Peptic ulcers that are actively bleeding or have bled recently may show stigmata of haemorrhage on endoscopy. These include localised active bleeding (i.e. pulsatile, arterial spurting or simple oozing), an adherent blood clot, a protuberant vessel or a flat pigmented spot on the ulcer base. Stigmata of haemorrhage are important predictors of recurrent bleeding (Table 36.2). The proximal postero inferior wall of the duodenal bulb and the high lesser curve of the stomach are common sites for severe recurrent bleeding, due probably to their respective large arteries (gastroduodenal and left gastric arteries).

## TREATMENT

### Pharmacological control

Acid-suppressing drugs such as H<sub>2</sub>-receptor antagonists and proton pump inhibitors are very effective drugs to

**Table 36.2** Stigmata of haemorrhage and risk of recurrent bleeding in peptic ulcers

Stigmata of haemorrhage	% recurrent bleeding
Spurter or oozer	85–90
Protuberant vessel	35–55
Adherent clot	30–40
Flat spot	5–10
None	5

promote ulcer healing. An acidic environment impairs platelet function and haemostasis. Therefore, reducing the secretion of gastric acid should reduce bleeding and encourage ulcer healing. A recent study has shown that potent acid suppression using intravenous proton pump inhibitors reduces recurrent bleeding after endoscopic therapy.<sup>4</sup> Proton pump inhibitors should be recommended in high-risk peptic ulcer bleeding patients as an adjuvant to endoscopic therapy. In contrast, antifibrinolytic agents such as tranexamic acid have not been effective in reducing the operative rate and mortality of acute GI haemorrhage. Recent studies show that in patients at high risk of recurrent bleeding, pharmacologic control without endoscopic hemostasis is inadequate.<sup>5</sup> Thus a combination of endoscopic and pharmacologic therapy offers the best therapy for ulcer bleeding patients.<sup>6,7</sup>

### Endoscopic therapy

Most patients with acute upper GI haemorrhage stop bleeding spontaneously and have an uneventful recovery. No specific intervention is required in these patients. Endoscopic haemostasis should be used in patients with a high risk of persistent or recurrent bleeding. In the last two decades, endoscopic haemostasis, with its high efficacy and low morbidity, has resulted in a dramatic decrease in emergency surgery, and has reduced the mortality of ulcer bleeding. The three most popular methods of haemostasis are as follows.

**Adrenaline (epinephrine) injection** Endoscopic injection of adrenaline (1:10 000 dilution) at 0.5–1.0-ml aliquots (up to 10–15 ml) into and around the ulcer bleeding point has achieved successful haemostasis in over 90% of cases.<sup>6</sup> Debate exists as to whether the haemostatic effect is a result of local tamponade by the volume injected, or vasoconstriction by adrenaline. Absorption of adrenaline into the systemic circulation has been documented, but without any significant effect on the haemodynamic status of the patient.<sup>8</sup> Adrenaline injection is an effective, cheap, portable and easy-to-learn method of haemostasis, and has acquired worldwide popularity.

**Coaptive coagulation** This method uses direct pressure and heat energy (heater probe) or electrocoagulation (bipolar coagulation probe (BICAP)) to control ulcer bleeding. The depth of tissue injury induced by these devices is minimised, as the bleeding vessel is tamponaded prior to coagulation. The overall efficacy of the adrenaline injection, heater probe and BICAP probe methods is comparable.<sup>9</sup> Occasionally, it is not possible to obtain a view en face of the bleeding ulcers, particularly those on the lesser curve or on the posterior wall of the duodenal bulb. In these situations, direct pressure cannot be applied, and the failure rate of coaptive coagulation in these situations is expected to be higher.

**Haemoclips** Endoscopic clipping of a bleeding vessel is an appealing alternative treatment which has gained popularity in recent years. The advantage of haemoclips over

thermocoagulation is that there is no tissue injury induced and hence the risk of perforation is reduced. Studies comparing haemoclips against injection and thermocoagulation have shown favourable results.<sup>10,11</sup> However, the application of haemoclips in certain sites, for example lesser curve, gastric fundus and posterior wall of the duodenum, is technically difficult. Loading of clips on to the application device is cumbersome and time-consuming and transfer of torque from the handle to the tip of the device is limited.

### SURGERY

Surgery remains the most definitive method of stopping haemorrhage. However, there is little agreement on the exact indications and best timing for surgical intervention. These issues are even less clear now that endoscopic treatment is so effective. Accordingly, good cooperation among intensivists, gastroenterologists and surgeons is essential. Indications for surgery can be:

- arterial bleeding that cannot be controlled by endoscopic haemostasis
- massive transfusion (i.e. total of 6–8 units of blood)
- required to maintain blood pressure
- recurrent clinical bleeding after initial success in endoscopic hemostasis
- evidence suggestive of GI perforation

Surgical procedures include underrunning of the ulcer, underrunning plus vagotomy and drainage, and various types of gastrectomy. The overall mortality of emergency surgery for GI bleeding is about 15–20%. In a study investigating the best salvage treatment for patients with recurrent bleeding after endoscopic therapy, surgery was found to be comparable to repeating endoscopic treatment in securing hemostasis.<sup>12</sup> However, morbidity is significantly higher in surgical patients than in endoscopic patients. Early surgery should be considered in patients with hypovolaemic shock and/or large peptic ulcer with protuberant vessels. A protocol to manage bleeding peptic ulcer is shown in Figure 36.1.<sup>13</sup>

### ACUTE STRESS ULCERATION

Acute stress ulceration is associated with shock, sepsis, burns, multiple trauma, head injuries, spinal injuries and respiratory, renal and hepatic failure. Lesions are most commonly seen in the gastric fundus, and range from mild erosions to acute ulcerations. The exact mechanism leading to acute mucosal erosion/ulceration in critically ill patients is still unclear. Hypoxia and hypoperfusion of the gastroduodenal mucosa are probably the most important factors. Besides haemodynamic instability, respiratory failure and coagulopathy are also strong independent factors in critically ill patients. The incidence of stress-related mucosal bleeding in ICU patients has reported to range from 8 to 45%.<sup>14</sup> It has been declining in the last decade as a result of highly effective management of hypotension and hypoxaemia. Bleeding may be

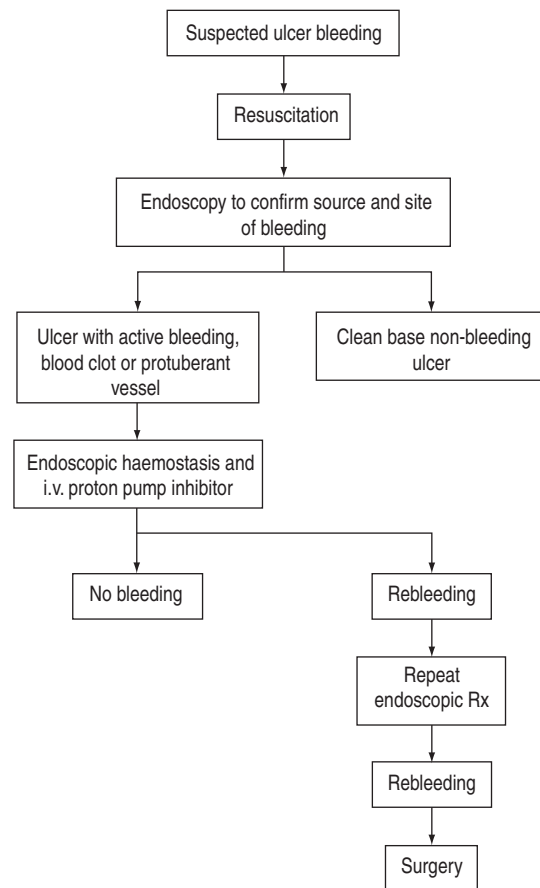

Figure 36.1 Management of peptic ulcer bleeding.

occult or overt, from ‘coffee-grounds’ aspirates to frank haemorrhage.

### PROPHYLAXIS AND TREATMENT

Significant ulcerations are managed as above. Minor bleeding and prophylactic treatment are considered together. Prophylactic treatment aims for gastric alkalisation (gastric pH > 3.5), with the rationale that gastric acidity is the main cause of stress ulceration.<sup>14</sup> The incidence of stress ulcerations appears to be lower with prophylactic gastric alkalisation than with placebos, although an improvement in survival has not been shown.<sup>15,16</sup> Gastric bacterial overgrowth and the associated nosocomial pneumonia have been concerns, but have not been substantiated by existing data. On balance, prophylactic treatment should probably be reserved only for at-risk patients. Scoring systems to estimate the risk of stress-ulcer bleeding have been proposed, for example Zinner and Tryba scores.<sup>17,18</sup> The mainstay of prophylaxis and treatment for minor bleeding remains supportive – optimise oxygenation and tissue perfusion and control of infection. There is little consensus among critical care experts in the choice of prophylactic treatment used.<sup>19</sup> Drugs given include the following:

### Antacids

Antacids given hourly via a nasogastric tube can maintain gastric alkalinisation. Gastric pH monitoring is necessary. Antacids contain magnesium, aluminium, calcium or sodium, and complications may arise from excessive intake of these minerals. Bowel stasis and diarrhoea can also be problems. They are used less commonly now.

### Sucralfate

This is a basic aluminium salt of sucrose octasulphate. It is effective in healing ulcers by increasing mucus secretion, mucosal blood flow and local prostaglandin production. These effects promote mucosal resistance against acid and pepsin (i.e. they are cytoprotective). As it does not alter gastric pH, Gram-negative bacterial colonisation of gastric juice is less likely. The incidence of nosocomial pneumonia may be less with sucralfate than with antacids or H<sub>2</sub>-receptor antagonists, but this is debatable and there is a potential risk of aspiration.<sup>15</sup> Sucralfate is given via a nasogastric tube as 1.0 g every 4–6 hours. Constipation is a side-effect, and aluminium toxicity may arise from renal dysfunction.

### H<sub>2</sub>-receptor antagonists

These drugs suppress acid secretion by competing for the histamine receptor on the parietal cell. Cimetidine is less potent and has interactions with anticonvulsants, theophyllines and warfarin. Famotidine and nizatidine are newer agents but have no particular advantage over ranitidine. The problem of H<sub>2</sub>-receptor antagonists is the development of tachyphylaxis after the first day of administration, leading to reduction of effectiveness in acid suppression. At least one meta-analysis showed that ranitidine did not confer any protection against stress ulcer in intensive care patients.<sup>21</sup>

### Proton pump inhibitors

These are potent acid-suppressing agents as they block the final common pathway of acid secretion by the parietal cell, namely the proton pump. All proton pump inhibitors (omeprazole, lansoprazole, pantoprazole and rabeprazole) can be given as oral medication. Omeprazole and pantoprazole are also available in intravenous form for those who cannot be fed orally. In two non-randomized studies, intravenous omeprazole has been shown to protect critically ill patients who required ventilation from the development of stress-related mucosal bleeding from the upper GI tract.<sup>20</sup> Yet, there are no prospective data indicating which are the high-risk patients who might benefit from this treatment.

## VARICEAL BLEEDING

Acute variceal bleeding is a serious complication of portal hypertension, with a high mortality. About 50% of patients with bleeding varices have had an earlier bleed during hospitalisation. The degree of liver failure, using Child–Pugh's classification (see Chapter 38), is the most

important prognostic factor for early rebleeding and survival.

### RESUSCITATION

Immediate resuscitation with whole blood and fluid is mandatory. Overtransfusion may cause a rebound increase in portal pressure (with a consequent increased risk of rebleeding) and must be avoided. Fresh frozen plasma and platelet concentrates transfusion may be indicated. A nasogastric cannula is often inserted for the removal of blood (and also drug administration). Forceful aspiration through the nasogastric tube should be discouraged as bleeding may be induced. Lactulose (15–30 ml every 4–6 hours) should be given to prevent or correct hepatic encephalopathy. A colonic wash-out can be used, but a magnesium-containing enema should be avoided in the presence of renal failure. Close attention must be given to haemodynamic monitoring.

When the patient is haemodynamically stable, upper endoscopy should be performed to identify the source of bleeding. Patients with portal hypertension could bleed from oesophageal or gastric varices, peptic ulcers and portal hypertensive gastropathy.

### PHARMACOLOGICAL CONTROL

Vasopressin (0.2–0.4 U/min) used to be the most widely used agent to reduce portal blood pressure and control variceal bleeding. Adverse effects of vasopressin such as cardiac ischaemia (in about 10% of patients) and worsening coagulopathy (by release of plasminogen activator) have discouraged the use of this drug in recent years. Terlipressin, a triglycyl synthetic analogue of vasopressin, has a longer half-life and fewer cardiac side-effects and appears more effective and safe when used in combination with glyceryl trinitrate.<sup>22</sup> Infusion of somatostatin and its analogue (octreotide, vapreotide) reduces portal blood pressure and splanchnic blood flow. They are safe and effective vasoactive agents to be used in acute variceal bleeding.<sup>23</sup> The benefit is more prominent if these vasoactive agents are given early, even before endoscopy.<sup>22,24</sup> Octreotide has also been shown to be effective when used as an adjuvant therapy in combination with endoscopic therapy.<sup>25</sup> Recurrent bleeding episodes and hence requirement of transfusion are significantly reduced.

### ENDOSCOPIC SCLEROTHERAPY

Endoscopic injection sclerotherapy is the mainstay of treatment. At endoscopy, sclerosants can be injected directly into the variceal columns (intravariceal injection) or into the mucosa adjacent to the varices (paravariceal injection) to cause venous thrombosis and inflammation, and tissue fibrosis. Commonly used sclerosants are ethanolamine oleate, sodium tetradecyl sulphate (1–3%), polidocanol and ethyl alcohol. None has appreciable advantage over the others and the choice is very much a personal preference of the endoscopist, and depends also on availability. Endoscopic sclerotherapy controls 80–90% of acute variceal bleeding. Complications such as ulcer formation, fever,

chest pain and mediastinitis are common. Bleeding from gastric varices is more difficult to control by injection sclerotherapy because of difficult access. Butylcyanoacrylate (Histoacryl) has recently been used for gastric variceal injections, with a claimed superior haemostatic effect. It is mixed with lipiodol to delay the rate of polymerisation and allow radiological monitoring of the injection.

#### **ENDOSCOPIC VARICEAL LIGATION**

Endoscopic variceal ligation was introduced in the late 1980s as a mechanical method to control bleeding from varices. Rubber bands mounted on the banding device at the tip of the endoscope are released to strangulate the bleeding varices. Numerous studies comparing endoscopic variceal ligation with endoscopic sclerotherapy showed that the technique is as effective as injection sclerotherapy in acute bleeding.<sup>9</sup> Procedure-related complications are significantly fewer, as there is no tissue chemical irritation. An overtube to facilitate banding avoids aspiration during the procedure, but may result in serious oesophageal injury if used improperly. The tunnel vision produced by the banding device as originally designed restricts visibility, and thus makes the procedure technically difficult when bleeding is heavy. With the introduction of multiple banding devices which are loaded with 5–10 rubber bands, and the use of transparent caps, the problems of overtube injury and tunnel vision have been overcome. In many centres, endoscopic variceal ligation has replaced injection sclerotherapy as the first choice for variceal haemorrhage. Many have combined the two endoscopic treatments together in an attempt to improve the outcome. Existing data so far do not support this combined therapy to be better. Combined endoscopic therapy cannot be recommended.

#### **BALLOON TAMPONADE**

Variceal bleeding can be controlled by exerting pressure directly on the bleeding point using a balloon. The Sengstaken–Blackmore tube has been replaced by the four-lumen Minnesota tube which allows aspiration of gastric and oesophageal contents. Inflation of the gastric balloon (by 250–350 ml of water) is often sufficient to stop the bleeding by occluding the feeding veins to the oesophageal varices. If bleeding continues, the oesophageal balloon can be inflated by air and kept at a pressure of 50–60 mmHg (6.7–8.0 kPa). Duration of using balloon tamponade should be limited to 24 hours to avoid tissue pressure necrosis. Because of available effective pharmacological and endoscopic therapies, balloon tamponade should only be used in the exceptional cases when these therapies fail to effect control of bleeding.

#### **TRANSJUGULAR INTRAHEPATIC PORTOSYSTEMIC SHUNT (TIPS)**

Using a transjugular approach, a catheter is inserted into the hepatic vein, and advanced under fluoroscopic guidance into a branch of the portal vein.<sup>26</sup> By means

of a guidewire and dilators, a self-expandable metal stent is introduced to create an intrahepatic portosystemic shunt. In good hands, success can be achieved in over 90% of cases. This procedure significantly reduces portal blood pressure and thus bleeding from varices. Major complications include intra-abdominal haemorrhage and stent occlusion. Hepatic encephalopathy has been reported in 25–60% of patients. Nevertheless, this is an effective salvage treatment for uncontrolled variceal bleeding. Meta-analysis comparing TIPS with endoscopic therapy showed that the former has secure haemostasis but at the cost of increasing risk of hepatic encephalopathy.<sup>27</sup>

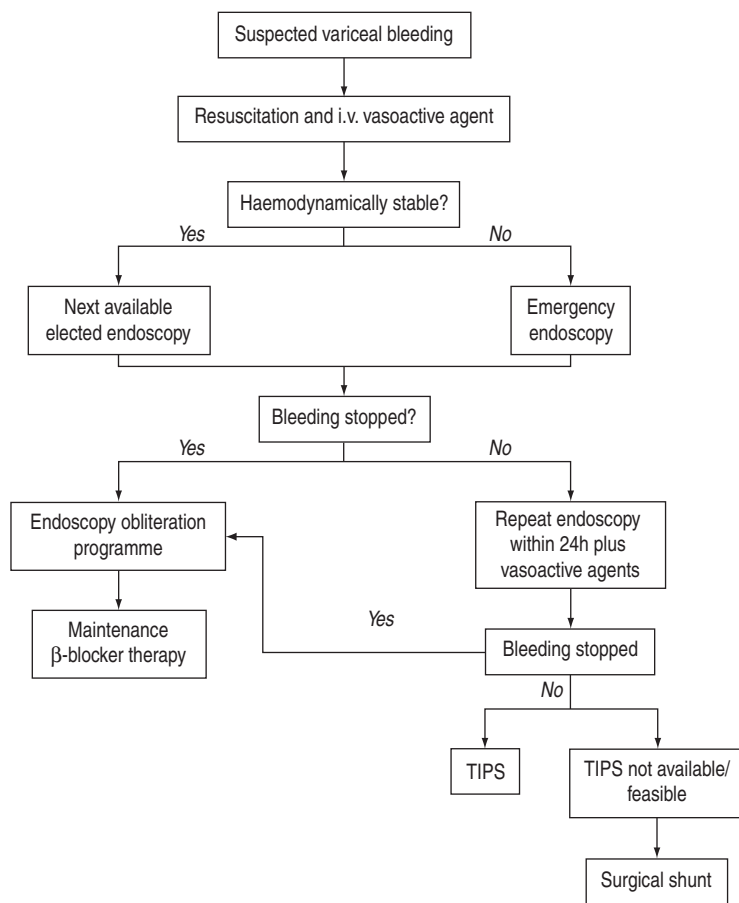

A number of markers of outcome after TIPS have been under investigation, including the Acute Physiology, Age and Chronic Health Evaluation (APACHE) score, presence of hyponatraemia and Child C liver disease, hepatic encephalopathy before TIPS, presence of ascites and serum albumin. Before a reliable marker of outcome can be identified, TIPS should be reserved for the subset of patients who continue to bleed or develop recurrent bleeding after endoscopic therapy. Unlike shunt surgery, TIPS will not reduce the chance of future liver transplantation.

#### **SURGERY**

Surgical treatments for variceal bleeding include direct devascularisation of the lower oesophagus plus the proximal stomach and a variety of surgical shunts. The role of surgery has diminished since the advent of endoscopic treatment and TIPS.<sup>28</sup> Surgery is now used as a second-line treatment, when bleeding continues or recurs after two sessions of injection sclerotherapy or banding ligation. Both staple transection of the oesophagus and portocaval shunt surgery are highly effective emergency measures. Despite successful control of bleeding, long-term survival is not significantly improved. Hepatic encephalopathy is one of the major complications of shunting operations. Expectations that the Warren distal splenorenal shunt will preserve antegrade portal flow and avoid accelerated deterioration of liver function have not been realised. The Warren shunt is technically more difficult, especially if performed as an emergency. Choice of surgery should be carefully made in those who are potential transplant candidates, as it may complicate subsequent surgery. A protocol to manage variceal bleeding is shown in Figure 36.2.

#### **LOWER GASTROINTESTINAL BLEEDING**

Lower GI bleeding arises from a source distal to the ligament of Treitz. It accounts for 10–20% of acute GI bleeding. Common causes of colonic bleeding include diverticular haemorrhage and angiodysplasia (both occur on the right-sided colon), colonic polyps and carcinoma, and inflammatory bowel diseases.

**Figure 36.2** Management of variceal haemorrhage. TIPS, transjugular intrahepatic portosystemic shunt.

### CLINICAL PRESENTATION

Haematochezia (bright-red blood) is the most common presentation of lower GI bleeding. However, bleeding from small intestine and right colon may also present as melaena. Abdominal pain preceding a massive bleeding episode suggests either ischaemia or inflammatory bowel disease. Painless massive bleeding is common in diverticulosis, angiodysplasia or from a Meckel's diverticulum. In a patient with portal hypertension, haemorrhoids may present with massive haematochezia.

### INVESTIGATIONS

Haemorrhoids and rectal tumour can easily be identified by proctosigmoidoscopy, which should always be performed. Since upper GI bleeding is about five times as common as lower GI bleeding, the former should be excluded. When both proctosigmoidoscopy and gastroscopy are negative, the lower GI tract should be examined by colonoscopy, angiography or radionuclide scan. Barium enema plays no role in the management of acute rectal bleeding.

### COLONOSCOPY

Patients with mild-to-moderate haematochezia can be examined safely by colonoscopy. Colonoscopy is difficult in an actively bleeding patient, and may carry an increased risk of perforation. Visualisation is often unsatisfactory due to the dark discoloration of blood. Colonoscopy yields much better results with adequate bowel preparation once bleeding has stopped.

### ANGIOGRAPHY OR RADIONUCLIDE SCAN

The diagnostic efficacy of radionuclide scan and angiography varies in different studies.  $^{99m}\text{Tc}$  sulphur colloid is quickly removed from the blood stream after injection. Its diagnostic yield is low because of its short circulatory half-life.  $^{99m}\text{Tc}$  labelling of red cells prolongs the duration of radioactivity in the body. Red cell scan has been reported to detect the source of active bleeding in over 80% of cases.

Diagnostic angiography is helpful in two situations: (1) when the view of endoscopy is completely obscured by active haemorrhage; (2) in defining abnormal vasculatures, where angiography is more sensitive even if

extravasation of contrast material is not seen. These lesions include angiodysplasia, arteriovenous malformation and various inherited vascular anomalies (e.g. Rendu–Osler–Weber syndrome, pseudoxanthoma elasticum and Ehlers–Danlos syndrome). Angiography may localise the site of bleeding in 80–85% of patients when the bleeding rate is more than 0.5 ml/min. Both superior and inferior mesenteric angiograms are often needed.

## MANAGEMENT

### ENDOSCOPY

Bleeding from vascular anomalies can be treated by electrocoagulation, heater probe and laser photocoagulation, unless the anomalies are too large or too diffuse. Bleeding colonic polyps can be removed by polypectomy or coagulated by hot biopsy forceps. Bleeding from colonic diverticula can also be controlled with thermocoagulation through colonoscopy.<sup>29</sup>

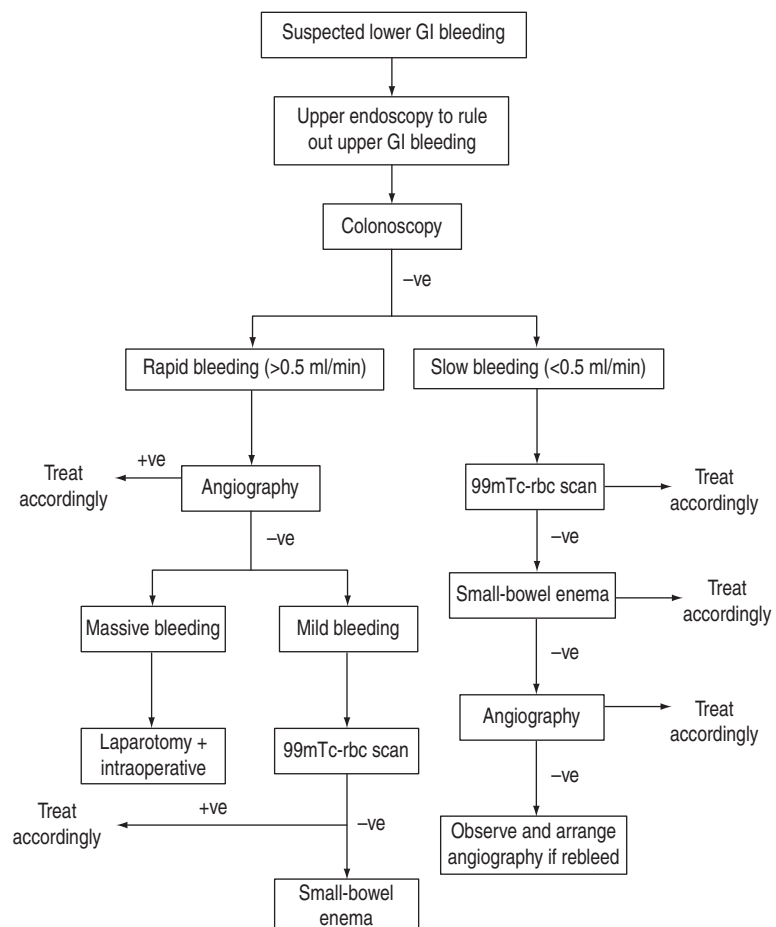

### ANGIOGRAPHY

Angiographic intra-arterial infusion of vasopressin or occlusion of the bleeding artery with embolic agents such as an absorbable gelatin sponge (Gelfoam) may be used in lower GI bleeding pathologies. Both diverticular bleeding and bleeding from angiodysplasia can be stopped by vasopressin infusion during angiography, but recurrence of bleeding frequently occurs with diverticular disease.

### SURGERY

Diverticular bleeding usually arises from a relatively large vessel, and may be difficult to control with endoscopic or angiographic therapy. Partial resection of the colon is warranted after localisation of the bleeding site. Surgery is also indicated in vascular anomalies when endoscopic treatment fails. When an obvious and refractory massive lower GI bleeding is not identified by endoscopic or angiographic examinations, immediate laparotomy with possible subtotal colectomy should be offered. A protocol to manage lower GI bleeding is shown in Figure 36.3.

# Severe acute pancreatitis

Duncan L A Wyncoll

Acute inflammation of the pancreas produces a spectrum of symptoms, which may be mild and self-limiting, or reflect severe disease that leads rapidly to multiple-organ failure and death. In a majority of patients a treatable underlying cause is identified. Although mild, interstitial, oedematous pancreatitis is more common, it is the more severe form, acute necrotising pancreatitis (ANP), that accounts for the associated mortality. Two decades ago the mortality was frequently quoted to be 25–35%, even in the best centres.<sup>1</sup> However, more recently published series have suggested a lower mortality (15%).<sup>2</sup> Management of patients with severe ANP is time-consuming, and labour- and resource-intensive. Long-term follow-up suggests that, although some survivors suffer permanent exocrine and endocrine insufficiency, most maintain a good quality of life.<sup>3</sup>

In the last 20 years there has been a gradual move towards aggressive supportive therapy for ANP. Numerous putative therapeutic interventions have been tried, but few have provided any objective evidence of clinical benefit.

## AETIOLOGY

Biliary disease and alcohol remain the two commonest causes of acute pancreatitis worldwide, accounting for 70% of cases. Although no discernible cause is found in many of the remaining cases, there are well-established associations with a number of infections, certain drugs, hyperlipidaemias and trauma. See Table 37.1 for a more exhaustive list.

## RANSON'S CRITERIA

Although the overall mortality rate for acute pancreatitis is approximately 10%, the vast majority of deaths occur in those with the severe form of the disease. Since 1974 the standard means of documenting the severity of disease and risk of mortality has been by Ranson's criteria (Table 37.2).<sup>4</sup> These factors were determined following the analysis of 100 patients with predominantly alcohol-induced pancreatitis using clinical and laboratory data obtained on admission and after 48 hours, and the number of positive criteria should predict outcome. A decade

later these criteria were re-evaluated and the first eight were found to be most predictive – this is now known as the Glasgow criteria, or Imrie score.<sup>5</sup>

## SCORING

The Acute Physiology and Chronic Health Evaluation (APACHE) II scoring system has also been used in predicting the severity of pancreatitis, and can be used daily throughout the patient's hospital admission rather than solely within the first 48 hours, thus potentially documenting progress or deterioration. However, such scoring systems are complex to perform and have only been evaluated prospectively 24–48 hours after the onset of pancreatitis, which means that the criteria may not be valid for patients subsequently admitted to the intensive care unit (ICU). Those factors with most predictive value for mortality include advanced age, presence of renal or respiratory insufficiency and presence of shock.

The scoring of patients with acute pancreatitis is important for a number of reasons. Firstly, the clinician can be alerted to the presence of potentially severe disease. Secondly, comparisons of severity can be made both within and between patient series; and thirdly, rational selection of patients can be made for inclusion in trials of potential new treatments or interventions. Unfortunately the scoring systems used at present are often inadequate in patients with severe ANP, which is characterised by rapidly progressive multiple-system organ dysfunction. In this setting the Ranson criteria and APACHE score do not take account of the effects of treatment upon measured parameters. The way forward may be to use a combination of the Ranson score, the radiological scoring systems (see below) and a descriptive organ failure score such as the Sepsis-related Organ Failure Assessment.<sup>6</sup>

## THE MANAGEMENT OF SEVERE PANCREATITIS

### IMAGING

Dynamic contrast-enhanced computed tomography (CT) provides the best means of accurately visualising the pancreas and diagnosing pancreatitis and its local

Blamey *et al.*<sup>5</sup> found only eight variables (not lactate dehydrogenase, base deficit and fluid deficit) were predictive and are often referred to as the Glasgow criteria or Imrie score.

complications. It may also be used for guiding percutaneous catheter drainage. Guidelines have been suggested for the efficacious use of CT scanning and these are shown in Table 37.3.<sup>7</sup>

In severe acute pancreatitis, there is lack of normal enhancement to contrast of the gland or a portion thereof. This is consistent with pancreatic necrosis, defined as diffuse or focal areas of non-viable parenchyma. Microscopically, there is evidence of damage to the parenchymal network, acinar cells and pancreatic ductal system and necrosis of perilobular fat. Areas of necrosis are often multifocal and rarely involve the whole gland, and may be confined to the periphery with preservation of the core. Necrosis develops early in the course of the disease and is usually established 96 hours after the onset of symptoms.<sup>8</sup> The extent of pancreatic necrosis and the degree of peripancreatic inflammation have been used to determine outcome. A grading system combining the two CT prognostic indicators (the extent of necrosis and the grade of peripancreatic inflammation) has been developed to give the 'CT severity index'. Most complications of acute pancreatitis occur in patients in whom the initial diagnosis is based upon peripancreatic fluid collections, and a strong correlation has been established between the CT depiction of necrosis and the development of complications and death.<sup>9</sup> For patients with necrosis in the pancreatic head, the outcome is as severe as when the entire pancreas is affected. By contrast, for patients with necrosis in only the distal portion of the gland, the outcome is favourable, with few complications.<sup>10</sup> The mechanism may be that necrosis in the pancreatic head causes obstruction of the pancreatic duct, and produces a rise in pressure in the acinar cells leading to damage and leakage of activated destructive proteases.

Following the initial CT scan, additional scanning is only indicated if the patient's clinical condition deteriorates, usually through the development of pancreatic necrosis, abscess or pancreatic pseudocyst, haemorrhage, or colonic ischaemia or perforation.

Ultrasonography in acute pancreatitis is less useful since visualisation of the gland may be obscured by 'gas-filled' bowel. Moreover, the degree of necrosis, which determines prognosis, cannot be assessed. However, there may be a role for this mode of imaging in

**Table 37.3** Guidelines for efficacious use of computed tomography scanning in suspected acute pancreatitis<sup>6</sup>

Patients in whom the clinical diagnosis is in doubt
Patients with hyperamylasaemia and severe clinical pancreatitis, abdominal distension, tenderness, high fever (> 39°C) and leukocytosis
Patients with Ranson score > 3 or APACHE II > 8
Patients showing lack of improvement after 72 hours of initial conservative therapy
Acute deterioration following initial clinical improvement

demonstrating gallstones, or in the subsequent management when ultrasound-guided fine-needle aspiration (FNA) of the pancreas or surrounding tissue may help to establish the presence of infection.

### SURGERY IN SEVERE PANCREATITIS

The role of surgery remains a controversial area in the management of severe ANP.<sup>11</sup> During the 1980s, most patients with acute pancreatitis of even moderate severity underwent operative intervention. The results were poor, with mortality rates in excess of 50%, although this was without ICU facilities. In 1991, Bradley and Allen introduced the concept of a conservative, non-surgical approach to severe ANP.<sup>12</sup> During the past decade, targeting surgical intervention according to infection status, based on Gram stain and culture of CT-guided FNA, has refined this conservative approach with beneficial results.<sup>13</sup>

A laparotomy for an acute abdomen is essential when the diagnosis of pancreatitis is in doubt. Surgery may increase the incidence of subsequent infection, but this risk is outweighed by the dangers of delaying the diagnosis and treatment of other serious intra-abdominal conditions. Accepted and controversial indications for surgery in severe ANP are summarised in Table 37.4. If severe acute pancreatitis is an unsuspected 'chance' finding at laparotomy, a T-tube should be inserted into the common bile duct, particularly if it has been explored and the opportunity taken for placement of a feeding jejunostomy tube. Some surgeons oppose this approach, as opening a hollow viscus risks peritonitis.

### INFECTED PANCREATIC NECROSIS

The presence of infected pancreatic necrosis seems to be an undisputed indication for urgent surgery. A contrast-enhanced CT scan documents necrosis, and infection is proven by FNA of localised fluid collections or of the necrotic tissue. All such patients require some form of surgical treatment, although whether this should consist of debridement and gravity drainage, continuous closed lavage of the lesser sac, staged repeated laparotomy or open packing remains to be established. Current surgical practice is not based on well-designed clinical trials and numerous surgical techniques have been described. Minimally invasive surgical techniques are gaining in

popularity, but no firm recommendations can be made at this stage.

### STERILE PANCREATIC NECROSIS

The observation that some patients with severe ANP survive without becoming infected and avoid surgery is well documented. Moreover, operating upon such patients may hypothetically increase the risk of subsequent infection and its associated mortality. This is the basis of the critical decision as to whether patients with sterile ANP should undergo operative intervention. Currently a conservative approach is recommended, but with regular surveillance looking for evidence of pancreatic infection.<sup>14</sup>

### PANCREATIC ABSCESSSES

Pancreatic abscesses are circumscribed collections of pus containing little or no pancreatic necrosis, which arise as a later consequence of acute pancreatitis or pancreatic trauma. They commonly occur about 3–4 weeks after the onset of severe pancreatitis, and CT scan most accurately makes the diagnosis. If the appropriate expertise is available, percutaneous catheter drainage may be successful. Some series report effective drainage of intra-abdominal collections with a single treatment in 70% of patients, increasing to 82% with a second attempt, although proceeding to open surgical drainage is more frequently required in pancreatic abscess, especially if complicated by yeast infection.<sup>15</sup>

### ENDOSCOPIC RETROGRADE CHOLANGIOPANCREATOGRAPHY (ERCP)

ERCP represents an alternative approach, particularly for patients with severe biliary pancreatitis. A number of prospective randomised studies have been carried out to compare early ERCP with conservative treatment in acute biliary pancreatitis. Although the studies are not entirely consistent, ERCP and papillotomy seem to be beneficial in confirmed or suspected severe biliary pancreatitis if undertaken by a skilled operator, whereas in mild pancreatitis the risks of intervention probably outweigh the benefits. This observation is confirmed by both a systematic review of the four ERCP trials,<sup>16</sup> and by the recommendations of the 2004 International Consensus Conference on the management of severe acute pancreatitis in the critically ill.<sup>17</sup>

### TREATMENT WITH PHARMACOLOGICAL AGENTS

Theories regarding the pathogenesis of acute pancreatitis have promoted the concept that autodigestion of the gland and peripancreatic tissue by activated pancreatic enzymes is a central component. This has led to the suggestion that the reduction of pancreatic exocrine secretion, thereby 'resting the pancreas', might improve outcome. The problem is that the secretory status of the

**Table 37.4** Indications for surgery in severe acute pancreatitis

Accepted	Controversial
Differential diagnosis	Stable but persistent necrosis
Persistent biliary pancreatitis	Deterioration in clinical course
Infected pancreatic necrosis	Organ system failure
Pancreatic abscess	Abdominal compartment syndrome

pancreas in severe ANP is not known. Consequently, it is not clear whether inhibition of secretion actually occurs or whether this is beneficial. Therapies designed to inhibit pancreatic secretion, such as H<sub>2</sub>-blockers, atropine, calcitonin, glucagon and fluorouracil, do not alter the course of the disease. However, other pharmacological therapies, such as aprotinin and gabexate mesilate, both protease inhibitors, and somatostatin and octreotide, are in widespread use in the hope of improving the outcome.

### SOMATOSTATIN AND OCTREOTIDE

Somatostatin and its long-acting analogue octreotide are potent inhibitors of pancreatic secretion. They also stimulate activity of the reticuloendothelial system and play a regulatory role, mostly inhibitory, in the modulation of the immune response via autocrine and neuroendocrine pathways. Both are cytoprotective with respect to the pancreas.<sup>18</sup> Other effects include:

- Somatostatin also blocks the release of tumour necrosis factor and interferon- $\gamma$  by peripheral mononuclear cells.
- Octreotide increases the phagocytotic activity of monocytes.

These actions may be important in the modulation of the pathogenesis of acute respiratory distress syndrome (ARDS) and septic shock, both of which can complicate severe ANP. Both agents are effective in experimental pancreatitis, and in the prevention of complications in patients undergoing surgery for chronic pancreatitis.<sup>19</sup> Potential difficulties include:

- Pre-emptive administration is not possible in the acute situation.
- Both agents are powerful splanchnic vasoconstrictors.
- The development of pancreatic necrosis has been linked to hypoperfusion of the gland and vasoconstrictors worsen the histological severity of experimental pancreatitis.<sup>20</sup>

Consequently, these agents have both beneficial and detrimental effects.

Systematic evaluation suggests that there is insufficient evidence at present to support the use of octreotide or somatostatin in the treatment of patients with moderate to severe acute pancreatitis.<sup>21</sup> Additionally, the therapeutic effect of octreotide, if present at all, is probably very small and therefore unlikely to have any significant impact on the management of ANP.

### PROTEASE INHIBITORS

A further pathogenic mechanism involved in acute pancreatitis is autodigestion of the pancreas by the activation of proteases. More accurately, there is an imbalance between proteases and antiproteases. Aprotinin and gabexate mesilate are proteolytic enzyme inhibitors that act on serine proteases such as trypsin, phospholipase A<sub>2</sub>, kallikrein, plasmin, thrombin and C1r and C1s esterases.

The only two prospective, randomised studies of the protease inhibitor gabexate mesilate in patients with moderate or severe pancreatitis, when combined, showed no significant reduction in mortality or the need for surgery.<sup>22</sup>

The reason why these agents, in clinical practice, do not have the expected beneficial effect on outcome may be the lag time between the onset of pancreatitis and administration. Additionally, derangement to the microvascular control of the pancreas combined with increased vascular permeability may contribute. Continuous regional arterial infusion or intraperitoneal administration may be more advantageous, but so far trials using these modes of administration have only involved small numbers of patients. At present, there is insufficient evidence to recommend protease inhibitors in ANP.<sup>23</sup>

### ANTI-INFLAMMATORY THERAPY

Patients with ANP exhibit a generalised uncontrolled inflammatory response. Potentially there is a therapeutic window between the onset of symptoms and the development of organ failure during which anti-inflammatory therapy might be successful. Potential targets include tumour necrosis factor- $\alpha$ , interleukin (IL)-1 $\beta$ , IL-6, IL-8, IL-10, platelet-activating factor and intracellular adhesion molecules.<sup>24</sup> Although many have been studied in animals, there are limited human data. Recombinant human activated protein C (rh-APC) has proven effectiveness in reducing mortality in severe sepsis.<sup>25</sup> Sixty-two patients with pancreatitis were enrolled in the PROWESS trial; mortality was 24% in the placebo arm and 15% in those receiving rh-APC.<sup>17</sup> All patients had a known or suspected source infection, which is not the case in many patients with ANP. There are currently no studies of rh-APC in patients without a documented source of infection, yet it seems that these patients demonstrate the same low levels of activity of protein C, antithrombin III, and higher concentrations of D-dimer and plasminogen activator inhibitor that are associated with poor outcome in patients with severe sepsis.<sup>26</sup>

It is also fascinating to observe that there is a constellation of changes in hypopituitary–adrenal axis hormone levels that strongly suggest that the existence of relative adrenocortical insufficiency in patients with ANP is very comparable to that of severe sepsis and multiple-organ failure.<sup>27</sup> There are currently no published trials of corticosteroid therapy in patients with ANP.

### PROPHYLACTIC ANTIBIOTICS

Bacterial infection of necrotic pancreatic tissue occurs in approximately 40–70% of patients with ANP, and infection is the major cause of morbidity and mortality.<sup>28</sup> Early studies investigating the role of antibiotics in acute pancreatitis showed no benefit, but most included patients with mild disease and employed agents (e.g. ampicillin) with inefficient penetration of pancreatic tissue. Subsequent studies are more encouraging.

Carbapenems have exceptional penetration into pancreatic tissues and broad activity against most of the

common pathogens encountered in this disease. One study compared imipenem with placebo in patients with early necrotising pancreatitis.<sup>29</sup> The incidence of septic complications was significantly reduced in the treated group (12.2 versus 30.3%), although there was only a trend towards decreased mortality (7 versus 12%). In another study of ethanol-induced ANP, cefuroxime was compared to placebo.<sup>30</sup> There were more infectious complications in the non-antibiotic group (mean per patient 1.8 versus 1.0;  $P < 0.01$ ) and mortality was also higher (7 versus 1 death;  $P = 0.03$ ). The most recent meta-analysis of the only three adequately controlled studies of prophylactic antibiotics in patients with contrast-enhanced CT proven ANP strongly suggests benefit, with a reduction in sepsis of 21%, and a reduced mortality of 12.3%.<sup>31</sup>

Patients with mild pancreatitis do not benefit from antibiotics.

#### PROPHYLACTIC ANTIFUNGAL THERAPY

The incidence of fungal infection correlates with the extent of pancreatic necrosis, as well as the severity of disease on admission. Antibiotic administration has been claimed to promote fungal infection; however, up to 25% of patients with ANP who do not receive antibiotics also develop fungal infection with an associated mortality rate of up to 84%.<sup>32</sup> One small, randomised study suggested fluconazole reduced the rate of fungal infection, but had no effect on mortality. Advocates of prophylactic antifungal therapy argue that it may delay the need for surgery, which is associated with a better outcome.<sup>33</sup>

#### SELECTIVE DECONTAMINATION OF THE GUT

The original selective digestive decontamination (SDD) strategy contained three components: oropharyngeal and gastric decontamination with polymyxin E, tobramycin, and amphotericin B and intravenous cefotaxime for 4 days.<sup>34</sup> There is ongoing debate as to the effectiveness of this strategy and results are conflicting regarding any reduction in mortality, particularly when applied to a general critically ill population. However, more promising results have been seen in specific patient populations.

Severe acute pancreatitis may be one clinical situation which supports the hypothesis that gut hypoperfusion promotes bacterial translocation, leading to infection of the inflamed pancreas and peripancreatic tissue.<sup>35</sup> The only controlled trial of SDD in pancreatitis was performed in 102 patients,<sup>36</sup> who were randomised to receive SDD: oral colistin, amphotericin and norfloxacin with addition of a daily dose of the three drugs given as a rectal enema and systemic cefotaxime until Gram-negative bacteria were successfully eliminated from the oral cavity and rectum. Surveillance samples were taken regularly to assess whether any subsequent infection was of exogenous or endogenous origin. There were 18 deaths (35%) in the control group, compared with 11 (22%) in the SDD group ( $P < 0.05$ ). This difference was caused by a fall in late mortality due to significant reduction in the

incidence of Gram-negative pancreatic infection. There was also a reduction in the mean number of laparotomies in the SDD patients. Since the SDD regimen used in this study incorporated intravenous cefotaxime it could be argued that the improvement in outcome was not due to the colistin, amphotericin or norfloxacin components, but merely due to a systemic antibiotic effect.

Meta-analyses of SDD suggest that there are clear trends towards a reduction in mortality in critically ill patients.<sup>37</sup> However, the perhaps unfounded fear of the emergence of resistant Gram-positive cocci prevents widespread adoption of this strategy.

#### NUTRITIONAL SUPPORT IN ACUTE NECROTISING PANCREATITIS

The provision of nutritional support for the patient with ANP is an essential component of supportive therapy, especially since many patients with pancreatitis are nutritionally depleted prior to their illness and face increased metabolic demands throughout the course of their disorder. Failure to reverse or prevent malnutrition, and a prolonged negative nitrogen balance, increases mortality rates. The route by which nutrition is administered is, none the less, still debated. In the last two decades there has been a trend away from the use of total parenteral nutrition (TPN) in favour of enteral nutrition (EN) in supporting the critically ill. Studies suggest that early EN started within 24 hours of admission to ICU, compared with TPN, is associated with reduced infective complications and hospital length of stay.<sup>38</sup>

#### TOTAL PARENTERAL NUTRITION

Severe pancreatitis is often quoted as an absolute contraindication to EN, and TPN is considered 'standard' therapy in some recently reported trials. This is largely because it is regarded as a way of 'resting the pancreas', based on the assumption that the necrotic pancreas is still a secretor of activated enzymes. In fact, the secretory state of the pancreas has never been prospectively studied in severe necrosis. Several retrospective and prospective evaluations of TPN in acute pancreatitis have failed to demonstrate conclusively an effect on survival, or on the incidence and severity of organ failure.

#### ENTERAL NUTRITION

An increasing number of reports on the use of EN in severe ANP continue to challenge the persisting dogma regarding the use of TPN in this condition. When EN is given it has been suggested that it should be delivered distal to the ligament of Treitz, below the area of the cholecystikinin (CCK) cells distal to the third part of the duodenum, as CCK stimulation may worsen the course of the disease. Intra-gastric delivery of nutrients results in an increased volume of pancreatic protein and bicarbonate secretion. By contrast, jejunal nutrient delivery is not associated with any increase in pancreatic exocrine secretion.

Consequently, jejunal tube feeding as far distally as possible in the upper gastrointestinal tract conforms to the concept of 'pancreatic rest'. A number of comparisons of EN with TPN have been made in mild and severe acute pancreatitis, all suggesting that EN is well tolerated without adverse effects on the course of the disease.<sup>39</sup> Patients who received EN experienced fewer total complications and were at lower risk of developing septic complications than those receiving TPN.<sup>40</sup> EN seems to modulate the inflammatory and sepsis response beneficially, and if tolerated, may be superior to TPN.<sup>41</sup> In spite of the enthusiasm for EN of some clinicians, in ANP where there is often an ileus and slow bowel transit time, some patients will not tolerate it.<sup>42</sup> It is not uncommon to be faced with the option of no nutrition or TPN; in this situation TPN enriched with glutamine should be used.<sup>43</sup>

A number of recommendations can be made:

1. Most patients with mild uncomplicated pancreatitis do not benefit from nutritional support.
2. In moderate to severe pancreatitis, let hyperacute inflammation settle, then start a trial of EN via a jejunal tube.
3. In patients who require surgery for diagnosis or treatment, a jejunal tube should be placed, either pulled down from the stomach, or a separate jejunostomy.
4. TPN (enriched with glutamine) is only indicated if a 5–7-day trial of EN is not tolerated.
5. In all patients, whether fed enterally or parenterally, a protocol ensuring strict glycaemic control is recommended.

## CONCLUSION

The main determinant of outcome in severe acute pancreatitis is the extent of pancreatic necrosis and the subsequent risk for the development of infected necrosis. A thorough assessment using appropriate scoring systems and the early use of dynamic contrast-enhanced CT will highlight those patients likely to benefit from early critical care. Despite numerous suggested specific therapies there is still no incontrovertible evidence that any one confers a significant mortality benefit. However, general supportive measures should include vigorous replacement of fluid losses to correct circulating volume, correction of electrolyte and glucose abnormalities, and respiratory, cardiovascular and renal support as necessary. Those patients with infected pancreatic necrosis should probably undergo surgery. Patients with sterile necrosis should receive a broad-spectrum prophylactic antibiotic that adequately penetrates pancreatic tissue. Due attention should also be paid to nutritional support, for which a jejunal feeding tube with EN is recommended prior to initiation of TPN.

# Acute liver failure

Elizabeth Sizer and Julia Wendon

## DEFINITION AND AETIOLOGY

Acute liver failure (ALF) is a complex multisystemic illness that evolves after significant liver insult. The liver damage is manifest by the development of coagulopathy and encephalopathy within days or weeks of the liver injury. ALF is a heterogeneous condition incorporating a range of clinical syndromes. The dominant factors that give rise to this heterogeneity are the variable aetiology, the age of the patient and concomitant comorbidity and the duration of time over which the disease evolves. There are multiple definitions used in this disease but the one used by O'Grady *et al.* is most commonly used, utilising the description of acute, hyperacute and subacute.<sup>1</sup> This system uses a trigger of jaundice and encephalopathy whilst others have used symptoms of encephalopathy. All the definitions used recognise that the syndrome may have a rapid presentation or a somewhat slower presentation, and the clinical features and outcomes are significantly different in the two presentations.

The O'Grady *et al.* definitions are given below.

- *hyperacute*: the onset of encephalopathy is within 7 days of the development of jaundice
- *acute*: encephalopathy develops 8–28 days after the onset of jaundice
- *subacute*: encephalopathy develops 4–26 weeks after the onset of jaundice

## HYPERACUTE DISEASE

Prevalent aetiologies in hyperacute disease include:

- paracetamol (acetaminophen)
- ischaemic
- viral
- toxins

This group will frequently demonstrate the greatest degree of coagulopathy, encephalopathy, organ dysfunction and cerebral oedema but also carries the greatest chance of spontaneous survival.

## SUBACUTE DISEASE

The aetiology is more frequently seronegative or idiopathic and drug-related, e.g. non-steroidal. Jaundice is

inevitable but the transaminitis is often less pronounced than in the former group. Patients frequently present with established ascites and so may be clinically difficult to distinguish from chronic liver disease (CLD). Encephalopathy is often late and carries a lower risk of cerebral oedema and intracranial hypertension. Once they develop poor prognostic criteria the chances of effective liver regeneration and thus of spontaneous recovery are low: the prognosis is very poor without liver transplantation.

The aetiology of ALF must always be sought, not just for prognosis but for treatment options (Table 38.1).

The relative incidence of aetiologies varies across the world. Paracetamol is common in the UK, USA and Denmark, whereas hepatitis B is more common in France. A recent paper from the USA Acute Liver Failure group highlights the increasing incidence of paracetamol toxicity and also the potential role it plays as a covert agent in patients with no history of excess ingestion and non-specific symptoms that would otherwise be attributed to the seronegative group.<sup>2</sup> The rate of hepatitis B virus-induced ALF is decreasing with immunisation but is still highly prevalent and should always be considered.

A good history and review of the results of blood tests over the preceding weeks can be essential to the diagnosis. Any new drug ingestion (prescribed, recreational or over-the-counter) should be considered a potential culprit and discontinued if possible. In addition any treatments that may be detrimental to liver recovery should be avoided.

Acute viral hepatitis accounts for 40–70% of patients with ALF worldwide. Clinical characteristics are shown in Table 38.2. Acute hepatitis A (HAV) infection rarely leads to ALF (0.35% of infections), but continues to account for up to 10% of cases; morbidity increases with the age of infection. It is hoped that the rate will decrease with improving hygiene standards generally and the uptake of vaccination. It is diagnosed by the presence of the immunoglobulin (Ig) M antibody to HAV. HAV-related ALF has a relatively good prognosis, although age and comorbidity are relevant.

Acute hepatitis B (HBV) has been the cause of 25–75% of instances of ALF from viral hepatitis. The liver injury is immunologically mediated with active destruction of infected hepatocytes. Diagnosis is by the

**Table 38.1** Causes of liver failure

Cause	Agent responsible
Viral hepatitis	Hepatitis A, B, D, E, cytomegalovirus, herpes simplex virus, seronegative hepatitis (14–25% of cases in the UK)
Drug-related	Dose-related, e.g. paracetamol, and idiosyncratic reactions, e.g. antituberculous drugs, statins, recreational drugs, anticonvulsants, non-steroidal anti-inflammatory drugs, cyproterone and many others
Toxins	Carbon tetrachloride, <i>Amanita phalloides</i>
Vascular events	Ischaemic hepatitis, veno-occlusive disease, Budd–Chiari, Heatstroke
Other	Pregnancy-related liver diseases, Wilson's disease, lymphoma, carcinoma, trauma

presence of the IgM antibody (HBcAb) to hepatitis B core antigen. Hepatitis B surface antigen (HbsAg) is frequently negative by the time of presentation. Hepatitis B DNA should also be assayed. ALF may also be seen with hepatitis D, as either a coinfection or superinfection. Reactivation of hepatitis B is an increasing cause of ALF and should always be considered in a patient who has received steroids or chemotherapy. High-risk patients should be screened for sAg and HBV DNA and treated with antiviral agents if they are positive. This is a recognised problem in oncology and haematology but it is also a potential risk to patients in intensive care where steroids may be administered.

Hepatitis C (HCV) infection is commonly associated with CLD. It is detected by the presence of antibodies to HCV in serum. It rarely if ever results in ALF.

Hepatitis E (HEV), like hepatitis A, is transmitted via the faecal–oral route. It is particularly prevalent in the Indian subcontinent and Asia generally and is responsible for sporadic instances of ALF in the western world. It can be diagnosed by the detection of antibodies to HEV in serum.

Other viruses, such as herpes simplex 1 and 2, varicella-zoster virus, cytomegalovirus, Epstein–Barr virus and measles virus, may all rarely cause ALF, but may be seen especially in the immunocompromised patient. Diagnosis is by serological and polymerase chain reaction (PCR) testing. Rift Valley fever, dengue, yellow fever, lassa fever and the haemorrhagic fevers should be considered in those who are at risk.

Seronegative hepatitis (so called) is seen in patients in whom there are no identifiable viral causes nor obvious candidate drugs. Such patients may present with a prodromal illness and with acute or subacute manifestations of the disease. Prognosis is less good than those with an identifiable virus and once they have poor prognostic criteria the chances of survival without liver transplant are exceptionally small. A subgroup may represent an acute autoimmune form of ALF, although many will not have any positive immune markers such as elevated IgG or positive smooth-muscle or liver kidney antibodies. The pattern of markers shows an increased incidence of auto-antibody positivity in seronegative cases and viral cases with elevated IgM in viral causes.<sup>2,3</sup>

**Table 38.2** Aetiology of acute liver failure and initial investigations

Hepatitis A (HAV)	Immunoglobulin M (IgM) anti-HAV
Hepatitis B + D (HBV, HDV)	HbsAg, IgM anti-core, HBeAg, HBeAb, HBV DNA, delta antibody
Hepatitis E (HEV)	IgM antibody
Seronegative hepatitis	All tests negative: diagnosis of exclusion
Paracetamol	Drug levels in blood and clinical pattern of disease – may be negative on third or subsequent days after overdose; markedly elevated aspartate and alanine serum transaminase (often > 10 000)
Idiosyncratic drug reactions	Eosinophil count may be elevated, although most diagnoses are based on temporal relationship
Ecstasy	Blood, urine, hair analysis and history
Autoimmune	Autoantibodies, immunoglobulin profile
<b>Pregnancy-related syndromes</b>	
Fatty liver	Uric acid elevated, neutrophilia, often first pregnancy, history, CT scan for rupture and assessment of vessels
HELLP syndrome	Platelet count, disseminated intravascular coagulation a prominent feature; CT scan as above
Liver rupture	May be seen in association with pre-eclampsia, fatty liver and HELLP
Wilson's disease	Urinary copper, ceruloplasmin (although low in many causes of acute liver failure), present up to second decade of life, Kayser–Fleischer rings, low alkaline phosphate levels
<i>Amanita phalloides</i>	History of ingestion of mushrooms, diarrhoea
Budd–Chiari syndrome	Ultrasound of vessels (HV signal lost, reverse flow in portal vein), CT angiography, ascites, prominent caudate lobe on imaging, haematological assessment
Malignancy	Imaging and histology; increased alkaline phosphate and LDH; often imaging may be interpreted as normal
Ischaemic hepatitis	Clinical context, marked elevation of transaminases (often > 5000); may demonstrate dilated hepatic veins on ultrasound, echocardiogram
Heatstroke	Myoglobinuria and rhabdomyolysis are often prominent features

CT, computed tomography; HELLP, haemolysis (microangiopathic haemolytic anaemia), elevated liver enzymes and low platelets; HIV, human immunodeficiency virus; LDH, lactate dehydrogenase.

Drug-induced hepatitis is responsible for approximately 15–25% of cases of ALF. In some patients there appears to be a true hypersensitivity reaction, and symptoms develop after a sensitisation period of 1–5 weeks, recur promptly with readministration of the drug and may be accompanied by fever, rash and eosinophilia. In others the clinical pattern is less acute. Some herbal remedies are implicated as putative hepatotoxins but their role is made more difficult to assess by the variable nature of the constituent parts. Halothane hepatitis is now almost unheard of.

Paracetamol, taken intentionally or inadvertently, remains one of the commonest forms of acute hepatotoxicity. The early signs of nausea and vomiting after overdose are followed by signs of liver failure 48–72 hours after paracetamol ingestion. Treatment is with *N*-acetylcysteine, which increases hepatic stores of glutathione and metabolism of the toxic metabolite.

The recommended dosage schedule is 150 mg/kg in 5% dextrose over 15 minutes, followed by 50 mg/kg in 5% dextrose over 4 hours, followed by 100 mg/kg in 5% dextrose over 16 hours.

Even late administration of *N*-acetylcysteine (up to 36 hours after ingestion) may improve outcome. Predisposition to paracetamol-induced hepatotoxicity may occur in the following instances:

- heavy chronic alcohol ingestion
- enzyme-inducing agents
- glutathione-depleted, e.g. anorexics

Mushroom poisoning can be seen even when only very small amounts have been ingested, e.g. *Amanita phalloides*. The initial presentation is often with diarrhoea. Patients subsequently develop signs of hepatic necrosis

at 2–3 days after ingestion. The liver injury is caused by amatoxins. Forced diuresis may be helpful as large amounts of toxin are excreted in urine, but inadvertent dehydration may result in renal failure. Thiocetic acid, silybinin and penicillin have been advocated as therapy, but have not been subjected to controlled trials.

### RECREATIONAL DRUGS AND ACUTE LIVER FAILURE

Ecstasy (methylenedioxymethamphetamine) may cause ALF although, given the amount of exposure to the drug, the incidence is presumably low. Proposed mechanisms of injury include immune mechanisms and/or heatstroke. Cocaine may result in an ischaemic hepatitis. Yellow phosphorus, carbon tetrachloride, chloroform, trichloroethylene and xylene (in glue sniffers) are very rare causes of ALF.

Miscellaneous causes account for a small proportion of cases of ALF but are very important to recognise.

### FULMINANT WILSON'S DISEASE

The characteristic features are those of cirrhosis, seen on imaging, with concomitant problems such as thrombocytopenia which may be long-standing, Kayser–Fleischer rings on examination and frequently non-immune-mediated haemolysis.

Pregnancy-related liver failure includes HELLP (*h*aemolysis (microangiopathic haemolytic anaemia), *e*levated *l*iver enzymes and *l*ow *p*latelets), acute fatty liver of pregnancy and liver rupture, often in association with pre-eclampsia. The prognosis of pregnancy-related ALF is usually good, although some develop severe liver injury with small-vessel disease, liver ruptures may require packing and occasionally transplantation is required (Figure 38.1).

**Figure 38.1** Liver CT in pregnancy related liver disease demonstrating abnormal perfusion (a and b) with rupture, packing (a) and associated areas of infarction. Major bleeding into the liver.

Heat shock injury is now relatively rarely seen but the ischaemic hepatitis remain relatively common. They are normally associated with a congested liver that is subjected to a secondary insult – hypoxia or decreased-flow arterial inflow. This is seen with hypoxaemic respiratory failure, cardiac arrhythmias and hypotension.

Hepatic venous obstruction (Budd–Chiari syndrome) may cause ALF. There are symptoms and signs of liver of necrosis, often with capsular pain from congestion and ascites. In Asia this may be associated with anatomical anomalies of the inferior vena cava, whereas in Europe and the USA the experience is normally of thrombosis of the hepatic veins, often with an underlying procoagulant condition (Figures 38.2 and 38.3).

Malignancy may also present with ALF, albeit rarely. The clinical pattern normally is that of elevated biliary

enzymes in addition to the transaminases. This pattern of disease may be seen in those with hepatic lymphoma, often with an elevated lactate dehydrogenase or indeed with diffuse infiltration with other malignancies.

## DIAGNOSIS

The aetiology of ALF must be accurately identified; some specific investigations are outlined in Table 38.2. History and clinical examination are paramount in this disease and the clinical course of biochemical and haematological parameters is important in assessing course and management. All patients should have routine chemistry, haematology and coagulation assessment; viral and autoimmune profiles should similarly be undertaken in all.

Ultrasound should be used to assess both the nature of the liver and its vascular pattern and will show the presence of ascites and splenomegaly if present.

Nodularity of the liver should not be assumed to represent cirrhosis and CLD. The imaging pattern of subacute liver failure, with focal areas of collapse and regeneration, may be inappropriately considered cirrhosis. The contribution of histology to the assessment of ALF is controversial. Histologic features may suggest specific diagnoses, including malignant infiltration, Wilson's disease (cirrhosis) and autoimmune features. Confluent necrosis is the commonest histological finding, which is not diagnostic. Its severity has been used to assess prognosis: > 50% necrosis is associated with poor prognosis. However, nodules of regeneration may occur randomly, particularly in subacute liver failure, and sampling error may thus make this a less than ideal tool for predicting outcome. Diagnostic clues may sometimes be found, however, and it is especially relevant if there is any concern with regard to lymphoma or other malignant process.

The biopsy is normally undertaken by the transjugular route.

## SPECIFIC TREATMENTS

The management of ALF is largely supportive, providing an optimal environment for either regeneration or stability until a suitable liver becomes available.

## SPECIFIC CONSIDERATIONS

*N*-acetylcysteine is administered for paracetamol-induced ALF, as mentioned above. Its role in non-paracetamol-induced ALF remains undefined and a US trial is at present assessing this.

Chelating agents are not of benefit in patients with established ALF secondary to Wilson's disease but play an important role in chronic presentations. Withdrawal

**Figure 38.2** CT of Budd Chiari demonstrating arterio portal shunting and clot in Hepatic veins and IVC.

**Figure 38.3** Budd–Chiari liver. Arrow shows liver necrosis; ischaemic/infarcted liver.

of such treatments, or indeed non-compliance, especially in teenagers, may precipitate ALF.

Antiviral therapy has a predominant role in preventing reactivation of hepatitis B in patients exposed to chemotherapy and steroids.

Thrombolytic therapies may be of benefit in patients with early acute Budd–Chiari syndrome, although increasingly the treatment option would be to undertake a trans-hepatic portosystemic shunt (TIPS) shunt, decompressing the liver with a stent passed either through the hepatic vein (if the clot is soft enough) or via the inferior vena cava and through to the portal vein. Such procedures should be undertaken in units with the facilities to transplant as there is a risk of precipitating ALF. Chemotherapy may be offered to those with lymphoma involving the liver and in these instances tissue is paramount, either of liver or from another diagnostic site.

Steroid therapy is beneficial in acute autoimmune hepatitis but its role in autoimmune ALF has been less clear. A recent publication from the Paris group suggests that steroids for those with established ALF are potentially detrimental.<sup>4</sup>

## CLINICAL COURSE, COMPLICATIONS AND MANAGEMENT

### ENCEPHALOPATHY

This is part of the syndrome of ALF. The spectrum extends from mild confusion progressing to deep coma, cerebral oedema and raised intracranial hypertension. ALF is also associated with renal, cardiovascular and respiratory failure along with significant metabolic disarray and coagulopathy.

### COAGULOPATHY

Coagulopathy is the hallmark of ALF, with prolongation predominantly of the prothrombin time and to lesser degrees the activated partial thromboplastin ratio (APTR). In a small percentage of patients the coagulopathy will respond, at least partially, to vitamin K. Intravenous vitamin K 10 mg is normally administered.

Thrombocytopenia is frequent and normally consumptive in nature. Bleeding is rare, although may be seen in those with severe prolongation of APTR, low fibrinogen and severe thrombocytopenia. Coagulation or repletion of coagulation factors is necessary for clinical bleeding and prophylactically before major invasive procedures. Coagulation support is normally not given routinely so that the international normalised ratio (INR) can be monitored with regard to prognosis.

### ENCEPHALOPATHY

Hepatic encephalopathy encompasses a wide spectrum of neuropsychiatric disturbances associated with both acute and chronic liver dysfunction. Importantly, encephalopathy in ALF may be complicated by cerebral oedema and progress from minor levels to deep levels of coma with great rapidity. This has to be considered when transferring patients with ALF between hospitals. Intubation and sedation prior to undertaking any transfer should be considered in any patient with progressive encephalopathy.

Encephalopathy is a clinical diagnosis, graded from 1 to 4 depending on clinical severity (Table 38.3). The development of encephalopathy is essential for the diagnosis of ALF. Patients with acute and hyperacute liver failure are at greatest risk of developing grade IV coma and cerebral oedema.

Clear aetiological factors in the development of encephalopathy remain under discussion but it is believed that there is a build-up of putative toxins, of which ammonia is thought to be most pertinent, resulting in glutamine intracerebral accumulation and the development of cerebral oedema.<sup>5–7</sup> In ALF there is a clear relationship between the development of higher grades of coma and arterial ammonia levels (cut-off between 150 and 200  $\mu\text{mol/l}$ ) renal dysfunction and aetiology.<sup>8–10</sup> The relationship in CLD exists but is less clear.

The development of cerebral oedema and intracranial hypertension in patients with ALF is thought to relate, amongst other things, to the speed of onset. In patients with CLD, adaptation occurs and there is improved control of intracellular osmolarity (myoinositol) so that cellular oedema is rare and of low grade.<sup>11</sup>

**Table 38.3** Modified Parsons–Smith scale of hepatic encephalopathy

Grade	Clinical features	Neurological signs	Glasgow Coma Score
0/subclinical	Normal	Only seen on neuropsychometric testing	15
1	Trivial lack of awareness, shortened attention span	Tremor, apraxia, incoordination	15
2	Lethargy, disorientation, personality change	Asterixis, ataxia, dysarthria	11–15
3	Confusion, somnolence to semistupor, responsive to stimuli	Asterixis, ataxia	8–11
4	Coma	± Decerebration	< 8

The association between the development of encephalopathy and markers of inflammation is well demonstrated, both in regard to systemic inflammatory response syndrome (SIRS) markers and inflammatory mediators such as tumour necrosis factor.<sup>12,13</sup> Curiously, a similar relationship between inflammation and encephalopathy is seen in patients with CLD.<sup>14</sup> What is not yet clear is whether treatments that modulate the inflammatory response will be of benefit. This and other avenues proposed from basic animal research may well result in several novel approaches to the treatment of cerebral oedema and possibly encephalopathy over the forthcoming years.

Cerebral blood flow shows marked variability in patients with ALF. Hyperaemia has increased prevalence in those who develop intracranial hypertension. The role of hyperventilation has not been shown to be beneficial in routine management but plays a role in the treatment of increased intracranial pressure (ICP) with associated hyperaemia.<sup>15</sup>

The clinical management of the cerebral complications of ALF has been developed pragmatically and by the extrapolation of data from the neurosurgical literature rather than from the results of large randomised controlled clinical trials. Patients whose conscious level deteriorates to grade 3/4 coma should undergo elective intubation, sedation and ventilation. Sedation may be undertaken with a variety of compounds but the standard would be to utilise an opiate and a sedative such as propofol.

Cerebral perfusion pressure of greater than 60 mmHg has been suggested as optimal. It is of note that patients with ALF often do not autoregulate to pressure and consequently increases in blood pressure may be associated with increased cerebral blood flow and potentially increased ICP, particularly if they are at a critical point on their pressure–volume curve. This promotes the use of ICP monitoring in patients requiring pressor agents.<sup>8</sup> Cardiovascular failure necessitates invasive monitoring to optimise treatment and to determine the optimal therapeutic agents. The issue of noradrenaline (norepinephrine) versus vasopressin or terlipressin is difficult. In one study terlipressin resulted in a significant increase in ICP but in another there were no such detrimental effects.<sup>14,16</sup> It may be that the effects of terlipressin are highly individual and potentially time course-dependent, again supporting the role of ICP monitoring in these situations.

### CARBON DIOXIDE

In most patients normocapnia is ideal as the relationship between cerebral blood flow and arterial CO<sub>2</sub> is maintained.

The complexity of these patients defines the importance of multimodule monitoring being considered in all patients with ALF who develop grade III/V coma, and especially those who are deemed high-risk. These

include those with respiratory dysfunction, of young age, hyperacute and acute presentations, renal failure, fever and other SIRS markers or any patients on vasopressors.

Arterial ammonia – both the level (levels greater than 150–200 µmol/l) and the failure of this level to fall with treatment – may help in prognostication.<sup>8,10</sup> The monitoring may comprise reverse jugular monitoring, middle cerebral artery Doppler measurements and ICP monitoring. ICP monitoring is more controversial as it has not been shown specifically to improve outcome (few monitoring devices in isolation have altered outcome). A recent retrospective study from the US Acute Liver Failure group showed that ICP monitoring carried a complication rate of 10%: half of the complications were serious and two-thirds possibly contributed to mortality. Monitoring did result in more treatment interventions being undertaken.<sup>17</sup>

Coagulation problems and the risk of bleeding associated with monitoring may be minimised by a combination of coagulation support at the time of placement and technical expertise. Some centres support coagulation at the time of insertion with plasma products and platelets whilst others utilise recombinant factor VII.

A standard baseline approach to the management of patients with ALF and grade III/IV coma would be as follows.

Appropriate sedation and ventilation – hypercarbia should be avoided, although in the setting of acute lung injury, lung-protective strategies should be undertaken, probably in conjunction with cerebral monitoring so as to ensure optimal manipulation of the physiological variables.

Hyponatraemia and hyperammonaemia have been shown to be detrimental, whereas a randomised controlled trial showed benefit to the patients whose serum Na was maintained between 140 and 150 mmol/l. (Bolus hypertonic saline, 30%, was used for episodes of ICP greater than 25 mmHg.)<sup>18</sup>

Cerebral perfusion pressure should be optimised using ICP monitoring to ensure that changes in mean arterial pressure do not compromise cerebral perfusion pressure.

Sustained ICP rises beyond 25 mmHg require treatment. First-line treatment remains mannitol 0.5 g/kg given as a bolus with an appropriate subsequent diuresis. It is essential that serum osmolarity is maintained at less than 320 mosmol to avoid damage to the blood–brain barrier and worsening of vasogenic oedema. Increasingly hypertonic saline may also be utilised in this setting.

Some patients remain resistant to treatment and in these cases other therapies may be considered. Hypothermia has been shown to decrease cerebral blood flow, decrease ICP and decrease cerebral ammonia uptake in one clinical study.<sup>19,20</sup> The role of hypothermia as an early preventive intervention in grade III/IV coma is contentious and, given the problems of hypothermia in

the neurosurgical arena, the results of controlled studies are awaited. Fever should be avoided in these patients and hypothermia reserved for intracranial hypertension that is resistant to standard treatment.

Other treatment options that have been shown to be potentially beneficial are thiopental and intravenous indomethacin (0.5 mg/kg).<sup>21</sup> Potential monitoring and treatment algorithms, as used by this unit, are seen in Figure 38.4.

### SEPSIS

Sepsis is common in ALF and both culture-positive and negative SIRS are seen in ALF patients. They are functionally immunosuppressed in terms of impaired cell-mediated immunity, complement levels and phagocytosis.<sup>22</sup> Functional immunoparesis can only be observed and depression of human leukocyte antigen (HLA) DR expression correlates with prognosis and severity of liver injury.<sup>23,24</sup> As such, scrupulous attention with regard to hand-washing and line care needs to be applied to decrease the risk of nosocomial infection. Regular culture screens are required and antimicrobials are indicated in patients with any clinical suggestion of sepsis. Prophylactic intravenous antifungals should be considered, especially in those listed for transplantation. The choice of antimicrobial agent should be driven by local resistance patterns. Antimicrobial therapy should be reviewed in the light of culture results on a daily basis.

### CARDIOVASCULAR

Patients with ALF develop a hyperdynamic circulation with peripheral vasodilation and central volume depletion. Hypotension is common and may initially respond to volume repletion. Assessment of volume responsiveness in the clinical setting may be difficult and pressure measurements are a poor indicator of volume status. Hypotension that does not respond to volume will normally require some form of invasive haemodynamic monitoring and frequently institution of vasopressor agents. Increasingly it is recognised that volume responsiveness, as in general intensive care unit patients is best determined by dynamic rather than static variables.

The requirement for pressor agents should raise the possibility of adrenal dysfunction. Patients with ALF have been demonstrated to have impaired response to adrenocorticotrophic hormone (ACTH).<sup>25, 26</sup> The response at 30 and 60 minutes in terms of cortisol should be examined following 250 µg ACTH in all patients with ALF who are requiring pressor agents. A subnormal response should result in consideration of hydrocortisone replacement therapy, normally given for a period of 10 days. Interestingly, adrenal dysfunction has similarly been reported in acute-on-chronic liver failure and steroid replacement may result in improved outcome.<sup>26,27</sup>

Elevated troponin levels can be observed in patients with liver failure, especially those with cardiovascular failure.<sup>28</sup>

### RESPIRATORY

Ventilatory support is frequently required in patients with ALF, usually because of decreased conscious level rather than hypoxia, at least in the initial stages of disease.

Common respiratory complications are pleural effusions, atelectasis and intrapulmonary shunts. Acute respiratory distress syndrome (ARDS) and acute lung injury may be seen and can be precipitated by extrapulmonary sepsis or inflammation.

Ventilatory strategies are influenced by both the respiratory and the multiorgan involvement that is characteristic of ALF. Thus patients with deep levels of coma and at risk of cerebral oedema will require close attention to CO<sub>2</sub> levels and tailored sedation regimens. Hypercapnia may have to be tolerated in patients progressing to ARDS. This requires balancing against the cerebral needs of these patients as hypercarbia and increased cerebral blood flow will tend to increase ICP. Pleural effusions may require drainage if they are impeding ventilation. Weaning may be facilitated by undertaking tracheostomy during the recovery period of ALF.

### RENAL

Renal failure is common, with an incidence as high as 50%. This is particularly the case with paracetamol-induced liver failure, where the drug may also exert a directly toxic effect on the renal tubule. The aetiology of acute renal dysfunction is frequently multifactorial, with hepatorenal failure being a rare occurrence. Acute tubular necrosis and prerenal renal failure are more common precipitants. As such, volume therapy and maintenance of intrathoracic blood volume are essential in the management of such patients, as is the avoidance of nephrotoxins. Intra-abdominal hypertension is frequent and may reduce renal perfusion pressure and contribute to renal dysfunction; the measurement of intra-abdominal pressure may be a valuable component of monitoring.

Established renal failure requires the institution of renal replacement therapy (RRT). In patients with ALF early consideration should be given to RRT to control fluid balance and acid-base disturbances and to avoid rapid changes in osmolarity. It may limit or control elevations of arterial ammonia and retard the development of cerebral complications. The haemodynamic instability and associated cerebral complications of this patient group have resulted in the application of continuous modes of RRT rather than intermittent haemodialysis. Inability of the liver to metabolise and utilise lactate or acetate buffer solutions results in the use of bicarbonate buffers. Extrapolation from data in critically ill patients with acute renal failure suggests that the optimal filtration rate is 35 ml/kg per hour.

### ANTICOAGULATION AND COAGULOPATHY

A balance needs to be achieved between risk of bleeding and platelet protection across an extracorporeal filter. A prostaglandin such as epoprostenol may be advantageous

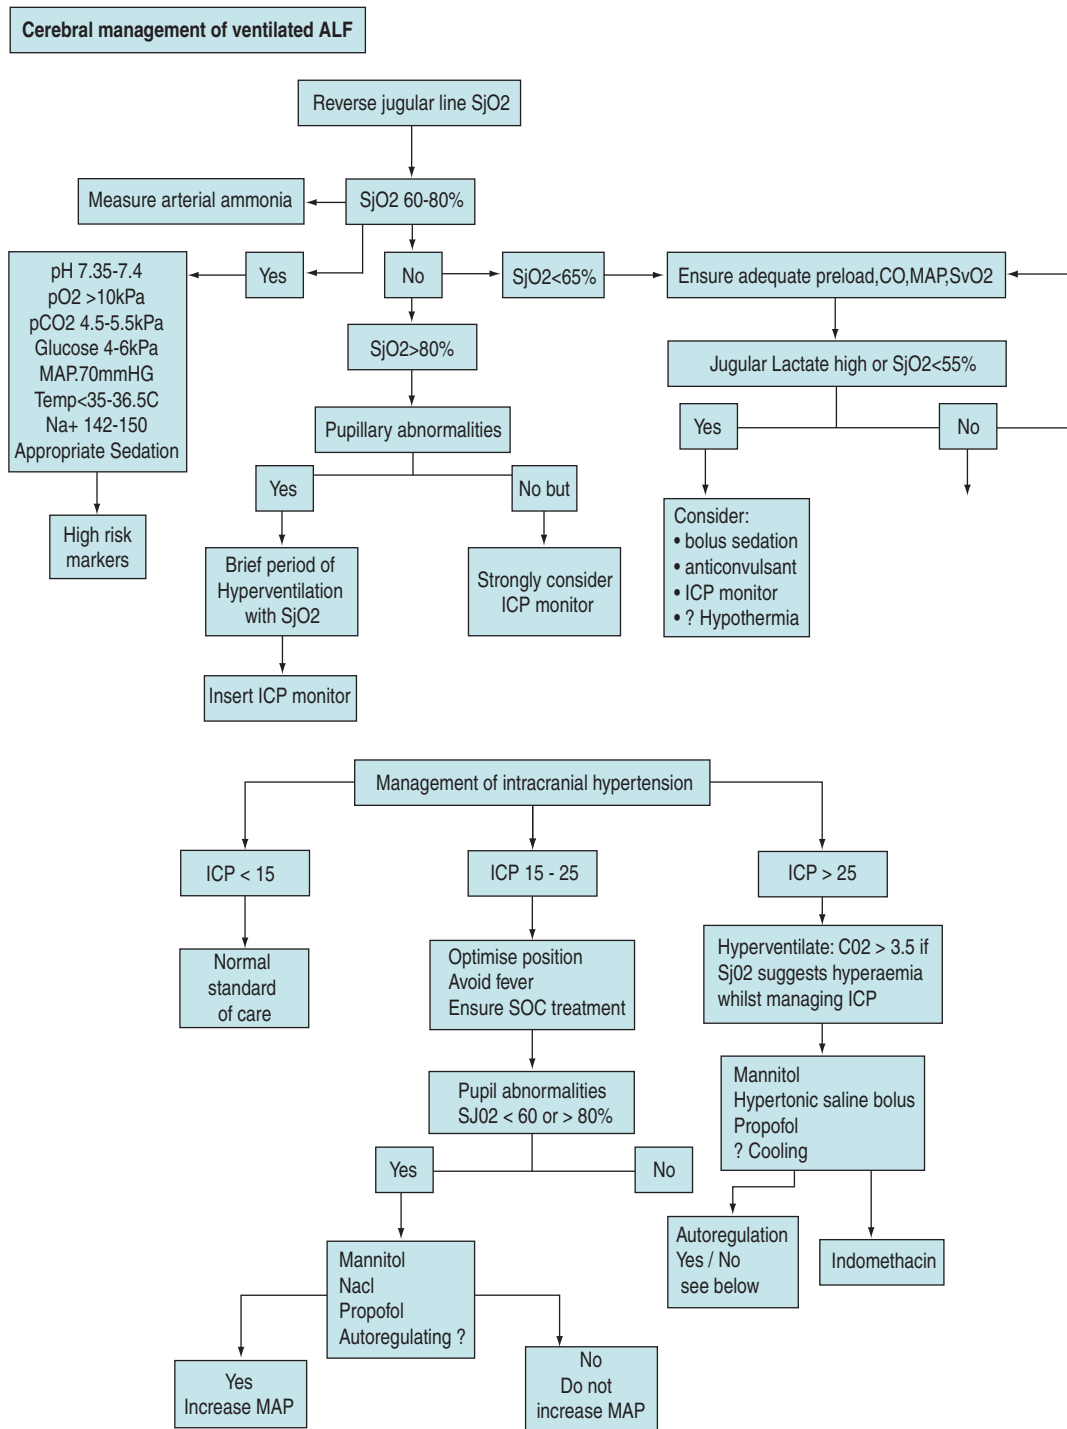

Figure 38.4 Treatment of raised intracranial pressure.

in terms of decreasing bleeding and prolonging filter life. Alternatively, circuits may be run without anticoagulation, with regional heparin or citrate or low-dose systemic heparin. In patients with thrombocytopenia consideration should be given to the diagnosis of heparin-induced thrombocytopenia and, if confirmed, heparin should be withdrawn and circuits primed with an alternative agent, e.g. lepirudin.

