$  during transport,<sup>5</sup> and when other factors including the adequacy of minute ventilation are unchanged, sudden changes in the  $P_{etO_2}$  may provide an early signal. Indeed,  $P_{etCO_2}$  directly correlates with cardiac output, and  $P_{etCO_2}$  monitoring has been used to assess adequacy of cardiopulmonary resuscitation, and its prognosis.<sup>6</sup>

The presence of exhaled  $CO_2$  is secondary confirmation of endotracheal tube placement, and is commonly recommended even when the tube is seen to pass through the vocal cords,<sup>7</sup> since clinical assessment is not always reliable. Simple colorimetric devices may be used for this purpose. However, detection of expired  $CO_2$  is not infallible<sup>7</sup> as false positives can rarely occur following ingestion of carbonated liquids, and false negatives may be

due to extremely low pulmonary blood flow, or very large alveolar dead space such as pulmonary embolus or severe asthma. Monitoring with capnography has also been recommended for transport<sup>8</sup> and respiratory monitoring<sup>9</sup> in critically ill patients, and should be available for every anaesthetised patient.<sup>10</sup>

### GAS TRANSFER (DIFFUSING CAPACITY)

This is a test of the transfer of a gas, typically carbon monoxide (CO), across the alveolocapillary barrier. The transfer factor is calculated as:

$$\text{Volume of CO taken up}/(P_{Aco} - P_{cco})$$

and, since CO is so completely taken up by Hb,  $P_{cco}$  is taken as zero. This test is usually performed as an outpatient, is not usually measured in the intensive care unit (ICU), and diffusion abnormality is rarely a cause of hypoxaemia. The transfer factor is often corrected for lung volume since diseases such as emphysema and pulmonary fibrosis may affect both lung volume and diffusion.

### LUNG VOLUME AND CAPACITIES (FIGURE 34.1)

The tidal volume ( $V_T$ ) is the volume of gas inspired and expired with each breath, with the volume at end-expiration termed the functional residual capacity (FRC). If a forced expiration is performed the expiratory reserve volume (ERV) is expired down to the residual volume (RV). If a maximum inspiratory effort is made from FRC, this is

**Figure 34.1** Lung volumes and capacities. TLC, total lung capacity; IRV, inspiratory reserve volume; TV, tidal volume; ERV, expiratory reserve volume; RV, residual volume; IC, inspiratory capacity; FRC, functional residual capacity; VC, vital capacity.

termed a vital capacity (VC) manoeuvre when the total lung capacity (TLC) is reached. Clinically, the most important of these are the FRC,  $V_T$  and VC, and the latter two are easily measured using a spirometer or integrated from flow.

### TIDAL VOLUME

Minute volume is composed of  $f$  and  $V_T$  – normally  $\sim 17$  breaths/min and  $\sim 400$  ml respectively in adults.<sup>11</sup> Rapid shallow breathing is common in patients with respiratory distress, and in those failing weaning. Although a proposed index, an  $f/V_T$  ratio  $> 100$  was initially shown to be highly predictive of weaning failure;<sup>12</sup> subsequent studies have reported varying results.

### VITAL CAPACITY

At TLC the forces due to the inspiratory muscles are counterbalanced by elastic recoil of the lung and chest wall. Consequently, the TLC is determined by the strength of the inspiratory muscles, the mechanics of the lung and chest wall and the size of the lung, which varies with body size and gender (Table 34.1). Since the VC is the difference between TLC and FRC, factors that reduce FRC, such as increased abdominal chest wall elastance and premature airway closure in chronic obstructive pulmonary disease (COPD), will also reduce it. The normal VC is  $\sim 70$  ml/kg and reduction to 12–15 ml/kg has previously indicated a probable need for mechanical ventilation. However, many other factors need to be considered, including the patient's general condition, the strength of the patient's expiratory muscles, glottic function and the

**Table 34.1** Factors that decrease vital capacity

#### Decreased muscle strength

- Myopathy
- Neuropathy
- Spinal cord injury

#### Increased lung elastance

- Pulmonary oedema
- Atelectasis
- Pulmonary fibrosis
- Loss of lung tissue

#### Increased chest wall elastance

- Pleural effusion
- Haemothorax
- Pneumothorax
- Kyphoscoliosis
- Obesity
- Ascites

#### Reduced functional residual capacity

- Atelectasis
- Premature airway closure (e.g. chronic obstructive pulmonary disease)

use of non-invasive ventilation. Indeed, many chronically weak patients are able to manage at home with extremely low VC with the assistance of non-invasive ventilation.

### FUNCTIONAL RESIDUAL CAPACITY

Direct measurement of FRC is rarely measured in ICU; however, techniques such as nitrogen wash-in and wash-out<sup>13</sup> to estimate FRC are becoming available on modern ventilators. When FRC is less than the closing volume, the lung volume at which airway closure collapse is present during expiration, there is a marked increase in  $\dot{V}/\dot{Q}$  mismatch. Consequently, positive end-expiratory pressure (PEEP) is commonly used to elevate FRC. Increases in lung volume above resting lung volume can be directly measured from a prolonged expiration to atmospheric pressure using either a spirometer or integration of flow,<sup>14</sup> or by repeated FRC measurements. FRC is decreased in ARDS and pulmonary oedema, in patients with abdominal distension and following abdominal and thoracic surgery. An increase in FRC places the diaphragm at a mechanical disadvantage, and is seen with severe airflow limitation and dynamic overinflation, and when there is loss of elastic recoil (e.g. emphysema).

### MEASUREMENT OF LUNG MECHANICS

The forces the respiratory muscles must overcome during breathing are the elastic recoil of the lung and chest wall, and airway and tissue resistance. During controlled mechanical ventilation the ventilatory pressures reflect the work done to overcome these forces; however during partial ventilatory support the pressure at the airway opening reflects both these forces and those generated by the respiratory muscles. Estimates of respiratory mechanics are often readily available, and can assist titration of ventilatory support.

### ELASTIC PROPERTIES OF LUNG AND CHEST WALL

The respiratory system (RS) is composed of the lung (L) and chest wall (CW), which is comprised of the ribcage and abdomen. Although it is often convenient to consider respiratory system mechanics as implying information about the lung, abnormal chest wall compliance can markedly influence these measurements.<sup>15–18</sup>

The pressure gradient across the lung ( $P_L$ ) that generates gas flow is equal to the difference between the pressure at the airway opening ( $P_{ao}$ ) and the mean pleural pressure ( $P_{pl}$ ) which is estimated as the oesophageal pressure ( $P_{es}$ ):

$$P_L = P_{ao} - P_{es}$$

Although the  $P_{es}$  is not always an accurate measure of the absolute  $P_{pl}$ , the change in  $P_{es}$  reflects the change in  $P_{pl}$ . However, this requires an appropriately positioned and functioning oesophageal balloon. In spontaneously

breathing subjects a thin latex balloon sealed over a catheter is introduced into the lower third of the esophagus and  $P_{es}$  and  $P_{ao}$  are measured simultaneously during an end-expiratory airway occlusion. A well-positioned oesophageal balloon will have a ratio of  $\Delta P_{es}/\Delta P_{ao}$  of  $\sim 1$ .<sup>19</sup> This technique is reliable in supine, intubated spontaneously breathing patients,<sup>20</sup> and in paralysed subjects it appears that a similar pressure change, induced by manual rib-cage pressure,<sup>21</sup> can be used to verify oesophageal balloon function.

Chest wall mechanics are derived from  $P_{es}$  referenced to atmospheric pressure, and in ventilated relaxed subjects respiratory system mechanics are derived from  $P_{ao}$  referenced to atmospheric pressure. It is not surprising then that  $P_{RS} = P_L + P_{CW}$ . Finally, abdominal mechanics can be estimated as either intravesical or intragastric pressure. However, despite these provisos, useful information can be obtained from respiratory system mechanics.

Measuring the slope of the  $V$ - $P$  relationship of the lung or respiratory system allows a simple estimate of the elastic properties of the lung. This is termed the *elastance*, which is the inverse of the compliance. The  $E_{RS}$  is directly related to its components ( $E_{RS} = E_L + E_{CW}$ ), and  $1/C_{RS} = 1/C_L + 1/C_{CW}$ . The normal  $E_{RS}$  is 10–15 cmH<sub>2</sub>O/l and the normal  $C_{RS}$  is 60–100 ml/cmH<sub>2</sub>O in ventilated patients. Since elastance directly refers to the elastic properties of the lung and respiratory system, mechanics will be described in terms of elastance rather than compliance.

### MEASUREMENT OF ELASTANCE

Elastance and resistance are frequency-dependent, and respiratory mechanics depend upon the volume and volume history of the lung.<sup>22</sup> With increasing frequency of breathing, total respiratory system resistance falls and elastance increases, and this is particularly obvious in patients with airflow obstruction.<sup>23,24</sup> Consequently these factors must be taken into account when interpreting respiratory mechanics. In a passively ventilated subject  $P_{ao}$  is the sum of: (1) the pressure required to overcome airway, endotracheal tube and circuit resistance ( $P_{res}$ ); (2) the elastic pressure required to expand the lung and chest wall ( $P_{el}$ ); (3) the elastic recoil pressure at end-expiration or total PEEP ( $P_o$ ); and (4) the inertial pressure required to generate gas flow ( $P_{inert}$ ):

$$P_{ao} = P_{el} + P_{res} + P_o + P_{inert}$$

Since the elastance ( $E$ ) is equal to  $\Delta P/\Delta V$ , with the resistance ( $R$ ) equal to  $\Delta P/\Delta \dot{V}$ , and ignoring the inertance,<sup>25</sup> this can be rewritten as the single-compartment equation of motion:

$$P_{ao} = E_{RS} V + R_{RS} \dot{V} + P_o$$

Elastance can then be measured using either static techniques, where cessation of gas flow allows dissipation of  $P_{res}$ , or using dynamic techniques where flow is not interrupted.

### END-INSPIRATORY OCCLUSION METHOD

The simplest estimate of  $E_{RS}$  can be made using a rapid end-inspiratory airway occlusion during a constant-flow breath, provided that the respiratory muscles are relaxed (Figure 34.2). If a plateau is introduced at end-inspiration there is a sudden initial pressure drop due to dissipation of flow resistance ( $P_{pk} - P_1$ ) followed by a slower, secondary pressure drop to a plateau ( $P_{dif} = P_1 - P_2$ ) due to stress relaxation. At least 1–2 seconds are taken for this plateau to be achieved, and  $P_2$  is often called the plateau pressure; however, if  $P_{plat}$  is measured too soon it will lie somewhere between  $P_1$  and  $P_2$ .

### Stress adaptation

Stress relaxation of the respiratory system is due to both tissue viscoelasticity and time-constant inequalities of the respiratory system (pendelluft). In the normal lung pendelluft has a minimal contribution to stress relaxation;<sup>26</sup> however, heterogeneity of regional resistance and elastance can markedly influence stress relaxation.<sup>27</sup> Pulmonary surfactant and its contribution to changes in surface tension, parenchymal factors including elastic fibres in the lung, contractile elements such as the alveolar duct muscle and changes in pulmonary blood volume have all been implicated in the viscoelastic properties of the lung. However, it is not possible to separate either of these factors or the role of pendelluft in stress adaptation.

**Figure 34.2** Schematic diagram of a volume-controlled breath with constant inspiratory flow. A period of no inspiratory gas flow has been interposed before expiration (pause) to illustrate dissipation of lung resistance as airways resistance (fall from  $P_{pk}$  to  $P_1$ ) and tissue resistance (fall from  $P_1$  to  $P_2$ ). The inspiratory pressure due to the elastic properties of the respiratory system is illustrated as the filled area,  $P_{el}$ , and the lung resistive pressure is labeled as  $P_{res}$ . See text for more detail.

### Calculation of respiratory mechanics

Returning to Figure 34.2, it is now simple to estimate respiratory system resistance and elastance from  $P_{ao}$ . The static elastance ( $E_{rs,st}$ ) and the dynamic elastance ( $E_{rs,dyn}$ ) are calculated as:

$$E_{rs,st} = (P_2 - P_o) / V_T$$

$$E_{rs,dyn} = (P_1 - P_o) / V_T$$

where  $P_o$  is the total PEEP (extrinsic plus intrinsic PEEP). The difference between  $P_{el,dyn}$  and  $P_{el,st}$  is the effective recoil pressure of the respiratory system during mechanical ventilation. Consequently, additional work is performed during inspiration to overcome stress adaptation, and this is stored and dissipated during expiration. This contributes to the hysteresis seen in dynamic volume–pressure curves during mechanical ventilation, and to the generation of expiratory flow. This latter component may be important in patients with airflow obstruction since the imposition of a pause at end-inspiration results in a 32% dissipation of the total energy loss within the respiratory system.<sup>28</sup>

### THE STATIC VOLUME–PRESSURE CURVE

The quasistatic volume–pressure ( $V$ – $P$ ) curve has become the de facto ‘gold standard’ for the measurement of respiratory elastance. However, it is infrequently performed, and the relevance of a measurement performed on a single occasion is questionable when lung mechanics are not constant. Various techniques have been described, but the overall concept is that incremental volume and pressure points are made after a sufficient period of no flow has allowed  $P_{res}$  to be dissipated. This allows definition of a sigmoidal-shaped curve with upper and lower inflection points, and a mid-section with relatively linear  $V$ – $P$  relations, allowing inflation elastance to be measured as this slope at a given lung volume. If similar measures are made during deflation a deflation curve and its hysteresis can also be described.

The  $V$ – $P$  curve provides an advantage over an end-inspiratory elastance since, with the latter, it is not possible to know which part of the  $V$ – $P$  curve is being measured. Consequently this ‘chord’ elastance may span either inflection point, yielding a falsely high figure. The upper inflection point represents a sudden decrease in elastance with increasing volume, and this has been interpreted as lung overinflation. The lower inflection point represents a sudden decrease in elastance with increased volume, and this has been interpreted as recruitment of atelectatic air spaces. Ventilation between these two inflection points should minimise both shearing forces secondary to repetitive collapse and reopening of alveoli, and overstretch of alveoli. However, this interpretation of the  $V$ – $P$  curve has been questioned. In patients with acute lung injury recruitment occurs well above the lower inflection point, along the entire  $V$ – $P$  curve and above the upper inflection point.<sup>29,30</sup> An alternative interpretation of these inflection points is that the lower inflection point represents a zone of rapid

recruitment, and that the upper inflection point is due to a reduced rate of recruitment.<sup>31</sup>

Conventionally the static  $V$ – $P$  curve has been measured in ventilated patients with the ‘supersyringe’ method.<sup>32</sup> In a paralysed patient the respiratory system is progressively inflated from FRC in 100-ml steps up to ~1700 ml or a predefined pressure limit. After each step sufficient time is allowed for a well-defined plateau to become apparent (using a pause of 3–6 seconds). The effects of temperature, humidity, gas compression and ongoing gas exchange during the manoeuvre need to be taken into account,<sup>33,34</sup> and the volume history standardised before it is performed. Since this technique is cumbersome and many patients become hypoxaemic following disconnection from the ventilator and the 60 seconds or so without PEEP, other techniques have been developed. The static  $V$ – $P$  curve can also be measured by randomly inserting a range of single-volume inflations, followed by a prolonged pause,<sup>35</sup> during normal mechanical ventilation. This is performed in the paralysed state at 0 cmH<sub>2</sub>O PEEP. This technique has a number of advantages, including its simplicity, the patient is not disconnected from the ventilator, the volume history is the same for each measurement and gas exchange during the measurement is negligible. However, again, many patients will become hypoxaemic due to prolonged periods without PEEP (this procedure may take ~15 minutes), particularly following a small-volume breath. Finally, an automated low-flow  $V$ – $P$  curve method allowing subtraction of  $P_{res}$  has been described, and is now available on some modern ventilators; this takes around 20 seconds to perform, and seems to correlate well with the static occlusion technique.<sup>36,37</sup>

### THE DYNAMIC V–P CURVE

Dynamic  $P_{ao}$ ,  $\dot{V}$  and  $V$  are displayed by many ventilators, but the volume signal is not referenced to FRC and the signals are not readily available for quantitative analysis. However,  $\dot{V}$  is readily measured with a heated pneumotachograph, and volume can then be derived by simple integration if the signal is collected after analogue-to-digital conversion. If  $P_{ao}$  is also collected it is relatively simple to measure dynamic mechanics.

The dynamic  $V$ – $P$  curve always shows hysteresis, mainly due to the effects of airway and tissue resistance; it is unlikely that hysteresis of the static  $V$ – $P$  occurs during tidal breathing.<sup>38</sup> In contrast to static  $V$ – $P$  relations, dynamic mechanics are collected during normal ventilation so they do not interfere with patient care, and they provide a ‘functional’ description of respiratory mechanics. Indeed the ‘effective’ alveolar distending pressure is more accurately  $P_{el,dyn}$ , not  $P_{el,st}$ . Since dynamic mechanics are potentially continuous they could also be used to servo-control ventilatory strategies.

There a number of ways to analyse dynamic  $V$ – $P$  data. A line can be drawn between no-flow points at end-inspiration and end-expiration to determine elastance; however, this is relatively inaccurate as it is based on

two points that can be hard to identify exactly. Multiple linear regression analysis is now the technique most commonly employed. The patient does not need to be paralysed<sup>39</sup> provided the respiratory muscles are not active during ventilation, and the signal can be split to allow analysis of inspiratory and expiratory mechanics.

Provided the model fit is acceptable, elastance and resistance are accurately and reproducibly calculated using the single-compartment equation of motion:

$$P_{ao} = E_{RS}V + R_{RS}\Delta\dot{V} + P_o$$

Static PEEPi is accurately calculated, as  $P_o - PEEPe$ , when compared to either an end-expiratory airway occlusion method,<sup>40</sup> or by direct measurement of end-expiratory alveolar pressure.<sup>41</sup> However, the single-compartment model only approximates the respiratory system, and frequency and volume dependence of the derived mechanics are observed. Provided these factors are recognised and accounted for, it is sound to compare data within and between patients.

A number of techniques have been used to analyse further dynamic  $V$ - $P$  data. The most promising of these are the stress index derived from power analysis of the  $P_{ao}$ - $t$  curve ( $P_{ao} = a^t + c$ ),<sup>42</sup> and addition of a volume-dependent term to the equation of motion:<sup>13,43</sup>

$$P_{ao} = (E_1 + E_2)V + R_{RS}\Delta\dot{V} + P_o$$

$$E_{rs} = E_1 + E_2V$$

Since power analysis requires a constant inspiratory  $\dot{V}$  pattern to discount resistive effects, it is not as versatile as the volume-dependent technique; however, both measures correlate highly with each other, suggesting they measure the same parameter. The volume-dependent technique allows conceptual placement of tidal breathing on a dynamic  $V$ - $P$  curve. If the  $\%E_2$  is calculated as:

$$\%E_2 = 100E_2V/E_{rs}$$

then a  $\%E_2 > 30\%$  quantitates high stress, often interpreted as overinflation, and a negative volume dependence (negative  $\%E_2$ ) suggests significant atelectasis during tidal breathing. During constant  $\dot{V}$  ventilation, and provided  $V_T$  is also constant, the change in either  $P_{pk} - PEEP_{tot}$  or  $P_1 - PEEP_{tot}$  (the delta pressure:  $\Delta P$ ) 20–30 minutes following a change in PEEP is highly correlated with  $\%E_2$ .<sup>13</sup> Using the 95% predictive interval for these data, an increase in  $\Delta P > 2$  cmH<sub>2</sub>O indicates overinflation, a  $\%E_2 > 30\%$ .

Similarly, a stress index of 0.9–1.1 suggests linear elastic mechanics during inflation; if the stress index is low then this suggests tidal recruitment, and a high stress index suggests overinflation. However, neither the stress index nor volume-dependent elastance has been validated in the clinical setting. High stress may not reflect regional lung hyperaeration; in COPD bullous lung disease is due to a loss of lung tissue and elastic recoil measured on CT

as hyperaeration. However the associated wall stress may be high or low, depending upon the degree of inflation.

### INTERPRETATION OF ELASTANCE

Elastance may be increased due to a reduction in lung volume or to an increase in specific elastance, the product of  $E$  and FRC. Small body size, female gender, lung resection and reduced aerated lung volume are important factors reducing effective lung volume, with this final factor one important reason for the elevated elastance seen in ARDS. Specific elastance is increased pulmonary oedema, pulmonary fibrosis, and reduced or dysfunctional surfactant.