### METABOLIC AND FEEDING

Enteral nutrition should commence as soon as feasible after admission if there are no contraindications. In patients with large aspirates (> 200 ml/4 hours) a prokinetic agent should be commenced: erythromycin (250 mg intravenously 6-hourly) appears to be more effective than metoclopramide. Endoscopic placement of a postpyloric feeding tube should be considered in refractory cases, although this may need to be delayed in patients with or at risk of cerebral oedema. In patients with profound coagulopathy, placement of a nasogastric tube may be associated with nasal/pharyngeal bleeding and oral tube placement may be preferred in ventilated patients. The optimal nature of enteral feed used has not been investigated but metabolic data on these patients demonstrate increased calorific requirements.<sup>27,29</sup> Patients with ALF demonstrate both peripheral and hepatological insulin resistance.<sup>30</sup> Tight glycaemic control would seem reasonable in this population.

Metabolic acidosis is a relatively frequent occurrence that may relate to lactic acidosis, hyperchloraemic acidosis or renal failure.

Hyperlactataemia may be secondary to volume depletion and hence will resolve with appropriate fluid loading or may reflect the inability of the liver to metabolise the lactate produced. A failure of blood lactate to normalise following volume loading is associated with a poor prognosis.<sup>30,31</sup> Metabolic acidosis may be a secondary effect of other drugs ingested as part of an episode of self-harm. Falls in serum phosphate levels are seen in ALF associated with liver regeneration and are associated with a good prognosis in paracetamol-induced ALF.<sup>32</sup> Pancreatitis is a common complication of ALF and should be actively sought.

### SPECIFIC TREATMENTS

Very few specific treatments are of proven benefit. *N*-acetylcysteine is useful for paracetamol-related liver failure. There are specific antiviral therapies to prevent reactivation of hepatitis B in at-risk individuals.

Therapies should aim to provide an environment for liver regeneration or stability until a suitable liver is available for orthotopic transplantation. The role of extracorporeal liver support systems remains a hope for the future but at present no system has been shown to have a definitive survival benefit in a controlled trial.

### PROGNOSIS

Prognostication is important in the management of ALF. It is essential to identify those patients who will not survive without liver transplant but also to identify those who will succumb even if offered such a procedure.<sup>33</sup> Several risk stratification systems are presented in Table 38.4. The most commonly used are those of O'Grady and Clichy. The model for end-stage liver disease (MELD) has also been examined with regard to prognosis in ALF and may be particularly useful in non-paracetamol cases.<sup>34</sup> It is essential that such systems are rigorously applied and in the context of paracetamol are only utilised at least 24 hours postingestion and following appropriate volume resuscitation.

### CIRRHOSIS AND ACUTE-ON-CHRONIC LIVER DISEASE

This is the commonest form of liver disease presenting to the intensive care environment. The commonest precipitants are:

- encephalopathy
- sepsis
- renal failure
- variceal bleeding
- cardiorespiratory failure

**Table 38.4** Prognostic criteria for acute liver failure

<b>O'Grady criteria</b>
<b>Paracetamol-related</b>
Acidosis (pH < 7.3) <i>or</i>
Prothrombin time of > 100 seconds (INR > 6.5), creatinine > 300 mol/l and grade III/IV encephalopathy – all occurring within a 24-hour time frame
<b>Non-paracetamol-related</b>
Any three of the following in association with encephalopathy:
Age less than 10 or greater than 40 years
Bilirubin > 300 mol/l
Time from jaundice to encephalopathy > 7 days
Aetiology: either non-A, non-B (seronegative hepatitis) or drug-induced
Prothrombin time > 50 seconds
<i>or</i>
Prothrombin time > 100 seconds/INR > 6.5
<b>French criteria (Clichy criteria)</b>
The criteria are the presence of encephalopathy (coma or confusion) <i>and</i>
Age < 20 years with factor V level < 20%
<i>or</i>
Factor V levels < 30% if greater than 30 years of age <sup>59</sup>

INR, international normalised ratio.

The cause of decompensation should be sought in all cases when it is not clinically apparent. Common causes include sepsis, dehydration, drug therapies, e.g. opiates and sedatives, hepatocellular carcinoma (HCC) and portal vein thrombosis.

Ultrasound should be undertaken in all patients, examining the hepatic veins and portal veins for patency. Signs of an HCC should be sought on ultrasound, alpha-fetoprotein and frequently axial imaging techniques. The therapies available for HCC have improved dramatically in recent years and prognosis can be good, especially with the option of cure with liver transplantation.

Sepsis should be actively sought and treated. In patients with ascites a diagnostic tap should always be undertaken for microbiological culture and cell count (a polymorphonuclear count  $> 250/\text{mm}^3$  is indicative of bacterial peritonitis).

Alcoholic hepatitis is a frequent cause of decompensation and requires aggressive treatment. The severity can be assessed using the Glasgow score or Madrey score and in high-risk patients steroid therapy may be considered.<sup>36,37</sup> Response to steroids over the first 7 days is associated with improved outcome.<sup>38</sup> The role of antioxidants has been examined but no benefit was seen.<sup>39,40</sup> Another approach has been to look at the value of enteral feeding, which was comparable with steroid treatment over a 4-week period, albeit in a small study.<sup>41</sup> The use of pentoxifylline has been reported in a single-centre study to decrease the risk of developing hepatorenal failure and hence impacting on outcome.<sup>42</sup>

### ENCEPHALOPATHY

This is frequently seen in patients with cirrhosis and a systemic inflammatory response – sepsis should be sought and treated. Unlike ALF, this group does not normally develop intracranial hypertension and as such the main thrust for managing encephalopathy is determined by control of the airway and prevention of aspiration.

Therapies to alleviate encephalopathy aim to decrease ammonia levels and thus focus on bowel cleansing with agents such as lactulose. There is little evidence-based research to support any particular avenue of treatment. A recent trial examining the role of albumin dialysis in the management of encephalopathy has been recently completed.<sup>43</sup>

As noted previously, the role of inflammation seems of importance in the development of encephalopathy.<sup>44,45</sup> The role of feeding and encephalopathy has always caused controversy. Recent guidance suggests that protein restriction is not appropriate and a study examining early versus slow introduction of protein into enteral nutrition showed no increase in encephalopathy and indeed appeared beneficial in respect of nitrogen balance.<sup>46,47</sup>

### VARICEAL HAEMORRHAGE

The management of variceal haemorrhage remains that of basic resuscitation and care of the airway. Coagulation

factors require appropriate supplementation along with other blood products. The role of sepsis in variceal haemorrhage has become clearer, with sepsis being a frequent precipitant of bleeding. Cultures should be taken and all patients with variceal haemorrhage should be given antibiotics and this has been shown to decrease the risk of rebleeding.<sup>48,49</sup> Splanchnic vasoconstrictors, such as glypressin, are beneficial in controlling oesophageal haemorrhage but their role in gastric variceal haemorrhage per se has not been examined.<sup>50,51</sup> Banding ligation therapy remains the treatment of choice for oesophageal haemorrhage, with tissue adhesives being utilised in gastric varices. Failure to control variceal bleeding after two endoscopic sessions should result in consideration of TIPS insertion.<sup>52,53</sup> In patients in whom TIPS might be considered to be of benefit in controlling variceal bleeding, consideration needs to be given to the severity of the underlying liver disease that may in its own right make TIPS ill advised.<sup>54</sup>

### RENAL FAILURE

Hepatorenal failure is seen in cirrhosis – the rapidly progressive form is more commonly seen in the critical care environment. It should be noted that this is a diagnosis of exclusion of other causes. The evidence base for colloid therapy (to ensure adequate central volume repletion) along with splanchnic vasoconstrictor therapy (glypressin) is reasonable but more recently data suggest that constrictors such as noradrenaline may be equally applied.<sup>51,55–57</sup> Prevention of renal failure should also be considered with appropriate volume resuscitation in patients with sepsis and bacterial peritonitis. Ascitic drainage should be undertaken with appropriate albumin loading if large-volume drainage is undertaken or in patients at risk of central volume depletion.<sup>58</sup>

Paracetamol-related hepatotoxicity should also be considered for transplantation if arterial lactate remains elevated following volume resuscitation ( $> 3.5 \text{ mmol/l}$ ) and serum phosphate is elevated.

It should be noted that these criteria were not developed in patients with acute Budd–Chiari syndrome, Wilson's disease or pregnancy-related liver failure. Nor have they been or should they be applied in the setting of trauma-related liver failure. Although these criteria demonstrate that being a child (age  $< 10$  years) is a poor prognostic feature, the decision to transplant children is not normally derived from these criteria.

In children the finding of an isolated INR  $> 4.5$  suggests the need for transplantation, assuming that the child has not ingested paracetamol (in this setting the paracetamol criteria would be applied).

The Pittsburgh data suggest that a poor outcome is associated with a liver volume of less than 1000 ml and greater than 50% hepatocyte necrosis of biopsy. The latter may be difficult to interpret due to sampling error.

In acute Budd–Chiari syndrome the combination of encephalopathy and renal failure should lead to

consideration for transplantation. Increasingly, TIPS shunts have a place in the earlier management of acute Budd–Chiari syndrome. Such an undertaking should be performed at a centre providing transplantation since a proportion of patients will decompensate with encephalopathy and severe ALF, requiring urgent transplantation.

# Abdominal surgical catastrophes

Stephen J Streat

Intra-abdominal surgical catastrophes are common conditions in intensive care units (ICUs)<sup>1</sup> and typically occur in elderly patients with comorbidity and reduced physiological reserve. They are often associated with sepsis, either primarily or secondarily, and with subsequent multiple-organ failure. Overall mortality is high<sup>2,3</sup> and those who do survive usually require a long period in intensive care. The long-term health outcomes of patients with these conditions may be poor, particularly if severe comorbidity and functional impairment were present before the catastrophe. These factors inevitably lead treating clinicians to consider carefully the costs and benefits<sup>4,5</sup> of various treatment strategies during an illness which often has many of the characteristics of a tragic saga.<sup>6</sup> The clinical issues alone are complex and decision-making is often hampered by the lack of controlled trials of various strategic approaches. These many difficulties create the potential for conflict to arise between intensivists and other involved clinicians, particularly surgeons, who inhabit different moral economies<sup>6</sup> and often have differing opinions of what are realistic goals and reasonable strategies,<sup>7</sup> particularly for patients who are near the end of life.<sup>8,9</sup> It is in the care of these patients that the particular day-to-day work skills of the intensivist<sup>10,11</sup> ('seeing the big picture', providing meticulous bedside care, and negotiating and maintaining consensus, good communication and teamwork between various clinicians and the family) are tested to the limits. In this chapter, vascular catastrophes, intra-abdominal sepsis and a few serious abdominal complications are discussed. Gastrointestinal bleeding and pancreatitis are covered elsewhere (Chapters 36 and 37).

## VASCULAR CATASTROPHES

### ABDOMINAL AORTIC ANEURYSM (AAA)

AAA is a disease of the elderly, which is up to six times more common in men than women.<sup>12</sup> Rupture of an AAA is the most common vascular catastrophe seen in ICUs and accounts for 2% of all deaths in men over 60 years of age.<sup>13</sup> The prevalence of AAA (defined as infrarenal aortic diameter of 30 mm or more), as detected by screening in men, rises from less than 1% at age 50 to

around 4% at aged 60, between 5 and 10% at age 70 and around 10% at age 80. Ultrasound screening of elderly men for AAA reduces mortality and is probably cost-effective.<sup>14</sup> Aortic diameter is the strongest predictor of the risk of rupture, which is below 1% per year with aortic diameter < 5 cm and about 17% per year with aortic diameter of 6 cm or more.<sup>13</sup> The risk of rupture is higher in women (who have faster aneurysm growth rates than men<sup>15</sup>) and is increased by current smoking and hypertension. Aortic aneurysm expansion is around 0.3 cm/year for aneurysms smaller than 5 cm and around 0.5 cm/year for those larger than 5 cm and this rate may be able to be reduced by a short course of macrolide or by stopping smoking. Perioperative mortality for open elective aneurysm repair is ~5% – somewhat higher when there is significant preoperative respiratory or renal dysfunction.<sup>16</sup> Increasingly endovascular repair is performed because of lower perioperative mortality (~1.5%), although 2-year survival is the same (~90%) after either open or endovascular repair.<sup>17</sup> A higher proportion of patients treated endovascularly will experience long-term complications (predominantly endoleaks, rupture and graft thrombosis), with associated increase in cost.<sup>18</sup> Endovascular repair does not improve survival in patients judged medically unfit for open repair.<sup>19</sup>

Operative mortality is increased to around 15% in urgently repaired (non-ruptured) aneurysms<sup>20</sup> and around 50% in ruptured aneurysms repaired as an emergency.<sup>20</sup> Ruptured aneurysm may lead to death before hospital admission in around 30% of cases,<sup>21</sup> is almost always lethal without repair<sup>22</sup> and not all patients are offered repair. Vascular surgeons are less selective (~10% non-operative) than general surgeons (~60% non-operative), without an increase in mortality in operated patients.<sup>22</sup>

These results have led to recommendations for population screening by ultrasound at age 65, continued surveillance for small aneurysms<sup>23</sup> and elective open (or endovascular) repair in patients without severe comorbidity when aneurysm diameter exceeds 5 or 6 cm.<sup>24</sup>

### RUPTURE OF AN ABDOMINAL AORTIC (OR ILIAC ARTERY) ANEURYSM

The clinical features of rupture include the sudden onset of shock and back pain or abdominal pain or tenderness

in a patient typically over the age of 70. Most ruptures are, initially at least, retroperitoneal with intraperitoneal rupture resulting in greater physiological disturbance and much higher subsequent operative mortality.<sup>25</sup> The correct clinical diagnosis is often not made by the first attending doctor<sup>26</sup> as a pulsatile abdominal mass is commonly not detectable<sup>25</sup> and many patients do not have shock when first seen. Although immediate bedside ultrasound may sometimes be able to confirm the clinical diagnosis without increasing delay, others have found that this investigation commonly delayed vascular surgical referral and subsequent operation without diagnostic benefit.<sup>27</sup> The diagnosis of ruptured aneurysm is confirmed (by computed tomography (CT) angiography) in only half of the patients in whom it is suspected<sup>28</sup> but CT carries a significant risk of sudden deterioration outside the operating room. It may sometimes be inappropriate to proceed to operation (very severe comorbidity, poor quality of life) and this decision should be very carefully considered.<sup>29</sup> Lack of physiological reserve (often associated with advanced age) predicts high operative mortality and long periods of intensive care and hospitalisation in survivors. Open repair remains the current treatment of choice but successful endovascular repair (sometimes with subsequent laparotomy for evacuation of haematoma<sup>30</sup>) is also possible in some of these aneurysms<sup>31</sup> and is the subject of an ongoing randomised controlled trial.<sup>28</sup> A very small number of patients with aortic aneurysm have infection of the aneurysm, usually with *Staphylococcus* or *Salmonella*, which is often diagnosed at rupture.<sup>32</sup> A period of postoperative intensive care is appropriate for most patients. During this time common physiological abnormalities (e.g. hypothermia, dilutional coagulopathy, minor bleeding, circulatory shock, renal tubular dysfunction) can be corrected and serious complications can be sought and if possible treated (Table 39.1).

Rapid ventilator weaning and extubation are recommended, perhaps with thoracic epidural anaesthesia<sup>33</sup> if coagulation allows. Abdominal decompression in these particular patients may not be helpful.<sup>34</sup> Finally, an assessment of overall progress should be made after 24–48 hours. Severe or progressive multiple-organ failure<sup>35</sup> or major visceral or limb infarction should lead to a reappraisal of the

appropriateness of continued intensive therapies. Persistent renal failure occurs more commonly after acute renal failure in this context than in other intensive care patients. Massive upper gastrointestinal haemorrhage (usually aortoduodenal) is a rare complication, usually resulting from infection of a previous aortic repair and less commonly from primary infection in an aortic aneurysm. Some of these patients can be rescued surgically.

### ACUTE AORTIC OCCLUSION

This is an uncommon syndrome, usually due to thrombotic occlusion (of a stenotic or aneurysmal aorta) or to saddle embolism. Presentation is with painful lower-limb paraparesis or paraplegia and absent distal circulation. Minimising delay to emergency revascularisation is of the essence but mortality and multisystem morbidity remain high.<sup>36</sup>

### MESENTERIC INFARCTION

This uncommon syndrome presents with an acute abdomen, may develop in critically ill patients and is commonly due to non-occlusive arterial ischaemia, arterial embolism or atherosclerotic arterial thrombosis and less often to venous occlusion, low-flow or hypercoagulable states.<sup>37</sup> Despite surgery (usually including gut resection), mortality is high. Successful endovascular revascularisation has been reported.<sup>38</sup>

### AORTIC DISSECTION

Aortic dissection<sup>39</sup> has an incidence of 5–30 per million per year. The typical patient is elderly, has a history of hypertension<sup>40</sup> and presents with pain in a distribution corresponding to the site of dissection. Cases have been reported in young people and after circumstances suggesting acute situational hypertension. Pericardial tamponade, haemothorax, myocardial infarction, stroke, paraplegia due to spinal cord ischaemia, anuria or an acute abdomen may be present. Most aortic dissections originate in the ascending thoracic aorta. Some dissections extend to involve the abdominal aorta but spontaneous dissection of the abdominal aorta alone is rare. Mortality remains high but is falling in association with earlier diagnosis and treatment.<sup>39</sup>

### SPONTANEOUS RETROPERITONEAL HAEMORRHAGE

Excluding rupture of an aortic aneurysm, spontaneous retroperitoneal haemorrhage is uncommon. It is usually associated with vascular or malignant disease of the kidney or adrenal gland and, less commonly, with spontaneous rupture of the retroperitoneal veins or with anticoagulant therapy, including warfarin, unfractionated heparin and low-molecular-weight heparin. The presentation is most often with acute abdominal pain, shock and a palpable abdominal or groin mass and CT will confirm the diagnosis.<sup>41</sup> Correction of coagulopathy and interventional

**Table 39.1** Some complications of a ruptured aortic aneurysm

Major bleeding
Renal failure
Myocardial infarction
Acute lung injury
Peripheral ischaemia
Stroke
Pulmonary embolism
Persistent ileus
Mesenteric ischaemia
Pancreatitis
Acalculous cholecystitis
Increased abdominal pressure – compartment syndrome

radiologic embolisation may control some situations but surgery may be required in others, either to stop bleeding or to relieve associated intra-abdominal hypertension.

## INTRA-ABDOMINAL SEPSIS

### OVERVIEW

Intra-abdominal sepsis is very common in the ICU. In our own experience the abdomen (including continuous ambulatory peritoneal dialysis (CAPD) peritonitis) was the most common septic site in patients admitted to ICU with severe sepsis and accounted for 583 (35.9%) of the 1624 such admissions over the 17 years from 1984 to 2000.<sup>42</sup> The incidence of sepsis in ICUs is reported to be increasing<sup>43</sup> and our experience reflects this. The mortality of intensive care patients with severe intra-abdominal infections is variously reported between 25 and 80% but varies greatly depending on the extent of comorbidity<sup>43</sup> and the severity of the acute illness.

The general principles of the treatment of severe sepsis are to support oxygen transport as required, if possible to remove the septic source<sup>44</sup> and to give appropriate antimicrobial therapy. Sepsis should be thought of as a time-critical condition<sup>45</sup> wherein delay in the execution of these principles is likely to worsen outcome. The place of other therapies remains controversial.<sup>46,47</sup> The issue of severe sepsis in general is covered in Chapter 61.

In the critically ill patient with intra-abdominal sepsis, effective source control usually involves surgery, although occasionally interventional procedures may suffice. Laparotomy without delay or further investigation is recommended for most patients presenting acutely with shock and clinical evidence of peritonitis. Diagnostic peritoneal aspiration or lavage, abdominal CT scanning or laparoscopy may have limited applicability in unusual circumstances that do not mandate immediate laparotomy.

Common syndromes include:

- faecal peritonitis
- primarily – diverticular disease or colonic malignancy
- secondarily – after prior anterior resection
- perforated upper abdominal viscus (usually of a gastric or duodenal ulcer)
- biliary obstruction (sometimes with perforation)
- intestinal infarction without perforation (usually adhesive, less commonly ischaemic)
- appendicitis (which is more often perforated in older patients)

Less common syndromes include localised intra-abdominal abscess, acalculous cholecystitis, toxic megacolon, perforation of a fallopian tube abscess, spontaneous bacterial peritonitis (SBP, in nephrotic syndrome or end-stage liver disease) and CAPD-associated peritonitis (not all of which is non-surgical).

### SURGICAL SOURCE CONTROL

Surgical source control should involve definitive control of the septic site at the first ('damage control') operation

but definitive surgical therapy for the underlying disease may not always be feasible or desirable at this time. Initial surgery<sup>44</sup> involves:

- removal of all peritoneal contamination (both macroscopically and by generous lavage)
- drainage of abscesses
- resection of devitalised tissue
- defunctioning the gut to prevent ongoing contamination

The abdomen may be left open (with a temporary fascial closure) if required for intra-abdominal hypertension or to facilitate repeat laparotomy. Successful primary colonic anastomosis (even left-sided) after resection in the presence of sepsis is supported by several case series.<sup>44</sup>

Failure of the sepsis syndrome to settle ('failure to thrive') after apparently definitive surgical source control should suggest ongoing contamination or ischaemia or the development of abscess. Repeat laparotomy on clinical grounds is recommended when early postoperative progress is unsatisfactory,<sup>3</sup> whereas CT scanning followed by either directed laparotomy<sup>48</sup> or interventional radiologic drainage are more successful strategies for late abscess formation.

## INTESTINAL-SOURCE PERITONITIS

Peritonitis secondary to contamination by intestinal contents usually results in mixed aerobic and anaerobic infection and recommended antibiotic regimens,<sup>42,49</sup> therefore usually involve either combination therapy with an aminoglycoside (or aztreonam) and metronidazole (or clindamycin) or alternatively monotherapy with a carbapenem. Similar antibiotic regimens are appropriate in sepsis following intestinal infarction without perforation. An agent active against *Staphylococcus aureus*<sup>50</sup> should probably be included in patients with peritonitis following gastric or duodenal perforation.

## BILIARY SEPSIS

Biliary ultrasound followed by endoscopic sphincteromy and stone removal is recommended for critically ill patients with cholangitis. Antibiotic regimens should cover enterococci and aerobic Gram-negative bacilli.

## ACALCULOUS CHOLECYSTITIS

Acalculous cholecystitis is a rare but serious condition in ICUs. A small number of patients with the syndrome of acute cholecystitis will have acalculous cholecystitis but these patients have low mortality and do not present to ICUs. Of greater concern are the perhaps half of all cases of acalculous cholecystitis that develop insidiously in intensive care patients who are already critically ill for another reason (e.g. recent trauma or surgery) and can therefore go unrecognised until gangrene, perforation or abscess develops. The gallbladder histology in such patients usually includes

prominent ischaemia and arteriosclerosis and low cardiac output may predispose to the condition. A high index of suspicion should be had in an intensive care patient who develops new abdominal pain or clinical signs of sepsis. Although a variety of investigations, including scintigraphy, CT scanning, ultrasound and laparoscopy, have been used to help establish the diagnosis, none performs reliably<sup>51</sup> and many surgeons advocate a low threshold to exploratory laparotomy on clinical grounds where suspicion exists. Percutaneous cholecystostomy<sup>44</sup> has been used successfully whereas early cholecystectomy is advocated by others<sup>52</sup> as infarction or perforation of the gallbladder is commonly found at laparotomy.

### TOXIC MEGACOLON

Toxic megacolon<sup>53</sup> is now a rare indication for intensive care admission. It is characterised by systemic toxicity accompanying a dilated, inflamed colon and is usually due to inflammatory bowel disease. Infection by *Clostridium difficile*, cytomegalovirus (in patients with human immunodeficiency virus (HIV) disease or immunosuppression) or rarely other organisms may also precipitate toxic megacolon. The diagnosis should be considered in patients with diarrhoea and abdominal distension. Limited colonoscopy (despite the risk of perforation) and biopsy may both yield important microbiological information and help in the decision to operate. Supportive therapy in an ICU is usually recommended and includes both antibiotics as for colonic perforation and steroids (equivalent of ~300 mg/day of hydrocortisone). Other immunosuppression (tacrolimus or anti-tumour necrosis factor (anti-TNF) monoclonal antibody) has also been used. Frequent surgical reassessment and abdominal X-rays are used to monitor progress. Intravenous nutrition may help to reduce the activity of Crohn's disease but does not reduce hospital stay or the need for surgery in ulcerative colitis. A period of several days of careful observation may be reasonable to assess the response to medical treatment but urgent surgery (subtotal colectomy with end-ileostomy) is indicated for increasing colonic dilatation, perforation, bleeding or progressive systemic toxicity.<sup>54</sup> Parenteral metronidazole may be effective in severe pseudomembranous colitis without megacolon (but early surgery is often recommended if megacolon develops).

### RUPTURE OF A TUBO-OVARIAN ABSCESS

Rupture of a tubo-ovarian abscess is a rare cause of peritonitis presenting to ICUs and is best treated with surgical extirpation. Antibiotic therapy should include activity against anaerobic organisms.

### SPONTANEOUS BACTERIAL PERITONITIS

SBP is usually a monomicrobial infection (usually with *Escherichia coli*, *Klebsiella pneumoniae*, pneumococci or

enterococci and rarely with anaerobes).<sup>42</sup> The development of SBP in patients with end-stage liver disease is a grave prognostic sign – hepatic decompensation and multiple-organ failure commonly develop and the median survival in such patients (without liver transplantation) is short. Early albumin supplementation has been shown to reduce both renal failure and mortality in SBP associated with end-stage liver disease.<sup>55</sup> Treatment with a broad-spectrum beta-lactam antibiotic should be followed by secondary oral antibiotic prophylaxis.

### CAPD-ASSOCIATED PERITONITIS

Peritonitis is not uncommon in CAPD patients but is rarely a cause of intensive care admission. The development of (extrarenal) organ failure is an ominous sign and usually reflects delay in effective treatment, abscess formation, the presence of unusual organisms (including a variety of fungi), or an unrecognised gastrointestinal septic source.<sup>56</sup>

### TERTIARY PERITONITIS

Tertiary peritonitis – ‘peritonitis in the critically ill patient that persists or recurs at least 48 hours after the apparently adequate management of primary or secondary peritonitis’<sup>57</sup> – occurs occasionally in severely ill patients with prior laparotomy. It is commonly due to *Staphylococcus epidermidis*, enterococci, *Enterobacter*, *Pseudomonas* or *Candida albicans*<sup>42,57</sup> and initial empiric treatment should include amoxicillin, gentamicin and metronidazole until culture results are available. When infection is due to *Candida* spp. other antimicrobial agents should be discontinued, any foreign bodies removed if possible, and treatment with amphotericin B given for at least 4 weeks.<sup>58</sup>

## COMPLICATIONS

### INTRA-ABDOMINAL HYPERTENSION AND THE ABDOMINAL COMPARTMENT SYNDROME

These phenomena occur uncommonly in critically ill patients, particularly after surgery for trauma or sepsis and in association with excessive crystalloid fluid administration. A recent consensus conference has defined intra-abdominal hypertension as intra-abdominal pressure (IAP) >12 mmHg and abdominal compartment syndrome as IAP >20 mmHg with associated organ dysfunction.<sup>59</sup> IAP can be conveniently and easily measured via intravesical pressure,<sup>34,59</sup> is normally 5–7 mmHg in critically ill adults and is increased in patients with increased body mass index. Physiological impairment (including cardiorespiratory, renal, splanchnic and neurological) can occur with acute increases in IAP to levels above 12 mmHg. However, in the absence of evidence from randomised controlled trials, expert opinion<sup>60</sup> suggests that the development of the abdominal

compartment syndrome (IAP > 20 mmHg with associated organ dysfunction) should prompt a search for decompressive measures. Traditionally this has involved urgent decompressive laparotomy and temporary fascial closure; however other measures include:

- avoidance of the prone position
- gastric and colonic decompression
- neostigmine or other prokinetic agents
- neuromuscular blockade

Diuresis or ultrafiltration or percutaneous drainage of intraperitoneal fluid or gas may be effective in some patients and should also be considered.<sup>60</sup> Despite abdominal decompression, mortality for such patients remains high (~50%).<sup>34</sup>

### THE OPEN ABDOMEN AND STAGED ABDOMINAL REPAIR

The use of synthetic materials to provide temporary fascial closure has facilitated the care of the patient with an open abdomen and allowed repeat laparotomy and staged abdominal repair to proceed in a timely and unhurried manner. Our own practice<sup>34</sup> has been to use polypropylene mesh alone for this purpose if the period of open abdomen is likely to be short (less than a week) and the mesh can be removed before significant adhesion occurs. Two or more drains on moderate suction are laid over the mesh and then covered with a clear plastic adhesive dressing to provide a sterile waterproof seal and allow continual removal of ascites. If a longer period is required with an open abdomen, then a non-adherent plastic material should be used either under or instead of the mesh to prevent adherence and minimise the risk of gut perforation and fistula during removal of the material and fascial closure. The management of fistulation in the open abdomen remains problematic as proximal defunctioning is often impossible and control of wound contamination is not ideal with soft-catheter intubation of the small bowel via the fistulous tract.

### ENTEROCUTANEOUS FISTULAS – INTESTINAL, BILIARY AND PANCREATIC

These are rare complications in intensive care patients but they usually present formidable problems because of their common associations with serious gastrointestinal comorbidity, e.g. inflammatory bowel disease, intestinal malignancy and pancreatitis as well as concurrent severe sepsis. In addition complex fistulation with multiple collections, fistulation through an open abdomen, inability to proximally defunction or distal obstruction are commonly present. A standard approach to fistula management should apply.<sup>61</sup>

This may include:

- attention to drainage of sepsis
- control of the fistula by drainage
- if necessary, by proximal defunctioning

- protection of the skin from the deleterious effects of the fistula fluid
- nutritional support
- replacement of fluid and electrolyte losses

Although somatostatin analogues have been shown to reduce high-output small-bowel fistula losses and they and H<sub>2</sub>-blockers are commonly recommended in fistulas of intestinal or pancreatic origin, their efficacy in achieving closure is less clear.<sup>62</sup> Parenteral nutrition is usually recommended for proximal small-bowel fistulas but more distal intestinal, biliary or pancreatic fistulas can probably be safely treated with a trial of enteral nutrition. Treatment with an anti-TNF antibody has been shown to be effective in chronic enterocutaneous fistulas in (non-ICU) patients with Crohn's disease.<sup>63</sup> Persistent high-output fistula should lead to investigation of possible causes, including complete disruption of the gut lumen, distal obstruction or persistent intra-abdominal sepsis. Definitive operative treatment for fistulas that do not close should await clinical recovery and, if possible, nutritional repletion.

### COLONIC PSEUDO-OBSTRUCTION

Colonic pseudo-obstruction (Ogilvie's syndrome, a severe form of colonic ileus) is not uncommon in critically ill patients. The syndrome may contribute to ventilatory difficulty, intra-abdominal hypertension and failure of enteral feeding. It carries a small risk of spontaneous perforation with high resultant mortality. Conventional conservative treatment includes nasogastric drainage, intravenous fluid replacement and avoidance of opioids and anticholinergic agents. Treatment with neostigmine has been found to be highly effective<sup>64</sup> but may cause symptomatic bradycardia. Colonoscopy or surgery may be required if these measures fail.<sup>65</sup>

# Acute renal failure

Rinaldo Bellomo

Acute renal failure (ARF) remains a major diagnostic and therapeutic challenge for the critical care physician. The term 'ARF' describes a syndrome characterised by a rapid (hours to days) decrease in the kidney's ability to eliminate waste products. Such loss of function is clinically manifested by the accumulation of end-products of nitrogen metabolism such as urea and creatinine. Other typical clinical manifestations include decreased urine output (not always present), accumulation of non-volatile acids and an increased potassium and phosphate concentration.

Depending on the criteria used to define its presence, ARF has been reported to occur in 15–20% of intensive care unit (ICU) patients.<sup>1</sup> Recently a consensus definition and classification for ARF have been developed and validated in hospital and ICU patients.<sup>2–4</sup> This definition, which goes by the acronym of RIFLE, divides renal dysfunction into the categories of risk, injury and failure (Figure 40.1) and is likely to be the dominant approach to defining ARF in ICUs for the next 5–10 years. Using this classification, the incidence of some degree of renal dysfunction has reported to be up to 67% in a recent study of > 5000 ICU patients.<sup>3</sup> In hospital patients, the development of failure (in the RIFLE classification) increases the odds ratio of death 10 times.<sup>4</sup>

## ASSESSMENT OF RENAL FUNCTION

Renal function is complex (control of calcium and phosphate, acid–base balance, water balance, tonicity, erythropoiesis, disposal of some cytokines, lactate removal). In the clinical context, however, monitoring of renal function is reduced to the indirect assessment of glomerular filtration rate (GFR) by the measurement of urea and creatinine in blood. These waste products are insensitive markers of GFR and are heavily modified by nutrition, the use of steroids, the presence of gastrointestinal blood, muscle mass, age, gender or muscle injury. Furthermore, they start becoming abnormal only when more than 50% of GFR is lost, they do not reflect dynamic changes in GFR and are grossly modified by aggressive fluid resuscitation. The use of creatinine clearance (2- or 4-hour collections) or of calculated clearance by means of formulae

might increase the accuracy of GFR estimation, but rarely changes clinical management. The use of more sophisticated radionuclide-based tests is cumbersome in the ICU and only useful for research purposes.

## DIAGNOSIS AND CLINICAL CLASSIFICATION

The most practically useful approach to the aetiological diagnosis of ARF is to divide its causes according to the probable source of renal injury: prerenal, renal (parenchymal) and postrenal.

## PRERENAL RENAL FAILURE

This form of ARF is by far the most common in ICU. The term indicates that the kidney malfunctions predominantly because of systemic factors, which decrease GFR. For example, GFR may be decreased if renal blood flow is diminished by decreased cardiac output, hypotension or raised intra-abdominal pressure. Raised intra-abdominal pressure can be suspected on clinical grounds and confirmed by measuring bladder pressure with a urinary catheter. A pressure of > 25–30 mmHg above the pubis should prompt consideration of decompression. If the systemic cause of renal failure is rapidly removed or corrected, renal function improves and relatively rapidly returns to near-normal levels. However, if intervention is delayed or unsuccessful, renal injury becomes established and several days or weeks are then necessary for recovery. Several tests (measurement of urinary sodium, fractional excretion of sodium and other derived indices) have been promoted to help clinicians identify the development of such 'established' ARF. Unfortunately, their accuracy is doubtful.<sup>5</sup> The clinical utility of these tests in ICU patients who receive vasopressors, massive fluid resuscitation and loop diuretic infusions is low. Furthermore, it is important to observe that prerenal ARF and established ARF are part of a continuum, and their separation has limited clinical implications. The treatment is the same – treatment of the cause while promptly resuscitating the patient using invasive haemodynamic monitoring to guide therapy.

	GFR criteria*	Urine output criteria	
<b>Risk</b>	Increased $S_{Creat}$ x2 or GFR decrease >25%	UO <.5 ml/kg per h x 6hr	<b>High sensitivity</b>
<b>Injury</b>	Increased $S_{Creat}$ x2 or GFR decrease >50%	UO <.5 ml/kg per h x 12hr	
<b>Failure</b>	Increased $S_{Creat}$ x3 GFR decrease 75% or $S_{Creat} \geq 4$ mg/dl acute rise $\geq 0.5$ mg/dl	UO <.3 ml/kg per h x 24hr or Anuria x12hrs	
<b>Loss</b>	Persistent ARF** = complete loss of kidney function >4 weeks		<b>High specificity</b>
<b>ESKD</b>	End-stage kidney disease (>3 months)		

**Figure 40.1** RIFLE (risk injury failure loss end-stage) classification scheme for acute renal failure. The classification system includes separate criteria for creatinine and urine output. The criteria, which lead to the worst possible classification, should be used. Note that RIFLE-F (F = failure) is present even if the increase in serum creatinine concentration ( $S_{Creat}$ ) is less than threefold as long as the new  $S_{Creat} > 4.0$  mg/dl (350  $\mu$ mol/l) in the setting of an acute increase of at least 0.5 mg/dl (44  $\mu$ mol/l). The designation RIFLE-F<sub>C</sub> should be used in this case to denote 'acute-on-chronic' disease. Similarly, when RIFLE-F classification is reached by urine output criteria only, a designation of RIFLE-F<sub>O</sub> should be used to denote oliguria. The shape of the figure denotes the fact that more patients (high sensitivity) will be included in the mild category, including some who do not actually have 'renal failure' (less specificity). In contrast, at the bottom, the criteria are strict and therefore specific, but some patients with renal dysfunction might be missed. GFR, glomerular filtration rate; ARF, acute renal failure; UO, urine output.

## PARENCHYMAL RENAL FAILURE

This term is used to define a syndrome where the principal source of damage is within the kidney and where typical structural changes can be seen on microscopy. Disorders which affect the glomerulus or the tubule can be responsible (Table 40.1).

Among these, nephrotoxins are particularly important, especially in hospital patients. The most common nephrotoxic drugs affecting ICU patients are listed in Table 40.2. Many cases of drug-induced ARF rapidly improve upon removal of the offending agent. Accordingly, a careful history of drug administration is *mandatory* in all patients with ARF. In some cases of parenchymal ARF, a correct working diagnosis can be obtained from history, physical examination and radiological and laboratory investigations. In such patients one can proceed to a therapeutic trial without the need to resort to renal biopsy. However,

if immunosuppressive therapy is considered, renal biopsy is recommended. Renal biopsy in ventilated patients under ultrasound guidance does not carry additional risks compared to standard conditions.

More than a third of patients who develop ARF in ICU have chronic renal dysfunction due to factors such as age-related changes, long-standing hypertension, diabetes or atheromatous disease of the renal vessels. Such chronic renal dysfunction may be manifest by a raised serum creatinine. However, this is not always the case. Often, what may seem to the clinician to be a relatively trivial insult, which does not fully explain the onset of ARF in a normal patient, is sufficient to unmask lack of renal functional reserve in another.

**Table 40.1** Causes of parenchymal acute renal failure

Glomerulonephritis
Vasculitis
Interstitial nephritis
Malignant hypertension
Pyelonephritis
Bilateral cortical necrosis
Amyloidosis
Malignancy
Nephrotoxins

**Table 40.2** Drugs which may cause acute renal failure in the intensive care unit

Radiocontrast agents
Aminoglycosides
Amphotericin
Non-steroidal anti-inflammatory drugs
$\beta$ -lactam antibiotics (interstitial nephropathy)
Sulphonamides
Acyclovir
Methotrexate
Cisplatin
Cyclosporin A
FK-506 (tacrolimus)

### HEPATORENAL SYNDROME

This condition is a form of ARF, which occurs in the setting of severe liver dysfunction in the absence of other known causes of ARF. Typically, it presents as progressive oliguria with a very low urinary sodium concentration (< 10 mmol/l). Its pathogenesis is not well understood. It is important to note, however, that, in patients with severe liver disease, other causes of ARF are much more common. They include sepsis, paracentesis-induced hypovolaemia, raised intra-abdominal pressure due to tense ascites, diuretic-induced hypovolaemia, lactulose-induced hypovolaemia, alcoholic cardiomyopathy, and any combination of these. The avoidance of hypovolaemia by albumin administration in patients with spontaneous bacterial peritonitis has been shown to decrease the incidence of renal failure in a recent randomised controlled trial (RCT).<sup>6</sup> These causes must be looked for and promptly treated. Recent small studies suggest that a vasopressin derivative called terlipressin may improve GFR in this condition.<sup>7</sup>

### RHABDOMYOLYSIS-ASSOCIATED ARF

This condition accounts for close to 5–10%<sup>8</sup> of cases of ARF in ICU depending on the setting. Its pathogenesis involves prerenal, renal and postrenal factors. It is now typically seen following major trauma, drug overdose with narcotics, vascular embolism, and in response to a variety of agents which can induce major muscle injury. The principles of treatment are based on retrospective data, small series and multivariate logistic regression analysis, because no RCTs have been conducted. They include prompt and aggressive fluid resuscitation, elimination of causative agents, correction of compartment syndromes, the alkalinisation of urine (pH > 6.5) and the maintenance of polyuria (> 300 ml/h). The role of mannitol is controversial.

### POSTRENAL RENAL FAILURE

Obstruction to urine outflow is the most common cause of functional renal impairment in the community,<sup>9</sup> but is uncommon in the ICU. Typical causes of obstructive ARF include bladder neck obstruction from an enlarged prostate, ureteric obstruction from pelvic tumours or retroperitoneal fibrosis, papillary necrosis or large calculi. The clinical presentation of obstruction may be acute or acute-on-chronic in patients with long-standing renal calculi. It may not always be associated with oliguria. If obstruction is suspected, ultrasonography can be easily performed at the bedside. However, not all cases of acute obstruction have an abnormal ultrasound and, in many cases, obstruction occurs in conjunction with other renal insults (e.g. staghorn calculi and severe sepsis of renal origin). Assessment of the role of each factor and overall management should be conducted in conjunction with a urologist. Finally the sudden and unexpected development of anuria in an ICU patient should always suggest

obstruction of the urinary catheter as the cause. Appropriate flushing or changing of the catheter should be implemented in this setting.

### PATHOGENESIS OF ACUTE RENAL FAILURE

The pathogenesis of obstructive ARF involves several humoral responses as well as mechanical factors. The pathogenesis of parenchymal renal failure is typically immunological. It varies from vasculitis to interstitial nephropathy and involves an extraordinary complexity of immunological mechanisms. The pathogenesis of prerenal ARF is of greater direct relevance to the intensivist. Several mechanisms have been reported to play a major role in the development of renal injury:

1. ischaemia of outer medulla with activation of the tubuloglomerular feedback<sup>10</sup>
2. tubular obstruction from casts of exfoliated cells<sup>11</sup>
3. interstitial oedema secondary to back-diffusion of fluid<sup>11</sup>
4. humorally mediated afferent arteriolar renal vasoconstriction<sup>11</sup>
5. inflammatory response to cell injury and local release of mediators<sup>11</sup>
6. disruption of normal cellular adhesion to the basement membrane<sup>11</sup>
7. radical oxygen species-induced apoptosis<sup>11</sup>
8. phospholipase A<sub>2</sub>-induced cell membrane injury<sup>12</sup>
9. mitogen-activated protein kinase-induced renal injury<sup>13</sup>

In septic patients with hyperdynamic circulations, ARF may occur in the setting of increased renal blood flow, with the loss of GFR being secondary to decreased intraglomerular pressure induced by efferent arteriolar vasodilatation.<sup>14</sup>

No studies exist to tell us which of the above mechanism/s are pathogenetically most important in ICU patients with or without sepsis and when they might be active in the course of a patient's illness.

### THE CLINICAL PICTURE

The most common clinical picture seen in ICU is that of a patient who has sustained or is experiencing a major systemic insult (trauma, sepsis, myocardial infarction, severe haemorrhage, cardiogenic shock, major surgery and the like). When the patient arrives in the ICU, resuscitation is typically well under way or surgery may have just been completed. Despite such efforts, the patient is already anuric or profoundly oliguric, the serum creatinine is rising and a metabolic acidosis is developing. Potassium and phosphate levels may be rapidly rising as well. Accompanying multiple-organ dysfunction (mechanical ventilation and need for vasoactive drugs) is common. Fluid resuscitation is typically undertaken in the ICU under the guidance of invasive hemodynamic monitoring.

Vasoactive drugs are often used to restore mean arterial pressure (MAP) to 'acceptable' levels (typically > 65–70 mmHg). The patient may improve over time and urine output may return with or without the assistance of diuretic agents. If urine output does not return, however, renal replacement therapy needs to be considered.

If the cause of ARF has been removed, and the patient has become physiologically stable, slow recovery occurs (from 4–5 days to 3–4 weeks). In some cases, urine output can be above normal for several days. If the cause of ARF has not been adequately remedied, the patient remains gravely ill, the kidneys do not recover and death from multiorgan failure may occur.

### PREVENTING ACUTE RENAL FAILURE

The fundamental principle of ARF prevention is to treat its cause. If prerenal factors contribute, these must be identified and haemodynamic resuscitation quickly instituted.

### RESUSCITATION

Intravascular volume must be maintained or rapidly restored, and this is often best done using invasive haemodynamic monitoring (central venous catheter, arterial cannula and pulmonary artery catheter or pulse contour cardiac output catheters in some cases). Oxygenation must be maintained. An adequate haemoglobin concentration (at least > 70 g/l) must be maintained or immediately restored. Once intravascular volume has been restored, some patients remain hypotensive (MAP < 70 mmHg). In these patients, autoregulation of renal blood flow may be lost. Restoration of MAP to near-normal levels may increase GFR.<sup>15,16</sup> Such elevations in MAP, however, require the addition of vasopressor drugs.<sup>15,16</sup> In patients with hypertension or renovascular disease, a MAP of 75–80 mmHg may still be inadequate. The nephroprotective role of additional fluid therapy in a patient with a normal or increased cardiac output and blood pressure is questionable. Despite these resuscitation measures renal failure may still develop if cardiac output is inadequate. This may require a variety of interventions from the use of inotropic drugs to the application of ventricular assist devices.

### NEPHROPROTECTIVE DRUGS

Following haemodynamic resuscitation and removal of nephrotoxins, it is unclear whether the use of additional pharmacological measures is of further benefit to the kidneys.

#### 'RENAL DOSE' OR 'LOW-DOSE' DOPAMINE

Evidence of the efficacy or safety of its administration in critically ill patients is lacking. However, this agent is a tubular diuretic and occasionally increases urine output.

This may be incorrectly interpreted as an increase in GFR. Furthermore, a recent large phase III trial in critically ill patients showed low-dose dopamine to be as effective as placebo in the prevention of renal dysfunction.<sup>17</sup>

#### MANNITOL

A biological rationale exists for the use of mannitol, as is the case for dopamine. However, no controlled human data exist to support its clinical use. The effect of mannitol as a renal-protective agent remains questionable.

#### LOOP DIURETICS

These agents may protect the loop of Henle from ischaemia by decreasing its transport-related workload. Animal data are encouraging, as are ex-vivo experiments. There are no double-blind RCTs of suitable size to prove that these agents reduce the incidence of renal failure. However, there are some studies which support the view that loop diuretics may decrease the need for dialysis in patients with developing ARF.<sup>18</sup> They appear to achieve this by inducing polyuria, which results in the prevention or easier control of volume overload, acidosis and hyperkalaemia, the three major triggers for renal replacement therapy in the ICU. Because avoiding dialysis simplifies treatment and reduces cost of care, loop diuretics are occasionally used in patients with renal dysfunction, especially in the form of continuous infusion.

#### OTHER AGENTS

Other agents, such as *theophylline*, *urodilatin* and *anaritide* (a synthetic atrial natriuretic factor), have also been proposed. Studies so far, however, have been experimental, too small or have shown no beneficial effect. In a randomised double-blind, placebo-controlled trial, *fenoldopam* has been shown to attenuate the deterioration in serum creatinine typically seen in septic patients.<sup>19</sup> Studies of this agent in other situations, however, have failed to show a benefit.<sup>20</sup> Its role in ARF remains uncertain. Similarly, in a single-centre study, rhANF has been shown to attenuate renal injury in higher-risk patients having cardiac surgery<sup>21</sup> but a large multicentre study of ARF failed to show a benefit.<sup>22</sup> Many more investigations are needed in this field.

### RADIOCONTRAST NEPHROPATHY

In patients receiving radiocontrast an RCT suggested that saline infusion to maintain intravascular fluid expansion is superior to the addition of mannitol or furosemide. Several RCTs of similar patients demonstrated a beneficial effect of *N-acetylcysteine* treatment before and after radiocontrast administration, as confirmed in a recent meta-analysis.<sup>23</sup> Since these preventive interventions have minimal toxicity, they should be considered whenever a patient is scheduled for the administration of intravenous radiocontrast. Their effectiveness in ICU patients who have already been fluid-resuscitated remains unknown.

## DIAGNOSTIC INVESTIGATIONS

An aetiological diagnosis of ARF must always be established. Such diagnosis may be obvious on clinical grounds. However, in many patients, it is best to consider all possibilities and exclude common treatable causes by simple investigations. Such investigations include the examination of urinary sediment and exclusion of a urinary tract infection (in most, if not all, patients), the exclusion of obstruction when appropriate (some patients) and the careful exclusion of nephrotoxins (all patients).

In specific situations, other investigations are necessary to establish the diagnosis, such as creatine kinase and free myoglobin for possible rhabdomyolysis. A chest radiograph, a blood film, the measurement of non-specific inflammatory markers and the measurement of specific antibodies (antiglomerular basement membrane, antineutrophil cytoplasm, anti-DNA, antismooth-muscle) are useful screening tests to help support the diagnosis of vasculitis or of certain types of collagen disease or glomerulonephritis. If thrombotic thrombocytopenic purpura is suspected, the additional measurement of lactic dehydrogenase, haptoglobin, unconjugated bilirubin and free haemoglobin is needed. In some patients, specific findings (cryoglobulins, Bence Jones proteins) are almost diagnostic. In a few rare patients, the clinical picture, laboratory investigations and radiological investigations are not sufficient to make a causative diagnosis with sufficient certainty. In such patients a renal biopsy might become necessary.

## MANAGEMENT OF ESTABLISHED ACUTE RENAL FAILURE

The principles of management of established ARF are the treatment or removal of its cause and the maintenance of physiological homeostasis while recovery takes place. Complications such as encephalopathy, pericarditis, myopathy, neuropathy, electrolyte disturbances or other major electrolyte, fluid or metabolic derangement should never occur in a modern ICU. Their prevention may include several measures, which vary in complexity from fluid restriction to the initiation of extracorporeal renal replacement therapy.

Nutritional support must be started early and must contain adequate calories (30–35 kcal/kg per day) as a mixture of carbohydrates and lipids. Adequate protein (at least 1–2 g/kg per day) must be administered. There is no evidence that specific renal nutritional solutions are useful. Vitamins and trace elements should be administered at least according to their recommended daily allowance. The role of newer immunonutritional solution remains controversial. The enteral route is preferred to the use of parenteral nutrition.

Hyperkalaemia (> 6 mmol/l) must be promptly treated with insulin and dextrose administration, the infusion of

bicarbonate if acidosis is present, the administration of nebulised salbutamol, or all of the above together. If the 'true' serum potassium is > 7 mmol/l or electrocardiographic signs of hyperkalaemia appear, calcium chloride (10 ml of 10% solution intravenously) should also be administered. The above measures are temporising actions while renal replacement therapy is being set up. The presence of hyperkalaemia is a major indication for the immediate institution of renal replacement therapy.

Metabolic acidosis is almost always present but rarely requires treatment per se. Anaemia requires correction to maintain a haemoglobin of at least > 70 g/l. More aggressive transfusion needs individual patient assessment.<sup>24</sup> Drug therapy must be adjusted to take into account the effect of the decreased clearances associated with loss of renal function. Stress ulcer prophylaxis is advisable and should be based on H<sub>2</sub>-receptor antagonists or proton pump inhibitors in selected cases. Assiduous attention should be paid to the prevention of infection.

Fluid overload can be prevented by the use of loop diuretics in polyuric patients. However, if the patient is oliguric, the only way to avoid fluid overload is to institute renal replacement therapy at an early stage (see Chapter 41). Marked azotaemia ([urea] > 40 mmol/l or [creatinine] > 400 µmol/l) is undesirable and should probably be treated with renal replacement therapy unless recovery is imminent or already under way and a return toward normal values is expected within 24–48 hours. It is recognized, however, that no RCTs exist to define the ideal time for intervention with artificial renal support.

## PROGNOSIS

The mortality of critically ill patients with ARF remains high (40–80% depending on case-mix). It is frequently stated that patients die *with* renal failure rather than *of* renal failure. However, growing evidence suggests that better uraemic control and more intensive artificial renal support may improve survival by perhaps 30%.<sup>25,26</sup> Such evidence supports a careful and proactive approach to the treatment of patients with ARF, which is based on the prevention of uncontrolled uraemia and the maintenance of low urea levels throughout the patient's illness.

# Renal replacement therapy

Rinaldo Bellomo

When acute renal failure (ARF) is severe, resolution can take several days or weeks. During this time, the kidneys cannot maintain homeostasis of fluid, potassium, metabolic acid and waste products. Life-threatening complications frequently develop. In these patients, extracorporeal techniques of blood purification must be applied to prevent such complications. Such techniques, broadly named renal replacement therapy (RRT), include continuous haemofiltration (HF), intermittent haemodialysis (IHD) and peritoneal dialysis (PD), each with its technical variations. All of these techniques rely on the principle of removing unwanted solutes and water through a semipermeable membrane. Such membrane is either biological (peritoneum) or artificial (haemodialysis or HF membranes), and each offers several advantages, disadvantages and limitations.

## PRINCIPLES

The principles of RRT have been extensively studied and described.<sup>1-3</sup> This is a summary of some aspects which are relevant to the critical care physician.

### WATER REMOVAL

The removal of unwanted solvent (water) is therapeutically as important as the removal of unwanted solute (acid, uraemic toxins, potassium and the like). During RRT, water is removed through a process called ultrafiltration. This process is essentially the same as that performed by the glomerulus; it requires a driving pressure to move fluid across a semipermeable membrane. This pressure is achieved by:

1. generating a transmembrane pressure (as in HF or during IHD) which is greater than oncotic pressure
2. increasing osmolarity of the dialysate (as in PD)

### SOLUTE REMOVAL

The removal of unwanted solute can be achieved by:

1. creating an electrochemical gradient across the membrane using a flow-past system with toxin-free dialysate (diffusion), as in IHD and PD

2. creating a transmembrane pressure-driven 'solvent drag', where solute moves together with solvent (convection) across a porous membrane, is discarded and then replaced with toxin-free replacement fluid, as in HF

The rate of diffusion of a given solute depends on its molecular weight, the porosity of the membrane, the blood flow rate, the dialysate flow rate, the degree of protein binding and its concentration gradient across the membrane. If standard, low-flux, cellulose-based membranes are used, middle molecules of >500 daltons (D) molecular weight (MW) cannot be removed. If synthetic high-flux membranes are used (cut-off at 10–20 kilodaltons (kD) in MW), larger molecules can be removed. With these membranes convection is superior to diffusion in achieving the clearance of middle molecules.

## INDICATIONS FOR RENAL REPLACEMENT THERAPY

In the critically ill patient, RRT should be initiated early, prior to the development of complications. Fear of early dialysis stems from the adverse effects of conventional IHD with cuprophane membranes, especially haemodynamic instability, and from the risks and limitations of continuous or intermittent PD.<sup>4-5</sup> However, continuous RRT (CRRT)<sup>6,7</sup> or slow low-efficiency daily dialysis (SLEDD)<sup>8</sup> minimises these effects. The criteria for the initiation of RRT in patients with chronic renal failure may be inappropriate in the critically ill.<sup>9,10</sup> A set of modern criteria for the initiation of RRT in the intensive care unit (ICU) is presented in Table 41.1.

With IHD, CRRT or SLEDD there are limited data on what is 'adequate' intensity of dialysis. However, this concept should include maintenance of homeostasis at all levels,<sup>10</sup> and better uraemic control may translate into better survival.<sup>11,12</sup> An appropriate target urea might be 15–25 mmol/l, with a protein intake around 1.5 g/kg per day. This can be easily achieved using CRRT at urea clearances of 35–45 l/day depending on patient size and catabolic rate. If intermittent therapy is used, daily and extended treatment as described with SLEDD becomes desirable.<sup>13</sup>

**Table 41.1** Modern criteria for the initiation of renal replacement therapy (RRT) in the intensive care unit\*

Oliguria (urine output < 200 ml/12 h)
Anuria (urine output: 0–50 ml/12 h)
[Urea] > 35 mmol/l
[Creatinine] > 400 µmol/l
[K <sup>+</sup> ] > 6.5 mmol/l or rapidly rising <sup>†</sup>
Pulmonary oedema unresponsive to diuretics
Uncompensated metabolic acidosis (pH < 7.1)
[Na <sup>+</sup> ] < 110 and > 160 mmol/l
Temperature > 40°C
Uraemic complications (encephalopathy/myopathy/neuropathy/pericarditis)
Overdose with a dialysable toxin (e.g. lithium)

\*If one criterion is present, RRT should be considered. If two criteria are simultaneously present, RRT is strongly recommended.

<sup>†</sup>Please be aware of differences between plasma versus serum measurement in your laboratory.

### MODE OF RENAL REPLACEMENT THERAPY

There is a great deal of controversy as to which mode of RRT is ‘best’ in the ICU, due to the lack of randomised controlled trials comparing different techniques. In their absence, techniques of RRT may be judged on the basis of the following criteria:

1. haemodynamic side-effects
2. ability to control fluid status
3. biocompatibility
4. risk of infection
5. uraemic control
6. avoidance of cerebral oedema
7. ability to allow full nutritional support
8. ability to control acidosis
9. absence of specific side-effects
10. cost

CRRT and SLEDD offer many advantages over PD and conventional IHD (3–4 h/day, 3–4 times/week),<sup>13</sup> and whereas CRRT is almost exclusively used in some centres,<sup>14</sup> only a minority of American ICU patients receive CRRT. Some salient aspects of CRRT, IHD and PD require discussion.

### CONTINUOUS RENAL REPLACEMENT THERAPY

First described in 1977, CRRT has undergone several technical modifications. Initially, it was performed as an arteriovenous therapy (continuous arteriovenous HF: CAVH). The need to cannulate an artery, however, is associated with 15–20% morbidity. Accordingly, double-lumen catheters and peristaltic blood pumps have come into use (continuous venovenous HF: CVVH) with or without control of ultrafiltration rate. Ultrafiltration rates of 2 l/h yield urea clearances > 30 ml/min. Diagrams illustrating typical HF circuits are presented in Figures 41.1–41.3.

In a venovenous system, dialysate can also be delivered countercurrent to blood flow (continuous veno-venous haemodialysis/haemodiafiltration) to achieve either almost pure diffusive clearance or a mixture of diffusive and convective clearance.

No matter what technique is used, the following outcomes are predictable:

1. continuous control of fluid status
2. haemodynamic stability
3. control of acid–base status
4. ability to provide protein-rich nutrition while achieving uraemic control
5. control of electrolyte balance, including phosphate and calcium balance
6. prevention of swings in intracerebral water
7. minimal risk of infection
8. high level of biocompatibility

However, CRRT mandates the presence of specifically trained nursing and medical staff 24 hours a day. Small ICUs often cannot provide such level of support. If CRRT is only used 5–10 times a year, the cost of training may be unjustified and expertise may be hard to maintain. Furthermore, depending on the organisation of patient care, CRRT may be more expensive than IHD. Finally, the issues of continuous-circuit anticoagulation and the potential risk of bleeding have been a major concern.

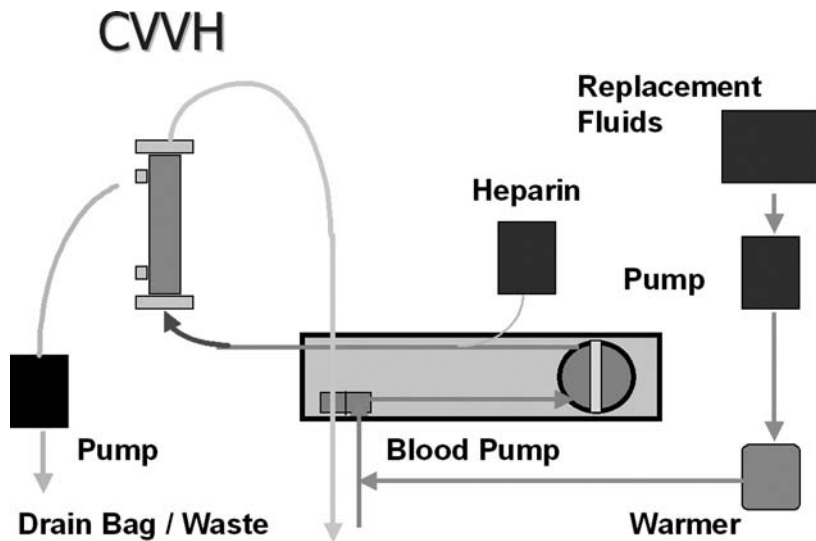

### DOSE OF CRRT AND CIRCUIT ANTICOAGULATION

The optimal dose (expressed as effective effluent per kilogram per hour) of CRRT remains unknown. Several studies suggest that higher dose may translate into better outcome.<sup>12,15</sup> However such studies have been single-centre in nature and require confirmation in multicentre randomised controlled trials. Such trials are now under way (see below).<sup>16</sup> It seems wise to wait for the results of larger studies before making any changes to the typical dose of approximately 25 ml/kg per hour currently delivered in Australia and New Zealand.

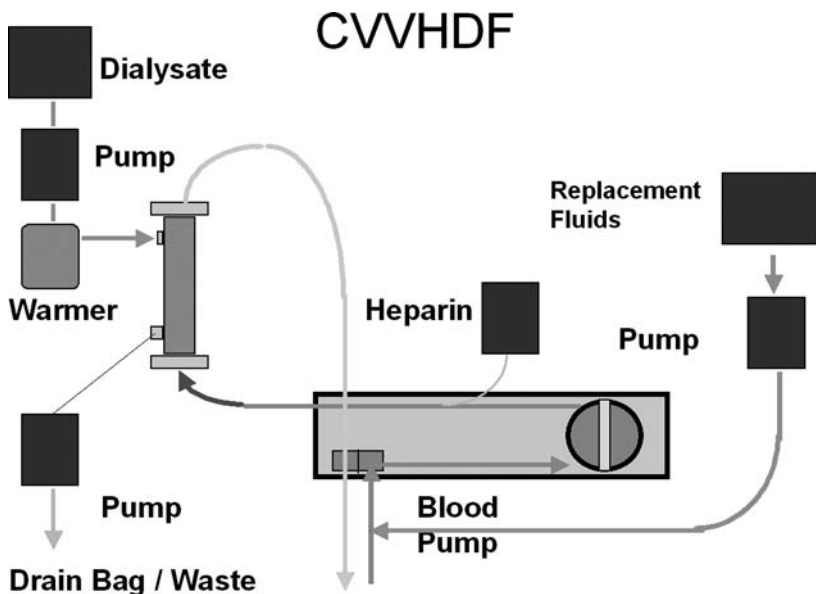

The flow of blood through an extracorporeal circuit causes activation of the coagulation cascade and promotes clotting of the filter and circuit itself. In order to delay such clotting and achieve acceptable operational lives (approximately 24 hours) for the circuit, anticoagulants are frequently used.<sup>17</sup> However, circuit anticoagulation increases risk of bleeding. Therefore, the risks and benefits of more or less intense anticoagulation and alternative strategies (Table 41.2) must be considered.

In the vast majority of patients, low-dose heparin (< 500 IU/h) is sufficient to achieve adequate filter life, is easy and cheap to administer and has almost no effect on the patient’s coagulation tests. In some patients, a higher dose is necessary. In others (pulmonary embolism, myocardial ischaemia), full heparinisation may actually be concomitantly indicated. Regional citrate anticoagulation is very effective but requires a special dialysate or replacement fluid.<sup>18</sup> Regional heparin/protamine anticoagulation is also somewhat complex but may be useful if frequent filter clotting occurs and further anticoagulation

**Figure 41.1** Diagrams illustrating a continuous venovenous haemofiltration circuit (CVVH).

**Figure 41.2** Diagrams illustrating a continuous venovenous haemodiafiltration circuit (CVVHDF).

of the patient is considered dangerous. Low-molecular-weight heparin is also easy to give but more expensive. Its dose must be adjusted for the loss of renal function. Heparinoids and prostacyclin may be useful if the patient has developed heparin-induced thrombocytopenia and thrombosis. Finally, in perhaps 10–20% of patients anticoagulation is best avoided because of endogenous coagulopathy or recent surgery. In such patients adequate filter life can be achieved provided that blood flow is kept at about 200 ml/min and vascular access is reliable.<sup>19</sup>

Many circuits clot for mechanical reasons (inadequate access, unreliable blood flow from double-lumen catheter

depending on patient position, kinking of catheter). Responding to frequent filter clotting by simply increasing anticoagulation without making the correct aetiological diagnosis (checking catheter flow and position, taking a history surrounding the episode of clotting, identifying the site of clotting) is often futile and exposes the patient to unnecessary risk. Particular attention needs to be paid to the adequacy or ease of flow through the double-lumen catheter. Smaller (11.5 Fr) catheters in the subclavian position are a particular problem. Larger catheters (13.5 Fr) in the femoral position appear to function more reliably.

**Figure 41.3** Diagram illustrating a continuous venovenous haemodialysis circuit (CVVHD).

**Table 41.2** Strategies for circuit anticoagulation during continuous renal replacement therapy

No anticoagulation
Low-dose prefilter heparin (< 500 IU/h)
Medium-dose prefilter heparin (500–1000 IU/h)
Full heparinisation
Regional anticoagulation (prefilter heparin and postfilter protamine, usually at a 100 IU:1 mg ratio)
Regional citrate anticoagulation (prefilter citrate and postfilter calcium – special calcium-free dialysate needed)
Low-molecular-weight heparin
Prostacyclin
Heparinoids
Serine proteinase inhibitors (nafamostat mesylate)

### CRRT TECHNOLOGY

The increasing use of venovenous CRRT has led to the development of a field of CRRT technology which offers different kinds of machines to facilitate its performance.<sup>20</sup> Some understanding of these devices is important to the successful implementation of CRRT in any ICU. One can have simple blood pump with safety features (air bubble trap and pressure alarms) and use widely available volumetric pumps to control replacement or dialysate flow and effluent flow. Such adaptive technology is inexpensive, but is not user-friendly. Also, volumetric pumps have an inherent inaccuracy of about 5%, which, in a system exchanging up to 50 l/day, can cause problems. Various manufacturers have now produced custom-made

machines for HF. These machines are safer and have much more sophisticated pump control systems, alarms and graphic displays. They are much more user-friendly, especially with the set-up procedure.

The choice of membrane is also a matter of controversy. There are no controlled studies to show that one confers a clinical advantage over the others. The AN 69 is the most commonly used CRRT membrane in Australia. The issue of membrane size is also controversial as no controlled studies have compared different membrane surface sizes. If high-volume haemofiltration is planned, however, the membrane surface needs to be in the 1.6–2 m<sup>2</sup> range.

### INTERMITTENT HAEMODIALYSIS

Vascular access is typically by double-lumen catheter, as in continuous HF. The circuit is also the same. Countercurrent dialysate flow is used as in CVVHD. The major differences are that standard IHD uses high dialysate flows (300–400 ml/min), generates dialysate by mixing purified water and concentrate and treatment is applied for short periods of time (3–4 hours), usually every second day. These differences have important implications. Firstly, volume has to be removed over a short period of time and this may cause hypotension. Repeated hypotensive episodes may delay renal recovery.<sup>4</sup> Secondly, solute removal is episodic. This translates into inferior uraemic control<sup>21</sup> and acid–base control. Limited fluid and uraemic control imposes unnecessary limitations on nutritional support. Furthermore, rapid solute shifts increase

brain water content and raise intracranial pressure.<sup>22</sup> Finally, much controversy has surrounded the issue of membrane bioincompatibility. Standard low-flux dialysing membranes made of cuprophane are known to trigger the activation of several inflammatory pathways, when compared to high-flux synthetic membranes (also used for continuous HF). It is possible that such proinflammatory effect contributes to further renal damage and delays recovery or even affects mortality. Given the minimal difference in cost between biocompatible and bioincompatible low-flux membranes, biocompatible membranes (polysulfone) are now preferred.

The limitations of applying 'standard' IHD to the treatment of ARF<sup>9</sup> has led to the development of new approaches (so-called 'hybrid techniques') such as SLEDD.<sup>13</sup> These techniques seek to adapt IHD to the clinical circumstances and thereby increase its tolerance and its clearances.

### PERITONEAL DIALYSIS

This technique is now uncommonly used in the treatment of adult ARF in developed countries.<sup>14</sup> However, it may be an adequate technique in developing countries or in children where the peritoneal membrane has a greater relative surface or alternatives are considered too expensive, too invasive, or are not available. Typically access is by the insertion of an intraperitoneal catheter. Glucose-rich dialysate is then inserted into the peritoneal cavity and acts as the 'dialysate'. After a given 'dwell time' it is removed and discarded with the extra fluid and toxins that have moved from the blood vessels of the peritoneum to the dialysate fluid. Machines are also available which deliver and remove dialysate at higher flows, providing intermittent treatment or higher solute clearances. Several major shortcomings make PD relatively unsuited to the treatment of adult ARF:

1. limited and sometimes inadequate solute clearance
2. high risk of peritonitis
3. unpredictable hyperglycaemia
4. fluid leaks
5. protein loss
6. interference with diaphragm function

There have not been any reports of the sole use of PD for the treatment of adult patients with ARF in the last 15 years. A randomised trial comparing PD to CVVH found that PD was associated with increased mortality.<sup>23</sup>

### OTHER BLOOD PURIFICATION TECHNIQUES

#### HAEMOPERFUSION

During haemoperfusion, blood is circulated through a circuit similar to one used for CVVH. However, a charcoal cartridge is perfused with blood instead of a dialysis membrane. In some cases an ion exchange resin (Amberlite)

has been used. Charcoal microcapsules effectively remove molecules of 300–500 D MW, including some lipid-soluble and protein-bound substances. Heparinisation is necessary to prevent clotting. Attention must also be paid to changes in intravascular volume at the start of therapy because of the large priming volume of the cartridge (260 ml). Glucose absorption is significant and monitoring of blood glucose is necessary to avoid hypoglycaemia. Also thrombocytopenia is common, and can be marked. The role of haemoperfusion is controversial, as no controlled trials have ever shown it to confer clinically significant advantages. It may be useful, however, in patients with life-threatening theophylline overdose because it removes the agent effectively.

### PLASMAPHERESIS OR PLASMA EXCHANGE

With this technique, plasma is removed from the patient and exchanged with fresh frozen plasma (FFP) and a mixture of colloid and crystalloid solutions. This technique can also be performed in an ICU familiar with CRRT techniques. A plasmafilter (a filter that allows the passage of molecules up to 500 kD) instead of a haemofilter is inserted in the CVVH circuit, and the filtrate (plasma) is discarded. Plasmapheresis can also be performed with special machines using the principles of centrifugation. The differences, if any, between centrifugation and filtration technology are unclear. Replacement (postfilter) will occur as in CVVH using, for example, a 50/50 combination of FFP and albumin. Plasmapheresis has been shown to be effective treatment for thrombotic thrombocytopenic purpura and for several diseases mediated by abnormal antibodies (Guillain-Barré syndrome, cryoglobulinaemia, myasthenia gravis, Goodpasture's syndrome) in which antibody removal appears desirable. Its role in the treatment of sepsis remains uncertain.<sup>24</sup>

### BLOOD PURIFICATION TECHNOLOGY OUTSIDE ARF

There is growing interest in the possibility that blood purification may provide a clinically significant benefit in patients with severe sepsis/septic shock by removing circulating 'mediators'. A variety of techniques, including plasmapheresis, high-volume HF, very-high-volume HF, coupled plasma filtration adsorption<sup>24–27</sup> and large-pore HF,<sup>27</sup> are being studied in animals and in phase I/II studies in humans. Initial experiments support the need to continue exploring this therapeutic option. However, no suitably powered randomised controlled trials have yet been reported. Also, blood purification technology in combination with bioreactors containing either human or porcine liver cells is under active investigations as a form of artificial liver support for patients with fulminant liver failure or for patients with acute-on-chronic liver failure. Albumin-based dialysis has been developed to deal with protein-bound toxins in patients with liver failure.

Table 41.3 Drug dosage during dialytic therapy\*

Drug	CRRT	IHD
Aminoglycosides	Normal dose q 36 h	50% normal dose q 48 h – 2/3 redose after IHD
Cefotaxime or ceftazidime	1 g q 8–12 h	1 g q 12–24 h after IHD
Imipenem	500 mg q 8 h	250 mg q 8 h and after IHD
Meropenem	500 mg q 8 h	250 mg q 8 h and after IHD
Metronidazole	500 mg q 8 h	250 mg q 8 h and after IHD
Co-trimoxazole	Normal dose q 18 h	Normal dose q 24 h after IHD
Amoxicillin	500 mg q 8 h	500 mg daily and after IHD
Vancomycin	1 g q 24 h	1 g q 96–120 h
Piperacillin	3–4 g q 6 h	3–4 g q 8 h and after IHD
Ticarcillin	1–2 g q 8 h	1–2 g q 12 h and after IHD
Ciprofloxacin	200 mg q 12 h	200 mg q 24 h and after IHD
Fluconazole	200 mg q 24 h	200 mg q 48 h and after IHD
Acyclovir	3.5 mg/kg q 24 h	2.5 mg/kg per day and after IHD
Gancyclovir	5 mg/kg per day	5 mg/kg per 48 h and after IHD
Amphotericin B	Normal dose	Normal dose
Liposomal amphotericin	Normal dose	Normal dose
Ceftriaxone	Normal dose	Normal dose
Erythromycin	Normal dose	Normal dose
Milrinone	Titrate to effect	Titrate to effect
Amrinone	Titrate to effect	Titrate to effect
Catecholamines	Titrate to effect	Titrate to effect
Ampicillin	500 mg q 8-hourly	500 mg daily and after IHD

CRRT, continuous renal replacement therapy; IHD, intermittent haemodialysis.

\*The above values represent approximations and should be used as a general guide only. Critically ill patients have markedly abnormal volumes of distribution for these agents which will affect dosage. CRRT is conducted at variable levels of intensity in different units, also requiring adjustment. The values reported here relate to continuous venovenous haemofiltration at 2 l/h of ultrafiltration. Vancomycin is poorly removed by continuous venovenous haemofiltration. IHD may also differ from unit to unit. The values reported here relate to standard IHD with low-flux membranes for 3–4 hours every second day.

This system, known as MARS (molecular adsorption recirculating system), has shown benefits in patients with elevated intracranial pressure and/or acute-on-chronic liver failure, but not in patients with fulminant liver failure.<sup>28</sup>

according to the technique of RRT, residual creatinine clearance and other determinants of pharmacodynamics is beyond the scope of this chapter and can be found in specialist texts.<sup>29</sup> Table 41.3 provides general guidelines for the prescription of drugs commonly used in the ICU.

#### DRUG PRESCRIPTION DURING DIALYTIC THERAPY

ARF and RRT profoundly affect drug clearance. A comprehensive description of changes in drug dosage

#### SUMMARY

The field of RRT has undergone remarkable changes over the last 10 years and is continuing to evolve rapidly. Technology is being improved to facilitate clinical

application and new areas of research are developing. CRRT is now firmly established throughout the world as perhaps the most commonly used form of RRT. Conventional dialysis, however, which was slowly losing ground, is reappearing in the form of extended, slow-efficiency treatment, especially in the USA. Two large phase IV trials (> 1000 patients) are under way in the USA and in Australia/New Zealand to compare different dialytic strategies (IHD or SLEDD or CRRT) or to define the optimal dose of CRRT and the results should be available in 2008. In the meantime the use of novel membranes, of sorbents and of different intensities of treatment is being explored in the area of sepsis management and liver support. Intensivists need to keep abreast of this rapid evolution if they are to offer their patients the best of care.

# Disorders of consciousness

Balasubramanian Venkatesh

## NEUROANATOMY AND PHYSIOLOGY OF WAKEFULNESS

A normal level of consciousness depends on the interaction between the cerebral hemispheres and the rostral reticular activating system (RAS) located in the upper brainstem. Although the RAS is a diffuse projection, the areas of RAS of particular importance to the maintenance of consciousness are those located between the rostral pons and the diencephalon. In contrast, consciousness is not focally represented in any of the cerebral hemispheres and is in many ways related to the mass of functioning cortex. Thus anatomical bilateral hemispheric lesions or brainstem lesions may result in an altered conscious state.<sup>1</sup> Large unilateral hemispheric lesions may produce impairment of consciousness by compression of the upper brainstem. In addition metabolic processes may result in coma from interruption of energy substrate delivery or alteration of neuronal excitability. Disorders of consciousness are characterised by an alteration in either the level or content of consciousness (Table 42.1). The last few conditions described in Table 42.1 are a frequent source of confusion and require further discussion (Table 42.2). These neurological states are seen more frequently in modern-day clinical practice partly because of the advances in therapy of severe brain injury and intensive care which have led to the survival of many patients who would otherwise have died.

## DIFFERENTIAL DIAGNOSIS OF COMA

Although the aetiology of coma is invariably multifactorial, the differential diagnosis of coma can be broadly grouped into three classes:

1. diseases that produce focal or lateralising signs
2. coma without focal or lateralising signs, but with signs of meningeal irritation
3. coma without focal or lateralising signs or signs of meningeal irritation

These are considered in greater detail in Table 42.3.

## CLINICAL EXAMINATION OF THE COMATOSE PATIENT

The neurological examination of the comatose patient is of crucial importance to assess the depth of coma and to locate the site of lesion. Although the detailed neurological examination which can be carried out in a conscious patient is not possible in a comatose individual, useful information can be obtained by performing a thorough general examination and a neurological examination, particularly evaluating the level of consciousness, brainstem signs and motor responses in coma.

## GENERAL EXAMINATION

General examination of the patient may point to the aetiology of coma. Skin changes may be seen in carbon monoxide poisoning (cherry-red discoloration of skin), alcoholic liver disease (telangiectasia, clubbing), hypothyroidism (puffy facies) and hypopituitarism (sallow complexion). The presence of cutaneous petechiae or ecchymoses may point to meningococcaemia, rickettsial infection or endocarditis as possible causes of coma. Needle puncture marks may suggest substance abuse. Bullous skin lesions are a feature of barbiturate overdose. An excessively dry skin may indicate diabetic ketoacidosis or anticholinergic overdose.

Periorbital haematomas (raccoon eyes) indicate an anterior basal skull fracture, particularly if there is associated cerebrospinal fluid rhinorrhoea. The other signs of a basal skull fracture include Battle's sign and cerebrospinal fluid otorrhoea. Nuchal rigidity may be seen in meningococcal meningitis and subarachnoid haemorrhage, although this sign may not be present in the elderly and in patients in deep coma.

The presence of hepatomegaly or stigmata of chronic liver disease may suggest hepatic encephalopathy. Bilateral enlarged kidneys may indicate polycystic kidney disease and should prompt one to consider subarachnoid haemorrhage as a possible aetiology of coma. The breath may smell of alcohol or other poisons (organophosphates). The smell of ketones on the breath is an unreliable sign and hepatic and uraemic foetor are rare.

Table 42.1 Disorders of consciousness

Consciousness	An awake individual demonstrates full awareness of self and environment
Confusion	Inability to think with customary speed and clarity, associated with inattentiveness, reduced awareness and disorientation
Delirium	Confusion with agitation and hallucination
Stupor	Unresponsiveness with arousal only by deep and repeated stimuli
Coma	Unarousable unresponsiveness
Locked-in syndrome	Total paralysis below third cranial nerve nuclei; normal or impaired mental function
Persistent vegetative state	Prolonged coma > 1 month, some preservation of brainstem and motor reflexes
Akinetic mutism	Prolonged coma with apparent alertness and flaccid motor tone
Minimally conscious state	Preserved wakefulness, awareness and brainstem reflexes, but poorly responsive

### LEVEL OF CONSCIOUSNESS

This is assessed by the Glasgow Coma Scale (GCS),<sup>2</sup> which takes into account a patient's response to command and physical stimuli. The GCS (Table 42.4) which was originally developed to grade the severity of head injury and prognosticate outcome, has now been extended for all causes of impaired consciousness and coma. Although it is a simple clinical score, easily performed by both medical and nursing staff by the bedside, there are a number of caveats:

1. The GCS should always be determined prior to administration of sedative drugs or endotracheal intubation.
2. It should also be defined with regard to a patient's vital signs, namely blood pressure, heart rate and temperature.
3. The GCS must be interpreted in the light of previous or concomitant drug therapy.
4. The presence of alcohol in the breath or in the serum should always be documented.
5. Because of the considerable interobserver variation in scoring, it is important to define the responses in descriptive terms rather than emphasising the numerical score associated with each response.
6. Measurement of awareness by the GCS is limited. Subtle changes in brainstem reflexes are not adequately assessed by the GCS.

### PUPILLARY RESPONSES IN COMA<sup>3</sup>

The presence of normal pupils (2–5 mm and equal in size and demonstrating both direct and consensual light reflexes) confirms the integrity of the pupillary pathway (retina, optic nerve, optic chiasma and tracts, midbrain and third cranial nerve nuclei and nerves). The size of the pupil is a balance between the opposing influences of both sympathetic (causing dilatation) and parasympathetic (causing constriction) systems. Pupillary abnormalities have localising and diagnostic value in clinical neurology (Table 42.5). When the pupils are miosed, the light reaction is difficult to appreciate and may require a magnifying glass.

### OPHTHALMOSCOPY IN COMA

The pupils *should never be dilated pharmacologically* without prior documentation of the pupillary size and the light reflex. The presence of papilloedema suggests the presence of intracranial hypertension, but is frequently absent when the lesion is acute. Subhyaloid and vitreous haemorrhages are seen in patients with subarachnoid haemorrhage.<sup>4</sup>

### EYE MOVEMENTS IN COMA<sup>5</sup>

Horizontal eye movements to the contralateral side are initiated in the ipsilateral frontal lobe and closely coordinated with the corresponding centre in the contralateral pons. To facilitate conjugate eye movements, yoking of the third-, fourth- and sixth-nerve nuclei is achieved by the medial longitudinal fasciculus.

To look to the left, the movement originates in the right frontal lobe and is coordinated by the left pontine region and vice versa. In contrast to horizontal gaze, vertical eye movements are under bilateral control of the cortex and upper midbrain.

The position and movements of the eyes are observed at rest. The presence of spontaneous roving eye movements excludes brainstem pathology as a cause of coma. In a paralytic frontal-lobe pathology, the eyes will deviate towards the side of the lesion, whilst in pontine pathologies, the eyes will deviate away from the side of the lesion. Ocular bobbing, an intermittent downward jerking eye movement, is seen in pontine lesions due to loss of horizontal gaze and unopposed midbrain controlled vertical gaze activity.<sup>6</sup> Skew deviation (vertical separation of the ocular axes) occurs with pontine and cerebellar disorders.<sup>7</sup>

The presence of full and conjugate eye movements in response to oculocephalic and oculovestibular stimuli demonstrates the functional integrity of a large segment of the brainstem. Corneal reflexes are preserved until late in coma. Upward rolling of the eyes after corneal stimulation (Bell's phenomenon) implies intact midbrain and pontine function.

Table 42.2 Coma-like syndromes and related states

Syndrome	Features	Site of lesion	EEG	Metabolism (% of normal) <sup>35</sup>	Comments
Locked-in syndrome <sup>31</sup> (de-efferented state)	Alert and aware, vertical eye movements present, and able to blink. Quadriplegic, lower cranial nerve palsies, no speech, facial or pharyngeal movements	Bilateral anterior pontine lesion which transects all descending motor pathways, but spares ascending sensory and reticular activating systems	Normal	90–100%	Similar state seen with severe polyneuropathies, myasthenia gravis and neuromuscular blocking agents
Persistent vegetative state (PVS) <sup>32,33</sup> (apallic syndrome, neocortical death)	Previously comatose, who now appear to be awake. Spontaneous limb movements, eye movements and yawning seen. However patient inattentive, no speech, no awareness of environment and total inability to respond to commands	Extensive damage to both cerebral hemispheres with relative preservation of the brainstem	Polymorphic delta or theta waves, sometimes alpha	40–60%	When vegetative state lasts longer than 4 weeks, it is termed persistent. PVS lasting for longer than 2 weeks implies a poor prognosis
Akinetic mutism <sup>34</sup> (coma vigilie)	Partially or fully awake patient, immobile and silent	Lesion in bilateral frontal lobes or hydrocephalus or third ventricular masses	Diffuse slowing	40–80%	'Abulia' is the term applied to milder forms of akinetic mutism
Catatonia	Awake patients, sometimes a fixed posture, muteness with decreased motor activity	Usually of psychiatric origin	Non-specific EEG patterns associated with associated medical conditions	Variable metabolic changes in prefrontal cortex	May be mimicked by frontal lobe disease and drugs
Minimally conscious state <sup>35</sup>	Globally impaired responsiveness, limited but discernible evidence of self and environment	Global neuronal damage	Theta and alpha waves	40–60%	Differs from PVS in that patients diagnosed with minimally conscious state have some level of awareness

EEG, electroencephalogram.

### LIMB MOVEMENTS AND POSTURAL CHANGES IN COMA

Restlessness, crossing of legs and spontaneous coughing, yawning, swallowing and localising movements suggest only a mild depression of the conscious state. Choreoathetotic or ballistic movements suggest a basal ganglion lesion. Myoclonic movements indicate a metabolic disorder, usually of postanoxic origin. Asterix is seen with metabolic encephalopathies. Hiccup is a non-specific sign and does not have any localising value.

Decerebrate rigidity is characterised by stiff extension of the limbs, internal rotation of the arms and plantar flexion of the ankles. With severe rigidity, opisthotonos and jaw clenching may be observed. These movements may be unilateral or bilateral, and spontaneous or in response to a noxious stimulus. Whereas animal studies suggest that the lesion is usually in the midbrain or caudal diencephalon (leading to exaggeration of antigravity reflexes), in humans such posturing may be seen in a variety of disease states: midbrain lesion, certain metabolic disorders such as hypoglycaemia, anoxia, hepatic coma and in drug intoxication.

Table 42.3 Differential diagnosis of coma

Category	Specific disorder	Features in history and examination	Investigations	Comments
Coma with focal signs	<i>Trauma</i> – extradural, subdural and parenchymal haemorrhage, concussions	History of trauma, findings of fracture at base of skull, scalp haematoma, other associated body injuries	Usually an abnormal CT	Exclude coexisting drug or alcohol ingestion
	<i>Vascular</i> –intracerebral haemorrhage	Sudden onset, history of headaches or hypertension, neck stiffness may be present	Abnormal CT scan	Consider causes of secondary hypertension in young hypertensives
	<i>Vascular</i> – thromboembolic	Sudden onset, atrial fibrillation, vascular bruits, endocarditis	An abnormal CT after a few days	Consider echocardiography to diagnose cardiac sources of emboli
	Brain abscess	Subacute onset, look for ENT and dental sources of infection	Abnormal CT and CSF	Consider infective endocarditis and suppurative lung disease as sources of sepsis
Coma without focal signs, but with meningeal irritation	Infection, meningitis, encephalitis	Onset of illness over a few hours to days, neck stiffness, rash of meningococcaemia	Abnormal CSF	Consider underlying immunosuppressive states
	Subarachnoid haemorrhage	Onset usually sudden, subhyaloid haemorrhages on fundoscopy	Abnormal CT and CSF	Consider polycystic kidney disease in subarachnoid haemorrhage
Coma without focal signs and no meningeal irritation	Metabolic causes Hyponatraemia Hypoglycaemia Hyperglycaemia Hypoxia Hypercapnia Hypo- and hyperthermia Hyper- and hypo-osmolar states	History might point to the cause of metabolic disturbance, asterix a feature of hypercapnia-induced coma	Abnormal blood results	Rapid correction of hyponatraemia and osmolality should be avoided
	Endocrine causes Myxoedema Adrenal insufficiency Hypopituitarism	Puffy facies, may be hypothermic	Abnormal electrolyte profile, hypoglycaemia	Multiple disorders may be present in the same patient
	Seizure disorders	History typical	Abnormal EEG, check anticonvulsant levels	CT scan to exclude an underlying space-occupying lesion
	Organ failure Hepatic Renal Toxic/drug Sedatives Narcotics Alcohol Psychotropic	History of jaundice, chronic alcohol ingestion, stigmata of liver disease, asterix History, may be hypothermic at presentation except in psychotropic drug overdose	Abnormal hepatic and renal functions Metabolic screen is usually normal	Presence of A-V fistula may be a pointer to chronic renal failure Rapid improvement in conscious states with antidotes

Continued

**Table 42.3** Differential diagnosis of coma—*Continued*

Category	Specific disorder	Features in history and examination	Investigations	Comments
	Carbon monoxide Poisons			
	Behavioural Sleep deprivation Pseudocoma	No typical features	No specific diagnostic tests	Diagnosis of exclusion

CT, computed tomography; CSF, cerebrospinal fluid; ENT, ear, nose and throat; EEG, electroencephalogram; A-V, arteriovenous.

**Table 42.4** Glasgow Coma Scale

Eye opening	Points
Spontaneous	4
To speech	3
To pain	2
Nil	1
<b>Best verbal response</b>	
Oriented	5
Confused	4
Inappropriate	3
Incomprehensible	2
Nil	1
Intubated	T
<b>Best motor response</b>	
Obeys commands	6
Localises to pain	5
Withdraws to pain	4
Abnormal flexion	3
Extensor response	2
Nil	1

Decorticate posturing is characterised by flexion of elbows and wrists and extension of the lower limbs. The lesion is usually above the midbrain in the cerebral white matter.

### RESPIRATORY SYSTEM<sup>8</sup>

Abnormal respiratory rate and patterns have been described in coma, but their precise localising value is uncertain. As a general rule, at lighter levels of impaired consciousness tachypnoea predominates, whereas respiratory depression increases with the depth of coma. Some of the commonly observed respiratory abnormalities are summarised in Table 42.6. Respiratory failure in comatose patients may result from hypoventilation, aspiration pneumonia and neurogenic pulmonary oedema, a sympathetic nervous system-mediated syndrome seen in acute brain injury.

### BODY TEMPERATURE IN COMA

The presence of altered core body temperature is a useful aid in the diagnosis of coma. Hypothermia (< 35°C) is frequently observed with alcohol or barbiturate

intoxication, sepsis with shock, drowning, hypoglycaemia, myxoedema, coma and exposure to cold. Severe hyperthermia may be seen in pontine haemorrhage, intracranial infections, heat stroke and anticholinergic drug toxicity.

### RECOGNITION OF BRAIN HERNIATION<sup>9,10</sup>

When patients with impaired level of consciousness deteriorate, it is important to consider brain herniation as a possible cause of worsening. Brain herniation results from the downward displacement of the upper brainstem (central herniation) with or without involvement of the uncus (lateral herniation). The clinical signs of a central herniation are progressive obtundation, Cheyne–Stokes respiration, small pupils followed by extensor posturing and medium-sized fixed dilated pupils. Uncal herniation differs from central herniation in that pupillary dilatation occurs early in the process because of third-nerve compression. The traditional Cushing's response of hypertension and bradycardia is not always a feature of herniation and any heart rhythm may be present.

### DIFFERENTIATING TRUE COMA FROM PSEUDOCOMA

Patients feigning coma resist passive eye opening and may even hold their eyes tightly closed. They may blink in response to a threat and do not demonstrate spontaneous roving eye movements. In contrast, they move the eyes concomitantly with head rotation and, with cold caloric testing, they may wake up or demonstrate preservation of the fast component of nystagmus. They also demonstrate avoidance of 'self-injury'. In addition, the pattern of clinical 'abnormalities' does not fit any specific neurological syndromes.

### MANAGEMENT OF THE COMATOSE PATIENT

#### EMERGENT THERAPEUTIC MEASURES

Irrespective of the aetiology of coma, certain emergent therapeutic measures apply to the care of all patients. These take precedence over any diagnostic investigation.

Table 42.5 Pupillary abnormalities in coma

Abnormality	Cause	Neuroanatomical basis
<b>Miosis (&lt; 2 mm in size)</b>		
Unilateral	Horner's syndrome Local pathology	Sympathetic paralysis Trauma to sympathetics
Bilateral	Pontine lesions Thalamic haemorrhage Metabolic encephalopathy Drug ingestion Organophosphate Barbiturate Narcotics	Sympathetic paralysis  Cholinesterase inhibition  Central effect
<b>Mydriasis (&gt; 5 mm in size)</b>		
Unilateral fixed pupil	Midbrain lesion Uncal herniation	Third-nerve damage Stretch of third nerve against the petroclinoid ligament
Bilateral fixed pupils	Massive midbrain haemorrhage Hypoxic cerebral injury Drugs Atropine Tricyclics Sympathomimetics	Bilateral third-nerve damage  Mesencephalic damage  Paralysis of parasympathetics Prevent local reuptake of catecholamines by nerve endings Stimulation of sympathetics

Table 42.6 Disorders of respiratory rate and pattern in coma

Abnormality	Significance
Bradypnoea	Drug-induced coma, hypothyroid coma
Tachypnoea	Central neurogenic hyperventilation (midbrain lesion), metabolic encephalopathy
Cheyne–Stokes respiration	Deep cerebral lesions, metabolic encephalopathy (hyperpnoea alternating regularly with apnoea)
Apneustic breathing (an inspiratory pause)	Pontine lesions
Ataxic breathing (Ataxic breathing normally progresses to agonal gasps and terminal apnoea)	Medullary lesions

1. Ensure adequate airway and oxygenation.
2. Secure intravenous access and maintain circulation.
3. Administer 50% dextrose after drawing a sample of blood for serum glucose levels. Although there are theoretical concerns about augmentation of brain lactic acid production<sup>11,12</sup> in anoxic coma, the relatively good prognosis for hypoglycaemic coma when treated expeditiously far outweighs any potential risks of glucose administration.
4. Thiamine must always be administered in conjunction with dextrose to prevent precipitation of Wernicke's encephalopathy.

5. Consideration should be given to administering naloxone when there is a suspicion of narcotic overdose with impending respiratory arrest.
6. If hypertension, bradycardia and fixed dilated pupils are present at the time of the initial presentation, suggestive of marked intracranial hypertension and tentorial herniation, 20% mannitol at a dose 0.5–1 g/kg body weight should be administered. Consideration should be given to the emergency placement of an external ventricular drain.
7. Treat suspected meningitis with antibiotics even if cerebrospinal fluid results are not available. A combination of penicillin and ceftriaxone is usually recommended for community-acquired bacterial meningitis.
8. Control of seizures must be achieved as outlined in Chapter 43.
9. Treat extreme body temperatures.

## INVESTIGATIONS

The order of investigation depends on the clinical circumstances. In the majority of cases, history and examination will provide enough information to be able to perform specific cause-related investigation. In general, the investigations can be grouped as follows.

### ROUTINE INVESTIGATIONS

Measurements of serum glucose, electrolytes, arterial blood gases, liver and renal function tests, osmolality, blood count and blood film are part of the routine

investigations. When drug overdose is suspected, a toxicology screen for alcohol, paracetamol, salicylates, benzodiazepines and tricyclic antidepressants should be performed. A sample of serum should be stored for later analysis for uncommon drug ingestions.

## NEUROIMAGING

### COMPUTED TOMOGRAPHY (CT) SCAN

The most commonly used radiological investigation for evaluation of the comatose patient is CT scan of the brain. This is useful for diagnosing central nervous system trauma, subarachnoid and intracerebral haemorrhage, haemorrhagic and non-haemorrhagic strokes, cerebral oedema, hydrocephalus and the presence of a space-occupying lesion (SOL) (Figures 42.1–42.10). Frequently a CT is performed prior to a lumbar puncture (LP) to exclude rather than confirm the presence of severe cerebral oedema or an SOL. Its other advantages include lower cost, easy availability, short examination time and safety in the presence of pacemakers, surgical clips and other ferromagnetic substances. The advent of helical CT whereby multiple images are possible has reduced scanning times and is suitable for the uncooperative patient. Limitations of a CT scan include:

1. the need to transfer the patient to a site where resuscitation and monitoring facilities are limited
2. the need to sedate and possibly endotracheally intubate patients who are agitated

**Figure 42.1** Right middle cerebral artery infarct. There is anterior and posterior sparing. Loss of right lateral ventricle. Moderate mass effect with midline shift.

3. its low sensitivity to demonstrate an abnormality in the acute phase of a stroke
4. its low sensitivity for detecting brainstem lesions
5. the need to administer intravenous contrast agents.

The two major side-effects of intravenous contrast include anaphylaxis (with an approximate death rate of 1 in 40 000) and renal failure. The use of *N*-acetylcysteine, sodium bicarbonate and haemodialysis has been reported to reduce the incidence of contrast-induced nephropathy, although data in critically ill patients are minimal.<sup>13</sup>

### MAGNETIC RESONANCE IMAGING (MRI)

MRI scans provide superior contrast and resolution of the grey and white matter as compared to CT scans, thus facilitating easy identification of the deep nuclear structures within the brain. MRI is more sensitive than CT for the detection of acute ischaemia, diffuse axonal injury and cerebral oedema, tumour and abscess. Brainstem and posterior fossa structures are better visualised (Figures 42.11–42.13). It can also show vasculature (see Figure 42.13b and c). The other advantage of MRI is the use of non-ionising energy. The use of gadolinium, a paramagnetic agent, as a contrast agent permits sharp definition of lesions. MR coupled with angiography (MRA) may enable diagnosis of vascular lesions. MRI is however limited by:

1. the need for special equipment
2. long imaging times
3. the need to transfer the patient to a site where resuscitation and monitoring facilities are limited
4. the need to sedate and possibly endotracheally intubate patients who are agitated
5. the risk of dislodgement of metal clips on blood vessels and resetting of pacemakers

### PET AND SPECT SCANS

Newer nuclear medicine scans such as single-photon emission with computed tomography (SPECT) and positron emission tomography (PET) are useful for the assessment of cerebral blood flow and oxygenation and in the prognostication of neurotrauma, but have little role to play in the management of acute disorders of consciousness. In PET scans, positron-emitting isotopes such as <sup>11</sup>C, <sup>18</sup>F and <sup>15</sup>O are incorporated into biologically active compounds such as deoxyglucose or fluorodeoxyglucose which are metabolised in the body. By determining the concentration of the various tracers in the brain and constructing tomographic images, cerebral blood flow and metabolism can be measured by PET scanning.

SPECT scans use iodine-containing isotopes incorporated into biologically active compounds and, like PET scans, their cranial distribution is determined after a dose

**Figure 42.2** Blood. Right thalamic intraparenchymal bleed with subarachnoid blood. (a) Fourth ventricle; (b) both lateral ventricles; (c) ventricles and intraparenchymal blood.

of tracer. Information on cerebral blood flow and metabolism can be obtained from SPECT scans. The advantage of a PET scan is that it does not require a cyclotron for the generation of isotopes. Despite their many advantages, both these technologies continue to be research tools and are not routinely available in many medical centres.

#### LUMBAR PUNCTURE<sup>14</sup>

Cerebrospinal fluid is most commonly obtained by means of an LP. This should be performed after ensuring that raised intracranial pressure has been excluded clinically or radiologically. The major use of an LP is to diagnose an intracranial infection and to detect abnormal cytology

**Figure 42.3** Subarachnoid haemorrhage. Blood in the Sylvian fissure and in basal cisterns.

**Figure 42.5** Chronic left subdural haematoma. Isodense fluid filling space. The small white area may suggest a recent acute bleed.

**Figure 42.4** Acute left subdural haematoma. Crescentic pattern within the skull with high attenuation. Loss of ventricle.

**Figure 42.6** Right extradural haematoma. Note soft-tissue swelling.

in cases of suspected malignant meningeal infiltration. The advent of CT scans has diminished the role of LP in the diagnosis of subarachnoid haemorrhage. Some of the commonly reported complications post-LP include postpuncture headache (12–39%) and traumatic tap (15–20%). Brain herniation is a rare potential complication seen with conditions associated with raised intracranial pressure due to an SOL.

#### ELECTROENCEPHALOGRAM (EEG) IN COMA<sup>15,16</sup>

The usefulness of EEG in coma is summarised in Table 42.7. Continuous EEG monitoring in the intensive care unit (ICU) has been reported to be useful in the

**Figure 42.7** Right frontoparietal bleed. Note oedema, loss of lateral ventricle and minor midline shift.

identification of acute cerebral ischaemia and non-convulsive seizures.

### EVOKED POTENTIALS

Visual, brainstem and somatosensory evoked potentials test the integrity of neuroanatomical pathways within the brain and the spinal cord. They may be used in the diagnosis of blindness in comatose patients and in the assessment of locked-in states. There are data to suggest that they have better prognostic value than clinical judgement in patients with anoxic coma.<sup>17</sup>

### BIOCHEMICAL ABNORMALITIES<sup>18</sup>

A number of biomarkers of brain injury have been evaluated as predictors of severity of brain injury and to assess progression of injury severity from traumatic and non-traumatic aetiologies. These include neurone-specific enolase (cytoplasm of neurons), S-100 B protein (astroglial cells), CK-BB fraction (astrocytes), glial fibrillary acidic protein (glial origin), calpain and caspase. Whilst early studies showed S-100B to be a reliable marker of traumatic brain injury, concerns remain about their sensitivity and specificity for assessment of severity and prediction of outcome.

### CARE OF THE COMATOSE PATIENT

#### AIRWAY

As mentioned before, assessment of airway adequacy should take precedence over any diagnostic investigation in comatose patients. This is best done by assessing the

**Figure 42.8** Multiple enhanced lesions – metastases. (a) Left frontal lesion; (b) right thalamic lesion.

patient's response to command and physical stimulation, and whether a gag reflex is present. Securing the airway will depend on the level of consciousness. This may entail simple manoeuvres such as jaw thrust, chin lift, use of oropharyngeal airways or in the comatose patient mandate endotracheal intubation. All of these patients are at risk of pulmonary aspiration and there must be a low threshold for establishing a definitive airway.

As a general rule, patients presenting with medical causes of coma may be nursed on their side (in the coma position) if the airway is adequate. However, all traumatised patients should be assumed to have a potential cervical spine injury and must be nursed with the cervical spine in the neutral position and/or with a rigid collar until an injury is excluded by definitive radiological views. All

**Figure 42.9** Frontal meningioma. (a) Precontrast; (b) postcontrast.

patients with disordered consciousness must receive supplemental oxygen.

### VENTILATION

It is important to ensure optimal gas exchange and avoid hypoxia and hypercapnia. Generally a  $P_{aO_2}$  of  $> 80$  torr and  $P_{CO_2}$  of 35–40 torr is desirable. If spontaneous ventilatory efforts are not adequate to achieve these levels of arterial blood gases, mechanical ventilatory support may be necessary.

### CIRCULATION

Adequacy of circulation should be assessed by conventional clinical endpoints. The goals of circulatory therapy in coma

**Figure 42.10** Abscess. (a) Precontrast; (b) postcontrast.

include prompt restoration of appropriate mean arterial blood pressure, correction of dehydration and hypovolaemia and urgent attention to life-threatening causes of shock.

### SPECIFIC TREATMENT

This will depend on the underlying aetiology of the coma and is discussed in the relevant chapters. Avoidance of

Figure 42.11 Cerebellar infarct.

Figure 42.12 Posterior cerebral bleed.

secondary insults is of paramount importance in the management of these patients.<sup>19</sup>

#### NURSING CARE

Meticulous eye and mouth care, regular changes in limb position, limb physiotherapy, bronchial toilet and psychological support are mandatory. Nosocomial infections and iatrogenic complications are associated with an increased mortality and morbidity in these patients and must be promptly diagnosed and treated. The rational use of daily investigations, invasive procedures and antibiotic prescription is essential.

Figure 42.13 (a) Pontine ischaemia seen on magnetic resonance imaging (MRI). MRI can also be used to show vasculature. (b) Occluded left vertebral artery;

Identification of non-convulsive status epilepticus
Diagnosis of hepatic encephalopathy
Presence of paroxysmal triphasic waves
Assessing severity of hypoxic encephalopathy
Presence of theta activity
Diffuse slowing
Burst suppression (seen with more severe forms)
Alpha coma (seen with more severe forms)
Herpes encephalitis
Periodic sharp spikes

### OTHER THERAPY

Stress ulcer and deep-vein thrombosis prophylaxis should be instituted. Early establishment of enteral feeding via a nasogastric tube is preferable. It is important to exclude a basal skull fracture before insertion of a nasogastric tube.

### ANOXIC COMA/ENCEPHALOPATHY

Cardiac arrest is the third leading cause of coma resulting in ICU admission after trauma and drug overdose. The symptomatology and clinical outcome of patients with anoxic brain damage depend on the severity and duration of oxygen deprivation to the brain. A number of criteria have been developed to prognosticate outcome in anoxic coma. Although a number of laboratory and imaging criteria contribute to the prognostic assessment, clinical signs still have major prognostic impact. The important clinical predictors of outcome are listed in Table 42.8. However there are data to suggest that electrophysiological studies using evoked potential have far greater prognostic accuracy compared to clinical assessment.<sup>20</sup>

**Table 42.8** Clinical and laboratory predictors of unfavourable prognosis in anoxic coma<sup>17,36–38</sup>

Clinical predictor	Unfavourable prognosis
Duration of anoxia (time interval between collapse and initiation of CPR)	8–10 min
Duration of CPR (time interval between initiation of CPR and ROSC)	> 30 min
Duration of postanoxic coma	> 72 hours
Pupillary reaction	Absent on day 3
Motor response to pain (absent = a motor response worse than withdrawal)	Absent on day 3
Roving spontaneous eye movements	Absent on day 1
Elevated neuron specific enolase	> 33 µg/l
SSEP recording	Absent N20

CPR, cardiopulmonary resuscitation; ROSC, restoration of spontaneous circulation; SSEP, somatosensory evoked potential.

### THE CONFUSED/ENCEPHALOPATHIC PATIENT IN THE ICU

'Encephalopathy' is a term used to describe the alteration in the level or content of consciousness due to a process extrinsic to the brain. Metabolic encephalopathy, particularly of septic aetiology, is the most common cause of altered mental status in the ICU setting.<sup>21</sup> A number of processes can lead to metabolic encephalopathy (Table 42.9). A number of features in the history and examination help to differentiate metabolic from structural causes of altered conscious states (Table 42.10).

Owing to their increased frequency in and exclusiveness to the critical care setting, two types of encephalopathy will be considered in detail: septic encephalopathy and ICU syndrome.

**Table 42.9** Aetiology of metabolic/toxic encephalopathy<sup>39–41</sup>

Hepatic failure
Renal failure
Respiratory failure
Sepsis
Electrolyte abnormalities: hyponatraemia, hypernatraemia, hypercalcaemia
Hypoglycaemia and hyperglycaemia
Acute pancreatitis
Endocrine – Addisonian crisis, myxoedema coma, thyroid storm
Drug withdrawal – benzodiazepine, opiates
Hyperthermia
Toxins: alcohols, glycols, tricyclic antidepressants
Intensive care unit syndrome
D-lactic acidosis

**Table 42.10** Distinguishing features of structural and metabolic encephalopathy<sup>41</sup>

Feature	Structural	Metabolic
State of consciousness	Usually fixed level of depressed conscious state, may deteriorate progressively	Milder alteration of conscious state, waxing and waning of altered sensorium
Fundoscopy	May be abnormal	Usually normal
Pupils	May be abnormal, either in size or response to light	Usually preserved light response (although pupil shape and reactivity affected in certain overdoses: see above)
Eye movements	May be affected	Usually preserved
Motor findings	Asymmetrical involvement	Abnormalities usually symmetrical
Involuntary movements	Not common	Asterixis, tremor, myoclonus frequently seen

*Sepsis-associated encephalopathy (SAE)* has been reported to occur in 8–80% of patients with sepsis.<sup>22</sup> The criteria to diagnose SAE include presence of impaired mental function, evidence of an extracranial infection and absence of other obvious aetiologies for the altered conscious state. Although the precise mechanism of damage to the brain has not been delineated, the pathogenesis of the encephalopathy is thought to be multifactorial: alteration in cerebral blood flow induced by mediators of inflammation, generation of free radicals by activated leukocytes resulting in erythrocyte sludging in the microcirculation, breakdown of the blood–brain barrier resulting in cerebral oedema, reduced brain oxygen consumption induced by endotoxin and cytokines, neuronal degeneration and increased neuronal apoptosis, increases in aromatic amino acids resulting in altered neurotransmitter function and increased gamma-aminobutyric acid (GABA)-mediated neurotransmission leading to general inhibition of the central nervous system. Hypotension may contribute to the encephalopathy. The asterixis, tremor and myoclonus – features of other metabolic encephalopathies – are uncommon in sepsis. The presence of lateralising signs are extremely rare in SAE and warrant exclusion of other causes, such as stroke. The mortality of patients with SAE is higher than in those with sepsis without encephalopathy.<sup>23</sup> Therapy is largely directed at the underlying septic process.

#### ICU ENCEPHALOPATHY OR ICU SYNDROME<sup>24,25</sup>

This is a term used to describe behavioural disorders which develop in patients 5–7 days after admission to intensive care. Clinically this may present as agitation, restlessness and frank delirium. The causes are multifactorial: prolonged ventilation, sleep deprivation,<sup>26,27</sup> distortion of perception with loss of day–night cycles, immobilisation, noisy environment and monotony. Coupled with administration of multiple sedatives and neurological consequences of the underlying disease, these

factors can precipitate psychotic behaviour in the ICU. It is important to bear in mind that *this is a diagnosis of exclusion and that all other reversible causes are looked for (see Table 42.7)* before this diagnostic label is applied.

Abnormal behaviour can increase patient morbidity (self-extubation, ripping of catheters, soft-tissue damage). It is important to identify the underlying cause of the abnormal behaviour to institute appropriate therapy. Management of this condition may require the use of restraints, sedation and major tranquillisers. Improvement of sleep quality (minimising interruption of nocturnal sleep, adjusting lighting in the ICU), reducing patient boredom by the use of television and music and better communication with the patient may reduce the incidence and severity of this syndrome.

#### PROGNOSIS IN COMA

Drug-induced comas usually have a good prognosis unless hypoxia and hypotension have resulted in severe secondary insults. Coma following head injury has a statistically better outcome compared to non-traumatic coma (coma occurring during the course of a medical illness). In non-traumatic coma lasting for 6 hours or greater, only 15% of the patients make a meaningful recovery to be able to return to their premorbid state of health.<sup>28</sup> The prognosis following anoxic coma has been described in a separate section. Within the non-traumatic coma category, coma resulting from infection, metabolic causes and multiple-organ dysfunction syndrome has a better outcome compared to anoxic coma.<sup>29</sup> A number of outcome scales have been developed to assess neurological recovery following brain injury.<sup>30</sup> These include the Barthel index, Rankin scale and the Glasgow Outcome Scale (GOS). The GOS is widely used to assess recovery after traumatic brain injury. It has five broad categories: 1 = good recovery; 2 = moderate disability; 3 = severe disability; 4 = persistent vegetative state; and 5 = death. It is simple, easy to administer and has been reported to have good interrater agreement.

# Status epilepticus

Helen Ingrid Opdam

Status epilepticus (SE) is a medical emergency requiring prompt intervention to prevent the development of irreversible brain damage.

The duration of seizure activity required to define SE has not been universally agreed upon. Most authors have defined SE as more than 30 minutes' duration of either a single seizure, or intermittent seizures with no regaining of consciousness between seizures.<sup>1–4</sup> This definition is most useful for epidemiological research and is based on experimental studies that show that irreversible neuronal damage occurs after 30 minutes of seizure activity.<sup>5,6</sup>

More recently an operational definition of SE as 5 minutes of continuous seizure activity, or two or more discrete seizures with no intervening recovery of consciousness, has been used.<sup>7</sup> This definition promotes earlier diagnosis and treatment of SE. It has arisen from the generally accepted need to initiate treatment for SE rapidly and the observation that seizures persisting beyond this duration are unlikely to remit spontaneously.<sup>8</sup>

Refractory SE is defined as failure of initial therapy, such as benzodiazepines and phenytoin, with seizures persisting beyond 1–2 hours and usually requiring agents that induce general anaesthesia to control them.<sup>9,10</sup> Refractory SE is associated with a worse prognosis.<sup>9,11</sup>

SE is commonly separated into two categories:

1. Generalised convulsive SE (GCSE). Seizures are primary or secondarily generalised and the patient has generalised tonic and/or clonic convulsive movements with loss of consciousness.
2. Non-convulsive SE (NCSE). There is altered consciousness without convulsive movements but electroencephalography (EEG) evidence of seizures. NCSE may evolve from GCSE when electrical seizure activity continues with loss of motor manifestations. NCSE includes absence SE and complex partial SE.

The incidence of SE is U-shaped, being greatest under 1 year and over 60 years of age.<sup>2</sup>

## PATHOPHYSIOLOGY

Ongoing or recurrent seizures result from failure of normal seizure-terminating mechanisms or excessive

excitation causing seizure activity to persist. The major inhibitory mechanism in the brain is  $\gamma$ -aminobutyric acid A (GABA<sub>A</sub>) receptor-mediated inhibition. Glutamate excitatory synaptic transmission is important in sustaining SE.<sup>12</sup>

The pathophysiological effects of seizures on the brain are thought to result from both direct excitotoxic neuronal injury and secondary injury due to systemic complications such as hypotension, hypoxia and hyperthermia. Ongoing excitation results in excessive intracellular calcium flux through the opening of NMDA (*N*-methyl-D-aspartate) receptor-mediated calcium channels, inducing a cascade of intracellular neurochemical events that damage or kill the cell.

## AETIOLOGY

SE may occur de novo (approximately 60% of presentations) or, less commonly, in a previously diagnosed epileptic.<sup>2</sup> The aetiologies of SE, in decreasing order of frequency as they occur in adults, are given in Table 43.1.<sup>2</sup>

For SE that has its onset in the intensive care unit (ICU), the following should be considered as possible causes:

- drug withdrawal (narcotics, benzodiazepines, omission of anticonvulsant medications)
- metabolic disturbance (hyponatraemia, hypocalcaemia, hyperglycaemia, hypoglycaemia, uraemia, hepatic encephalopathy)
- drug toxicity (pethidine, theophylline, ciclosporin, tacrolimus, antibiotics, e.g. penicillins, cephalosporins, ciprofloxacin, imipenem in renal failure)
- stroke – vascular occlusion or haemorrhage

## GENERALISED CONVULSIVE STATUS EPILEPTICUS

GCSE is the most common and dangerous type of SE and accounts for approximately 75% of cases.<sup>2</sup> It encompasses a broad spectrum of clinical presentations, from overt generalised tonic-clonic seizures to subtle convulsive movements in a profoundly comatose patient.<sup>13</sup>

**Table 43.1** Causes of status epilepticus in adults

Low antiepileptic drug levels (poor compliance, recent dose reduction or discontinuation)
Temporally remote causes (previous central nervous system injury e.g. stroke, trauma, tumour, meningitis)
Stroke – vascular occlusion or haemorrhage
Cerebral hypoxia/anoxia
Metabolic disturbances (electrolyte abnormalities, uraemia, hyperglycaemia, hypoglycaemia)
Alcohol – withdrawal or intoxication
Central nervous system tumours – primary or secondary
Systemic infection
Idiopathic
Central nervous system infection – meningitis, encephalitis
Head trauma
Drug toxicity (tricyclic antidepressants, phenothiazines, theophylline, isoniazid, cocaine, amphetamine)

## CLINICAL

Typically, early in the evolution of seizures, patients are unresponsive with obvious tonic (sustained contractions) and/or clonic (rhythmic jerking) movements (overt GCSE). Motor manifestations may be symmetrical or asymmetrical.

With time, the clinical manifestations may become subtle, and patients have only small-amplitude twitching movements of the face, hands or feet or nystagmoid jerking of the eyes (late or subtle GCSE).<sup>13</sup>

Later still some patients will have no observable repetitive motor activity and the detection of ongoing seizures requires EEG (electrical GCSE). Most authors classify this as a form of NCSE.<sup>14–16</sup> Such patients are still at risk of central nervous system (CNS) injury and require prompt treatment.

## EEG CHANGES

Just as there is a progression from overt to increasingly subtle motor manifestations, there is also a predictable sequence of EEG changes during untreated GCSE. Initially, discrete electrographic seizures merge to a waxing and waning pattern of seizure activity, followed by continuous monomorphic discharges, which become interspersed with increasing periods of electrographic silence and, eventually, periodic epileptiform discharges on a relatively flat background.<sup>13,17</sup> The presence of any of these EEG patterns should suggest the diagnosis of GSCE.

## ENDOCRINE AND METABOLIC EFFECTS

Early in GCSE there is a marked increase in plasma catecholamines, producing systemic physiologic changes that resolve if SE is stopped early (Table 43.2). However, if seizures continue, many of these early physiologic changes reverse and the resultant hypotension and hypoglycaemia may exacerbate neurological injury.<sup>18</sup>

**Table 43.2** Physiological changes in generalised convulsive status epilepticus<sup>18,56</sup>

Hypoxia
Respiratory acidosis
Lactic acidosis
Hyperpyrexia
Hypertension (early)/hypotension (late)
Hyperglycaemia (early)/hypoglycaemia (late)
Tachycardia
Cardiac arrhythmias
Blood leukocytosis
Cerebrospinal fluid pleocytosis, increased cerebrospinal fluid protein
Intracranial hypertension
Neurogenic pulmonary oedema
Aspiration pneumonitis
Rhabdomyolysis

Hyperthermia is due to both muscle activity and central sympathetic drive, and thus may still occur when paralyzing agents prevent motor activity. In early SE, both cerebral metabolic activity and cerebral blood flow (CBF) are increased. In late SE, although cerebral metabolic activity remains high, CBF may fall due to hypotension and loss of cerebral autoregulation, leading to cerebral ischaemia.

## PSEUDOSEIZURES

An important differential diagnosis of generalised convulsive epilepsy is pseudoseizures. These can occur in patients with or without a history of epilepsy.<sup>19</sup> Clinical features suggestive of pseudoseizures are listed in Table 43.3. Distinction between the two may be extremely difficult, and can only be made with complete certainty using EEG monitoring.<sup>19</sup> Pseudo-status, misdiagnosed as true SE, is often refractory to initial therapy and can lead to patients receiving general anaesthesia and mechanical ventilation.

**Table 43.3** Features suggestive of pseudoseizures

Lack of stereotyped seizures, with behavioural manifestations varying from event to event
Lack of sustained convulsive activity – ‘on-off’ appearance
Increase in movement if restraint is applied
Abolition of motor movements with reassurance or suggestion
Resistance to eye opening and gaze aversion
Poor response to treatment, refractory status epilepticus
Absence of pupillary dilatation
Normal tendon reflexes and plantar responses immediately after convulsion
Lack of metabolic consequences despite some hours of apparent fitting

### NON-CONVULSIVE STATUS EPILEPTICUS

This may account for approximately 25% of SE, though its incidence is probably underestimated because of failure to recognise and diagnose the condition.

The diagnosis of NCSE should be considered in any patient with an unexplained altered conscious state, particularly those with CNS injury, metabolic disturbance, hepatic encephalopathy and sepsis. Series where EEG has been performed in critically ill patients with an unexplained depressed conscious state have found a high incidence of NCSE (8–18%).<sup>20–22</sup> EEG monitoring is required in patients with GCSE who do not recover consciousness after resolution of overt convulsive activity; in one study more than 14% of such patients had NCSE.<sup>14</sup>

Considerable debate exists regarding the precise criteria for diagnosing NCSE and published reports often describe diverse cohorts of patients. The diagnosis of NCSE generally requires a change in behaviour and/or mentation from baseline for at least 30 minutes, no overt seizure activity and an EEG with epileptiform discharges. A response to intravenous antiepileptic drugs (e.g. benzodiazepines), with clinical improvement and resolution or improvement in EEG epileptic activity, is helpful in confirming the diagnosis.<sup>23</sup>

Various classifications for NCSE have been suggested.<sup>4,23–25</sup> Traditionally NCSE is divided into absence SE (ASE) and complex partial SE (CPSE), though it may not always be possible to differentiate between the two types.<sup>23,24</sup>

ASE is characterised by bilateral diffuse synchronous seizures.<sup>23</sup> Typical ASE has generalised 3-Hz spike-wave discharge EEG activity occurring with altered behaviour or loss of responsiveness and is seen in children with idiopathic generalised epilepsy who are otherwise normal. This form of SE is relatively benign. Atypical ASE is a heterogeneous syndrome occurring in patients with mental retardation and epilepsy with multiple seizure types, or with other forms of diffuse cerebral dysfunction. The prognosis is usually poor and is related to the underlying condition.

CPSE, also referred to as ‘epileptic twilight state’ and ‘temporal-lobe SE’, is accompanied by lateralised seizure activity on EEG.<sup>23</sup> A wide variety of clinical features and degree of impairment of consciousness is possible and includes confusion, agitation, bizarre or aggressive behaviour and coma. Behavioural accompaniments such as lip smacking, automatisms and gaze deviation may occur, depending on the seizure origin within the brain. Debate exists over whether the seizure activity causes brain injury and much of the morbidity appears attributable to the underlying illness.

NCSE is often mistaken for other conditions, resulting in a delay in diagnosis and treatment. A high index of suspicion must therefore be present to trigger investigation with an EEG.

The differential diagnosis of NCSE is:

- metabolic encephalopathy
- drug intoxication

- cerebrovascular disease
- psychiatric syndromes (dissociative reactions, acute psychosis)
- postictal confusion

### EPILEPTIFORM ENCEPHALOPATHIES

Some variants of SE deserve mention, such as comatose patients with epileptiform patterns on EEG who do not fit into the traditional classification of NCSE. Some of these cases may be late GCSE but many occur without prior clinical convulsions. In such situations it is unclear whether the abnormal discharges seen on the EEG are responsible for, or contribute to, the altered consciousness and abnormal movements, or are merely a reflection of a severe cerebral insult.<sup>24</sup>

Myoclonic SE that follows a hypoxic insult falls into this category. Patients have incessant, at times asynchronous, rhythmic jerks that may involve the entire body. This clinical appearance after an anoxic insult is associated with an extremely poor outcome.<sup>26</sup>

### INVESTIGATIONS

Not all of the investigations listed in Table 43.4 need to be performed in every patient. The selection of tests depends on both the patient’s history and presentation.

### NEUROIMAGING

Most patients with SE should have a computed tomography (CT) scan of the brain performed at some point. Many patients with established epilepsy who have already been thoroughly evaluated do not require another brain-imaging procedure after an episode of SE.<sup>1</sup> However, if there is reason to suspect a new problem, and when the need for imaging is not urgent, magnetic resonance

**Table 43.4** Investigations in status epilepticus

#### Initial studies

Blood glucose, electrolytes (sodium, potassium, calcium, magnesium), urea  
Oximetry  $SpO_2$  or arterial blood gases  
Anticonvulsant drug levels  
Full blood count  
Urinalysis

#### Further investigations after stabilisation

Liver function tests, lactate, creatine kinase  
Toxicology screen  
Lumbar puncture  
Electroencephalogram  
Brain imaging with computed tomography or magnetic resonance imaging

imaging (MRI) may be preferable because it occasionally reveals abnormalities not visualised on CT scans. In children, emergent imaging is required if there is a persisting neurological deficit or abnormal mental state, and electively for focal seizures. Imaging should only be performed after control of SE and patient stabilisation.<sup>27</sup>

### LUMBAR PUNCTURE

In any patient, especially in young children with fever and SE, CNS infection and lumbar puncture along with blood cultures should be considered. Meningitis is an uncommon cause of SE in adults and, unless the suspicion of CNS infection is high, brain imaging should be performed before a lumbar puncture. Contraindications to lumbar puncture include intracranial hypertension, mass lesion and hydrocephalus. If meningitis is suspected but a lumbar puncture cannot be performed expediently, antibiotics should be administered immediately rather than delayed. Approximately 20% of patients have a modest CSF white cell count pleocytosis after SE and such patients should be treated for suspected meningitis until the diagnosis is excluded by culture or other means.<sup>1</sup>

### MANAGEMENT

#### GENERALISED CONVULSIVE STATUS EPILEPTICUS

An accurate history should be obtained, with particular emphasis on eye-witness accounts of the onset and nature of the seizures, and a full physical examination performed. However, neither should delay initial emergency management. There is evidence that the longer SE goes untreated, the harder it is to control with drugs.<sup>28,29</sup>

Management of SE involves termination and prevention of recurrence of seizures, treating precipitating causes and underlying conditions, and avoidance of complications.

Few controlled data are available to support the use of any particular agents. The most useful evidence comes from a randomised, double-blind clinical trial for treatment of GCSE which found that lorazepam, phenobarbital or diazepam followed by phenytoin are all acceptable as initial treatment, but that phenytoin alone was not as effective as lorazepam.<sup>29</sup> Another randomised controlled trial in the pre-hospital setting found intravenous lorazepam and diazepam to be equally effective and superior to placebo in terminating GCSE.<sup>7</sup>

The EEG goal of treatment for refractory SE remains controversial, with some advocating EEG background suppression (isoelectric) and others suppression of seizures regardless of the EEG background activity.<sup>10,16,30</sup>

Various protocols for SE management have been suggested.<sup>1,16,30</sup> One approach is outlined in Box 43.1.

#### NON-CONVULSIVE STATUS EPILEPTICUS

Patients with NCSE are a heterogeneous group who are likely to vary in their response to treatment depending on the underlying aetiology.<sup>23</sup>

There is considerable debate as to whether NCSE presents the same degree of risk of neurological injury as GCSE.<sup>25</sup> Prompt treatment is generally recommended and the use of additional non-anaesthetising anticonvulsants, such as phenobarbital and valproate, prior to embarking on general anaesthesia has been suggested.<sup>16,23</sup> Others recommend that, for comatose patients with NCSE, a similar treatment approach to GCSE be taken.<sup>30</sup>

The potential side-effects of aggressive treatment (hypotension, immunosuppression) need to be balanced against the potential neurologic morbidity of NCSE.<sup>24,31</sup> Particularly in elderly patients, aggressive treatment and anaesthesia may be associated with more risk than benefit and result in a worse outcome.<sup>31,32</sup>

Prognosis is most closely related to the underlying aetiology.<sup>33</sup>

### DRUGS FOR STATUS EPILEPTICUS

#### BENZODIAZEPINES

Benzodiazepines are fast-acting antiseizure drugs and are therefore preferred as initial therapy. They act mainly by enhancing the neuroinhibitory effects of GABA<sub>A</sub>. The efficacy of benzodiazepines may diminish with prolonged use in SE due to reduced receptor affinity for benzodiazepines.<sup>12</sup>

Diazepam is a highly lipid-soluble drug with rapid CNS penetration, but with a short duration of action. It can be administered intravenously or by the rectal route. Rectal administration can be achieved using a specially formulated rectal gel or the intravenous preparation can be diluted with an equal amount of saline and flushed into the rectum. Rectal administration should be considered when vascular access is delayed and may be particularly useful in the pre-hospital setting.

Lorazepam is less lipid-soluble than diazepam and after intravenous injection, brain and CSF levels rise at a slower rate than those of diazepam. However, a double-blind, randomised comparison of intravenous diazepam and lorazepam in SE in the pre-hospital setting found both drugs to be equally safe and effective.<sup>7</sup> Despite their equivalence as initial therapies, lorazepam has a longer duration of antiseizure effect than diazepam, and has a lower incidence of seizure recurrence when used alone.<sup>1</sup>

Midazolam has a short duration of action that may allow earlier assessment of the patient's postictal neurologic condition than longer-acting benzodiazepines. Midazolam has the advantage of being able to be administered via buccal, intranasal and intramuscular routes.

**Box 43.1 Protocol for management of status epilepticus**

1. Assess A, B, C, GCS
2. Give O<sub>2</sub> and consider need for intubation/ventilation
3. Monitor blood pressure, ECG, pulse oximetry
4. Obtain IV access and draw blood for investigations
5. If patient is hypoglycaemic, or if blood glucose estimation is not available, give glucose:
  - Adults: give thiamine 100 mg IV and 50 ml of 50% glucose IV
  - Children: give 2 ml/kg of 25% glucose IV
6. Seizure control:
  - A. Give benzodiazepine,\* for example:
    - Diazepam 0.2 mg/kg IV at 5 mg/min up to total dose of 20 mg
    - Lorazepam 0.1 mg/kg IV at 2 mg/min up to total dose of 10 mg
    - Clonazepam 0.01–0.02 mg/kg IV at 0.5 mg/min up to total dose of 4 mg
 If diazepam stops the seizures, phenytoin should be given next to prevent recurrence  
 Repeat dose every 2–5 min if required. Note: risk of respiratory depression with cumulative doses
  - B. If seizures persist, give phenytoin:
    - Phenytoin 15–20 mg/kg (adults ≤ 50 mg/min; children ≤ 1 mg/kg per min) or fosphenytoin 15–20 phenytoin equivalents (PE) mg/kg IV (adults ≤ 150 mg/min; children ≤ 3 mg/kg per min)
    - Additional doses of 5 mg/kg IV, to a maximum dose of 30 mg/kg, can be given for persistent seizures
    - Monitor blood pressure and ECG during infusion. If hypotension or arrhythmias develop, stop or slow the rate of the infusion
  - C. If seizures persist (refractory status epilepticus), intubate and ventilate patient. Give either:
    - Thiopental: slow bolus 3–5 mg/kg IV, followed by infusion 1–5 mg/kg per h *or*
    - Propofol: slow bolus 1–2 mg/kg IV, followed by infusion 2–5 mg/kg per h<sup>†</sup> *or*
    - Midazolam: slow bolus 0.1–0.2 mg/kg, followed by infusion 0.1–1.0 mg/kg per h
 Titrate doses based on clinical and electrographic evidence of seizures, targeting electrographic suppression of seizures or EEG background suppression (isoelectric)  
 Monitor BP and maintain normotension by reducing infusion rate and/or giving fluids/pressor agents
  - D. Insert nasogastric tube and administer usual anticonvulsant medications if patient is receiving treatment for pre-existing epilepsy
  - E. Beware of ongoing unrecognised seizures
    - Use EEG monitoring until seizures are controlled and then for 1–2 h after seizures stop. Continue to monitor the EEG continuously, or for periods of more than 30 min every 2 h, during the maintenance phase
    - Avoid muscle relaxants (use continuous EEG if giving repeated doses of muscle relaxants)
  - F. Discontinue midazolam or thiopental, or start reducing propofol, approximately 12 h after resolution of seizures. Use continuous EEG monitoring and observe for further clinical and/or EEG seizure activity. If seizures recur, reinstate the infusion and repeat this step at 12–24-h intervals or longer if the patient's seizures remain refractory

In addition:

Look for and treat cause and precipitant<sup>‡</sup>

Look for and treat complications: hypotension, hyperthermia, rhabdomyolysis

\*If IV access is not obtainable, consider rectal diazepam, buccal/sublingual or intranasal or intramuscular midazolam, intramuscular fosphenytoin.

<sup>†</sup>High infusion rates for prolonged periods require caution.

<sup>‡</sup>In refractory status epilepticus, consider giving pyridoxine for children < 18 months or if isoniazid toxicity is suspected in adults.

GCS, Glasgow Coma Score; ECG, electrocardiogram; IV, intravenous; EEG, electroencephalogram; BP, blood pressure.

Intranasal midazolam is as effective as intravenous diazepam in children<sup>34</sup> and buccal midazolam is as effective as rectal diazepam in prolonged seizures.<sup>35</sup> Whereas intramuscular administration of diazepam and lorazepam is not recommended owing to their slow absorption, intramuscular midazolam is rapidly absorbed and in one study it was equally efficacious as intravenous diazepam in treating motor seizures in children.<sup>36</sup> These alternative routes

of administration may be more convenient and acceptable than intravenous and rectal administration, particularly in the pre-hospital setting and when intravenous access is difficult.

Midazolam administered by bolus and infusion may terminate seizures when other agents have failed. It may also have fewer side-effects than alternative agents available for the treatment of refractory SE.<sup>37</sup> A limiting

factor in its use is tachyphylaxis, which may necessitate a several-fold increase in the dose to maintain seizure control.<sup>30</sup> There is a wide variation in recommended infusion rates, from 0.1–0.4 mg/kg per hour<sup>16</sup> to 0.2–2.9 mg/kg per hour.<sup>10</sup>

Clonazepam has a longer duration of action than diazepam and is given by intravenous bolus. Early reports suggested that it has better efficacy and fewer side-effects than diazepam, though there are no published comparisons.

### PHENYTOIN

Phenytoin is useful for maintaining a prolonged antiseizure effect after rapid termination of seizures with a benzodiazepine, or when benzodiazepines fail. When used alone as initial therapy phenytoin is not as efficacious as benzodiazepines for terminating seizures.<sup>29</sup>

The recommended intravenous loading dose is 20 mg/kg. The common practice of giving a standard loading dose of 1000 mg of phenytoin may provide inadequate therapy for some adults.

When phenytoin is infused at the maximal adult recommended rate of 50 mg/min, hypotension occurs in up to 50% of patients and cardiac rhythm disturbance occurs in 2%. These adverse effects are more common in older patients and those with cardiac disease and are due to the phenytoin itself as well as the propylene glycol diluent. Blood pressure and the ECG should be monitored during infusion of phenytoin and the infusion slowed or stopped if cardiovascular complications occur.

Intramuscular administration of phenytoin is not recommended as absorption is erratic and it can cause local tissue reactions.

Fosphenytoin, a new water-soluble prodrug of phenytoin, is converted to phenytoin by endogenous phosphatases.<sup>38</sup> Doses of fosphenytoin are expressed as phenytoin equivalents (PE). Fosphenytoin can be administered at rates of up to 150 PE mg/min, since it is not formulated with propylene glycol, allowing therapeutic serum concentrations of fosphenytoin to be attained within 10 minutes. However, this may not necessarily result in more rapid CNS penetration and onset of action.<sup>39</sup>

Systemic side-effects are similar for phenytoin and fosphenytoin, although reactions at the infusion site are less common with fosphenytoin.<sup>38</sup>

Fosphenytoin can also be administered intramuscularly, though absorption is slower than intravenous administration, and this route should only be used when intravenous access is not possible.

### SODIUM VALPROATE

There are reports of intravenous valproate being used to treat both GCSE and NCSE in adults and children. It is non-sedating and it appears to be well tolerated with few reports of hypotension or respiratory depression.<sup>40</sup> An initial dose of 25–45 mg/kg administered at a

maximum rate of up to 6 mg/kg per min has been recommended.<sup>16</sup> The exact role of valproate in the management of SE remains to be established and there are insufficient data to recommend its use before phenytoin.

### BARBITURATES

Phenobarbital is a potent anticonvulsant with a long duration of action. The usual dose is 15–20 mg/kg intravenously. It has equal efficacy to benzodiazepines and phenytoin when used first-line, but may cause greater depression of respiration, blood pressure and consciousness and therefore is often only used if these agents fail. However, many would advocate alternative and more aggressive measures for treatment of refractory SE at this point as the likelihood of phenobarbital controlling seizures when these other agents have failed is small.<sup>10,15</sup>

Thiopental is an intravenous anaesthetic agent used for refractory SE. A dose of 3–5 mg/kg is usually given for intubation, followed by repeated doses of 0.5–1 mg/kg until seizures are controlled. Following bolus intravenous administration, the drug is rapidly redistributed into peripheral fat stores and an infusion of 1–5 mg/kg per hour is required for ongoing suppression of seizures. Once lipid stores are saturated the duration of action is prolonged and recovery may take hours to days. Prolonged therapy requires the use of EEG monitoring to ensure that the seizures remain suppressed and to allow titration to the lowest dose that achieves the EEG target of seizure and/or EEG background suppression. Side-effects include hypotension, myocardial depression and immunosuppression with increased risk of infection.

Pentobarbital (the first metabolite of thiopental) is available in the USA as the alternative to thiopental.

Compared with other agents used in refractory SE (midazolam and propofol), barbiturates may result in a lower frequency of short-term treatment failure and breakthrough seizures but more hypotension and slower recovery from anaesthesia.<sup>41</sup>

### PROPOFOL

Propofol (2,6-diisopropylphenol) is an anaesthetic agent that has become increasingly popular for the treatment of refractory SE. It is administered as an intravenous bolus followed by infusion and intubation and ventilation are required.

Compared with high-dose barbiturates (pentobarbital) in adult patients with refractory SE, propofol has been found to control seizures more quickly and, because of its shorter duration of action, allows earlier re-emergence from anaesthesia.<sup>42</sup> However, seizures tend to recur with sudden discontinuation of propofol, necessitating recommencement of the infusion and a more gradual tapering of the dose, such that both drugs may ultimately result in similar duration of ventilation and ICU stay.<sup>42</sup>

There is concern that prolonged high-dose propofol use (e.g. > 5 mg/kg per hour) may result in myocardial failure, hypoxia, metabolic acidosis, lipaemia, rhabdomyolysis and death (propofol infusion syndrome).<sup>43</sup> Initial reports were in children but later also adults and, as such, its use requires caution. There are series, however, of prolonged high-dose propofol use in adults with SE without major adverse effects.<sup>44</sup>

### NEUROMUSCULAR-BLOCKING AGENTS

Paralysis is indicated if uncontrolled fitting causes difficulty with providing adequate ventilation or severe lactic acidosis. Neuromuscular blockade should only be used if continuous EEG monitoring is available, as the clinical expression of seizure activity is abolished.

### OTHER AGENTS OF POTENTIAL USE IN REFRACTORY STATUS EPILEPTICUS

Ketamine may be a useful adjuvant in the treatment of refractory SE.<sup>45</sup> The newer antiepileptic drugs such as topiramate may also have a role in refractory SE treatment.<sup>46</sup> Inhalational anaesthetic agents such as isoflurane may also be useful.<sup>47</sup>

### SURGERY

Surgery has occasionally been used in refractory SE with procedures based on standard epilepsy surgery techniques. Some success has been reported with focal resections, subpial transection, corpus callosotomy, hemispherectomy and vagus nerve stimulation.<sup>48–50</sup>

### INTENSIVE CARE MONITORING

Monitoring using ECG, intra-arterial and central venous catheters, capnography and pulse oximetry should be considered in patients with, or at risk of, cardiorespiratory compromise. Indications for EEG monitoring are listed in Table 43.5. Cerebral function monitors are useful in titrating doses of anaesthetic agents to EEG background

**Table 43.5** Indications for electroencephalogram (EEG) monitoring<sup>14</sup>

Refractory status epilepticus, to aid the titration of anticonvulsant anaesthetic drugs (minimising dose and toxicity) and ensure suppression of seizure activity*
Patients receiving neuromuscular blockade*
Patients who continue to have a poor conscious state after apparent cessation of seizures
Suspected non-convulsive status epilepticus in a patient with an altered conscious state
Suspected pseudoseizures

\*Continuous or regular intermittent EEG monitoring is recommended.

suppression, but may not have sufficient sensitivity to detect seizure activity at other times. Intracranial pressure monitoring should be considered if elevated intracranial pressure is suspected.

### OUTCOME

The prognosis of patients with SE is most strongly related to age and aetiology.<sup>3,33</sup> Overall 30-day mortality is 15–20%.<sup>3,4</sup> Children have a much lower mortality of 3%<sup>51</sup> whereas those aged over 65 years have a mortality rate of 30%.<sup>3,4</sup> SE that is precipitated by low antiepileptic drug levels or systemic infection has a very low mortality.<sup>3</sup> Patients who develop SE secondary to an acute CNS or systemic metabolic insult have a higher mortality than those who develop SE without a clear precipitant.<sup>3</sup> SE precipitated by hypoxia is usually fatal.<sup>26</sup> NCSE detected in comatose critically ill patients, despite recognition and treatment, has a poor outcome.<sup>22,32</sup> Refractory SE carries a worse prognosis that is mainly determined by the underlying cause.<sup>9,11</sup>

The duration of SE and time to provision of adequate treatment are also important factors that may influence the ease with which seizures can be controlled, the risk of residual neurological deficits and mortality.<sup>9,28,29</sup> The degree of impairment of consciousness at presentation may also be an important factor influencing outcome.<sup>4</sup>

The EEG may provide useful prognostic information, with periodic epileptiform discharges present at any time during or after SE being associated with a worse outcome.<sup>52</sup>

Neurone-specific enolase (NSE) is a well-studied marker of brain injury and high serum levels have been found in GCSE and NCSE, particularly CPSE.<sup>53</sup> Elevated levels may reflect either the severity of brain injury resulting from SE, the underlying brain pathology, or both. Increases in serum NSE have been correlated with the duration and prognosis of GCSE.<sup>53</sup>

### STATUS EPILEPTICUS IN CHILDREN

The majority of paediatric cases of SE occur in young children, with 80% occurring in those below 4 years of age.<sup>51</sup> The vast majority of cases are convulsive and generalised.<sup>27</sup>

The distribution of causes is highly age dependent, with febrile SE and that due to acute neurological disease (e.g. CNS infection) being more common in children under 4 years. Remote symptomatic causes and SE in a child with previously diagnosed epilepsy are more common in older children.<sup>51</sup> The most frequent aetiologies of SE in children are listed in Table 43.6.<sup>27,51</sup>

The likelihood of bacterial meningitis is much higher (12%) in febrile children presenting with a first-ever episode of SE as opposed to a brief seizure (1%) and a high index of suspicion is required to investigate and treat for meningitis.<sup>51</sup>

**Table 43.6** Causes of status epilepticus in children<sup>27,51</sup>

Febrile (previously neurologically normal, temperature > 38°C, central nervous system infection excluded)
Acute symptomatic – meningitis, encephalitis, trauma, metabolic derangement, hypoxia, drug-related, cerebrovascular disease
Remote symptomatic causes – previous traumatic brain injury or cerebral insult, central nervous system malformation, cerebral palsy
Progressive neurologic conditions
Cryptogenic

Treatment of SE in children is essentially the same as in adults.<sup>54</sup>

The underlying cause is the main determinant of mortality, which is negligible for prolonged febrile seizures and 12–16% for acute symptomatic causes.<sup>55</sup> Similarly, the risk of subsequent epilepsy is low in neurologically normal children but higher than 50% in those with acute or remote symptomatic causes.<sup>55</sup>

# Acute cerebrovascular complications

Bernard Riley

Cerebrovascular disease is common and its acute manifestations, known as stroke, produce considerable morbidity and mortality. Stroke is defined as an acute focal neurological deficit caused by cerebrovascular disease, which lasts for more than 24 hours or causes death before 24 hours. Transient ischaemic attack (TIA) also causes focal neurology, but this resolves within 24 hours. In the UK, stroke is responsible for 12% of all deaths and is the most common cause of physical disability in adults. The incidence in most developed countries is about 1–2/1000 population per year.<sup>1</sup> The main causes of stroke are cerebral infarction as a consequence of thromboembolism and spontaneous intracranial haemorrhage (either intracerebral or subarachnoid haemorrhage (SAH)), causing about 85% and 15% of strokes, respectively. The main risk factors are increasing age, hypertension, ischaemic heart disease, atrial fibrillation, smoking, obesity, some oral contraceptives and raised cholesterol or haematocrit. The manifestations of stroke are:

- cerebral infarction
  - thrombosis
  - embolism
- spontaneous intracranial haemorrhage
  - intracerebral haemorrhage
  - SAH

## PROGNOSIS IN ACUTE CEREBROVASCULAR DISEASE

Mortality after stroke averages 30% within a month, with more patients dying after SAH or intracerebral haemorrhage than after cerebral infarction, although survival to 1 year is slightly better in the haemorrhagic group. In all types of stroke about 30% of survivors remain disabled to the point of being dependent on others. Risk of stroke increases with age, so that it rises from 3/100 000 in the third and fourth decades to 300/100 000 in the eighth and ninth decades.<sup>2</sup> Thus stroke is often accompanied by significant age-related medical comorbidity. In the past this may have been partially responsible for a relatively non-aggressive approach to the treatment of stroke patients, so that the gloomy prognosis of stroke becomes a self-fulfilling prophecy. The challenge for intensivists is to identify those patients who are most likely to survive

and not to offer aggressive therapy to those who are not. It has been suggested that, by regarding stroke as a medical emergency, a 'brain attack' analogous to 'heart attack', and ensuring early intensive care support, outcome may be improved.<sup>3,4</sup>

## CEREBRAL INFARCTION

Infarction of cerebral tissue occurs as a result of inadequate perfusion from occlusion of cerebral blood vessels in association with inadequate collateral circulation. It may occur due to cerebral thrombosis or embolism.

## AETIOLOGY AND PATHOLOGY

### CEREBRAL THROMBOSIS

Atherosclerosis is the major cause of major arterial occlusion and most often produces symptoms if it occurs at the bifurcation of the carotid artery or the carotid siphon. Progressive plaque formation causes narrowing and forms a nidus for platelet aggregation and thrombus formation. Ulceration and rupture of the plaque expose its thrombogenic lipid core, activating the clotting cascade. Hypertension and diabetes mellitus are common causes of smaller arterial thrombosis. Rarer causes of thrombosis include any disease resulting in vasculitis, vertebral or carotid artery dissection (either spontaneous or posttraumatic) or carotid occlusion by strangulation or systemic hypotension after cardiac arrest. Cerebral venous thrombosis, responsible for less than 1% of strokes, may occur in hypercoagulable states such as dehydration, polycythaemia, thrombocythaemia, some oral contraceptive pills, protein C or S deficiency or antithrombin III deficiency, or vessel occlusion by tumour or abscess. Cerebral infarction may also result from sustained systemic hypotension from any cause, particularly if associated with hypoxaemia.

## CEREBRAL EMBOLISM

Embolism commonly occurs from thrombus or platelet aggregations overlying arterial atherosclerotic plaques, but 30% of cerebral emboli will arise from thrombus in the left atrium or ventricle of the heart. This is very likely

in the presence of atrial fibrillation, left-sided valvular disease, recent myocardial infarction, chronic atrial enlargement or ventricular aneurysm. The presence of a patent foramen ovale or septal defects allows paradoxical embolism to occur. Iatrogenic air embolism may occur during cardiopulmonary bypass, cardiac catheterisation or cerebral angiography. Embolisation may also occur as a complication of attempted coil embolisation of cerebral aneurysms or arteriovenous malformations (AVMs) after SAH.

### CLINICAL PRESENTATION

In cerebral thrombosis, there is initially no loss of consciousness or headache and the initial neurological deficit develops over several hours. Cerebral embolism may be characterised by sudden onset and rapid development of complete neurological deficit. No single clinical sign or symptom can reliably distinguish a thrombotic from an embolic event. Where infarction occurs in a limited arterial territory the clinical signs are often characteristic. The commonest site involves the middle cerebral artery, which classically produces acute contralateral brachiofacial hemiparesis with sensory or motor deficits, depending on the precise area of infarction.

- Infarction of the middle cerebral territory leads to a dense contralateral hemiplegia, contralateral facial paralysis, contralateral hemianopia and ipsilateral eye deviation.
- Dominant left-hemisphere lesions result in language difficulties from aphasia, dysphasia, dysgraphia and dyscalculia.
- Non-dominant right hemispheric lesions cause the patient to neglect the left side, and may not communicate with anyone approaching from that side.
- In strokes involving the posterior fossa the precise pattern of symptoms depends on the arterial territories involved and the presence or absence of collaterals. The onset of symptoms such as gait disturbance, headache, nausea, vomiting and loss of consciousness may be very rapid.
- Venous thrombosis may occur particularly in the cerebral veins, sagittal or transverse dural sinuses, causing headache, seizures, focal neurology and loss of consciousness.

Other cognitive effects of stroke include memory impairment, anxiety, depression, emotional lability, aprosody and spatial impairment. Bilateral brainstem infarction after basilar artery thrombosis may produce deep coma and tetraparesis. Pontine stroke may produce the 'locked-in' syndrome. The precise clinical presentation depends on the size of the infarcted area and its position in the brain.

### INVESTIGATIONS

A full history and examination of the patient are required, and the results of this will produce a differential diagnosis that will require specific investigations. The aim is to make the diagnosis, establish the nature, size and position

of the pathology, so that correct treatment can be administered to compensate for the effects of the primary injury, and prevent extension of the lesion or complications occurring.

### BLOOD TESTS

Haemoglobin, white cell count and platelets are determined to look for polycythaemia, infection or thrombocytopenia. A raised erythrocyte sedimentation rate or C-reactive protein level may indicate vasculitis, infection or carcinoma, warranting further appropriate investigations.

Coagulation screen should be taken together with serum cholesterol, triglyceride and syphilis serology. Specific investigation for thrombophilia due to protein C, protein S, Leiden factor V and antithrombin III abnormalities should be undertaken in patients with venous thrombosis or patients with otherwise unexplained cerebral infarction or TIA.

### ELECTROCARDIOGRAPHY

This may demonstrate atrial fibrillation or other arrhythmia, or recent myocardial infarct.

### ECHOCARDIOGRAPHY

Either transthoracic or transoesophageal echocardiography (TOE) may demonstrate mural or atrial appendage thrombus as a source of embolism. TOE is more effective in detecting patent foramen ovale, aortic arteriosclerosis or dissection.

### COMPUTED TOMOGRAPHY (CT) OR MAGNETIC RESONANCE IMAGING (MRI) SCANNING

These techniques are used to distinguish infarction from haemorrhage. Tumour, abscess or subdural haematoma may also produce the symptoms and signs of stroke. Ideally, the scans should be undertaken as soon as possible to exclude conditions that are treatable by neurosurgery. Early scanning is vital if interventional treatment such as thrombolysis, anticoagulation, antiplatelet therapy or surgery is planned.

The CT scan may be normal or show only minor loss of grey/white matter differentiation in the first 24 hours after ischaemic stroke but haemorrhage is seen as areas of increased attenuation within minutes. After a couple of weeks the CT appearances of an infarct or haemorrhage become very similar and it may be impossible to distinguish them if CT is delayed beyond this time. CT angiography will often demonstrate vascular abnormalities and vasospasm but multimodal MRI, a combination of diffusion and perfusion-weighted MRI and MR angiography (MRA), is much more sensitive in demonstrating small areas of ischaemia and targeting those patients most suitable for thrombolysis.<sup>5</sup> Where cerebral infarction has occurred as a result of venous thrombosis, the best imaging technique is MRA. Other imaging techniques are appropriate to identify the source of stroke in specific areas. Any patient with a stroke or TIA in the internal carotid artery territory should have duplex Doppler

ultrasonography which may demonstrate stenosis, occlusion or dissection of the internal carotid. Where trauma is an aetiological factor reconstruction CT bone window views.

## MANAGEMENT

Ideally, treatment for stroke patients should be coordinated within a stroke unit, as there is a 28% reduction in mortality and disability at 3 months compared to patients treated on general medical wards.<sup>6</sup> In general only those patients with a compromised airway due to depressed level of consciousness or life-threatening cardiorespiratory disturbances require admission to medical or neurosurgical ICUs. In either case, attention to basic resuscitation, involving stabilisation of airway, breathing and circulation, is self-evident.

### AIRWAY AND BREATHING

Patients with Glasgow Coma Scores (GCS) of 8 or less or those with absent gag will require intubation to preserve their airway and prevent aspiration. Where this requirement is likely to be prolonged, early tracheostomy should be considered. Adequate oxygenation and ventilation should be confirmed by arterial blood gas analysis, and supplemental oxygen prescribed if there is any evidence of hypoxia. If hypercarbia occurs then ventilatory support to achieve normocarbia is necessary to prevent exacerbation of cerebral oedema. Ventilatory support in such cases has been shown to result in improved prognosis.<sup>7</sup>

### CIRCULATORY SUPPORT

A large number of stroke patients will have raised blood pressure on admission, presumably as an attempt by the vasomotor centre to improve cerebral perfusion. Hypertensive patients may have impaired autoregulation and regional cerebral perfusion may be very dependent on blood pressure.<sup>8</sup> The patient's clinical condition and neurological status should determine treatment rather than an arbitrary level of blood pressure. Control of even very high blood pressure (220/120 mmHg; 29.3/16.0 kPa) is not without risk and may result in progression of ischaemic stroke, so reduction should be monitored closely.<sup>9</sup> It would seem reasonable on physiological grounds to avoid drugs that cause cerebral vasodilatation in that they may aggravate cerebral oedema, although there is no hard evidence for this. Animal experiments have suggested that haemodilution could improve blood flow by reducing whole blood viscosity but a recent multicentre study has failed to identify any clinical benefit.<sup>10</sup> Cardiac output should be maintained and any underlying cardiac pathology such as failure, infarction and atrial fibrillation treated appropriately.

### METABOLIC SUPPORT

Both hypo- and hyperglycaemia have been shown to worsen prognosis after acute stroke, therefore blood sugar levels should be maintained in the normal range.<sup>11</sup>

In the long term, nutritional support must not be neglected and early enteral feeding instituted by nasogastric intubation. In the longer term, particularly where bulbar function is reduced, percutaneous endoscopic gastrostomy is necessary.

### ANTICOAGULATION

In theory, the use of anticoagulation reduces the propagation of thrombus and should prevent further embolism. In practice, the reduction in risk of further thromboembolic stroke is offset by a similar number of patients dying from cerebral or systemic haemorrhage as a result of anticoagulation.<sup>12,13</sup> Anticoagulation can only be recommended in individuals where there is a high risk of recurrence, such as in those patients with prosthetic heart valves, atrial fibrillation with thrombus or those with thrombophilic disorders. A CT scan must be obtained prior to commencing therapy to exclude haemorrhage, and careful monitoring used. In patients with large infarcts there is always the risk of haemorrhage (haemorrhagic conversion) into the infarct and early heparinisation is best avoided.

### THROMBOLYSIS

Systemic thrombolysis with streptokinase carries a very high risk of cerebral haemorrhage and should not be used.<sup>14</sup> There is some evidence that intravenous recombinant tissue plasminogen activator (alteplase) has a better safety/efficacy profile. The National Institute of Neurological Disorders and Stroke (NINDS) trial showed a significant improvement in those patients given alteplase rather than placebo within 3 hours of acute stroke.<sup>15</sup> This benefit was not found to be statistically significant in two European trials<sup>16,17</sup> and the ATLANTIS trial showed no significant benefit at 90 days in the alteplase group together with an increased risk of intracranial haemorrhage.<sup>18</sup> The 2006 Cochrane Library database states that thrombolysis appears to result in a significant net reduction in the proportion of patients dead or dependent in activities of daily living. However, there appears to be an increase in deaths within the first 7–10 days, symptomatic intracranial haemorrhage and deaths at follow-up at 3–6 months. The data from trials using intravenous recombinant tissue plasminogen activator, from which there is the most evidence on thrombolytic therapy so far, suggest that it may be associated with less hazard and more benefit. There is heterogeneity between the published trials for some outcomes so that the optimum criteria to identify patients most likely to benefit and least likely to be harmed, the latest time window, the agent, dose and route of administration are all unclear. Nevertheless, the data are promising and may justify the use of thrombolytic therapy with intravenous recombinant tissue plasminogen activator in experienced centres in highly selected patients where a licence exists. However, the data do not support the widespread use of thrombolytic therapy in routine clinical practice at this time, but suggest that further trials are needed to identify which patients are most likely to benefit

from treatment and the environment in which it may best be given.<sup>19</sup>

### CEREBRAL PROTECTION

Various agents such as free-radical scavengers, calcium antagonists, magnesium, amino-3-hydroxy-5-methyl-4-isoxazolepropionate (AMPA) antagonists, glutamate antagonists and  $\gamma$ -aminobutyric acid antagonists have been used in attempts to limit the deleterious effects of the biochemical changes that occur intracellularly following ischaemia. No agent has been shown to be effective in placebo-controlled phase III trials.

### DECOMPRESSIVE CRANIOTOMY

This is an option in young patients with large middle cerebral artery territory infarcts in the non-dominant hemisphere. Untreated, these normally have a mortality of 80% and it is suggested that this procedure can reduce mortality to around 30%, but with residual neurological deficit. This procedure is limited to specialist centres. Other forms of surgical intervention proven to be effective in making more intracranial space and reducing intracranial pressure are drainage of secondary hydrocephalus by extraventricular drain (EVD) insertion or evacuation of haemorrhage into infarcted areas, resulting in new compressive symptoms. This is especially useful in the posterior fossa where the room for expansion of mass lesions is limited by its anatomy.

### COMPLICATIONS

Local complications include cerebral oedema, haemorrhage into infarcted areas or secondary hydrocephalus. General complications include bronchopneumonia, aspiration pneumonia, deep-vein thrombosis, urinary tract infections, pressure sores, contractures and depression. A team approach of specialist nursing, physiotherapists, occupational and speech and language therapists is best able to avoid these complications.

### SPONTANEOUS INTRACRANIAL HAEMORRHAGE

Spontaneous intracranial haemorrhage producing stroke may occur from either intracerebral haemorrhage (10%) or SAH (5%).

### INTRACEREBRAL HAEMORRHAGE

The incidence of intracerebral haemorrhage is about 9/100 000 of the population, mostly in the age range of 40–70 years, with an equal incidence in males and females.

### AETIOLOGY AND PATHOLOGY

The commonest cause is the effect of chronic systemic hypertension. This results in degeneration of the walls

of vessels or microaneurysms, by the process of lipohyalinosis, and these microaneurysms then suddenly rupture. This may also occur in:

- malignant tumour neovasculature
- vasculitis
- mycotic aneurysms
- amyloidosis
- sarcoidosis
- malignant hypertension
- primary haemorrhagic disorders
- overanticoagulation

Occasionally, cerebral aneurysms or AVMs may cause intracerebral haemorrhage without SAH. Where intracerebral haemorrhage occurs in young patients the most likely cause is an underlying vascular abnormality. In some areas this is also associated with the abuse of drugs with sympathomimetic activity such as cocaine. The rupture of microaneurysms tends to occur at the bifurcation of small perforating arteries. Common sites of haemorrhage are the putamen (55%), cerebral cortex (15%), thalamus (10%), pons (10%) and cerebellum (10%). Haemorrhage is usually due to rupture of a single vessel, and the size of the haemorrhage is influenced by the anatomical resistance of the site into which it occurs. The effect of the haemorrhage is determined by the area of brain tissue that it destroys. Cortical haemorrhages tend to be larger than pontine bleeds but the latter are much more destructive owing to the anatomical density of neural tracts and nuclei.

### CLINICAL PRESENTATION

Usually, there are no prodromal symptoms and a sudden onset of focal neurology or depressed level of consciousness occurs. Headache and neck stiffness will occur in conscious patients if there is subarachnoid extension by haemorrhage into the ventricles. Where intraventricular extension occurs there may be a progressive fall in GCS as secondary hydrocephalus occurs, and this may be accompanied by ocular palsies, resulting in 'sunset eyes'. As with ischaemic stroke, focal neurology is determined by which area of the brain is involved. The only way to differentiate absolutely between ischaemic, intracerebral or SAH is by appropriate imaging. The symptoms relate to tissue destruction, compression and raised intracranial pressure which, if progressive, will result in brainstem ischaemia and death.

### INVESTIGATIONS

The general investigations are essentially those listed previously for ischaemic stroke, since it is difficult to distinguish between the two in the early stages. In addition, CT and/or MRI should be performed at the earliest opportunity. Lumbar puncture may be performed to exclude infection if mycotic aneurysm is suspected, but

only after CT has excluded raised intracranial pressure or non-communicating hydrocephalus. Digital subtraction angiography will enable localisation of the source of the haemorrhage and will facilitate any surgical intervention for aneurysm or AVM (see Figures 42.7, 44.1 and 44.2).

**Figure 44.1** Left frontal intraparenchymal bleed with local oedema.

**Figure 44.2** Magnetic resonance imaging: thalamic bleed.

## MANAGEMENT

The general management principles are identical to those for ischaemic stroke. There is, of course, no place for anticoagulation or thrombolysis, and reversal of any coagulation defect either primary or secondary to therapeutic anticoagulation must be undertaken as a matter of urgency. A full coagulation screen must be performed and the administration of vitamin K, fresh frozen plasma, cryoprecipitate, etc. directed by the results. Where intraventricular extension has occurred the insertion of an EVD may increase conscious level, particularly in the presence of secondary hydrocephalus. The EVD level should be set such that the cerebrospinal fluid (CSF) drains at around 10 mmHg. The normal production of CSF should produce an hourly output and a sudden fall in output to zero should alert staff to the possibility that the drain has blocked. This is particularly likely if the CSF is heavily blood-stained. The meniscus of the CSF within the drain tubing should be examined for transmitted vascular pulsation or the level of the drain temporarily lowered by a few centimetres to see if drainage occurs. If the drain is blocked, secondary hydrocephalus will recur. Because of the risk of introducing infection and causing a ventriculitis, the drain must be unblocked in a sterile manner by the neurosurgeons. Operative decompression of the haematoma should only be undertaken in neurosurgical centres and safe transfer must be assured if this is considered. This is a controversial treatment as the most recently published trial shows that patients with spontaneous supratentorial intracerebral haemorrhage in neurosurgical units show no overall benefit from early surgery when compared with initial conservative treatment.<sup>20</sup> Subgroup analysis showed that those patients with intracerebral haemorrhage less than 1 cm from the cortical surface benefited from early surgery. Patients presenting with a GCS of less than 8/15 had an almost universally poor outcome. Not all intracerebral haematomata are amenable to surgery, and the CT scans should be reviewed by the Neurosurgical Unit, preferably prior to transfer by digital image link. Ideally clot evacuation within 6 hours maximum should be the goal.

The management of hypertension following spontaneous intracerebral haemorrhage may be difficult as too high a blood pressure may provoke further bleeding whereas too low a blood pressure may result in ischaemia. The Stroke Council of the American Heart Association has recommended that in patients with chronic hypotension the mean arterial pressure should not exceed 130 mmHg and that, if systolic blood pressure falls to 90 mmHg, then vasopressors should be used.<sup>21</sup> The administration of mannitol prior to transfer should be discussed with the Neurosurgical Unit. There is no place for steroids, and hyperventilation to  $P_{aCO_2}$  of 30 mmHg (4 kPa) or less to control raised intracranial pressure will have detrimental effects on cerebral blood flow in other areas of the brain.

### SUBARACHNOID HAEMORRHAGE

SAH refers to bleeding which occurs principally into the subarachnoid space and not into the brain parenchyma. The incidence of SAH is around 6/100 000: the apparent decrease, compared with earlier studies, is due to more frequent use of CT scanning which allows exclusion of other types of haemorrhage. Risk factors are the same as for stroke, but SAH patients are usually younger, peaking in the sixth decade, with a female-to-male ratio of 1.6:1. Black people have twice the risk for SAH as whites. Between 5 and 20% of patients with SAH have a positive family history, with first-degree relatives having a three- to sevenfold risk, whereas second-degree relatives have the same degree of risk as the general population. Specific inheritable disorders are rare and account for only a minority of all patients with SAH.<sup>22</sup> The only modifiable risk factors for SAH are smoking, heavy drinking and hypertension, which increase the risk odds ratio by 2 or 3.<sup>23</sup> Overall mortality is 50%, of which 15% die before reaching hospital, with up to 30% of survivors having residual deficit producing dependency.

### AETIOLOGY AND PATHOLOGY

The majority of cases of SAH are caused by ruptured saccular (berry) aneurysms (85%), the remainder being caused by non-aneurysmal perimesencephalic haemorrhage (10%) and rarer causes such as arterial dissection, cerebral or dural AVMs, mycotic aneurysm, pituitary apoplexy, vascular lesions at the top of the spinal cord and cocaine abuse. Saccular aneurysms are not congenital, almost never occur in neonates and young children and develop during later life. It is not known why some adults develop aneurysms at arterial bifurcations in the circle of Willis and some do not. It was thought that there was a congenital weakness in the tunica media, but gaps in the arterial muscle wall are equally as common in patients with or without aneurysms and once the aneurysm is formed, the weakness is found in the wall of the sac and not at its neck.<sup>24</sup> The association with smoking, hypertension and heavy drinking would suggest that degenerative processes are involved. Sudden hypertension plays a role in causing rupture, as shown by SAH in patients taking crack cocaine or, rarely, with sulfenidil.