### MEASUREMENT OF THE RESISTANCE OF THE LUNG AND CHEST WALL

Lung resistance ( $R_L$ ) is the sum of airway ( $R_{aw}$ ) and tissue resistance ( $R_{ti}$ ). Resistance is flow-, volume- and frequency-dependent, and  $R_L$  decreases as  $f$  increases. It is also important to compare measurements at similar lung volumes since there is a hyperbolic relation between lung volume and  $R$ . This is particularly obvious in ARDS, where the incremental administration of PEEP can result in a decrease in  $R_{aw}$  due to concurrent recruitment and an increase in lung volume. Indeed, although the absolute values are increased, when corrected for end-expiratory lung volume  $R_L$ ,  $R_{aw} + R_{ti}$  are unchanged in ARDS.<sup>14</sup> Finally, since gas flow may be a mixture of laminar and turbulent flow, resistance is often flow-dependent.

### END-INSPIRATORY OCCLUSION TECHNIQUE

The total inspiratory airways resistance, including the endotracheal tube and associated ventilatory apparatus, can be calculated in a relaxed patient following an inspiratory pause (Figure 34.2) as:

$$R_{aw} = (P_{pk} - P_1)/\dot{V}$$

and  $R_L$  calculated by using  $P_2$  instead of  $P_1$ . Since the endotracheal tube and apparatus will make a significant contribution to  $R_{aw}$  it is best to measure  $P_{ao}$  distal to the endotracheal tube with an intratracheal catheter. An alternative approach is to calculate and subtract endotracheal tube resistance using the Rohrer equation ( $R = K_1 + K_2$ ),<sup>44</sup> and this is now automatically included in some ventilators. However, as in vivo endotracheal tube resistance is often greater than in vitro resistance<sup>45</sup> due to the effect of secretions and interaction with the tracheal wall, these corrections may be inaccurate. Despite these provisos, this simple measure of resistance, or the  $P_{pk}$  to  $P_{plat}$  difference at a constant  $\dot{V}$ , can be clinically useful in both the diagnosis and monitoring of airflow obstruction.<sup>46</sup>

### DYNAMIC TECHNIQUES

Total, inspiratory and expiratory  $R$  can also be made, using either multiple linear regression analysis or from linear interpolation of the  $V$ - $P$  curve at a constant volume.

However, this latter technique assumes a constant elastance during tidal inflation, and may be inaccurate because it relies on only two measurements. Finally, an average expiratory  $R$  can be calculated from the time constant ( $\tau$ ) derived from passive expiration if the  $E$  is known, since:

$$\tau = R/E$$

However, the lung does not empty as a single compartment in patients with airflow obstruction, and  $E$  is assumed to be constant over the tidal expiration.

#### OTHER MEASUREMENT TECHNIQUES

The interrupter technique consists of a series of short (100–200 ms) interruptions to relaxed expiration by a pneumatic valve.<sup>47</sup> This results in an expiratory plateau in  $P_{ao}$  following equilibration with alveolar pressure. From the  $V$ ,  $P$  and  $\dot{V}$  data expiratory elastance and the expiratory  $P$ – $\dot{V}$  relationship are measured. This technique does not make assumptions about the behaviour of the respiratory system and can identify dynamic airflow limitation.

Assuming that the respiratory system behaves linearly, it can be analysed following a forced-flow oscillation at the airway opening.<sup>48</sup> The resultant pressure waveform depends upon the impedance of the respiratory system, which can be analysed following Fourier analysis of the  $P$  and  $\dot{V}$  waveforms into resistance and reactance. This will then allow measurement of  $R_{aw}$ ,  $R_{ti}$ ,  $E_{rs}$  and inertance, and information can be gained regarding small-airways disease by examining  $R_{aw}$  at different oscillatory frequencies.

#### FORCED EXPIRATORY FLOW

Maximum expiratory flow rates from TLC, the forced vital capacity (FVC), the forced expiratory volume in the first second of expiration ( $FEV_1$ ) and the peak expiratory flow rate (PEFR) are commonly measured in cooperative subjects with a spirometer or flow meter. The PEFR is cheap but is relatively effort-dependent, and is less specific and reliable than the  $FEV_1$ . It is most useful for office or home use. The normal PEFR is 450–700 l/min in males and 300–500 l/min in females. It is reduced with obstructive diseases and gross muscle weakness.

The  $FEV_1$  is usually expressed as a ratio of the FVC since both may be reduced in restrictive disease, with a normal ratio. The  $FEV_1$  is normally 50–60 ml/kg and 70–83% of FVC. In asthma and COPD the  $FEV_1$  is reduced out of proportion to the FVC and the ratio is less than 70%.

#### MEASUREMENT OF INTRINSIC PEEP

This is an important measurement in critically ill patients. PEEPi: (1) may have unrecognised haemodynamic consequences;<sup>49</sup> (2) adds an elastic load to inspiratory work during partial ventilatory modes, which may be reduced by application of small amounts of PEEPe;<sup>50</sup> and (3) reflects dynamic hyperinflation with the consequent risks

of barotrauma<sup>51</sup> and right heart failure. If PEEPi is not taken into account during calculation of chord compliance, an incorrect denominator is used, which may markedly alter the result.<sup>52</sup>

The two most commonly described techniques for measuring PEEPi are end-expiratory airway occlusion in a relaxed subject, and the fall in oesophageal pressure during inspiration prior to initiation of inspiratory  $\dot{V}$ . However, these are not really comparable measures since static and dynamic PEEPi respectively are measured. Static PEEPi is measured as the plateau  $P_{ao}$  that is reached after ~5 seconds following an end-expiratory occlusion. With the cessation of gas flow alveolar pressure equilibrates with  $P_{ao}$ . Since the lung is composed of non-homogeneous units, this will represent the average static PEEPi. All respiratory effort must be absent since they may independently influence end-expiratory  $P_{ao}$ , and end-expiration must be accurately identified. This is most easily done by the ventilator itself either using an end-expiratory hold manoeuvre or by using the next inspiration, the onset of which is concurrent with expiratory valve closure, to close a valve that directs inspiratory flow to atmosphere and seals the circuit. Static PEEPi is a surrogate measure of dynamic hyperinflation, and this volume may be directly measured using a spirometer<sup>49</sup> or a pneumotachograph<sup>13</sup> during a prolonged expiration.

Dynamic PEEPi is measured as the pressure change required to initiate inflation. In ventilated subjects this will be the change in  $P_{ao}$  prior to initiation of inspiratory  $\dot{V}$ ,<sup>50</sup> and in spontaneously breathing subjects the change in oesophageal<sup>48</sup> or transdiaphragmatic<sup>53</sup> pressure from their expiratory relaxation values prior to inspiratory  $\dot{V}$ . Measurement of dynamic PEEPi in spontaneously breathing subjects is not particularly straightforward. The changes in pressure are small and influenced by cardiogenic oscillations which are preferably filtered out.<sup>54</sup> Further dynamic PEEPi is not constant, with breath-to-breath variation probably due to variation in the extent of dynamic hyperinflation, and many patients with airflow obstruction have an active expiration. This ‘falsely’ increases PEEPi, at least with respect to its elastic load, since cessation of active expiration does not require work, with part of the measured elastic load suddenly dissipated.<sup>55</sup> Consequently, it is preferable to measure intragastric pressure concurrently as a measure of active expiration.

Finally, PEEPi can be measured as  $P_o$  from dynamic  $P$ ,  $V$  and  $\dot{V}$  data in ventilated subjects. This is thought to be a measure of dynamic PEEPi since static PEEPi systematically yields a slightly greater result,<sup>40</sup> with similar discrepancies reported between other dynamic measures of PEEPi and static PEEPi.<sup>56,57</sup> This systematic difference correlates with, and is thought to be due to, the viscoelastic properties and regional time-constant inequalities of the respiratory system.<sup>56</sup> This has clinical significance since, although matching dynamic PEEPi with PEEPe reduces respiratory work through a decrease in elastic load,<sup>50</sup> it does not counterbalance these forces, which represent an additional elastic load to inspiration.

### PATIENT–VENTILATOR DYSSYNCHRONY

Dyssynchrony between the patient and ventilator is common during both intubated and non-invasive ventilatory support. Clinical findings include agitation and anxiety, tachycardia, tachypnoea and increased work of breathing. Failure to trigger the ventilator can be documented by comparing the frequency of ventilator breaths and inspiratory efforts. Bedside analysis of ventilator respiratory waveforms can be used to identify and help match ventilatory assistance to neural drive.<sup>58</sup>

### INSPIRATION

#### TRIGGERING OF INSPIRATION

Ineffective respiratory efforts are best detected from the  $P_{es}$  waveform; however, this is rarely monitored. Ineffective triggering due to PEEPi may be detected from the expiratory  $\dot{V}$  waveforms as abrupt decrease in  $\dot{V}$  at either the onset of inspiratory muscle activity or relaxation of the expiratory muscles. Monitoring of  $P_{ao}$  is less sensitive unless the circuit expiratory resistance is increased (e.g. heat and moisture exchanger or poorly functioning expiratory valve) so that small changes in expiratory  $\dot{V}$  are reflected in  $P_{ao}$ . Inadequate sensitivity may also lead to ineffective triggering with similar but more obvious waveform effects.

Autotriggering, a triggered assisted or supported breath without patient effort, may occur due to excessively low trigger threshold or due to  $P_{ao}$  or  $\dot{V}$  distortion, as commonly seen with large cardiogenic oscillations, hiccups, condensate in tubing or a circuit leak. Again, waveform analysis may help detect and manage the problem; for example, it may be necessary to reduce trigger sensitivity to prevent cardiogenic oscillations from being detected as inspiratory effort.

#### INSPIRATION

During an assisted-volume control breath,  $P_{ao}$  may fall, often seen as a scalloped shape, if there is excessive inspiratory muscle effort as seen in  $\dot{V}$  starvation. Expiratory muscle effort, as may be seen with an excessive  $V_T$  or prolonged inspiratory time ( $T_i$ ), leads to a rise in  $P_{ao}$ . During an assisted-pressure control breath or during pressure support, changes in patient effort are detected from the  $\dot{V}$  waveform. Finally, excessively rapid development of the set delivered pressure, a rapid rise time, may be detected by an overshoot in  $P_{ao}$ ; an excessively long rise time will be seen as a rounded inspiratory  $\dot{V}$  profile, similar to that seen with continued inspiratory muscle effort.

#### CESSATION OF INSPIRATION

Mismatch of the mechanical and neural  $T_i$  can be detected from waveform changes at the cessation of inspiration.

#### Mechanical $T_i$ shorter than neural $T_i$

There will be prolonged inspiratory muscle effort during early expiration; if this leads to a sufficient fall in  $P_{ao}$  or  $\dot{V}$ , an early triggered breath follows. During pressure-cycled

ventilation this will lead to a second small  $V_T$  breath due to the high baseline lung volume, but in assist-volume control  $P_{ao}$  will be excessive. Typically this is seen with a stiff respiratory system, PEEPi or inadequate pressure support.

#### Mechanical $T_i$ longer than neural $T_i$

This leads to features of passive inflation such as a linear increase in  $P_{ao}$  during assist-volume control ventilation; during pressure-cycled ventilation there may be an increase in  $P_{ao}$  due to loss of inspiratory effort, or an unexplained fall in  $\dot{V}$ .

### EXPIRATION

Changes in  $P_{ao}$  during expiration are usually small unless expiratory circuit resistance is abnormally high. However, in patients with expiratory flow limitation the expiratory  $\dot{V}$  waveform shows a typical ‘tick’ pattern; there is a rapid spike in expiratory flow due to dynamic compression of large conducting airways at the beginning of expiration, and this is followed by low, slowly declining expiratory  $\dot{V}$  due to high  $\dot{V}$  expiratory resistance. When PEEPi is present the expiratory  $\dot{V}$  fails to cease prior to the inspiratory trigger; however, this may be difficult to detect due to the poor fidelity present on most commercial ventilators.

### MONITORING NEUROMUSCULAR FUNCTION

#### INSPIRATORY OCCLUSION PRESSURE

The pressure 100 ms ( $P_{100}$  or  $P_{0.1}$ ) after a random occlusion timed at the beginning of inspiration is a measure of respiratory drive. There is a large range of normal values (1.5–5 cmH<sub>2</sub>O), but it is reproducible in an individual patient. In ventilated patients the  $P_{0.1}$  correlates with the work of breathing during pressure support ventilation, and changes in the same direction as PEEPe is increased if work is reduced.<sup>59</sup> Consequently,  $P_{0.1}$  may prove to be a useful method of titrating PEEPe in patients with dynamic hyperinflation; however, this is not valid when flow triggering is used.

#### MAXIMUM MOUTH PRESSURES

Maximum inspiratory (MIP) and expiratory (MEP) mouth pressures can be used to estimate the power of the respiratory muscles. MIP is usually measured in ventilated patients using a unidirectional expiratory valve for ~20 seconds.<sup>60</sup> This ensures the procedure is performed from a low lung volume and does not require patient cooperation. However, despite this, the results are quite variable.<sup>61</sup> Normal values vary with age and gender; young females may exceed ~90 cmH<sub>2</sub>O, and young males ~130 cmH<sub>2</sub>O. A MIP <–20 cmH<sub>2</sub>O is predictive of weaning failure; however, this is associated with too many false positives and negatives to be useful.<sup>11</sup> MEP may be useful in myopathic patients with expiratory

muscle weakness. Transdiaphragmatic pressure is assessed using an oesophageal and gastric balloon to measure the pressure in these two cavities.

### WORK OF BREATHING

The work of breathing ( $W_B$ ) is the sum of elastic work ( $W_{el}$ ), flow-resistive work ( $W_{res}$ ) and inertial work (negligible), and can be estimated from  $V$ - $P$  data during spontaneous or assisted ventilation. An oesophageal balloon is used to examine changes in pleural pressure,  $\dot{V}$  is measured with a pneumotachograph and volume is derived as its integral. Although conceptually  $W_B$  is the inspiratory area of a  $V$ - $P$  loop, this needs to be referenced to the chest wall  $V$ - $P$  curve, and the appropriate area measured from a Campbell diagram.<sup>62</sup>

The normal  $W_B$  is  $\sim 0.5$  J/l of  $\dot{V}_E$ , and this may be significantly increased in patients with acute respiratory failure, and by additional work imposed by ventilatory apparatus, including the endotracheal tube and connector, humidifier and ventilator circuit.<sup>63</sup> The consequences of a large increase in  $W_B$  may include an increase in the  $O_2$  attributable to breathing ( $O_{2\text{ resp}}$ ), respiratory muscle insufficiency,  $CO_2$  retention and acute respiratory failure. However,  $W_B$  is rarely measured outside research projects since the Campbell diagram is a relatively tedious approach. Simplifications have been used, but these are not as accurate, and  $W_B$  only estimates energy expenditure during muscle shortening, with relatively poor correlation with  $O_{2\text{ resp}}$ .<sup>64</sup> Consequently, the pressure-time product (PTP), which does correlate with  $O_{2\text{ resp}}$ ,<sup>65</sup> is more commonly measured.<sup>10</sup>

### PRESSURE-TIME PRODUCT

PTP is usually calculated from the oesophageal pressure-time integral during inspiration. In mechanically ventilated patients the oesophageal pressure during assisted breathing is compared with that during a controlled breath, or that pressure calculated from the chest wall elastance and lung volume.<sup>10</sup> However, the early correlation of  $O_{2\text{ resp}}$  with PTP used the transdiaphragmatic pressure in spontaneously breathing subjects.<sup>62</sup> Using either technique, importantly, the effort expended before  $\dot{V}$  occurs due to PEEP<sub>i</sub> is measured, probably accounting for the better correlation of  $O_{2\text{ resp}}$  with PTP than  $W_B$ .<sup>62</sup> Although incremental pressure support ventilation may reduce PTP in COPD patients, the effect can be variable, with some patients also showing evidence of expiratory muscle activity due to delayed sensing of neural expiration.<sup>10</sup>

# Imaging the chest

Simon P G Padley

## RADIOLOGICAL TECHNIQUES

Of the imaging techniques available for investigating patients in the intensive care unit (ICU), the chest radiograph remains the most important, with ultrasound being utilised in a selected group of patients. High-resolution and spiral computed tomography (CT) allow further investigation of these patients in certain situations.

## CONVENTIONAL CHEST RADIOGRAPHY

The views of the chest most frequently performed in the ambulant patient are the erect posteroanterior (PA) and lateral projections, taken with the patient breath-holding at total lung capacity. While portable or mobile chest radiography, as undertaken on an ICU, has the obvious advantage that the examination can be done without moving the patient from the ward, there are many disadvantages. These include:

- shorter focus–film distance causing magnification
- limited X-ray output necessitating long exposure times with resultant movement blurring
- difficulties with satisfactory patient positioning

## DIGITAL CHEST RADIOLOGY

In the ICU, digital chest radiographs may be obtained utilising conventional X-ray generators, but the image is captured on a reusable photostimulable plate instead of conventional film. The digital information is then manipulated, displayed and stored in whatever format is desired. Traditional systems suffer greatly from the large day-to-day variations in the density of the radiograph due to small differences in exposure. Digital radiographic systems are able to capture and display a standard density image from a much wider range of exposures (Figure 35.1).

## COMPUTED TOMOGRAPHY

CT relies on differing absorption of X-rays by tissues with constituents of differing atomic number, so slight differences in X-ray absorption can be interpreted to produce a cross-sectional image. The components of a CT scanner are an X-ray tube, which rotates around the patient, and an array of X-ray detectors opposite the tube. The speed with which

a CT scanner acquires an image depends upon the time it takes to rotate the anode around the patient. Modern CT machines have tube rotation times of as little as 0.33 seconds.

Spiral (also known as volume or helical) scanning entails sustained patient exposure by the rotating X-ray tube during continuous movement of the examination couch through the CT gantry aperture. In this way a continuous data set or ‘spiral’ of information may be acquired in a single breath-hold. The information is reconstructed into axial sections, perpendicular to the long axis of the patient, identical to conventional CT sections. Three-dimensional reconstructions of complex anatomical areas can also be produced.

When short rotation times are coupled with the ability to acquire multiple spirals simultaneously (currently up to 64 slices), the speed of these systems is now so great that breath-holding or suspended ventilation is no longer necessary for high-quality imaging. Furthermore, the detector thickness that determines the minimum slice width of the reconstructed images is now commonly less than 1 mm. Thus a 64-channel scanner can acquire almost 200 submillimetre images per second.

## INTRAVENOUS CONTRAST ENHANCEMENT

Because of the high contrast on CT between vessels and surrounding air in the lung, and vessels and surrounding fat within the mediastinum, intravenous contrast enhancement only needs to be given in specific instances, for example to aid the distinction between hilar vessels and a soft-tissue mass. The exact timing of the injection of contrast media depends most on the time the CT scanner takes to scan the thorax. Rapid scanning protocols with automated injectors tend to improve contrast enhancement of vascular structures at the expense of enhancement of solid lesions because of the rapidity of scanning. With spiral CT, it is possible to achieve good opacification of all the thoracic vascular structures with small volumes of contrast media. Optimal contrast enhancement of the pulmonary arteries occurs 10–15 seconds after the start of contrast injection, usually at 3–5 ml/s by a power injector. Timing of image acquisition is vital for accurate diagnosis of pulmonary embolism. However, when examining inflammatory lesions, such as the reaction around an empyema, it may be necessary to delay scanning by 30–40 seconds to allow contrast to diffuse into the extravascular space.

**Figure 35.1** Digital radiograph. The image has been edge-enhanced, which makes the multiple chest drains, Swan–Ganz catheter and endotracheal tube position more conspicuous. Note that two of the chest drain side holes lie within the soft tissues of the chest wall (arrows).

#### HIGH-RESOLUTION COMPUTED TOMOGRAPHY (HRCT)

Narrow collimation images of the lung correlate closely with the macroscopic appearances of pathological specimens. In diffuse lung disease, HRCT allows a substantial improvement in diagnostic accuracy compared with chest radiography. Narrow section images can be acquired either as part of a volumetric acquisition or as interspaced images, usually 1.5 mm thickness, obtained every 1 cm. The radiation burden to the patient of this interspace or sequential technique is considerably less than with volumetric scanning – typically by a factor of 10 times.

#### CLINICAL APPLICATIONS OF HRCT IN THE ICU PATIENT

HRCT is increasingly being used to confirm the impression of an abnormality seen on a chest radiograph. HRCT may also be used to achieve a histospecific diagnosis in some patients with obvious but non-specific radiographic abnormalities. Furthermore, HRCT has provided a number of useful insights into chest disease in the severely ill patient in an ICU setting.