### CLINICAL PRESENTATION

Classically, there is a 'thunderclap' headache developing in seconds, with half of patients describing its onset as instantaneous. This is followed by a period of depressed consciousness for less than an hour in 50% of patients, with focal neurology in about 30% of patients.<sup>25</sup> About a fifth of patients recall similar headaches and these may have been due to 'warning leaks'. The degree of depression of consciousness depends upon the site and extent of the haemorrhage. Meningism – neck stiffness, photophobia,

**Table 44.1** Clinical neurological classification of subarachnoid haemorrhage

Grade	Signs
I	Conscious patient with or without meningism
II	Drowsy patient with no significant neurological deficit
III	Drowsy patient with neurological deficit – probably intracerebral clot
IV	Deteriorating patient with major neurological deficit (because of large intracerebral clot)
V	Moribund patient with extensor rigidity and failing vital centres

WFNS grade	GCS	Motor deficit
I	15	Absent
II	14–13	Absent
III	14–13	Present
IV	12–7	Present or absent
V	3–6	Present or absent

WFNS, World Federation of Neurological Surgeons; GCS, Glasgow Coma Score.

vomiting and a positive Kernig's sign – is common in those patients with higher GCS. The clinical severity of SAH is often described by a grade, the most widely used being that described by the World Federation of Neurological Surgeons (WFNS),<sup>26</sup> which is summarised in Table 44.1.

This grading, together with the extent of the haemorrhage and the age of the patient, gives some indication of the prognosis, in that the worse the grade the bigger the bleed, and the older the patient, the less likely a good prognosis.

### COMPLICATIONS

The clinical status of the patient may be complicated by factors other than the physical effect of initial bleed, and factors such as acute hydrocephalus, early rebleeding, cerebral vasospasm, parenchymal haematoma, seizures and medical complications must be considered.

### ACUTE HYDROCEPHALUS

This may occur within the first 24 hours postictus and is often characterised by a one-point drop in the GCS, sluggish pupillary responses and bilateral downward deviation of the eyes ('sunset eyes'). If these signs occur, CT scan should be repeated and, if hydrocephalus is confirmed, or there is a large amount of intraventricular blood, then a ventricular drain may be inserted. This is not without risk as it may provoke more bleeding and introduce infection. Only observational studies exist and these are

**Figure 44.3** Spontaneous subarachnoid haemorrhage and secondary hydrocephalus.

contradictory so no firm recommendation can be made (Figure 44.3).

#### REBLEEDING

This may occur within the first few hours after admission and 15% of patients may deteriorate from their admission status.<sup>26</sup> They may require urgent intubation and resuscitation but not all rebleeds are unsurvivable and such deterioration should be treated. The chance of rebleeding is dependent on the site of the aneurysm, presence of clot, degree of vasospasm, age and sex of the patient. A preliminary report of the Co-operative Aneurysm Study gave the rebleeding rate in the first 2 weeks after the initial SAH was reported as 19% cumulative and then approximately 1.5% per day for the next 13 days in 1983.<sup>27,28</sup>

#### CEREBRAL VASOSPASM

This is the term used to describe narrowing of the cerebral blood vessels in response to SAH seen on angiography. It occurs in up to 70% of patients, but not all of these patients will have symptoms.<sup>29</sup> Use of transcranial Doppler (TCD) to estimate middle cerebral artery blood velocity has shown that a velocity of more than 120 cm/s correlates with angiographic evidence of vasospasm. This technology allows diagnosis in the ICU and provides a means of monitoring the success of treatment to reduce vasospasm, which is undertaken to reduce the severity of delayed neurological deficit secondary to vasospasm. The problem is that not all patients who have angiographic vasospasm or high Doppler velocities have symptoms. If there is evidence of a depressed level of consciousness in the absence of rebleeding, hydrocephalus or metabolic disturbances, but there is evidence of vasospasm on TCD or angiogram, then it would seem appropriate to initiate treatment to reduce the vasospasm. If vasospasm occurs at the time of angiography or coiling, then intravascular vasodilators such as papaverine have been used.

**Table 44.2** Types of medical complication seen in patients with subarachnoid haemorrhage

Medical complication	Incidence
Arrhythmias	35%
Liver dysfunction	24%
Neurogenic pulmonary oedema	23%
Pneumonia	22%
ARDS and atelectasis	20%
Renal dysfunction	5%

ARDS, acute respiratory distress syndrome.

#### PARENCHYMAL HAEMATOMA

This may occur in up to 30% of SAH following aneurysm rupture and has a much worse prognosis than SAH alone.<sup>29</sup> If there is mass effect with compressive symptoms then evacuation of haematoma and simultaneous clipping of the aneurysm may improve outcome.

#### MEDICAL COMPLICATIONS

During the placebo-controlled study of nicardipine in WFNS grade I and II SAH patients, there was a 40% incidence of at least one life-threatening medical complication in the placebo group.<sup>30</sup> The mortality due to medical complications was almost the same as that due to the combined effects of the initial bleed, rebleeds and vasospasm. The types of medical complication seen are shown in Table 44.2.

#### INVESTIGATIONS

The general investigations for stroke should be performed and early CT imaging is mandatory. Blood appears characteristically hyperdense on CT and the pattern of haemorrhage may enable localisation of the arterial territory involved. Very rarely, a false-positive diagnosis may be made if there is severe generalised oedema resulting in venous congestion in the subarachnoid space. Small amounts of blood may not be detected and the incidence of false-negative reports is around 2%.<sup>31</sup> It may be difficult to distinguish between post-traumatic SAH and primary aneurysmal SAH, which precipitates a fall in the level of consciousness that provokes an accident or fall.<sup>32</sup> MR scanning is particularly effective for localising the bleed after 48 hours when extravasated blood is denatured, and provides a good signal on MRI.<sup>33</sup>

*Lumbar puncture* is still necessary in those patients where the suspicion of SAH is high despite a negative CT, or there is a need to exclude infection. There must be no raised intracranial pressure and at least 6 hours should have passed to give time for the blood in the CSF to lyse, enabling xanthochromia to develop.

*Angiography* via arterial catheterisation is still the most commonly used investigation for localising the aneurysm

or other vascular abnormality prior to surgery. It is generally performed on patients who remain, or become, conscious after SAH. It is not without risk and aneurysms may rupture during the procedure and a meta-analysis has shown a complication rate of 1.8%.<sup>34</sup> Other methods under investigation include CT angiography and MR angiography, and it is likely that these techniques may replace catheter angiography for diagnosis, although intra-arterial catheterisation would still be needed for endovascular therapy.<sup>35,36</sup>

*Intracranial pressure monitoring* is of limited use in SAH patients except in those where hydrocephalus or parenchymal haematoma is present and early detection of pressure increases may be the trigger for drainage or decompressive surgery.

*Transcranial Doppler* studies may be useful in detecting vasospasm or those patients in whom autoregulation is impaired.<sup>37</sup> The technique is dependent on there being a 'window' of thin temporal bone allowing isonation of the Doppler signal along the middle cerebral artery. It is very user-dependent and 15% of patients do not have an adequate bone window.

## MANAGEMENT

### GENERAL CARE

The initial management of SAH is influenced by the grading, medical comorbidity or complications, and the timing or need for surgery. Patients with decreased GCS may need early intubation and ventilation, simply for airway protection, whereas those with less severe symptoms require regular neurological observation, analgesia for headache and bedrest prior to investigation and surgery. Other management options are:

- stress ulcer prophylaxis
- deep-vein thrombosis prophylaxis using compression stockings or boots
- seizures control with phenytoin or barbiturates

If the patient is sedated and ventilated, the use of an analysing cerebral function monitor should be considered to detect subclinical seizure activity.

Hyponatraemia is a common finding and adequate fluid therapy with normal saline is required with electrolyte levels maintained in the normal range. Occasionally, as in other types of brain injury, excessive natriuresis occurs and may result in hyponatraemic dehydration – cerebral salt-wasting syndrome (CSWS). Its aetiology is not known but some suggest increased levels of atrial natriuretic peptide. It usually occurs within the first week after insult and resolves spontaneously in 2–4 weeks. Failure to distinguish CSWS from the syndrome of inappropriate secretion of antidiuretic hormone (SIADH) could lead to inappropriate treatment by fluid restriction, which would have adverse effects on cerebral perfusion. Urine sodium concentrations are usually elevated in both SIADH and CSWS (> 40mmol/l) but urinary sodium excretion, urine

sodium concentration [ $\text{Na mmol/l}$ ]  $\times$  urine volume [ $l/24$  hours] is high in CSWS and normal in SIADH. If CSWS does not respond to fluid replacement with saline or is not self-limiting then fludrocortisone therapy may be useful.

### BLOOD PRESSURE CONTROL

Elevation of blood pressure is commonly seen after SAH and there are no precise data on what constitutes an unacceptably high pressure that is likely to cause rebleeding. Equally, there are no precise data on a minimum level of pressure below which infarction is likely to occur, since this will depend on the patient's normal pressure, degree of cerebral oedema and the presence or absence of intact autoregulation. One observational study has demonstrated reduced rebleeding but higher rates of infarction in newly treated compared with untreated post-SAH hypertensive patients.<sup>38</sup> If blood pressure exceeds 200 mmHg (26.6 kPa) systolic or 100 mmHg (13.3 kPa) diastolic, then empirically it would seem wise to reduce this pressure in SAH patients who have unclipped aneurysms.  $\beta$ -adrenergic blockers or calcium antagonists are the most widely used agents, since drugs producing cerebral vasodilation may increase intracranial pressure.

### VASOSPASM

Angiographic demonstration of vasospasm may be seen in about 70% of SAH patients but only about 30% develop cerebral symptoms related to vasospasm. Transcranial Doppler-derived flow velocities in the middle cerebral arteries of more than 120 cm/s are accurate in predicting ischaemia.<sup>37</sup> Symptoms tend to occur between 4 and 14 days postbleed, which is the period when cerebral blood flow is decreased after SAH.

One method of pre-empting vasospasm is the prescription of oral nimodipine at 60 mg given 4-hourly for 21 days, which has been shown to achieve a reduction in the risk of ischaemic stroke of 34%.<sup>39</sup> Intravenous nimodipine should be used in the patients who are not absorbing, but it must be titrated against blood pressure to avoid hypotension. Other calcium antagonists, notably nicardipine and the experimental drug AT877, reduce vasospasm but do not improve outcome.

Low cerebral blood flow is known to worsen outcome and this resulted in the development of prophylactic hypertensive hypervolaemic haemodilution – so-called triple-H therapy.<sup>40</sup> As originally described, the therapy involved the use of fluid loading to achieve haemodilution and vasopressor therapy to increase cerebral blood flow, and was combined with surgery within 24 hours if possible. The therapy was continued for 21 days and all patients remained neurologically stable or improved as a result, apparently, of the absence of vasospasm. Very few centres use the strict protocol as originally described, but fluid loading rather than fluid restriction is the norm and inotropes or vasopressors are used subsequently if neurological function

decreases. Despite its widespread use, there remains no prospective randomised trial that demonstrates its utility.

The use of intravascular catheters to deliver papaverine into vasospastic vessels remains experimental. Where symptoms develop it is important to exclude other causes such as rebleeding, hydrocephalus or metabolic disorder.

### SURGERY

Clipping of the aneurysm is the surgical treatment of choice, with wrapping, proximal ligation or bypass grafting being used if the aneurysm is inaccessible to Yasargil clipping. The timing of surgery remains debatable. Early surgery, within 3 days of the bleed, has the advantage of fewer deaths occurring from rebleeding but is technically difficult due to the friability of associated tissues. Delayed surgery, around 10–12 days postbleed, gives better operating conditions but allows some patients to suffer a rebleed. There is no type 1 evidence but an observational study suggested that there is no difference in outcome after early or late operation.<sup>41</sup>

### ENDOVASCULAR COILING

The development of detachable microcoils made of platinum by Guglielmi in 1990 has resulted in endovascular embolisation of aneurysms or AVMs by interventional radiology.<sup>42</sup> A microcatheter is passed from the femoral artery to the cerebral aneurysm and the coils positioned sequentially in the lumen of saccular aneurysms to occlude it. Rupture of the aneurysm or adjacent vessel occlusion, causing ischaemia, is the most frequent complication.<sup>43</sup> The International Subarachnoid Aneurysm Trial (ISAT) of neurosurgical clipping versus endovascular coiling in 2143 patients with ruptured intracranial aneurysms – a randomised comparison of effects on survival, dependency, seizures, rebleeding, subgroups and aneurysm occlusion – has come down in favour of coiling over the open surgical technique at 1-year follow-up. In patients with ruptured intracranial aneurysms suitable for both treatments, endovascular coiling is more likely to result in independent survival at 1 year than neurosurgical clipping; the survival benefit continues for at least 7 years. The risk of late rebleeding is low, but is more common after endovascular coiling than after neurosurgical clipping.<sup>44</sup> Additional complications of coiling include rupture during catheter placement in the aneurysm, coil embolisation and vasospasm. Not all aneurysms, particularly those with wide necks, multiple filling vessels or giant aneurysms, are suitable for coiling.

### NEUROPROTECTIVE THERAPY

There has been a great deal of research on the cellular and biochemical responses to brain injury and several drugs have been investigated to try and reduce mortality in SAH. The 21-amino steroid tirilizad, nicaraven and ebsefen, all free-radical scavengers, have been the most widely

investigated. None has been shown to improve outcome consistently in all types of patient with SAH.

### THERAPY OF MEDICAL COMPLICATIONS

This is obviously specific to the type of complication. Pneumonia may require continuous positive airways pressure or ventilatory support together with directed antimicrobial therapy; acute respiratory distress syndrome requires lung-protective/recruitment ventilatory strategies; and renal failure necessitates an appropriate means of renal replacement therapy. Arrhythmias require correction of trigger factors such as hypovolaemia and electrolyte or acid–base disturbances prior to the appropriate antiarrhythmic drug or DC cardioversion. Neurogenic pulmonary oedema may be associated with severe cardiogenic shock, which may require inotropic support or even temporary intra-aortic balloon counterpulsation. The cardiogenic shock is reversible and patients can make a good recovery despite the need for aggressive support.<sup>45</sup>

# Cerebral protection

Victoria Heaviside and Michelle Hayes

The cerebral circulation is arguably the most important and most vulnerable in the body. Arrest of the circulation for only a few minutes can cause neuronal death. The concept of cerebral protection has been engaged across a broad spectrum of clinical scenarios. It has been incorporated into the prophylaxis, treatment and subsequent management of ischaemia and infarction and even into attempts to ameliorate postischaemic or anoxic damage following cardiorespiratory resuscitation. A complete review is beyond the scope of this chapter, but an understanding of the current approaches to cerebral protection is certainly helpful in the management of cerebral insults.

## NORMAL BRAIN PHYSIOLOGY

The brain has a high energy requirement, utilising approximately 3–5 ml O<sub>2</sub>/min per 100 g tissue (45–75 ml O<sub>2</sub>/min per 1500 g brain) and 5 mg glucose/min per 100 g tissue (75 mg glucose/min per 1500 g brain). It has little ability to store precursors of metabolism and thus depends on a constant supply of nutrients from the blood.

At a cerebral blood flow (CBF) of 50 ml/min per 100 g tissue (750 ml/min per 1500 g brain) and a normal oxygen content of 20 ml O<sub>2</sub>/100 ml blood, the brain receives approximately 150 ml O<sub>2</sub>/min per 1500 g brain, or 2–3 times the amount needed for normal brain activity.

At the same CBF of 50 ml/min per 100 g tissue and a blood glucose concentration of 5.5 mmol/l (100 mg/100 ml blood), there is 50 mg/min per 100 g tissue (750 mg/min per 1500 g brain) delivery of glucose. Glucose extraction by the brain, at 5 mg/min per 100 g brain tissue, is a tenth of that delivered – minimal compared with oxygen.

Cerebral injury has many aetiologies, but the mechanisms of injury are thought to be few. The most common is lack of the essential nutrients, oxygen and glucose, either separately with preserved blood flow (i.e. hypoxia or hypoglycaemia), or together, because of reduced or absent perfusion (i.e. ischaemia or infarction). A reduction in these energy precursors is a major contributor in the mechanism of brain injury, regardless of the aetiology.

## NATURAL PROTECTIVE MECHANISMS

The importance of the brain to the whole being is highlighted by the mechanisms in place to protect the cerebral elements from ischaemia.

## COLLATERAL BLOOD SUPPLY

An elaborate vascular architecture is designed to ensure adequate CBF. The anterior cerebral circulation is provided by bilateral internal carotid arteries as they each divide into anterior and middle cerebral arteries. They provide approximately 70% of the cerebral circulation and supply the anterior cerebrum (frontal, parietal and temporal lobes) and anterior diencephalon (basal ganglia and hypothalamus). The remaining 30% of the cerebral circulation is provided posteriorly by the vertebrobasilar system which runs the length of the posterior fossa, supplying the brainstem, cerebellum and posterior portion of the cerebrum (occipital lobes) and diencephalon (thalamus). These two circulations are joined by communicating arteries, ultimately forming the circle of Willis (Figure 45.1). This joining of the anterior and posterior circulations at the base of the brain is the major component of cerebral vasculature in humans. Between these arterial distributions are watershed zones fed by leptomeningeal connections. In addition, persistent fetal arteries can infrequently provide collateral routes between the anterior and posterior arterial systems in the brain.

## CEREBRAL BLOOD FLOW

### CEREBRAL PERFUSION PRESSURE

The amount of blood delivered to the brain is highly regulated and is determined by several factors. CBF is determined in part by the perfusion pressure across the brain, called cerebral perfusion pressure (CPP). CPP, is the difference between the arterial pressure in the feeding arteries as they enter the subarachnoid space and the pressure in the draining veins before they enter the major dural sinuses. Because these pressures are difficult to measure, CPP is derived from the difference between the systemic mean arterial pressure (MAP) and the intracranial pressure (ICP), which is an estimate of tissue pressure.

**Figure 45.1** Circle of Willis.

The cerebral vessels change diameter inversely with changing perfusion pressure: as CPP rises, the vessels constrict and as CPP falls the vessels dilate, such that blood flow is kept constant over a wide range of CPP (Figure 45.2a). This pressure autoregulation is thought to be controlled by local myogenic responses of the vessel wall to changes in intra-arterial pressure. At pressures above and below this range of 6.7–20 kPa (50–150 mmHg), cerebral perfusion becomes pressure-passive and increases or decreases in direct proportion to changes in CPP. The autoregulatory range varies with age, being

shifted to the left in newborns and to the right in those with chronic hypertension. The latter is important to remember to avoid overtreating systolic blood pressure in such patients and thus incur the risk of cerebral ischaemia at the lower limits of autoregulation. Alternatively, cerebral perfusion above normal can be caused by acute hypertension overcoming the upper limits of autoregulation. This may lead to cerebral oedema secondary to increased hydrostatic pressures (hypertensive encephalopathy) and potentially lead to seizures or cerebral haemorrhage.

**Figure 45.2** (a) The relationship between the partial pressure of oxygen ( $P_{O_2}$ ) and carbon dioxide ( $P_{CO_2}$ ) and cerebral blood flow (CBF). (b) The relationship between mean arterial pressure (MAP) and cerebral blood flow under normal circumstances, illustrating the range of autoregulation.

### **Pao<sub>2</sub> AND Paco<sub>2</sub> EFFECTS**

A second group of factors control CBF through an influence on the local metabolic milieu. Prominent in this mechanism are oxygen and carbon dioxide. Arterial content or partial pressure of oxygen in the normal or hyperoxic ranges causes very little change in CBF. Perhaps this represents a demand for another nutrient (i.e. glucose) or a need to remove waste products (i.e. carbon dioxide or metabolic acid). With the onset of hypoxaemia ( $P_{aO_2}$  60 mmHg or 8 kPa), there is a prompt increase in CBF proportional to the decrease in blood oxygen content, in order to maintain oxygen delivery constant (Figure 45.2b).

There is also a direct relationship between CBF and  $P_{aCO_2}$ , such that cerebral perfusion increases with increasing  $P_{aCO_2}$  (Figure 45.2b). This probably represents the need of the brain to maintain homeostatic pH by removing metabolic breakdown products more efficiently by increased blood flow. Unlike the response to oxygen, the CBF response to changes in  $P_{aCO_2}$  is dramatic in the physiological range, such that for every 0.13 kPa (1.0 mmHg) change in  $P_{aCO_2}$  there is a 1–2 ml/min per 100 g tissue change in CBF. Therefore, an increase in  $P_{aCO_2}$  to 10.6 kPa (80 mmHg) will increase CBF to approximately 100 ml/min per 100 g and a decrease in  $P_{aCO_2}$  to 2.7 kPa (20 mmHg) will decrease CBF to 25 ml/min per 100 g. Thus:

- doubling  $P_{aCO_2}$  doubles CBF
- halving  $P_{aCO_2}$  halves CBF within this range

Understanding this basic physiology will make treatment logical (see below), as increases in CBF often lead to increases in cerebral blood volume, which in turn can increase ICP – a common cause of cerebral ischaemia.

### **CEREBRAL INJURY**

Vascular insufficiency or disruption, trauma, tumour, infection, inflammation and metabolic and nutritional derangement can all cause damage. Whatever the cause, the mechanism of injury is usually hypoxic and/or ischaemic injury.

- Hypoxia is lack of oxygen.
- Ischaemia is lack of flow.

Therefore, it is possible to have high flow but no oxygen or, alternatively, no flow but plenty of oxygen. At the cellular level the consequence is the same.

The protective mechanisms afforded by the ability to increase CBF manifold in response to hypoxaemia and the generous oversupply of nutrients under normal conditions allow for sufficient blood flow, with maintenance of oxygen delivery and supply of other nutrients in many cases. Limitation in the ability to alter CBF, whether through cerebrovascular disease restricting perfusion or intracranial masses, oedema and increased ICP exerting excess local pressure, and altering blood flow, will cause

hypoxic/ischaemic injury. Systemic problems such as severe or prolonged hypoxaemia will eventually disturb systemic circulatory homeostasis, leading to hypotension and eventual ischaemia. Thus hypoxic and ischaemic injury may be considered synonymous, although there may be aetiological differences between them. A more important distinction is to be made between global and focal hypoxic or ischaemic insults.

### **GLOBAL HYPOXIC/ISCHAEMIC INSULTS**

These types of insult are caused by hypoxaemia and cardiovascular insufficiency or arrest, respectively. These are usually sudden, short and severe. If there is to be recovery, prompt return of oxygen delivery and spontaneous circulation are necessary. The recovery may be variable, depending on the severity and duration of the insult and the selective vulnerability of the cell types involved. Different mechanisms are responsible for reversible loss of cellular function and for irreversible cell death and there are also differences between the mechanisms that cause death of neurones, glia and endothelial cells. After 4–6 minutes of complete global ischaemia, there are signs of permanent histological damage in selective neuronal populations and the beginnings of neurological deficits in survivors. Outcome worsens significantly after 15 minutes of global ischaemia.<sup>1</sup>

### **FOCAL HYPOXIC/ISCHAEMIC INSULTS**

These insults often occur suddenly but are usually of more prolonged duration. Only a subtotal of the brain is affected and the injury may be less severe if the surrounding brain is preserved by collateral blood supply.

The area of the focal ischaemia supplied by end-arteries will result in cell death unless reperfusion is established rapidly. The periphery of an infarcted area is the ischaemic penumbra. Here, CBF is greater than at the infarcted core, but less than in the normal tissue around it. Animal studies suggest that the time course for infarction and irreversible damage to brain from a focal hypoxic/ischaemic event is around 30–60 minutes. The focus of therapeutic intervention is the penumbral area, on the basis that if blood flow can be normalised in this region, or pharmacological agents can be delivered despite the reduced blood flow, there is a potential for recovery. Conversely, failure to maintain this area will result in a coalescing of the penumbra into the infarcted area, as the ischaemic stimulus continues.

It is likely that the ongoing ischaemic penumbral area of a focal insult and transient whole-brain ischaemia (e.g. during early cardiac arrest, low-flow cardiopulmonary resuscitation (CPR) or elevated ICP states) are subject to similar pathophysiological processes. As pretreatment is usually impossible, prevention and treatment of the secondary insults are the focus in neuroprotection and tissue salvage strategies.

### BRAIN ISCHAEMIC AND INFARCTION PROCESSES

Changes in normal physiology begin to occur when blood flow is reduced.

- At CBF below 50 ml/min per 100 g neurological function is impaired and there is slowing of the electroencephalogram (EEG).
- A CBF of 15–25 ml/min per 100 g results in loss of electrical activity.
- A CBF between 10 and 15 ml/min per 100 g can maintain adenosine triphosphate (ATP) levels sufficiently to support ionic pump function for a time, despite the lack of electrical activity and normal neurological function.
- At a CBF of 10 ml/min per 100 g membrane failure occurs, due to a critical loss of ATP, which causes ionic imbalance between the cell and the extracellular milieu. If prolonged or worsened, CBF at this level will lead to permanent neurological impairment as a result of cell death.

### EFFECTS OF ISCHAEMIA

Ischaemia results in reduced available oxygen and glucose to support aerobic production of ATP. Levels of ATP are depleted within 2–3 minutes of complete ischaemia (animal studies). There is little brain storage of either glucose or oxygen, and ATP production during ischaemia relies on anaerobic glycolysis for as long as stores last. This results in continued ATP use, but suboptimal production of ATP to fuel aerobic metabolism, so a lactic acidosis develops. Loss of ATP causes failure of membrane ionic pump function, leading to an efflux of potassium and an influx of sodium, calcium and chloride ions, the beginnings of cytotoxic oedema.

This begins a cascade of events resulting in eventual cell death:

- Potassium leakage causes cell depolarisation, ion channel opening and the release of excitatory amino acid (EAA) neurotransmitters (glutamate and aspartate and others).
- EAA cause further depolarisation of neighbouring cells and distal, otherwise unaffected, parts of the brain which result in:
- sodium and chloride influx via kainate (K) and quisqualate (Q) receptors (with water worsening intracellular oedema)
- calcium influx via *N*-methyl-D-aspartate (NMDA) receptors
- release of excitatory transmitters
- conversion of phosphorylases, uncoupling of oxidative phosphorylation, activation of proteases, degradation of cytosolic protein and stimulation of lipases. Lipases liberate arachidonic acid and other free fatty acids that cause tissue damage via production of oxygen radicals and prostaglandins

Other effects within the cell influence DNA and RNA production, hence inhibiting protein production. This may explain why cellular and clinical recovery is partial, even with restoration of ionic equilibrium and near-normal ATP levels after successful reperfusion. Necrosis is thought to occur in the core of the cerebral infarct following acute vascular occlusion, with further neurodegeneration occurring more slowly in the penumbra, by apoptosis or release of various immunological mediators.<sup>2</sup>

### EXTRACELLULAR EFFECTS

Leukocytes are thought to be major contributors to reperfusion injury in that:

- they may plug up small capillaries under conditions of low blood flow and prevent reflow in certain areas, thus hindering restoration of perfusion
- they may enhance production of oxygen radicals and begin a cascade of inflammatory mediators, which may potentiate cell destruction in injured tissue

This results in tissue oedema, which may affect the core lesion by narrowing blood vessels and worsening chances of reperfusion. Local mechanical compression of tissue or its blood supply can cause deterioration in neighbouring tissue. The alteration in volume is of extreme importance in the adult brain because the cranial vault is non-distensible, preventing accommodation to an expanding lesion. This will impede CBF both locally and globally.

Hypoxic/ischaemic insults are rarely predictable, so that the process is usually well established when clinicians intervene. It is therefore highly likely that the injury will be only partially remediable.

### MANAGEMENT

In neurological injury, the initial aims are to provide basic support. Assessment of the airway and respiration are the first priority, closely followed by optimisation of the circulation.

In cases of head trauma, it is very important to prevent secondary brain injury. Reviews of intensive care practice have resulted in recommendations for treatment in this group of patients.<sup>3</sup> These involve:

- institution of monitoring
- early treatment of hypotension, hypoxia, hyperthermia and intracranial hypertension
- maintenance of CPP

Following stroke, it is also important to optimise homeostasis and address any hypertension, hyperglycaemia, hyperthermia and intracranial hypertension, as these are independent factors of a poor prognosis.

### HYPERTENSION

Most patients have elevated blood pressure in the early phase after an acute ischaemic stroke. The mechanism

and effects of this blood pressure elevation are not well understood and the benefits of intervention remain debated. Most experts would not advocate antihypertensive treatment in the acute phase after stroke, unless the blood pressure is particularly high. Currently hypertension (systolic blood pressure > 180 mmHg) should be treated if thrombolytics are to be administered, based on the trials involving these agents in which the blood pressure was lowered prior to treatment.<sup>4</sup> Ongoing studies such as Blood Pressure in Acute Stroke Collaboration (BASC) should help define optimal management.

### HYPERGLYCAEMIA

Hyperglycaemia has also been associated with an increased mortality and reduced functional outcome after stroke irrespective of whether the patient has a diabetic history or not.<sup>5</sup> Proposed explanations for this are:

- Hyperglycaemia may be directly toxic to the ischaemic brain.
- Decreased levels and reduced peripheral uptake of insulin in these patients result in increased cerebral glucose availability which may impair endothelial-dependent vasodilatation.
- Hyperglycaemia may indicate dysglycaemia, which is associated with vascular disease and endothelial dysfunction, both of which may exacerbate ischaemic damage at the time of stroke.

Hyperglycaemia may result in a hypercoagulable state, with decreased plasma fibrinolytic activity, which may delay reperfusion and increase haemorrhagic infarct conversion in tissue plasminogen activator-treated patients.<sup>6</sup>

Insulin, as well as having a glucose-lowering effect, has also been shown to be directly neuroprotective and this is the subject of a number of ongoing trials<sup>7</sup> (Treatment of Hyperglycaemia in Ischaemic Stroke (THIS) trial, the Glucose Regulation in Acute Stroke Patients (GRASP) trial and the Glucose Insulin Stroke Trial UK (GIST-UK).

### HYPERTHERMIA

An increased temperature increases cerebral metabolism, oxygen requirements, CBF and ICP. Hyperpyrexia following acute stroke adversely influences stroke severity, infarct size, functional outcome and mortality.<sup>8</sup> A raised temperature should, therefore, be treated aggressively and any evidence of infection identified early and treated with appropriate antibiotics.

### REVASCULARISATION

For global ischaemia following cardiac arrest, the theoretical principles are to re-establish systemic blood pressure and to consider the no-reflow phenomenon in certain areas of the brain. Current research is addressing attempts to increase blood pressure during CPR and to open up capillaries that may have collapsed during the arrest period.

For focal cerebral ischaemia:

- Start treatment as early as possible.
- Increase local CBF (fibrinolysis).
- Try to ameliorate ischaemic cascade (neuroprotection).

Ischaemic neuronal degeneration follows the onset of perfusion failure so that interventional therapy must begin immediately. Diagnostic imaging is required before using thrombolytic agents. For acute ischaemic stroke the National Institute of Neurological Disorders and Stroke (NINDS study) suggested efficacy if intravenous thrombolytic therapy is initiated within the first 3 hours of stroke symptoms (using recombinant tissue plasminogen activator).<sup>9</sup>

Current issues in implementing this treatment include:

- diagnosis, including imaging within this time frame
- the potential risks of thrombolysis
- accurately selecting patients eligible for thrombolysis

### HAEMODILUTION

Current practice includes the use of hypervolaemic haemodilution and deliberate hypertension with augmentation of cardiac output using vasopressors and inotropic agents, particularly in the treatment of delayed ischaemic deficits after subarachnoid haemorrhage related to vasospasm. This therapy can be administered safely with intensive monitoring, but benefits are anecdotal, as it has not been tested with concurrent controls.<sup>10</sup>

Decreasing haematocrit and viscosity by haemodilution may improve flow and hence blood and oxygen delivery to areas with impaired arterial supply. Benefit in animal models of ischaemia has not been found in clinical trials of stroke. Trials of normovolaemic<sup>11</sup> and hypervolaemic haemodilution<sup>12</sup> have had complications from volume therapy in patients with associated heart disease.

Theoretical neuroprotective benefits of human haemoglobin-derived blood substitutes have not translated into clinical benefit, largely due to adverse events, and therefore clinical development of substitutes were discontinued.<sup>13</sup>

### INTRACRANIAL PRESSURE

Raised ICP can cause global ischaemia. Treating ICP requires knowledge of the three compartments contributing to ICP within a fixed cranium:

1. blood
2. relatively non-compliant brain tissue
3. cerebrospinal fluid (CSF)

The relationship between ICP and intracranial volume is described by a non-linear pressure–volume curve. At lower intracranial volumes the ICP remains low and reasonably constant. Any increases in intracranial volume are compensated for by decreases in intracerebral blood or CSF volume. If greater intracranial volumes persist, this compensation is lost and ICP rises considerably, despite

relatively small increases in intracerebral blood volume. Eventually at high levels of ICP cerebrovascular responses are lost, ICP equals MAP and CPP is very low.<sup>14</sup>

To maintain adequate cerebral perfusion, treatment should be targeted at ensuring an adequate perfusion pressure and a reduction in ICP. MAP should be raised to a level at or above the usual pressure for that patient, within the zone of pressure autoregulation – hence knowledge of premorbid blood pressure is important. If the majority of the vasculature is autoregulating, raising the blood pressure may decrease vascular diameter and reduce blood volume within the cranium. If the cause of the raised ICP cannot be corrected (e.g. blood clot or brain tumour), then the focus should be to prevent secondary injury around the lesion. An increased ICP can cause further ischaemia, and a reduction in ICP may facilitate adequate perfusion to areas at risk. Whenever possible, the offending compartment should be treated primarily (e.g. tumour removal, blood evacuation, drainage of hydrocephalus and, on occasion, craniectomy). If this is not advisable, reducing the relative volumes of other compartments may improve compliance overall and reduce the ICP.

### MONITORING OF ICP (FIGURE 45.3)

ICP-monitoring devices have been ranked by the Brain Trauma Foundation<sup>14</sup> on their accuracy, stability and ability to drain CSF. Intraventricular and intraparenchymal catheters are seen as most favourable, followed by subdural, subarachnoid and epidural devices.

#### INTRAVENTRICULAR DEVICES

ICP is measured from an external pressure transducer attached to an intraventricular catheter inserted in one of the lateral ventricles using the external auditory meatus as the reference point. This device allows CSF sampling for culture or therapeutic drainage, the administration of antibiotics and the ability to rezero following insertion. The main disadvantage is the high infection rate associated with their use.<sup>14,15</sup> Infection rates increase significantly after 5 days of catheter insertion and with repeated use of the device's flushing system. The use of antibiotic-impregnated catheters may lower the infection rate. Air, blood, tissue debris and ventricular collapse can all adversely affect measurement.

#### INTRAPARENCHYMAL DEVICES

ICP can be measured by either a miniature strain gauge pressure transducer mounted at the end of a thin catheter or by a fiberoptic cable which directs light to a miniature mirror at the end of the cable placed in brain tissue. These monitors are advantageous when lateral ventricles have collapsed secondary to raised ICP. This system is not dependent on fluid coupling for pressure transduction so waveform damping and artefacts are avoided. The infection rates are very low. Its main disadvantages include lack

**Figure 45.3** Intracranial pressure (ICP) waveforms. A-waves are plateau waves of 50–100 mmHg, sustained for 5–15 minutes, associated with raised ICP and compromised cerebral blood flow. B-waves are small changes in pressure every 0.5–2 minutes, often associated with breathing patterns and possibly due to local variations in the partial pressure of oxygen and carbon dioxide. C-waves are low-amplitude oscillations with a frequency of about 5 per minute, associated with variation in vasomotor tone. Resps, respirations; BP, blood pressure.

of recalibration *in vivo*, a tendency for baseline drift requiring transducer replacement, the inability to drain CSF and the ability to measure only localised pressure which may not be representative of the global ICP.<sup>15</sup>

Alternative invasive ICP monitoring includes epidural, subarachnoid and subdural devices, although these are not as accurate. All invasive ICP monitoring devices are associated with a risk of parenchymal damage with the potential for parenchymal and subdural bleeding. When it is not possible to insert an ICP-monitoring device, e.g. because of severe coagulopathy, ICP can be estimated from non-invasive alternatives, e.g. transcranial Doppler examination. However all ICP-monitoring devices have their limitations. Clarification should be sought by computed tomographic (CT) scanning if there is doubt about whether to intervene with treatment of an elevated ICP.

## REGULATION OF INTRACRANIAL PRESSURE

### BRAIN COMPARTMENT

Reduction in the parenchymal compartment depends on removal of either free water or the lesion causing the raised ICP.

Free water must be moved across an intact blood–brain barrier. Mannitol increases plasma osmolarity and reduces brain oedema. In addition, it may have a beneficial effect on microcirculatory flow. It is also thought to have antioxidant effects, although these may not be clinically important. Hypertonic saline has reduced ICP in patients with haemorrhagic shock and traumatic brain injury when used for volume resuscitation (7.5%), and also for treatment of raised ICP refractory to mannitol (23.4%).<sup>16</sup>

Removal of tumour or blood clot, drainage of abscesses and extirpation of infarcted brain are all therapies aimed at improving compliance. Mounting evidence now suggests that there is a penumbra of functionally impaired but potentially reversible neuronal injury surrounding a haematoma. Indications for clot removal, despite numerous studies performed over the last four decades, has been controversial. The Surgical Trial in Intracerebral Haemorrhage (STICH) compared early surgical evacuation of haematoma with initial conservative treatment, but found no significant difference in outcomes between the two treatments.<sup>17</sup>

The rationale for removing part of the skull overlying the stroke in patients with or at risk of developing cerebral oedema and intracranial hypertension is simply to decompress the brain swelling and prevent herniation. Decompressive craniectomy has been assessed in experimental cerebral infarction and was effective in reducing death and neurological impairment whether performed 1 hour or 24 hours after induction of permanent middle cerebral artery occlusion.<sup>18</sup> An uncontrolled trial comparing patients with hemicraniectomy with historical controls found that mortality rates were reduced from 80% to 35% in the surgical group.<sup>19</sup> These non-randomised studies are clearly at risk of bias and properly controlled trials of craniectomy for malignant middle cerebral artery infarction are required.

### BLOOD COMPARTMENT

Although a small component of intracranial volume, the blood compartment is the most compliant. Reduction in blood volume is useful in the treatment of raised ICP, especially in the acute setting. As explained above, hypoxia and hypercarbia can lead to hyperaemia and an increase in cerebral blood volume, potentially worsening ICP. Alternatively, induced hypocarbia leads to very rapid changes in blood flow and blood volume. Hyperventilation for raised ICP is controversial. Up until 10 years ago, patients were often aggressively hyperventilated to a  $P_{aCO_2}$  of 25 mmHg in order to reduce ICP rapidly as

a result of arteriolar vasoconstriction. Unfortunately, the resultant reduction in cerebral blood volume may be accompanied by a fall in global CBF, which may result in ischaemia and a worsened outcome. The Brain Trauma Foundation guidelines in the 1990s recommended that chronic hyperventilation ( $P_{aCO_2} = 25$  mmHg) should not be instituted in severe traumatic brain injury in patients with a normal ICP and that prophylactic hyperventilation to a  $P_{aCO_2}$  of 35 mmHg should also be avoided in the first 24 hours after a severe traumatic brain injury, as it can reduce cerebral perfusion during a time of reduced CBF. Current studies suggest that ICP reduction, as a result of moderate hyperventilation within the first 24 hours and the resultant decrease in CBF, do not compromise cerebral metabolism.<sup>20</sup> It is recommended that a secondary treatment be instituted as soon as possible to allow slow withdrawal of hyperventilation.<sup>21</sup> If adaptation to hypocapnia has not occurred, hyperventilation can be reinstated with the same effect. Prevention of seizures and hyperthermia lower the cerebral metabolic demand and reduce CBF and volume.

### CEREBROSPINAL FLUID COMPARTMENT

CSF drainage can be used to reduce ICP but is only possible if there is a ventricular catheter in place. Care is taken regarding the route and rate of CSF drainage to avoid herniation of a mass lesion, either towards the other side of the brain or through the tentorium. In recent years there has been a move towards the use of less invasive methods to measure ICP. However, the Brain Trauma Foundation guidelines for the management of severe head injury provide some evidence supporting the increased use of CSF drainage for ICP control.<sup>22</sup>

### HYPOTHERMIA

Injury to the central nervous system is temperature-dependent. Fever can make an existing neurological dysfunction more apparent and may worsen an ongoing dysfunction. Potential mechanisms by which hyperthermia worsens cerebral ischaemia may include:

- neurotransmitter and oxygen free radical production
- blood–brain barrier failure
- damaging depolarisations in the ischaemic penumbra
- impaired recovery of energy metabolism
- cytoskeletal proteolysis<sup>23</sup>

Hyperthermia is harmful so treatment of fever should be aggressive, using cooling blankets, cool water, cool intravenous fluids, fans and antipyretic medications.

Hypothermia has been known to offer protection for years. In particular, drowning victims who were hypothermic have survived long periods of ischaemia. The mechanism of ICP reduction is unknown but may be due to a reduction in intracranial blood volume secondary

to cerebral vasoconstriction or to alterations in metabolism. The protective effect of cooling appears to be much greater than that explained by changes in metabolism alone.

In contrast to preventing hyperthermia, the use of induced hypothermia is more complex. It has been used for protection extensively in coronary artery bypass surgery where hypothermia (28–30°C) is commonplace and deep hypothermia (< 20°C) has allowed prolonged circulatory arrest for surgery such as high thoracic and giant cerebral aneurysms. Animal work suggests that moderate, systemic hypothermia reduces the cerebral oedema and death after injury to the cerebral cortex. In several centres cooling has been used as therapy for severe head injuries. Unfortunately, a study which evaluated the efficacy of hypothermia in head injuries was halted after the enrolment of 392 patients because the treatment was ineffective.<sup>24</sup> Cooling patients to 33°C within 8 hours after injury and maintaining hypothermia for 48 hours were not effective in improving the clinical outcome at 6 months and patients older than 45 years of age had a poorer outcome. This contrasted with two earlier studies,<sup>25,26</sup> both of which demonstrated an improvement in outcome with cooling to 32°C.

In conclusion, at present:

- There is no evidence that hypothermic therapy after traumatic brain injury reduces risk of death or neurological outcome.
- Hypothermia may put the patient at more harm, with the risk of pneumonia, arrhythmias and coagulopathies.
- It may be more problematic in patients over 45 years of age.

In stroke patients there are no randomised controlled trials of hypothermia. Animal models suggest that hypothermia reduces ischaemic stroke lesion size.<sup>27</sup> A small uncontrolled study of moderate hypothermia found reduced mortality from an expected value of 78% to 44% in patients with severe middle cerebral artery infarction.<sup>28</sup> There are ongoing studies such as the Nordic Cooling Stroke Study (NOCSS).

In cardiac arrest the situation is changing. Although 50 years ago therapeutic hypothermia was used post cardiac arrest, it was abandoned because of the uncertain benefit. In the 1980s, animal studies indicated benefit with mild (32–35°C) rather than moderate or deep hypothermia. Two randomised clinical trials of hypothermia, after witnessed out-of-hospital cardiac arrest, demonstrated improved survival and neurological outcome after 12 or 24 hours of hypothermia at 33°C.<sup>29,30</sup> The evidence from these two relatively small trials has led to recommendations as set out by the International Liaison Committee on Resuscitation:

*Unconscious adult patients with spontaneous circulation after out-of-hospital cardiac arrest should be cooled to 32°C to 34°C for 12 to 24 hours when the initial rhythm is ventricular fibrillation (VF).*

It has also been suggested, currently without evidence, that hypothermia may be beneficial for other rhythms or for in-hospital cardiac arrest. It is not recommended in patients with severe cardiogenic shock, life-threatening arrhythmias, pregnant patients or those with a coagulopathy.<sup>31</sup>

The uptake of these recommendations is variable. Recently, in the UK, a survey suggested that only 26% of units currently undertook therapeutic hypothermia after cardiac arrest. The main reasons for not using therapeutic hypothermia appeared to be due to logistical or resource issues and a perceived lack of evidence or lack of consensus within individual intensive care unit teams.<sup>32</sup>

There is currently insufficient evidence to recommend therapeutic hypothermia in children resuscitated from cardiac arrest. Neonatal animal studies, however, have shown promising results with regard to neuroprotection offered by posthypoxic hypothermia, although it has been shown that the protective effects of hypothermia are lost without adequate sedation.<sup>33</sup>

## ANAESTHETIC AGENTS

Barbiturates have shown convincing benefit, especially for focal ischaemia in many animal species. In one small clinical study of induced barbiturate coma during coronary bypass surgery, there was a reduction in focal deficits.<sup>34</sup> Barbiturate-mediated neuroprotection was initially attributed to suppression of cerebral metabolic rate but more recently to redistribution of CBF to injured areas, the blockade of glutamate receptors and sodium channels, inhibition of free radical formation and potentiation of GABAergic activity.<sup>35</sup> At present barbiturates are not commonly used either in coronary bypass surgery or in situations of global ischaemia. Barbiturates are now less commonly used in head-injured patients but can play a role in those patients who have intractable intracranial hypertension.

Propofol has been shown to be neuroprotective in vivo, in focal and global models of cerebral ischaemia. It decreases cerebral metabolic rate and hence CBF. It has been shown to have antioxidant properties, potentiate GABA-A-mediated inhibition of synaptic transmission and inhibit glutamate release. It delays neuronal death by being a free radical scavenger, preventing lipid peroxidation and modulating apoptosis-regulating proteins.<sup>35,36</sup> Its side-effects include hypotension with a reducing CPP and hyperlipidaemia when an infusion of 200 µg/kg per min is used to produce burst suppression.<sup>37</sup> This latter problem has been lessened by the introduction of a more concentrated formulation.

Inhalational agents have significant neuroprotective effects but the precise mechanism by which they reduce cerebral injury is unclear.<sup>36</sup> It is possible that isoflurane may attenuate excitotoxicity by inhibiting glutamate release and its postsynaptic responses at both anaesthetic and EEG burst suppression concentrations. The neuroprotection provided by volatile agents may also be attributable to their

effect at GABA-A receptors and an ability to reduce the sympathetic vascular response to ischaemia. Certainly their effect on reducing cerebral metabolic rate is not sufficient to explain their neuroprotective properties.<sup>35,36</sup> These potential benefits in adults are offset by recent studies which have suggested that in neonatal animal studies there may be disturbing increases in cerebral apoptosis, although this has yet to be confirmed. There is an increasing interest in xenon, which presently looks promising.

Nitrous oxide exhibits the neuroprotective and neurotoxic features of an NMDA antagonist. Studies, however, have shown that, when combined with an opioid, e.g. fentanyl, its neuroprotective effect during incomplete cerebral ischaemia is still inferior when compared to volatile agents.<sup>36</sup>

Midazolam reduces the cerebral metabolic rate for oxygen, CBF and volume. It does not produce burst suppression or an isoelectric EEG, even in large doses.

Neuromuscular blockade is often used in head-injured patients to prevent any coughing on the tracheal tube and subsequent rise in ICP. Their use is not associated with better outcome despite the improvements in ICP control.

### CALCIUM ANTAGONISTS

The influx of calcium from the extracellular space and from intracellular organelles has been implicated as the common mediator of cell death from a variety of causes. Calcium antagonists were among the first neuroprotective agents studied to prevent cerebral ischaemia. Despite the effects seen in animal models, human studies in both global and focal ischaemia have been disappointing. Two large trials of intravenous nimodipine in patients with acute ischaemic stroke were terminated early as neurological and functional outcome were significantly poorer in the nimodipine group.<sup>38,39</sup> A close relationship was found between a reduction in diastolic and mean blood pressure in the group treated with nimodipine and an unfavourable neurological outcome. A review of 29 randomised acute stroke trials involving calcium antagonists concluded that the use of calcium antagonists could not be justified in patients with ischaemic stroke and that, although the published trials showed no overall effect on death and dependency, unpublished trials were associated with a statistically significant worse outcome.<sup>40</sup> Nimodipine, however, has become the standard prophylactic treatment for cerebral vasospasm after subarachnoid haemorrhage, with a consequent decrease in cerebral infarction and better patient outcome.<sup>41</sup> Benefits appear to be due to an effect on smaller penetrating vessels not seen by angiography, or a neuroprotective effect at the cellular level, rather than cerebral vasodilatation identifiable by angiography.

Nimodipine was shown to be neuroprotective in head-injured patients with traumatic subarachnoid haemorrhage.<sup>42</sup> Regrettably, further studies to test the neuroprotective effect of nimodipine in severely head-injured patients with traumatic subarachnoid haemorrhage (including the multicentre study, HIT IV) failed to confirm the beneficial

effects of nimodipine. A small group of patients with a Glasgow Coma Score < 9 did appear to have a better outcome in the nimodipine-treated group;<sup>43</sup> however, a recent systematic review concluded that there was no beneficial effect on outcome.<sup>44</sup> Its use therefore remains contentious.

### STEROIDS

Glucocorticoids were used for over 30 years in the treatment of head injury despite the fact that randomised trials had failed to demonstrate their effectiveness reliably. They were thought to decrease cerebral oedema associated with breakdown of the blood–brain barrier (i.e. vasogenic oedema) and show improvement in central nervous system function with brain tumours and abscesses.<sup>45,46</sup>

The Corticosteroid Randomisation After Significant Head injury (CRASH) trial investigated the effects of a 48-hour infusion of methylprednisolone on death within 14 days or disability at 6 months in 10 008 adults with clinically significant head injury. The trial was stopped early, as at interim analysis, the steroid-treated subjects had significantly higher all-cause 2-week mortality (21.1% versus 17.9%,  $P = 0.0001$ ). The 6-month mortality was also higher in steroid-treated subjects (25.7% versus 22.3%,  $P = 0.0001$ ), with a trend toward increases in the combined endpoint of death or severe disability (38.1% versus 36.3%,  $P = 0.08$ ). In neither report did the results differ by injury severity or time since injury.<sup>47</sup> The cause for the increased mortality is unclear.

In subarachnoid and primary intracerebral haemorrhage, corticosteroids have also been commonly used. In 2005, a Cochrane Review concluded that there was no evidence to support the use of mineralocorticoids or glucocorticoids in subarachnoid haemorrhage or to support the use of glucocorticoids in primary intracerebral haemorrhage. Corticosteroid use may also be associated with adverse events.<sup>48</sup>

In acute spinal cord injury, high-dose methylprednisolone for 24 hours has been shown to offer a small but significant benefit, provided treatment begins within 8 hours of injury (National Spinal Cord Injury Study (NASCIS) II trial).<sup>49,50</sup> This is still controversial. Adverse side-effects such as sepsis and poor wound healing were associated with the use of methylprednisolone, although some of these side-effects did not reach statistical significance. Currently steroid therapy in spinal cord injury is an unproven standard of care.<sup>51</sup>

### EXPERIMENTAL THERAPY – THE FUTURE

There are a range of laboratory studies which have identified numerous potential therapeutic interventions for the treatment of head injury and stroke, some of which have progressed to clinical trials:

- Glutamate receptor antagonists. Dizocilpine (MK-801) is a non-competitive glutamate antagonist acting

at the NMDA receptor. No clinical trials have been performed because of fears regarding hippocampal neurotoxicity.

- Free radical scavengers. In high concentrations free radicals react with almost all cellular structures and ultimately cause cell damage and cell death. Free radical scavengers attempt to attenuate this effect by a direct antioxidant effect or by providing a free radical degradation enzyme. Polyethylene glycol-conjugated superoxide dismutase (PEG-SOD) converts these harmful molecules into harmless metabolites. Neither mechanism has yet had clinically useful results.<sup>43</sup>
- Cyclosporin A may protect against traumatically induced mitochondrial damage by blocking mitochondrial permeability pores and preventing influx and efflux of harmful ions and free radicals. It is neuroprotective in animal models and phase II studies are currently ongoing.

In stroke, several classes of cerebral protective agents have been investigated in phase II and III trials.

- Gavestinel, an antagonist of the glycine site of the NMDA receptor, was administered in acute ischaemic or haemorrhagic stroke (Glycine Antagonist In Neuroprotection: GAIN) with no improvement in functional outcome.<sup>52</sup>
- Magnesium acts as an endogenous vasodilator of brain circulation and is a non-competitive antagonist of NMDA receptors and of the voltage-dependent calcium channels. The phase III trial (Intravenous Magnesium Efficacy in Acute Stroke: IMAGES) found no benefit in administration of magnesium within 12 hours of stroke.<sup>53</sup> An ongoing trial is evaluating whether giving magnesium within 2 hours of stroke is beneficial (Field Administration of Stroke Therapy–Magnesium: FAST-MAG).<sup>54</sup>
- Topiramate is a gamma-aminobutyric acid (GABA) agonist and an anticonvulsant that stabilises the cell membrane through increased chloride conductivity and might be useful in traumatic brain injury. As a GABA agonist, it acts as a stabiliser by hyperpolarising the cell membrane.<sup>43</sup> Clomethiazole is another GABA agonist.<sup>55</sup>
- A sodium channel and nitric oxide blocker (lubeluzole) is also being trialled.<sup>56</sup> Lubeluzole inhibits glutamate release in the penumbra area and decreases postischaemic excitotoxicity.
- Albumin, 25%, at 1.25–2.5 g/kg reduces infarct volume and brain swelling in rats. It has been suggested that the protective effect is not just due to haemodilution but rather to the multiple actions of the albumin molecule in binding to free fatty acids, inhibiting oxygen free radical production and supporting endothelial function.<sup>57</sup>

Intracerebral haemorrhage is the least treatable form of stroke and is associated with a high morbidity and mortality. Recombinant activated factor VIIa (rFVIIa)

administered within 4 hours of onset and within 1 hour of a diagnostic CT scan has been shown in one trial to limit haematoma growth, reduce mortality and improve 90-day functional outcome. There was, however, a small increase in the frequency of thromboembolic events.<sup>58</sup>

Thrombolysis within the first few hours has been effective following ischaemic stroke. The search continues for safe neuroprotective strategies to use in ischaemic stroke which can be used alone or in combination with thrombolysis.

To date the completed trials have yielded disappointing efficacy results and some have shown safety problems. Despite this, it is believed that, with the increased understanding of the mechanism of cell death and new targets for drug treatment, it is only a matter of time before an effective cerebral protective agent will become available.

# Brain death

Marcus Peck and Martin Smith

Most people die a ‘conventional’ death when their heart stops beating. In others the advent of intensive organ support has complicated the diagnosis of death. Patients who have sustained irreversible structural brain damage as a result of head injury, subarachnoid haemorrhage, stroke or cerebral anoxia lie in a deep coma without the capacity to breathe. Prompt medical attention may have taken over ventilation, but recovery is impossible. It therefore became necessary to reappraise death based on the integrity of the central nervous system.<sup>1–3</sup> Brain death describes a state of irreversible loss of brain function, including loss of brainstem function. The ability to certify death under such circumstances allows intensivists to withdraw treatment on ethical, humanitarian and utilitarian grounds. Relatives are relieved of unnecessary prolonged anxiety and false hopes, and the burden on expensive medical resources is reduced. A further benefit for society is the availability of organs for transplantation from heart-beating donors.

## DEFINITION OF DEATH

Three distinct mechanisms of death are recognised – cardiac arrest, respiratory arrest and brain death. This distinction is artificial. Cardiorespiratory arrest only results in inevitable death if the period of arrest has been long enough to result in irreversible damage to the brainstem due to lack of perfusion with oxygenated blood. Shorter periods of cardiac or respiratory arrest may result in survival with differing degrees of brain damage. As the neurones of the brainstem are the most resistant to anoxia, patients may retain the ability to breathe but survive with severe, irreversible cortical damage (the persistent vegetative state: PVS). The key feature of both cardiorespiratory death and brainstem death is irreparable brain damage. Death of the brainstem, whether caused by intracranial events or extracranial phenomena such as hypoxia, represents death of a person as a whole.

Dying is a process but death is an event that can be defined in a number of ways. In the UK there is no statutory definition of death, but English law has adopted widely accepted criteria and considers death to be the ‘the irreversible loss of the capacity for consciousness, combined with the irreversible loss of the capacity to breathe’. In Australia,

for the purpose of organ harvest, the statutory definition is ‘irreversible cessation of all brain function’.

Brain death results from massive swelling of the traumatised brain, a sustained rise in intracranial pressure equal to or above systemic arterial pressure causing cessation of cerebral circulation, and brainstem herniation. The principal causes in adults are traumatic brain injury (50%), subarachnoid haemorrhage (30%) and severe hypoxic–ischaemic injury (20%). Complete and irreversible loss of brainstem function may also be seen in isolated brainstem injury without the typical features of herniation (e.g. brainstem infarction), which may or may not be accompanied by complete loss of hemispheric function.

## PERSISTENT VEGETATIVE STATE

Severe brain damage is distinct from brain death. Comatose patients with severe brain damage may recover, albeit with varying degrees of disability, or remain in persistent coma. PVS is an irreversible condition in patients who have lost cortical activity. Coma has progressed to a state of wakefulness without detectable awareness and the patient is able to breathe spontaneously. PVS is therefore compatible with life if supportive care is provided. This is in contrast to brain death, where there is irreversible loss of the capacity to breathe and independent survival is impossible. PVS is not recognised as death in any jurisdiction and, in most, withdrawal of support to patients with PVS requires legal authority.

## ROLE OF THE BRAINSTEM

There is sometimes a lack of clarity between brain death and brainstem death and this reflects differing diagnostic practices.<sup>4</sup> In the USA the Uniform Determination of Death Act describes brain death as death of the *whole* brain and states: ‘an individual who has sustained irreversible cessation of all functions of the entire brain, including the brainstem, is dead’.<sup>5</sup> This formulation is one of the most commonly applied worldwide and forms the basis of the legal status in many countries. A notable exception exists in the UK, where a brainstem-based definition of death is in place.<sup>2</sup>

The brainstem contains the cranial nerve nuclei and respiratory and cardiovascular control centres. It is also the conduit for all ascending and descending pathways that connect the cortex with the rest of the body and is an essential part of the reticulo-activating system (RAS). Awareness depends on the integrity of the RAS. The mechanism of loss of consciousness in brainstem death is related to disruption of the RAS. After onset of brainstem death, brainstem reflexes are lost sequentially in a craniocaudal direction. This process may take several hours to become complete but finally results in apnoea due to failure of the medulla oblongata. Because of the fundamental controlling role of the brainstem, myocardial and other systemic physiological functions deteriorate after the onset of brainstem death.<sup>6</sup> Without cardiovascular support most patients confirmed as brain-dead progress to asystolic cardiac arrest within 24–48 hours.

### ESTABLISHMENT OF BRAIN DEATH CRITERIA

Brain death was first described in 1959 by Mollaret and Goulon,<sup>7</sup> two French physicians, who coined the phrase ‘coma dépassé’ (meaning literally a state beyond coma) to describe 23 unconscious apnoeic patients who had lost brainstem reflexes.

In 1968 an ad hoc committee of the Harvard Medical School defined irreversible coma, or brain death, as unresponsiveness and lack of receptivity, the absence of movement and breathing, the absence of brainstem reflexes and coma whose cause has been identified (the Harvard criteria).<sup>1</sup> In the following year the committee indicated that brain death could be diagnosed on clinical grounds alone. This was affirmed in 1971 by two neurosurgeons (Mohandas and Chou) who described irreversible loss of brainstem function as the ‘point of no return’ (the Minnesota criteria).<sup>8</sup> At this time it was reiterated that brain death could be diagnosed on clinical judgement alone, without the need for a confirmatory electroencephalogram (EEG), so long as certain aetiological preconditions were present.

In 1976 a memorandum from the Conference of Medical Colleges and their Faculties in the UK stated that ‘permanent functional death of the brainstem constitutes brain death’ and that this could be diagnosed clinically in the context of irremediable structural brain damage after certain specified conditions had been excluded.<sup>2</sup> The memorandum established a set of guidelines and clinical tests for the diagnosis of brainstem death that became the foundation of practice worldwide. A subsequent memorandum in 1979 concluded that the identification of brain death means that the patient is dead, whether or not the function of some organs, such as the heart beat, is still maintained by artificial means. A further memorandum in 1983 made additional recommendations about the timing of the clinical tests and who

should perform them. It also confirmed that there may be circumstances in which it is impossible or inappropriate to carry out every one of the tests and it is for the doctor at the bedside to decide when the patient is dead.

Simultaneously to the guidance being issued in the UK, other countries were formalising practice. In the USA, the 1981 Report to the President’s Commission confirmed the requirement for the irreversible cessation of brain and brainstem functions to diagnose death.<sup>5</sup> Because death of the whole brain is diagnosed in the USA, this report recommended that confirmatory tests be used to support the clinical diagnosis and reduce the required time of observation.

### CRITERIA FOR THE DIAGNOSIS OF BRAIN DEATH

Common to the determination of brain death in the UK and USA is the confirmation of the absence of clinical function of the brainstem, i.e. loss of consciousness, unresponsiveness, coma and loss of brainstem reflexes, including the capacity to breathe. The UK criteria form the basis of the clinical diagnosis of brain death in other countries and will be used as an exemplar of clinical testing. The diagnostic algorithm has three sequential but interdependent steps. Certain preconditions and exclusions must be fulfilled before clinical tests of brainstem function are performed.<sup>9</sup>

### PRECONDITIONS

- The patient should be in apnoeic coma, i.e. unresponsive and dependent on mechanical ventilation.
- The patient’s condition must be due to structural brain damage that is consistent with the diagnosis of brainstem death.
- The underlying disorder that has led to this state must be established.

In all cases a cranial computed tomography (CT) scan and full neurological examination are essential. Establishing the causative diagnosis is relatively straightforward in the case of head injury or intracranial haemorrhage but may take longer in coma arising from hypoxia or other causes.

### EXCLUSIONS

Reversible causes of coma must be excluded. These include:

- *Alcohol intoxication or drug overdose.* Drug history must be reviewed and, in case of any doubt, a toxicology screen obtained.
- *The effects of therapeutic depressant drugs.* Narcotics, hypnotics and tranquillisers are likely to have been administered in the period leading up to brain death. These can have lengthy and unpredictable elimination

times, particularly in critically ill patients. The drug's type, dose, pharmacokinetics, half-life and the presence of organ dysfunction are all factors that contribute to duration of effect. Adequate time must be allowed for the residual sedative effects of these drugs to be excluded and, in the absence of organ dysfunction, a period of 3–4 times the half-life of the drug is recommended. Most commonly used drugs are cleared within 10–12 hours. Measurement of plasma concentration of active drug or metabolite will indicate whether drug levels are below the usual therapeutic range. However, plasma concentration does not always correlate with therapeutic effect in critically ill brain-injured patients. The use of specific pharmacological antagonists may be used in certain circumstances.

- *Residual action of neuromuscular-blocking agents.* This must be excluded by confirmation of the absence of deep tendon reflexes or lack of response to peripheral nerve stimulation.
- *Hypothermia.* Extreme hypothermia (< 28°C) invariably results in depressed brainstem reflexes but higher temperatures (32–34°C) can also have effects on conscious level. Core temperature should be > 35°C prior to testing brainstem reflexes.
- *Metabolic and endocrine disturbances.* There must be no profound abnormality of serum urea and electrolytes, acid–base status or blood glucose.
  - Serum sodium values < 115 mmol/l and > 160 mmol/l should be corrected prior to testing brainstem reflexes. Diabetes insipidus (DI) is a regular sequela of brain death and significant hypernatraemia is common. The 1998 UK Code of Practice allows differentiation between abnormalities which arise as a consequence of brainstem failure (e.g. hypernatraemia due to DI) from causative abnormalities of endocrine or biochemical function.<sup>9</sup>
  - Blood glucose should be between 2 and 20 mmol/l.
  - Potassium must be greater than 2 mmol/l to avoid effects on neuromuscular function.
  - Coexistent endocrine disorders must be excluded or treated before testing brainstem reflexes.
- *Neurological conditions that can mimic brainstem death.* These should be excluded by careful clinical examination (see below).

## CLINICAL TESTS

These demonstrate the absence of brainstem reflexes and confirm the presence of persistent apnoea. They should be performed only when the preconditions and exclusions have been met. Confirmation of absence of the oculoccephalic reflex ('doll's-eye' movements) is not part of the UK criteria. However, the presence of this reflex confirms that brainstem function persists and that further tests are inappropriate. Examination for 'doll's-eye' movement is a part of protocols in other countries. Facial trauma or

obstruction to external ear canals may make assessment of brainstem reflexes difficult, but injury preventing bilateral examination does not invalidate the diagnosis.

## CRANIAL NERVE EXAMINATION

The following signs of brainstem areflexia must be present to confirm the diagnosis of brainstem death:<sup>3,9</sup>

- Both pupils should be fixed in diameter and unresponsive to bright light. Pupil size is irrelevant but usually dilated – tests optic (II) and oculomotor (III) nerves.
- Corneal reflexes are absent during firm pressure over the cornea with a gauze swab – tests trigeminal sensory (V) and facial (VII) nerves.
- A standardised painful stimulus in the three areas of trigeminal nerve distribution (e.g. supraorbital pressure or jaw thrust) should not elicit a motor response in cranial or somatic distributions. Peripheral stimulation such as nailbed pressure should also not result in facial grimacing, although somatic spinal reflexes may persist – tests trigeminal (V) and facial (VII) nerves.
- There should be no gag or cough reflex in response to pharyngeal, laryngeal or tracheal stimulation – tests glossopharyngeal (IX) and vagus (X) nerves.
- The occulovestibular reflexes (caloric response) must be absent. Ice-cold water (50 ml) is injected slowly into each auditory meatus over 1 minute with the head flexed at 30°. There is absence of tonic deviation of the eyes towards the side being tested. Clear access to each tympanic membrane must first be confirmed by visual access – tests oculomotor (III), abducens (VI) and vestibulocochlear (VIII) nerves.

## APNOEA TEST

The apnoea test confirms the absence of spontaneous respiratory effort despite  $P_{aCO_2}$  at a level above the threshold for stimulation of respiration (usually 6.5 kPa). Severe hypoxaemia, excessive hypercarbia and changes in arterial blood pressure can occur if the apnoea test is not carried out correctly. To minimise the risk of further damage to potentially recoverable brain tissue, the apnoea test should not be performed if any of the preceding tests confirm the presence of brainstem reflexes. The following method describes a safe method for conduct of the apnoea test. The patient should be preoxygenated with 100% for 10 minutes. Arterial blood gases (ABGs) are checked to ensure correlation with end-tidal  $CO_2$  ( $EtCO_2$ ) and oxygen saturation ( $SaO_2$ ). When  $SaO_2$  is above 95%, minute ventilation is reduced until  $EtCO_2$  rises to 6.5 kPa. ABGs are then checked to ensure that  $P_{aCO_2}$  is also > 6.5 kPa and  $pH < 7.35$ . In patients with  $CO_2$  retention the  $P_{aCO_2}$  may need to be higher to achieve the target pH. If blood pressure is stable, this state should be maintained for 10 minutes, after which the patient is disconnected from the ventilator. Oxygenation is maintained by endotracheal insufflation of oxygen at 5 l/min via a suction catheter. Prior recruitment manoeuvres and continuous positive airway

pressure may be necessary if maintenance of oxygenation is difficult. The patient should be observed for spontaneous ventilatory effort during the following 5 minutes. If there is no respiratory effort, absence of respiratory centre activity is confirmed and documented after repeat ABG analysis demonstrates that  $P_{aCO_2}$  remains  $> 6.5$  kPa. After testing, normal minute ventilation should be restored to return ABGs to pretesting values.

### OTHER ISSUES DURING CLINICAL TESTING

In some jurisdictions, including the UK, Australia and some states in the USA, two medical practitioners are required to confirm the diagnosis of brain death.<sup>10</sup> The base speciality is not important but each doctor must be competent in carrying out such an assessment. It is often recommended that the apnoea test be supervised by an anaesthetist or intensivist. The doctors should be senior and not involved in organ transplantation programmes. Although the two doctors may carry out the tests together or independently, two sets of tests are recommended to demonstrate irreversibility. The interval between the two sets of tests is not proscribed for adults in the UK but other jurisdictions set minimum time limits between the tests.<sup>10</sup> Although death is confirmed by the second set of brainstem tests in the UK, the legal time for certification of death is that of the initial testing. In other countries, such as Australia, the time of death for certification purposes is the time after the second confirmatory examination.

The confidence in application of clinical criteria for the diagnosis of brainstem death comes from over 30 years of experience. There is no report in the world literature of response during the second tests in a patient who has satisfied the clinical criteria for brain death during the first tests. Furthermore, there has been no subsequent recovery in those in whom ventilation was not discontinued.

Despite robust guidelines for the diagnosis of brainstem death, interpretation of this guidance varies widely.<sup>11</sup> In a study examining compliance with guidelines in the UK, marked differences in the timing of testing, the exclusion of residual sedative agents, the management of deranged biochemistry and the conduct of the caloric and apnoea test were noted.<sup>12</sup>

### SUPPLEMENTARY DIAGNOSTIC TECHNIQUES

Clinical tests are the gold standard for assessment of brainstem function and supplementary tests are not required in the UK, Australia or New Zealand. They are required by law in some European countries where the diagnosis of whole brain death is made.<sup>13</sup> They are optional in the USA, but recommended if special circumstances limit clinical assessment or render it unreliable.

Supplementary investigations do not test brainstem function but are surrogate markers of cortical function. Many have been validated against clinical diagnosis and

**Table 46.1** Indications for confirmatory tests to diagnose brain death

- No clear cause for coma exists
- Possible drug or metabolic effect on coma that cannot be excluded
- Cranial nerves cannot be adequately tested bilaterally
- Cervical cord injury is present or suspected
- Cardiorespiratory instability that precludes testing for apnoea

are not 100% specific or sensitive. They are therefore usually recommended as confirmatory rather than absolute tests.<sup>14,15</sup> Ancillary tests are of assistance if brainstem function cannot be adequately assessed clinically (Table 46.1). They are also required in very young children.

### ASSESSMENT OF BLOOD FLOW IN THE LARGER CEREBRAL ARTERIES

Investigations of cerebral blood flow are independent of confounding variables such as sedation, metabolic disturbance or hypothermia. However, the presence of residual cerebral blood flow does not preclude a diagnosis of brain death. These techniques may therefore produce false-negative results and this is particularly likely in the presence of decompressive craniectomy, skull fracture or cerebrospinal fluid drains.

- *Four-vessel cerebral angiography*: injection of contrast into both vertebral and carotid arteries confirms no filling of the intracerebral vessels. Absence of flow beyond the foramen magnum will be observed in the posterior circulation and no flow beyond the petrosal portion of the carotid artery in the anterior circulation. Isolated or minimal filling necessitates repeat examination. Cerebral angiography is invasive, time-consuming and readily available only in the radiology suites of neuroscience units. However, it is reliable and easy to interpret and the gold-standard confirmatory test for brain death in some jurisdictions.
- *Magnetic resonance or CT angiography*: this is non-invasive but has similar logistical problems to formal angiography.
- *Transcranial Doppler ultrasonography (TCD)*: TCD is a non-invasive, bedside investigation that is being increasingly used as a confirmatory test during diagnosis of brain death. Blood flow through both middle cerebral and vertebral arteries is compared with that through extracranial vessels. Absence of signal may be artefactual and should not be taken as diagnostic. Typical findings after brain death include diastolic reverberating flow and little or no forward systolic flow. TCD has 91–99% sensitivity with 100% specificity in skilled hands. However the technique has significant operator dependence and previous surgery or the presence of a ventricular drain may make waveform interpretation difficult.

**ASSESSMENT OF BRAIN TISSUE PERFUSION**

- *Contrast-enhanced CT cerebral perfusion*: These techniques are becoming more widely available and their use to confirm brain death is likely to increase.
- *Single-photon emission computed tomography*: This technique is sensitive and specific, although interpretation can be difficult.
- *Positron emission tomography (PET)*: PET is accurate and unambiguous but access to this technique is limited to a few centres.
- *Nuclear imaging*: brain images obtained sequentially up to 2 hours after injection of radionuclide confirm the absence of intracerebral uptake.

**ASSESSMENT OF NEUROPHYSIOLOGICAL FUNCTION**

- *EEG*: EEG is a widely used confirmatory test. However, specialist expertise is required for interpretation. Absence of cortical electrical activity is demonstrated by recordings from 16 or 18 channels for over 30 minutes using high sensitivity. Artefacts from the intensive care unit (ICU) environment are common because of the high levels of sensitivity required. A silent EEG in the absence of metabolic or drug effects suggests cortical death but cannot confirm or exclude brainstem activity. Equally, electrical activity in some cortical cells does not mean that the brain as a whole is alive. Confirmatory EEG is mandatory in many European countries. In the USA the choice of supportive test is at the discretion of the attending physician, but confirmatory EEG is strongly recommended because loss of whole-brain function must be demonstrated.
- *Somatosensory evoked potentials (SSEPs) and brainstem auditory evoked potentials (BAEPs)*: SSEPs and BAEPs demonstrate successive loss of function of various afferent pathways of the brainstem. Multimodality evoked potentials are non-invasive, relatively unaffected by sedative agents and increasingly used as a confirmatory test.

**DIAGNOSING BRAIN DEATH IN SPECIAL CIRCUMSTANCES****HIGH CERVICAL CORD INJURY**

Confirmation of apnoea is fundamental to the clinical diagnosis of brain death. The possibility that apnoea may be related to high cervical cord injury may bring some difficulty to the diagnosis.<sup>16</sup> It is important to quantify the degree of any spinal cord injury clinically, structurally and functionally by meticulous clinical examination, magnetic resonance imaging and electrophysiological tests, including SSEPs and motor evoked potentials. Confirmatory tests may also assist the clinician in being confident that the patient is brain-dead.

**NEUROLOGICAL CONDITIONS**

Some rare neurological conditions may mimic brain death.<sup>3</sup> In the 'locked-in syndrome' the patient is tetraplegic but conscious, with preservation of conjugate vertical

gaze and the ability to blink. Cranial nerve involvement and respiratory paralysis are associated with Guillain-Barré syndrome and may lead to diagnostic confusion<sup>17</sup> but pupil dilatation in this condition is rare. Brainstem reflexes may also be absent in brainstem encephalitis but the patient is usually drowsy rather than comatose. The preconditions for diagnosis of brain death are not met in these neurological conditions. Meticulous application of the clinical criteria and careful clinical examination will ensure that these neurological conditions cannot be mistaken for brain death.

**BARBITURATES**

There has been resurgence in the use of barbiturates to treat intractable intracranial hypertension and some patients will progress to brain death. The usual exclusion criteria apply but previous barbiturate infusion brings particular problems to the diagnosis of brain death because of its long and unpredictable action. Plasma barbiturate levels may not reflect clinical effect, particularly in the context of brain injury, and there is no consensus regarding an acceptable minimal plasma concentration.<sup>18</sup> Access to the assay may also be restricted and there is often a delay in obtaining the results. Another option is to wait an arbitrary period of time to allow the barbiturate effects to wear off: a period of between 2 and 5 days has been recommended. However, this 'best-guess' approach represents an inefficient use of ICU resource and represents additional pressures for relatives because of delays. The effects of high-dose barbiturates can mimic brain death, particularly in the presence of hypothermia. However, except in children, this is exceptionally rare and some aspect of brainstem function, such as the pupil response to light, often remains intact. In the presence of other stigmata of brain death, such as dilated unreactive pupils, characteristic cardiovascular changes and DI, the diagnosis is rarely in doubt. Confirmatory tests, particular cerebral angiography or BAEPs, may also be of assistance.

**CHILDREN**

Special care is recommended in diagnosing brain death in children less than 5 years of age.<sup>19</sup> The general criteria are the same as for adults but the period of observation should be longer and confirmatory investigations, such as EEG or cerebral angiography, are often conducted. A higher  $P_{aCO_2}$  target is also recommended during the apnoea test.<sup>20</sup>

- *Less than 37 weeks' gestation*: apnoea and coma are common in this age group and the development of brainstem reflexes is uncertain. In the UK it has been suggested that the concept of brain death is inappropriate in this age group and decisions to withdraw intensive support should be made on the basis of futility.<sup>21</sup>
- *37 weeks to 2 months*: coma in this age group may occur for a wide variety of reasons, but hypoxic-ischaemic encephalopathy, sustained in utero or at the time of birth, is common. Making a diagnosis of brain death at this age can be difficult. Because associated severe multisystem failure is common at such a young age, it

may not be appropriate or necessary to confirm brain death if care can be withdrawn on the grounds of futility. In the USA two sets of clinical tests are conducted 48 hours apart in the presence of an isoelectric EEG.

- *Children older than 2 months:* in the UK and USA the clinical criteria for assessing brainstem death in adults are applicable to this age group. However, the clinical tests should always be carried out by two senior doctors, one of whom should be a paediatrician and one not primarily involved with the child's care.

### INTERNATIONAL DIFFERENCES IN BRAIN DEATH CRITERIA

Whilst the fundamentals of the guidance for the diagnosis of brain death are common worldwide, specific criteria and requirements are often inconsistent.<sup>4</sup> The guidelines for the diagnosis of brain death in 80 countries encompassing a broad diversity of culture and religious belief were reviewed in 2002.<sup>10</sup> Only 88% had national guidelines and those that did showed considerable variation. Criteria for the clinical testing of brainstem areflexia were identical in all national guidelines but there were marked differences in other areas of practice (Table 46.2).

**Table 46.2** International differences in the diagnosis of brain death in 80 countries

	National practice	No. of countries
National guidelines in place		70
Confirmation of brainstem areflexia by clinical testing		70
Apnoea testing	With $P_{aCO_2}$ target	41
	Without $P_{aCO_2}$ target	20
	Not required	19
Confirmatory tests	Not required or optional	52
	Mandatory	28
Number of physicians required to make clinical diagnosis	1	31
	2	24
	> 2	11
	Unspecified	14
Minimum observation time prior to testing (hours)	2	4
	3	2
	6	20
	12	8
	24	8
	Unspecified	38

(Modified from Wijdicks E. Brain death worldwide – accepted fact but no global consensus in diagnostic criteria. *Neurology* 2002; **58**: 20–5.)

### SUMMARY

The care of the injured brain has advanced since the clinical criteria for the diagnosis of brain death were first established. Lack of worldwide agreement on how to diagnose brain death and brainstem death remains a problem. There is an urgent need for international consensus for the diagnosis of brain death. This should retain clinical tests as fundamental but include confirmatory investigations when appropriate. Flexibility should be maintained and, as in other areas of medicine, the clinical findings should be interpreted with common sense by an experienced and humane physician.<sup>22</sup>

# Meningitis and encephalomyelitis

Angus M Kennedy

Infections of the cranial contents can be divided into those which affect the meninges (meningitis) and those which affect the brain parenchyma (encephalitis). Chronic, insidious or rare infections are beyond the scope of this chapter, which will focus on acute bacterial and viral causes of meningitis and encephalomyelitis.

- *Meningitis*: defined as infection or inflammation of the meninges and subarachnoid space. The infection can be caused by viruses, bacteria, fungi or protozoa. Meningeal inflammation may be caused by subarachnoid haemorrhage or vaccination or be a manifestation of other multiorgan diseases, such as systemic lupus erythematosus, sarcoidosis, lymphoma or meningeal micrometastases from a disseminated carcinoma.
- *Aseptic meningitis*: aseptic meningitis is a generic term for cases of meningitis in which bacteria cannot be isolated from the cerebrospinal fluid (CSF). The differential diagnosis in this situation includes: (1) viral meningitis; (2) partially treated bacterial meningitis; (3) tuberculous meningitis; (4) fungal meningitis; (5) lymphoma; (6) sarcoidosis; and (7) other collagen vascular diseases. The most common causes of aseptic meningitis are due to viral infection most often due to an enterovirus or coxsackie infection.
- *Encephalitis*: encephalitis is an infection of the brain parenchyma. The patient may have a history of preceding seizures together with cognitive or behavioural symptoms.
- *Tuberculous meningitis*: this causes a subacute lymphocytic meningitis. Patients may have a non-specific prodromal phase, including symptoms such as headache, vomiting and fever.
- *Subdural empyema*: subdural empyema is a suppurative process in the space between the pia and dura mater.
- *Brain abscess*: brain abscess is a collection of pus within the brain tissue.

## BACTERIAL MENINGITIS

### GENERAL POINTS

Bacterial meningitis is an inflammatory response due to infection of the leptomeninges and subarachnoid space.

This is characterised by the clinical syndrome of fever, headache, neck stiffness and CSF pleocytosis. Despite the existence of antibiotic therapy, patients continue to suffer significant morbidity and mortality.

The bacterial organisms are usually not confined to the brain and meninges and frequently cause systemic illness, for example, severe sepsis, shock, acute respiratory distress syndrome, and bleeding disorders such as disseminated intravascular coagulation.<sup>1,2</sup>

A variety of other pathogens cause meningeal inflammation, resulting in very similar clinical presentations. Bacterial infections must be treated urgently and appropriately to limit ongoing central nervous system (CNS) damage. It is also important to treat the complications of meningitis such as seizures and raised intracranial pressure (ICP).