#### HRCT in uncomplicated acute respiratory distress syndrome (ARDS):<sup>1</sup>

- reveals that the apparently homogeneous opacification apparent on the chest radiograph has an anterior-to-posterior graded increase in density – an appearance referred to as a gravitational gradient (Figure 35.2)
- demonstrates early dilatation of the smaller airways within areas of ground-glass density, an appearance that suggests development of fibrosis, and may prompt anti-inflammatory treatment
- demonstrates that a shift from the supine to the prone position results in redistribution of the previously

**Figure 35.2** Computed tomography of a patient with acute respiratory distress syndrome. Note the marked anterior-to-posterior density gradient. The anterior lung is of almost normal density, becoming of ground-glass attenuation in the mid-part of the lung before fading into consolidation posteriorly. There are also moderate-sized bilateral pleural effusions.

dependent dense parenchymal opacification to the now dependent anterior lung, a phenomenon that may be accompanied by improvements in patient oxygenation

#### HRCT of complications of ARDS<sup>2,3</sup>

- Infection is common in ARDS. Diagnosis may be difficult. Radiographically there may be a lack of specific findings, often due to superimposition of changes attributable to ARDS. This is a particular problem in the critically ill patient when the usual indicators of pneumonia are also unreliable. Although the diagnosis may still be in question following HRCT, associated pneumonic changes such as abscess formation, emphysema and mediastinal disease, as well as development of non-dependent areas of consolidation, are all useful pointers to superadded infection (see Figure 35.2).
- Barotrauma – mediastinal and interstitial emphysema, as well as pneumothorax, are all increasingly common at higher levels of peak end-expiratory pressure (PEEP). The incidence of barotrauma has been reported to be as high as 50%.
- HRCT delineates early change and allows exact location of loculated air collections to be defined.

#### NORMAL RADIOGRAPHIC ANATOMY

##### THE MEDIASTINUM, CENTRAL AIRWAYS AND HILAR STRUCTURES

Appreciation of abnormality requires a sound grasp of normal radiological anatomy. The mediastinum is delimited by the lungs on either side, the thoracic inlet above,

the diaphragm below and the vertebral column posteriorly. Because the various structures that make up the mediastinum are superimposed on each other on the chest radiograph, they cannot be separately identified. Nevertheless, because a chest radiograph is usually the first imaging investigation, it is necessary to have an appreciation of the normal appearances of the mediastinum, together with variations due to the patient's body habitus and age. Key points include:

- Only the outline of the mediastinum and the air-containing trachea and bronchi (and sometimes oesophagus) are clearly seen on a normal chest radiograph.
- The right superior mediastinal border is formed by the right brachiocephalic vein and superior vena cava, and becomes less distinct as it reaches the thoracic inlet. The right side of the superior mediastinum can appear to be considerably widened in patients with an abundance of mediastinal fat.
- The left mediastinal border above the aortic arch is the result of summation of the left carotid and left subclavian arteries together with the left brachiocephalic and jugular veins.
- The left cardiac border comprises the left atrial appendage which merges inferiorly with the left ventricle. The silhouette of the heart should always be sharply outlined. Any blurring of the border is due to loss of immediately adjacent aerated lung, usually by collapse or consolidation.
- The density of the heart shadow to the left and right of the vertebral column should be identical and any difference indicates pathology (for example, an area of consolidation or a mass in a lower lobe).
- The trachea and main bronchi should be visible through the upper and middle mediastinum.
- In older individuals, the trachea may be displaced by a dilated aortic arch. In approximately 60% of normal subjects, the right wall of the trachea (the right paratracheal stripe) can be identified as a line of uniform thickness (less than 4 mm in width); when it is visible it excludes the presence of an adjacent space-occupying lesion, most usually lymphadenopathy.
- The carinal angle is usually less than  $80^\circ$ . Splaying of the carina is an insensitive sign of subcarinal disease, either in the form of massive subcarinal lymphadenopathy, or a markedly enlarged left atrium.
- The origins of the lobar bronchi, where they are projected over the mediastinal shadow, can usually be identified but the segmental bronchi within the lungs are not generally seen on plain radiography.
- Normal hilar shadows on a chest radiograph represent the summation of the pulmonary arteries and veins.
- The hila are approximately the same size and the left hilum normally lies between 0.5 cm and 1.5 cm above the level of the right hilum. The size and shape of the hila show remarkable variation in normal individuals, making subtle abnormalities difficult to identify.

### THE PULMONARY FISSURES, VESSELS AND BRONCHI

The two lungs are separated by the four layers of pleura behind and in front of the mediastinum. The resulting posterior and anterior junction lines are often visible on chest radiographs as nearly vertical stripes, the posterior junction line lying higher than the anterior. The junction lines are not invariably seen and their presence or absence is not usually of significance (Figure 35.3).

**Figure 35.3** (a) Close-up of the mediastinum of a patient in whom both the anterior and posterior junction lines are evident. The anterior junction line is more inferior and slants from right to left (short arrows), whereas the posterior junction line is more vertical, superior and is delineated by the arrowheads. (b) Computed tomography scan through the upper mediastinum demonstrating the anterior (arrowheads) and posterior (arrows) junction lines in a different patient.

The upper and lower lobes of the left lung are separated by the major (or oblique) fissure. The upper, middle and lower lobes of the right lung are separated by the major fissure and the minor (horizontal or transverse) fissure. The minor fissure is visible in over half of normal PA chest radiographs. The major fissures are not visible on a frontal radiograph and are inconstantly identifiable on lateral radiographs. In a few individuals, fissures are incompletely developed; a point familiar to thoracic surgeons performing a lobectomy, because of incomplete cleavage between lobes. Accessory fissures are occasionally seen.

All of the branching structures seen within normal lungs on a chest radiograph represent pulmonary arteries or veins. It is often impossible to distinguish arteries from veins in the lung periphery. On a chest radiograph taken in the erect position, there is a gradual increase in the diameter of the vessels, at equidistant points from the hilum, travelling from lung apex to base; this gravity-dependent effect disappears if the patient is supine or in cardiac failure.

#### THE DIAPHRAGM AND THORACIC CAGE

The interface between aerated lung and the hemidiaphragms is sharp and the highest point of each dome is normally medial to the mid-clavicular line. The right dome of the diaphragm is higher than the left by up to 2 cm in the erect position unless the left dome is elevated by air in the stomach (Figure 35.4).

**Figure 35.4** Erect chest radiograph of a patient with a pneumoperitoneum demonstrating the normal thickness in position of the hemidiaphragms. The right lies slightly higher than the left.

Filling-in or blunting of these costophrenic angles usually represents pleural disease, either pleural thickening or an effusion.

#### POSITIONING OF TUBES AND LINES<sup>4</sup>

##### CENTRAL VENOUS CATHETERS (CVC)

The end of a CVC needs to be intrathoracic, and is ideally in the superior vena cava. CVCs may be introduced via an antecubital, subclavian or jugular vein. Subclavian venous puncture carries a risk of pneumothorax and mediastinal hematoma. Rarely, perforation of the subclavian vein leads to fluid collecting in the mediastinum or pleura. All catheters have a potential risk of coiling, misplacement, knotting and fracture (Figure 35.5). The tip should not abut the vessel wall at an obtuse angle.

##### PULMONARY ARTERY FLOTATION CATHETERS

Ideally the end of the catheter should be maintained 5–8 cm (2–3 inches) beyond the bifurcation of the main pulmonary artery in either the right or left pulmonary artery (see Figure 35.5). When the pulmonary artery occlusion pressure is measured the balloon is inflated, and the flow of blood carries the catheter tip peripherally, to an occluded position. After the measurement has been

**Figure 35.5** Intensive care unit patient with multiple tubes and lines in place. The endotracheal tube tip position is satisfactory, and there are sternotomy wires, an intra-aortic balloon pump (radiopaque tip) and a prosthetic heart valve. The central line inserted into the left internal jugular vein passes into the right internal jugular vein. The Swan–Ganz catheter, which has been inserted via the right internal jugular vein, loops into the left brachiocephalic vein, before taking a satisfactory course through the cardiac chambers (black arrows).

made the balloon is deflated and the catheter returns to a central position; otherwise there is a risk of pulmonary infarction. The inflation balloon is radiolucent. The balloon should normally be kept deflated.

#### **NASOGASTRIC TUBES**

These should reach the stomach but may coil in the oesophagus or occasionally are inserted into the tracheobronchial tree (Figure 35.6).

#### **ENDOTRACHEAL TUBES**

Extension and flexion of the neck may make the tip of an endotracheal tube move by as much as 5 cm. With the neck in neutral position the tip of the tube should ideally be about 5–6 cm above the carina. A tube that is inserted too far usually passes into the right bronchus, with the risk of non-ventilation or collapse of the left lung (Figure 35.7).

#### **TRACHEOSTOMY TUBES**

The tube tip should be situated centrally in the airway at the level of T3. Acute complications of tracheostomy include pneumothorax, pneumomediastinum and subcutaneous

emphysema. Long-term complications include tracheal ulceration, stenosis and perforation.

#### **PLEURAL TUBES**

These are used to treat pleural effusions and pneumothoraces. A radiopaque line usually runs along pleural tubes, and is interrupted where there are side holes. It is important to check that all the side holes are within the thorax. Tracks may remain on the chest X-ray following removal of chest tubes, causing tubular or ring shadows. When doubt remains about tube position, then CT scanning should be considered (Figure 35.1 and 35.8).

#### **MEDIASTINAL DRAINS**

These are usually present following sternotomy. Apart from their position, they look like pleural tubes.

#### **INTRA-AORTIC BALLOON PUMP**

These are used in patients with cardiogenic shock, often following cardiac surgery. The ideal position of the catheter tip is just distal to the origin of the left subclavian artery (Figure 35.9). If the catheter tip is advanced too far it may occlude the left subclavian artery, and if it is

**Figure 35.6** Misplaced nasogastric tube. (a) The tip of the tube is in the bronchus intermedius. (b) The tube is looped in the oesophagus (black arrowheads) before passing into the trachea, as demonstrated on this lateral spine view. Note the anterior wedge fracture of C5.

*Continued*

**Figure 35.6** *Continued* (c) The tube is coiled in the oesophagus without passing into the stomach. Note the bullet projected over the left upper zone and the adequately positioned Swan-Ganz catheter (white arrow).

**Figure 35.7** Endotracheal tube inserted into the right main bronchus as demonstrated on computed tomography. This image, obtained in expiration, demonstrates air trapping in the left lung.

too distal the balloon may occlude branches of the abdominal aorta. The intra-aortic balloon pump may only be visible by its radiopaque tip (see Figure 35.5).

#### PACEMAKERS

These may be permanent or temporary (Figure 35.10). Temporary epicardial wires are sometimes inserted

**Figure 35.8** Computed tomography scan demonstrating loculated pneumothoraces in a patient with acute lung injury. The posteromedial pneumothorax on the left is not being drained by the multiple chest tubes.

during cardiac surgery, and may be seen as thin, almost hair-like metallic opacities overlying the heart. Temporary pacing electrodes are usually inserted transvenously via a subclavian or jugular vein. If a patient is not pacing properly, a chest X-ray may reveal that the position of the electrode tip is unstable, or a fracture in the wire may be seen.