Where possible, spinal fluid examination following a lumbar puncture is required in order to confirm the diagnosis and establish the pathogenic organism responsible. A CSF examination may be contraindicated if there are signs of raised ICP, including:

- papilloedema
- focal neurological signs
- seizures

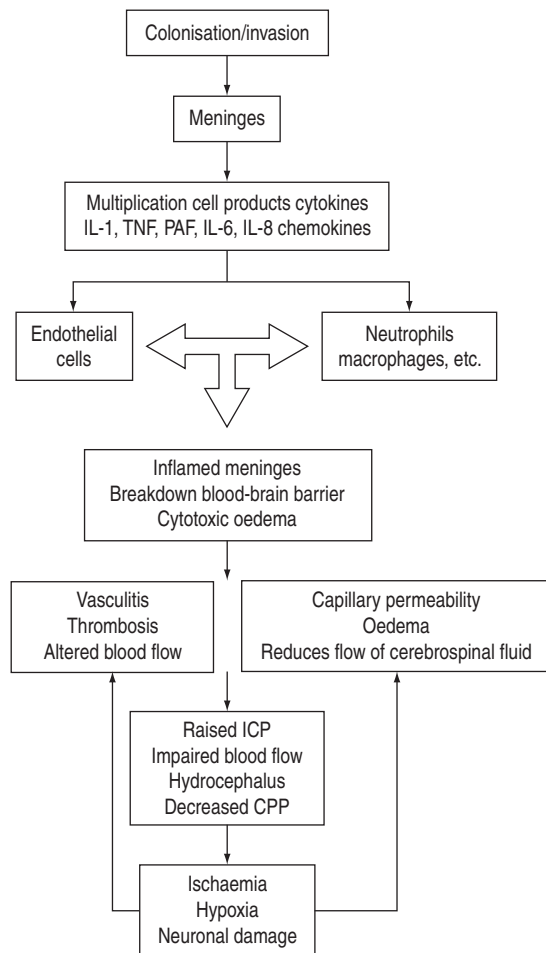

These features raise the possibility of an undiagnosed cerebral mass lesion which, in turn, could cause cerebral herniation if lumbar puncture is performed. A computed tomography (CT) brain scan is required prior to CSF examination in order to explore this possibility and lessen but not obviate the risk of cerebral herniation. Even if the CT brain scan is normal, ICP may still be raised. The importance of performing a safe CSF examination must be balanced against the need to commence immediate treatment in each individual patient.<sup>3,4</sup>

## AETIOLOGY

The main causes of meningitis are spread by droplet infection or exchange of saliva. Meningitis may occur when pathogenic organisms colonise the nasopharynx and reach the blood–brain barrier. Meningitis can occur as a result of infection in the middle ear, sinus or teeth,

leading to secondary meningeal infection. Most bacteria obtain entry into the CNS via the haematogenous route. As the organisms multiply, they release cell wall products and lipopolysaccharide, and generate a local inflammatory reaction which in itself also releases inflammatory mediators. The net result of the release of cytokines, tumour necrosis factor and other factors is associated with a significant inflammatory response. Vasculitis of CNS vessels, thrombosis, cell damage and exudative material all contribute to vasogenic and cytotoxic oedema, altered blood flow and cerebral perfusion pressure. Later on infarction and raised ICP occur.<sup>5</sup>

The inflammatory events seen with infection are summarised in Figure 47.1.

**Figure 47.1** Cascade of events in meningitis. IL-1, interleukin-1; TNF, tumour necrosis factor; PAF, platelet-activating factor; ICP, intracranial pressure; CPP, cerebral perfusion pressure.

## ORGANISMS

Acute bacterial meningitis can be caused by many species of bacteria, although three organisms are commonly reported:

1. *Haemophilus influenzae*
2. *Streptococcus pneumoniae*
3. *Neisseria meningitidis* (which accounts for 70% of cases in the neonatal period)

Until the advent of the meningitis vaccination programme, *H. influenzae* type B was the most common cause of bacterial meningitis. Recently *S. pneumoniae* and *N. meningitidis* have been considered the main causes, although one study suggested that *Listeria monocytogenes* is the second most common isolate in adult population. The occurrence of pneumococcal strains which are resistant to penicillin has also influenced the epidemiology of meningitis.<sup>6</sup>

## NOSOCOMIAL INFECTIONS

Common systemic nosocomial pathogens such as *Escherichia coli*, *Pseudomonas* spp., *Klebsiella* and *Acinetobacter* spp. account for a high percentage of nosocomial infections of the meninges.

## IMMUNOCOMPROMISED HOSTS

In the immunocompromised patient with meningitis (e.g. human immunodeficiency virus: HIV), fungal viral and cryptococcal meningitis should be considered.<sup>7</sup>

## NEUROSURGERY AND TRAUMA

Infections following skull trauma are frequently caused by *Staphylococcus aureus* and *S. epidermidis*, which should be considered in those with shunts or other intracranial devices.

## CLINICAL PRESENTATION

The history may reveal evidence of trauma or infection. Meningitis usually presents with an acute onset of:

- fever
- headache
- neck stiffness
- photophobia
- altered conscious level
- irritability
- seizures (paediatric)

However, in the immunocompromised, elderly or infant patient, non-specific features such as a low-grade fever or mild behavioural change may be all that is apparent. Many of the classic symptoms are late manifestations of meningitis: preceding trivial early symptoms such as leg pain or cold hands may not immediately suggest the more serious underlying diagnosis.

It is important to identify from the history reported about preceding trauma, upper respiratory tract infection or ear infection. Symptoms may develop over hours or days. Specific infections relate partly to an individual's age.

Neurological signs can be present with meningitis but signs such as nuchal rigidity, or a positive Kernig's sign (pain and hamstring spasm resulting from attempts to straighten, the leg with the hip flexed) are not universally found. A number of recent studies have shown that the classic signs were present in less than 50% of cases. Systemic signs may occur most often in meningococcal disease, where a haemorrhagic, petechial or purpuric rash may be observed. Digital gangrene or skin necrosis may occur. Some patients are severely septic, with acute respiratory distress syndrome and disseminated intravascular coagulation.

Approximately 25% of patients have a seizure during the course of the illness. Differential diagnosis may include subarachnoid haemorrhage, migraine, encephalitis and tumour.

### INVESTIGATIONS

The patient with suspected bacterial meningitis requires immediate blood cultures and should be given empirical intravenous (IV) antibiotics if there is likely to be any delay in further assessment (Table 47.1).

### CEREBROSPINAL FLUID FINDINGS

A CSF examination is a vitally important investigation which may definitively confirm the diagnosis of bacterial meningitis. In this regard its value should not be dismissed. Concern about the risks of coning following lumbar puncture should be considered in the context of patients' symptoms where the presence of seizures, focal neurological signs and papilloedema may suggest raised ICP. Neuroimaging may provide some level of reassurance that it is safe to proceed with a lumbar puncture; however, the clinician should be aware that all factors need to be taken into consideration.

Bacterial meningitis is suggested when there is:

- polymorph leukocytosis
- low CSF glucose relative to the plasma value
- raised CSF protein concentration

An urgent Gram stain and microbiological culture are mandatory. The Gram stain is usually positive in approximately 50–60% of cases. A CSF examination shortly after empirical antibiotics does not necessarily decrease the diagnostic sensitivity of CSF culture. Polymerase chain reaction (PCR) techniques can be used to detect different organisms. A throat swab should be routinely taken. The clinical decision-making process that determines whether somebody does or does not have bacterial meningitis cannot be modelled easily and depends on multiple factors including clinical, laboratory findings and observation of the patient over time.

Blood cultures comprise an important investigation in patients with meningitis, as spread is haematogenous, and a number of sets of cultures should be sent. It is advisable to check routinely a full blood count clotting profile (to exclude disseminated intravascular coagulation) and biochemistry, including blood glucose level. A chest X-ray and blood gases should be performed to identify systemic involvement. Obviously, relevant areas such as infected sinuses or ears should be examined if there is an indication that they are implicated.

### MANAGEMENT

Antibiotics should be started as early as possible and broad-spectrum coverage is recommended until bacterial identification is made (Table 47.2). The selection of antibiotics is influenced by the clinical situation in conjunction with known allergies or local patterns of antibiotic resistance and the CSF findings. Delays in administering antibiotics are a significant risk factor for a poor prognosis. In the absence of a known organism, empirical choice for antibiotics has been complicated by the development of resistant strains. Penicillin G, ampicillin and third-generation cephalosporins are typical first-line agents. Until recently, ampicillin was appropriate for pneumococcal, meningococcal and *Listeria* infections. The emergence of resistant strains influences local antibiotic practice. If there is a history of recent head injury, a broad-spectrum cephalosporin may be indicated with vancomycin. Discussions with local

**Table 47.1** Cerebrospinal fluid changes in meningitis

	Normal	Bacterial	Viral
Appearance	Clear	Turbid/purulent	Clear/turbid
White cell count	< 5 per mm <sup>3</sup> mononuclear	200–10 000 per mm <sup>3</sup> predominantly polymorphonuclear	< 500 per mm <sup>3</sup> mainly lymphocytes
Protein	0.2–0.4 g/l	0.5–2.0 g/l	0.4–0.8 g/l
Glucose	Blood glucose	≤ Blood glucose	Blood glucose pressure is usually raised

Table 47.2 Empiric antibiotics for meningitis

Indication	Antibiotic	Dose
<50 years	Ceftriaxone or cefotaxime	2–4 g q 24 h 2 g q 4 h
>50 years or impaired cell immunity	Ceftriaxone or cefotaxime Cefotaxime + ampicillin or penicillin G	2–4 g q 24 h 2 g q 4 h 2 g q 4 h or 3–4 MU q 4 h
Drug-resistant <i>Streptococcus pneumoniae</i>	Ceftriaxone + rifampicin or vancomycin	2–4 g q 8 h 2 g q 4 h 0.5 g q 6 h
Neurosurgery shunts trauma	Ceftazidime + nafcillin <i>or</i> Vancomycin + aminoglycoside (gentamicin 5–7 mg/kg stat)	2 g q 8 h 2 g q 4 h 0.5 g q 6 h 2 mg / kg q 8 h

microbiology services are recommended. If the CSF examination identifies the organism, then specific regimens can be prescribed (Table 47.3).

It is more difficult to select an appropriate empirical antibiotic in the immunocompromised patient. When the organism has been identified and sensitivity results are available, it may be necessary either to change the antibiotic or to rationalise those being given.<sup>8</sup>

In all cases, it is important to monitor the clinical response to therapy and, if necessary, antibiotics should be reviewed and appropriately altered once antibiotic sensitivities are known or a patient is not considered to be improving. A repeat CSF examination should be performed if there is concern about antibiotic sensitivity or selection. In those with penicillin-resistant pneumococcal meningitis, a CSF examination 48 hours after presentation is recommended to ensure bacteriological improvement. Antibiotics should be given for 10–14 days, although a shorter course may be adequate in some circumstances. Intrathecal antibiotics are not recommended.

### STEROID ADMINISTRATION

The benefit of steroid administration in adult meningitis has been debated. Clear guidance is now available to support its routine use from the Cochrane Database, including 1800 adults and children, which demonstrated a reduction in mortality, hearing loss and neurological complications. Some concerns remain, including the possibility that dexamethasone may adversely affect CSF penetration or cause longer-term cognitive problems.<sup>9</sup> A longer and more established literature exists for the use of steroids in bacterial meningitis in children. These studies confirm a benefit for those with *Haemophilus influenzae* type B infection and reduce the frequency of postmeningitis deafness.

### RECOMMENDATIONS IN ADULTS

Dexamethasone is an adjuvant treatment and should be given with the first dose of antibiotics and continued 6-hourly for 4 days (0.6 mg/kg daily).

Table 47.3 General recommendation for known organisms\*

Organism	Antibiotic	Second line or allergy
<i>Streptococcus pneumoniae</i> (Penicillin-resistant)	Ceftriaxone + vancomycin or rifampicin	Vancomycin + rifampicin
<i>Streptococcus pneumoniae</i> (Penicillin-sensitive)	Penicillin G	Ceftriaxone or chloramphenicol
β-haemolytic streptococcus	Penicillin or ampicillin	Cefotaxime or chloramphenicol or vancomycin
<i>Haemophilus influenzae</i>	Ceftriaxone or cefotaxime	Chloramphenicol
<i>Neisseria meningitidis</i>	Penicillin G	Ceftriaxone or chloramphenicol
<i>Listeria monocytogenes</i>	Ampicillin + gentamicin	Trimethoprim + sulfamethoxazole
Enterobacteriaceae	Ceftriaxone + gentamicin	Quinolones
<i>Pseudomonas aeruginosa</i>	Ceftazidime + tobramycin	Quinolones

\*Always check local sensitivity as resistance patterns are variable.

### ANTICONSULSANTS

Focal or generalised seizures should be treated immediately with IV benzodiazepines to stop the seizures and the individual should then subsequently be loaded with IV phenytoin. The possibility of the following should be considered:

- raised ICP
- cerebritis
- cerebral abscess
- venous thrombosis

The development of seizures may be indicative of a poor prognosis.

### INTRACRANIAL PRESSURE

Intracranial hypertension is a common complication of meningitis. ICP monitoring may be required and standard measures such as hyperventilation, mannitol infusion or CSF drainage may be considered. Depending upon the particular circumstance, serial lumbar punctures or external ventricular drainage should be implemented.

### GENERAL MANAGEMENT CONSIDERATIONS<sup>10</sup>

#### INTRAVENOUS FLUID THERAPY

Normal haemodynamics should be maintained. Currently, there is emphasis on maintaining the cerebral perfusion pressure at around 70 mmHg. Inappropriate antidiuretic hormone secretion may occur in meningitis.

#### RESPIRATORY SUPPORT

It is important to secure the airway and respiratory support may be required for those with severe shock or profound coma. Attention should be paid to management of the unconscious patient with appropriate mouth and eye care. Physiotherapy will be required in order to prevent the onset of pressure sores. Surgical evaluation may be needed for skin necrosis.<sup>11,12</sup>

#### PUBLIC HEALTH

Meningitis prophylaxis is commended for close (kissing contacts) associates and for those medical personnel with close contact. A 2-day course of oral rifampicin 600 mg 12-hourly is recommended. There should be procedures for alerting infectious disease team.

### PROGNOSIS

Untreated, bacterial meningitis is usually fatal. Appropriate therapy significantly reduces the mortality rate; however, recent studies still show that the overall mortality is approximately 18%. Mortality is slightly higher in those who have seizures and when there have been delays introducing treatment, or if the patient is elderly or very young<sup>12,13</sup> (see Table 47.3).

### VIRAL MENINGITIS

The majority of cases of viral meningitis are benign, usually self-limiting conditions which are often caused by enterovirus or coxsackie infection. Some are caused by arboviruses. The same viruses that produce meningitis can also cause encephalitis. Herpes simplex virus type 1 (HSV 1) usually produces encephalitis but rarely causes meningitis. Other viruses causing CNS infections include echoviruses, mumps, polio and HIV. Patients with migrainous headaches often receive a lumbar puncture to rule out viral meningitis, which may prolong their hospital stay with a post lumbar puncture headache and migraine.

### CLINICAL PRESENTATION

Patients usually present with symptoms of meningeal irritation, fever, headache, neck stiffness, retrobulbar pain, photophobia, vertigo, nausea and vomiting which are less severe than those with bacterial meningitis. The presence of intellectual impairment, focal neurological symptoms or seizures suggests that the brain parenchyma is involved and, consequently, these are due to meningoencephalitis. True viral meningitis develops over hours to days but rarely lasts longer than 7–10 days. A variety of associated symptoms, such as nausea, vomiting and generalised malaise, may accompany this condition.<sup>14</sup>

### INVESTIGATIONS

A CSF examination is important and usually shows:

- a mild to moderate lymphocytic pleocytosis
- a mildly elevated CSF protein concentration
- normal glucose concentration

Staining for microorganisms, including bacteria, *Mycobacterium tuberculosis* and cryptococcal meningitis, is necessary. Sites for culture include the mucous membranes, throat, skin and rectum.

### MANAGEMENT

Acute viral meningitis is usually a self-limiting condition and only supportive therapy is required, with analgesia and bedrest. Viral meningitis caused by HSV 1 or 2 may require IV aciclovir. Acute HIV infection causing meningitis may respond to retroviral therapy.

### ENCEPHALITIS

Encephalitis is a viral infection of the brain. HSV 1 is the most common and serious cause of focal encephalitis, which usually affects the temporal and frontal lobes. There are a large number of arboviruses that cause epidemics of encephalitis. These are usually borne by

arthropod vectors, such as mosquitoes and ticks, and therefore are considered as airborne viruses.<sup>15</sup> West Nile virus is now the most common cause of epidemic viral encephalitis in some countries. Neuroimaging changes in basal ganglia may suggest the diagnosis but the CSF pleocytosis may have a predominance. Specific CSF antibodies can be sent for West Nile virus.

### CLINICAL PRESENTATION

The key clinical pointer of encephalitis is the presence of focal neurological symptoms, indicating involvement of the brain parenchyma. In particular, the presence of speech disturbance, seizures, altered cognition and disturbance of conscious level suggests this.

Diagnosis can be difficult.

- Abnormalities on cranial imaging, such as T2-weighted magnetic resonance imaging (MRI), may support this diagnosis (Figure 47.2)
- Electroencephalogram (EEG) studies may show slow-wave activity or epileptiform discharges in temporal lobe.
- PCR examination of the CSF examination may confirm the virus at a later date.

**Figure 47.2** Enhanced temporal lobe with herpes encephalitis.

### TREATMENT

Specific treatment for HSV encephalitis requires IV aciclovir at a dose of 30 mg/kg per day for 14 days. Left untreated, the mortality of HSV encephalitis is approximately 70% but there is still a 25% mortality in patients treated with optimal therapy. Patients can be left with significant disability in terms of cognitive dysfunction or seizures. Most patients with significant cerebral oedema receive empirical steroids, although there are no clinical trials to support this therapy. Aciclovir can cause renal impairment and the patient should be hydrated intravenously and renal function monitored.<sup>16</sup> Aggressive treatment of seizures is important.

Cytomegalovirus (CMV) infection requires antiviral therapy with ganciclovir or valganciclovir. CMV may cause a ganglionitis and polyradiculitis, which may suggest this diagnosis clinically in an immunocompromised patient.

Most CNS viruses cause neuronal damage but chronic JC virus infection in oligodendrocytes causes the syndrome of progressive multifocal leukoencephalopathy (PML). This condition presents with a subacute onset of confusion, weakness and visual symptoms, usually in an immunosuppressed individual. The MRI scan is usually suggestive but CSF examination with PCR amplification of the JC virus particles may be required. Currently, no specific therapy for PML exists. The survival of HIV patients with associated PML is poor, averaging 6 months in 90% of individuals.

Viral infection with HIV 1, measles and rubella can also cause chronic CNS infection, leading to chronic encephalitides.

A number of systemic neurological conditions (e.g. lymphoma, Lyme disease, sarcoidosis and vasculides such as Behçet's disease) may present with aseptic meningitis. It is therefore important to consider these systemic conditions in those presenting with viral meningitis or encephalitis.

### TUBERCULOUS MENINGITIS

Tuberculous meningitis has a variable natural history with a range of different clinical presentations. This and the lack of specific and sensitive tests hinders the diagnosis of this condition. Approximately 10% of individuals with tuberculosis develop meningeal involvement. A variety of risk factors, such as HIV, diabetes mellitus and recent steroid use, may increase the risk of tuberculous meningitis.<sup>17</sup>

### CLINICAL FEATURES

Tuberculous meningitis has a very varied clinical presentation. Often, it is heralded by a non-specific prodromal phase, frequently but not necessarily including headache, vomiting and fever. Of one case series which included those admitted to an intensive care unit, only 65% had fever, 52% had focal neurology and 88% had signs of

meningism. A variety of cranial nerve palsies can occur but other presentations include those seen with stroke, hydrocephalus and tuberculoma.

### DIAGNOSIS

An investigation of the differential diagnosis of tuberculous meningitis is important. PCR amplification of mycobacterial DNA has not been fully evaluated in this technique which, in the case of tuberculous meningitis, usually requires a lumbar puncture examination. Those who are immunosuppressed may have atypical CSF appearance, including normal CSF examinations in occasional HIV individuals. Tuberculosis culture from CSF is required but may take up to 6 weeks before a positive culture result is available. Imaging studies may show a basal meningitis and hydrocephalus but these features are non-specific.<sup>18</sup>

Current advice suggests that the first 2 months of treatment should comprise quadruple therapy:

- Isoniazid oral/IV 10 mg/kg per day up to 300 mg. It is bactericidal and has good CNS penetration.
- Pyrazinamide oral/IV 25 mg/kg per day up to 2.5 g/day.
- Rifampicin high dosage as poor penetration, 10 mg/kg per day up to 600 mg.
- Ethambutol IV high dosage, as it is highly protein-bound and therefore has poor penetration.

Streptomycin is used rarely. The toxicity of the agents must be monitored in terms of renal and liver function and the effect on other organs such as the eye.

There is increasing multidrug-resistant tuberculous meningitis, especially in the HIV-positive population, and so sensitivity is important. Some clinical trials suggest that steroids have a beneficial effect in some groups of patients.<sup>19</sup> Patients may require neurosurgical intervention for the treatment of hydrocephalus.

### SUBDURAL EMPYEMA

This is a collection of pus between the dural and arachnoid space and is usually a consequence of middle-ear or sinus disease. It may follow cranial osteomyelitis related to previous neurosurgery. Head trauma can also be responsible.

Individuals present acutely with headache, fever, neck stiffness, seizures and focal neurological symptoms. Meningeal signs and evidence of hemispheric dysfunction with sinusitis should suggest the diagnosis.

### DIAGNOSIS

CT and MRI are both effective in demonstrating a fluid collection.

Surgical intervention, drainage and appropriate antibiotic regimes are required. Both Gram-positive *Staphylococcus* and *Streptococcus* and Gram-negative organisms

may be implicated. Initial broad-spectrum cover should be narrowed to targeted treatment when the organism or organisms are known.

### PROGNOSIS

If left untreated, this condition is invariably fatal. With treatment, mortality is in the order of 20% and neurological sequelae are common.

### EPIDURAL INFECTION

Cranial and spinal epidural abscess is an infection between skull and dura, often as a consequence of osteomyelitis, from an orbital infection or malignancy. There is a very low but occasional incidence following an epidural. It is similar to subdural empyema. The organism involved where a catheter or drain is implicated is often the same as that found at the skin; hence, *Staphylococcus aureus* is frequently responsible.

### PRESENTATION

Epidural infection commonly presents on the back, and may be generalised to the area of the back involved. There may be local tenderness over the site associated with redness of the catheter insertion site. Fever is common. Initially mild neurological deficit may rapidly progress, leading to para/quadriplegia.

Blood cultures may be positive and may indicate the organism.

### DIAGNOSIS

CT and MRI are both effective in diagnosis.

Spinal decompression and drainage are urgently required. This is usually a nosocomial infection and therefore resistant organisms are commonly found. Antibiotics should be specific for the organisms involved and may need to be continued for prolonged periods, often weeks, to eradicate the infection.

Where there have been neurological symptoms and signs prior to surgery, residual deficit is common. In one series, the recovery rate for patients with paresis/plegia after lumbar epidural abscess was 50%, while no patients with paresis/plegia following a thoracic abscess recovered. The majority of long-term survivors had severe neurological deficits.

### CEREBRAL VENOUS AND SAGITTAL SINUS THROMBOSIS

Venous and sinus thrombosis may occur in the context of infection; in particular meningitis, and epidural or subdural abscess. It may also be secondary to facial or dental

**Figure 47.3** Magnetic resonance imaging (MRI) of superior sagittal sinus thrombosis. Coronal T1-weighted postcontrast MRI. Patient developed a sinus thrombosis following protracted labour and delivery.

infection. It may have no septic aetiology but can occur either as an isolated event or in association with prothrombotic problems such as diabetic ketoacidosis, methylenedioxymethamphetamine (MDMA) abuse (ecstasy), oral contraceptives and hereditary prothrombotic conditions in pregnancy.<sup>20</sup>

Clinical signs at presentation include:

- headache
- focal neurological deficits – in particular, cranial nerves
- seizures
- papilloedema

The diagnostic sensitivities of CT, MRI and digital subtract angiography are 59%, 86% and 100%, respectively, but MRI with magnetic resonance angiography reaches 96% (Figure 47.3).

### TREATMENT

- Treat the primary infection if present.
- Anticoagulants are the mainstay of treatment. Paradoxically, there are often areas of intracerebral haemorrhage in a patient with sinus thrombosis. The presence of such haemorrhages is not a contraindication to anticoagulation.

### BRAIN ABSCESS

#### AETIOLOGY

A brain abscess may spread directly from bone or dura or spread may be haematogenous. Predisposition includes cranial trauma, neurosurgery, chronic ear or sinus disease, suppurative lung disease, congenital heart disease and recurrent sepsis. Immunological compromise may predispose to more exotic organisms: more common organisms include *Staphylococcus* spp. associated with trauma, and *Streptococcus*, *Bacteroides* and Gram-negative bacteria, which are common with lung disease or recurrent sepsis.

#### PRESENTATION

The presentation is severe headache, vomiting, obtundation, seizures and focal neurological signs. Neck stiffness is often absent. Clinical sepsis may not be obvious.

#### DIAGNOSIS (FIGURE 47.4)

- An obvious primary source of infection
- Evidence of raised ICP
- Focal cerebral or cerebellar signs

#### INVESTIGATIONS

- Lumbar puncture is potentially dangerous and is contraindicated.
- CT scan: contrast will usually show ring-enhancing lesions.
- MRI.
- Assessment of a patient's immune status.
- Specific blood tests, such as HIV and *Toxoplasma* serology.

#### TREATMENT

Indications for surgery include large single lesions, relief of raised ICP and the need for tissue diagnosis.

Antibiotics are the mainstay of therapy. If the organism is known, then the treatment should be specific. In the absence of a definitive organism, penicillin plus chloramphenicol (as for meningitis) and metronidazole 500 mg IV 8-hourly or 500 mg rectally 12-hourly should be empirical therapy. Cefotaxime 1–2 g can be given IV 6–8-hourly and metronidazole 500 mg IV 8-hourly. If there is a recent history of trauma or neurosurgery, then a regimen that will cover *Staphylococcus* should be used. Antibiotics should be continued for 3–6 weeks.

Supportive therapy limits morbidity, which is nevertheless high. Mortality from cerebral abscesses is still 10–20%.<sup>21</sup>

Figure 47.4 Abscess: (a) precontrast and (b) postcontrast.

### LYME DISEASE

This is a tickborne multisystem disease with dermatological, cardiological, rheumatological and neurological effects caused by the spirochaete *Borrelia burgdorferi*.

Lyme disease usually presents as an acute febrile illness with gastrointestinal upset, but it may present in a variable fashion neurologically, including as a cranial neuropathy (commonly a facial palsy) or as a meningoencephalitis or radiculopathy. It may also cause a lymphocytic meningitis and may have been diagnosed as a

'viral' meningitis in the past. A variety of longer-term neurological sequelae have been described.<sup>22</sup>

### INVESTIGATIONS

#### CEREBOSPINAL FLUID

White cell count is equivocal but may be raised. Protein is normal or marginally raised and sugar is normal or marginally low. Serology and enzyme-linked immunosorbent assay may be difficult. PCR may be helpful. It may have characteristic MRI appearances. Vaccination is the only empirically demonstrated method of preventing Lyme disease.

### TREATMENT

$\beta$ -lactam antibacterials, such as penicillin V, amoxicillin and cefuroxime, are effective first-line treatment. The optimal duration of treatment is not known, but 10–21 days is recommended.<sup>23,24</sup> Practice parameters for the treatment of nervous system Lyme disease state that nervous system infection responds favourably to penicillin, ceftriaxone, cefotaxime and doxycycline. Prolonged treatment with antibiotic appears to have no benefit in preventing post-Lyme syndrome.

### OTHER DISEASES

There are several other diseases that may have an encephalopathic component. Cerebral malaria is dealt with elsewhere. *Legionella* may lead to subclinical or clinical neurological manifestations, ranging from headache to coma or encephalopathy, usually seen in conjunction with pneumonia, in addition to possible renal impairment. Similarly, *Mycoplasma* has been associated with an encephalitic picture characterised by impaired consciousness and seizures, and by normal or non-specific neuroradiological findings. Occasionally, symmetrical lesions in the putamen and its external surrounding areas have been seen.

Septic encephalopathy has been described as a common complication in the critically ill, presenting in a panoply of ways, from the agitated confused state seen in acute sepsis through to profound loss of consciousness. The aetiology is almost certainly multifactorial, involving changes in cerebral blood flow, alteration in oxygen extraction, cerebral oedema, disruption of the blood-brain barrier, the presence and effects of diverse inflammatory mediators and abnormal neurotransmitter activity. Deranged liver and renal function contribute. It is a syndrome of exclusion based on observation and circumstantial evidence. The EEG is usually abnormal with decreased fast activity and an increase of slow-wave activity, but the findings are not pathognomonic. There are no specific treatments. In general terms, outcome appears to correlate with the management of the underlying sepsis.<sup>25</sup>

# Tetanus

Jeffrey Lipman

Tetanus is a preventable, often Third-World disease, frequently requiring expensive First-World technology to treat. It is an acute, often fatal disease caused by exotoxins produced by *Clostridium tetani*, and is characterised by generalised muscle rigidity, autonomic instability and sometimes convulsions.

## EPIDEMIOLOGY

Recently, tetanus has become a disease of the elderly and debilitated in developed countries, as younger people are likely to have been immunised.<sup>1</sup> In the USA, its incidence decreased from 0.23 per 100 000 in 1955 to 0.04 per 100 000 in 1975, and remained stable thereafter.<sup>1</sup> The annual world mortality from tetanus is estimated to be 400 000–2 000 000. Tetanus claimed the lives of over 433 000 infants in 1991, and accounts for 5 deaths for every 1000 live births in Africa. It is geographically prevalent in rural areas with poor hygiene and medical services. Thus, tetanus remains a significant public health problem in the developing world, primarily because of poor access to immunisation programmes. In addition, modern management requires intensive care unit (ICU) facilities, which are rarely available in the most severely afflicted populations.<sup>2</sup> Therefore, tetanus will continue to afflict developing populations in the foreseeable future.

## PATHOGENESIS

*C. tetani* is an obligate anaerobic, spore-bearing, Gram-positive bacillus. Spores exist ubiquitously in soil and in animal and human faeces. After gaining access to devitalised tissue, spores proliferate in the vegetative form, producing toxins, tetanospasmin and tetanolysin. Tetanospasmin is extremely potent; an estimated 240 g could kill the entire world population,<sup>3</sup> with 0.01 mg being lethal for an average man. Tetanolysin is of little clinical importance.

*C. tetani* is non-invasive. Hence, tetanus occurs only when the spores gain access to tissues to produce vegetative forms. The usual mode of entry is through a puncture wound or laceration, although tetanus may follow

surgery, burns, gangrene, chronic ulcers, dog bites, injections such as with drug users, dental infection, abortion and childbirth. Tetanus neonatorum usually follows infection of the umbilical stump. The injury itself may be trivial, and in 20% of cases there is no history or evidence of a wound.<sup>1</sup> Germination of spores occurs in oxygen-poor media (e.g. in necrotic tissue), with foreign bodies, and with infections. *C. tetani* infection remains localised, but the exotoxin tetanospasmin is widely distributed via the blood stream, taken up into motor nerve endings and transported into the nervous system. Here it affects motor neurone end-plates in skeletal muscle (to decrease release of acetylcholine), the spinal cord (with dysfunction of polysynaptic reflexes) and the brain (with seizures, inhibition of cortical activity and autonomic dysfunction). Tetanus is not communicable from person to person.

The symptoms of tetanus appear only after tetanospasmin has diffused from the cell body through the extracellular space, and gained access to the presynaptic terminals of adjacent neurons.<sup>1</sup> Tetanospasmin spreads to all local neurons, but is preferentially bound by inhibitory interneurons, i.e. glycinergic terminals in the spinal cord, and  $\gamma$ -aminobutyric acid (GABA) terminals in the brain.<sup>2</sup> Its principal effect is to block these inhibitory pathways. Hence stimuli to and from the central nervous system (CNS) are not 'damped down'.

## ACTIVE IMMUNOPROPHYLAXIS<sup>1,3</sup>

Natural immunity to tetanus does not occur. Tetanus may both relapse and recur. Victims of tetanus must be *actively immunised*. Tetanus toxoid is a cheap and effective vaccine which is thermally stable.<sup>3</sup> It is a non-toxic derivative of the toxin which, nevertheless, elicits and reacts with antitoxic antibody. By consensus, an antibody titre of 0.01 u/ml serum is protective.<sup>4</sup> None the less, tetanus has been reported in a few victims with much higher serum antibody titres.<sup>1</sup>

In adults, a full immunisation course consists of three toxoid doses, given at an optimal interval of 6–12 weeks between the first and second doses, and 6–12 months between the second and third doses. A single dose will

offer no immediate protection in the unimmunised, but a full course should never be repeated. Neonates have immunity from maternal antibodies. Children over 3 months should be actively immunised, and need four doses in total. Two or more doses to child-bearing females over 14 years will protect any child produced within the next 5 years. Pregnant females who are not immunised should thus be given two spaced-out doses 2 weeks to 2 months before delivery. Booster doses should be given routinely every 10 years.

Side-effects of tetanus toxoid are uncommon and not life-threatening. They are associated with excessive levels of antibody due to indiscriminate use.<sup>5</sup> Common reactions include urticaria, angioedema and diffuse, indurated swelling at the site of injection.

### CLINICAL PRESENTATION<sup>1,4,6</sup>

The incubation period (i.e. time from injury to onset of symptoms) varies from 2 to 60 days. The period of onset (i.e. from first symptom to first spasm) similarly varies. Nearly all cases (90%), however, present within 15 days of infection.<sup>6</sup> The incubation period and the period of onset are of prognostic importance, with shorter times signifying more severe disease.

Presenting symptoms are pain and stiffness. Stiffness gives way to rigidity, and there is difficulty in mouth-opening – trismus or lockjaw. Most cases (75%) of non-neonatal generalised tetanus present with trismus.<sup>6</sup> Rigidity becomes generalised, and facial muscles produce a characteristic clenched-teeth expression called risus sardonicus. The disease progresses in a descending fashion. Typical spasms, with flexion and adduction of the arms, extension of the legs and opisthotonos, are very painful, and may be so intense that fractures and tendon separations occur.<sup>1</sup> Spasms are caused by external stimuli, e.g. noise and pressure. As the disease worsens, even minimal stimuli produce more intense and longer-lasting spasms. Spasms are life-threatening when they involve the larynx and/or diaphragm.

Neonatal tetanus presents most often on day 7 of life,<sup>4</sup> with a short (1-day) history of failure of the infant to feed. The neonate displays typical spasms that can easily be misdiagnosed as convulsions of another aetiology. In addition, because these infants vomit (as a result of the increased intra-abdominal pressure) and are dehydrated (because of their inability to swallow), meningitis and sepsis are often considered first.

Autonomic dysfunction occurs in severe cases,<sup>6–8</sup> and begins a few days after the muscle spasms. (The toxin has further to diffuse to reach the lateral horns of the spinal cord.) There is increased basal sympathetic tone, manifesting as tachycardia and bladder and bowel dysfunction. Also, episodes of marked sympathetic overactivity involving both  $\alpha$ - and  $\beta$ -receptors occur. Vascular resistance, central venous pressure and, usually, cardiac output are increased, manifesting clinically as labile

hypertension, pyrexia, sweating, and pallor and cyanosis of the digits.<sup>7</sup> These episodes are usually of short duration and may occur without any provocation. They are caused by reduced inhibition of postsynaptic sympathetic fibres in the intermediolateral cell column, as evidenced by very high circulating noradrenaline (norepinephrine) concentrations.<sup>1,8</sup> Other postulated causes of this variable sympathetic overactivity include loss of inhibition of the adrenal medulla with increased adrenaline (epinephrine) secretion, direct inhibition by tetanospasmin of the release of endogenous opiates and increased release of thyroid hormone.<sup>1,2</sup>

The role of the parasympathetic nervous system is debatable. Episodes of bradycardia, low peripheral vascular resistance, low central venous pressure and profound hypotension are seen, and are frequently preterminal.<sup>7</sup> Sudden and repeated cardiac arrests occur, particularly in intravenous drug abusers.<sup>8</sup> These events have been attributed to total withdrawal of sympathetic tone, since it is unresponsive to atropine.<sup>9</sup> However they may be caused by catecholamine-induced myocardial damage<sup>8,10</sup> or direct brainstem damage.<sup>8</sup> Whatever the mechanism, patients afflicted with the autonomic dysfunction of tetanus are at risk of sudden death.

*Local tetanus* is an uncommon mild form of tetanus with a mortality of 1%. The signs and symptoms are confined to a limb or muscle, and may be the result of immunisation. *Cephalic tetanus* is also rare. It results from head and neck injuries, eye infections and otitis media. The cranial nerves, especially the seventh, are frequently involved, and the prognosis is poor. This form may progress to a more generalised form. Tetanus in heroin addicts seems to be severe, with a high mortality, but numbers are small.<sup>8,11</sup>

### DIAGNOSIS

The diagnosis is clinical and often straightforward. There are no laboratory tests specific to tetanus. *C. tetani* is cultured from the wound only in a third of cases. The most common differential diagnosis is dystonic reaction to tricyclics. Other differential diagnoses include strychnine poisoning, local temporomandibular disease, local oral disease, convulsions, tetany, intracranial infections or haemorrhage and psychiatric disorders.

### MANAGEMENT

Initial objectives of treatment are to neutralise circulating toxin (i.e. passive immunisation) and prevent it from entering peripheral nerves (i.e. wound care), as well as eradicating the source of the toxin (i.e. extensive surgery, hygiene, wound care and antibiotics). Treatment then aims to minimise the effect of toxin already bound in the nervous system, and to provide general supportive care.

### PASSIVE IMMUNISATION<sup>1,12</sup>

Human antitetanus toxin has now largely replaced antitetanus serum (ATS) of horse origin, as it is less antigenic. Antitetanus toxin will at best neutralise only circulating toxin, but does not affect toxins already fixed in the CNS, i.e. it does not ameliorate symptoms already present. Although never prospectively tested, present recommendations for human antitetanus toxin in tetanus are 3000–6000 units intravenously (IV). It has been suggested that unimmunised patients or those whose immunisation status is unknown should be given human rich antiserum on presentation with contaminated wounds. No controlled study has shown this to be more effective than wound toilet and penicillin administration.

Intrathecal administration of antitetanus toxin is still controversial. A large meta-analysis reported it to be ineffective.<sup>13</sup> A recent trial comparing intrathecal antitetanus immunoglobulin showed better clinical progression than those treated by the intramuscular route with no difference in mortality.<sup>14</sup> Moreover, suitable intrathecal preparations are not widely available. Side-effects of human antitetanus toxin include fever, shivering and chest or back pains. Cardiovascular parameters need to be monitored, and the infusion may need to be stopped temporarily if significant tachycardia and hypotension present.<sup>1,5,12</sup> If human antiserum is not available, equine ATS can be used after testing and desensitisation.<sup>1</sup>

### ERADICATION OF THE ORGANISM

#### WOUND CARE

Once human antitetanus toxin has been given, the infected site should be thoroughly cleaned and all necrotic tissue extensively debrided.

#### ANTIBIOTICS

Tetanus spores are destroyed by antibiotics. The vegetative form (bacillus) is sensitive to antibiotics *in vitro*. However, *in vivo* efficacy depends on the antibiotic concentration at the wound site, and large doses may be required. Recommended antibiotic regimens include:

1. Metronidazole 500 mg IV 8-hourly for 10 days: The drug has a spectrum of activity against anaerobes, is able to penetrate necrotic tissue and has been shown to be more effective than penicillin in this situation.<sup>15</sup>
2. Penicillin G 1–3 Mu IV at 6-hourly intervals for 10 days: penicillin is a GABA antagonist in the CNS,<sup>16</sup> and may aggravate the spasms. Nevertheless, it is still often used in this situation.
3. Erythromycin has been used, but should not be routinely used.

### SUPPRESSION OF EFFECTS OF TETANOSPASMIN

#### CONTROLLING MUSCLE SPASMS

In the early stages of tetanus, the patient is most at risk from laryngeal and other respiratory muscle spasm. Therefore, if muscle spasms are present, airway should be urgently secured by endotracheal intubation or tracheostomy. If respiratory muscles are affected, mechanical ventilation should be instituted. In severe tetanus, spasms usually preclude effective ventilation, and muscle relaxants may be required. Any muscle relaxant can be used.<sup>17</sup> Heavy sedation alone may prevent muscle spasms and improve autonomic dysfunction (see below).

#### MANAGEMENT OF AUTONOMIC DYSFUNCTION

Autonomic dysfunction manifests in increased basal sympathetic activity<sup>18</sup> and episodic massive outpourings of catecholamines.<sup>18–20</sup> During these episodes, noradrenaline and adrenaline may be up to 10 times basal levels.<sup>18,19</sup> The clinical picture is variable.<sup>20</sup> Hypertension, tachycardia and sweating do not always occur concurrently.

Traditionally, a combination of  $\alpha$ - and  $\beta$ -adrenergic blockers has been used to treat sympathetic overactivity. Phenoxybenzamine, phentolamine, bethanidine and chlorpromazine have been used as  $\alpha$ -receptor blockers. Ganglion blockers and nitroprusside have occasionally been used. Propranolol and labetalol have had limited success.<sup>21–23</sup> However, unopposed  $\beta$ -adrenergic blockade cannot be advised. Deaths from acute congestive cardiac failure have resulted.<sup>21,22</sup> Removal of  $\beta$ -mediated vasodilatation in limb muscle causes a rise in systemic vascular resistance, and  $\beta$ -blocked myocardium may not be able to maintain adequate cardiac output. Also, with  $\beta$ -blockade, hypotension follows when sympathetic overactivity abates. Esmolol, a very-short-acting  $\beta$ -adrenergic blocker given IV, has been reported to be useful.<sup>24</sup> However, although sympathetic crises can be controlled by esmolol, catecholamine levels remain raised.<sup>20</sup> This raises concern, because excessive catecholamine secretion is associated with myocardial damage.<sup>10</sup>

From above, it appears more logical to decrease catecholamine output. This can be done with sedatives. Benzodiazepines and morphine are successfully used.<sup>19</sup> Morphine and diazepam act centrally to minimise the effects of tetanospasmin. Morphine probably acts by replacing deficient endogenous opioids.<sup>1</sup> Benzodiazepines increase the affinity and efficacy of GABA.<sup>1</sup> Very large doses of these agents, e.g. diazepam 3400 mg/day<sup>19</sup> and morphine 235 mg/day,<sup>25</sup> may be required, and are well tolerated.

Magnesium has been used as an adjunct to sedation,<sup>19,26</sup> now confirmed by a large trial.<sup>27</sup> Magnesium sulphate infusions to keep serum concentrations between 2.5 and 4.0 mmol/l have decreased systemic vascular resistance and pulse rate, with a small decrease in cardiac output.<sup>19,26</sup> In animal studies, magnesium inhibits release

of adrenaline and noradrenaline, and reduces the sensitivity of receptors to these neurotransmitters. Magnesium also has a marked neuromuscular-blocking effect, and may reduce the intensity of muscle spasms. Nevertheless, it could not be shown to decrease the need for mechanical ventilation.<sup>27</sup> However, magnesium sulphate must be used with sedatives,<sup>19</sup> and calcium supplements may be needed when it is infused. Anecdotally, clonidine, a central  $\alpha_2$ -stimulant, has successfully produced sedation with control of autonomic dysfunction.<sup>28</sup> It seems sensible to attempt to make use of the central nervous system effects of an  $\alpha_2$ -adrenergic agonist, namely sedation and vasodilatation.<sup>29</sup> Intrathecal baclofen has produced similar beneficial results in a series of cases, but significant respiratory depression occurred in a third.<sup>30</sup> When given intrathecally, baclofen can diminish spasms and spasticity, allowing for a reduction in sedative and paralysis requirements.<sup>31</sup>

### SUPPORTIVE TREATMENT

Steps should be taken to prevent contractures, nosocomial pneumonias and deep-vein thrombosis. The patient (including the mother if a neonate is afflicted) must be actively immunised. Where possible, supportive psychotherapy should be offered to both patient and family.

### COMPLICATIONS<sup>1,4,6,10,32</sup>

Muscle spasms disappear after 1–3 weeks, but residual stiffness may persist. Although most survivors recover completely by 6 weeks, cardiovascular complications, including cardiac failure, arrhythmias, pulmonary oedema and hypertensive crises, can be fatal. No obvious cause of death can be found at autopsy in up to 20% of deaths. Other complications include those associated with factors shown in Table 48.1.

### OUTCOME

Recovery from tetanus is thought to be complete. However, in 25 non-neonatal patients followed for up to 11

**Table 48.1** Factors contributing to death in tetanus

Hypoxia
Complications of mechanical ventilation
Myoglobinuria and its attendant problems
Sepsis, particularly pneumonia
Fluid and electrolyte problems (including inappropriate antidiuretic hormone secretion)
Deep-vein thrombosis and embolic phenomena
Bed sores
Bony fractures

years,<sup>33</sup> 15 were reported to have one or more abnormal neurological features, such as intellectual or emotional changes, fits and myoclonic jerks, sleep disturbance, and decreased libido. Of the 10 apparently normal survivors, 6 had electroencephalogram changes. Some of these symptoms resolved within 2 years.

Mortality figures depend on the availability of intensive care. In neonates, the mortality from African countries with no ICU facilities can be up to 80% of cases, but falls to about 10% when artificial ventilation is used. In the USA, mortality in non-neonates relates directly to age, with rates from 0% in patients under 30 years rising to 50% in those 60 years or older. An average of 10% mortality would seem to be reasonable for most ICUs. However, as this disease is easily and completely preventable, loss of life is unacceptable.

# Neuromuscular disorders in intensive care

George A Skowronski

A number of disorders producing generalised neuromuscular weakness can require admission to the intensive care unit (ICU), or complicate the course of ICU patients. These may involve:

- spinal anterior horn cells – motor neurone disease, poliomyelitis
- peripheral nerve conduction – Guillain-Barré syndrome (GBS) and related disorders
- the neuromuscular junction – myasthenia gravis (MG), botulism
- muscle contraction – critical-illness myopathy, periodic paralysis

Table 49.1 lists a differential diagnosis of muscle weakness in critically ill patients.

## GUILLAIN-BARRÉ SYNDROME AND RELATED DISORDERS

In 1834 James Wardrop reported a case of ascending sensory loss and weakness in a 35-year-old man, leading to almost complete quadriparesis over 10 days, and complete recovery over several months.<sup>1</sup> In 1859, Landry described an acute ascending paralysis occurring in 10 patients, 2 of whom died. Guillain, Barré and Strohl in 1916<sup>2</sup> reported 2 cases of motor weakness, paraesthesiae and muscle tenderness in association with increased protein in the cerebrospinal fluid (CSF: lumbar puncture for CSF examination was first described only in the 1890s).

Many variants of this syndrome have since been reported, and this has resulted in confusion in nomenclature. The lack of specific diagnostic criteria has also been a problem. Clinical, electrical and laboratory criteria for the predominant variant – acute inflammatory demyelinating polyradiculopathy (AIDP) – are now well described,<sup>3</sup> though 10–15% of cases do not fit these criteria, and GBS is best regarded as a heterogeneous group of immunologically mediated disorders of peripheral nerve function.

## INCIDENCE

Since the incidence of poliomyelitis has declined markedly due to mass immunisation programmes, GBS has become the major cause of rapid-onset flaccid paralysis

in previously healthy people, with an incidence of approximately 1.7 per 100 000. Epidemics have occurred in large populations exposed to viral illness or immunisation.<sup>4</sup> Immunosuppression and concurrent autoimmune disease may also be predisposing factors.<sup>5</sup> The disorder is slightly commoner in males, and up to four times commoner in the elderly. No consistent seasonal or racial predilection has been demonstrated.

## AETIOLOGY

Most recent evidence supports the proposition that GBS is caused by immunologically mediated nerve injury.<sup>6</sup> Cell-mediated immunity, in particular, probably plays a significant role, and inflammatory cell infiltrates are often seen in association with demyelination, which is generally regarded as the primary pathologic process. Antibodies to a number of nervous system components have been demonstrated in GBS patients, with most interest in recent years focusing on antiganglioside antibodies.

Although the precise mechanism of sensitisation is not known, clinical associations suggest that antecedent viral infections or immunisations are commonly involved. Infective agents implicated include influenza A, parainfluenza, varicella-zoster, Epstein-Barr, chickenpox, mumps, human immunodeficiency virus (HIV),<sup>7</sup> measles virus and *Mycoplasma*. *Campylobacter jejuni* gastroenteritis now appears to be the most common predisposing infection and may be associated with a more severe clinical course; 26–41% of GBS patients show evidence of recent *C. jejuni* infection.<sup>8</sup> Cytomegalovirus infection accounts for a further 10–22% of cases.<sup>9</sup> Immunisations against viral infections, tuberculosis, tetanus and typhoid have all preceded the development of GBS. Most of these associations are anecdotal and of doubtful aetiological significance, but 65% of patients present within a few weeks of minor respiratory (43%) or gastrointestinal (21%) illness.

## PATHOGENESIS<sup>6</sup>

The peripheral nerves of patients who have died of GBS show infiltration of the endoneurium by mononuclear cells in a predominantly perivenular distribution. The inflammatory process may be distributed throughout

the length of the nerves, but with more marked focal changes in the nerve roots, spinal nerves and major plexuses. Electron micrographs show macrophages actively stripping myelin from the bodies of Schwann cells and axons. In some cases, wallerian degeneration of axons is also seen, and failure of regeneration in these cases may correspond with a poor clinical outcome.

The underlying immune response is complex and poorly understood, but serum from GBS patients produces myelin damage in vitro when complement is present.<sup>10</sup> Although antibodies to various glycolipids have been demonstrated in GBS, these are generally in low titre and can occasionally be seen in controls. Patients with recent *C. jejuni* infection have a high incidence of antibodies to the ganglioside GM1.<sup>8</sup> Antibodies to GD1a and GQ1b gangliosides are associated with the rarer acute motor axonal neuropathy (AMAN) and acute motor sensory axonal neuropathy (AMSAN) variants (see below).<sup>11</sup> The basis of the effectiveness of plasma exchange and immunoglobulin therapy is likely to be blocking of demyelinating antibodies by several mechanisms.<sup>12</sup>

## CLINICAL PRESENTATION

The majority of patients describe a minor illness in the 8 weeks prior to presentation, with a peak incidence 2 weeks beforehand. Approximately half the patients initially experience paraesthesiae, typically beginning in the hands and feet. One-quarter complain of motor weakness, and the remainder have both.<sup>13</sup> Motor weakness proceeds to flaccid paralysis, which becomes the predominant complaint. Objective loss of power and reduction or loss of tendon reflexes usually commence distally and ascend, but a more haphazard spread may occur. Cranial nerves are involved in 45% of cases, most commonly the facial nerve, followed by the glossopharyngeal and vagus nerves. One-third of patients require ventilatory support.

In the Miller–Fisher syndrome, a variant of GBS,<sup>14</sup> cranial nerve abnormalities predominate, with ataxia, areflexia and ophthalmoplegia as the main features. This is strongly associated with recent *C. jejuni* infection and with the presence of GQ1b antibodies.

Another subgroup of patients presents with a primarily axonal neuropathy – AMSAN. In these cases motor and sensory axons appear to be the primary targets of immune attack, rather than myelin. These patients have a more fulminant and severe course, and there is again a strong association with *C. jejuni* infection.

Sensory loss is generally mild, with paraesthesiae or loss of vibration and proprioception, but occasionally sensory loss, pain or hyperaesthesia can be prominent features. Autonomic dysfunction is common, and a major contributor to morbidity and mortality in ventilator-dependent cases.<sup>15</sup> Orthostatic or persistent hypotension, paroxysmal hypertension and bradycardia are all described, as are fatal ventricular tachyarrhythmias. Sinus tachycardia is seen in 30% of cases. Paralytic ileus, urinary retention and abnormalities of sweating are also commonly seen.

## DIFFERENTIAL DIAGNOSIS

Most of the important alternative diagnoses are listed as exclusion criteria in Table 49.2. In patients with prolonged illness, the possibility of chronic inflammatory demyelinating polyradiculopathy (CIDP) should be considered.<sup>16</sup> In this condition, which is usually distinguished from GBS, preceding viral infection is uncommon, the onset is more insidious and the course is one of slow worsening or stepwise relapses. Corticosteroids and plasma exchange are possibly effective in this disorder, but adequate studies of immunosuppressive drugs have not been carried out.

An intermediate *subacute* polyradiculopathy (SIDP) as well as a recurrent form of GBS are also described, and all of these variants may be part of the spectrum of a single condition. However, a purely motor axonal neuropathy (AMAN), which causes seasonal childhood epidemics mimicking classical GBS in China and elsewhere,<sup>17</sup> appears to be a distinct entity. Once again, this is strongly associated with *C. jejuni* infection.

**Table 49.2** Diagnostic criteria for typical Guillain–Barré syndrome<sup>3</sup>

<b>Features required for diagnosis</b>
Progressive weakness in both arms and both legs
Areflexia
<b>Features strongly supportive of the diagnosis</b>
Progression over days to 4 weeks
Relative symmetry of symptoms
Mild sensory symptoms or signs
Cranial nerve involvement, especially bilateral weakness of facial muscles
Recovery beginning 2–4 weeks after progression ceases
Autonomic dysfunction
Absence of fever at onset
High concentration of protein in cerebrospinal fluid protein, with fewer than $10 \times 10^6$ cells/l
Typical electrodiagnostic features
<b>Features excluding diagnosis</b>
Diagnosis of botulism, myasthenia, poliomyelitis or toxic neuropathy
Abnormal porphyrin metabolism
Recent diphtheria
History or evidence of lead intoxication
Purely sensory syndrome, without weakness

## INVESTIGATIONS

In over 90% of patients, CSF protein is increased (greater than 0.4 g/l), within a week of onset of symptoms. The level does not correlate with the clinical findings. A pleocytosis with lymphocytes and monocytes in the CSF may be seen in a small proportion of patients, especially later in the disease. Nerve conduction studies typically demonstrate reduced conduction velocity and prolonged distal latencies,<sup>18</sup> but there is no consensus on precise electrophysiological criteria for the various subtypes.<sup>11</sup> Severely reduced distal motor amplitude and a predominantly axonal pattern are associated with more severe disease and a guarded prognosis.

## MANAGEMENT

The management of the patient with severe and protracted GBS provides a major challenge, as the prognosis is generally excellent if complications can be treated early or avoided. These complications may be life-threatening, affect any of the major organ systems or result in permanent disability, and can be prevented only by meticulous attention to detail.

## SPECIFIC THERAPY

Plasma exchange (plasmapheresis) is of value in GBS. Two large controlled trials showed a reduction in patients requiring mechanical ventilation, reduced duration of mechanical ventilation for those who required it, reduced

time to motor recovery and time to walking without assistance.<sup>19</sup> Mortality, however, was not altered. Plasma exchange was most effective when carried out within 7 days of onset of symptoms. The plasma exchange schedules consisted of three to five exchanges of 1–2 plasma volumes each, over 1–2 weeks. Adverse events are common, and some relate to the disease itself. Fresh frozen plasma is reported to have more side-effects than albumin as the replacement fluid.

Immunoglobulin therapy was as effective as plasmapheresis<sup>20</sup> and previous concerns of higher recurrence rates are probably unfounded. Because of its ease of use, many authorities now advocate immunoglobulin as the treatment of choice. A dose of 0.4 g/kg body weight intravenously, daily for 5 days, was used in the most recent trials.

About 10% of patients relapse after initial treatment with either plasmapheresis or immunoglobulin; most respond well to a further course.

A recent Cochrane review confirms that low- or high-dose corticosteroids are of no value,<sup>21</sup> and may even slow recovery. The combination of high-dose steroids with immunoglobulin may hasten recovery, but does not affect the long-term outcome.

## SUPPORTIVE CARE

### RESPIRATORY

In the spontaneously breathing patient, chest physiotherapy and careful monitoring of respiratory function are of paramount importance. Regular measurement of vital capacity is probably the best way to predict respiratory failure, and is more reliable than arterial blood gases.<sup>22</sup> The latter nevertheless remain a useful guide. Any patient with a vital capacity less than 15 ml/kg or 30% of the predicted level, or a rising arterial  $P_{CO_2}$  is likely to require mechanical ventilation.

Bulbar involvement should be carefully sought, as there is a significant risk of aspiration of upper-airway secretions, gastric contents or ingested food. The cough reflex may be inadequate, and airway protection by tracheal intubation or tracheostomy is then required. Oral feeding should be stopped in any patient in whom bulbar involvement is suspected.

Mechanical ventilation is mandatory if coughing is inadequate, pulmonary collapse or consolidation develop, arterial blood gases are significantly abnormal, vital capacity is less than predicted tidal volume (approximately 10 ml/kg) or the patient is dyspnoeic, tachypnoeic or appears exhausted. Mechanical ventilation, if necessary, will probably be required for several weeks (although there is wide variation), and early tracheostomy should be considered.

### CARDIOVASCULAR

Cardiac rhythm and blood pressure should be monitored. Sinus tachycardia is the commonest autonomic manifestation of GBS and usually requires no active treatment.

**Table 49.3** Drugs associated with cardiovascular instability in Guillain–Barré syndrome

<b>Exaggerated hypotensive response</b>
Phentolamine

<b>Exaggerated hypertensive response</b>
Phenylephrine
Ephedrine
Dopamine
Isoprenaline
<b>Arrhythmias</b>
Suxamethonium
<b>Cardiac arrest</b>
General anaesthesia

(Modified from Dalos NO, Borel C, Hanley DF. Cardiovascular autonomic dysfunction in Guillain–Barré syndrome. Therapeutic implications of Swan Ganz monitoring. *Arch Neurol* 1988; **45**: 115–17, with permission.)

Induction of anaesthesia appears particularly likely to induce serious arrhythmias. Use of suxamethonium may contribute significantly to this,<sup>23</sup> and, as with many other neuromuscular disorders, should be avoided. Endotracheal suctioning has also been associated with serious arrhythmias. Cardiovascular instability may also be exacerbated by a number of other drugs (Table 49.3). These, likewise, should be avoided or used with great care.

Mild hypotension and bradycardia may require no treatment, particularly if renal and cerebral function are maintained. However, blood volume expansion or inotropic drugs may be required in some cases. Hypertension is often transient, but occasionally requires appropriate drug therapy. Hypoxia, hypercarbia, pain and visceral distension should be excluded as causes.

#### FLUIDS, ELECTROLYTES AND NUTRITION

Paralytic ileus is not uncommon, especially immediately following the institution of mechanical ventilation, and a period of parenteral nutrition may be required. However, wherever possible, nasoenteric feeding should be instituted because of its significantly greater safety. Energy and fluid requirements are considerably reduced in these patients.

#### SEDATION AND ANALGESIA

In non-ventilated patients, sedation should be avoided because of the potential for worsening respiratory and upper-airway function. In ventilated patients, sedation becomes less necessary as the patient becomes accustomed to the ventilator, but night sedation may help to preserve diurnal rhythms. Limb pain, particularly with passive movement, is very common and often quite

severe. Quinine, minor and non-steroidal analgesics and antidepressant drugs may all be tried, but the pain can be difficult to control and opioids are often required. Methadone, transdermal fentanyl, gabapentin and tramadol have all been advocated.

#### GENERAL AND NURSING CARE

A comprehensive programme of physiotherapy should be implemented by nurses and physiotherapists, with careful attention to pressure area care, the maintenance of joint mobility and pulmonary function. Opportunistic infection should be actively sought with culture of urine and respiratory secretions at least twice weekly. Sites of vascular access should be inspected frequently, and changed whenever necessary. It may be possible to manage stable long-term patients without venous access. Care should be taken to prevent corneal ulceration and faecal impaction.

Prophylaxis against venous thromboembolism should be given, and enterally administered low-dose warfarin may be preferable to twice-daily heparin injections in long-stay patients. Psychological problems, especially depression, are common, and some patients are helped by antidepressant drugs. Good communication and rapport between the patient and staff, involvement of allied health practitioners, the provision of television, radio and reading aids, and, where possible, occasional trips out of the ICU are all of great value.

#### PROGNOSIS

The nadir of the disease is reached within 2–4 weeks, and gradual resolution follows over weeks to months. Of those who survive the acute illness, 70% are fully recovered within 1 year, and a further 20% are left with only minor limitation. Poor prognostic features include age over 60 years, rapid progression to quadriplegia in less than 7 days, the need for mechanical ventilation (except for children), and a preceding diarrhoeal illness. Even in patients ventilated for more than 2 months, gradual improvement may continue for 18 months to 2 years.<sup>24</sup> These severely affected patients require a protracted period of rehabilitation.

Death in up to 25% of GBS patients has been reported in those requiring intensive care.<sup>25</sup> Many of these deaths were due to potentially avoidable problems such as respiratory arrest, ventilator malfunction and intercurrent sepsis, and considerably better results have been achieved. A more representative estimate of the overall mortality is 5–8%.<sup>26</sup>

#### WEAKNESS SYNDROMES COMPLICATING CRITICAL ILLNESS<sup>27</sup>

A number of neuromuscular disorders specifically associated with critical illness have been described over the last 30 years, and remain poorly understood. They are

probably much more common than previously appreciated, demonstrable to some degree in up to 50% of patients.<sup>28</sup> These include neuropathies, myopathies and combinations of both. Variations in nomenclature, the lack of a satisfactory classification or diagnostic test, and confusion with other disorders, such as GBS and corticosteroid-induced myopathy, have further complicated this area. There is also considerable overlap among the various subtypes. Sepsis, neuromuscular-blocking agents (NMBA), disuse atrophy, asthma, corticosteroids and the multiple-organ dysfunction syndrome (MODS) have all been implicated. Although the two major subgroups are outlined below, a number of rarer variants have also been described. No specific therapies are available, but most patients improve after a period of supportive care.

### CRITICAL-ILLNESS POLYNEUROPATHY

This acute, diffuse, mainly motor neuropathy is probably the commonest of these disorders. It usually presents in the recovery phase of a severe systemic illness with persistent quadriparetic weakness, hyporeflexia and difficulty in weaning from respiratory support. There appears to be a specific association with severe sepsis and MODS. Histological and electrophysiological features are consistent with axonal degeneration. The mortality in this group is high, presumably reflecting that of the underlying condition. However, among those who survive the acute illness, the outlook for recovery of function appears quite good, with 70% recovering completely over an average of 4–5 months.<sup>29</sup>

### CRITICAL-ILLNESS MYOPATHY

This disorder is linked with asthma and with the use of corticosteroids, NMBA and, less convincingly, aminoglycosides and  $\beta$ -adrenergic agonists. Reflexes are preserved except in severe cases, as is sensation. Elevated blood creatine phosphokinase (CPK) concentrations are often seen. A few patients have a more severe, fulminant form with very high CPK levels, frank rhabdomyolysis and, rarely, renal failure. Electrophysiological findings are somewhat variable, though muscle necrosis is usually apparent on histology. Although steroidal muscle relaxants (pancuronium or vecuronium)<sup>30</sup> have been particularly implicated, the disorder has also been seen with other types of NMBA. On the basis of two small case series, the outlook for functional recovery appears good.<sup>30</sup>

### DIFFERENTIAL DIAGNOSIS

The influence of drugs, metabolic abnormalities and hyperthermia should always be excluded when unexplained neuromuscular weakness appears in an intensive care patient. The possibility of a coincident illness such as the Eaton–Lambert syndrome, MG, vasculitis or GBS must also be carefully considered. Severe catabolism and

disuse atrophy are common in many of these patients and can themselves result in significant weakness.

## MYASTHENIA GRAVIS

MG is an autoimmune disorder caused by antibodies directed against acetylcholine (ACh) receptors in skeletal muscle. Despite its relative rarity, it is the most studied and best-understood clinical disorder of neuroreceptor function, and arguably the best-understood organ-specific autoimmune disease. It is characterised clinically by weakness or exaggerated fatigability on sustained effort. Intensive care is most commonly required because of severe involvement of the bulbar or respiratory muscles, which may be the result of a spontaneous exacerbation of the disease, a complication of drug therapy, intercurrent illness or surgery or following surgical thymectomy – a definitive treatment for many patients.

### INCIDENCE

The incidence of MG is approximately 1 in 20 000 in the USA. There is no racial or geographic predilection. Although MG can occur at any age, it is very rare in the first 2 years of life, and the peak incidence is in young adult females. Overall, females are affected about twice as often as males. This sexual predilection decreases with increasing age, and there is a smaller, second incidence peak in elderly males.<sup>31</sup>

### AETIOLOGY AND PATHOPHYSIOLOGY

In 75% of cases, there is histological evidence of thymic abnormality. Thymic hyperplasia is present in the majority of patients, but approximately 10% have a thymoma. The latter appears more common in the older age group. The precise role of the thymus is uncertain, but ACh receptors are present in the myoid cells of the normal thymus, and there is evidence that anti-ACh receptor antibody production is mediated by both B and T lymphocytes of thymic origin. Other organ-specific autoimmune disorders, most commonly thyroid disease,<sup>32</sup> but also rheumatoid arthritis, lupus erythematosus and pernicious anaemia, are significantly associated with MG, and autoantibodies to other organs may be seen in MG patients without evidence of disease.

Children born to mothers with MG demonstrate transient weakness ('neonatal MG') in about 15% of cases. A number of congenital myasthenic syndromes exist, in which symptoms develop in infancy, without evidence of autoantibody production.<sup>33</sup> A familial tendency is more common in this group, and structural changes at the neuromuscular junction have been demonstrated.

The stimulus to autoantibody production is not known, but these can be detected in about 90% of patients with generalised myasthenia. They may interfere with neuromuscular transmission by competitively blocking receptor

sites, by initiating immune-mediated destruction of receptors, or by binding to portions of the receptor molecule which are not part of the ACh receptor site, but which, nevertheless, are important in allowing ACh to bind.

### CLINICAL PRESENTATION

Ptosis and diplopia are the most common initial symptoms, and in 20% of cases, the disorder remains confined to the eye muscles (ocular MG).<sup>34</sup> Bulbar muscle weakness is common and may result in nasal regurgitation, dysarthria and dysphagia. Limb and trunk weakness can occur with varying distribution, and is usually asymmetrical. Some patients complain of fatigue rather than weakness, and may be misdiagnosed as having psychiatric problems. However, weakness can be elicited by sustained effort of an involved muscle group, e.g. sustained upward gaze is often worse at the end of the day and improves with rest.

### INVESTIGATIONS

Impairment of neuromuscular transmission may be confirmed by a positive edrophonium (Tensilon) test. However, this traditional test is waning in popularity as it has high sensitivity but rather poor specificity.<sup>35</sup> Atropine 0.6 mg is given intravenously to prevent muscarinic side-effects, and this is followed by 1 mg edrophonium. If there is no obvious improvement within 1–2 minutes, a further 5 mg may be given. Some authors recommend the use of a saline placebo injection, and the presence of a second doctor as a 'blinded' observer. Resuscitation facilities should be available, as profound weakness may ensue, especially in patients already receiving anticholinesterase drugs. Intramuscular neostigmine, 1–2 mg, may produce a positive response in 5–10% of patients who do not respond to edrophonium.

The presence of autoantibodies against ACh receptors is quite specific, but false positives may occur in patients with penicillamine-treated rheumatoid disease, other autoimmune diseases and in some first-degree relatives of myasthenic patients.<sup>36</sup> About 20% of patients are seronegative.

Electromyography shows characteristic changes in 90% of patients with generalised MG, and also in many patients with ocular symptoms only.

A syndrome of myasthenic weakness occurs in association with malignancy and other autoimmune diseases (Eaton–Lambert syndrome). Although fatigability is present, the pelvic and thigh muscles are predominantly affected, whereas ocular and bulbar involvement is rare. Tendon reflexes are reduced or absent, and there are specific electromyographic changes.

### MANAGEMENT

1. *Symptomatic treatment* is provided by anticholinesterase drugs which potentiate the action of ACh at receptor sites. Pyridostigmine (Mestinon) is the most

commonly used, and is usually commenced at a dose of 60 mg orally four times daily. Considerable adjustment of dosage may be required.

2. *Corticosteroids* are effective in approximately 70% of patients, and give best results when high doses (e.g. prednisolone 50–100 mg/day) are used initially, and then gradually reduced. However, transient exacerbation upon commencement of steroids is very common,<sup>37</sup> and severely affected patients are often hospitalised for the initiation of therapy with gradually increasing doses. Older patients are more likely to respond, but an average of 4 months' treatment is required to achieve clinical stability, and the majority will require continuing treatment indefinitely.<sup>38</sup>
3. *Azathioprine and cyclophosphamide* are both effective adjuncts to corticosteroid therapy. Overall, 80% of patients are helped, but improvement may be seen only after some months. A few patients may achieve complete remission.<sup>39</sup> Cyclosporin is also effective, and patients may show benefit more quickly than with azathioprine.<sup>40</sup>
4. *Thymectomy* offers the best chance of long-term, drug-free remission and, despite the lack of unequivocal clinical trial evidence, early thymectomy is now advocated in most patients, particularly those under 60, with more than mild disease, regardless of the presence of a thymoma.<sup>41</sup> Compared with medical therapy, thymectomy results in an earlier onset of remission, lower mortality and greater delay in the appearance of extrathymic recurrences.
 

Preoperative optimisation of neuromuscular function is essential, using anticholinesterase drugs and steroids, supplemented by plasma exchange if necessary. Though anticholinesterase requirements are usually reduced in the immediate postoperative period to about three-quarters of the preoperative dose, sustained improvement following thymectomy may not be seen for months or even years. A transcervical approach has been advocated, but doubts remain about the completeness of excision by this route. A thoracoscopic approach may achieve equivalent results with less short-term morbidity, but the traditional sternotomy approach continues to be much more widely used.<sup>42</sup>
5. *Plasma exchange* is effective in producing short-term clinical improvement. It is mainly used in myasthenic crisis or to improve severely affected patients before thymectomy. Its use should be considered, particularly in patients with severe respiratory failure refractory to conventional therapy (see below).<sup>43</sup> Typically, five exchanges of 3–4 litres each are performed over a 2-week period, and this results in improvement within days. However, the benefits are short-lived, lasting only weeks.<sup>44</sup>
6. *Intravenous  $\gamma$ -globulin* has similar effects to those of plasma exchange. A dose of 400 mg/kg per day is usually given for 5 successive days, and occasional patients derive long-term benefit. Interestingly,  $\gamma$ -globulin has

no consistent effect on ACh receptor antibody concentrations, and its mechanism of action is unknown. Clinical trial evidence suggests that  $\gamma$ -globulin is as effective as plasmapheresis,<sup>45</sup> but some clinical experts continue to favour the latter, claiming the clinical response is more rapid.

### MYASTHENIC AND CHOLINERGIC CRISIS

Patients with known MG may undergo life-threatening episodes of acute deterioration affecting bulbar and respiratory function. These may occur spontaneously, or may follow intercurrent infection, pregnancy, surgery, the administration of various drugs (Table 49.4)<sup>46</sup> or attempts to reduce the level of immunosuppression. Such episodes, known as myasthenic crises, usually resolve over several weeks, but occasionally last months. The incidence of myasthenic crisis increases markedly with age.

Rarely, a patient may deteriorate due to excessive dosage of anticholinesterase drugs ('cholinergic crisis'). Abdominal cramps, diarrhoea, excessive pulmonary secretions, sweating, salivation and bradycardia may be present, but these can also occur in patients with myasthenic crisis on high doses of pyridostigmine. Though the two situations may be difficult to distinguish, myasthenic crisis is far more likely unless extremely large doses of pyridostigmine, at least 120 mg every 3 hours, have been administered.

**Table 49.4** Drugs which may exacerbate myasthenia gravis

<b>Antibiotics</b>
Streptomycin
Kanamycin
Tobramycin
Gentamicin
Polymyxin group
Tetracycline
<b>Antiarrhythmics</b>
Quinidine
Quinine
Procainamide
<b>Local anaesthetics</b>
Procaine
Lidocaine
<b>General anaesthetics</b>
Ether
<b>Muscle relaxants</b>
Curare
Suxamethonium
<b>Analgesics</b>
Morphine
Pethidine

A Tensilon test is now considered an unreliable method of distinguishing between these two possibilities, may be hazardous, and is generally not recommended.

Patients with myasthenic crisis should be admitted directly to the ICU, as there is a significant risk of pulmonary aspiration due to bulbar involvement, bacterial pneumonia due to stasis, acute respiratory failure or cardiorespiratory arrest. After initial stabilisation and resuscitation, every effort should be made to identify and correct reversible causes, especially respiratory infections and electrolyte disturbances.

Frequent estimations of vital capacity and maximum inspiratory force should be made and recorded. Tracheal intubation and mechanical ventilation should be considered in patients with significant bulbar involvement or clinical evidence of worsening respiratory failure. As with other neuromuscular disorders, deterioration of blood gases may occur late, and is an unreliable sign of progressive respiratory failure. Aggressive chest physiotherapy, urinary drainage and nasogastric feeding may be required. Hypokalaemia, hypocalcaemia and hypermagnesaemia should be avoided, as all may exacerbate muscle weakness.

If the patient's clinical status cannot be rapidly improved by the adjustment of anticholinesterase dosage and aggressive treatment of intercurrent illness, high-dose corticosteroids and plasma exchange should be commenced simultaneously, and may produce some benefit within as little as 24 hours.<sup>47</sup>

### PERIOPERATIVE MANAGEMENT

MG patients often require intensive care in relation to surgery for intercurrent illness or, more often, thymectomy. Unstable patients should be admitted to hospital some days in advance for stabilisation. In severely affected patients, preoperative high-dose corticosteroids and/or plasma exchange may be used to improve the patient's fitness for surgery. It may be prudent to omit premedication, and an anaesthetic technique which avoids the use of non-depolarising muscle relaxants is usually advocated, though vecuronium and atracurium are probably acceptable in reduced dosage.<sup>48,49</sup> Suxamethonium can be used safely in normal dosage.<sup>50</sup>

Up to one-third of patients require continuing mechanical ventilation postoperatively following thymectomy. Predictive factors include a long preoperative duration of myasthenia, coexistent chronic respiratory disease, high anticholinesterase requirements (e.g. pyridostigmine >750 mg/day), and a preoperative vital capacity of less than 2.9 litres.<sup>51</sup> In those cases requiring mechanical ventilation, some authors advocate temporary cessation of anticholinesterase drugs to reduce respiratory secretions but in all other cases they should be continued, though dosage requirements must be reassessed carefully and repeatedly.

### MOTOR NEURONE DISEASE (AMYOTROPHIC LATERAL SCLEROSIS, LOU GEHRIG'S DISEASE)<sup>52</sup>

Motor neurone disease refers to a large group of related disorders (Table 49.5), a few of which are clearly genetically determined, while most arise sporadically, are of completely unknown aetiology and are generally untreatable. The most common variant is the sporadic form known as amyotrophic lateral sclerosis (ALS), a relentlessly progressive degenerative disease which most commonly affects males over 50 years of age. In North America the term 'ALS' is often used more generically, essentially equivalent to the broader term 'motor neurone disease'.

#### PATHOGENESIS

The disease affects both upper and lower motor neurones. The involvement of either can predominate early on, giving rise to several clinically recognisable subgroups (see Table 49.5). The cerebral cortex as well as the anterior horns of the spinal cord are involved, with shrinkage, degenerative pigmentation and, eventually, disappearance of the affected cells accompanied by gliosis of the lateral columns ('lateral sclerosis'). As muscles are denervated, there is progressive atrophy of muscle fibres ('amyotrophy'), but, remarkably, sensory neurones as well as those concerned with autonomic function, coordination and higher cerebral function are all spared. The precise cause remains unknown. Postulated pathogenetic causes include oxygen free radicals, viral or prion infection, excess excitatory neurotransmitters and growth factors, and immunological abnormalities.<sup>53</sup> Heavy-metal exposure has also been implicated. The only established clinical risk factors are age and family history.

#### CLINICAL PRESENTATION

The earliest symptoms are those of insidiously developing limb weakness, often asymmetrical, accompanied by obvious muscle wasting. This classically affects the small muscles of

the hand and may be accompanied by fasciculation. As time passes, the disease becomes more generalised and more symmetrical, with a mixture of upper and lower motor neurone signs (i.e. spasticity and hyperreflexia in addition to gross wasting), eventually involving bulbar and respiratory muscles. Awareness and intellect were previously thought to be preserved, but it is now recognised that up to half the patients have evidence of cognitive dysfunction.<sup>54</sup> Death occurs in 50% of cases within 3–5 years, usually due to respiratory infection, aspiration or ventilatory failure from profound weakness. However, there is wide variability, and a few patients may survive for many years.

#### DIAGNOSIS

There are no specific investigations, and the diagnosis must be made on clinical grounds together with electromyogram (EMG) evidence of denervation in at least three limbs. Experienced neurologists correctly diagnose the condition with 95% accuracy.<sup>55</sup> The most important differential diagnosis is multifocal motor neuropathy. The distinction is of clinical importance, as the latter is amenable to treatment. Poliomyelitis can also result in a syndrome of progressive weakness, wasting and fasciculation, beginning many years after the initial illness (the post-polio syndrome), and leading occasionally to respiratory failure and death.<sup>56</sup>

#### MANAGEMENT

Treatment is essentially symptomatic and supportive. No benefit has been shown with antioxidants, growth factors and immunosuppressants.<sup>53</sup> However, the centrally acting glutamate antagonist riluzole has been shown to slow slightly the progression of ALS.<sup>57</sup> Admission to ICU is sometimes requested when these patients present with an acute deterioration or intercurrent illness. The intensivist may be asked to assist with ambulatory or home respiratory support for gradually worsening chronic respiratory failure. Such cases present major ethical as well as clinical problems, but the provision of assisted ventilation can result in an improved quality of life, and possibly prolonged survival for carefully selected individuals.<sup>58</sup> Respiratory support may be given by facemask, nasal mask or, rarely, by tracheostomy using simple, compact ventilators. Some patients require only intermittent support, particularly at night or during periods of acute deterioration due to intercurrent illness. Long-term respiratory support outside the ICU is a major undertaking, requiring specific equipment and extensive liaison with the patient, the family and numerous specialised support services.

### RARE CAUSES OF ACUTE WEAKNESS IN THE ICU

#### PERIODIC PARALYSIS<sup>59</sup>

This term describes a group of rare primary disorders, mostly inherited as autosomal-dominant traits, producing episodic weakness. They must be distinguished from

**Table 49.5** Degenerative motor neurone diseases

#### Amyotrophic lateral sclerosis

Spinal muscular atrophy

other causes of intermittent weakness, including electrolyte abnormalities, MG and transient ischaemic attacks. In the inherited disorders, the underlying abnormality is a defect of skeletal muscle ion channels. Symptoms begin early in life (before age 25), and follow rest or sleep rather than exertion. Alertness during attacks is completely preserved, and muscle strength between attacks is normal. Treatment is usually successful in preventing both the attacks and the chronic weakness, which can develop after many years in untreated patients.

The *hypokalaemic* form of periodic paralysis is predominantly inherited, but can also arise sporadically in association with thyrotoxicosis. Involvement of bulbar or respiratory muscles occurs rarely, as can cardiac arrhythmias. The degree of hypokalaemia during attacks is mild, but patients rapidly respond to potassium administration. Effective prophylaxis is conferred by acetazolamide, but not by oral potassium.

The *hyperkalaemic* form is milder, almost always inherited and virtually never requires intensive care. During attacks the serum potassium may be modestly elevated or normal. Patients respond to carbohydrate administration, and thiazide diuretics or acetazolamide provide effective prophylaxis.

## BOTULISM<sup>60</sup>

Botulism is a widespread but very uncommon potentially lethal disease caused by exotoxins produced by *Clostridium botulinum* – an anaerobic, spore-forming Gram-positive bacillus. The vast majority of botulism is *food-borne* and outbreaks are largely due to home-preserved vegetables (type A toxin), meat (type B) or fish (type E), but high-risk foods also include low-acid fruit and condiments. Signs and symptoms are caused by toxin produced in vitro and then ingested.

*Wound botulism* arises rarely, when wounds (typically open fractures) are contaminated by soil containing type A or B organisms. Intravenous drug abusers are an increasing source of this condition through infected injection sites.

*Infantile botulism* arises in infants under 6 months of age, and is due to the active production of toxin by organisms in the gut rather than the direct ingestion of toxin.

*Hidden botulism* describes the adult equivalent of infantile botulism, and is a rare complication of various gastrointestinal abnormalities.

*Inadvertent botulism* is the most recently described form, and occurs as a complication of the medical or cosmetic use of botulinum toxin.

*Inhalational botulism* is the form that would occur as a result of aerosolised toxin released in the context of bioterrorism.

In most cases, exogenously produced exotoxin is absorbed (primarily in the upper small intestine), and carried by the blood stream to cholinergic nerves at the neuromuscular junction, postganglionic parasympathetic nerve endings and autonomic ganglia, to which it

irreversibly binds. The toxin enters the nerve endings to interfere with ACh release.

Most patients become ill about 3 days after ingestion of toxin, with gastrointestinal symptoms (nausea, vomiting, abdominal pain, diarrhoea or constipation), dryness of the eyes and mouth, dysphagia and generalised weakness, which progresses in a symmetrical, descending fashion, with ventilatory failure in severe cases. Cranial nerve dysfunction is manifested by ptosis and diplopia, facial weakness and impaired upper-airway reflexes.

The differential diagnosis includes food poisoning from other causes, MG and GBS. Botulism can be confirmed by the presence of toxin (either in the patient's serum or stool, or in contaminated food) in about two-thirds of cases.

Treatment is mainly supportive, with airway protection and mechanical ventilation when required. Clearance of toxin from the bowel with enemas and cathartics has been advocated. Guanidine hydrochloride, which enhances the release of ACh from nerve terminals, has been reported to improve muscle strength, especially in ocular muscles, and may be useful in milder cases. Antibiotics have not been clearly shown to be useful. Equine antitoxins are available, but side-effects are common and their efficacy is limited. A human-derived antitoxin has been shown to be effective in *infantile botulism*,<sup>61</sup> and the US Defense Department has a pentavalent antitoxin, which is not available for public use. In *wound botulism*, antibiotics (penicillin or metronidazole) and aggressive debridement are recommended.

Most patients begin to improve after a week or so, but hospitalisation is usually required for 1–3 months. The mortality is low (5–8%) with good supportive care, including mechanical ventilation. Mild weakness and constipation may persist for many months.

# Diabetic emergencies

Richard T Keays

Diabetes mellitus is due to an absolute or relative deficiency of insulin. The sustained effect of poor glycaemic control results in a wide array of end-organ damage as a consequence of small- and large-vessel pathology. Mortality and morbidity are related to the progress of this damage but often there are acute metabolic deteriorations that can be life-threatening. Diabetic ketoacidosis (DKA) and hyperosmolar hyperglycaemic state (HHS) are two of the most common acute complications of diabetes, both accompanied by hyperglycaemia. The pathophysiologic changes that occur in both disease states represent an extreme example of the superfasted state. Coma may also result from severe hypoglycaemia due to overtreatment, usually with insulin.