### RADIOGRAPHIC SIGNS OF PATHOLOGY

#### CONSOLIDATION

Consolidation, or synonymously air space shadowing, is due to opacification of the air-containing spaces of the lung, usually without a change in volume of the affected area. It is not possible to tell what the air space filling is due to in the absence of a clinical history, except perhaps for shadowing due to cardiogenic alveolar oedema, when there will be associated signs of cardiac failure. Typical features of all forms of consolidation (Figure 35.11) include:

- ill-defined margins, except where it directly abuts a pleural surface
- sharply demarcated by fissures
- loss of vascular markings
- air bronchograms – the bronchi, usually invisible, may become apparent in negative contrast to the air space opacification
- acinar opacities, due to individual acini or secondary pulmonary lobules being opacified but still surrounded by normally aerated lung, usually seen at the periphery of a more confluent area of consolidation, and 0.5–1 cm in diameter

**Figure 35.9** Intra-aortic balloon pump. Two chest radiographs in the same patient demonstrating the balloon pump during the inflated (a) and deflated (b) phases. The tip of this balloon pump will be impinging upon the origin of the left subclavian artery and is slightly too high.

- ground-glass opacification, when consolidation has caused only partial filling of the air spaces
- silhouette sign – consolidation abutting a soft-tissue structure causes the silhouette of that structure to be lost

When an area of consolidation undergoes necrosis, either due to infection or infarction, then liquefaction may result, and if there is either a gas-forming organism or communication with the bronchial tree, then an air–fluid level may develop in addition to cavity formation.

### COLLAPSE

When there is partial or complete volume loss in a lung or lobe this is referred to as collapse or atelectasis, implying a

diminished volume of air in the lung with associated reduction of lung volume. There are several different mechanisms for lung or lobar collapse, for example relaxation or passive collapse, when fluid or air accumulates in the pleural space, cicatrization collapse when volume loss is associated with pulmonary fibrosis, adhesive collapse as in ARDS, or resorption collapse, as in bronchial obstruction.

The radiographic appearance in pulmonary collapse depends upon a number of factors. These include the mechanism of collapse, the extent of collapse, the presence or absence of consolidation in the affected lung and the pre-existing state of the pleura. This latter factor includes the presence of underlying pleural tethering or thickening and the presence of pleural fluid.

**Figure 35.10** There is a fracture in the now redundant pacing wire on the right side. The functioning pacing wire is sharply kinked as it passes over the first rib and is at increased risk of subsequent fracture.

**Figure 35.11** Close-up view of an area of consolidation adjacent to the right heart border, which is obscured. Air bronchograms can be identified passing through this area. A chest tube is in situ.

The direct signs of collapse include:

- displacement of interlobar fissures
- loss of aeration resulting in increased density or the presence of the silhouette sign
- crowding of vessels and bronchi

The indirect signs of collapse include:

- elevation of the hemidiaphragm, especially with lower lobe collapse
- mediastinal displacement, especially in upper lobe collapse
- hilar displacement, where the hilum is elevated in upper lobe collapse and depressed in lower lobe collapse
- compensatory hyperinflation of remaining normal lung, resulting in increased transradiancy or herniation across the midline from the normal side
- crowding of the ribs reflecting diminished overall volume of the affected hemithorax

#### COMPLETE LUNG COLLAPSE

Complete collapse (Figure 35.12) will cause complete opacification of the hemithorax, with displacement of the mediastinum to the affected side and elevation of the hemidiaphragm. Compensatory hyperinflation of the contralateral lung with herniation across the midline may be apparent. Herniation may occur in the retrosternal space, anterior to the ascending aorta, or may be posterior to the heart.

**Figure 35.12** Complete lung collapse. The left hemithorax is opaque and the mediastinum has shifted to that side, together with deviation of the trachea. There was an obstructing tumour in the left main stem bronchus.

**INDIVIDUAL OR COMBINED LOBAR COLLAPSE**

In any situation, some or all of the signs may be present.

**Right upper lobe collapse (Figure 35.13)**

- horizontal fissure moves upwards and medially towards the superior mediastinum
- trachea deviates to the right
- compensatory hyperinflation of the right middle and lower lobes

**Middle lobe collapse (Figure 35.14)**

- horizontal fissure and lower half of the oblique fissure move towards each other – best seen on the lateral projection
- frontal radiograph changes may be subtle, with obscuration of the right heart border
- indirect signs of volume loss are rarely obvious

**Right lower lobe collapse**

- partial depression of the horizontal fissure
- triangular opacity of the collapsed lower lobe on the frontal projection, usually obscuring the diaphragm but preserving the right heart border
- eventually a completely collapsed lower lobe may be so small that it flattens and merges with the mediastinum, producing a thin, wedge-shaped shadow

**Left lower lobe collapse (Figure 35.15)**

- collapsed lobe may be obscured by the heart and a penetrated view may be required

**Figure 35.13** Right upper lobe collapse. The horizontal fissure has become elevated and the right upper lobe has become a wedge-shaped density extending from the hilum to the right lung apex. There is evidence of volume loss with shift of the trachea to the right side.

**Figure 35.14** Middle lobe collapse. The horizontal fissure is depressed and demarcates the collapsed middle lobe as a wedge-shaped density best demonstrated on the lateral (arrows).

**Figure 35.15** Left lower lobe collapse. The left lower lobe has become a wedge-shaped density behind the heart forming a double left heart border (arrows). The left hilar vessel to the lower lobe has disappeared as a result of collapse.

- mediastinal structures and the diaphragm adjacent to the non-aerated lobe are obscured
- extreme volume loss may cause the lobe to be so small as to be invisible as a separate opacity
- loss of lower lobe artery silhouette at the hilum

**Figure 35.16** Left upper lobe collapse. A hazy opacity extends from the hilum towards the left lung apex. It is sharply demarcated inferiorly and laterally (white arrows) due to the presence of a large tumour at the left hilum which is obstructing the left upper lobe bronchus. Note the signs of volume loss, particularly the elevation of the left hemidiaphragm.

#### Lingula collapse

- often involved in collapse of the left upper lobe
- may collapse individually
- radiographic features are similar to those of middle lobe collapse

#### Left upper lobe collapse (Figure 35.16)

- Lateral view demonstrates anterior displacement of the entire oblique fissure, oriented almost parallel to the anterior chest wall, demarcating the posterior surface of the upper lobe as an elongated opacity extending from the apex almost reaching the diaphragm and lying anterior to the hilum.
- Eventually the upper lobe retracts posteriorly and loses contact with the anterior chest wall.
- Frontal radiograph demonstrates an ill-defined hazy opacity in the upper, mid and sometimes lower zones, with loss of hilar clarity.
- Hilum is often elevated, and the trachea deviated to the left.

#### COMBINED COLLAPSE

Right lower and middle lobe collapse is the most common pairing since a lesion may occur in the bronchus intermedius. The appearances are similar to right lower lobe collapse except that the horizontal fissure is not apparent, and the opacification reaches the lateral chest wall on the frontal radiograph, and similarly extends to the anterior chest wall on the lateral view.

Right upper and middle lobe collapse is much less common because of the distance between the origins of their bronchi, and can generally be taken to imply the presence of more than one lesion. This combination will produce appearances almost identical to those of left upper lobe collapse (see Figure 35.16). On occasion isolated right upper lobe collapse will also produce appearances that are identical to left upper lobe collapse.

#### UNILATERAL INCREASED TRANSRADIANCY

The commonest causes are technical and include:

- patient rotation
- poor beam centring
- offset grid

Pathological causes include:

- chest wall changes
- mastectomy
- congenital unilateral absence of pectoral muscles, known as Poland's syndrome
- reduced vascularity when interruption or significant reduction in the blood supply to one lung may cause that lung to be of increased transradiancy
- lung hyperexpansion due to air trapping or asymmetric emphysema

When there is relative increased transradiancy of one hemithorax for which there is no obvious cause then the possibility of generalised increase in radiopacity of the opposite side should be considered – for example, the posterior layering of a pleural effusion in a supine patient. Usually hypertransradiancy due to technical factors can be identified by comparison of the soft tissues around the shoulder girdle, and particularly over the axillae.

#### ABNORMALITIES OF THE MEDIASTINUM

Pneumomediastinum or mediastinal emphysema is the presence of air between the tissue planes of the mediastinum (see section on injuries to the mediastinum, below). Chest radiography may show vertical translucent streaks in the mediastinum, representing air separating the soft-tissue planes. The air may extend up into the neck and over the chest wall, causing subcutaneous emphysema, and also over the diaphragm. The mediastinal pleura may be displaced laterally and then be visible as a thin stripe alongside the mediastinum.

Acute mediastinitis is usually due to perforation of the oesophagus, pharynx or trachea and chest radiograph usually shows widening of the mediastinum and pneumomediastinum.

Mediastinal haemorrhage may occur from venous or arterial bleeding (Figure 35.17). The mediastinum appears widened, and blood may be seen tracking over the lung apices. It is imperative to identify a life-threatening cause such as aortic rupture.

**Figure 35.17** Aortic rupture. (a) There is opacification of the left hemithorax due to a large haemothorax which is layering posteriorly in this supine patient. There is widening of the mediastinum due to mediastinal haemorrhage. (b) Arch aortogram demonstrating widening of the descending thoracic aorta due to the aortic wall rupture. The point of return to normal calibre is demarcated by the arrows. (c) Computed tomography angiography of a different patient demonstrating a penetrating ulcer resulting in an aorto-oesophageal fistula that caused massive haematemesis. Note the local irregularity in the otherwise smooth anterior aortic wall on this oblique sagittal reformat.

### PLEURAL FLUID

The most dependent recess of the pleural space is the posterior costophrenic angle and this is where a small effusion will tend to collect. As little as a few millilitres of fluid may be detected using decubitus views with a horizontal beam, ultrasound or CT. Larger volumes of fluid eventually fill in the costophrenic angle on the frontal view, and with increasing fluid a homogeneous opacity spreads upwards, obscuring the lung base (Figure 35.18). The fluid usually demonstrates a concave upper edge, higher laterally than medially, and obscures the diaphragm. Fluid may track into the fissures. A massive effusion may cause complete opacification of a hemithorax with passive atelectasis. The space-occupying effect of the effusion may push the mediastinum towards the opposite side, especially when the lung does not collapse significantly. Effusions in a supine patient redistribute into the paravertebral sulcus and produce an even increased density throughout that hemithorax.