## DIABETES MELLITUS

### TYPE 1

Insulin-dependent diabetes mellitus (IDDM) has a peak incidence in the young, rising from 9 months to 14 years and declining thereafter. In 25% of patients the presentation is with ketoacidosis, especially in those under 5 years of age.<sup>1</sup> Usually the fasting plasma glucose is  $> 7.8$  mmol/l and glucose and ketones may be present in the urine. In the asymptomatic patient with equivocal fasting plasma glucose an impaired glucose tolerance test may be demonstrated.

### TYPE 2

Non-insulin-dependent diabetes mellitus (NIDDM) is prevalent in the elderly but can occur at any age. Truncal obesity is a risk factor and there is ethnic variation in susceptibility. Diagnosis is often delayed and may be incidental from blood or urine sugar screening.<sup>2</sup> It may present with classical symptoms, as a diabetic emergency, with complications of organ damage or vascular disease.

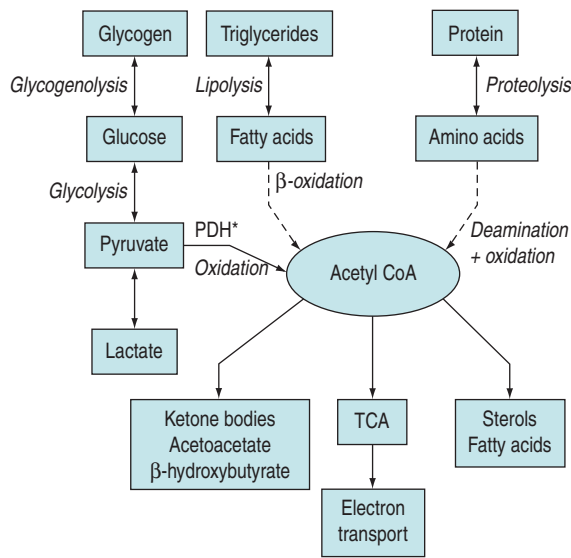

### EPIDEMIOLOGY

Diabetes mellitus affects about 6% of the world's population and is set to rise to 300 million sufferers by 2025.<sup>3</sup> Most of these (97%) will have type 2 diabetes but the

resources required to treat the complications of type 1 diabetes are such that health-care costs are equivalent between the two groups. The annual incidence of DKA is 4.6–8 episodes per thousand patients with type 1 diabetes and in the USA it has been estimated that about \$1 billion is spent each year in treating DKA. HHS represents approximately 1% of primary admissions to hospital with diabetes as compared with DKA. An interplay of both genetic and environmental factors contributes to disease development. In type 1 diabetes there is some evidence for genetic susceptibility, but environmental factors play a greater part. It varies across race and regions, being highest in northern Europe and the USA and lowest in Asia and Australasia.<sup>4</sup> Genetic factors in type 2 diabetes are evidently crucial, with a concordance between monozygotic twins approaching 100%.

### PATHOGENESIS

Normal carbohydrate metabolism depends upon the presence of insulin (Figure 50.1). However, different tissues handle glucose in different ways; for example, red blood cells lack mitochondria and therefore lack pyruvate dehydrogenase and the enzymes involved in  $\beta$ -oxidation, whereas liver parenchymal cells are able to perform the full range of glucose disposal (Figure 50.2). Both DKA and HHS result from a reduction in the effect of insulin with a concomitant rise in counterregulatory hormones such as glucagon, catecholamines, cortisol and growth hormone. Hyperglycaemia occurs as a consequence of three processes: (1) increased gluconeogenesis; (2) increased glycogenolysis; and (3) reduced peripheral glucose utilisation. The increase in glucose production occurs in both the liver and the kidneys as there is a high availability of gluconeogenic precursors such as amino acids (protein turnover shifts from balanced synthesis and degradation to reduced synthesis and increased degradation). Lactate and glycerol also become available due to an increase in skeletal muscle glycogenolysis and an increase in adipose tissue lipolysis respectively. Lastly, there is an increase in gluconeogenic enzyme activity, enhanced further by stress hormones. Whilst hepatic gluconeogenesis is the main mechanism for producing hyperglycaemia, a significant proportion can be produced by the kidneys.<sup>5</sup> What is unclear is the temporal relationship of these changes,

**Figure 50.1** Sources and fate of acetyl coenzyme A (CoA). \*Pyruvate conversion by pyruvate dehydrogenase (PDH) is essentially irreversible, therefore no net conversion of fatty acids to carbohydrates can occur. TCA, tricarboxylic acid.

**Figure 50.2** Glucose metabolism within hepatocyte. (1) Glucose transport: GLUT-1. (2) Hexokinase phosphorylation. (3) Pentose phosphate pathway (hexose monophosphate shunt). (4) Glycolysis. (5) Lactate transport out of cell. (6) Pyruvate decarboxylation. (7) Tricarboxylic acid (TCA) cycle. (8) Glycogenesis. (9) Glycogenolysis. (10) Lipogenesis. (11) Gluconeogenesis. (12) Glucose-6-phosphate (G-6-P) hydrolysis and release of glucose. (13) Glucuronidation.

although an increase in both catecholamines and the glucagon/insulin ratio are early features.<sup>6</sup>

Decreased insulin and increased adrenaline (epinephrine) levels activate adipose tissue lipase, causing a breakdown of

triglycerides into glycerol and free fatty acids (FFAs). Once again glucagon is implicated, as hepatic oxidation of FFAs to ketone bodies is predominantly stimulated by its inhibitory effect on acetyl-coenzyme A (CoA) carboxylase. The resultant reduced synthesis of malonyl-CoA causes a disinhibition of acyl-carnitine synthesis and subsequent promotion of fatty acid transport into mitochondria, where ketone body formation occurs. Both cortisol and growth hormone are capable of increasing FFA and ketone levels and once again the exact contribution of insulin deficiency or stress hormone increase to ketogenesis is undetermined. As ketone bodies are comparatively strong acids, a large hydrogen ion load is produced due to their dissociation at physiologic pH. The need to buffer hydrogen ions depletes the body's alkali reserves and ketone anions accumulate, accounting for the elevated plasma anion gap.

By contrast HHS does not share the ketogenic features of DKA and it is of interest in what ways these two conditions differ. Reduced levels of FFAs, glucagon, cortisol and growth hormone have been demonstrated in HHS relative to DKA, although this is by no means a consistent observation. However, the presence of higher levels of C-peptide in HHS (with lower levels of growth hormone) relative to DKA suggests there is just enough insulin present in HHS to prevent lipolysis but not enough to promote peripheral glucose utilisation.<sup>7</sup>

Hyperosmolarity, which is a prominent feature of HHS, is caused by the prolonged effect of an osmotic diuresis with impaired ability to take adequate fluids. It has been shown that, even when well, patients who have suffered from HHS have impaired thirst reflexes. However the hyperosmolarity seen in about one-third of patients with DKA results from a shorter osmotic diuresis and to variable fluid intake due to nausea and vomiting – often ascribed to the brainstem effects of ketones.

Interestingly, hyperglycaemia, with or without ketoacidosis, leads to a significant increase in proinflammatory cytokine production, which resolves when insulin therapy is commenced.<sup>8</sup> This has led others to postulate a wider beneficial anti-inflammatory effect attributable to insulin therapy.

## CLINICAL PRESENTATION

DKA and HHS represent the two extremes of presentation due to the absolute or relative deficiency of insulin. However, up to one-third of cases can present with mixed features.<sup>9</sup> DKA develops over a shorter time period whereas HHS appears more insidiously (Table 50.1). Polyuria, polydipsia and weight loss are experienced for a variable period prior to admission and, in patients with DKA, nausea and vomiting are also common symptoms. Abdominal pain is commonly seen in children and occasionally in adults and may mimic an acute abdomen. Dehydration presents with loss of skin turgor, dry mucous membranes, tachycardia and hypotension. Mental obtundation occurs more frequently in HHS than DKA as more patients, by definition, are hyperosmolar

**Table 50.1** Comparison of DKA and HHS

Presentation	DKA	HHS
Prodromal Illness	Days	Weeks
Coma	++	+++
Blood glucose	++	+++
Ketones	+++	0 or +
Acidemia	+++	0 or +
Anion Gap	++	0 or +
Osmolality	++	+++
Typical deficits		
Total water (litres)	6	9
Water (ml/kg)	100	100–200
Na <sup>+</sup> (mEq/kg)	7–10	5–13
Cl <sup>-</sup> (mEq/kg)	3–5	5–15
K <sup>+</sup> (mEq/kg)	3–5	4–6
PO <sub>4</sub> (mEq/kg)	5–7	3–7
Mg <sup>2+</sup> (mEq/kg)	1–2	1–2
Ca <sup>2+</sup> (mEq/kg)	1–2	1–2

and the presence of stupor or coma in patients who are not hyperosmolar requires consideration of other potential causes for altered mental status.<sup>10</sup> However, loss of consciousness is not a common presentation with DKA or HHS (< 20%). Most hospitalisations are caused by infection (29%) or non-compliance with medication (17%) in previously diagnosed diabetics; however, in some patients it is the first presentation with undiagnosed diabetes (17%).<sup>11</sup> Given that there is a high likelihood of concurrent infection, most patients have a normal or low temperature and most patients also have a leukocytosis, whether there is infection present or not.

### DIABETIC KETOACIDOSIS

DKA tends to occur more often in patients with type 1 diabetes. Rapid, deep breathing due to acidosis (Kussmaul breathing) may be present, as may the breath odour that is characteristic of ketones, which is somewhat like nail polish remover. A history of insulin therapy omission is common, and patients using continuous insulin delivery devices are particularly at risk due to the use of short-acting insulin which provides no insulin reserve if the pump fails. Diagnostic criteria include pH < 7.3, HCO<sub>3</sub><sup>-</sup> < 15 mmol/l and blood glucose > 14 mmol/l. Increasing acidemia, ketonaemia and deteriorating conscious level indicate increasing severity. Blood glucose per se is not a good determinant of severity and euglycaemic ketoacidosis is possible, depending on the hepatic glycogen stores *prior* to the onset of DKA – a patient who has not been eating well in the recent past may well have a minimally elevated blood glucose. A high amylase is frequently seen and may be extrapancreatic in origin. It should be interpreted cautiously as evidence of pancreatitis.

### HYPEROSMOLAR HYPERGLYCAEMIC SYNDROME

HHS is more often seen in patients with type 2 diabetes and the dominant feature is hyperosmolarity (> 320 mosmol/kg). HHS is typically observed in elderly patients with NIDDM, although it may rarely be a complication in younger patients with IDDM, or those without diabetes following severe burns,<sup>12</sup> parenteral hyperalimentation, peritoneal dialysis or haemodialysis. Patients receiving certain drugs, including diuretics, corticosteroids, β-blockers, phenytoin and diazoxide, are at increased risk of developing this syndrome. HHS may be caused by lithium-induced diabetes insipidus.<sup>13</sup> Not only may mental obtundation occur but occasionally focal neurological features or seizures are present.

### MANAGEMENT

Intensive care unit admission is indicated in the management of DKA, HHS and mixed cases in the presence of cardiovascular instability, inability to protect the airway, altered sensoria, the presence of acute abdominal signs or symptoms suggestive of acute gastric dilatation.

### INITIAL ASSESSMENT

These conditions are medical emergencies and a prompt and thorough history and physical examination should be obtained, with special attention paid to airway patency, conscious level, cardiovascular and renal status, possible sources of infection and state of hydration. Some assessment of the severity of DKA is also aided by the degree of acidosis. The majority of patients have a leukocytosis irrespective of whether they have a source of sepsis or not.

### FLUID REQUIREMENTS

Dehydration and sodium depletion develop as a result of the osmotic diuresis that accompanies hyperglycaemia in both DKA and HHS. In DKA there is an additional ketoanion excretion which is approximately half that of glucose. This obligates cation (sodium, potassium and ammonium) excretion and contributes to the electrolyte losses. Despite the dual osmotic load of glucose and ketones in DKA, dehydration is often worse in HHS due to the more prolonged onset. Insulin itself also promotes salt, water and phosphate reabsorption in the kidney and its lack can contribute further to these losses. The total osmolar load on the kidney in DKA can be as much as 2000 mosmol/day.<sup>14</sup> Fluid resuscitation is initially directed to repleting the intravascular volume, and colloids achieve this more rapidly than crystalloids. There is individual variation as to how much fluid will be required and simple vital signs, such as heart rate, blood pressure and peripheral perfusion, should guide the resuscitation. Fluid challenges with assessment of response may be less likely to avoid the problems of fluid overload. The usual urinary sodium concentration is 60–70 mmol/l, which is roughly similar to half-normal saline, and this is the logical fluid to use for rehydration.<sup>15</sup> This avoids

too great a sodium load and is less likely to produce a hyperchloraemic acidosis which, if rhabdomyolysis occurs, will further acidify the urine and promote precipitation of myoglobin in the renal tubule. As insulin therapy is commenced extracellular water is driven into the intracellular compartment, exacerbating hypovolaemia.

Inappropriate fluid replacement can lead to problems. Studies of DKA and cerebral oedema are limited but there is some evidence that overly aggressive replacement of water losses can precipitate cerebral and other forms of oedema. Water losses do not need to be corrected rapidly and hyperosmolality should not be corrected more rapidly than 3 mosmol/kg H<sub>2</sub>O per hour. Inappropriate resuscitation fluid can also lead to further overshoot in plasma sodium levels and a further increase in plasma osmolality which has been associated with pontine myelinolysis.<sup>16</sup>

General guidelines are given in Figure 50.3, but it must be remembered that each case needs individual tailoring of treatment. It is mostly agreed that the first litre should be isotonic saline, even in patients with marked hypertonicity. This should be given over the first hour. If there is any evidence of cardiovascular compromise due to hypovolaemia, plasma expansion with colloids should also be given as a matter of urgency. For the next 2 hours 0.45% saline can be given if the serum sodium is normal or high. If the corrected sodium is low, then 0.9% saline should be continued. When the blood glucose falls to 15 mmol/l or below, then a combination of 5% dextrose solution (100–250 ml/h) with some further saline-containing solution should be

commenced. Assuming cardiovascular stability, the aim should be to correct the remaining fluid deficit gradually over the next 24–48 hours whilst also taking account of ongoing urinary losses.

### INSULIN THERAPY

It is now clear that an initial bolus dose of 0.15 U/kg followed by low-dose (0.1 U/kg per hour) insulin infusions and gradual correction of hyperglycaemia in DKA results in a reduced mortality.<sup>17</sup> This is because there are fewer therapy-induced episodes of hypoglycaemia and hypokalaemia. Intravenous rather than subcutaneous or intramuscular delivery is preferable as glucose decrement is the same whatever route is chosen, but intravenous insulin reduces ketone body production faster. It is mandatory to use the intravenous route where hypovolaemic shock is present. Appropriate rehydration also acts to reduce blood glucose levels by increased glomerular filtration and a reduction in counterregulatory hormone levels. Inadequate glucose decrement may indicate inadequate fluid resuscitation. Severe insulin resistance occurs in 10% of cases and will necessitate the use of higher doses.

### ELECTROLYTE THERAPY

#### Potassium

Hyperosmolality causes a shift of potassium from within cells to the extracellular space and this potassium is lost as a result of the osmotic diuresis. Renal losses are augmented by secondary hyperaldosteronism and ketoanion

**Figure 50.3** Fluid regimen in hyperglycaemic emergencies. There are no major differences between diabetic ketoacidosis (DKA) and hyperosmolar hyperglycaemic state (HHS), except glucose supplement needs to be given at an earlier stage of correction in HHS when the blood glucose is 17 mmol/l or less. MAP, mean arterial pressure.

excretion as potassium salts. Typical total body deficits are shown in Table 50.1. Serum potassium levels may initially be high and potassium replacement should not commence until this has fallen to  $< 5.5$  mmol/l. Potassium can be replaced as a combination of the chloride and phosphate salt, as this can avoid hyperchloraemia and hypophosphataemia. Occasionally the presenting potassium level will be low ( $< 3.3$  mmol/l), which represents profound potassium depletion (600–800 mmol), and replacement should commence immediately and before insulin therapy is initiated. If the patient is in between these two levels then 20–40 mmol of potassium may be given in the first hour – this should not generally be exceeded. Further decisions regarding potassium replacement need to be adjusted with respect to serum levels and the urine output, but usually 20–30 mmol/h is required. Electrocardiogram monitoring has been recommended where potassium replacement is required for hypokalaemia or cardiac rhythms other than sinus tachycardia.<sup>7</sup>

### Phosphate

A total body phosphate deficit of greater than 1 mmol/kg is typical. Once again the shift is from the intracellular compartment with subsequent urinary loss; however, serum levels are typically normal or increased. Insulin causes an intracellular shift of phosphate and, although hypophosphataemia rarely results in adverse complications, muscle weakness, haemolytic anaemia and impaired cardiac systolic performance can occur. Routine phosphate replacement has not been shown to be beneficial in DKA<sup>18</sup> but correction of severely low levels ( $< 0.4$  mmol/l) may be necessary. Excessive phosphate replacement leads to hypocalcaemia and serum calcium should be monitored.

### Magnesium

A chronic magnesium deficiency may be present in type 1 or 2 diabetes and may be exacerbated by renal impairment. The benefits of magnesium replacement have not been demonstrated in diabetic emergencies, but the principles of magnesium supplementation are similar to other critical care situations.

### CORRECTION OF ACIDOSIS

This occurs more slowly than the correction of blood glucose but the use of bicarbonate in DKA remains controversial. In most studies the use of sodium bicarbonate fails to provide any haemodynamic benefit that could not be attributed purely to osmotic load of sodium administered.<sup>19</sup> There is no doubt that blood pH can be improved, but at the expense of worsening the intracellular acidosis.<sup>20</sup> In addition to cerebrospinal fluid acidosis, sodium bicarbonate is associated with other side-effects that may overshadow any potential benefits, such as increased CO<sub>2</sub> production, hypokalaemia, rebound alkalosis, volume overload and altered tissue oxygenation. In the context of DKA sodium bicarbonate also delays the clearance of ketones and may further enhance hepatic production, even when insulin and glucose are being delivered.<sup>21</sup> At pH  $> 7.0$  insulin will block lipolysis and

ketoacid production; however, when the pH is between 6.9 and 7.1 it remains uncertain whether bicarbonate is beneficial or otherwise. Below pH 6.9 most authorities would recommend the use of bicarbonate to correct the pH partially. The threshold for correction is debatable (between pH 6.9 and 7.15) but life-threatening hyperkalaemia is an undisputed indication for bicarbonate therapy.

Sometimes there is a persistent acidosis without ketosis. Regeneration of bicarbonate in DKA once insulin activity has been restored occurs via two mechanisms: renal and hepatic. The latter requires a metabolisable substrate, typically ketones, which are lost to the body, especially if the diuresis is substantial. The former is slow and hyperchloraemia may persist, particularly when a high chloride-containing fluid such as normal saline is used.<sup>22</sup>

### UNDERLYING CAUSE

Attention must also focus on any underlying precipitant. The two major factors involved are inadequate insulin treatment and infection causing a change in insulin responsiveness. The latter must be actively looked for in the management of these patients.

### MONITORING

The following monitoring parameters are also undertaken as investigations on presentation:

1. Blood glucose concentration: initially every hour, then less frequently.
2. Blood urea and creatinine concentrations: on admission and then at least daily. Creatinine assays that rely on a colorimetric method may be interfered with by the presence of acetoacetate, giving a falsely elevated value.
3. Serum electrolytes:
  - (a) *Serum sodium*: on admission and at least daily. It represents the relative water and electrolyte losses and cannot be used to infer a state of hydration. It may be normal (50% of cases), raised or lowered. Each 1.0 mmol/l rise in blood glucose will decrease serum sodium by 0.3 mmol/l, so hypernatraemia represents a profound loss of water.
  - (b) *Serum potassium*: initially every hour, then less frequently (every 2–4 hours). DKA patients have a K<sup>+</sup> deficit of 3–5 mmol/kg. However, serum concentrations are usually normal or raised because of a shift from the intracellular to the extracellular compartment due to acidaemia, insulin deficiency and hypertonicity. Hypokalaemia on admission represents severe potassium depletion ( $> 600$ –800 mmol) and requires potassium administration before starting insulin therapy.
  - (c) *Serum chloride*: as indicated.
  - (d) *Serum phosphate*: on admission and every 1–2 days. Routine replacement is not of any benefit. Despite evidence that hypophosphataemia leads to a decrease in 2,3-diphosphoglycerate levels, subsequent correction has no impact on the oxyhaemoglobin dissociation curve, and dangerous hypocalcaemia may result.<sup>18</sup>

- (e) *Serum magnesium*: on admission and every 1–2 days. Chronic hypomagnesaemia may be present and may contribute to insulin resistance, carbohydrate intolerance and hypertension. Severe uncontrolled diabetes also results in magnesium depletion. Although the benefits of replacement therapy have not been demonstrated, correction may be necessary if arrhythmias are present.
4. Serum ketones (if available): on admission. This test relies on the nitroprusside reaction and, because it does not measure  $\beta$ -hydroxybutyrate (which is the main ketoacid in DKA), it consequently underestimates the degree of ketoacidosis.
  5. Urinary glucose and ketones: 4-hourly. Ketonuria may persist up to 2 days after the correction of acidosis due to the presence of acetone, which is not an acid anion and is highly lipid-soluble.
  6. Arterial blood gases: frequently as indicated.
  7. Serum osmolality and anion gap: initially and as indicated. Serum osmolality can be measured with an osmometer or estimated from the equation:

$$\text{Osmolality (normal 285 – 300 mosmol/l)} = 2(\text{Na}^+ + \text{K}^+) + \text{glucose} + \text{urea (all values in mmol/l)}$$

The anion gap is calculated by the equation:

$$\text{Anion gap (normal 10 – 17 mmol)} = (\text{Na}^+ + \text{K}^+) - (\text{Cl}^- + \text{HCO}_3^-) \text{ (all values in mmol/l)}$$

8. Serum lactate: if acidosis is severe and anion gap is large.
9. Full blood count and coagulation studies: daily and as indicated. Leukocytosis with left shift may occur in the absence of sepsis.
10. Chest X-ray.
11. Blood cultures, urine and sputum microscopy and culture and culture of relevant specimens as indicated.
12. Pulse oximetry continuously.
13. Electrocardiogram – 12-lead recording and continuous monitoring.
14. Invasive haemodynamic monitoring as indicated.
15. Neurological status and observations: including Glasgow Coma Score and computed tomography scans as indicated for persistent coma or worsening neurological state.
16. Other investigations as indicated (e.g. liver function tests, serum amylase, cardiac enzymes and creatinine clearance).

## COMPLICATIONS

### EARLY

The commonest early complications are hypoglycaemia due to overtreatment with insulin, hypokalaemia due to inadequate replacement and hyperglycaemia due to

interruption of insulin. A hyperchloraemic acidosis can develop in about 10% of patients with DKA. It can be exaggerated by excessive saline use and is not usually clinically significant except in cases of acute renal failure or extreme oliguria.

Clinically apparent cerebral oedema is a rare (0.5–1%) but extremely serious complication of DKA, occurring predominantly in children. Recent studies have suggested a subclinical incidence approaching 50%.<sup>23</sup> Risk factors for developing cerebral oedema include: degree of hypocapnia and dehydration, the failure of serum sodium to rise with treatment and the use of sodium bicarbonate.<sup>24</sup> It does also occur in young adults and may be associated with rapid deterioration in conscious level with or without seizures. If progressive signs of brainstem herniation are present the mortality is high, with only 7–14% likely to make a complete recovery. The risks of brain herniation are related to the degree of acidosis and the volume of initial fluid resuscitation. Oedema formation most likely occurs due to a vasogenic mechanism,<sup>25</sup> and cerebral hyperaemia with loss of autoregulation is evident, which can take up to 36 hours to resolve.<sup>26,27</sup> It has been recommended that plasma osmolality is slowly reduced and that glucose must be added to the hydrating fluids when the plasma glucose has fallen to 15 mmol/l in DKA, and possibly before this in HHS. Fatal cases of cerebral oedema have been reported in HHS as well, and treatment is aimed at maintaining plasma osmolality with intravenous mannitol.

Some degree of brain dysfunction is apparent even in those patients who are not comatose but who have severe DKA, as measured by sensory evoked potentials. This reverts to normal with correction of the ketoacidosis.<sup>28</sup>

Hypoxia and non-cardiogenic pulmonary oedema can also occur, and the increase in lung water and resultant reduced lung compliance are again attributed to the reduction in colloid oncotic pressure. Myocardial infarction can also occur, particularly in the elderly.

### INTERMEDIATE

A reversible critical-illness motor weakness syndrome has been described in HHS, and led to slowness to wake up and reversible tetraplegia.<sup>29</sup> Deep-venous thrombosis and pulmonary embolism occur more frequently in DKA and are a significant cause of mortality in HHS.<sup>30,31</sup> Prophylaxis with subcutaneous heparin is advisable.

### LATE

Various movement disorders can rarely persist after recovery from HHS.<sup>32</sup> The effects of neuroglycopenia can result in an array of late complications ranging from amnesia to optic atrophy.

## PROGNOSIS

In a series of 610 patients with DKA or HHS the overall mortality was 6.2%. HHS is a more serious disease and

has an associated mortality 2–3 times higher than DKA; nevertheless DKA is approximately six times commoner. A retrospective analysis of causes of death in this group of patients revealed that pneumonia was the commonest cause of death (37%), followed by myocardial infarction (21%), with mesenteric or iliac thrombosis accounting for 16% of deaths.<sup>33</sup> Rhabdomyolysis has been reported in both DKA and HHS and, when present, increases the mortality.<sup>34</sup> The likelihood of a poorer outcome in HHS was associated with older age, low blood pressure, low sodium, pH and bicarbonate plasma levels, and high urea plasma levels, of which urea has the strongest association.<sup>35</sup> Mortality is also age-related in DKA. Pregnant women with type 1 diabetes are more likely to have worse outcome from DKA than non-pregnant diabetic women who develop DKA. The presence of hypothermia is also a poor prognostic sign.

Survival depends upon establishing a high index of suspicion and making a rapid diagnosis.<sup>36</sup>

#### HYPOGLYCAEMIC COMA

This results from overtreatment with insulin, and is the commonest cause of diabetic coma. Clinically, there is confusion and agitation, progressing to coma and fitting. Tremor, tachycardia and sweating may be blunted by diabetic autonomic neuropathy. It may be precipitated in known type 1 diabetic patients (up to 10% of patients per year) by missed meals, exercise and overdose of insulin or oral hypoglycaemic agents. Changing therapy or insulin periods are susceptible periods and there is an increased risk associated with long-acting sulphonylurea agents. Alcoholic ketoacidosis is a syndrome of hypoglycaemia, ketoacidosis and dehydration associated with starvation, vomiting, upper abdominal pain and neurological changes, including seizures and coma. Hypoglycaemia may complicate other disease states (e.g. liver and renal failure, or adrenocortical insufficiency).

Severe hypoglycaemia (blood glucose < 1 mmol/l) is a medical emergency. Brain metabolism uses half the glucose produced by the liver and neuronal stores of glycogen are depleted in 2 minutes, after which the brain is susceptible to damage. Urgent glucose infusion (50 ml of 50% glucose) is required and leads to rapid resolution of coma. Intramuscular glucagon is an alternative that is especially suited to out-of-hospital circumstances, but achieves a slower result when compared to intravenous glucose.<sup>37</sup> Hypoglycaemia due to long-acting insulins or oral hypoglycaemic agents will require ongoing glucose infusion.

# Diabetes insipidus and other polyuric syndromes

Craig Carr

Diabetes insipidus (DI: literal translation, ‘tasteless siphon’) refers to a syndrome characterised by pathological polyuria, excessive thirst and polydipsia. Polyuria is arbitrarily defined as a urine loss of > 3 l/day in an adult of normal mass. The urine produced in DI is inappropriately dilute, having both low specific gravity and low osmolality in the face of a high or normal plasma osmolality.

Three subtypes of DI are recognised:

1. *nephrogenic DI (NDI)* – caused by insensitivity of the kidney to antidiuretic hormone (ADH)
2. *central/hypothalamic/neurogenic DI* – caused by reduced or absent production of ADH
3. *gestational DI (GDI)* – caused by an increase in the placental production of vasopressinase or as a variant of central or NDI developing during pregnancy

A separate disorder is occasionally classified as a fourth form of DI – *primary polydipsia* (also called psychogenic or neurogenic polydipsia or polydipsic DI). This is caused by excessive water ingestion, usually due to psychological disturbance but occasionally associated with a lesion of the hypothalamus. In the context of hospital inpatients, a similar iatrogenic condition is created by overenthusiastic administration of intravenous solutions of dextrose 5% or hypotonic saline. Whilst water overload will reduce plasma osmolality and reduce the ability of the kidney to concentrate urine maximally, the diuresis of hypo-osmolar urine seen with water overload is not pathological but physiological and appropriate. In this instance, plasma osmolality is low or in the low-normal range and the body is attempting to restore plasma osmolality to normality by reducing water reabsorption in the kidneys and inducing a water diuresis.

In critically ill patients, polyuria may be the sole part of the DI syndrome apparent to the clinician. Patients are seldom in control of their own fluid intake and are frequently unable to report thirst. The recognition of DI is important as failure to recognise and treat the syndrome appropriately will result in severe dehydration and hyperosmolality with a significant risk of morbidity and mortality. As there are many causes of polyuria in the critically ill (Table 51.1), it is important to adopt a systematic

approach to the clinical assessment, investigations, diagnosis and management of such patients.

The classification as a solute or water diuresis is not always absolute; the table provides a convenient structure but a diuresis should be considered in terms of the individual patient and both physical and biochemical examinations. A diuresis may frequently represent the clearance of both an excess of water and solute, such as is usually the case following the resolution of septic shock with multiorgan failure.

## BACKGROUND PHYSIOLOGY AND ANATOMY

### OSMOLALITY

Osmolality is the measure of osmoles of solute per kilogram of solvent and includes both permeant (e.g. urea) and impermeant solutes (e.g. sodium) and thus osmolality may change due to both water movement and the movement of permeant solute. *Osmolarity* is the measure of osmoles per litre of solute and thus is temperature-dependent. *Osmolality* is temperature-independent. Normal plasma osmolality is in the range of 275–295 mosmol/kg. Plasma osmolality can be estimated from several equations.<sup>1</sup> The formula of Worthley *et al.*<sup>2</sup> below is both simple and correlates well with measured values.<sup>3</sup>

$$\text{Plasma osmolality (mOsm/kg)} = 2 [\text{Na}^+] + [\text{Urea}] + [\text{Glucose}]$$

All units of solute are mmol/l.

Where a patient is markedly uraemic, a value of 8 mmol/l is substituted for the actual urea. Actual osmolality may differ markedly from estimated osmolality in the presence of unmeasured, osmotically active solutes such as mannitol, ethanol, bicarbonate, lactate and amino acids. Whenever concern exists that a patient may be hyper- or hypo-osmolar, osmolality should be measured by assessing the freezing-point depression of the plasma or urine. Increasing the osmolality results in depression of the freezing point.

The osmolal gap is the difference between the calculated and measured osmolality in plasma or urine.

Table 51.1 Causes of polyuria

<b>Water diuresis</b>
<b>Pathological</b>
Diabetes insipidus: cranial, nephrogenic, gestational
<b>Physiological</b>
Psychogenic polydipsia (excess drinking is pathological but the diuresis is not)
Iatrogenic – excessive administration of hypotonic solutions, e.g. 5% dextrose solution, 0.45% saline, 0.18% saline 4% dextrose solutions
<b>Solute diuresis</b>
<b>Pathological</b>
Fanconi's syndrome
Renal tubular acidosis
Glomerulonephritis
Hyperaldosteronism
Anorexia nervosa
Migraines
Paroxysmal tachycardia (via increased atrial natriuretic peptide release)
<b>Poisons/drugs:</b>
Ethanol
Methanol
Ethylene glycol
Mannitol
Loop diuretics
Thiazide diuretics
Hyperglycaemia
<b>Physiological</b>
Resolving sepsis (redistribution of fluid into the vascular compartment from the third space)
Iatrogenic – excessive administration of isotonic or hypertonic solutions, e.g.
0.9% saline
Hypertonic saline
Hartmann's solution
Gelofusin

The normal osmolal gap is  $< 10$  mosmol/l. An increased osmolal gap indicates the presence of an unmeasured osmotically active solute.

## TONICITY

Tonicity describes the ability of a solution of impermeant solute (such as sodium) to cause the movement of water between itself and another fluid compartment. It may be considered an index of the water concentration rather than the solute concentration as the solute is impermeant. The tonicity of plasma is largely determined by its sodium content, the main solute in extracellular fluid, which is not freely permeable to cross into the intracellular space. This characteristic facilitates the regulation of extracellular fluid volume through the regulation of sodium balance.

It is possible for a solution to be both hypotonic and iso-osmolar. Dextrose solution 5% is an example of this;

the solution contains no impermeant solute (assuming no absence of insulin, glucose freely enters the cell), but is iso-osmolar with the intracellular milieu.

## SOLUTE AND WATER INTAKE AND LOSSES

In order to understand disorders of osmolality, tonicity, fluid balance and urine output, it is necessary to be aware of the essential physiological mechanisms which maintain the fluid and osmolal states of the body in health. Assuming a normal diet, in a 75-kg man, every day there is an obligatory loss of around 800 mmol of solute – approximately 300 mmol of urea and 500 mmol of cations and anions. The maximum concentrating ability of the healthy kidney is around 1200 mosmol/kg; consequently, a minimum of 666 ml of urine a day is required to excrete osmotically active solutes. Additionally, insensible losses of water (respiratory water, faecal water and sweat) approximate to 10 ml/kg per day and this rises markedly with fever and hot dry climates. Thus obligatory water losses of around 1.5 l/day arise due to insensible losses and obligatory solute excretion.

## NORMAL URINARY OSMOLALITY

In health, urinary osmolality is usually maintained between 500 and 700 mosmol/kg. As the obligatory solute load to be excreted is relatively constant in value, urine osmolality will fall in response to an increased intake in free water and rise in response to dehydration or water restriction (Figure 51.1). The minimum osmolality of urine achievable in

**Figure 51.1** Urine output rises and urine osmolality falls in health as a function of increasing water intake. Assuming normal solute ingestion, normal solute excretion (around 800 mmol/day) is preserved between water intakes of 1.5 and 32 litres/day.

humans is around 25 mosmol/kg. Diuresis refers to the passage of a high volume of urine ( $> 1.5$  ml/kg per hour) and may be transient or persistent, physiological or pathological. The production of  $> 3$  l/day is arbitrarily defined as polyuria. Water diuresis occurs when the total solute in the urine excreted per day is within the normal range but the osmolality of the urine passed is low. An osmotic or solute diuresis occurs when the total solute passed per day is higher than normal, and the urine passed is usually iso-osmolar to plasma if the extracellular fluid volume is expanded or hyperosmolar if the patient is hypo- or euvoalaemic.

### PLASMA OSMOLALITY AND PLASMA VOLUME REGULATION

Changes in plasma osmolality and changes in plasma volume can occur in tandem or independently of one another. Although normal plasma osmolality lies in a population range of 275–295 mosmol/kg (265–285 mosmol/kg in pregnancy), individuals tend to vary less than  $\pm 1\%$  around their set value. In pregnancy this set value falls but the limited variability around it does not. The body regulates osmolality and volume by separate mechanisms. Water balance and osmolality are maintained via osmoreceptors which mediate their control via control of thirst and ADH production. Control of the plasma volume is maintained via volume receptors and sodium receptors, which mediate their actions through the sympathetic nervous system, the renin–angiotensin–aldosterone system and atrial natriuretic peptide (ANP). Additionally, the volume receptors have inputs to the hypothalamus via which they too can mediate ADH release and the sensation of thirst.

### THIRST

In health fluid intake is determined by the sensation of thirst and the subsequent ingestion of fluid; a plasma osmolality of  $> 290$  mosmol, elevated angiotensin II concentration, sympathetic nervous system activation and circulating volume depletion of 5–10% are all associated with the onset of thirst. Fluid and solute excretion are largely regulated through the kidney, although some solutes such as ethanol and glucose are largely cleared through metabolism rather than excretion.

In the intensive care unit (ICU), the patient loses control over intake of fluids and solute and frequently has impaired excretory mechanisms. Thus both volume and solute homeostasis may become heavily dependent upon the skills of attending clinicians.

### OSMORECEPTORS AND OTHER INPUTS TO THE SUPRAOPTIC AND PRAVENTRICULAR NUCLEI

Detection of osmolality occurs largely at osmo- ( $\text{Na}^+$ ) receptors sited around the anterior aspect of the third ventricle of the brain. These are sensitive to plasma osmolality and cerebrospinal fluid sodium concentration. Hypertonic saline is a more potent stimulus than equi-

isotonic equiosmolar solutions of other solutes.<sup>4</sup> These osmoreceptors link to the cells of the paraventricular nuclei (PVN) and supraoptic nuclei (SON), the sites of ADH synthesis. The axons of the cells in the PVN and SON form part of the pituitary stalk linking the hypothalamus to the pituitary gland in which they terminate. A smaller proportion of the axons terminate in the median eminence where they release ADH and oxytocin, which is transported to the anterior lobe of the pituitary by portal vessels. The ADH and oxytocin so released cause release of adrenocorticotrophic hormone (ACTH) and prolactin respectively; the ADH acts synergistically with corticotrophin-releasing factor (CRF) but is also believed to have ACTH secretagogue properties in its own right.<sup>5,6</sup>

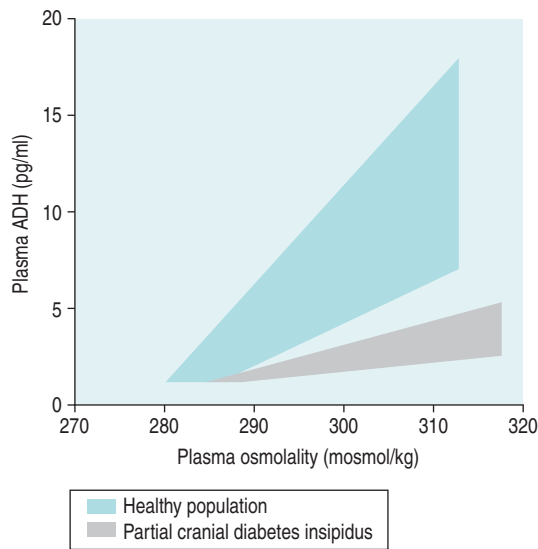

Direct inputs from the sympathetic nervous system to the PVN and SON can stimulate ADH release via  $\alpha$ -adrenoreceptors. Other central osmoreceptors lie outside the blood–brain barrier in the subfornical organ and come into contact with plasma. It is believed that ANP and angiotensin II<sup>7</sup> act via these receptors to inhibit or elicit ADH synthesis and ADH release and to modify the sensation of thirst. Additional osmoreceptors in the mouth, stomach and liver are believed to play a role in the anticipation of an osmolar load following ingestion of food and can preemptively stimulate ADH synthesis in the hypothalamus.

As the baroreceptor and osmoreceptor inputs to the PVN and SON are distinct, it is possible to lose the normal ADH response to hyperosmolality but maintain a normal ADH response to hypovolaemia.<sup>8</sup> Additionally, in animal experiments, when hypotension increases the basal plasma ADH concentration, there is a simultaneous resetting of the osmolality–plasma ADH response curve in an attempt to preserve osmoregulatory function from the new higher baseline.<sup>9</sup> If this did not occur, the ADH response to hypotension would always result in the development of a hypo-osmolal state in addition to causing vasoconstriction.

The normal response of osmoreceptors to changing plasma osmolality in terms of ADH is illustrated in Figure 51.2. At plasma osmolalities of  $< 275$  mosmol/kg, the osmoreceptors remain hyperpolarised and virtually no ADH release occurs via them. At osmolalities  $> 295$  mosmol/kg, the osmoreceptors are maximally depolarised and plasma concentrations of ADH of  $> 5$  pg/ml are attained. Other inputs and influences upon ADH release are summarised in Figure 51.3 and Table 51.2.

### ANTIDIURETIC HORMONE/ARGININE VASOPRESSIN (AVP)

ADH (8-arginine vasopressin) is a nine-amino-acid peptide which differs from oxytocin at only two residues but shares the disulphide bond between the first and sixth ones. This similar structure and conformation results in some cross-reactivity at receptors and in function.<sup>10</sup> It is synthesised in the SON and PVN, bound to neurophysin, transferred through axons to the posterior pituitary gland and stored in granules prior to release. Synthesis

**Figure 51.2** Plasma antidiuretic hormone (ADH) and plasma osmolality in health and partial cranial diabetes insipidus.

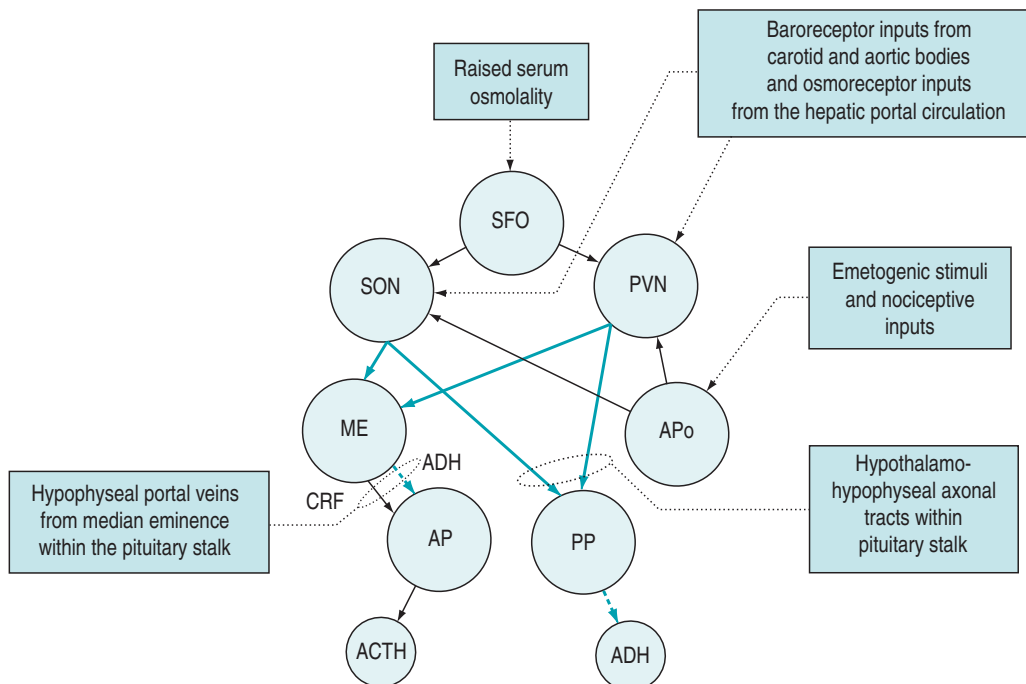

**Table 51.2** Factors influencing antidiuretic hormone (ADH) release

**Increased ADH release with:**

- Hyperosmolality
- Hypovolaemia
- Hypotension
- Hypoxia
- Hypothyroidism
- Hyperthermia
- Positive-pressure ventilation
- Pain
- Emotional stress
- Exercise
- Nausea
- Nicotine
- Trauma/surgery

**Decreased ADH release with:**

- Hypo-osmolality
- Hypervolaemia
- Hypertension
- Ethanol
- Cranial diabetes insipidus

**Figure 51.3** A schematic representation of anatomical and physiological connections of the supraoptic and paraventricular nuclei (SON and PVN), the principal sites of antidiuretic hormone (ADH) synthesis within the hypothalamus. Blue arrows represent the transport of ADH or its precursor between anatomically distinct sites. Baroreceptor inputs into these nuclei travel via the vagus nerve to reach the central nervous system. Whilst the majority of ADH produced in the SON and PVN is transported to the posterior pituitary (PP) for storage, some is transported to the median eminence (ME) then onwards to the anterior pituitary (AP), where it acts synergistically as a secretagogue for adrenocorticotropic hormone (ACTH). APo, area postrema; SFO, subfornical organ; CRF, corticotrophin-releasing factor.

to replace any released stores is a rapid process (1–2 hours from synthesis to storage) and patients with damage to the pituitary can achieve near-normal plasma concentrations of ADH, in terms of osmoregulatory function, via release of newly synthesised ADH via the axons terminating in the median eminence. However, the higher plasma concentrations associated with hypovolaemia cannot be achieved. Normal osmoregulatory plasma ADH concentrations are in the range of 1–8 pg/ml but rise as high as 40 pg/ml in hypovolaemic patients under the influence of the sympathetic nervous system, baroreceptor responses and angiotensin II.

Once released from the pituitary, ADH has a plasma half-life of around 10–35 minutes.<sup>11</sup> It is metabolised by hepatic and renal vasopressinases and around 10% of the active hormone is excreted unchanged in the urine.

#### **ACTIONS OF ADH**

ADH has antidiuretic, vasopressor, haemostatic and ACTH secretagogue actions. Additionally, it has roles in memory, water permeability of the blood–brain barrier, nociception, splenic contraction and thermoregulation. These actions are mediated through  $V_1$ ,  $V_2$  and  $V_3$  receptors. It also has actions on the uterus and mammary tissue mediated through oxytocin receptors. Cardiac inotropic effects are reported to be mediated through purinergic  $P_2$  receptors but this remains controversial.<sup>12</sup>

#### **Antidiuresis**

ADH binds to  $V_2$  receptors on the basal membranes of the principal cells of the collecting duct and distal tubule. The activated receptor induces production of cyclic adenosine monophosphate (cAMP) by adenylate cyclase and this in turn activates protein kinases which effect the integration into the luminal membrane of vesicles containing aquaporin-2 highly selective water channels. The production of prostaglandin  $E_2$  ( $PGE_2$ ) inhibits cAMP production.  $PGE_2$  synthesis is stimulated by the action of ADH on  $V_1$  receptors on the luminal membrane of the collecting duct.<sup>13</sup> Thus, a form of autoregulatory limitation of the antidiuretic effect of ADH may exist. Hypokalaemia, lithium and hypercalcaemia also antagonise the renal actions of ADH.

ADH also increases the urinary concentrating ability of the kidney by increasing the expression of urea transport proteins in the collecting duct and reducing renal medullary blood flow ( $V_1$ -mediated), facilitating an increase in medullary interstitial hypertonicity. This hypertonicity additionally depends upon intact functioning of the ascending loop of Henle where sodium and chloride are reabsorbed without absorption of water at the same time. Interference with this process reduces the osmolal gradient between the collecting duct and the interstitium and reduces water absorption even in the presence of ADH and functioning aquaporin-2.

In low dose, administration of exogenous ADH may paradoxically cause a diuresis in patients with septic shock.<sup>14</sup> Whether this is due to increased renal perfusion pressure and raised glomerular filtration rate (GFR) is unclear.

#### **Vasoconstriction**

At higher concentrations (> 40 pg/ml), ADH activates not only  $V_2$  receptors but also  $V_1$  receptors, through which it causes preferential vasoconstriction in muscle, skin and fat with relative sparing of coronary, cerebral and mesenteric circulations. However, these relative sparing effects are controversial, with some authors reporting relative sparing and others reporting significant vasoconstriction.<sup>15–18</sup> Activation of  $V_1$  receptors activates phospholipase C and increases inositol triphosphate intracellularly. Ultimately this increases intracellular free calcium and leads to smooth-muscle constriction in the blood vessel wall.

In brain-dead organ donors, a failure to produce ADH may result in the development of both hypotension and cranial DI (CDI) with disturbances of osmolality and organ function. Treatment with  $\alpha$ -adrenoreceptor agonists may restore organ perfusion pressure but cause ischaemic damage too. The use of low-dose ADH infusions at 0.5–3 U/h titrated against urine output reduces the need for catecholamine support and also reduces perturbations in plasma osmolality and fluid balance. 1-deamino-8-O-arginine vasopressin (DDAVP) has similar benefits but causes less vasoconstriction. It is preferred for the treatment of CDI associated with brainstem death where hypotension is not a concomitant feature.

#### **Coagulation**

ADH increases circulating levels of tissue plasminogen activator, factor VIII and von Willebrand factor.<sup>19</sup> These effects may be mediated by  $V_2$  receptors but this remains controversial. At high but physiological concentrations it can act as a platelet-aggregating agent.<sup>20,21</sup> Platelet aggregation is mediated through activation of platelet  $V_1$  receptors.<sup>22</sup> ADH and its analogue DDAVP are used as first-line treatments in patients with von Willebrand's disease, and may be used in bleeding associated with renal failure and platelet dysfunction.

#### **ACTH secretion**

ADH transported via the portal venous system between the median eminence and the anterior pituitary acts upon  $V_3$  receptors in the anterior pituitary to stimulate release of ACTH which in turn increases plasma cortisol. The ADH both increases the efficacy of CRF in releasing ACTH and also has independent efficacy in stimulating ACTH release itself. In septic shock, it is possible that ADH insufficiency partially accounts for the relative adrenal insufficiency noted in certain patients. The relative importance and potency of ADH compared with CRF in stimulating ACTH release in humans are unclear.

#### **VOLUME RECEPTORS**

Volume homeostasis takes precedence over sodium homeostasis and so rises and falls in sodium will occur in order to preserve the circulating volume. In euvoelaemic patients sodium homeostasis is maintained. Sodium concentration is detected by both the osmoreceptors of

the subfornical organ outside the blood–brain barrier and also by the juxtaglomerular apparatus which secretes renin in response to reduced GFR and a lower sodium load in the tubule.<sup>23</sup>

The predominant determinants of sodium balance, however, are the high-pressure baroreceptors in the pulmonary veins, left atrium, carotid sinus and aortic arch.<sup>24</sup> Reduced stretch of these receptors increases sympathetic nervous system activity and activation of the renin–angiotensin–aldosterone system, resulting in reduced sodium excretion (via reduced GFR) and increased reabsorption of sodium in the proximal and distal convoluted tubules. Additionally, release of ADH can be stimulated, resulting in concomitant water retention. Conversely, stretch of the baroreceptors will result in a fall in sodium retention through reduced activity of the sympathetic nervous system and renin–angiotensin–aldosterone systems. Stretch additionally results in the release of ANP and a natriuresis through reduced sodium reabsorption in the distal convoluted tubule and collecting duct. ADH release is reduced by the fall in sympathetic nervous tone from the baroreceptors. ADH secretion may also be inhibited by the action of ANP on cerebral osmoreceptors lying outside the blood–brain barrier.<sup>25</sup>

The role of low-pressure baroreceptors in the systemic venous circulation and right atrium is less clearly defined. When venodilatation occurs, as is seen in sepsis, or when there is a reduction in cardiac output, reduced baroreceptor signalling in the high-pressure system will result in both sodium and water retention, as outlined previously. This will expand the extracellular fluid compartment and potentially cause tissue oedema. As sepsis resolves, venous tone is restored, capillary leak reduces, an increase in the loading of the high-pressure baroreceptors results and a natriuresis takes place. Patients may become transiently polyuric as they clear the excess salt and water accumulated whilst shocked. During this physiological diuresis, plasma osmolality remains tightly within the normal range, provided that renal concentrating mechanisms have not been injured during the septic episode or by drug administration.

## CRANIAL DIABETES INSIPIDUS

### CONGENITAL CDI

Congenital CDI is rare and usually inherited as an autosomal-dominant characteristic which results from mutations of the gene encoding an ADH precursor – prepro-vasopressin neurophysin II. The onset of the disease may occur anywhere between 1 year of age and middle adult life and is associated with the final destruction of the ADH-producing cells due to an accumulation of the abnormal ADH precursor. Until the destruction of the SON and PVN cells occurs, ADH secretion (facilitated by expression of the normal gene) and regulation of plasma osmolality are often unaffected.

### ACQUIRED CDI

Acquired CDI may be transient or permanent and can arise due to an absolute (complete) or relative (incomplete) lack of ADH. Complete central DI is usually associated with lesions above the level of the median eminence in the SON or PVN or of the neurohypophyseal stalk whereby the production of ADH in the hypothalamus is terminated.<sup>26</sup> Permanent central DI tends to be associated with transecting, obliterating or chronic inflammatory lesions, whereas transient DI is more likely to be associated with acute inflammatory or oedematous lesions with some recovery of ADH secretion occurring as the inflammation or oedema resolves. An exception to this is the transient DI seen following excision or destruction of the posterior pituitary; ADH produced in the hypothalamus can still be released into the systemic circulation from capillaries in the median eminence.

In the past the majority of acquired non-traumatic CDI was categorised as idiopathic but it has become apparent that the majority of these cases are associated with abnormality of the inferior hypophyseal arterial system<sup>27</sup> or auto-immune reactivity against ADH-producing cells.<sup>28</sup> These findings may indicate causality or association.

When the normal release of ADH into the circulation in response to rising plasma osmolality is reduced or absent, inappropriately high urine volumes are passed and the urine osmolality becomes inappropriately low for the state of water depletion being suffered by the patient. Where ADH is entirely absent from the circulation, over 20 litres of very dilute urine (25–200 mosmol/kg) per day may be produced. If patients are unable to drink freely (most ICU patients) or their thirst mechanisms are impaired, profound dehydration will result very rapidly unless appropriate interventions are made by the physician.

Where ADH deficiency is relative rather than absolute, it is possible for the patient to concentrate the urine partially and values of 500–800 mosmol/kg would not be atypical. However, these osmolalities are inappropriately low relative to the plasma osmolality. In partial ADH deficiency volumes of urine as low as 3 l/day may be evidenced. These are still inappropriately high when assessed in terms of the solute excretion of the patient but are more difficult to recognise as being due to DI as there are many other causes of diureses of this magnitude. Additionally, extrinsic stimulants of ADH release (see Table 51.2) may have an anti-diuretic effect, further complicating the diagnosis.

The plasma osmolality measured in central DI is usually in the higher regions of the normal range or very slightly supranormal. It is remarkably constant in those with free access to water and intact thirst mechanisms as they will drink huge quantities of water to regulate and maintain their water balance. Hyperosmolality or hypernatraemia suggest impaired sensation of thirst or inability to access water (see water deprivation test later) and can also be seen if patients are administered large quantities of isotonic saline or Hartmann's solution to replace their hypotonic urine losses. If unrecognised and untreated, hyperosmolality and hypernatraemia may result in death.

CDI is usually associated with reduced production of ADH or damage to the normal release mechanisms of ADH. However, there can be dysfunction of the osmolality-sensing mechanism at receptor or intracellular signalling levels whilst actual ADH production and storage are normal. It is possible to have a normal release of ADH in response to baroreceptor detection of hypotension but subnormal release in response to hyperosmolality. This has been described in association with chronic hypernatraemia.<sup>29</sup>

The main recognised causes of central DI are listed in Table 51.3. A particularly common cause of DI seen in the ICU is traumatic or postsurgical brain injury.

**Table 51.3** Causes of cranial diabetes insipidus

<b>Acquired</b>
<b>Idiopathic</b>
<b>Autoimmune</b>
<b>Tumours (especially suprasellar, lung, breast, lymphoma and leukaemia)</b>
<b>Surgery (especially transsphenoidal surgery)</b>
<b>Traumatic head injury (strongly associated with base-of-skull fracture*)</b>
<b>Hypoxic brain injury</b>
<b>Brainstem death</b>
<b>Electrolyte disturbance – profound hyponatraemia</b>
<b>Radiotherapy</b>
<b>Drugs – amiodarone, lithium (lithium more likely to cause nephrogenic diabetes insipidus)</b>
<b>Inflammatory/infectious diseases</b>
Sickle-cell disease
Tuberculosis
Abscesses
Encephalitis
Meningitis
Sarcoidosis (may also cause nephrogenic diabetes insipidus)
Wegener's granulomatosis
Histiocytosis X
<b>Vascular disease</b>
Ischaemic or haemorrhagic strokes
Aneurysmal bleeds (especially anterior communicating artery subarachnoid haemorrhage)
Sheehan's syndrome
Pituitary apoplexy
<b>Congenital</b>
Autosomal-dominant mutations of antidiuretic hormone expression (despite the dominant expression of the gene, the onset of clinical diabetes insipidus may take up to 30 years to develop)†
Wolfram syndrome – autosomal-recessive condition characterised by diabetes insipidus, diabetes mellitus, optic atrophy and deafness

\*Doczi T, Tarjanyi J, Kiss J. Syndrome of inappropriate antidiuretic hormone after head injury. *Neurosurgery* 1982; **10**: 685–8.

†Repaske DR, Medlej R, Gulteken EK *et al.* Heterogeneity in clinical manifestation of autosomal dominant neurohypophyseal diabetes insipidus caused by a mutation encoding Ala<sup>1</sup>-Val in the signal peptide of the arginine vasopressin/neurophysin II/copeptin precursor. *J Clin Endocrinol Metab* 1997; **82**: 51–6.

Transsphenoidal surgery for treatment of suprasellar tumours can result in DI in 10–70% of patients; the frequency parallels the magnitude of the tumour being removed. Additionally, transcranial surgery may cause the development of DI in the absence of a fall in plasma ADH. This is postulated to be due to the release of a hypothalamic ADH precursor which acts as a competitive antagonist of both ADH and synthetic analogues. The presence of a competitive antagonist effectively creates an endocrinologic picture similar to NDI with normal or high plasma ADH levels but an inappropriate diuresis of dilute urine.

Following surgery or traumatic brain injury, several different patterns of polyuria can be seen: immediate permanent or transient polyuria, initial normal or low urine production followed by transient or permanent polyuria, or initial low followed by normal urine output. Additionally, a classical triphasic pattern of urine output may be observed with:

1. transient polyuria due to transient impairment of the release of ADH (0–5 days in duration), then
2. a phase of normal or reduced urine output; the ADH previously stored in the pituitary gland is gradually released into the circulation as the cells storing it involute (3–6 days in duration)
3. persistent polyuria as the pituitary stores exhaust and no replacement hormone from the hypothalamus is produced

During the second phase of this pattern, administration of fluids may result in volume overload and hyponatraemia as the ADH release is not under feedback control from osmoreceptors but occurring in an uncontrolled manner as a result of pituitary degeneration. Effectively, there is a transient syndrome of inappropriate ADH (SIADH) secretion. The triphasic pattern is usually associated with sudden severe damage to the hypothalamus or pituitary from trauma, surgery or intracranial bleed, and careful, regular clinical and biochemical assessment is essential to ensure normal water balance and osmolality during this transition from DI to SIADH and back to DI again.

The exact nature of the urinary pattern seen in DI is relatively unimportant and gradual resolution may occur over several months in those with transient DI. What is essential is that meticulous assessments of patients and their plasma and urinary biochemistry as well as fluid inputs and outputs are made to prevent the development of unnecessary fluid and solute imbalances which could lead to worsening morbidity or mortality.

It is important to maintain a high level of suspicion for the development of DI in anyone who is suffering from pituitary disease or who has suffered a pituitary injury as the symptoms may have gradual onset. Anterior pituitary failure can lessen the impact of central DI because of the deficiency of ACTH and cortisol, which reduces GFR and free water loss. Additionally, the loss of feedback inhibition may stimulate increased release of ADH from the

median eminence. Thus in Sheehan's syndrome and pituitary apoplexy, the presenting symptoms tend not to be those of DI with polyuria. However, once corticosteroid therapy is commenced, polyuria indicating DI may become apparent or exacerbated. Conversely, patients with persistent DI of idiopathic origin should have long-term endocrine follow-up as a number will go on to develop tumours of the pituitary several years following the diagnosis of DI.<sup>30,31</sup>

### TREATMENT OF CDI

Four separate problems have to be addressed when treating CDI:

1. Associated anterior pituitary dysfunction needs to be considered.
2. Hypernatraemia must be recognised and treated with painstaking care.
3. Any deficit of total body water must be recognised and addressed (this may be urgent if the patient is shocked).
4. The underlying deficiency of ADH causing the polyuria must be addressed.

In all ICU patients with DI, hourly urine measurements, hourly fluid losses and fluid inputs and at least twice-daily urine and plasma osmolalities are recommended. In shocked patients and those with hypernatraemia, hourly monitoring of plasma sodium is recommended to prevent worsening of hyperosmolality or over-rapid correction of hypernatraemia.

### ANTERIOR PITUITARY DYSFUNCTION

If this is present, it requires recognition and treatment. In the emergent situation with a shocked patient, hydrocortisone 100 mg can be administered as an intravenous bolus, and steroid replacement continued if needed. Steroid administration may worsen the diuresis but will improve cardiovascular stability in patients with pituitary ablation.

### HYPERNATRAEMIA

If the patient with CDI and ongoing water diuresis has had restricted access to fluids and has developed hyperosmolality/hypertonicity or alternatively has developed hypertonicity through replacement of dilute urine with equal volumes of isotonic (to plasma) intravenous fluids, then sudden reduction in plasma tonicity may result in pontine myelonecrosis and permanent neurological damage. When a euvolaemic state is present, AVP or DDAVP may be administered to reduce urine output (see below). At the same time, fluid restriction should be imposed and replacement of the previous hour's urine output undertaken with an appropriate fluid to avoid a fall in concentration of sodium by more than 0.5 mmol/h.<sup>32</sup> Absolute safety data are not available to determine the ideal rate of reduction of plasma sodium. However, a fall of more than 5 mmol/l in any 24-hour period should be avoided.

### DEHYDRATION AND HYPOVOLAEMIA

If associated with shock, hypovolaemia requires rapid resuscitation. If hypovolaemia is also associated with hypernatraemia, extreme caution is required in the resuscitation, which should take place with isotonic saline solution and frequent reassessments of plasma sodium and cardiovascular and neurological status. Where the hypernatraemia is very marked (>155 mmol/l), consideration of a combination of isotonic (0.9%) and hypertonic saline should be given to reduce the rate of sodium reduction. In the face of hypertonicity of the plasma, cells reduce their chloride and potassium conductance and synthesise intracellular osmolytes such as amino acids, taurine and sorbitol. If 0.9% saline (effective osmolality 290 mosmol/kg when diluted by plasma proteins) is infused rapidly into hypertonic plasma with a sodium of 160 mmol/l, an effective osmolality of 330 mosmol/kg, a rapid drop in plasma osmolality may cause cerebral and other organ oedema; seizures and death. By reducing the tonicity of the plasma gradually, the cells have time to downregulate their synthesis of intracellular osmolytes and increase potassium and chloride conductance to reduce swelling as plasma tonicity falls.

### CORRECTION OF POLYURIA AND ADH DEFICIENCY

At mild levels of polyuria (2–3 ml/kg per hour) where there is an expectation that the condition may resolve, it may be appropriate merely to replace the previous hour's urine output with an appropriate fluid (usually 5% dextrose or 0.18% saline/4% dextrose) whilst undertaking regular measurements of plasma and urine osmolality and electrolytes. Care must be taken not to give so much dextrose as to result in hyperglycaemia, hyperosmolality and osmotic diuresis.

Where polyuria is expected to be persistent or is excessive, either ADH or its synthetic analogue DDAVP may be administered. DDAVP is a selective V<sub>2</sub> receptor agonist and thus is less likely to cause hypertension. It is also longer-acting, resisting breakdown by vasopressinases, and is usually administered once or twice daily. The usual daily dose rate, when administered intravenously, intramuscularly or subcutaneously, is 1–4 µg daily. ADH may be administered subcutaneously or by intravenous infusion and DDAVP may be presented intranasally, subcutaneously, intravenously or orally. In the acute situation, an ADH infusion (0.1–3 U/h) can be conveniently titrated against urine output. The use of the infusion ensures 100% bioavailability and facilitates re-establishment of the hypertonic renal medullary interstitium before changing the patient to the longer-acting DDAVP. The dose of ADH or DDAVP is often higher during the acute-onset phase of CDI – this may be due to the loss of hypertonicity in the medullary interstitium or due to biologically inactive ADH precursors released from the damaged hypothalamic–pituitary tract which act as competitive antagonists at the V<sub>2</sub> renal receptors.

The dose of ADH or DDAVP used is the minimum dose required to control urine output to an acceptable

rate. Excessive administration can result in water retention and the development of hypo-osmolal syndromes.

Other drugs may also be used to reduce the polyuria of CDI. Provided there is some residual ADH synthesis, chlorpropamide, clofibrate and carbamazepine are all reported to enhance ADH release and also increase the renal responsiveness to ADH. Thiazide diuretics can also be used effectively. Whilst these agents all reduce urine output, there is little place for them in the modern management of CDI in the ICU where DDAVP and ADH have excellent safety profiles and are more easily titrated to effect. These alternative drugs are discussed later in the treatment of NDI.

## NEPHROGENIC DIABETES INSIPIDUS

NDI may be congenital or acquired (Table 51.4). As the majority of congenital cases present in the first week of life, the majority of cases seen in the adult ICU are acquired. The commonest of these are lithium toxicity due to long-term drug treatment, hypercalcaemia and postobstructive uropathy following relief of ureteric or urethral obstruction.

### CONGENITAL NDI

Some 80–90% of patients with congenital NDI have an X-linked recessive abnormality of the *AVPR<sub>2</sub>* gene coding for the V<sub>2</sub> receptor. Different mutations of the gene are described but the majority result in trapping of the V<sub>2</sub> receptor intracellularly, unable to integrate into the membrane of the collecting duct cell. Drugs have been developed which can facilitate receptor integration into the membrane, restoring some of the urine-concentrating abilities of ADH.<sup>33</sup> The sex linkage results in the vast

majority of affected patients being male. However, female children can also present less severe polyuria and polydipsia due to expression of the abnormal gene.

Non-sex-linked genetic abnormalities can also cause NDI. Approximately 10% of cases of congenital NDI have mutations of the *AQP<sub>2</sub>* (aquaporin 2) gene which codes for the AQP<sub>2</sub> channel. Over 40 mutations, both autosomal-dominant and recessive, have been described to date.

The remainder of cases of congenital NDI have a variety of pathologies which result in failure to generate a hypertonic renal medulla, with inability to reabsorb water even if the V<sub>2</sub> receptor and aquaporin<sub>2</sub> channels are normal.

A lack of the Kidd antigen (a blood group antigen) results in an inability to concentrate urine to more than 800 mosmol/kg even with water deprivation and exogenous ADH administration. This is because the antigen is also expressed in the collecting duct epithelium where it functions as a urea transporter (urea transport B protein) and facilitates movement of urea from urine into the medullary interstitium maintaining some of the gradients required to facilitate water reabsorption. Similarly, patients with mutations in chloride channel genes, potassium channel genes or the sodium–potassium–chloride co-transporter gene resulting in the Bartter syndrome are unable to generate a hypertonic medullary interstitium. However, in these patients the defect is more marked and urine can rarely be concentrated above 350 mosmol/kg.

With congenital NDI, early diagnosis and management are essential as avoidance of hypernatraemia and dehydration facilitates the achievement of normal developmental milestones and avoids the cerebral damage once commonly accepted as an inevitable association of NDI.

### ACQUIRED NDI

Lithium-associated nephrotoxicity remains the commonest form of acquired NDI with more than 20% of patients on chronic lithium therapy developing polyuria. Lithium is taken up into the principal cells of the collecting duct via sodium channels and inhibits intracellular adenylate cyclase antagonising the effects of ADH. Additionally, it reduces the medullary interstitial hypertonicity, possibly through reducing expression of urea transport protein B. If patients with early lithium-related NDI are prescribed amiloride, some reversal of both the polyuria and lithium-mediated toxicity is possible. Amiloride's natriuretic action is achieved through closure of the luminal sodium channels in the collecting duct; the sodium channels through which lithium enters the cells.<sup>34</sup> Indomethacin increases intracellular cAMP and counteracts the diminution of this and AQP<sub>2</sub> caused by lithium, resulting in a marked and immediate drop in urine output. However, care is required as non-steroidal anti-inflammatory drugs (NSAIDs) may worsen renal failure, reducing GFR and lithium excretion, thereby worsening toxicity.

Hypercalcaemia, hypokalaemia, release of ureteric or urethral obstruction and hypoproteinaemia are also recognised

**Table 51.4** Causes of Nephrogenic DI

<b>Acquired</b>	
(i)	lithium toxicity
(ii)	post-obstructive diuresis
(iii)	hypercalcaemia
(iv)	hypokalaemia
(v)	hypoproteinaemia
(vi)	Sjogren's syndrome
(vii)	Amyloid
(viii)	sickle cell disease
(ix)	poly-cystic kidney disease
(x)	other drugs: amiodarone, amphotericin B, clozapine, demeclocycline, foscarnet, gentamicin, loop diuretics, rifampicin
<b>Congenital</b>	
(i)	x-linked recessive – <i>AVPR<sub>2</sub></i> gene mutations
(ii)	autosomal recessive or dominant – <i>AQP<sub>2</sub></i> gene mutations
(iii)	Bartter's syndrome
(iv)	Gitelman's syndrome
(v)	Urea Transport Protein B (Kidd Ag) deficiency/absence

as causing NDI and are associated with reduced expression of AQP<sub>2</sub> channels, urea transport proteins and a loss of interstitial hypertonicity. These defects normally cause milder polyuria than that associated with lithium toxicity.

### TREATMENT OF NDI

The treatment of NDI aims to minimise the occurrence of hypernatraemia and hypovolaemia and wherever possible to remove the underlying cause.

1. Correct reversible causes:
  - (a) Stop any drugs suspected in the aetiology.
  - (b) Correct hypokalaemia, hypercalcaemia and hypoproteinaemia.
2. Reduce solute load. As urine output is determined by the solute load to be excreted, reducing the solute intake will reduce the urine volume accordingly; if maximum urine concentration is 250 mosmol/kg, a solute intake of 750 mosmol/day requires production of at least 3 litres of urine to clear the solute whereas if intake is reduced to 500 mmol, 2 litres of urine will suffice. In ICU, the reduction of solute can be difficult as many drugs and diluents have a high solute load. Additionally, patients may be catabolic and have a high protein requirement. It may be more appropriate not to aim to restrict solute intake for certain patients but to closely monitor fluid balance and ensure adequate appropriate replacement.
  - (a) Regulate salt intake (aiming at < 100 mmol/day).
  - (b) Reduce protein intake, aiming to provide the minimum daily requirement including essential amino acids – this should be done with specialist dietetic advice and requires careful follow-up to avoid protein malnutrition. It is not appropriate to protein-restrict children as this may adversely affect normal growth and development.
3. Diuretics – thiazides and amiloride:
  - (a) Thiazides – whereas DI loses water in excess to solute, rendering the plasma hyperosmolar and resulting in intracellular dehydration to maintain the intravascular volume, thiazide diuretics cause solute loss in excess of water and lead to a drop in intravascular volume. This causes activation of the sympathetic nervous system, the renin–angiotensin–aldosterone system and a fall in glomerular filtration and ANP. Additionally, thiazides are associated with an increased expression of AQP<sub>2</sub> channels in the collecting duct.<sup>35</sup> There is an increase in proximal tubular reabsorption of sodium and water and an increase in ADH release. Thus, less ultrafiltrate reaches the collecting duct and urine volume can fall by as much as 30%. Combined with a solute-reduced diet, the fall in urine production can be as high as 50%.
    - (b) Amiloride – this is a useful adjunct to thiazide diuretics in NDI where it causes a further slight reduction in urine output and combats the hypokalaemia associated with the thiazides. It may have benefit in its own right in lithium-associated nephrotoxicity, where it blocks the sodium channels through which lithium enters the principal cells. If administered before lithium damage becomes irreversible, it can both reduce the damage to the cells themselves and reverse the antagonism of lithium on the effects of ADH.
4. ADH. Where NDI is not absolute (most cases of acquired NDI), supplementing endogenous ADH to create supraphysiological concentrations in the plasma can result in a fall of urine production by up to 25%. This effect may occur by antagonising the effects of any V<sub>2</sub> receptor antagonists or by causing greater receptor occupation. Care is required with long-term use as hypertension and its associated complications may result.
5. NSAIDs. NSAIDs reduce the formation of renal PGE<sub>2</sub> which increases GFR and urine flow and decreases intracellular cAMP and thus aquaporin expression. Reduction of PGE<sub>2</sub> using NSAIDs alone may reduce urine output by up to 50%.<sup>36</sup> Combination with low-solute diet and a thiazide diuretic may provide additional antidiuretic benefit.<sup>37</sup> However, the use of NSAIDs has to be weighed against their long-term complications. This is particularly true in the ICU population who are at increased risk of both renal impairment and gastric erosions. Indomethacin is cited to have greater treatment benefit than other NSAIDs in NDI.<sup>38</sup> It is also more likely to produce unwanted adverse effects.
6. Chlorpropamide. This oral hypoglycaemic agent enhances both ADH release and the sensitivity of the kidney to it. It is suggested to act via increasing the hypertonicity of the renal medulla. Doses of 250 mg od or bd are prescribed but are likely to cause hypoglycaemia.<sup>39</sup> Its use is therefore reserved for severe refractory cases of partial NDI.
7. Clofibrate. This oral lipid-lowering agent is reported to enhance ADH release and increase renal sensitivity to ADH.<sup>40</sup> Its use in CDI has largely stopped because of the efficacy and safety of DDAVP. Its use in treatment of DI has been associated with myopathy.<sup>41</sup> If considered for treatment of partial NDI, biochemical markers of myopathy should be measured regularly.
8. Carbamazepine. Carbamazepine can also be tried as a treatment in partial NDI, although it is more effective in treating partial CDI. It increases the renal responsiveness to ADH but requires a dose rate three times higher than that effective as an antiepileptic. This high dose rate limits its usefulness in therapy.

9. Molecular chaperones. Novel drugs described as ‘molecular chaperones’ are being developed to treat NDI where the  $V_2$  receptor is functional and intact but confined to the intracellular space, unable to integrate into the basolateral membrane of the principal cell. The drugs are membrane-permeable  $V_2$  receptor antagonists and are believed to cause refolding of the receptor in a form that allows normal processing of the receptor into the membrane.<sup>42</sup> These are showing some success in animal models of congenital NDI and with human  $V_2R$  mutations associated with NDI in *in vitro* testing. Early studies in humans report some success.<sup>43</sup>

#### GESTATIONAL DIABETES INSPIDUS (TABLE 51.5)

In pregnancy the normal range of plasma osmolalities falls to 265–285 mosmol/kg and the plasma sodium is < 140 mmol/l. The reduction in osmolality is attributed to a resetting of the central osmostat.<sup>44,45</sup> The retention of water and sodium is mediated by reduced baroreceptor stimulation.<sup>46</sup> During pregnancy, the placenta produces vasopressinases, which increase ADH metabolism up to fourfold, and relaxin, which contributes to the 50% increase in GFR and venodilatation.<sup>47</sup> Aldosterone concentrations rise up to fivefold. Solute elimination also rises so a small reduction in urine-concentrating ability may have a more marked effect. The volume of urine passed per day increases as a result of passage of an increased solute load (including urinary proteins, glucose and amino acids), increased drinking and a raised GFR. A diagnosis of DI therefore requires careful differentiation from a physiological polyuria or potentially pathological polyuria of separate aetiology (e.g. gestational diabetes) in pregnancy.

GDI can result from:

1. Increased destruction of ADH by excessive production of placental vasopressinases.<sup>48</sup> This may be unresponsive to exogenous ADH administration as it too is rapidly metabolised. DDAVP can be used instead as it is resistant to degradation by placental vasopressinase.
2. Permanently deficient reserve of ADH secretion, which in the non-pregnant state is asymptomatic but which in the pregnant state is unmasked by the higher vasopressinase activity which cannot be compensated for by increased secretion.<sup>49</sup> This condition responds to treatment with ADH.
3. Central DI associated with acute fatty liver of pregnancy,<sup>50</sup> Sheehan’s syndrome and pituitary apoplexy.

**Table 51.5** Causes of Gestational DI

- |   |
|---|
| (i) Sheehan’s Syndrome                                |
| (ii) Pituitary Apoplexy                               |
| (iii) Acute fatty liver of pregnancy                  |
| (iv) Vasopressinase release by placenta               |
| (v) Idiopathic gestational NDI (resolves post-partum) |

Sheehan’s syndrome is commonest, and is usually preceded by major bleeding or hypotension at the time of delivery. Pituitary apoplexy has been described antenatally too.<sup>51</sup>

4. Gestational NDI of unknown aetiology, which is resistant to both ADH and DDAVP, with resolution in the postnatal period, has also been described.<sup>52</sup>

The treatment of GDI varies depending on the underlying cause. In all cases, it is important not to allow the patient to become hypernatraemic and hyperosmolal as this is likely to have adverse effects on both mother and child. Where hypernatraemia and hyperosmolality do occur, careful correction is required in a closely monitored, very gradual, stepwise fashion. A lowering of sodium by as little as 10 mmol/day has been associated with pontine myelinolysis.<sup>53</sup>

#### POLYDIPSIA (PSYCHOGENIC/NEUROGENIC)

Polydipsia may result from:

1. a psychiatric disorder or disturbance<sup>54</sup>
2. drugs which give the sensation of dry mouth<sup>55</sup> or airways, e.g. oxygen therapy, phenothiazines, anticholinergics
3. hypothalamic lesions which directly disturb the thirst centre,<sup>56</sup> e.g. sarcoidosis

In all three of the above causes of polydipsia, excessive drinking is associated with the production of large quantities of urine of appropriate osmolality. If the fluid ingested is largely hypotonic, the urine will be hypo-osmolal and result from a fall in ADH secretion. If the fluid ingested is hypertonic, the urine will have high osmolality but remain of high volume because of the interplay of ADH production (determined by osmoreceptors and volume receptors) and ANP production (determined by volume receptors) resulting in a solute diuresis.

Polydipsia may also result from the appropriate detection by osmoreceptors of a raised plasma osmolality due to raised glucose or sodium. The glycosuria itself will cause an osmotic diuresis and plasma osmolality may be normal or raised depending on the severity of the hyperglycaemia and any accompanying ketoacidosis and dehydration.

#### SOLUTE DIURESIS

Just as failure to reabsorb water can result in polyuria, failure to reabsorb solute can result in an osmotic load in the tubule which opposes water absorption in the convoluted tubules and collecting duct. The commonest cause of this in the general patient population is glycosuria. In the ICU setting a solute diuresis may also be associated with the administration of diuretic drugs, high-protein feeds (increased urea load), supranormal quantities of sodium and other solutes through fluids, feeds and drugs, recovery from acute renal failure with

tubular inability to reabsorb solute, and drug-induced tubular damage.

To differentiate a solute diuresis from a water diuresis it is advisable to measure the 24-hour excretion of solute in the urine. Normally, between 600 and 900 mosmol/day of solute is excreted in the urine. Values higher than this indicate a solute diuresis. A spot urine osmolality may be measured; osmolality higher than 300 mosmol/kg, is suggestive of a solute diuresis. It would not be uncommon in the critically ill patient to encounter simultaneous impairment of both water reabsorption and impaired solute handling in the nephron. In this instance, 24-hour solute excretion may be increased but the urine may remain hypo-osmolal.

### THE DIAGNOSIS OF POLYURIC SYNDROMES

#### MEASURE AND CALCULATE PLASMA OSMOLALITY AND URINE OSMOLALITY

A high urine osmolality in the presence of a high plasma osmolality is appropriate and, if the plasma osmolality is higher than 295 mosmol/l, urine osmolality should reach 1000–1200 mosmol/kg. Urine osmolalities of less than this imply that there is a urine-concentrating defect and lead to consideration of the causes of DI and also the use of medications that might reduce renal interstitial hypertonicity, such as loop diuretics. Urine osmolalities of < 150 mosmol/kg in this circumstance are sufficient to make the diagnosis of DI provided there is not obvious gross fluid and solute overload of the patient.

Where the patient is polyuric with a high plasma osmolality and maximum urine osmolalities are being achieved, an osmotic diuresis is implied. The diuresis may be inappropriate in as much as it is leading to dehydration but appropriate in that the kidneys are retaining as much water as they can for the large solute load being excreted. If there is a normal *osmolal gap* (the difference between measured and calculated plasma osmolality, normal < 10 mosmol/kg), then hyperglycaemia, hypernatraemia or hyperkalaemia is implied. If the osmolal gap is greater than 10 mosmol/kg, investigation should be undertaken to look for an unmeasured solute such as ethanol, mannitol, ethylene glycol, sorbitol or methanol.

If plasma osmolality is less than 280 mosmol/kg, urine osmolality would also be expected to be lower than this as the body attempts to clear free water. This picture implies water overload which may be iatrogenic or patient-mediated. Low plasma osmolality with high urine osmolality implies SIADH and would not normally be associated with polyuria.

#### WATER DEPRIVATION AND ADH TESTS

In health, being deprived of water rapidly results in an increase in plasma osmolality which causes ADH release and an increase in urine osmolality to between 1000

and 1200 mosmol/kg in order to preserve water and reduce plasma osmolality back towards its normal value. When the cause of polyuria is unclear and the patient is not already clinically dehydrated, a water deprivation test may be useful to determine the cause of the diuresis. In patients with severe polyuria, the test is potentially dangerous as dehydration and hyperosmolality can develop very rapidly, resulting in permanent cerebral damage and cardiovascular collapse. It is therefore wise to undertake the test under very close supervision during daylight hours.

The limitations of the test should also be appreciated:

1. In acute CDI, release of ADH precursors from injured brain tissue may render interpretation of ADH tests unreliable and cross-react with ADH measurement assays.
2. At high concentrations of ADH, the urine concentrations achieved in partial NDI and primary polydipsia may be similar.
3. Patients with partial CDI may occasionally become hypersensitive to relatively small rises in ADH which may be induced by the rise in osmolality associated with water deprivation and thus maximally concentrate urine once osmolality is raised, leading to an erroneous diagnosis of primary polydipsia.<sup>57</sup>
4. In patients with chronic hypernatraemia and CDI secondary to osmoreceptor dysfunction, hypovolaemia with water deprivation may cause sufficient baroreceptor stimulus to release ADH and suggest normal urine-concentrating abilities.<sup>58</sup>

Step 1: Plasma and urine osmolalities and plasma ADH are measured at time zero and access to intravenous/oral fluids is denied.

Step 2: Plasma and urine osmolalities are measured hourly until either three consecutive urine osmolalities are within 50 mosmol/kg of one another or plasma osmolality is > 295 mosmol/kg. At this time, plasma ADH is measured again.