Lamellar effusions are shallow collections between the lung surface and the visceral pleura, sometimes sparing the costophrenic angle, and occur early in heart failure.

Subpulmonary effusions accumulate between the diaphragm and undersurface of a lung, mimicking elevation of the hemidiaphragm, altering the diaphragmatic contour so the apex moves more laterally than usual. When

**Figure 35.18** A large right pleural effusion is present in this patient. There is a typical configuration of its upper border, a meniscus extending up the lateral chest wall.

left-sided, there is increased distance between the gastric air bubble and lung base.

Fluid may become loculated in the interlobar fissures and is most frequently seen in heart failure. Loculated interlobar effusions may disappear rapidly and are sometimes known as pulmonary pseudotumours.

Differentiation between a simple effusion and a complicated parapneumonic effusion or an empyema usually requires thoracentesis. Loculation is best demonstrated with ultrasound.

### PNEUMOTHORAX

In an erect patient, air will usually collect at the apex (Figure 35.19). The lung retracts towards the hilum and on a frontal chest film the sharp white line of the visceral pleura will be visible, separated from the chest wall by the radiolucent pleural space, which is devoid of lung markings. This should not be confused with a skin fold, which mostly occurs in supine or recumbent patients. The lung usually remains aerated, although perfusion is reduced in proportion to ventilation and therefore the radiodensity of the partially collapsed lung remains relatively normal. A large pneumothorax may lead to complete retraction of the lung, with some mediastinal shift towards the normal side. Because it is a medical emergency, tension pneumothorax is often treated before a chest radiograph is obtained. However, if a radiograph is taken in this situation it will show marked displacement of the mediastinum. Radiographically the lung may be squashed against the mediastinum, or herniate across the midline, and the ipsilateral hemidiaphragm may be depressed. A supine pneumothorax may produce increased transradiancy towards the diaphragm, and a deep sulcus sign.

### COMPLICATIONS OF PNEUMOTHORAX

Pleural adhesions may limit the distribution of a pneumothorax and result in a loculated or encysted pneumothorax (see Figure 35.8). The usual appearance is an ovoid air collection adjacent to the chest wall, and it may be radiographically indistinguishable from a thin-walled subpleural pulmonary cyst or bulla. Pleural adhesions are occasionally seen as line shadows stretching between the two pleural layers, preventing relaxation of the underlying lung. Rupture of an adhesion may produce a haemopneumothorax. Collapse or consolidation of a lobe or lung in association with a pneumothorax is important because they may delay re-expansion of the lung.

Since the normal pleural space contains a small volume of fluid, blunting of the costophrenic angle by a short fluid level is commonly seen in a pneumothorax. In a small pneumothorax this fluid level may be the most obvious radiological sign. A larger fluid level usually signifies a complication and represents exudate, pus or blood, depending on the aetiology of the pneumothorax. A hydro-pneumothorax is a pneumothorax containing

**Figure 35.19** Pneumothorax. (a) This patient, with underlying lung abnormality, has developed a pneumothorax. The fine white line that represents the visceral pleura delineates the edge of the lung. (b) Close-up of the pleural line. Note how there are no vascular markings beyond this point.

**Figure 35.20** Hydro-pneumothorax developing in a patient who has had a previous pneumonectomy on the right for carcinoma. Spontaneous development of a bronchopleural fistula has occurred.

a significant amount of fluid (Figure 35.20). On a radiograph obtained with a horizontal beam, a fluid level is evident. A hydro- or pyopneumothorax may arise as a result of a bronchopleural fistula, and may be a complication of surgery, tumour or infection.

#### PULMONARY EMBOLISM

CT diagnosis of pulmonary embolism is becoming routinely available, and depends upon the ability to acquire, within a single breath-hold, a volume of data large enough to include the entire thorax. This rapid acquisition allows excellent contrast opacification of the pulmonary arterial tree for the duration of the scan, revealing any thrombus within the central pulmonary vessels (Figure 35.21). There are numerous studies evaluating helical and electron beam CT in the diagnosis of acute pulmonary embolus, with excellent reported sensitivity and specificity for the detection of clot down to the segmental level.<sup>5–8</sup> Most of these studies also allow other diagnoses to be made that explain the symptoms of chest pain or dyspnoea, even when no pulmonary embolism is present.

### TRAUMA AND THE ICU PATIENT

#### SKELETAL INJURY<sup>9</sup>

Following trauma rib fractures are common and may be single, multiple, unilateral or bilateral. In cases of chest trauma, the chest X-ray is more important in detecting a complication of rib fracture than the fracture itself. Fracture of one of the first three ribs is often associated with major intrathoracic injury, and fracture of the lower three ribs may be associated with important hepatic, splenic or renal injury. Complications of rib fracture include a flail segment, pneumothorax, haemothorax and subcutaneous emphysema. A flail segment is usually apparent clinically

**Figure 35.21** (a) Large pulmonary embolus in the right lower lobe pulmonary artery demonstrated by spiral computed tomography scanning. Both pulmonary arteries are outlined by contrast except for the embolus itself. (b) Coronal reformat in the same case, demonstrating thrombus in the lower lobe artery.

and radiologically. The fractured ends of ribs may penetrate underlying pleura and lung and cause a pneumothorax, haemothorax, haemopneumothorax or intrapulmonary haemorrhage. Air may also escape into the chest wall and cause subcutaneous emphysema. Fractures of the sternum usually require a lateral film or CT for visualisation. Fractures of the thoracic spine may be associated with a

paraspinal shadow, which represents haematoma. Fractures of the clavicle may be associated with injury to the subclavian vessels or brachial plexus, and posterior dislocation of the clavicle at the sternoclavicular joint may cause injury to the trachea, oesophagus, great vessels or nerves of the superior mediastinum.

### DIAPHRAGMATIC INJURY<sup>10</sup>

Laceration of the diaphragm may result from penetrating or non-penetrating trauma to the chest or abdomen. Rupture of the left hemidiaphragm is encountered more frequently in clinical practice than rupture on the right (Figure 35.22). The typical plain film appearance is of obscuration of the affected hemidiaphragm and increased shadowing in the ipsilateral hemithorax due to herniation of stomach, omentum, bowel or solid viscera, although such herniation may be delayed. Ultrasound may demonstrate diaphragmatic laceration and free fluid in both the pleura and peritoneum. Barium studies may be useful to confirm herniation of stomach or bowel into the chest.

### PLEURAL INJURY<sup>9,11</sup>

Pneumothorax may be a complication of rib fracture, and is then usually associated with a haemothorax. If no ribs are fractured, pneumothorax is secondary to a pneumo-mediastinum, pulmonary laceration or penetrating chest injury. Pneumothorax due to a penetrating injury is liable

**Figure 35.22** Ruptured left hemidiaphragm. Previous trauma resulted in rupture of the hemidiaphragm. A chest radiograph obtained some months later demonstrates herniation of the stomach into the left hemithorax.

to develop increased pressure, resulting in a tension pneumothorax, which may require emergency decompression. Haemothorax may also occur with or without rib fractures, and is due to laceration of intercostal or pleural vessels. If a pneumothorax is also present a fluid level will be seen on a horizontal-beam film. Pleural effusion may also result from trauma. Open injuries to the pleura are prone to infection and development of an empyema.

### **INJURIES TO THE LUNG<sup>12–14</sup>**

Pulmonary contusion is due to haemorrhagic exudation into the alveoli and interstitial spaces and appears as patchy, non-segmental consolidation within the first few hours of penetrating or non-penetrating trauma. There is usually improvement within 2 days and clearance within 3–4 days. Pulmonary lacerations may be obscured by pulmonary contusion, but, as this resolves, the laceration will become evident. If filled with blood it appears as a homogeneous round opacity, and if partly filled with blood it may show a fluid level. Such pulmonary haematomas or blood cysts gradually decrease in size, but may take a few months to resolve completely. Fat embolism is a rare complication of multiple fractures, with poorly defined nodular opacities throughout both lungs, which resolve within a few days.

### **INJURIES TO THE TRACHEA AND BRONCHI<sup>13,15</sup>**

Laceration or rupture of a major airway is an uncommon result of severe chest trauma. Fracture of the first three ribs and mediastinal emphysema and pneumothorax may also be evident. The injury is usually in the trachea just above the carina, or in a main bronchus just distal to the carina. If the bronchial sheath is preserved there may be no immediate signs or symptoms, but tracheostenosis or bronchiectasis may occur later. CT may be helpful in diagnosis, but bronchoscopy is the best diagnostic method in the acute stage.

### **INJURIES TO THE MEDIASTINUM<sup>16</sup>**

Pneumomediastinum and mediastinal emphysema, discussed above, are the presence of air between the tissue planes of the mediastinum. Air may reach here as a result of pulmonary interstitial emphysema, perforation of the oesophagus, trachea or bronchus, or from a penetrating chest injury. Pulmonary interstitial emphysema is a result of alveolar wall rupture due to high intra-alveolar pressure, and may occur during violent coughing, severe asthma or crush injuries, or be due to positive-pressure ventilation. Air dissects centrally along the perivascular sheath to reach the mediastinum. Rarely, air may dissect into the mediastinum from a pneumoperitoneum. A pneumomediastinum may extend beyond the thoracic inlet into the neck, and over the chest wall. Pneumothorax is a common complication of pneumomediastinum, but the converse rarely occurs. Pneumomediastinum

usually produces vertical translucent streaks in the mediastinum. This represents gas separating and outlining the soft-tissue planes and structures of the mediastinum. Gas shadows may extend up into the neck, or dissect extrapleurally over the diaphragm, or extend into the soft-tissue planes of the chest wall, causing subcutaneous emphysema. The mediastinal pleura may be displaced laterally, and become visible as a linear soft-tissue shadow parallel to the mediastinum. If mediastinal air collects beneath the pericardium the central part of the diaphragm may be visible, producing the ‘continuous diaphragm’ sign. Mediastinal haemorrhage may result from penetrating or non-penetrating trauma, and be due to venous or arterial bleeding. Many cases are probably unrecognised, as clinical and radiographic signs are absent. Important causes include automobile accidents, aortic rupture and dissection, and introduction of CVCs. There is usually bilateral mediastinal widening, but a localised haematoma may occur.