Step 3: If plasma osmolality is > 295 mosmol/kg and urine osmolality is < 1000 mosmol/kg, ADH (5 units AVP subcutaneously or 4 µg DDAVP subcutaneously) is administered to the patient and urine osmolality is measured hourly for 3 hours (this time is necessary to allow time for at least partial recovery of the medullary interstitial hypertonic gradient in patients with primary polydipsia).

[DDAVP is preferred to AVP as it avoids misinterpretation of results in the presence of vasopressinases which would rapidly metabolise AVP and suggest a diagnosis of NDI rather than CDI. Although neither is the correct diagnosis if vasopressinases are present, the treatment is as for CDI, i.e. the administration of DDAVP.]

Step 4: Urine osmolality is then plotted against plasma osmolality (Figure 51.4).

Step 5: Plasma and urine osmolalities are plotted against plasma ADH concentrations (Figure 51.5).

**Figure 51.4** Urine versus plasma osmolality during water deprivation testing. DDAVP, 1-deamino-8-O-arginine vasopressin; CDI, cranial diabetes insipidus; NDI, nephrogenic diabetes insipidus. Adapted from Sands JM, Bichet DG. *Ann Intern Med* 2006; 144: 186–94.

### INTERPRETATION OF THE TESTS (SEE FIGURES 51.4 AND 51.5)

In complete DI, plasma osmolality will rise but urine osmolality will not rise above 300 mosmol/kg. Upon administration of ADH, patients with complete CDI will raise their urine osmolality to 500 mosmol/kg or higher whereas there will be no rise in urine osmolality in complete NDI.

In complete CDI, the original plasma ADH measurement will be zero, whereas in complete NDI, the initial ADH measurement will be normal or high depending on the corresponding plasma osmolality at the time of measurement.

In partial DI, plasma osmolality will rise and urine osmolality will also increase but usually plateaus between 400 and 800 mosmol/kg. In partial CDI the ADH will initially be normal or low and will rise with increasing plasma osmolality but is unlikely to rise above 4–5 pg/ml. In partial NDI, the ADH will initially be normal or high and will increase with plasma osmolality to > 8 pg/ml but without achieving a correspondingly appropriate rise in urine concentration.

Following administration of ADH or DDAVP, urine osmolality is expected to double at least in complete CDI and rise by 10–50% in partial CDI or NDI. In complete NDI, there will be no rise in urine osmolality. Partial CDI may be inferentially differentiated from partial NDI on the basis of urine osmolality alone; in the former, urine osmolality rises above plasma osmolality whereas in partial NDI it tends to remain hypo-osmolal or iso-osmolal to

**Figure 51.5** (a) As plasma osmolality increases as a result of water deprivation or hypertonic saline infusion, the measured concentration of antidiuretic hormone (ADH) should rise. Failure to do so suggests cranial diabetes insipidus. (b) At a given value of plasma ADH, whether endogenous or exogenous in origin, urine osmolality is expected to lie within a corresponding range of osmolality. However, the range of expected osmolalities is high as osmoreceptors adjust regulation around the basal level of ADH, which is also partly determined by volume receptors. In nephrogenic diabetes insipidus (NDI), the urine osmolality remains low even when high plasma ADH concentrations are measured.

plasma following ADH/DDAVP administration. However, this generalisation is indicative only and for greater certainty, it is preferred to have measured sequential ADH concentrations to assess hypothalamic–pituitary function independently of the renal concentrating ability.

Water deprivation tests should not be conducted in infants or patients with pre-existing hypovolaemia or

hyperosmolality. In the latter two categories, treatment of the fluid deficit and/or solute excess should precede further investigations. In infants and in adults with equivocal water deprivation test results, an infusion of hypertonic saline should be considered.

### HYPERTONIC SALINE INFUSION

In patients with equivocal results from a water deprivation test and in those at high risk of dehydration and hypovolaemia from water deprivation, a hypertonic saline infusion test may be undertaken to establish the cause of a water diuresis. Interpretation of the test is as for the water deprivation test but there is a clearer demarcation between partial CDI and primary polydipsia and the risk of missing a diagnosis of CDI secondary to osmoreceptor dysfunction is reduced.<sup>59</sup>

Hypertonic saline is available in multiple different concentrations. Care is required in calculating the appropriate infusion rate to use for the test as this varies with the concentration of the hypertonic preparation stocked. Hypertonic sodium chloride solution (0.0425 mmol/kg per min) is infused for up to 3 hours or until a plasma osmolality of 300 mosmol/kg is achieved.

Blood samples are taken 30 minutes before and at 30-minute intervals throughout the duration of the test and plasma sodium, osmolality and ADH are measured. Urine samples are collected before and where possible at 60-minute intervals throughout the test period and measurements of osmolality and sodium are performed. Thirst and blood pressure are recorded at 30-minute intervals.

# Thyroid emergencies

Jonathan Handy

Thyroid emergencies are a rare cause for admission to critical care. However, mortality is high unless specific treatment is provided in an expeditious manner. Abnormal thyroid function tests are commonly encountered during critical illness; numerous factors must be considered before interpreting these findings as indicating thyroid disease.

## BASIC PHYSIOLOGY

Thyroid hormones affect the function of virtually every organ system and must be constantly available for these functions to continue. The two biologically active hormones are tetraiodothyronine (thyroxine or  $T_4$ ) and triiodothyronine ( $T_3$ ). These are synthesised by incorporating iodine into tyrosine residues, a process which occurs in thyroglobulin contained within the lumina of the thyroid gland. Stimulation of hormone release by thyroid-stimulating hormone (TSH) results in endocytosis of thyroglobulin from the lumen into the follicular cells, followed by hydrolysis to form  $T_4$  and  $T_3$ , which are released into the circulation.<sup>1</sup>

Both  $T_4$  and  $T_3$  contain two iodine atoms on their inner (tyrosine) ring. They differ in that  $T_4$  contains two further iodine atoms on its outer (phenol) ring, whereas  $T_3$  contains only one.  $T_4$  is produced solely by the thyroid gland whereas the majority of  $T_3$  is synthesised peripherally by the removal of one iodine atom (deiodination) from the outer ring of  $T_4$ . If deiodination of an inner-ring iodine atoms occurs, the metabolically inert reverse- $T_3$  ( $rT_3$ ) is formed. This is produced in preference to  $T_3$  during starvation and many non-thyroidal illnesses, and the ratio of inactive ( $rT_3$ ) to active  $T_3$  synthesis appears to play an important role in the control of metabolism.<sup>2</sup> Numerous factors can affect the peripheral deiodination process (Table 52.1). Both  $T_4$  and  $T_3$  are highly protein-bound in the serum, predominantly to thyroid-binding globulin (TBG), but to a lesser extent to albumin and prealbumin. Changes in concentration of these serum-binding proteins have a large effect on total  $T_4$  and  $T_3$  serum concentrations. Such protein changes do not, however, affect the concentration of free hormone or their rates of metabolism. The serum-binding

proteins act as both a store and a buffer to allow an immediate supply of the metabolically active free  $T_4$  ( $fT_4$ ) and free  $T_3$  ( $fT_3$ ). In addition, protein binding reduces the glomerular filtration and renal excretion of the hormones.

On reaching the target organs,  $fT_4$  and  $fT_3$  enter the cells predominantly by diffusion. Here, microsomal enzymes deiodinate the  $fT_4$  to form  $fT_3$ . This varies in differing tissues, the majority occurring in the liver, kidneys and muscles. The  $fT_3$  subsequently diffuses into the nucleus where it binds nuclear receptors and exerts its effect through stimulation of messenger RNA (mRNA) with subsequent synthesis of polypeptides, including hormones and enzymes. The role of thyroid hormones in development and homeostasis is widespread and profound: the most obvious effects are to stimulate basal metabolic rate and sensitivity of the cardiovascular and nervous systems to catecholamines.

The regulation of thyroid function is predominantly determined by three main mechanisms, the latter two providing physiological control. Firstly, availability of iodine is crucial for the synthesis of the thyroid hormones. Dietary iodide is absorbed and rapidly distributed in the extracellular fluid, which also contains iodide released from the thyroid gland and from peripheral deiodination processes. This becomes trapped within thyroid follicular cells, from which it is actively transported into the lumen to be oxidised into iodine and subsequently combined with tyrosine.<sup>3</sup> Other ions, such as perchlorate and pertechnetate, share this follicular cell active transport mechanism, acting as competitive inhibitors for the process.

Secondly, thyroid hormone release is controlled by a closed feedback loop with the anterior pituitary. Diminished levels of circulating hormones trigger secretion of TSH which acts on the follicular cells of the thyroid gland, causing them to release thyroglobulin-rich colloid from the lumen, which is hydrolysed to form  $T_4$  and  $T_3$  for systemic release. Increased levels of  $T_4$  and  $T_3$  cause diminished TSH secretion, resulting in the follicular cells becoming flat and allowing increased capacity for colloid storage. As a result, less thyroglobulin is mobilised and hydrolysed with less  $T_4$  and  $T_3$  release. The degree to which TSH is secreted in response to changes in circulating thyroid hormones is dependent on the hypothalamic

**Table 52.1** States associated with decreased deiodination of thyroxine to triiodothyronine

- Radiographic contrast agents (ipodate, ipanoate)

hormone thyrotrophin-releasing hormone (TRH), which is itself modulated by feedback from the thyroid hormones. TRH secretion is inhibited by dopamine, glucocorticoids and somatostatin.

Lastly, further regulation occurs during the enzyme-dependent peripheral conversion of  $fT_4$  to  $fT_3$ . It is this latter stage that provides the rapid and fine control of local  $fT_3$  availability. All of these mechanisms may be altered by drugs, and in pathological states.

### THYROID CRISIS (THYROID STORM)

Thyrotoxic storm is arguably the most serious complication of hyperthyroidism, with reported mortality ranging from 10 to 75% in hospitalised patients.<sup>4,5</sup> Crisis most commonly occurs as a result of unrecognised or poorly controlled Graves disease; however, other underlying diseases may be the cause.<sup>6,7</sup> Females outnumber males. Laboratory findings are inconsistent due to acute disruption of the normal steady state of the circulating hormones, and there is no definitive value that separates thyrotoxicosis from thyroid storm. The latter is a clinical diagnosis and a scoring system has been proposed to guide the likelihood of the diagnosis (Figure 52.1).<sup>8</sup> Precipitating factors are not always present, though many have been identified (Table 52.2).

### CLINICAL PRESENTATION (TABLE 52.3)

The classic signs of thyroid crisis include fever, tachycardia, tremor, diarrhoea, nausea and vomiting.<sup>9</sup> However presentation is extremely variable and may range from apathetic hyperthyroidism (apathy, depression, hyporeflexia and myopathy)<sup>10</sup> to multiple-organ dysfunction.<sup>11,12</sup> Differential diagnosis includes sepsis and other causes of hyperpyrexia such as adrenergic and anticholinergic syndromes.

#### FEVER

This is the most characteristic feature. Temperature may rise above 41°C. There have been suggestions that pyrexia is present in all cases of thyroid storm,<sup>13</sup> though normothermia has been reported.<sup>11</sup> Pyrexia is rare in

uncomplicated thyrotoxicosis and should always raise suspicion of thyroid storm. It is not clear whether this febrile response is due to alteration of central thermoregulation or elevation of basal metabolic thermogenesis beyond the body's ability to lose heat.

#### CARDIOVASCULAR FEATURES

Fluid requirements may be substantial in some patients, whereas diuresis may be required in those with severe cardiac congestion. Cardiac decompensation can occur in young patients with no known antecedent cardiac disease. Systolic hypertension with widened pulse pressure is common initially; however hypotension supervenes later. Cardiogenic shock with vascular collapse is a preterminal sign.<sup>14</sup> Arrhythmias are common and include atrial and polymorphic ventricular tachycardias. The latter may result from prolonged QTc interval, the presence of which may complicate and contraindicate the use of amiodarone therapy.

#### NEUROMUSCULAR FEATURES

Tremor is a common early sign, but as 'storm' progresses, central nervous dysfunction evolves with progression to encephalopathy or even coma.<sup>15</sup> Thyroid storm has been reported in association with status epilepticus and cerebrovascular accident.<sup>16</sup> Weakness may be a feature, particularly with apathetic thyrotoxicosis.<sup>10</sup> Thyrotoxic myopathy and rhabdomyolysis may be present,<sup>11,17</sup> the latter being differentiated from the former by its association with markedly elevated creatine phosphokinase levels. A number of other syndromes of neuromuscular weakness have been described, including hypokalaemic periodic paralysis<sup>18</sup> and myasthenia gravis.<sup>19</sup>

#### GASTROINTESTINAL FEATURES

Diarrhoea, nausea and vomiting are common, though the patient may present with symptoms of an acute abdomen.<sup>20</sup> Severe abdominal tenderness should raise the possibility of an abdominal emergency. Liver function tests may be abnormal due to congestion or necrosis and tenderness over the hepatic area may be present. Hepatosplenomegaly may be present. The presence of jaundice is a poor prognostic sign.<sup>14</sup>

#### RESPIRATORY CONSIDERATIONS

Dyspnoea at rest or on exertion may be present for a number of reasons. Oxygen consumption and carbon dioxide production are increased with subsequent increase in the respiratory burden. This may be exacerbated by pulmonary oedema, respiratory muscle weakness and tracheal obstruction from enlarged goitre (rare).

#### LABORATORY FINDINGS

Numerous abnormalities may be found:

- $fT_4$  and  $fT_3$  are usually increased, though this does not correlate with clinical severity: TSH is undetectable

Temperature (°C)	Pulse	Cardiac failure	CNS effects	GI symptoms	Score
Normal	<99	Absent	Normal	Normal	0
37.2–37.7	99–109	Pedal oedema	-	-	5
37.8–38.2	110–119	Bibasal crepitations Atrial fibrillation	Agitation	Diarrhoea Nausea Vomiting Abdominal pain	10
38.3–38.8	120–129	Pulmonary oedema	-	-	15
38.9–39.3	130–139	-	Delirium	Unexplained jauntice	20
39.4–39.9	>140	-	-	-	25
>40	-	-	Seizure Coma	-	30

**Calculations:**

- Add the scores for each of the five clinically observed parameters
- Add a further 10 points if atrial fibrillation is present
- Add a further 10 points if an identifiable precipitating factor is present
- Total score of 45 or greater is highly suggestive of thyroid storm
- Total score of 25–44 supports impending crisis
- Total score of less than 25 makes thyroid storm unlikely

**Figure 52.1** Severity assessment in thyroid crisis. CNS, central nervous system; GI, gastrointestinal. (Adapted from Tewari K, Balderston KD, Carpenter SE *et al.* Papillary thyroid carcinoma manifesting as thyroid storm of pregnancy: case report. *Am J Obstet Gynecol* 1998; **179**: 818–19.)

- hyperglycaemia in non-diabetics
- leukocytosis with a left shift, even in the absence of infection (leukopenia may be present in patients with Graves disease)
- abnormal liver function tests and hyperbilirubinaemia
- hypercalcaemia due to haemoconcentration and the effect of thyroid hormones on bone resorption
- hypokalaemia and hypomagnesaemia (particularly in apathetic thyrotoxicosis)
- serum cortisol should be elevated. If low values are found, adrenal insufficiency should be considered and treated. Adrenal reserve in thyrotoxic patients is often exceeded in the absence of absolute adrenal insufficiency

**MANAGEMENT**

Treatment is aimed at:

- control and relief of adrenergic symptoms
- correction of thyroid hormone abnormalities
- the precipitating cause
- investigation and treatment of the underlying thyroid disease
- supportive measures

 **$\beta$ -ADRENERGIC BLOCKADE**

This is the mainstay of controlling adrenergic symptoms.<sup>21</sup> Intravenous propranolol titrated in 0.5–1-mg increments,

**Table 52.2** Factors associated with precipitating thyroid storm

- Infection; sepsis
- Withdrawal of antithyroid treatment
- Surgery; trauma
- Parturition
- Diabetic ketoacidosis
- Radioactive iodine therapy
- Iodinated contrast dyes
- Hypoglycaemia
- Excessive palpation of the thyroid gland
- Emotional stress
- Burn injury
- Pulmonary thromboembolism
- Cerebrovascular accident; seizure disorder (including eclampsia)
- Thyroid hormone overdose

**Table 52.3** Clinical features of hyperthyroidism/thyroid crisis

while monitoring cardiovascular response, diminishes the systemic hypersensitivity to catecholamines. In addition it inhibits peripheral conversion of  $T_4$  to  $T_3$ .<sup>22</sup> Concurrent administration of enteral propranolol is the norm, with doses as high as 60–120 mg 4–6-hourly often being necessary due to enhanced elimination during thyroid crisis.<sup>23</sup> An alternative regimen uses intravenous esmolol with a loading dose of 250–500  $\mu\text{g}/\text{kg}$  followed by infusion at 50–100  $\mu\text{g}/\text{kg}$  per min. This allows rapid titration of  $\beta$ -blockade while minimising adverse reactions.<sup>24</sup>  $\beta_1$ -selective antagonists such as metoprolol may be of use, particularly in the presence of reactive airways and heart failure. These agents do not inhibit conversion of  $T_4$  to  $T_3$  to the extent of non-selective  $\beta$ -antagonists and should be combined with other therapy. Patients who exhibit resistance to  $\beta$ -adrenergic blockade may be successfully treated with reserpine or guanethidine, though their onset of action is slow and side-effects may be significant.

### DIGOXIN

Control of heart rate and rhythm may result in significant improvement in cardiac performance. Electrolyte imbalance, particularly hypokalaemia and hypomagnesaemia, should be corrected prior to drug therapy. Relative resistance to digoxin may occur due to increased renal clearance<sup>25</sup> and increased Na/K-ATPase units in cardiac muscle.<sup>26</sup> Arterial thromboembolic phenomena are common (10–40%) in thyrotoxicosis-related atrial fibrillation. This may be due to a procoagulant state or an increased incidence of mitral valve prolapse. Anticoagulation is controversial given the increased sensitivity to warfarin and potential for bleeding; however it should be considered in the management of these patients.

### AMIODARONE

Amiodarone has theoretical benefits in thyrotoxicosis as it inhibits peripheral conversion of  $T_4$  to  $T_3$  and reduces the concentration of  $T_3$ -induced adrenoceptors.<sup>27</sup> It does however cause profound (and sometimes physiologically irrelevant) changes to thyroid function tests and should not therefore be used as the first-line agent. The presence of prolonged QTc interval should be excluded before commencing therapy.

### THIONAMIDES

These drugs block de novo synthesis of thyroid hormones within 1–2 hours of administration, but have no effect on the release of preformed glandular stores of thyroid hormones. Transient leukopenia is common (20%) and agranulocytosis can rarely occur with carbimazole use.

### Propylthiouracil

This is usually considered the drug of choice in thyroid storm due to its ability to block partially peripheral conversion of  $T_4$  to  $T_3$ . Its main mechanism of action is to block the iodination of tyrosine. Only enteral preparations are available and absorption may be unpredictable during thyroid crisis. Rectal administration has been reported. Loading dose is 100 g followed by 100 mg every 2 hours.

### Methimazole

Methimazole lacks peripheral effects, but has a long duration of action, making administration easier and more reliable. It may be used in combination with drugs that block peripheral  $T_4$ -to- $T_3$  conversion (such as iopanoate or ipodate). Only enteral preparations are available, though rectal administration has been reported. Loading dose is 100 g followed by 20 g every 8 hours.

### Carbimazole

This is metabolised to methimazole and is rarely associated with agranulocytosis. Only enteral preparations are available.

### IODINE

The release of preformed glandular thyroid hormones is inhibited by administering either inorganic iodine or

lithium. Enterally administered iodides include Lugol's solution and sodium or potassium iodide. Intravenous infusion of sterile sodium iodide may be used at a dose of 1 g 12-hourly; however, this is not always available commercially. If not, it may be prepared by the hospital pharmacy. Iodine therapy should not commence without prior thionamide administration. Used alone, it will enrich hormone stores within the thyroid gland and exacerbate thyrotoxicosis.

Iodine-containing contrast media (e.g. ipodate and iopanoate) may be used instead of the simple iodides; the former blocking  $T_4$ -to- $T_3$  conversion and inhibiting the cardiac effects of  $T_4$ . Iodate is administered orally as a loading dose of 3 g followed by 1 g daily. As with the iodides, treatment should always be preceded by thionamide administration.

### LITHIUM

Lithium carbonate has a similar, though weaker, action to iodine and can be used in patients with iodine allergy. An initial dose regime of 300 mg 6-hourly has been used with subsequent dosage adjusted to maintain serum drug levels at about 1 mmol/l.<sup>28</sup> Renal and neurological toxicity tends to limit its use.

### STEROIDS

Glucocorticoids reduce  $T_4$ -to- $T_3$  conversion and may modulate any autoimmune process underlying the thyroid crisis (e.g. Graves disease). In addition, relative glucocorticoid deficiency may be a feature of the crisis. An adrenocorticotrophic hormone (ACTH) stimulation test is desirable prior to administration of hydrocortisone (100 mg 6–8-hourly); alternatively dexamethasone (4 mg 6-hourly) can be administered until the test has been performed. Combination therapy with iodides can produce rapid results. Glucocorticoids are the most effective treatment for type 2 amiodarone-induced thyrotoxicosis.<sup>29</sup>

### OTHER THERAPIES

Plasmapheresis, charcoal haemoperfusion and dantrolene have all been used as novel therapies in thyroid storm; however their use is not established or proven.

### SUPPORTIVE THERAPY

#### Fluid management

Fluid management may be extremely difficult in patients suffering from thyroid storm, particularly the elderly. Fluid losses may be profound due to diarrhoea, vomiting, pyrexia and reduced intake. However, cardiac failure may also develop as a result of the high cardiac demand. Echocardiography and cardiac output monitoring may be invaluable in guiding therapy for such patients.

#### Nutrition

Thyrotoxic patients have high energy expenditure and may present with a significant energy, vitamin and nitrogen deficit. Nutritional requirements should take account

of any deficit and the ongoing hypercatabolic state. Thiamine is usually supplemented.

### Drug therapy

Consideration should be given to the enhanced metabolism and elimination of drugs that occur in thyrotoxic patients. Salicylates and furosemide should be avoided as they both displace thyroid hormones from their binding proteins and can rapidly exacerbate systemic symptoms.

### Precipitating factors

Both the precipitating factors and the disease process underlying the thyroid crisis should be sought and treated aggressively. Infection is the leading precipitant of crisis; thus early microbiological cultures and antibiotic therapy should be considered.

## MYXOEDEMA COMA

Myxoedema coma is the extreme manifestation of hypothyroidism which, although rare, carries a mortality ranging from 30% to 60%. The term is a misnomer in that the majority of patients present with neither the non-pitting oedema, known as myxoedema, nor coma.<sup>30</sup> The condition should be considered in any patient presenting with reduced level of consciousness and hypothermia. The crisis occurs most commonly in elderly women with long-standing undiagnosed or undertreated hypothyroidism in whom an additional significant stress is experienced. Numerous precipitating factors have been identified (Table 52.4).

**Table 52.4** Factors precipitating myxoedema coma

- Infection
- Cold environmental temperatures/hypothermia
- Burns
- Stroke
- Surgery
- Trauma
- Chronic heart failure
- Carbon dioxide retention
- Gastrointestinal haemorrhage
- Hypoglycaemia
- Carbon dioxide retention
- Gastrointestinal haemorrhage
- Hypoglycaemia
- Medications
  - Amiodarone
  - Anaesthetic agents
  - Analgesics/narcotics
  - Beta-blockers
  - Diuretics
  - Lithium
  - Phenytoin
  - Rifampicin
  - Sedatives/tranquillisers

**CLINICAL PRESENTATION (TABLE 52.5)**

Myxoedema coma can be defined when decreased mental status, hypothermia and clinical features of hypothyroidism are present (see Table 52.5). When these features are present, diagnosis is straightforward; however, asymptomatic or atypical presentation (e.g. decreased mobility) may occur.<sup>31</sup>

**NEUROMUSCULAR**

Alteration of conscious or mental state is present in all patients. This can range from personality changes to coma, with about 25% of patients experiencing seizures prior to the onset of coma. Electroencephalogram usually reveals non-specific changes. Weakness is common and skeletal muscle dysfunction may develop secondary to increased membrane permeability. The latter can lead to a rise in creatine phosphokinase. Hyponatraemia is present in up to 50% of patients and may contribute to

alterations in conscious level (see below). Lumbar puncture often reveals elevated protein levels and a high opening pressure.

**HYPOTHERMIA**

Hypothermia represents the decrease in thermogenesis that accompanies reduced metabolism and is exacerbated by low ambient temperatures. Mortality is proportional to the degree of hypothermia. A low-reading thermometer should be used during assessment.

**CARDIOVASCULAR FEATURES**

Diastolic hypertension is due to increased systemic vascular resistance and blood volume reduction;<sup>32</sup> however myxoedema is associated with bradycardia and impaired myocardial contractility, with reduced cardiac output and hypotension a common feature. While pericardial effusions may occur, tamponade is uncommon. Creatine phosphokinase may be elevated, though this more commonly originates from skeletal rather than cardiac muscle. Acute coronary syndrome must nevertheless be excluded as a precipitant of the crisis. Electrocardiographic changes include bradycardia, decreased voltage, non-specific ST and T changes, varying types of block and prolonged QT interval. All of the cardiovascular abnormalities are reversible with thyroid hormone treatment.<sup>33</sup>

**RESPIRATORY FEATURES**

Hypothyroidism causes numerous respiratory alterations (see Table 52.5). There is a propensity to respiratory alkalosis, particularly during artificial ventilation. This is due to low metabolic rate, which may be compounded by iatrogenic hyperventilation.<sup>34</sup> Diaphragmatic weakness may occur due to abnormalities of the phrenic nerve; as a result, exercise tolerance may be significantly reduced. These abnormalities improve with thyroid hormone replacement, though full recovery can take several months.

**LABORATORY FINDINGS**

Thyroid function tests will reveal low T<sub>4</sub> and T<sub>3</sub>; TSH is raised in primary and low in secondary and tertiary hypothyroidism. Hyponatraemia is common and usually develops due to free water retention resulting from excess vasopressin secretion or impaired renal function.<sup>35</sup> It may be severe and can contribute to diminished mental function. Although total body water is increased, intravascular volume is usually decreased. Hypoglycaemia may result from hypothyroidism alone, or as a result of concurrent adrenal insufficiency (Schmidt's syndrome). The mechanism is probably reduced gluconeogenesis, but infection and starvation may contribute. Azotaemia and hypophosphataemia are common; renal function may be severely abnormal due to low cardiac output and vasoconstriction. Mild leukopenia and normocytic anaemia are frequently present, though macrocytic and pernicious anaemia due to autoimmune dysfunction may occur. Arterial blood gases often reveal respiratory acidosis, hypoxia and hypercapnia.

**Table 52.5** Clinical features of myxoedema coma

- **Cold intolerance**
- **Coarse hair**
- **Dry, pale, cool skin**
- **Laboratory abnormalities**

## MANAGEMENT

The mainstay of therapy consists of thyroid hormone replacement, steroid replacement and supportive measures. Once clinical diagnosis has been made or is suspected, blood should be collected for thyroid function and plasma cortisol tests. This should be followed by thyroid hormone treatment, which should not be delayed to await laboratory results. Consideration should be given to identifying and treating precipitating factors and complications of the crisis.

### THYROID HORMONE THERAPY

All patients with suspected myxoedema coma should receive presumptive treatment with thyroid hormone. The optimum speed, type, route and dose of thyroid hormone replacement in myxoedema coma are unknown due to the rarity of the condition and paucity of trials. The severity of clinical presentation does not correlate with the doses of replacement hormone required. Rapid replacement can result in life-threatening myocardial ischaemia or arrhythmias; delayed therapy exposes patients to prolonged risk of complications from the crisis. Both scenarios are associated with increased mortality.

Some experts favour administration of  $T_3$  as it is biologically more active; has more rapid onset of action; and bypasses the impaired deiodination of  $T_4$  to  $T_3$  which occurs in hypothyroidism and non-thyroidal illness. High serum  $T_3$  concentration has, however, been associated with increased mortality<sup>36</sup> and  $T_3$  is expensive and may be difficult to obtain.  $T_3$  may be administered orally or intravenously and has been combined with  $T_4$  therapy.<sup>37</sup>

Most authorities recommend use of  $T_4$  alone<sup>38,39</sup> as the delayed conversion to  $T_3$  allows more gradual replacement of the deficient hormone. Bioavailability of orally administered  $T_4$  is unpredictable given the high incidence of gastrointestinal dysfunction; therefore intravenous administration is more frequently used. A loading dose of intravenous levothyroxine 100–500 mcg is recommended<sup>38</sup> as this saturates the binding proteins. This should be followed by 50–100 mcg daily until conversion to the bioequivalent oral formulation is possible. The doses must be adjusted to allow for patient age, weight and cardiovascular risk factors; the lower doses should be administered to patients who are elderly, frail or have comorbidities (particularly cardiovascular disease).

### CORTICOSTEROIDS

Corticosteroids are an important part of treatment as relative or absolute hypoadrenalism may occur concurrently with hypothyroid disease. A random serum cortisol level should be collected prior to commencing hydrocortisone therapy at 100 mg 8-hourly. If ACTH stimulation test is warranted, dexamethasone 4 mg 6-hourly should be commenced with conversion to hydrocortisone or cessation of treatment once the results are known. If random serum cortisol levels return at normal levels, steroid treatment can be discontinued.

### SUPPORTIVE THERAPY

Hypothermia should be treated by passive rewarming where possible but active measures may be required. Appropriate cardiovascular, temperature gradient, electrolyte and acid–base monitoring should be provided during the rewarming phase in order to prevent haemodynamic and metabolic compromise.

Numerous alterations in respiratory physiology occur, including hypoventilation and altered response to arterial oxygen and carbon dioxide tensions. In addition, anatomical changes to the airway, delayed gastric emptying and increased sensitivity to sedative drugs may be present. These changes should be considered when mechanical ventilation is required, particularly during intubation and the weaning process.<sup>34</sup>

Patients usually present with intravascular fluid depletion despite peripheral oedema. Cardiac output monitoring may help guide fluid resuscitation and therapy. Echocardiography is useful in identifying cardiac dysfunction and pericardial effusions and assisting in assessment of intravascular volume status. Cardiac monitoring should be used to alert to the presence of arrhythmias. Inotropes and vasopressors should be avoided where possible due to their potential to precipitate cardiac arrhythmias. Where inotropes are required, increased dosage may be necessary as reduction in  $\beta$ -adrenoceptors is common.  $\alpha$ -adrenoceptor function is usually preserved.

Hyponatraemia is reversible with thyroid hormone treatment, but severe abnormalities contributing to neurological dysfunction may require more expeditious correction. Free water intake should be restricted and hypertonic saline solutions may be required. Hypotonic fluid therapy should be avoided. If glucose therapy is required, hypertonic solutions (20–50%) should be infused via a central venous catheter.

Precipitating factors must be considered. As with all critically ill patients, microbial cultures should be collected and antibiotic therapy commenced unless cultures are negative. Prophylaxis against venous thromboembolism and peptic ulceration should be considered. Enteral feeding should be attempted but may be unsuccessful if gastrointestinal dysfunction and stasis are present.

## NON-THYROIDAL ILLNESS

Non-thyroidal illness describes the phenomenon of starved or systemically unwell patients with abnormal serum thyroid function tests but with no apparent thyroidal illness. Low  $T_3$ ,  $T_4$  and TSH are commonly found; the degree of abnormality correlates with the severity of illness. Variants of these hormone levels are well described. Low serum  $T_3$  is a frequent finding and occurs due to downregulation of the monodeiodinase enzyme that converts  $T_4$  to  $T_3$ , while r $T_3$  may increase due to increased activity of the  $T_4$ -to-r $T_3$  monodeiodinase.<sup>40</sup>

Serum  $T_4$  is also commonly low in the critically ill. This is due to a decrease in the concentration of thyroid

**Table 52.6** Changes in thyroid hormone concentrations

	fT <sub>4</sub>	T <sub>3</sub>	TSH
Euthyroid	N	N	N
Hyperthyroid	↑	↑	↓
Hypothyroid	↓	↓ N	↑
Non-thyroidal illness	↑ N ↓	↓	N ↓

fT<sub>4</sub>, free tetraiodothyronine; T<sub>3</sub>, triiodothyronine; TSH, thyroid-stimulating hormone; N, normal; ↑ increased; ↓ decreased.

hormone-binding proteins and the presence of inhibitors that reduce T<sub>4</sub> binding to these proteins. There is also the suggestion that T<sub>4</sub> entry into cells may be impaired.<sup>41</sup> Free T<sub>4</sub> levels should be normal in less severe illness; however, in severe illness, the level may be low due to inadequate correction during the fT<sub>4</sub> assay.<sup>42</sup>

Low serum TSH levels were previously thought to be associated with the euthyroid state; however more recent work suggests that acquired transient central hypothyroidism is present in these patients.<sup>43</sup> Cytokines such as tumour necrosis factor- $\alpha$  are known to inhibit TSH secretion. Such phenomena are probably evolutionary adaptations to conserve protein and energy during severe illness. Elevated TSH may also occur in non-thyroidal illness, but few of these patients prove to have hypothyroidism following recovery from their acute illness.

Changes in thyroid function test are well described during starvation, sepsis, bone marrow transplantation, surgery, myocardial infarction, coronary artery bypass surgery and probably any critical illness. However, replacement of thyroid hormone in these patients is of no benefit and may be harmful;<sup>44</sup> hence thyroid function should not be assessed in critically ill patients unless there is a strong clinical indication to do so. A number of specific non-thyroidal illnesses are associated with abnormal thyroid function tests. These include: some psychiatric illnesses; hepatic disease; nephritic syndrome; acromegaly; acute intermittent porphyria; and Cushing's syndrome.<sup>45</sup> Where assays are performed, TSH should not be interpreted in isolation as low values will not discriminate between true thyroid and non-thyroidal disease. If low T<sub>4</sub> is also present, non-thyroidal illness is likely. If T<sub>4</sub> is elevated then hyperthyroidism is the likely diagnosis, though elevated T<sub>4</sub> has been documented in non-thyroidal illness.

Given the alterations in these hormones and difficulties with their assay during critical illness, thyroid hormone replacement should not be undertaken on the strength of thyroid function test results alone: additional laboratory and clinical indications must also be present (Table 52.6).

# Adrenocortical insufficiency in critical illness

Balasubramanian Venkatesh and Jeremy Cohen

The adrenal glands form an essential part of the organism's response to stress. Hence, in intensive care, an adequate adrenal response is considered to be of prime importance. Whilst primary adrenal insufficiency (AI) is a well-recognised but rare condition in intensive care, secondary, or RAI, is thought to be more prevalent. Adrenocortical insufficiency may present as an insidious, occult disorder, unmasked by conditions of stress, or as a catastrophic syndrome that may result in death.

## PHYSIOLOGY

The adrenal glands are functionally divided into medulla and cortex; the cortex is responsible for the secretion of three major classes of hormones: glucocorticoids, mineralocorticoids and sex hormones. The major pathogenic effects of disease result from cortisol and aldosterone deficiency.

Cortisol, the major glucocorticoid synthesised by the adrenal cortex, plays a pivotal role in normal metabolism. It is necessary for the synthesis of adrenergic receptors, normal immune function, wound healing and vascular tone. These actions are mediated by the glucocorticoid receptor, a member of the nuclear hormone receptor superfamily. The activated receptor migrates to the nucleus and binds to specific recognition sequences within target genes, but also interacts with numerous transcription factors and cytosolic proteins. Numerous isoforms of the glucocorticoids receptor have now been described; the alpha subtype, a 777-amino-acid polypeptide chain, was initially felt to be the primary mediator of glucocorticoid action. In contrast the beta isoform, a 742-amino-acid chain was felt to have no physiological activity. More recently it appears that the beta subtype has a negative effect on alpha-mediated gene transactivation, the physiological relevance of which remains controversial. Furthermore, additional isoforms have now been described, suggesting that glucocorticoid receptor diversity may be an important factor in understanding the complex effects of corticosteroid action.<sup>1</sup>

Under normal circumstances, cortisol is secreted in pulses, and in a diurnal pattern.<sup>2</sup> The normal basal output of cortisol is estimated to be 15–30 mg/day, producing a peak plasma cortisol concentration of 110–520 nmol/l (4–19 µg/dl) at 8–9 a.m., and a minimal cortisol level of < 140 nmol/l (< 5 µg/dl) after midnight. The daily output of aldosterone is estimated to be 100–150 µg/day.

Secretion is under the control of the hypothalamic–pituitary axis. There are a variety of stimuli to secretion, including stress, tissue damage, cytokine release, hypoxia, hypotension and hypoglycaemia. These factors act upon the hypothalamus to favour the release of corticotrophin-releasing hormone (CRH) and vasopressin. CRH is synthesised in the hypothalamus and carried to the anterior pituitary in portal blood, where it stimulates the secretion of adrenocorticotrophic hormone (ACTH), which in turn stimulates the release of cortisol, mineralocorticoids (principally aldosterone) and androgens from the adrenal cortex. CRH is the major (but not the only) regulator of ACTH release and is secreted in response to a normal hypothalamic circadian regulation and various forms of 'stress'. Vasopressin, oxytocin, angiotensin II and β-adrenergic agents also stimulate ACTH release while somatostatin, β-endorphin and enkephalin reduce it. Cortisol has a negative feedback on the hypothalamus and pituitary, inhibiting hypothalamic CRH release induced by stress, and pituitary ACTH release induced by CRH. During periods of stress, trauma or infection, there is an increase in CRH and ACTH secretion and a reduction in the negative-feedback effect, resulting in increased cortisol levels, in amounts roughly proportional to the severity of the illness.<sup>3–5</sup>

The majority of circulating cortisol is bound to an α-globulin called transcortin (corticosteroid-binding globulin, CBG). At normal levels of total plasma cortisol (e.g. 375 nmol/l or 13.5 µg/dl) less than 5% exists as free cortisol in the plasma; however it is this free fraction that is biologically active. Circulating CBG concentrations are approximately 700 nmol/l. In normal subjects CBG can bind approximately 700 nmol/l (i.e. 25 g/dl).<sup>6</sup> At levels greater than this, the increase in plasma cortisol is largely

in the unbound fraction. The affinity of CBG for synthetic corticosteroids, with the exception of prednisolone, is negligible. CBG is a substrate for elastase, a polymorphonuclear enzyme that cleaves CBG, markedly decreasing its affinity for cortisol.<sup>7</sup> This enzymatic cleavage results in the liberation of free cortisol at sites of inflammation. CBG levels have been documented to fall during critical illness,<sup>8–10</sup> and these changes are postulated to increase the amount of circulating free cortisol.

Cortisol has a half-life of 70–120 minutes. It is primarily eliminated by hepatic metabolism and glomerular filtration. The excretion of free cortisol through the kidney represents 1% of the total secretion rate. Currently, available routine assays measure only total cortisol levels – bound and free.

The metabolic effects of cortisol are complex and varied. In the liver, cortisol stimulates glycogen deposition by increasing glycogen synthase and inhibiting the glycogen-mobilising enzyme glycogen phosphorylase.<sup>11</sup> Hepatic gluconeogenesis is stimulated, leading to increased blood glucose levels. Concurrently, glucose uptake by peripheral tissues is inhibited.<sup>12</sup> Free fatty acid release into the circulation is increased, and triglyceride levels rise.

In the circulatory system, cortisol increases blood pressure both by direct actions upon smooth muscle, and via renal mechanisms. The actions of pressor agents such as catecholamines are potentiated, whilst nitric oxide-mediated vasodilation is reduced.<sup>13,14</sup> Renal effects include an increase in glomerular filtration rate, and sodium transport in the proximal tubule, and sodium retention and potassium loss in the distal tubule.<sup>15</sup>

The primary effects of cortisol upon the immune system are anti-inflammatory and immunosuppressive. Lymphocyte cell counts decrease, whilst neutrophil counts rise.<sup>15</sup> Accumulation of immunologically active cells at inflammatory sites is decreased. The production of cytokines is inhibited, an effect that is mediated via nuclear factor (NF)- $\kappa$ B. This occurs both by induction of NF- $\kappa$ B inhibitor and by direct binding of cortisol to NF- $\kappa$ B, thus preventing its translocation to the nucleus. Whilst the well-defined effects of cortisol upon the immune system are primarily inhibitory, it is also suggested that normal host defence function requires some cortisol secretion. Cortisol has been described as having a positive effect upon immunoglobulin synthesis, potentiation of the acute-phase response, wound healing and opsonisation.<sup>16</sup>

## CLASSIFICATION

AI may be considered to be primary, secondary or relative. Primary AI, otherwise known as Addison's disease, results from hypofunction of the adrenal cortex. Secondary AI occurs when there is suppression or absence of ACTH secretion from the anterior pituitary. RAI describes a situation of inadequate cortisol response to stress in the setting of critical illness.

## PRIMARY ADRENAL INSUFFICIENCY

Primary AI or Addison's disease is a rare disorder. In the western world its estimated prevalence is 120 per million.<sup>17</sup> In adulthood, the commonest cause is autoimmune, but in the intensive care setting, consideration should be given to other causes of adrenal gland destruction (Table 53.1). These include infection, haemorrhage and infiltration. Tuberculosis is the commonest infective cause worldwide, but rarer infections such as histoplasmosis, coccidiomycosis and cytomegalovirus (especially in patients with human immunodeficiency virus (HIV)) have also been implicated. Haemorrhage into the glands is associated with septicaemias, particularly meningococcal (Waterhouse–Friedrichsen syndrome). Asplenia and the antiphospholipid syndrome may also be associated with adrenal haemorrhage. Adrenal gland destruction may also be secondary to infiltration with tumour, or amyloid.

Drugs may impair adrenal function either by inhibiting cortisol synthesis (etomidate, ketoconazole) or by inducing hepatic cortisol metabolism (rifampicin, phenytoin). High levels of circulating cytokines are also reported to have a suppressive effect upon ACTH release.<sup>18</sup>

Table 53.1 Causes of primary adrenal insufficiency

<b>Infections</b>
Tuberculosis
Histoplasmosis
Coccidiomycosis
Cytomegalovirus
<b>Autoimmune-mediated</b>
<b>Haemorrhagic</b>
Sepsis (especially meningococcal)
Antiphospholipid syndrome
Trauma
Surgery
Coagulation disorders
<b>Infiltrative</b>
Tumour
Amyloid
Sarcoidosis
Haemochromatosis
<b>Drug-related</b>
Etomidate
Fluconazole
Ketoconazole
Metyrapone
Suramin
Rifampicin
Phenytoin
<b>Congenital</b>
Adrenal dysgenesis
Adrenoleukodystrophy
Impaired steroidogenesis
<b>Cytokine-mediated</b>

**PRESENTATION (Table 53.2)**

The disease is often unrecognised in its early stages as the presenting features are ill-defined. Symptoms include tiredness and fatigue, vomiting, weight loss, anorexia and postural hypotension. Hyperpigmentation is seen in non-exposed areas (such as palmar skin creases) and is due to the hypersecretion of melatonin, a breakdown product from the ACTH precursor pro-opiomelanocortin (POMC).

Presentation to an intensive care physician is likely to be in the form of adrenal crisis. This may be precipitated by concurrent illness or surgery, or by failure to take replacement medication. Classically adrenal crisis will present as refractory shock with a poor response to inotropic or pressor agents. Abdominal or flank pain is often present and may lead to an erroneous diagnosis of an acute surgical abdomen.

Treatment should consist of immediate supportive measures, fluid resuscitation and high-dose intravenous glucocorticoid therapy. A standard dose would be 100 mg hydrocortisone 6-hourly, or as an infusion. At these doses separate mineralocorticoid replacement is not required.<sup>19</sup>

Adrenal crisis should be suspected in cases of undifferentiated shock not responding to standard management. Suggestive features would include a history of symptomatology consistent with the diagnosis, hyperpigmentation on examination, and demonstration of hyponatraemia, hyperkalaemia and peripheral blood eosinophilia. A random plasma total cortisol taken during a crisis will be low (below 80 nmol/l) and in the acute phase ACTH stimulation testing is not required.

**Table 53.2** Clinical features of Addison's disease

<b>Symptoms</b>
Muscular weakness
Fatigue
Abdominal pain
Vomiting
Diarrhoea
Salt craving
Weight loss
Arthralgia and myalgia
Mood change
Headache
Sweating
Syncope
<b>Signs</b>
Hyperpigmentation – skin creases, buccal mucosa
Postural hypotension
Associated vitiligo
Decreased axillary and pubic hair
Auricular calcification
Vasodilated shock (in crisis)

**SECONDARY ADRENAL INSUFFICIENCY**

The commonest cause of ACTH deficiency is sudden cessation of exogenous glucocorticoid treatment. Patients who have been taking more than 30 mg/day hydrocortisone or equivalent for more than 3 weeks are at risk of adrenal suppression.<sup>20</sup> Other causes include pituitary surgery, pituitary infarction (Sheehan's syndrome) or pituitary tumour.

Presentation is similar to that of primary AI. The major distinguishing characteristics are a lack of hyperpigmentation, and the absence of mineralocorticoid deficiency; hence hyperkalaemia is not a feature of secondary AI, although hyponatraemia may still be present due to increased vasopressin levels.

**INVESTIGATION OF ADRENAL INSUFFICIENCY**

In a stable patient suspected AI is routinely investigated by an ACTH stimulation test. The test is performed by administering 250 µg of a synthetic ACTH molecule comprising the first 24 amino acids – tetracosactrin (Synacthen). Plasma total cortisol is measured at 0 and 30 minutes after administration, and a normal response is defined as a cortisol measurement over 525 nmol/l.<sup>21</sup> However, it should be noted that current immunoassays exhibit a significant degree of variability, and thus local laboratory reference ranges should be used.<sup>22</sup> The test cannot be performed if the patient is currently being prescribed hydrocortisone as this will cross-react with the assays; an alternative replacement therapy such as dexamethasone should be used in these cases.

Secondary AI may be differentiated from primary by a prolonged ACTH test. This is performed by the use of a depot preparation or an intravenous infusion of tetracosactrin for 24–48 hours. Patients with secondary hypoadrenalism show a greater plasma cortisol response at 24 hours than at 4 hours; alternatively measurement of a baseline ACTH level may be used. In patients with primary AI this will be elevated.

Other biochemical tests that may be used in investigation of AI include the insulin hypoglycaemia test, the overnight metyrapone test and the CRH stimulation test. These investigations are not normally necessary in uncomplicated cases. In addition the use of the low-dose ACTH stimulation test has been advocated, in which only 1 mcg of tetracosactrin is used. This approach has not yet gained widespread acceptance.

**RELATIVE ADRENAL INSUFFICIENCY**

The term *relative AI* (RAI) was coined to describe a syndrome where the adrenal gland partially responds to stress but the magnitude of response is not commensurate.

Annane *et al.* prospectively studied 189 patients with septic shock and detailed a three-level classification system based upon the basal cortisol level and response to ACTH.<sup>23</sup> Mortality was found to be highest in those patients with a basal cortisol level above 34 µg/dl (938 nmol/l) and

**Table 53.3** Controversies in the diagnosis of adrenal insufficiency in the critically ill**Limitations of a random cortisol**

In the critically ill there is a marked fluctuation in plasma cortisol concentration limiting the utility of a random cortisol<sup>30</sup>

The 'normal' range of cortisol in critical illness is not defined

There is no consensus 'cut-off' value below which adrenal insufficiency is present

**Limitations of total cortisol**

Free cortisol is the bioactive fraction of cortisol

There is a large variation in total cortisol assay results when the same specimen is tested in different laboratories and using different assays<sup>22</sup>

Peripheral tissue-specific glucocorticoid resistance is not tested

**Limitations of the conventional Synacthen test**

The HDSST results in plasma Synacthen concentrations that are supraphysiological

Published data may have overestimated the incidence of adrenal insufficiency, as many studies have not excluded patients who received etomidate

The low-dose SST may be more a better predictor of outcome

HDSST, high-dose short Synacthen test; SST, short Synacthen test.

response to ACTH of less than 9 µg/dl (248 nmol/l). Patients with a basal cortisol above 34 µg/dl but a cortisol response greater than 9 µg/dl did better, whilst the best prognosis was seen in the group with a lower basal cortisol level and high response to ACTH. This pattern – a high basal cortisol and blunted response to ACTH,<sup>24–27</sup> which is associated with increasing mortality – has now come to be referred to as RAI. The significance of this observation, however, is not clear. It has been suggested either to represent a partially suppressed adrenal axis, implying a role for cortisol replacement therapy, or alternatively as indicating an 'overstressed' axis, in which case steroid treatment would be inappropriate. Treatment of septic patients fulfilling RAI criteria with hydrocortisone has been shown to improve outcome in one study,<sup>28</sup> but these results have not been widely accepted (see below). Alternative diagnostic criteria, relying on baseline plasma cortisol levels without ACTH stimulation, have been proposed,<sup>29</sup> but the lack of a consistently observed relationship between cortisol levels and mortality means that the optimal diagnostic criteria for RAI remain controversial (Table 53.3). Possible explanations for the difficulties in assessing adrenal function in this patient group include spontaneous fluctuations in the measured cortisol values,<sup>30</sup> increased variability of assays,<sup>22</sup> and changes in CBG levels affecting free cortisol values.<sup>10,31</sup>

**STEROID THERAPY IN CRITICAL ILLNESS**

Steroids have an established role in the management of a number of critical illnesses, as outlined in Table 53.4.

**Table 53.4** Proven role for steroids in critical illness

Addisonian crisis
Anaphylaxis
Asthma
Bacterial meningitis
Chronic obstructive pulmonary disease with acute respiratory failure
Croup
Fulminant vasculitis
Hypercalcaemia
Idiopathic thrombocytopenic purpura
Myasthenic crisis
Myxoedema coma
Organ transplantation
<i>Pneumocystis carinii</i> pneumonia
Thyroid storm

However their use in other conditions has not been without controversy.

**SPINAL INJURY**

High-dose methylprednisolone has been advocated in the management of patients with spinal cord injury following the publication of the National Acute Spinal Cord Injury Study (NASCIS) II and III trials. The major criticism of these studies is the lack of a demonstrable improvement in the primary outcome measures. For a more detailed review of the use of steroids in spinal cord injury, the reader is referred to Chapter 70.

**HEAD INJURY**

The role of steroids in the management of cerebral oedema secondary to tumours is well documented and accepted. However, their role in the management of head injury has been the subject of intense debate. Several prospective studies have not been able to prove any benefit with steroids in head trauma. However, these studies were not adequately powered to detect a difference. The recent Corticosteroid Randomization After Significant Head Injury (CRASH) trial, with nearly 10 000 patients, clearly demonstrated the lack of any benefit with steroids in head injury.<sup>32</sup>

**ACUTE RESPIRATORY DISTRESS SYNDROME (ARDS)**

The first clinical trial to report a beneficial effect of steroids in ARDS was the one by Meduri *et al.* in 1998.<sup>33</sup> In a randomised, placebo-controlled, cross-over single-centre trial enrolling 24 patients, steroids were shown to improve lung injury score and reduce mortality. The ARDS clinical trial network published the results of its multicentre study where corticosteroids were administered to patients with ARDS persisting beyond 7 days. Although steroid use was associated with earlier ventilatory wean, improved arterial oxygenation and increased respiratory compliance, there was a higher rate of return

to assisted ventilation and neuromuscular weakness.<sup>34</sup> No overall mortality difference was demonstrable between steroid and placebo groups. Commencement of steroids more than 2 weeks after onset of ARDS led to almost a fourfold increase in mortality as compared to the placebo group. Consequently, steroids cannot be routinely recommended for persistent ARDS and may be harmful in late-stage ARDS.

### SEPTIC SHOCK

Since the first reported use of steroids in sepsis in 1951, therapy with this drug has undergone several transformations from 'steroid success' in sepsis and malaria in the 1970s and early 1980s to 'steroid excess' (30 mg/kg methylprednisolone) in severe sepsis in the mid to late 1980s, to total abandonment in the early 1990s and finally a resurgence of its use in the new millennium. The results of the only prospective randomised trial of steroids in septic shock by Annane *et al.*,<sup>28</sup> which found a beneficial effect, have not been widely accepted owing to problems of randomisation, change of protocol and the use of etomidate (an adrenal suppressant drug) in the study. A recently published European multicenter randomised trial of steroids in septic shock Corticosteroid Therapy of Septic Shock (CORTICUS), did not demonstrate a mortality difference between steroids and placebo. However, this study has in turn been criticised for potential selection bias.

### SIDE-EFFECTS OF STEROID THERAPY

Steroid therapy is associated with numerous side-effects. Those that would be of particular relevance to intensive care are discussed below. A full list is given in Table 53.5.

1. Suppression of the adrenal axis (discussed above). Patients who have been receiving steroid treatment for less than a week are unlikely to be affected.
2. Hyperglycaemia – this may be associated with adverse outcomes in critically ill patients.<sup>35</sup>
3. Myopathy: steroid therapy has been known to be associated with muscle weakness since 1932, but has only more recently been shown to be an independent risk factor for developing muscle paresis acquired in the intensive care unit.<sup>36</sup> This has significant clinical implications for weaning patients from mechanical ventilation.
4. Hypokalaemia.
5. Leukocytosis: corticosteroids increase the neutrophil count by a shift from the marginating to the circulating pool. This effect may lead to concerns that the patient has developed an occult infection.
6. Poor wound healing.
7. Immunosuppression.
8. Pancreatitis.

**Table 53.5** Side-effects of corticosteroid therapy

Adrenal suppression
Hypokalaemia
Glucose intolerance
Truncal obesity
Myopathy
Mood alterations, including psychosis
Hypertension
Osteoporosis
Peptic ulcer disease
Glaucoma
Hyperlipidaemia
Aseptic necrosis of femoral/humeral head

### ROLE OF FLUDROCORTISONE IN SEPSIS

The role of fludrocortisone in septic shock also remains controversial. The study by Annane *et al.*, quoted above, included a dose of 50 µg fludrocortisone administered orally.<sup>28</sup> It has been argued, however, that doses of cortisol above 50 mg/day provide sufficient mineralocorticoid cover, and thus separate supplementation is unnecessary.<sup>19</sup>

Furthermore, the oral route of administration is unreliable in critically ill patients. A study comparing fludrocortisone plus hydrocortisone versus hydrocortisone alone in septic patients is currently recruiting.

# Acute calcium disorders

Balasubramanian Venkatesh

Calcium is an important cation and the principal electrolyte of the body. A total of 1–2 kg is present in the average adult, of which 99% is found in bone. Of the remaining 1%, nine-tenths is present in the cells and only a tenth in the extracellular fluid. In plasma, 50% of the calcium is ionised, 40% bound to plasma proteins, mainly to albumin, and the remaining 10% is chelated to anions such as citrate, bicarbonate, lactate, sulphate phosphate and ketones.<sup>1</sup> The chelated fraction is usually of little clinical importance, but is increased in conditions where some of these anionic concentrations might be elevated, as in renal failure. Whilst most calcium inside the cell is in the form of insoluble complexes, the concentration of intracellular ionised calcium is about 0.1  $\mu\text{mol/l}$ , creating a gradient of 10 000:1 between plasma and intracellular fluid levels of ionised calcium.<sup>2</sup> A schematic illustration of calcium distribution within the various body compartments is shown in Figure 54.1.

Because ionised calcium is the biologically active component of extracellular fluid calcium with respect to physiological functions (Table 54.1) and is also the reference variable for endocrine regulation of calcium homeostasis, its measurement is recognised as being one of prime importance in the management of disorders of calcium homeostasis.

## HORMONAL REGULATION OF CALCIUM HOMEOSTASIS<sup>1,3</sup>

The concentration of ionised calcium in the plasma is subject to tight hormonal control, particularly parathyroid hormone (PTH). A G-protein-coupled calcium receptor plays a significant role in the maintenance of calcium homeostasis. This receptor, responsible for sensing extracellular calcium concentration, is present on the cell membrane of the chief cells of the parathyroid and in bone, gut and the kidney. In response to ionised hypocalcaemia, PTH secretion is stimulated, which in turn serves to restore serum calcium levels back to normal by increasing osteoclastic activity in the bone and renal reabsorption of calcium and stimulating renal synthesis of 1,25 OH-D<sub>3</sub> (calcitriol – the active metabolite of vitamin D), which increases gut absorption of calcium.

Calcitriol production is stimulated by hypocalcaemia, and vice versa. Calcitriol increases serum calcium by largely promoting gut reabsorption, and to a lesser extent renal reabsorption of calcium.

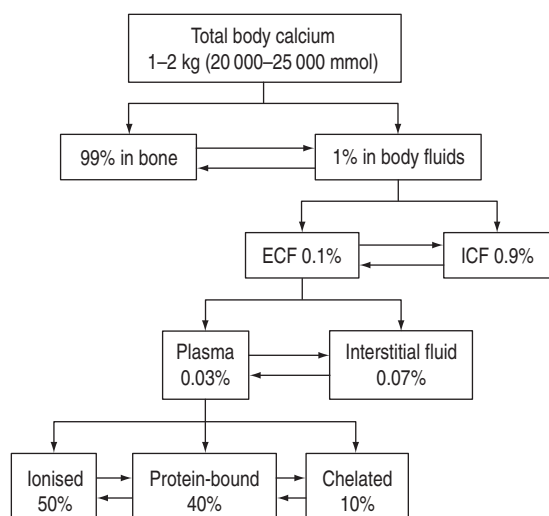

Calcitonin, a hypocalcaemic peptide hormone produced by the thyroid, acts as a physiological antagonist to PTH. Although calcitonin has been shown to reduce serum calcium levels in animals by increasing renal clearance of calcium and inhibiting bone resorption, its role in humans is less clear. Despite extreme variations in calcitonin levels, for example total lack in patients who have undergone total thyroidectomy, or excess plasma levels as seen in patients with medullary carcinoma of the thyroid gland, no significant changes in calcium and phosphate metabolism are seen. Calcitonin is useful as a pharmacological agent in the management of hypercalcaemia.

## METABOLIC FACTORS INFLUENCING CALCIUM HOMEOSTASIS

Alterations in serum protein, pH, serum phosphate and magnesium closely impact on serum calcium concentrations. Total plasma calcium levels vary with alterations in plasma protein concentration. A correction is made for hypoalbuminaemia by adding 0.2 mmol/l to the measured serum calcium concentration for every 10 g/l decrease in serum albumin concentration below normal (40 g/l). The corresponding correction factor for globulins is – 0.04 mmol/l of serum calcium for every 10 g/l rise in serum globulin.

Changes in pH alter calcium protein binding. An increase in pH by 0.1 pH units results in a decrease in ionised calcium by approximately 0.1 mmol/l.<sup>4</sup>

Calcium and phosphate are closely linked by the following reaction in the extracellular fluid:  $\text{HPO}_4^{2-} + \text{Ca}^{2+} = \text{CaHPO}_4$ . Increases in serum phosphate shift the reaction to the right. When the calcium phosphate solubility product exceeds the critical value of 5 mmol/l, calcium deposition occurs in the tissues, resulting in a fall in serum calcium concentration and a secondary increase in PTH secretion. Reductions in phosphate concentration lead to corresponding changes in the opposite direction.

**Figure 54.1** Distribution of body calcium. ECF, extracellular fluid; ICF, intracellular fluid.

**Table 54.1** Functions of calcium<sup>1,15</sup>

Excitation – contraction coupling in cardiac, skeletal and smooth muscle
Cardiac action potentials and pacemaker activity
Release of neurotransmitters
Coagulation of blood
Bone formation and metabolism
Hormone release
Ciliary motility
Catecholamine responsiveness at the receptor site <sup>7</sup>
Role as a strong cation
Regulation of cell growth and apoptosis

As magnesium is required for PTH secretion and end-organ responsiveness, alterations in serum magnesium have an impact on serum calcium concentration.

Turnover of calcium in the bone is predominantly under the control of PTH and calcitriol, although prostaglandins and some of the cytokines also play a role in it. Bone resorption is mediated by osteoclasts, whereas osteoblasts are involved in bone formation. The daily calcium balance is summarised in Table 54.2.

### MEASUREMENT OF SERUM CALCIUM

Most hospital laboratories measure total serum calcium. The normal plasma concentration is 2.2–2.6 mmol/l. However, the ionised form (1.1–1.3 mmol/l) is the active fraction and its measurement is not routine in many laboratories, although most state-of-the-art blood gas analysers can measure serum ionised calcium concentrations. Estimation of ionised calcium from total serum calcium

**Table 54.2** Daily calcium balance

<b>Gastrointestinal tract</b>	
Diet	600–1200 mg/day
Absorbed	200–400 mg/day
Secreted	150–800 mg/day
<b>Renal</b>	
Filtered	11 000 mg/day
Reabsorbed (97% in the proximal convoluted tubule)	10 800 mg/day
Urinary calcium	200 mg/day
<b>Bone</b>	
Turnover	600–800 mg/day

concentration using mathematical algorithms is unreliable in critically ill patients.<sup>5–7</sup> Heparin forms complexes with calcium and decreases ionised calcium.<sup>8</sup> A heparin concentration of < 15 units/ml of whole blood is therefore recommended for the measurement of ionised calcium.<sup>9</sup> Anaerobic collection of the specimen is recommended, as CO<sub>2</sub> loss from the specimen may result in alkalosis and reduction in ionised calcium concentration. Calcium levels are also reduced by a concomitant lactic acidosis owing to chelation by lactate ion.<sup>10</sup> Free fatty acids (FFAs) increase calcium binding to albumin and may form a portion of the calcium-binding site.<sup>11</sup> Increases in FFAs may be seen in relation to stress, use of steroids, catecholamines and heparin. The impact of pH on calcium measurements has been described above. The normal reference levels of serum calcium are reduced in pregnancy and in the early neonatal period.<sup>12</sup>

### HYPERCALCAEMIA IN CRITICALLY ILL PATIENTS

The frequency of hypercalcaemia in critically ill patients is not well established, although it is not as common as hypocalcaemia. Depending on the patient population, the reported incidence ranges from 3–5% to as high as 32%.<sup>13,14</sup> Admission to the intensive care unit (ICU) with a primary diagnosis of a hypercalcaemic crisis is uncommon. Although a number of aetiologies has been described (Table 54.3), in the critical care setting it is usually due to malignancy-related hypercalcaemia, renal failure or posthypocalcaemic hypercalcaemia.<sup>15</sup> Before undertaking a work-up for hypercalcaemia, it is important to exclude false-positive measurements. This is usually the result of inadvertent haemoconcentration during venepuncture and elevation in serum protein, although ionised calcium levels are not reported to be affected by haemoconcentration.<sup>16</sup> *Pseudohypercalcaemia* has also been described in the setting of essential thrombocythaemia. The erroneous result is thought to be due to in vitro release of calcium from platelets, analogous to the pseudohyperkalaemia seen in the same condition.<sup>17</sup>

Table 54.3 Causes of hypercalcaemia

Common causes of hypercalcaemia in the critically ill patient
Complication of malignancy
Bony metastases
Humoral hypercalcaemia of malignancy
Posthypocalcaemic hypercalcaemia
Recovery from pancreatitis <sup>15</sup>
Recovery from acute renal failure following rhabdomyolysis <sup>37–41</sup>
Primary hyperparathyroidism
Adrenal insufficiency <sup>23,24</sup>
Prolonged immobilisation <sup>18–21</sup>
Disorders of magnesium metabolism
Use of total parenteral nutrition <sup>42</sup>
Hypovolaemia
Iatrogenic calcium administration
Less common causes of hypercalcaemia in the critically ill patient
Granulomatous diseases – sarcoidosis, tuberculosis, berylliosis
Vitamin A and D intoxication
Multiple myeloma
Endocrine
Thyrotoxicosis
Acromegaly
Pheochromocytoma
Lithium – chronic therapy
Rare association between drugs and hypercalcaemia
Theophylline, omeprazole and growth hormone therapy

From a pathophysiological standpoint, hypercalcaemia may be due to an elevation in PTH, in which case the homeostatic regulatory and feedback mechanisms are preserved, and this is termed *equilibrium hypercalcaemia*. Alternatively, it could be a non-parathyroid-mediated hypercalcaemia with associated breakdown of homeostatic mechanisms, and this situation is termed *dys-equilibrium hypercalcaemia*.

### MECHANISMS OF HYPERCALCAEMIA

Malignancy-related hypercalcaemia might arise from bony metastases or humoral hypercalcaemia of malignancy. In the latter (seen with bronchogenic carcinoma and hypernephroma), tumour osteolysis of bone resulting from the release of PTH-like substances (these cross-react with PTH in the radioimmunoassay, but are not identical to PTH), calcitriol, osteoclast-activating factor and prostaglandins is thought to be the major underlying mechanism. Aggravating factors include dehydration, immobilisation and renal failure.

Posthypocalcaemic hypercalcaemia is a transient phenomenon seen in patients following a period of hypocalcaemia.<sup>15</sup> This has been attributed to a parathyroid hyperplasia which develops during the period of hypocalcaemia, resulting in a rebound hypercalcaemia following resolution of the underlying hypocalcaemic disorder.

Immobilisation hypercalcaemia results from an alteration in balance between bone formation and resorption.<sup>18–21</sup> This leads to loss of bone minerals, hypercalcaemia, hypercalciuria and increased risk of renal failure. In patients with normal bone turnover, immobilisation rarely causes significant hypercalcaemia. However, in patients with rapid turnover of bone (children, postfracture patients, hyperparathyroidism, Paget's disease, spinal injuries and Guillain-Barré syndrome), this may result in severe hypercalcaemia.

Intravascular volume depletion reduces renal calcium excretion by a combination of reduced glomerular filtration and increased tubular reabsorption of calcium. Hypercalcaemia further compounds this problem by causing a concentrating defect in the renal tubules, thus creating a polyuria and further aggravating the hypovolaemia.

Extrarenal production of calcitriol by lymphocytes in granulomata is thought to be the predominant mechanism of hypercalcaemia in granulomatous diseases.<sup>22</sup>

Only 10–20% of patients with adrenal insufficiency develop hypercalcaemia.<sup>23,24</sup> The aetiology of this is thought to be multifactorial: intravascular volume depletion, haemoconcentration of plasma proteins and the loss of antivitamin D effects of glucocorticoids.

For rarer causes of hypercalcaemia, the reader is referred to a recent review.<sup>25</sup>

### MANIFESTATIONS OF HYPERCALCAEMIA

The clinical manifestations of hypercalcaemia (commonly encountered when total serum calcium exceeds 3 mmol/l) are outlined in Table 54.4. *Hypercalcaemic crisis* is defined as severe hypercalcaemia (total serum Ca > 3.5 mmol/l) associated with acute symptoms and signs.

### INVESTIGATIONS

A detailed diagnostic algorithm is outside of the scope of this chapter. The basic work-up should include serum calcium, phosphorus and alkaline phosphatase estimation, PTH assay, renal function assessment and a skeletal survey.

### THERAPY OF HYPERCALCAEMIA AND HYPERCALCAEMIC CRISIS

Mild asymptomatic hypercalcaemia does not require emergent treatment. Therapy is usually directed at the underlying cause.

The management of hypercalcaemic crisis consists of two principal components:

1. increasing urinary excretion of calcium
2. reducing bone resorption

#### INCREASING URINARY EXCRETION OF CALCIUM

As almost all patients with hypercalcaemia are volume-depleted, the initial therapy consists of rehydration with normal saline followed by diuresis with furosemide. Rehydration with normal saline improves intravascular volume,

**Table 54.4** Clinical manifestations of hypercalcaemia\*

Coma
Seizures

\*Ectopic calcification is usually seen with chronic hypercalcaemia.

reduces serum calcium by extracellular dilution and saluresis promotes calcium loss in the urine. Volume expansion should be titrated to clinical endpoints and central venous pressure monitoring. A urine output of 4–5 litres should be aimed for in these patients to promote calciuresis. In many patients, these measures would achieve a reduction in serum calcium by about 0.4–0.5 mmol/l. Hypokalaemia, hypomagnesaemia and calcium stone formation in the urine are potential side-effects of this mode of treatment.

In patients with established renal failure in whom forced diuresis cannot be instituted, dialysis against a dialysate with zero or low calcium concentrations should be the treatment of choice.

#### REDUCING BONE RESORPTION

Measures to increase urinary excretion of calcium should be followed up with administration of agents minimising bone resorption. A number of agents are available and these are listed in Table 54.5.

Disodium ethylenediaminetetraacetic acid (EDTA) at a dose of 15–50 mg/kg intravenously rapidly lowers serum calcium. However, its propensity to reduce serum calcium rapidly coupled with its nephrotoxic effects limits its usefulness in life-threatening hypercalcaemia. Other therapeutic modalities include the use of non-steroidal anti-inflammatory drugs and parathyroidectomy. Calcimimetics are agents which increase the activation of the calcium receptor, thus reducing serum PTH concentrations. Cinacalcet is a first-generation calcimimetic which has shown promise in early randomised trials for the management

of hypercalcaemia. However, their role in the management of acute hypercalcaemia needs to be established.<sup>26</sup>

At the present time, several newer and more potent bisphosphonates are under development. Their efficacy, combined with a relative lack of side-effects, makes them the agents of choice for the treatment of malignancy-related hypercalcaemia.

Other drugs that have been used in the management of hypercalcaemia include prostaglandin inhibitors for cancer-related hypercalcaemia, ketoconazole and chloroquine (for sarcoid-induced hypercalcaemia).<sup>27</sup>

#### ADJUNCT MEASURES IN THE MANAGEMENT OF HYPERCALCAEMIA

Monitoring of cardiorespiratory function and biochemical status is mandatory during therapy of hypercalcaemia. Thiazide diuretics, vitamin D and absorbable antacids should be avoided. Hypercalcaemia potentiates digitalis effect and dosage should be adjusted accordingly. Endocrinologists should be consulted for further management.

#### HYPOCALCAEMIA

Hypocalcaemia is more common than hypercalcaemia in critically ill patients, with an estimated incidence of around 70–90%.<sup>5</sup> As the ionised calcium is the biologically active moiety, it is important to look at ionised hypocalcaemia. The frequency of this is far more varied, ranging from 15 to 70%.<sup>5,28,29</sup> Spurious hypocalcaemia may be seen in the following circumstances: a) prolonged storage of specimens prior to analysis (resulting in CO<sub>2</sub> loss from specimens) or b) if the blood sample is drawn with a syringe containing large doses of heparin as an anticoagulant or c) inadvertent collection of the blood sample into EDTA containing tubes (due to calcium chelation). Gadolinium agents (used as contrast for MRI) may also cause a pseudohypocalcaemia if a colorimetric assay is used for the measurement of calcium.

#### AETIOLOGIES

The aetiology of ionised hypocalcaemia based on the predominant pathophysiological mechanism is listed in Table 54.6. The other contributory mechanisms of hypocalcaemia in each of the conditions are shown in brackets.

Although a long list of causes exists for hypocalcaemia, calcium chelation and hypoparathyroidism constitute the common mechanisms of ionised hypocalcaemia in intensive care. Frequently, hypocalcaemia is accompanied by a number of other biochemical abnormalities; thus a pattern recognition approach towards the cause of hypocalcaemia will point to its aetiology and save a considerable amount of investigations for the patient. Common diagnostic patterns are listed in Table 54.7.

Whilst alkalosis is frequently associated with ionised hypocalcaemia, the presence of a metabolic acidosis in the face of a low serum ionised calcium narrows the differential diagnosis even further (Table 54.8).

Table 54.5: Therapeutic agents for reducing bone restoration

Therapy	Indications	Dose	Onset time/ duration	Limitations	Mechanism of action	Comments
Bi-Phosphonates* Etidronate (first-generation)	Malignancy-related hypercalcaemia	5 mg/kg per day	1–2 days, lasts 5–7 days	Hyperphosphataemia, short duration of action	Inhibit osteoclast activity, may have some effect on osteoblasts	High-potency group. Pamidronate lowers Ca levels more rapidly than etidronate
Pamidronate (second-generation)		90 mg as an infusion every 4 weeks	1–2 days, lasts 10–14 days	Hypophosphataemia, fever and hypomagnesaemia		
Calcitonin	Hypercalcaemia, Paget's disease	Initial IV dose 3–4 U/kg followed by 4 U/kg SC 12-hourly	Hours, lasts 2–3 days	Nausea, abdominal pain, flushing, tachyphylaxis, limited efficacy	Inhibit osteoclast activity, reduces renal tubular reabsorption of calcium	Tachyphylaxis minimised by concomitant steroid therapy
Glucocorticoids	Vitamin D toxicity, myeloma, lymphoma, granulomata	IV hydrocortisone 200–400 mg/day	Days, lasts days to weeks	Glucocorticoid side-effects	Inhibit inflammatory cell production of calcitriol, reduce gut absorption of calcium	Improve the efficacy of calcitonin
Gallium nitrate	Malignancy-related hypercalcaemia	100–200 mg/m <sup>2</sup> per day for 5–7 days	5–6 days, lasts 7–10 days	Nephrotoxic	Inhibits bone resorption and alters bone crystal structure	Recent phase II data suggest equivalent efficacy with pamidronate <sup>43</sup>
Plicamycin	Malignancy-related hypercalcaemia	25 µg/kg IV	Rapid onset, lasts for a few days	Hepatotoxic, nephrotoxic and thrombocytopenia	Inhibits cellular RNA synthesis	Side-effect profile limits the use of this drug
Intravenous phosphates	Limited clinical role	10–15 mmol as an infusion repeated at regular intervals	Hours, lasts 24–48 hours after cessation	Ectopic calcification, severe hypocalcaemia	Ectopic calcification, reduce gut absorption, inhibition of bone resorption	Use superseded by the other modalities described

\*Other bisphosphonates include ibandronate, risedronate and zoledronate. As compared to pamidronate, zoledronate has the advantage of simplicity of administration and better control of hypercalcaemia.

IV, intravenous; SC, subcutaneous.

Table 54.6 Aetiology of ionised hypocalcaemia

**Calcium chelation**

Alkalosis (increased binding of calcium by albumin)  
 Citrate toxicity (calcium chelation)  
 Hyperphosphataemia (calcium chelation, ectopic calcification, reduced vitamin D<sub>3</sub> activity)  
 Pancreatitis (calcium soap formation, reduced parathyroid secretion)  
 Tumour lysis syndrome (hyperphosphataemia)  
 Rhabdomyolysis (hyperphosphataemia and reduced levels of calcitriol)

**Hypoparathyroidism**

Hypo- and hypermagnesaemia  
 Sepsis (decreased parathyroid hormone secretion, calcitriol resistance, intracellular shift of calcium)  
 Burns (decrease in parathyroid hormone secretion)  
 Neck surgery (removal of parathyroid gland, calcitonin release during thyroid surgery and 'hungry-bone' syndrome postparathyroidectomy)

**Hypovitaminosis D**

Inadequate intake  
 Malabsorption  
 Liver disease (impaired 25-hydroxylation of cholecalciferol)  
 Renal failure (impaired 1-hydroxylation of cholecalciferol, hyperphosphataemia)

**Reduced bone turnover**

Osteoporosis  
 Elderly  
 Cachexia

**Drug-induced**

Phenytoin (accelerated metabolism of vitamin D<sub>3</sub>)  
 Diphosphonates (see under hypercalcaemia)  
 Propofol  
 Ethylenediaminetetraacetic acid (EDTA: calcium chelation)  
 Ethylene glycol (formation of calcium oxalate crystals in the urine)  
 Cis-platinum (renal tubular damage leading to hypermagnesuria)  
 Protamine  
 Gentamicin (hypermagnesuria leading to hypomagnesaemia and therefore hypocalcaemia)

**CLINICAL MANIFESTATIONS OF HYPOCALCAEMIA**

Mild degrees of hypocalcaemia are usually asymptomatic. Ionised calcium levels less than 0.8 mmol/l may cause neuromuscular irritability and result in clinical symptoms. The clinical manifestations of hypocalcaemia are summarised in Table 54.9. The manifestations listed in Table 54.9 are by no means a comprehensive list of all the clinical features, but include the ones most commonly seen in the critical care setting.

When eliciting tetany, Trousseau's sign (carpopedal spasm) is more specific for hypocalcaemia than Chvostek's

Table 54.8 Hypocalcaemia with metabolic acidosis

Acute renal failure  
 Tumour lysis  
 Rhabdomyolysis  
 Pancreatitis  
 Ethylene glycol poisoning  
 Hydrofluoric acid intoxication

Table 54.9 Clinical manifestations of hypocalcaemia

**Central nervous system**

Circumoral and peripheral paraesthesia  
 Muscle cramps  
 Tetany  
 Seizures  
 Extrapyrmidal manifestations: tremor, ataxia, dystonia  
 Proximal myopathy  
 Depression, anxiety, psychosis

**Cardiovascular**

Arrhythmias  
 Hypotension, inotrope unresponsiveness  
 Prolonged QT intervals, T-wave inversion  
 Loss of digitalis effect

**Respiratory**

Apnoea  
 Laryngospasm  
 Bronchospasm

Table 54.7 Pattern recognition in the diagnosis of common causes of hypocalcaemia

Aetiology of hypocalcaemia	Clinical/biochemical patterns
Low serum albumin	Reduced total calcium, normal ionised calcium
Alkalosis	Normal total calcium, reduced ionised calcium
Hypomagnesaemia	Reduced ionised calcium and hypokalaemia
Pancreatitis	Hypocalcaemia, elevated serum lipase and glucose
Renal failure	Elevated blood urea nitrogen, elevated phosphate
Rhabdomyolysis	Hypocalcaemia, elevated phosphate, creatine kinase and urinary myoglobin
Tumour lysis syndrome	Hypocalcaemia, elevated phosphate, potassium and urate

sign (facial twitch in response to facial nerve stimulus – present in 10–30% of the normal population). Electrocardiogram changes do not correlate well with the degree of hypocalcaemia. The symptoms of hypocalcaemia are exacerbated by a coexisting hypokalaemia and hypomagnesaemia.

The laboratory work-up should include serum calcium, phosphorus, magnesium and alkaline phosphatase, PTH and vitamin D assays and renal function assessment.

### APPROACH TO THE TREATMENT OF ASYMPTOMATIC AND SYMPTOMATIC HYPOCALCAEMIA

#### ARGUMENTS FOR AND AGAINST CORRECTION OF ASYMPTOMATIC HYPOCALCAEMIA

As stated before, it is not clear if asymptomatic hypocalcaemia needs correction. Based on published data which suggest that critical care hypocalcaemia is associated with a higher mortality and increased length of stay in intensive care,<sup>30–32</sup> it is advocated that ionised hypocalcaemia be corrected routinely, irrespective of the level. However, arguments exist against the routine correction of asymptomatic ionised hypocalcaemia. Increases in cytosolic calcium lead to disruption of intracellular processes and activation of proteases and can lead to ischaemia and reperfusion injury.<sup>33</sup> Also, there are data suggesting that ionised calcium is an important participant in the pathogenesis of coronary and cerebral vasospasm.<sup>34</sup> In rodent models of endotoxic shock, there are also data demonstrating an increased mortality when these rats were administered intravenous calcium.<sup>35</sup> Most clinicians agree that an ionised calcium level of < 0.8 mmol/l needs correction, even if asymptomatic.

#### MANAGEMENT OF ACUTE SYMPTOMATIC HYPOCALCAEMIA

Acute symptomatic hypocalcaemia is a medical emergency that requires immediate therapy. In addition to treatment of underlying cause and support of airway, breathing and circulation, the definitive treatment includes administration of intravenous calcium. Intravenous calcium is available as a calcium salt of chloride or gluconate or acetate. The main difference between these formulations is the amount of elemental calcium available at equivalent volumes of drug (Table 54.10). The dose of calcium

**Table 54.10** Commonly used intravenous calcium preparations

Preparation	Dosage	Elemental calcium/gram
Calcium gluconate	10 ml	93 mg (2.3 mmol)
Calcium chloride	10 ml	272 mg (6.8 mmol)

**Table 54.11** Indications for calcium administration

#### Absolute

Symptomatic hypocalcaemia  
Ionised Ca < 0.8 mmol/l  
Hyperkalaemia  
Calcium channel blocker overdose

#### Relative

β-blocker overdose  
Hypermagnesaemia  
Hypocalcaemia in the face of high inotrope requirement  
Massive blood transfusion post cardiopulmonary bypass to augment cardiac contractility

required should be based on the elemental calcium.<sup>36</sup> Intravenous calcium can be administered as a bolus or as an infusion. Rapid administration of calcium may cause nausea, flushing, headache and arrhythmias. Digitalis toxicity may be precipitated. Extravasation of calcium may lead to tissue irritation, particularly with the chloride salt.

Calcium chloride may be better than calcium gluconate for the management of hypocalcaemia, if there is concomitant alkalosis. Following an initial bolus, an infusion may be commenced at a rate of 1–2 mg/kg per hour of elemental calcium to maintain target levels of ionised calcium. With correction of the underlying disorder and restoration of calcium to normal levels, the infusion can be tapered and stopped. Adequacy of calcium therapy can be monitored clinically and by performing serial determinations of ionised calcium. Failure of ionised calcium to increase after commencement of intravenous calcium may indicate an underlying magnesium deficiency. This can be corrected by administration of 10 mmol of intravenous magnesium over 20 minutes. Administration of calcium in the setting of hyperphosphataemia may result in calcium precipitation in the tissues. Calcium salts should not be administered with bicarbonate since the two precipitate. The other indications for calcium administration are listed in Table 54.11. Other therapy for hypocalcaemia consists of oral calcium supplements and calcitriol administration, although these are usually used in the management of chronic hypocalcaemia.

# Pre-eclampsia and eclampsia

Warwick D Ngan Kee and Tony Gin

Pre-eclampsia is a syndrome specific to pregnancy. It has no definitive biomarkers and is diagnosed clinically by new onset of hypertension and proteinuria after 20 weeks' gestation (Table 55.1). Oedema and hyperreflexia typically also occur. Diagnostic criteria have varied among countries and over time, although in recent years international working groups have worked towards consensus.<sup>1,2</sup> There is overlap among pre-eclampsia, pre-existing hypertension, pre-eclampsia superimposed on pre-existing hypertension and non-proteinuric gestational hypertension. Eclampsia describes the occurrence in a pre-eclamptic woman of seizures not attributable to other causes.