### **ACUTE AORTIC INJURY**

Aortic rupture (see Figure 35.17)<sup>17</sup> is usually the result of an automobile accident. Most non-fatal aortic tears occur at the aortic isthmus, the site of the ligamentum arteriosum. Only 10–20% of patients survive the acute episode, but a small number may develop a chronic aneurysm at the site of the tear. The commonest acute radiographic signs are widening of the superior mediastinum, and obscuration of the aortic knuckle. Other radiographic signs include deviation of the left main bronchus anteriorly, inferiorly and to the right, and rightward displacement of the trachea, a nasogastric tube or the right parasternal line. A left apical extrapleural cap or a left haemothorax may be visible. Although aortography is the definitive investigation, CT, transoesophageal echocardiography or magnetic resonance imaging may be diagnostic. In everyday practice, many departments will have emergency access to a CT scanner, but will not be centres of cardiothoracic surgery. A properly conducted CT scan demonstrating a normal mediastinum has a very high negative predictive value for aortic rupture. However, if CT is equivocal or shows a mediastinal haematoma then generally angiography will be required prior to surgery.

### **CARDIAC INJURY<sup>18</sup>**

This is rare but may result from penetrating or blunt trauma. Penetrating injuries are usually rapidly fatal but may cause tamponade, ventricular aneurysm or septal defects. Blunt trauma may cause myocardial contusion and infarction and may be associated with transient or more permanent rhythm disturbance.

### **OE SOPHAGEAL RUPTURE<sup>19</sup>**

This is usually the result of instrumentation or surgery, but occasionally occurs in penetrating trauma, and is rarely

spontaneous and due to sudden increase of intraoesophageal pressure (Boerhaave syndrome). Clinically there is acute mediastinitis; radiographically there are signs of pneumomediastinum, with or without a pneumothorax or hydropneumothorax, which is usually left-sided. The diagnosis should be confirmed by a swallow. This should initially be with water-soluble contrast medium in order to avoid the small risk of granuloma formation in the mediastinum that has been described following barium leakage. Chylothorax due to damage to the thoracic duct may become apparent hours or days after trauma. Thoracic surgery is the commonest cause.

## THE POSTOPERATIVE CHEST

### THORACIC COMPLICATIONS OF GENERAL SURGERY

#### ATELECTASIS

Atelectasis is the commonest pulmonary complication of thoracic or abdominal surgery. The chest X-ray usually shows elevation of the diaphragm, due to a poor inspiration. Linear opacities are present in the lower zones, and represent a combination of subsegmental volume loss and consolidation. The shadows usually appear about 24 hours postoperatively and resolve within 2–3 days.

#### PLEURAL EFFUSIONS

Pleural effusions are common immediately following abdominal surgery and usually resolve within 2 weeks. They may be associated with pulmonary infarction. Effusions due to subphrenic infection usually occur later.

#### PNEUMOTHORAX

Pneumothorax, when it complicates extrathoracic surgery, is usually a complication of positive-pressure ventilation or central venous line insertion. It may complicate nephrectomy.

#### ASPIRATION PNEUMONITIS

Aspiration pneumonitis is common during anaesthesia, but fortunately is usually insignificant. When significant, patchy consolidation appears within a few hours, usually basally or around the hila. Clearing occurs within a few days, unless there is superinfection.

#### PULMONARY OEDEMA

In the postoperative period oedema may be cardiogenic or non-cardiogenic.

#### PNEUMONIA

Postoperative atelectasis and aspiration pneumonitis may be complicated by pneumonia. Postoperative pneumonias, therefore, tend to be associated with bilateral basal shadowing.

#### SUBPHRENIC ABSCESS

Subphrenic abscess usually produces elevation of the hemidiaphragm, pleural effusion and basal atelectasis. Loculated gas may be seen below the diaphragm, and fluoroscopy may show splinting of the diaphragm. Subphrenic abscess can be demonstrated by CT or ultrasound.

#### PULMONARY EMBOLISM

Pulmonary embolism may produce pulmonary shadowing, pleural effusion or elevation of the diaphragm, but is not excluded by a normal radiograph. In the ICU setting the radiological investigation of choice is spiral CT scanning.

### THORACIC COMPLICATIONS OF CARDIAC SURGERY

Most cardiac operations are performed through a sternotomy incision, and wire sternal sutures are often seen on the postoperative films. Mitral valvotomy is now rarely performed via a thoracotomy incision, but this route is still used for surgery of coarctation of the aorta, patent ductus arteriosus, Blalock–Taussig shunts and pulmonary artery banding.

Widening of the cardiovascular silhouette is usual, and represents bleeding and oedema. Marked or progressive widening of the mediastinum suggests significant haemorrhage (Figure 35.23). Some air commonly remains in the pericardium following cardiac surgery, so that the signs of pneumopericardium may be present.

Left basal shadowing is almost invariable, representing atelectasis. This shadowing usually resolves over a week or two. Small pleural effusions are also common in the immediate postoperative period.

Pneumoperitoneum is sometimes seen, due to involvement of the peritoneum by the sternotomy incision. It is of no pathological significance (see Figure 35.4).

Violation of left or right pleural space may lead to a pneumothorax. Damage to a major lymphatic vessel may lead to a chylothorax or a more localised chylooma. Phrenic nerve damage may cause paresis or paralysis of a hemidiaphragm.

Surgical clips or other metallic markers have sometimes been used to mark the ends of coronary artery bypass grafts. Prosthetic heart valves are usually visible radiographically, but they may be difficult to see on an underpenetrated film.

Sternal dehiscence may be apparent radiographically by a linear lucency appearing in the sternum and alteration in position of the sternal sutures on consecutive films. The diagnosis is usually made clinically and may be associated with osteomyelitis. A first or second rib may be fractured when the sternum is spread apart. The importance of this observation is that it may explain chest pain in the postoperative period.

Acute mediastinitis may complicate mediastinal surgery, although it is more commonly associated with oesophageal perforation or surgery. Radiographically there may be mediastinal widening or pneumomediastinum, and these features are best assessed by CT scan.

**Figure 35.23** Following cardiac surgery (a) the postoperative chest radiograph appears satisfactory. A few hours later (b) the mediastinum has widened considerably, due to mediastinal haemorrhage.

# Acute gastrointestinal bleeding

Joseph J Y Sung

Acute gastrointestinal (GI) bleeding is a common admission to the intensive care unit (ICU) and a major cause of morbidity and mortality. Peptic ulcer disease accounts for 75% of upper GI bleeding.<sup>1,2</sup> Bleeding from varices, oesophagitis, duodenitis and Mallory–Weiss syndrome each account for between 5% and 15% of cases. About 20% of GI bleeding arises from the lower GI tract. Common aetiological causes for GI bleeding are listed in Table 36.1. Mortality from upper GI bleeding has remained at approximately 10% for decades, but recent reports suggest that mortality from bleeding ulcers has fallen substantially to about 5%.<sup>3</sup> On the other hand, variceal bleeding has a much higher mortality of about 30%. Risk factors for mortality include old age, associated medical problems, coagulopathy and magnitude of bleeding.

## UPPER GASTROINTESTINAL BLEEDING

### CLINICAL PRESENTATION

The patient may or may not present with a history of upper GI problems. There may be pain but bleeding ulcers can be painless, especially in elderly patients and users of non-steroidal anti-inflammatory drugs. Frequently, the symptoms of hypovolaemia such as tachycardia, pallor, sweating, cyanosis, mental confusion and oliguria may be present, especially in massive GI bleeding. A history of vomiting and retching preceding haematemesis suggests Mallory–Weiss syndrome.

Haematemesis and melaena are the most common presentations of acute upper GI bleeding. Haematochezia is the passage of bright red or maroon blood from the rectum, in the form of pure blood or admixed with stool. It usually represents a lower intestinal source of bleeding, but can also be a feature of massive upper GI bleeding.

### INVESTIGATION

#### ENDOSCOPY OR BARIUM STUDY

As history and physical examination are seldom useful in identifying the source of bleeding, investigations are necessary in most cases of GI bleeding. Endoscopy has replaced barium studies as the investigation of choice. It should be performed as soon as the patient is

haemodynamically stabilised, and adequate supportive personnel are available. Endoscopy is preferred to barium X-rays for the following reasons:

- Endoscopy allows more precise identification of the site and nature of bleeding.
- Endoscopic appearance often predicts the risk of recurrent bleeding from ulcer and varices (see below).
- Lesions such as gastritis, portal hypertensive gastropathy and duodenitis are difficult to diagnose by barium X-ray.
- Treatments such as injecting ulcers may be instigated during endoscopy (see below).
- Barium X-ray is notoriously unreliable in patients with previous gastric surgery.

However, endoscopy can induce serious hypoxia in patients with cardiorespiratory diseases. Continuous monitoring of blood pressure, pulse and oxygen saturation with a pulse oximeter is mandatory. Oxygen should be administered by nasal cannula when necessary.

#### ANGIOGRAPHY

Angiography is seldom used for the diagnosis of upper GI bleeding. Theoretically, when the bleeding is very brisk and obscures the endoscopic view, angiography may help to identify the sources of bleeding and may sometimes be used to embolise the bleeding point. In practice, however, most patients with this degree of haemorrhage should be considered for emergency laparotomy.

### MANAGEMENT OF NON-VARICEAL UPPER GI BLEEDING

The goals of managing a patient with acute GI bleeding are first, to resuscitate; second, to control active bleeding; and third, to prevent recurrence of haemorrhage.

#### RESUSCITATION

Blood and plasma expanders should be given through large-bore intravenous cannulae. Vital signs should be closely monitored. In patients with hypovolaemic shock, central venous pressure and hourly urine output should also be observed (see Chapter 11). Following adequate resuscitation, management is directed to identify the

**Table 36.1** Common causes of acute gastrointestinal bleeding

Upper gastrointestinal bleeding
Peptic ulcers (DU:GU 3:1)
Varices (oesophageal varices:gastric varices 9:1)
Portal hypertensive gastropathy
Mallory–Weiss syndrome
Gastritis, duodenitis and oesophagitis
Lower gastrointestinal bleeding
Diverticular bleeding
Angiodysplasia and arteriovenous malformation
Colonic polyps or tumours
Meckel's diverticulum
Inflammatory bowel diseases

DU, duodenal ulcer; GU, gastrointestinal ulcer.

lesion and distinguish the high-risk patient, who is likely to require early endoscopic or surgical treatment.

### THE HIGH-RISK PATIENT

Significant GI bleeding is indicated by syncope, haematemesis, systolic blood pressure below 100 mmHg (13.3 kPa), postural hypotension and, if more than 4 units of blood have to be transfused in 12 hours, to maintain blood pressure. Patients over 60 years old and with multiple underlying diseases are at even higher risk.<sup>3</sup> Those admitted for other medical problems (e.g. heart or respiratory failure, or cerebrovascular bleed) and who have GI bleeding during hospitalisation also have a higher mortality.

### THE HIGH-RISK ULCER