Pre-eclampsia complicates 2–7% of pregnancies in developed countries and is a leading cause of maternal deaths.<sup>2,3</sup> Associated maternal mortality is 1.5 per 100 000 live births in the USA.<sup>4</sup> The incidence of eclampsia is 0.04–0.1% in the USA and UK,<sup>5</sup> with maternal mortality in the UK of 1.8% and fetal/neonatal mortality of around 7%.<sup>6</sup> Incidence and mortality for both pre-eclampsia and eclampsia are much higher in developing countries.<sup>5</sup>

Factors associated with increased maternal risk include:

- onset at  $\leq$  32 weeks' gestation
- greater maternal age and parity
- pre-existing hypertension or medical complications
- Afro-Caribbean descent
- nausea and vomiting and epigastric pain
- abnormal laboratory tests, including raised liver enzymes, increased serum creatinine and increased serum uric acid<sup>7,8</sup>

Patients may be referred to the intensive care unit (ICU) for poorly controlled hypertension or convulsions, post-operative care or following complications such as pulmonary oedema, renal failure, haemorrhage, coagulopathy and stroke.

## AETIOLOGY

The cause of pre-eclampsia is unknown. As yet, there is no satisfactory single unifying aetiological hypothesis. Although there is a genetic predisposition, the exact mode of inheritance is unclear and there may be multiple phenotypes.<sup>9</sup> Immunologic factors such as an abnormal

maternal response to fetopaternal antigens have been implicated. Pre-eclampsia is more common in primigravidae, multiple gestation, obesity, black race, molar pregnancy, when there is pre-existing hypertension, underlying disease (e.g. autoimmune disease, renal disease, diabetes and thrombophilias) and when there is a previous or family history of pre-eclampsia.<sup>10</sup> A change in partner has been considered a risk factor but this may be partially related to increased risk associated with extended intervals between pregnancies.<sup>11</sup>

## PATHOGENESIS

Pre-eclampsia is a systemic disease that affects most organ systems. Many theories of pathogenesis have been proposed,<sup>12–14</sup> but a common concept is that of a two-stage disease with an initial stage of abnormal placentation followed by a second stage of clinical disease. Initially, there is inadequate endovascular invasion of fetal trophoblast into the spiral arteries with reduced dilatation of uterine spiral arteries and placental hypoxia. This acts as a precipitating factor that leads to a generalised inflammatory response, of which diffuse endothelial dysfunction is a prominent component. The result is an increase in sensitivity to vasoactive substances, a decrease in endothelial synthesis of vasodilator substances such as prostaglandin and nitric oxide, activation of platelet and coagulation and an increase in capillary permeability. This causes widespread vasoconstriction, fluid extravasation, proteinuria, decreased intravascular volume, haemoconcentration and decreased organ perfusion. The link between placental triggering and the systemic response is unknown, but has been theorised to involve oxidative stress and circulating cytotoxic factors. Candidates for the latter include circulating angiogenic factors such as vascular endothelial growth factors, placental growth factor and fms-like tyrosine kinase-1 (sFlt1).<sup>13,14</sup>

## CLINICAL PRESENTATION

Pre-eclampsia is a syndrome with a spectrum of presentations. Although hypertension is the cardinal sign, some women present with convulsions, abdominal pain or general

**Table 55.1** Basic diagnostic criteria for pre-eclampsia

Hypertension	Systolic arterial pressure > 140 mmHg or Diastolic arterial pressure* > 90 mmHg
and	
Proteinuria	≥ 300 mg protein in a 24-hour collection

\*Korotkoff phase V.

A rise in blood pressure above baseline and oedema are now not usually included.

A positive dipstick test for proteinuria should be confirmed by 24-hour urine collection.

**Table 55.2** Clinical features suggestive of severe pre-eclampsia

Blood pressure	Systolic arterial pressure > 160 mmHg Diastolic arterial pressure > 110 mmHg
Renal	Proteinuria ≥ 2 g/24 h Oliguria < 500 ml/24 h Serum creatinine > 0.09 mmol/l
Hepatic	Epigastric or right-upper-quadrant pain Elevated bilirubin and/or transaminases
Neurological	Persistent headaches Visual disturbances  Convulsions (eclampsia)
Haematological	Thrombocytopenia Deranged coagulation tests Haemolysis
Cardiac/respiratory	Pulmonary oedema Cyanosis

malaise<sup>15</sup> and some complications may be life-threatening without a marked increase in blood pressure. Features typical of severe disease are listed in Table 55.2. Rarely, cocaine intoxication and phaeochromocytoma may be confused with pre-eclampsia.

*Haemodynamic changes* of pre-eclampsia consist of hypertension, increased systemic vascular resistance and decreased intravascular volume. Cardiac output is usually decreased, usually secondary to changes in preload and afterload rather than contractility.<sup>16</sup> Sympathetic activation occurs, and this may account for observations of increased cardiac output in the early stage.<sup>17</sup> Pulmonary oedema may occur because of iatrogenic fluid overload, decreased left ventricular function, increased capillary permeability and narrowing of the colloid osmotic–pulmonary capillary wedge pressure gradient; this is more likely to occur after delivery. Sudden ventricular tachycardia may occur during hypertensive crises.

*Neurological complications* include eclamptic convulsions, cerebral oedema, raised intracranial pressure and stroke. Intracranial haemorrhage is an important cause of death.<sup>3</sup>

*Renal changes* include reduced glomerular filtration rate and renal plasma flow, which are associated with the characteristic lesion of glomeruloendotheliosis. Hyperuricaemia is associated with increased prenatal risk, particularly if serum uric acid concentration rises rapidly.

*Haemostatic abnormalities* include thrombocytopenia, which may be associated with decreased platelet function. Associated coagulation abnormalities may occur but are unlikely unless the platelet count is < 100 000 × 10<sup>9</sup>/l.<sup>18,19</sup>

*Hepatic complications* include liver oedema, hepatocellular necrosis, periportal and subcapsular haemorrhage, hepatic infarcts and rupture. Patients with HELLP syndrome (see below) are particularly at risk.

The leading causes of maternal death in pre-eclampsia/eclampsia are intracranial haemorrhage, pulmonary oedema and hepatic complications.<sup>3,4</sup> Fetal morbidity results from placental insufficiency, prematurity and abruptio placentae.

## MANAGEMENT

The treatment of pre-eclampsia is delivery of the placenta and fetus. Before delivery, and during the immediate postpartum period, management is supportive and focused on control of blood pressure, prevention of seizures, maintenance of placental perfusion and prevention of complications. If complications are avoided, the disease normally resolves completely after delivery. Transfer of the mother to a tertiary centre before delivery should be considered if a level III neonatal unit is not available (see Chapter 1). Pregnant and postnatal women may have special requirements which not all staff are experienced with.<sup>20</sup> Admission into an ICU before delivery may be appropriate in severe cases, or when the labour ward lacks the expertise or equipment for intensive monitoring. Because prematurity is a major cause of neonatal morbidity, expectant management to prolong pregnancy has been described in patients < 34 weeks' gestation.<sup>21</sup> This requires careful balancing of the maternal and perinatal risks. After delivery, severe cases should preferably be managed in an ICU for 24–72 hours.

## GENERAL MEASURES

Before delivery, patients should be kept in the lateral or semilateral position and the fetal heart rate should be monitored. Regular oral or intravenous histamine H<sub>2</sub> antagonists will decrease gastric acidity and volume. Prophylactic dexamethasone or betamethasone should be considered for fetal lung maturity if gestation is less than 34 weeks and early delivery is anticipated. Routine monitoring should include frequent clinical assessment, blood pressure, electrocardiogram (ECG) and fluid balance. Pulse oximetry aids the detection of incipient pulmonary oedema.<sup>22</sup> Central venous pressure (CVP) monitoring, preferably via an antecubital vein, and/or pulmonary artery catheterisation may

assist in fluid balance (see below). Full blood count, coagulation screen, electrolytes, uric acid, renal function, liver function and urinalysis should be performed serially to monitor disease progression.

### ANTIHYPERTENSIVE THERAPY

The aim of antihypertensive therapy is to prevent maternal complications (intracerebral haemorrhage, cardiac failure and abruptio placentae) while maintaining placental blood flow. It is important to appreciate that hypertension is a marker and not a causal factor in pre-eclampsia. Therefore, although controlling hypertension reduces the risk of complications, it does not ameliorate the underlying pathological process. Acute treatment is indicated when blood pressure is greater than 160 mmHg systolic or 105–110 mmHg diastolic. Reduction of systolic pressure is particularly important for the prevention of stroke.<sup>23</sup> Initially, systolic blood pressure should only be reduced by about 20–30 mmHg and diastolic pressure by 10–15 mmHg while monitoring the fetus.<sup>1</sup> Concomitant plasma expansion reduces the risk of sudden hypotension when vasodilators are used.<sup>1</sup> Recommended antihypertensive drugs for acute treatment are summarised in Table 55.3 and described below.<sup>1,2</sup> The most commonly used drugs are hydralazine, labetalol and nifedipine; insufficient data are currently available to prove which of these is superior.<sup>24</sup>

#### HYDRALAZINE

Hydralazine is a direct arteriolar vasodilator with a long history of use in pre-eclampsia. It has a relatively slow onset of action of 10–20 minutes and a duration of action of 6–8 hours. Concomitant volume expansion may reduce the incidence of associated hypotension and fetal distress. Adverse effects include headache, tachycardia, tremor, nausea and rare cases of neonatal thrombocytopenia.

**Table 55.3** Main drugs used for acute management of hypertension in pre-eclampsia

Drug	Dosage guide
Hydralazine	<i>Bolus</i> 5 mg IV followed by 5–10 mg every 20 min to maximum of 40 mg
Labetalol	<i>Bolus</i> 20–40 mg IV every 10–15 min to a maximum of 220 mg <i>Infusion</i> 1–2 mg/min, reducing to 0.5 mg/min or less after blood pressure is controlled
Nifedipine	<i>Orally</i> 10 mg, repeated after 30 min as required

IV, intravenously.

#### LABETALOL

Labetalol is a non-selective  $\beta$ -adrenergic receptor blocker with some  $\alpha_1$ -blocking effect. When given intravenously, it rapidly reduces blood pressure without decreasing uteroplacental blood flow,<sup>25</sup> and does not cause reflex tachycardia, headache or nausea. Although labetalol crosses the placenta, neonatal bradycardia and hypoglycaemia are rarely seen. Duration of action is variable. It should not be given to patients with asthma or myocardial dysfunction.

#### NIFEDIPINE

Nifedipine is a calcium-channel blocker that directly relaxes arterial smooth muscle. In pre-eclamptic patients with severe hypertension it causes a steady decrease in blood pressure and systemic vascular resistance within 30 minutes with a concomitant increase in maternal cardiac index and heart rate.<sup>26</sup> Nifedipine is recommended to be given orally. It is also effective sublingually or chewed but this may be associated with sudden hypotension and fetal compromise. Hypotension and potentiation of neuromuscular block have been reported in patients receiving magnesium sulphate. Nifedipine causes relaxation of uterine muscle which may increase the risk of postpartum haemorrhage. Mild side-effects include headache, flushing, and nausea.

#### OTHER AGENTS

*Sodium nitroprusside* (initial dose 0.25  $\mu\text{g}/\text{kg}$  per min, maximum dose 5  $\mu\text{g}/\text{kg}$  per min) can be used to reduce blood pressure rapidly in a hypertensive emergency<sup>3</sup> but care should be taken in patients with depleted intravascular volume and duration should be limited to < 4 hours to avoid fetal cyanide poisoning.<sup>3</sup> *Nitroglycerine* infusion (initial dose 5  $\mu\text{g}/\text{min}$ , maximum dose 100  $\mu\text{g}/\text{min}$ ) may be useful in cases complicated by pulmonary oedema. *Methyldopa* is often used for mild cases but its slow onset time makes it unsuitable for acute treatment. *Diazoxide*, *ketanserin*, *nimodipine* and *magnesium* are not recommended as first-line agents.<sup>24</sup> *Beta-blockers* other than labetalol may cause decreased uteroplacental perfusion, fetal bradycardia and decreased fetal tolerance to hypoxia. *Angiotensin-converting enzyme inhibitors* and *angiotensin antagonists* should not be used before delivery because of adverse fetal effects.<sup>1,3</sup> *Diuretics* should be avoided since pre-eclamptic patients have reduced plasma volume.

### ANTICONVULSANT THERAPY

Anticonvulsants are used to prevent recurrent convulsions in eclampsia or to prevent initial convulsions in pre-eclampsia. Magnesium sulphate is the drug of choice, although it may not be effective in all cases.<sup>27–29</sup>

### MAGNESIUM SULPHATE

There is universal agreement that patients with eclampsia should receive magnesium sulphate. However, because only a small proportion of patients with pre-eclampsia progress to eclampsia, the effectiveness and risk–benefit and cost–benefit ratios of prophylactic administration in pre-eclampsia are controversial.<sup>30–32</sup> The authors' practice is to start magnesium when there are clinical signs of severe pre-eclampsia, although the concept that eclampsia follows on from severe pre-eclampsia has been questioned.<sup>33</sup> The mechanism of action of magnesium for preventing eclamptic seizures is unknown. Although abnormal electroencephalograms are frequent in pre-eclampsia and eclampsia, they are not altered by magnesium sulphate. Part of magnesium's action has been considered to be reduction of cerebral vasospasm via antagonism of calcium at membrane channels or intracellular sites. However, the cerebral vasodilator nimodipine was shown to be ineffective for preventing seizures.<sup>34</sup> Magnesium amplifies release of prostacyclin by vascular endothelium, and this may inhibit platelet aggregation and vasoconstriction. Doppler ultrasonography suggests that magnesium vasodilates smaller-diameter intracranial blood vessels, and some of its effects may be from relieving cerebral ischaemia. Part of the anticonvulsant activity of magnesium may be mediated by blockade or suppression of *N*-methyl-D-aspartate (NMDA) receptors. Magnesium has tocolytic effects and mild general vasodilator and antihypertensive actions and increases renal and uterine blood flow.

Guidelines for administration of magnesium sulphate are summarised in Table 55.4. An intravenous loading dose followed by an infusion is preferred, although intramuscular administration is an alternative. Magnesium is rapidly excreted by the kidney. The half-life in patients with normal renal function is 4 hours and 90% of the dose is excreted by 24 hours after the infusion.<sup>35</sup> When there is renal impairment or oliguria the dose should be reduced and serum concentration should be monitored. Suggested target serum concentration for severe pre-eclampsia is 2–3.5 mmol/l (4–7 mEq/l or 4.8–8.4 mg/dl). Magnesium toxicity is associated with muscle weakness and may lead to respiratory paralysis (> 7.5 mmol/l). Increased conduction time with increased PR and QT intervals and QRS duration can lead to sinoatrial and atrioventricular block (> 7.5 mmol/l) and cardiac arrest in diastole (> 12.5 mmol/l). Toxicity is unlikely when deep tendon reflexes are present (the upper limb should be used during

**Table 55.4** Dosage regimens for magnesium sulphate

Intravenous regimen	Loading dose: 4–6 g over 20 min Maintenance: 1–2 g/h
Intramuscular regimen	4 g every 4 h

Renal function and tendon reflexes should be monitored. Reduce dose and monitor serum concentrations in oliguria or renal impairment. (1 g magnesium sulphate = 98 mg = 4.06 mmol = 8.12 mEq elemental magnesium).

epidural analgesia). Magnesium toxicity can be treated with small intravenous doses of calcium. Other reported adverse effects of magnesium include death from overdose, increased bleeding, slowed cervical dilatation and increased risk of pulmonary oedema. Magnesium crosses the placenta and can cause neonatal flaccidity and respiratory depression.

### OTHER ANTICONVULSANTS

If repeated seizures occur despite therapeutic levels of magnesium, conventional anticonvulsants can be considered, but it is important to exclude other causes of convulsions. Although *phenytoin* is inferior to magnesium for preventing eclamptic seizures,<sup>36</sup> it may be considered when there is renal failure. An initial intravenous loading dose of 10 mg/kg is followed 2 hours later by 5 mg/kg. Doses are diluted in normal saline and given no faster than 50 mg/min. Electrocardiogram and arterial pressure should be monitored. Maintenance doses of 200 mg orally or intravenously are started 12 hours after the second bolus and given 8-hourly. Similarly, intravenous infusion of *diazepam* has been used (40 mg diazepam in 500 ml normal saline titrated to keep patients sedated but rousable).<sup>37</sup>

### ECLAMPSIA

Eclampsia may occur without marked preceding hypertension or without proteinuria,<sup>33</sup> and up to one-third of cases occur postpartum, often more than 48 hours after delivery.<sup>38</sup> Priorities in the management of eclamptic seizures are airway protection, oxygenation, and termination and prevention of seizures. Delivery of the fetus should be considered after maternal stabilisation. Patients should be placed in the left lateral position and given oxygen. Magnesium should be given if not already started. Approximately 10% of eclamptic patients will have a recurrent seizure despite receiving magnesium.<sup>39</sup> Prolonged seizures can be terminated by diazepam 5–10 mg intravenously. If seizures are refractory, thiopental and suxamethonium should be given and the airway secured. Recurrent convulsions or prolonged unconsciousness may indicate additional cerebral pathology (e.g. cerebral oedema, intracerebral haemorrhage, venous thrombosis) and a computed tomographic (CT) scan should be done. Intensive neurological management, aimed at controlling intracranial pressure and optimising cerebral perfusion, has significantly reduced mortality in unconscious eclamptic patients.<sup>40</sup>

### FLUID BALANCE

Fluid management in pre-eclampsia is controversial. Pre-eclamptic patients usually have reduced circulating intravascular volume and oliguria is common in patients with

pre-eclampsia. Therefore, fluid loading with crystalloid or colloid solution has been advocated. However, the effectiveness of this is uncertain and, because of the risk of pulmonary oedema, this practice can be questioned.<sup>41</sup> A suggested fluid regimen is to start maintenance crystalloid at 75–125 ml/h intravenously, aiming for urine output > 0.5 ml/kg per hour, averaged over 3–4 hours. When there is oliguria or other signs of poor perfusion, repeated fluid challenge with 250–500 ml crystalloid or 100–200 ml colloid may be given, while monitoring with a pulse oximeter and examining for fluid overload. Urinary sodium < 20 mmol/l, osmolality > 500 mosmol/kg or fractional excretion of sodium of < 1 supports a prerenal cause for oliguria. Renal failure in pre-eclampsia is uncommon. Some patients with persistent oliguria and a rising serum creatinine concentration may require a period of continuous renal replacement therapy but the majority of cases recover. However, the risk of irreversible renal damage is greater when there is associated abruptio placentae, disseminated intravascular coagulation (DIC), hypotensive shock, or sepsis.<sup>15</sup> Low-dose dopamine (3 µg/kg per min) and furosemide (5 mg/h) infusions have been used after correction of hypovolaemia to improve urine output and renal function in oliguric pre-eclamptic patients,<sup>42</sup> but whether this reduces the need for dialysis is undetermined.

There is controversy over the effectiveness of CVP and pulmonary capillary wedge pressure (PCWP) for assisting fluid management in pre-eclamptic patients. CVP and PCWP have poor correlation, especially when CVP is greater than 6 mmHg (0.8 kPa).<sup>43</sup> Optimal CVP and PCWP values are unknown but the measured response to fluid challenge may be informative and useful. Pulmonary artery catheterisation has risks in patients who are oedematous and coagulopathic and should only be considered when there are clear indications (e.g. refractory hypertension, pulmonary oedema and refractory oliguria).<sup>43</sup> Pulmonary oedema is unlikely with a CVP less than 6 mmHg, but when it occurs, should be managed with oxygen therapy, positive end-expiratory pressure with or without ventilation, inotropes, vasodilators, morphine or diuretics as indicated.

#### POSTPARTUM CARE

Patients are frequently referred to an ICU for postpartum care, particularly after caesarean delivery. The risk of pulmonary oedema is greatest after delivery and most maternal deaths occur then.<sup>44</sup> After delivery, there is often an initial improvement with a relapse in the first 24 hours. Magnesium should be continued for 24–48 hours. Antihypertensive drugs may be reduced according to the blood pressure. Some patients may require a change to oral medication which may need to be continued for several weeks. Psychological support is important, especially if there has been an adverse neonatal outcome. Full recovery from the organ dysfunction of pre-eclampsia is normally expected within 6 weeks.

#### HELLP SYNDROME AND HEPATIC COMPLICATIONS

HELLP syndrome is a particularly high risk form of pre-eclampsia characterised by more pronounced hepatic rather than cerebral or renal involvement. Diagnosis is based on laboratory findings showing haemolysis (microangiopathic haemolytic anaemia), elevated liver enzymes and low platelets, although exact criteria vary.<sup>45,46</sup> Clinical presentation is variable. Many patients have non-specific signs such as right-upper-quadrant or epigastric pain, nausea, malaise or headache. Although most patients will have hypertension and proteinuria, these can be mild or absent. Important differential diagnoses include idiopathic thrombocytopenic purpura, systemic lupus erythematosus, thrombotic thrombocytopenic purpura, haemolytic-uraemic syndrome and acute fatty liver of pregnancy.<sup>45,46</sup> Typically, HELLP syndrome presents at early gestational ages and is more common in white and multiparous women.<sup>47</sup> In about 30% of cases, it first presents in the postpartum period, sometimes with no evidence of pre-eclampsia before delivery.<sup>46</sup> After delivery, patients usually show a continuing deterioration in platelet count and liver enzymes, with a peak in severity 24–48 hours after delivery followed by gradual resolution and complete recovery if complications are avoided. Complications of HELLP syndrome include DIC, abruptio placentae, acute renal failure, pulmonary oedema, severe ascites, pleural effusion, liver haemorrhage or failure, acute respiratory distress syndrome (ARDS), sepsis and stroke.<sup>46</sup>

Patients with HELLP should be managed aggressively, similarly to pre-eclampsia, with an emphasis on stabilisation and delivery. Expectant management of patients with gestation less than 34 weeks has been described but the relative benefits and risks of this are controversial.<sup>45,46</sup> Use of high-dose intravenous corticosteroids (e.g. dexamethasone 10 mg 6-hourly for 2 doses, then 6 mg 6-hourly for 2 doses) has been reported to accelerate recovery, but this is also controversial.<sup>45,46,48</sup> Plasma exchange with fresh frozen plasma has been described for postpartum patients with delayed resolution of HELLP with variable response.<sup>49</sup>

Life-threatening hepatic complications may occur in pre-eclampsia, particularly in patients with HELLP syndrome.<sup>45,46</sup> These include segmental hepatic infarction, parenchymal haemorrhage and subcapsular haematoma with or without rupture. If suspected, patients should have an urgent CT scan.<sup>46</sup> Hepatic rupture is a surgical emergency. Hepatic haemorrhage without rupture has been managed conservatively.<sup>45</sup>

#### ANAESTHESIA AND ANALGESIA

Platelet count and coagulation tests should be checked before regional anaesthesia. Epidural analgesia in labour reduces fluctuations in arterial pressure and improves

placental blood flow.<sup>50</sup> For caesarean section, the use of epidural or spinal anaesthesia avoids the risks of aspiration, difficult intubation from airway oedema, exaggerated hypertensive response to intubation and magnesium-induced sensitivity to muscle relaxants associated with general anaesthesia. If general anaesthesia is required, smaller-size endotracheal tubes may be required. The hypertensive response to intubation should be attenuated with drugs such as fentanyl (2.5 µg/kg), alfentanil (10 µg/kg), magnesium sulphate (40 mg/kg), a combination of alfentanil (7.5 µg/kg) with magnesium sulphate (30 mg/kg), or remifentanyl (1 µg/kg). Occasionally, awake intubation under topical anaesthesia may be necessary when there is airway obstruction.

# General obstetric emergencies in the ICU

Tony Gin and Warwick D Ngan Kee

The intensive care unit (ICU) will receive obstetric patients with the usual range of medical and surgical emergencies, and also provide supportive care for patients who suffer specific obstetric complications. The pattern of admission varies widely among countries with different standards of obstetric care, but complications of hypertensive disorders and haemorrhage usually make up a large proportion of cases,<sup>1</sup> while respiratory failure and sepsis are also common.<sup>2</sup> The proportion of obstetric patients in most ICUs is still low, and this may lead to relative inexperience in management and teamwork between the intensivist and obstetrician. The latest report of the UK Confidential Enquiries into Maternal Deaths noted that one-third of mothers who died had some intensive care involvement.<sup>3</sup> Unfortunately, major problems identified on the ward were:

- failure to recognise the severity of disease
- late referral to the ICU
- inadequate management of the ill patient while awaiting ICU admission

Maternal outcome is usually favourable because patients are often young and healthy. Scoring systems appear to be valid when the primary problem is medical, but overestimate mortality when the problem is obstetric.<sup>1</sup> This is partly because normal pregnant physiological variables are scored as abnormal.

## PATHOPHYSIOLOGY

Two important points to recognise in treating obstetric patients are:

1. During pregnancy, the normal ranges for physiological variables change<sup>4</sup> (Table 56.1). This may modify the presentation of the problem, the normal physiological variables used to guide treatment and also the response to treatment. The majority of physiological changes revert to normal several days after delivery.
2. Both mother and fetus are affected by the pathology and subsequent treatment.

## AIRWAY AND VENTILATION

Several factors may complicate tracheal intubation in pregnancy:

- altered anatomy in pregnancy predisposes to a potentially difficult airway
- oedematous tissues
- delayed gastric emptying
- increased oxygen consumption

Intensivists must be familiar with the difficult airway algorithm and the use of the laryngeal mask airway.<sup>36,37</sup> Avoidance of intubation and the use of non-invasive ventilation may be a good option in selected cases.

Some causes of respiratory failure are modified by pregnancy (e.g. aspiration of gastric contents, viral pneumonia) and some are unique to pregnancy (e.g. amniotic fluid embolism (AFE), pre-eclampsia).<sup>5</sup> Pregnant patients are more susceptible to pulmonary oedema because of the increased blood volume and lower oncotic pressure. Mechanical ventilation can be more problematic in the pregnant patient.<sup>6</sup> Respiratory alkalosis is normal during pregnancy and fetal gas exchange must be considered when titrating respiratory support. Although the changes in anatomy and lung compliance present no difficulty to the mechanics of ventilation, strategies for managing adult respiratory distress syndrome (ARDS) such as permissive hypercapnia may be more difficult to implement<sup>5,7</sup> (see below).

## CIRCULATION

### ALTERED SIGNS

Tachycardia, low blood pressure, increased cardiac output and warm peripheries are normal in late pregnancy, but these can mask early signs of sepsis and hypovolaemia. After 20 weeks' gestation, aortocaval compression by the gravid uterus can decrease uterine perfusion and venous return to the heart. This is best prevented by using the full left lateral position, but a left lateral tilt or manual displacement of the uterus may be more practicable.

Haemodynamic support should generally start with good hydration, and assessment should take into account the altered cardiovascular variables in pregnancy. Non-invasive cardiac output monitoring is inaccurate and

**Table 56.1** Changes in physiological variables during late pregnancy

Systolic arterial pressure	-5 mmHg
Mean arterial pressure	-5 mmHg
Diastolic arterial pressure	-10 mmHg
Central venous pressure	No change
Pulmonary capillary wedge pressure	No change
Heart rate	+15%
Stroke volume	+30%
Cardiac output	+45%
Systemic vascular resistance	-15%
Pulmonary vascular resistance	-30%
Tidal volume	+40%
Respiratory rate	+10%
Minute volume	+50%
Oxygen consumption	+20%
pH	No change
Pa <sub>o</sub> <sub>2</sub>	+10 mmHg
Pa <sub>c</sub> o <sub>2</sub>	-10 mmHg
HCO <sub>3</sub> <sup>-</sup>	-4 mmol/l
Total blood volume	+40%
Haematocrit	-0.06
Plasma albumin	-5 g/l
Oncotic pressure	-3 mmHg

invasive monitoring with pulmonary artery catheters may be helpful in severe pre-eclampsia, pulmonary oedema and cardiac disease.<sup>8</sup> The uterine vascular bed is considered maximally dilated but still responsive to stimuli that cause vasoconstriction, such as circulating catecholamines. Ephedrine has traditionally been the vasoconstrictor used in obstetrics because it was thought to preserve uterine blood flow better than pure alpha-agonists. However, alpha-agonists such as phenylephrine are more effective and not associated with fetal acidosis when used to manage hypotension during caesarean delivery.<sup>9</sup> There is no evidence favouring any particular inotrope.

## COAGULATION

Pregnancy is associated with a fivefold increase in thromboembolism, and patients should be given prophylaxis for thromboembolism, typically with unfractionated heparin or low-molecular-weight heparin (LMWH) and elastic compression stockings.

## MOTHER AND FETUS

The mother's welfare usually takes precedence over fetal concerns, especially as fetal survival is dependent on optimal maternal management. However, the possibility of fetal viability also creates ethical dilemmas. In the critically ill it is important to monitor the fetus because of the problems associated with:

- premature labour
- the placental transfer of drugs
- maintenance of placental perfusion and oxygenation

An obstetric opinion should be sought as soon as possible regarding cardiotocography, ultrasound examination and timing of delivery. Nutrition is also very important for the fetus and adequate maternal feeding should be started as soon as possible. Perineal and breast nursing care should not be neglected.

## CARDIOPULMONARY RESUSCITATION<sup>10</sup>

Cardiac arrest is rare in pregnancy and estimated to occur once in every 30 000 deliveries.

At more advanced gestation, one must consider potential fetal viability and recognise that the aetiology of cardiac arrest may include particular obstetric complications, such as AFE or drug toxicity from magnesium sulphate and local anaesthetics. As soon as the cardiac arrest call is activated, an obstetrician should be notified and preparations made for perimortem caesarean delivery if appropriate (see below).

Normally, external cardiac massage produces only 30% of cardiac output and this is reduced further if there is vena caval compression. After about 20 weeks' gestation it becomes increasingly necessary to relieve aortocaval compression during basic life support (BLS). Left lateral tilt decreases the efficiency of closed-chest compression, but a wedge providing an angle of 27° gives significant relief of vena caval obstruction while allowing 80% of the maximal force for chest compression.<sup>11</sup> During BLS, aortocaval compression may be minimised by manually displacing the uterus using a wedge, or positioning the pregnant patient's back on the rescuer's thighs. Chest compression should be performed with a slightly higher hand position (slightly above centre of sternum). Early tracheal intubation after cricoid pressure will facilitate ventilation and decrease the risk of acid aspiration. During advanced life support (ALS), drugs are given and defibrillation performed according to the normal protocols. Apical placement of the paddle may be difficult because of position and breast enlargement, and adhesive defibrillation pads are preferred.

*Fetal or uterine monitors should be removed before defibrillation.*

Case reports at advanced gestation indicate that both maternal and fetal survival from cardiac arrest may depend on prompt caesarean delivery to relieve the effects of aortocaval compression. The European Resuscitation Council Guidelines<sup>12</sup> and International Liaison Committee on Resuscitation (ILCOR) advisory statement<sup>13</sup> suggest that, if there is no immediate response to ALS, perimortem caesarean delivery should be considered. The decision must be made quickly because the surgery should start within 4 minutes of the arrest, with the aim of delivering the infant within 5 minutes of the arrest. There is no need to perform the delivery if the fetus is less than 20 weeks because aortal caval compression is not problematic then.

There is now some experience with somatic support after brain death to allow the fetus to mature.<sup>10</sup>

## TRAUMA

Trauma occurs in approximately 6–7% of all pregnancies but only requires hospital admission in 0.3–0.4% of pregnancies. Trauma is the leading non-obstetric cause of maternal mortality and survivors have a high rate of fetal loss.<sup>14</sup> Head injuries and haemorrhagic shock account for most maternal deaths, while placental abruption and maternal death are the most frequent causes of fetal death.<sup>15</sup> Most injuries occur as the result of motor vehicle accidents, but other common causes are suicide (usually postpartum), falls and assaults.

Initial resuscitation should follow the normal plan of attention to airway, breathing and circulation.<sup>16</sup> Oxygen 100% should be given and cricoid pressure applied during tracheal intubation. Blood volume is increased during pregnancy and hypotension may not be evident until 35% or more of total blood volume is lost. Uterine blood flow is not autoregulated and may be decreased despite normal maternal haemodynamics, so that slight overhydration may be preferred to underhydration. Excessive resuscitation with crystalloids or non-blood colloids may increase the mortality from severe haemorrhage.

Treatment of hypotension always includes positioning or manual uterine displacement to avoid aortocaval compression. Drug treatment of modest hypotension can be started with ephedrine, but more potent vasopressors should be used if necessary. AFE has been reported after blunt abdominal trauma.

Assessment of trauma should note the increased significance of pelvic fractures for uterine injury and retroperitoneal haemorrhage.

- Ultrasound is the investigation of choice.
- Diagnostic peritoneal lavage, if performed, should be through an open surgical incision above the fundus.
- Chest drains are placed slightly higher than normal, in the third or fourth intercostal space.
- It is important to exclude herniation of abdominal contents through a ruptured diaphragm.

Necessary radiological investigations should be performed as indicated because radiation hazard to the fetus is very unlikely, except in the early first trimester, where exposure to more than 50–100 mGy is a cause for concern. A chest X-ray delivers less than 5 mGy to the lungs and very little to the shielded abdomen. The fetal radiation dose from abdominal examinations can range from 1 mGy for a plain film, up to 20–50 mGy for an abdominal pelvic computed tomography (CT) with fluoroscopy.<sup>17</sup>

Cardiotocographic monitoring is considered essential, but there is wide variation in practice and in the recommended duration of monitoring. Premature labour and placental abruption may not be diagnosed unless regular monitoring is continued for at least 6 hours and even

24 hours if indicated.<sup>18</sup> Rh immune globulin 300 g should be considered for all Rh D-negative within 72 hours of injury. The Kleihauer–Betke test can be used to detect fetal blood in the maternal circulation and give an estimate of the volume of transplacental haemorrhage.

## BURNS

Serious burns during pregnancy are seen more commonly in the developing world. Although the women are usually young and healthy, pregnancy is already a hypermetabolic state and the fetus is at great risk from many complications.<sup>19</sup>

- Severe burns and sepsis are associated with high levels of prostaglandins that may cause preterm labour.
- Replacement of fluid loss from burns must keep in mind the normally increased circulating volume of pregnancy.
- Inhalational injuries with hypoxia and carbon monoxide are especially detrimental to the fetus.
- Infection is responsible for many of the maternal and fetal deaths but prophylactic antibiotic policies are controversial.

Patients of advanced gestation should not be kept supine and nutritional support for the fetus is necessary early. Topical povidone-iodine solution should be avoided because the iodine may be absorbed and affect fetal thyroid function. Premature delivery may have to be considered, especially with extensive burns.

## SEVERE OBSTETRIC HAEMORRHAGE

Severe bleeding is the most important cause of maternal death worldwide. Peripartum haemorrhage contributes to 15% of maternal deaths, but if one includes ectopic pregnancy, 25% of maternal deaths are a result of haemorrhage. It seems obvious that the treatment of massive haemorrhage requires sufficient intravenous access and the logistic capability to replace circulating volume quickly with warmed fluids, blood and clotting factors. Adequate preparation may even require the use of cell saver technology and operating in the angiography suite after the placement of catheters in preparation for embolisation. Unfortunately, many deaths have occurred because blood loss was often underestimated and volume replacement delayed. Conversely, excessive resuscitation with crystalloids or non-blood colloids when blood is required may increase the mortality from severe haemorrhage.

Antepartum haemorrhage is mostly from placenta praevia or placental abruption and both are ultimately managed by delivery. In placenta praevia, the placenta implants in advance of the presenting part and classically presents as painless bleeding during the second or third trimester. Placenta praevia is relatively common (1 in 200 pregnancies) but severe haemorrhage is relatively

rare. In placental abruption, a normally implanted placenta separates from the uterine wall. The incidence of placental abruption is low (0.5–2%) but perinatal mortality may be as high as 50%. Several litres of blood may be concealed in the uterus as a retroplacental clot. Bleeding may continue after delivery for a variety of reasons, including:

- uterine atony
- lacerations to cervix or vagina
- disseminated intravascular coagulation
- placenta accreta

Postpartum haemorrhage is usually from uterine atony or placenta accreta. In an emergency, the aorta can be compressed against the vertebral column by a fist pressed on the abdomen above the umbilicus. The control of haemorrhage allows time for resuscitation and more definitive surgical treatment.

Uterine atony is managed initially with bimanual compression, uterine massage and intravenous oxytocin given intravenously by bolus (5 units) or infusion (20 units). Oral misoprostol (0.6–1.0 mg) can also be used, while methylergonovine (0.2 mg) or 15-methyl-prostaglandin F<sub>2α</sub> (0.25 mg) is given intramuscularly or intramyometrially for persistent atony. Recombinant factor VIIa has also been used but the place of this therapy is still unclear.<sup>38,39</sup> If bleeding persists, tamponade techniques using gauze packs or balloons may be useful. Otherwise specific invasive management such as angiographic arterial embolisation, surgical ligation of the uterine, ovarian or internal iliac arteries or hysterectomy may be required.<sup>20</sup>

With massive bleeding and transfusion, there should be no need to wait for a coagulation profile before giving coagulation factors. Disseminated intravascular coagulation still develops in 10–30% of cases, partly because tissue thromboplastin is released during abruption. Blood should be sent for measurement of fibrinogen and fibrin degradation products and blood component therapy, and cryoprecipitate given as appropriate.

### SEPSIS AND SEPTIC SHOCK<sup>21,22</sup>

Although sepsis is a major problem in intensive care, maternal sepsis and septic shock are relatively uncommon and the prognosis is usually better than in the general population. The most common sources of infection are chorioamnionitis, postpartum endometritis, urinary tract infections, pyelonephritis and septic abortion. The physiological changes of pregnancy may influence the course and presentation of septic shock. Animal studies suggest that pregnancy increases the susceptibility to endotoxin, and that metabolic acidosis and cardiovascular collapse occur earlier.

Management of septic shock follows normal guidelines with eradication of the infectious source, although the normal range for haemodynamic variables may be different. Gram-negative organisms are the frequent causative

organisms but streptococci and *Bacteroides* may also be present. Antimicrobial therapy is dependent on hospital prevalence and susceptibility patterns, but empirical broad-spectrum therapy should be started early. Typical combinations are ampicillin, gentamicin and clindamycin, or imipenem, cilastatin and vancomycin. Tetracyclines and quinolones should not be used in pregnancy.

Newer approaches such as insulin therapy, corticosteroids and activated protein C have not been properly evaluated in pregnancy.<sup>2</sup>

### VENOUS THROMBOEMBOLISM<sup>23</sup>

Pulmonary thromboembolism is a common cause of maternal death, accounting for 15–25% of maternal mortality. Pregnancy is associated with a fivefold increase in thromboembolism because of:

- venous stasis
- hypercoagulable state
- vascular injury associated with delivery.

Patients with acquired and hereditary thrombophilias have an even greater risk.

Accurate diagnosis of venous thromboembolism is crucial because of the long-term implications for therapy. Symptoms of dyspnoea or pain in the leg or chest require accurate diagnosis, especially in the immediate postpartum period. Although contrast venography is the gold-standard test for diagnosing deep-vein thrombosis, the radiation exposure and invasive nature of the test mean that duplex Doppler ultrasonography is the usual first choice. D-dimer testing may also be useful but a positive test must be interpreted in the clinical context because D-dimer values normally increase throughout pregnancy. Venography, perfusion lung scanning, pulmonary angiography and helical CT scan should not be avoided if indicated.<sup>2</sup>

There are various reviews summarising the guidelines for anticoagulant therapy during pregnancy.<sup>24,25</sup> Although LMWH has gradually replaced unfractionated heparin for the prophylaxis and treatment of deep-vein thrombosis and pulmonary embolism in pregnancy, there is not adequate evidence for a definitive recommendation in pregnancy. Patients with suspected or proven deep-vein thrombosis or pulmonary embolism should be given full anticoagulant therapy that is continued throughout pregnancy. Warfarin should not be used before delivery so heparin is continued until labour begins and restarted in the postpartum patient for at least 6–12 weeks.

With life-threatening massive pulmonary embolus, surgical treatment or thrombolysis must be considered. Thrombolysis was thought to be relatively contraindicated during pregnancy because of the risk of maternal and fetal haemorrhagic complications. No controlled trials are feasible and outcome data must be extracted from case reports. A recent review found that thrombolytic therapy was associated with a low maternal mortality

rate of 1%, with a 6% rate of fetal loss and 6% rate of premature delivery.<sup>26</sup> The fetal risks appear to be lower than that obtained with surgical intervention in pregnant patients, and maternal risks lower than reported risks for surgery, thrombolysis or transvenous filters in non-pregnant patients. Although heparin remains the treatment of choice, thrombolysis appears to be a viable option except during the immediate postpartum period.

### AMNIOTIC FLUID EMBOLISM

AFE remains largely an unpredictable and unpreventable disease of uncertain pathophysiology.<sup>27,28</sup> Most of the information about AFE has been derived from case reports, maternal mortality reviews and reports from national registries of AFE, such as those in the USA<sup>29</sup> and UK.<sup>30</sup> The incidence of AFE varies between 1 in 8000 and 1 in 80 000 deliveries, although there must be undetected and unsuspected cases where minimal amounts of amniotic fluid produce few symptoms. AFE is the cause of 5–10% of maternal deaths, and 25–50% of patients with suspected or proven AFE die within the first hour. The overall maternal mortality has been as high as 86% in symptomatic patients, with a perinatal and neonatal mortality up to 40% and significant neurological problems in surviving neonates. However, recent figures of 26–37% mortality are more encouraging and this may be the result of early suspicion of AFE and early intensive care support.

AFE was thought to be associated with vigorous labour and the use of oxytocics, but it may occur in any parturient. The exact pathogenic factors for the syndrome of AFE remain unclear.<sup>31</sup> Amniotic fluid is thought to enter the maternal circulation through endocervical or uterine lacerations, uterine veins at the site of placental separation or placental abruption. Amniotic fluid normally contains prostaglandins, leukotrienes, endothelin and fetal debris that can cause complement activation, pulmonary vasoconstriction and physical blockage of pulmonary capillaries, with resultant damage and release of further mediators. By these mechanisms, AFE has more in common with anaphylaxis and septic shock than other embolic diseases.

The initial diagnosis of AFE is made on clinical grounds and is often one of exclusion. Classically, patients may present with severe dyspnoea, cyanosis, sudden cardiovascular collapse, coma or convulsions during labour but AFE may occur earlier during pregnancy, during delivery or in the early puerperium. Some patients may present with bleeding and most patients eventually develop a coagulopathy.

Animal studies indicate that AFE causes a biphasic haemodynamic response. The early phase probably lasts less than half an hour and is characterised by severe hypoxia and right heart failure as a result of pulmonary hypertension from vasoconstriction or vessel damage. Patients who survive this first phase develop left ventricular failure with return of normal right ventricular function. Left ventricular failure may be a result of the initial hypoxia or the

depressant effects of mediators. Disseminated intravascular coagulation is present in most patients but the mechanism is unknown. It could be caused by a specific activator of factor X, tissue factor or other substances, such as trophoblasts, in the amniotic fluid. Traditionally, AFE is confirmed by detection of squamous cells and fetal debris in the pulmonary circulation either at autopsy or in blood samples from a pulmonary artery catheter, but squamous cells are a contaminant that can be found in other parturients and even in non-pregnant patients.

No specific therapy is available. Immediate cardiopulmonary resuscitation and 100% oxygen are necessary. Assessment of central venous pressure may be misleading, and early pulmonary artery catheterisation has been advocated in a series reporting 100% survival in 5 patients by treating left ventricular failure aggressively.<sup>32</sup> The differential diagnoses must be evaluated quickly because urgent delivery of the fetus by caesarean section may improve resuscitation and prevent further AFE. Patients who survive the first few hours will continue to require supportive treatment for their acute lung injury. Blood component therapy is given as necessary to manage the coagulopathy. Cryoprecipitate has sometimes provided significant improvement in patient oxygenation, and recombinant factor VIIa has also been used. Survivors of AFE regain normal cardiorespiratory function but may have neurological sequelae.

### ACUTE RESPIRATORY FAILURE

Asthma is the commonest respiratory condition complicating pregnancy but specific concerns are mainly related to the possibility of fetal toxicity from pharmacologic therapy. However there is no evidence that systemic corticosteroids or short-term use of beta-agonists are associated with adverse fetal outcomes.<sup>6</sup>

Pulmonary oedema is more likely in the pregnant patient (1:1000 pregnancies) because of the increased cardiac output and blood volume, and the decreased plasma oncotic pressure. The principles of treatment are relatively straightforward in terms of determining the cause of the oedema and improving oxygenation, although it can be difficult to distinguish between hydrostatic and permeability oedema.<sup>2,7</sup>

The prevalence of acute respiratory distress syndrome during pregnancy has been estimated at 16–70 cases per 100 000 pregnancies, with mortality rates from 23 to 50%.<sup>5,7</sup> Some of the recommended strategies for managing this condition may be problematic. Low tidal volumes make it difficult to maintain the increased ventilatory requirements of pregnancy, and higher tidal volumes and alveolar plateau pressures up to 35 cmH<sub>2</sub>O (0.34 kPa) may be necessary. Transfer of CO<sub>2</sub> across the placenta requires a gradient of 10 mmHg (1.33 kPa). Permissive hypercapnia may cause fetal respiratory acidosis that will reduce the ability of fetal haemoglobin to bind oxygen, and *P*<sub>aCO<sub>2</sub></sub> should probably be kept below 45 mmHg (6.0 kPa) and *P*<sub>aO<sub>2</sub></sub>

above 70 mmHg (9.3 kPa).<sup>5</sup> If conventional ventilation fails, the effectiveness of alternative strategies is unknown. There are no data on the prone position and only a few reports of inhaled nitric oxide.

Unlike in other obstetric-related conditions, delivery of the fetus does not appear to result in marked improvement of maternal respiratory failure.

#### ACID ASPIRATION (MENDELSON'S SYNDROME)

Obstetric patients are at increased risk of acid aspiration because of decreased gastric emptying, increased gastric acidity and volume and increased intra-abdominal pressure. Aspiration of acidic material will cause acute lung injury, the severity being related to the amount, content and acidity of the aspirate.

The initial presentation is hypoxaemia and bronchospasm. Chemical pneumonitis and increased permeability pulmonary oedema develop over several hours.

Treatment includes standard respiratory support. Rigid bronchoscopy may be required to remove large food particles. Bronchoalveolar lavage and steroids are not useful and antibiotics should only be given for proven infection.

#### TOCOLYTIC THERAPY AND PULMONARY OEDEMA<sup>33</sup>

Pulmonary oedema is an uncommon (1 in 400 pregnancies) but serious complication of tocolytic therapy with beta-adrenergic agonists. The underlying mechanism for pulmonary oedema is unclear, but it is probably related to fluid overload and the cardiovascular effects of beta-adrenergic agonists leading to increased pulmonary capillary hydrostatic pressure. The initial management of pulmonary oedema is discontinuation of the beta-adrenergic agonist and oxygen therapy, with further monitoring, diuretics and respiratory support as necessary. This problem should disappear as alternative tocolytics such as nifedipine and atosiban are used.

#### COCAINE TOXICITY<sup>34</sup>

Cocaine abuse during pregnancy has become a significant problem in the USA, affecting more than 30 million people, with 90% of the women of child-bearing age. Cocaine has local anaesthetic and sympathomimetic actions and can cause:

- hypertension, dysrhythmias, myocardial ischaemia and infarction
- tachycardia and increased cardiac output, but decreased uterine blood flow
- increased uterine contractility

Patients commonly present with chest pain, cardiovascular complications or placental abruption and fetal distress.

Acute toxicity may also mimic pre-eclampsia by presenting with cerebral haemorrhage or convulsions.

For the treatment of hypertension, the drug of choice is controversial. Although hydralazine is often used in obstetrics to treat maternal hypertension, labetalol is also widely used. However, concerns about beta-blockers allowing unopposed alpha-adrenergic stimulation may also apply to a lesser extent with labetalol, and calcium-channel antagonists and nitroglycerine have also been advocated. Nitroglycerine and benzodiazepines have been recommended for the treatment of cocaine-related myocardial ischaemia and infarction.

#### OVARIAN HYPERSTIMULATION SYNDROME<sup>35</sup>

Ovarian hyperstimulation syndrome (OHSS) remains a significant but unpredictable and incompletely understood complication of ovarian stimulation. The syndrome is typically associated with:

- exogenous human chorionic gonadotrophin (hCG) regimens, used to induce ovulation in assisted reproduction techniques
- increased capillary permeability, leading progressively to hypovolaemia with haemoconcentration, oedema and accumulation of fluid in the abdomen and pleural spaces

The pathophysiology of OHSS has not been fully determined. A likely mediator is vascular endothelial growth factor, but many interacting cytokines and endocrine factors may be involved.

OHSS is most severe at several days to a week after a stimulated cycle, but early signs and symptoms can often be seen during the stimulatory phase. Fertility clinics will have their own protocols to try and minimise the incidence of OHSS and to detect its early stages. In general, symptoms resolve spontaneously over 2 weeks, in parallel with the decline in hCG from the last doses given. However, a successful pregnancy implantation will increase endogenous hCG and may temporarily worsen OHSS. Although subclinical OHSS may be found in most patients, only a small percentage require ward admission for careful fluid management to restore circulating volume with saline or albumin, prevention of thrombosis with heparin, and treatment of ascites by ultrasound-guided paracentesis as necessary. Severe OHSS may cause renal failure, respiratory failure or thromboembolism, which requires supportive intensive care therapy. Invasive monitoring is essential for fluid management.

# Severe pre-existing disease in pregnancy

Steve M Yentis

The two main sources of information about the spectrum of pre-existing conditions that result in severe morbidity in pregnancy are national or local registries/databases and published case series of admissions to intensive care, high-dependency units or obstetric units. Information about mortality comes from registries of maternal death such as the Confidential Enquiries into Maternal and Child Health (CEMACH; formerly Reports on Confidential Enquiries into Maternal Deaths) in the UK, or from individual case series. Taken together, the most important pre-existing conditions likely to lead to intensive care unit (ICU) admission and/or death overall are cardiac disease, respiratory disease, neurological disease, psychiatric disease (including drug addiction) and haematological, connective tissue and metabolic disease.

With increasingly successful medical care during childhood and early adulthood, the number of women with severe disease who survive to child-bearing age has increased. Part of such women's wishes to live a normal life includes the desire to have children, and this places increasing demands on obstetric, anaesthetic and ICU services, as well as on women's physiological reserves.

It is important that women with severe disease are appropriately counselled before pregnancy since the risks to both them and their fetuses may be considerable. This early counselling should ideally include anaesthetic input.

## CARDIAC DISEASE

There are more maternal deaths in the UK from cardiac disease than from pre-eclampsia and haemorrhage combined.<sup>1</sup> Over the last 20–40 years, there has been a shift away from acquired cardiac disease (mainly rheumatic heart disease) towards congenital heart disease as modern techniques of cardiac surgery in early life enable female babies with previously fatal conditions to reach maturity. More recently, there has been an increase in prevalence of ischaemic heart disease resulting from increased obesity, maternal age and smoking. Mortality varies from less than 1% in uncomplicated conditions to over 40% in Eisenmenger's syndrome, even with modern methods of medical management.<sup>2</sup>

## PHYSIOLOGY AND PATHOPHYSIOLOGY

The physiological changes of pregnancy are discussed in Chapter 56. The changes most relevant to cardiac disease are:

- susceptibility to aortocaval compression
- reduction in systemic vascular resistance
- increases in blood volume and cardiac output by up to 40–50% by the 20th week of gestation, with a potential further increase in cardiac output (up to 50%) during labour

In patients whose cardiac function is already impaired, such as those with cardiomyopathy or valvular stenoses, inability to meet these challenges may result in cardiac failure. If there is a right-to-left shunt, the fall in systemic vascular resistance encourages blood to bypass the lungs; this, together with the increasing demands of the fetus and the reduced maternal pulmonary reserve, may lead to severe exacerbation of hypoxaemia.

## GENERAL ANTEPARTUM AND PERIPARTUM MANAGEMENT

Antepartum management consists mainly of regular assessments and measures to reduce cardiac workload, for example, by reducing activity and treating arrhythmias/cardiac failure.

Electrocardiography, chest X-ray and echocardiography are the most useful investigations. Flow gradients across stenosed valves can be expected to increase in pregnancy because of the increase in cardiac output that occurs, and echocardiographic measurement of valve areas provides a more consistent and useful measure of severity in such cases. Pulse oximetry is a simple, non-invasive tool for monitoring the degree of right-to-left shunt and can easily be repeated during pregnancy.

An obstetric and anaesthetic plan should be prepared and the intensivists informed of the anticipated delivery date. Antithromboembolic prophylaxis should be considered since cardiac patients are more at risk, even without prolonged bedrest. Low-molecular-weight heparins are now standard for prophylaxis, although both heparin and warfarin have been used for patients with prosthetic

heart valves, the main decision being between the better safety profile of heparin for the fetus but with greater risk of thrombosis in the mother, and the more effective anticoagulation achieved with warfarin but with greater risk of fetal complications.<sup>3</sup> The requirements for heparin increase in pregnancy, so greater doses than normal are usually required.

The principles of peripartum management have moved over the last few years towards vaginal delivery unless caesarean section is indicated for obstetric indications. Elective caesarean section has been advocated in the past as a matter of course, traditionally under general anaesthesia, but the stresses and complications of surgery are now generally felt to exceed those of a well-controlled vaginal delivery. Low-dose epidural regimens using weak solutions of local anaesthetic (e.g. 0.1% bupivacaine or less) with opioids such as fentanyl have been found to be effective and cardiostable.<sup>4</sup> Combined spinal epidural analgesia using similar low concentrations are also suitable, and continuous spinal analgesia has also been described. In patients with marked exercise intolerance, outlet forceps or ventouse delivery is usually recommended to limit pushing and the duration of the second stage. If caesarean section is required, both regional and general anaesthesia have their advocates,<sup>5,6</sup> but either is acceptable so long as due care is taken.

Peripartum complications such as bleeding, pulmonary oedema, arrhythmias and sudden increases in pulmonary vascular resistance or drops in systemic vascular resistance may be tolerated badly by patients with limited reserves.

Oxytocin analogue (Syntocinon) has marked cardiovascular effects<sup>7,8</sup> that, although tolerable in normal patients, may cause a calamitous drop in systemic vascular resistance with hypotension, tachycardia and worsening of shunt in susceptible patients. If Syntocinon is required it should be diluted and given very slowly (e.g. 5 units infused over 10–20 minutes). Withholding of oxytocics altogether may be a problem as such patients may be especially sensitive to acute blood loss. In patients with fixed cardiac outputs and no pulmonary hypertension, ergometrine may be preferable. At caesarean section, mechanical compression of the uterus with a 'brace' suture may be used to reduce or avoid the need for oxytocics.<sup>9</sup> Exacerbation of right-to-left shunt is manifested by worsening hypoxaemia, which may be improved by vasoconstrictors such as phenylephrine – the chronotropic and inotropic effects of ephedrine are often undesirable in patients with cardiac disease.

Monitoring ranges from simple non-invasive methods to peripheral arterial, central venous and pulmonary arterial cannulation, depending on the severity of the underlying disease.<sup>10</sup> Arterial cannulation is usually straightforward but central venous cannulation is often difficult because of the increased maternal body weight and fluid retention, and the inability to lie flat, let alone head-down. The antecubital fossa should be considered as a route for cannulation first. Scrupulous

**Table 57.1** Common peripartum problems in patients with pre-existing cardiac disease

- Arrhythmias
- Cardiac failure/pulmonary oedema
- Pulmonary embolism
- Bacterial endocarditis
- Increased susceptibility to the effects of haemorrhage
- Increased risk of cardiovascular collapse in response to iatrogenic reductions in systemic vascular resistance, e.g. regional anaesthesia, intravenous bolus of oxytocin
- Myocardial ischaemia (certain lesions)
- Increased risk from air embolism (certain lesions)

attention must be paid to avoiding intravascular air in patients with right-to-left shunts, because of the risk of systemic embolism.

The principles of haemodynamic support are generally the same as in non-pregnant patients, remembering that pregnant women have a propensity to acute lung injury if overloaded with fluid. The physiological changes of pregnancy, especially tachycardia and increased cardiac output, should be remembered. The risk from aortocaval compression is often forgotten and this must be reinforced at all times, with the woman placed in the lateral or supine wedged position. If a pregnant woman requires intensive care before the baby is born, there may be a conflict between the maternal need for vasopressors and/or inotropes and the adverse effects of these drugs on uteroplacental blood flow. Similarly, attempts to prolong pregnancy with steroids and  $\beta_2$ -adrenergic agonists such as terbutaline or salbutamol may cause adverse cardiovascular effects (primarily pulmonary oedema) in the mother.

Common peripartum complications are summarised in Table 57.1.

## POSTPARTUM COMPLICATIONS

Women may continue to be at risk from bleeding, arrhythmias and cardiac failure postpartum. Specific problems need to be considered:

- If oxytocin has been withheld, postpartum haemorrhage may become a problem.
- Pulmonary embolism is a particular risk in the postpartum period, and the risks and benefits of anticoagulant therapy must be weighed up in each individual case.
- Patients with Eisenmenger's syndrome typically die on or around the 10th postpartum day of pulmonary haemorrhage, embolism or both.<sup>11</sup>
- Endocarditis should be prevented with appropriate antibacterial drugs (typically amoxicillin and gentamicin, or vancomycin if allergic to penicillin). The threat of endocarditis should always be considered.
- There is susceptibility to chest infection and its effects (and those of wound or other infection) may be devastating; thus a high index of suspicion and aggressive early management are required.

## RESPIRATORY DISEASE

The most common respiratory causes of morbidity and mortality in pregnancy are pneumonia, asthma and cystic fibrosis; thus the latter two conditions are the most common pre-existing respiratory diseases that cause mothers to present to ICUs.<sup>1,12–14</sup>

Asthma is very common but rarely causes serious morbidity in its own right, although there is a higher risk of maternal and neonatal morbidity.<sup>12</sup>

Cystic fibrosis is relatively rare but is more likely to be associated with poor outcomes.<sup>13,14</sup> Studies suggest that pregnancy itself does not increase mortality in women with mild cystic fibrosis and that the risk factors are the same as in non-pregnant patients (pre-pregnancy forced expiratory volume in 1 second (FEV<sub>1</sub>) < 50–60% of predicted; colonisation with *Burkholderia cepacia*; and pancreatic insufficiency). Overall mortality has been reported as 5% within 2 years of pregnancy, 10–20% within 5 years of pregnancy and 20–21% within 10 years. Psychological support is an important consideration. The decision to have a child, with the risk of passing on the cystic fibrosis gene and the adverse effect that pregnancy might have on the mother, is one that imposes a great deal of stress on the mother, her partner and their relatives.

## PHYSIOLOGY AND PATHOPHYSIOLOGY

If respiratory function is already impaired, the physiological effects of pregnancy add an extra burden on the respiratory system that may precipitate respiratory failure:

- reduced functional residual capacity
- splinting of the diaphragm
- increased oxygen demand

In cystic fibrosis, an additional stress is the increased nutritional demand in a patient who may already be malnourished because of malabsorption. In addition, chronic hypoxaemia may lead to chronic pulmonary vasoconstriction, cor pulmonale and pulmonary hypertension.

## GENERAL MANAGEMENT AND COMPLICATIONS

Antepartum management comprises regular assessment and adjustment of medical treatment when required. Patients may be taking a variety of drugs, including steroids. This is particularly relevant in asthma, in which there is a trend nowadays towards aggressive treatment of acute exacerbations of asthma, with early use of steroids. Although prednisolone is about 90% metabolised by the placenta, large doses have been associated with neonatal adrenal suppression.

Regional analgesia is indicated in patients with moderate or severe functional limitation, in order to reduce the demands of labour. If caesarean section is required, regional anaesthesia is thought to reduce the risk of post-operative pulmonary complications, although objective

evidence is lacking. Care is required, for if regional anaesthesia extends too high, ventilation and the ability to cough may be impaired.

In cystic fibrosis, the principles of intensive care are generally the same as in non-pregnant patients. Assessment of patients with respiratory disease requires knowledge of the physiological changes induced by pregnancy and parameters such as blood gases need to be considered in that context. An arterial partial pressure of carbon dioxide of 45 mmHg (6 kPa) represents a much greater deviation from the normal value in pregnancy than in non-pregnant patients. The mainstay of supportive treatment is regular physiotherapy and antibiotic therapy. It is important to know whether the patient has been previously colonized with unusual and/or resistant organisms, for example, *Burkholderia cepacia*. The biggest single hazard for the mother is an acute infective exacerbation in the middle/third trimester provoking incipient respiratory failure. Infection has to be treated both early and aggressively. Exhaustion and respiratory failure have been managed with non-invasive ventilatory techniques with some success.

Problems with intermittent positive-pressure ventilation during an acute exacerbation in severe disease appear to relate to widely disparate compliance in different lung areas. This produces  $\dot{V}/\dot{Q}$  mismatch with a large effective physiological dead space. The key to management is control and clearance of the underlying infection but this can be very difficult.

The beneficial effect of delivery on maternal oxygenation is usually immediate, although pain following caesarean section may limit deep inspiration and encourage basal atelectasis. Fatigue can also be a problem. Just because the baby has been delivered, scrupulous respiratory support cannot be forgone.

## NEUROLOGICAL DISEASE

Epilepsy has been highlighted as an important cause of maternal death, often related to poor medical control secondary to altered pharmacodynamics and pharmacokinetics of anticonvulsant drugs in pregnancy. A convulsion while in the bath is a particular risk. In terms of pre-existing neurological disease leading to admission to the ICU during or shortly after pregnancy, no single condition stands out, although those potentially affecting respiratory function (e.g. myasthenia gravis, multiple sclerosis and high spinal cord lesions) might be expected to cause particular problems.

## GENERAL MANAGEMENT

Until recently, regional analgesia and anaesthesia was traditionally avoided in most neurological disease, for fear of exacerbating the condition, or being blamed for an exacerbation should it occur. Nowadays, most authorities actively encourage regional analgesia for labour since it

**Table 57.2** Guide to converting oral to systemic medication in mothers with myasthenia gravis. Approximate conversion doses are given

Drug	Oral dose	Intramuscular dose	Intravenous dose
Neostigmine	15 mg	0.7–1.0 mg	0.5 mg
Pyridostigmine	60 mg	3–4 mg	2 mg

reduces the physiological demand and thus the risk of respiratory insufficiency or excess fatigue. Similarly, regional anaesthesia for caesarean section avoids the problems of excessive postoperative sedation and how or whether to use neuromuscular-blocking drugs, including suxamethonium. Initial fears about an increased relapse rate of multiple sclerosis following regional anaesthesia have fortunately not been borne out by large prospective series.<sup>15</sup>

If there is raised intracranial pressure, the use of regional techniques is more controversial. On the one hand, labour and vaginal delivery without effective analgesia can result in marked increases in intracranial pressure; on the other, accidental dural puncture can be disastrous. Even if successfully placed, rapid epidural injection may be associated with increases in intracranial pressure.<sup>16</sup> This risk still exists with epidural analgesic techniques continued into the postoperative period.

Management of conditions in which there are spinal abnormalities is also controversial. Spina bifida and other lesions have been successfully managed using regional techniques, although in each case a careful balance between risk and benefit must be achieved. These patients are unlikely to present to intensivists unless they are associated with respiratory impairment.

Myasthenia gravis poses a particular problem because of the need for regular medication throughout labour and after delivery. Gastric emptying may be decreased during labour, especially if systemic opioids are given, although this effect can also occur (albeit to a lesser extent) with boluses of epidural opioids. It is therefore important to consider alternative routes of administering the mother's drug therapy if opioids are given in this way. A useful guide is offered in Table 57.2. Epidural analgesia can be very helpful in limiting maternal fatigue during and after labour. The mother needs watching carefully for signs of increasing weakness up to 7–10 days postpartum.

#### PSYCHIATRIC DISEASE (INCLUDING DRUG ADDICTION)

Psychiatric disease features consistently in surveys of maternal morbidity and mortality, for example through parasuicide or suicide, violence or the complications of drug addiction. In recent CEMACH reports, suicide and psychiatric disease are relatively common causes of

death overall.<sup>1</sup> Psychiatric patients may be more vulnerable to becoming pregnant, and pregnant women more vulnerable to suffering from psychiatric disease either during or after pregnancy.

Abuse of drugs poses similar problems to those in the non-pregnant population, with the additional effect of fetal addiction and retarded growth. In particular, cocaine is commonly abused in parts of the developed world and has been implicated in causing placental abruption and maternal convulsions, hypertension and tachycardia, with increased morbidity and mortality for both mother and fetus.<sup>17</sup> Unplanned operative intervention for delivery is more likely, which may contribute to an increased requirement for intensive care. The combination of substance abuse and human immunodeficiency virus (HIV) infection poses a particular challenge in the obstetric patient.

Management in terms of intensive care is usually similar to that in non-pregnant patients, with special attention to the effects of maternal drugs on the fetus (if antepartum), for example those taken in overdose or those used for sedation and as antidotes.

#### HAEMATOLOGICAL, CONNECTIVE TISSUE AND METABOLIC DISEASE

Several haematological conditions may predispose to critical illness in pregnancy, sickle-cell disease being one of the most common. Patients with coagulopathy are clearly at increased risk of haemorrhage but, in general, ICU management of patients with haematological disease is as for non-pregnant patients. It is important that all staff appreciate that significant amounts of blood may be lost into the uterus or vagina without its being visible externally.

Connective tissue disease rarely presents to the intensivist unless there is widespread and severe systemic involvement. Cardiac and pulmonary manifestations are the usual culprits, and these may be exacerbated by pregnancy because of the increased demands. Such patients are also at risk of obstetric complications such as bleeding (including postpartum).

Diabetes mellitus is the most important pre-existing metabolic disease in pregnancy. It is well known to increase both maternal and fetal morbidity but usually features in the ICU as a contributory factor to other conditions, for example, sepsis. Anecdotal reports suggest that diabetic coma presenting in pregnancy may be particularly difficult to treat and stability of blood glucose may only be achieved after delivery of the fetus.

# Anaphylaxis

Malcolm McD Fisher

Anaphylaxis is a symptom complex accompanying the acute reaction to a chemical recognised as hostile. In the classical reaction the patient has been previously sensitised (immediate hypersensitivity or type 1 hypersensitivity), although the sensitising agent may be unknown. The term 'anaphylactoid reaction' is used to describe reactions clinically indistinguishable from anaphylaxis, in which the mechanism is non-immunological, or has not been determined. Recent consensus meetings have suggested the use of the term 'anaphylactoid' be discontinued and 'anaphylaxis' used to describe the symptom complex which may be either 'non-immune' or 'immune'.<sup>1</sup> Non-immune anaphylaxis may be produced by direct drug effects, physical factors or exercise, and a causative agent cannot always be determined. The mediators involved are the same as those in other acute inflammatory responses such as sepsis, but the rate of release is more rapid and of shorter duration.

## AETIOLOGY

Clinical anaphylaxis in hospital commonly follows injection of drugs, blood products, plasma substitutes, contrast media, or exposure to latex products or chlorhexidine. Outside hospital, ingestion of foods or food additives (especially peanut products) or insect stings may be more common causes than drugs.

Neugut *et al.*<sup>2</sup> estimated 1400–1500 deaths per year in the USA and between 3.3 and 40.9 million patients at risk. They estimated radiocontrast media and penicillin to be the greatest cause of death, with food and stings the next groups. In contrast a postmortem study of 56 deaths in the UK<sup>3</sup> attributed 19 deaths to venoms, 16 to foods and 19 to drugs and radiocontrast media.

In anaphylaxis, sensitisation occurs following exposure to an allergenic substance, which either alone, or by combination with a protein or hapten, stimulates the synthesis of immunoglobulin E (IgE). Some IgE binds to the surface of mast cells and basophils. Later, re-exposure to antigen produces an antigen–cell surface IgE antibody interaction where two IgE molecules are bridged. This results in mast cell degranulation, and the release of histamine and

other mediators, including interleukin, prostaglandins and platelet-activating factor. Histamine is responsible for the early signs and symptoms, but is rapidly cleared from plasma. The overall effects of the mediators are to produce vasodilatation, smooth-muscle contraction, increased glandular secretion and increased capillary permeability. The mediators act both locally and upon distant target organs.

Anaphylactoid reactions may be due to a direct histamine-releasing effect of drugs or other triggers on basophils and mast cells. The symptom complex may also be produced by other mechanisms. Some intravenous drugs and X-ray contrast media may activate the complement system. Plasma protein and human serum albumin reactions may be induced by either albumin aggregates or stabilising agent-modified albumin molecules. Other reactions, including those to dextrans and gelatin preparations, may be activated by non-IgE antibody already present in the plasma or osmotic factors (dextrose, mannitol).

The direct histamine-releasing effects of some drugs may produce reactions due to the effect of histamine alone, and such reactions are related to volume, rate and amount of infusion. Recent work suggests that the site of release of histamine may be important in its clinical effects. Drugs such as morphine and Haemaccel release histamine from skin alone,<sup>4</sup> and are unlikely to produce symptoms such as bronchospasm, whereas drugs which produce release from lung mast cells (e.g. atracurium, vecuronium and propofol) may be more likely to produce bronchospasm.<sup>5</sup> Direct histamine release is usually a transient phenomenon, but in some patients severe manifestations may occur, particularly with Haemaccel and vancomycin.

Anaphylactic reactions are usually seen in fit and well patients. It is likely that the adrenal response to stress 'pre-treats' sick patients, and blocks the release and effects of anaphylactic mediators. The exception to this appears to be patients with asthma, in whom reactions to the additives in steroid and aminophylline preparations may occur, and this may be related to the reduced catecholamine response in asthma.<sup>6</sup> Patients on  $\beta$ -blockers and with epidural blockade may be more likely to develop adverse responses due to histamine release, and this may also be related to reduced catecholamine responsiveness. Reactions occurring in these groups are more difficult to treat.

### CLINICAL PRESENTATION

The latent period between exposure and development of symptoms is variable, but usually occurs within 5 minutes if the provoking agent is given parenterally. Reactions may be transient or protracted (lasting days), and may vary in severity from mild to fatal. Recurrent anaphylaxis is described. Cutaneous, cardiovascular, respiratory or gastrointestinal manifestations may occur singly or in combination.

Cutaneous features include piloerection, erythematous flush, generalised or localised urticaria, angioneurotic oedema, conjunctival injection, pallor and cyanosis. Awake patients may experience an aura, warning of an impending reaction. Cardiovascular system involvement occurs most commonly and may occur as a sole clinical manifestation.<sup>7</sup> It is characterised by initial bradycardia then sinus tachycardia, hypotension and the development of shock.

In patients reacting due to venom desensitization, bradycardia may be severe and require treatment.<sup>8</sup> Respiratory manifestations include rhinitis, bronchospasm and laryngeal obstruction. Gastrointestinal symptoms of nausea, vomiting, abdominal cramps and diarrhoea may be present. Other features include apprehension, metallic taste, choking sensation, coughing, paraesthesiae, arthralgia, convulsions, clotting abnormalities and loss of consciousness. Pulmonary oedema is a rare sign. Rarely, some women develop a profuse, watery, vaginal discharge 3–5 days after anaphylaxis. It is self-limiting.

Anaphylaxis is rare in the intensive care unit (ICU), probably because of the protective effects of the adrenal response to stress. However, use of the mast cell tryptase assay (see below) may detect anaphylaxis as an unsuspected cause of shock in intensive care.

### PATHOPHYSIOLOGY OF CARDIOVASCULAR CHANGES

The traditional concept of the cardiovascular changes in clinical anaphylaxis is that of an initial vasodilatation, followed by capillary leak of plasma which produces endogenous hypovolaemia, reduced venous return and lowered cardiac output.

Whether or not cardiac function is impaired has been controversial. Although most anaphylactic mediators adversely affect myocardial function *in vitro*, most case reports of anaphylaxis in which invasive cardiovascular monitoring has been used suggest minimal impairment of cardiac function. Patients with normal cardiac function before the reaction rarely show evidence of cardiac failure or arrhythmias other than supraventricular tachycardia, but the incidence of serious arrhythmias and cardiac failure increases in those with prior cardiac disease.<sup>7</sup> Echocardiography in anaphylaxis usually shows an 'empty', normally contracting heart. Troponins are elevated after anaphylaxis, but these elevations do not normally predict coronary artery disease requiring intervention. A recent study of patients with

anaphylaxis during venom desensitisation showed that bradycardia requiring treatment was a common finding.<sup>8</sup> Two reactions in patients with no previous cardiac disease, where the major manifestation was prolonged global myocardial dysfunction, and the use of a balloon counterpulsator was life-saving, have been reported.<sup>9</sup>

### TREATMENT

There are no randomised controlled trials of treatment in anaphylaxis, and the unexpected onset, rapid course and usual rapid response to treatment preclude performing such trials. Treatment recommendations are based on historical practice, case reports, series of cases and animal models.

### OXYGEN

Oxygen is given by facemask. Endotracheal intubation may be required to facilitate ventilation, especially if angioedema or laryngeal oedema is present. Oedema of the upper airway is more common when anaphylaxis is due to foods than to drugs.<sup>3</sup> Mechanical ventilation is indicated for severe bronchospasm, apnoea or cardiac arrest.

### ADRENALINE (EPINEPHRINE)

Epinephrine is universally recommended as the drug of choice for severe reactions. In the community epinephrine may be given intramuscularly in a dose of 0.3–1.0 mg early in anaphylaxis. Intramuscular epinephrine produces higher levels earlier in stable allergic patients than subcutaneous epinephrine.<sup>10</sup> In severe shock or in patients in whom muscle blood flow is thought to be compromised by shock, intravenous injection of 3–5 ml of 1:10 000 epinephrine is given. A second dose is necessary in 35%<sup>11</sup> and an infusion in 10%.

Epinephrine, by increasing intracellular levels of cyclic adenosine monophosphate (cAMP) in leukocytes and mast cells, inhibits further release of histamine. It has beneficial effects on myocardial contractility, peripheral vascular tone and bronchial smooth muscle, and stabilises mast cells. A common management error is not to institute external cardiac massage (ECM) as the arrhythmia is 'benign'. If the patient is pulseless, ECM should be instituted irrespective of rhythm, although there are no data to support its efficacy.

There has been controversy regarding the best route of administration of epinephrine outside hospital. Both case reports and patients self-injecting show efficacy for intramuscular epinephrine when given early. Intravenous epinephrine may rarely cause arrhythmias and myocardial infarction, particularly in unmonitored patients. In our series it seems to be more hazardous when the diagnosis

of anaphylaxis is incorrect. Recent recommendations endorse the use of intramuscular epinephrine.<sup>12</sup>

### OTHER SYMPATHOMIMETIC AMINES

Other sympathomimetic drugs may reverse the symptoms, but appear (albeit in the absence of any randomised trials) to be less effective than epinephrine. Norepinephrine by infusion may be life-saving in the absence of a response to fluid loading and epinephrine. Vasopressin has been described as effective in one patient with hypotension refractory to norepinephrine.

### COLLOIDS

Plasma expanders are given rapidly to correct the hypovolaemia consequent to acute vasodilatation and leakage of fluid from the intravascular space.<sup>13</sup> The author favours plasma protein solution or gelatin preparations rather than crystalloids, as they remain in the vascular compartment earlier and for longer. There are, however, no data showing improved outcomes from colloid over crystalloid, and there are many patients who have been successfully resuscitated with crystalloid alone. Greater volumes of crystalloid are necessary and on occasions very large volumes of fluid may be required; central venous pressure monitoring and measurement of haematocrit are helpful.

### BRONCHOSPASM

Epinephrine should be given. Nebulised salbutamol should be given for severe asthma. Aminophylline 5–6 mg/kg intravenously may be given over 30 minutes, if bronchospasm is unresponsive to epinephrine alone. Aminophylline increases intracellular cAMP by phosphodiesterase inhibition, and its effect on inhibiting histamine and interleukin release is theoretically additive to that of epinephrine. Adverse responses have not been observed in our series but a recent comprehensive review<sup>14</sup> suggested safer agents with proven efficacy should be preferred. Volatile anaesthesia, ketamine and magnesium sulphate may produce improvement in some patients with severe asthma.

### CORTICOSTEROIDS

Steroids have no proven benefit, particularly early, and should be reserved for refractory bronchospasm. Conversely, steroids are often given and there is no evidence of harm.

### ANTIHISTAMINES

Antihistamines are the treatment of choice in localised non-severe reactions. In severe reactions they are only indicated in protracted cases or in those with angioneurotic oedema which may recur. The data on antihistamines are not conclusive, but in protracted anaphylaxis, improvement is often reported with H<sub>2</sub>-blockers.

### DIAGNOSIS

The most important advance in the diagnosis of anaphylaxis has been the introduction of an assay for mast cell tryptase. The mast cell enzyme is elevated 1 hour after a reaction begins, and the elevation may persist for up to 4 hours. It can also be used to diagnose anaphylaxis from postmortem specimens.<sup>15,16</sup> The assay is highly specific and sensitive for anaphylaxis, although elevated levels are found with direct histamine release, and at postmortem in some patients with myocardial infarction. A negative mast cell tryptase assay does not exclude anaphylaxis as the diagnosis. Mast cell tryptase has been used to diagnose anaphylaxis postmortem.

### FOLLOW-UP

Following successful acute management, the drug or agent responsible should be determined by in vitro or in vivo testing if possible. Hyposensitisation should be considered for food, pollen and bee venom allergy. A medic alert bracelet should be worn and the patient should be given a letter stating the nature of the reaction to the particular causative agent.

If re-exposure to the allergen is likely at home, patients or their relatives should be instructed in the use of epinephrine, salbutamol inhalation and antihistamines. Clinical anaphylaxis may be modified by pretreatment with disodium cromoglicate, corticosteroids, antihistamines, salbutamol and isoprenaline.

In patients with recurrent anaphylaxis in whom no cause can be found corticosteroids on alternate days reduce the incidence and severity of attacks.

# Host defence mechanisms and immunodeficiency disorders

Steve Wesselingh and Martyn A H French

There is a coordinated immunological response to infection involving both cellular and humoral components. The outcome of an infection will be determined by the balance between the body's ability to eliminate invading microorganisms and the microorganism's virulence. Humans have diverse host defence mechanisms to protect the different anatomical compartments of the body from a great variety of microorganisms (Table 59.1). There are many ways in which the immune system can be defective, leading to an increased propensity to infections. The immune response also needs to be controlled to avoid inappropriate and excessive activation, which may damage the host. A certain degree of host damage is inevitable during the response to infection, particularly if there is systemic activation resulting in disseminated intravascular coagulation (DIC) and an excessive inflammatory response.

## INNATE IMMUNE RESPONSES

The immune system is capable of reacting to microorganisms without having been previously exposed to antigens from those microorganisms. This innate immune system consists of plasma proteins, including alternative-pathway components of the complement system and mannose-binding lectin (MBL), a subset of lymphocytes with cytotoxic activity (natural killer or NK cells), and some macrophage functions. Innate immune responses provide a first line of defence against many pathogenic microorganisms.

## ACUTE-PHASE REACTION

The acute-phase reaction is a response of the haematopoietic and hepatic systems, involving at least 20 plasma proteins and the cellular components of the blood. The reaction occurs within hours of acute physical stress or infection. The functions of many of these acute-phase proteins remains unclear, but teleologically, they should be assumed to be beneficial to the patient. The falls in haemoglobin, serum iron and albumin are all normal in the acute-phase reaction. Most of the proteins are

inflammatory mediators or inhibitors of transport proteins. Fibrinogen, the bulk protein of the coagulation system, is one of the plasma proteins to show the greatest rise in the acute-phase reaction, and is responsible for the elevation in the erythrocyte sedimentation rate. The fall in albumin is due to redistribution and decreased synthesis and generally does not require supplementation.

## THE ADAPTIVE IMMUNE SYSTEM

Adaptive immune responses are characterised by specificity, memory, amplification and diversity. The specificity of an immune response against a particular antigenic component of a microorganism, and the memory which results in a prompt response on subsequent exposures, is determined by lymphocytes and antigen receptors on their surface. Amplification and diversity of immune responses are regulated by cytokines, which are secreted by lymphocytes and other cells, and through the effects of various lymphocyte surface molecules, including adhesion molecules and co-stimulatory molecules. Cytokines have various activities, the most important of which are cell activation (e.g. interferon-gamma (IFN- $\gamma$ )), regulation of immune responses (e.g. interleukin (IL)-10) and proinflammatory effects (e.g. tumour necrosis factor (TNF)) and lymphotoxins).

## ANTIGEN PRESENTATION

The most important events in the initiation of an immune response are the processing and presentation of fragments of the microorganism in a form which makes the fragments antigenic to lymphocytes. Major histocompatibility complex (MHC) class I (human leukocyte antigen (HLA)-A, B, C) and class II (HLA-DR, DP, DQ) molecules are the major cell-surface antigen presentation molecules. These molecules also determine the nature of the subsequent response against the antigen. Class I MHC molecules are present on most nucleated cells, and present processed endogenous peptides (such as fragments of viruses) to the antigen receptor (T-cell receptor;

TcR) of T cells expressing CD8 molecules. Class II MHC molecules present antigenic fragments of microorganisms which are exogenous to cells and have been taken into the cell by phagocytosis, in the case of macrophages and monocytes, or by binding to antigen-specific surface immunoglobulins (the B-cell antigen receptor), in the case of B cells. Antigens presented on class II MHC molecules bind to TcRs on CD4+ T cells.

### T CELLS AND B CELLS

CD8+ T cells have a cytotoxic effect on cells expressing class I MHC-associated viral antigens, resulting in the death of the cell and inhibition of viral replication. Antigen-induced stimulation of CD4+ T cells results in activation of the T cell and the expression of cell-surface molecules and secretion of cytokines with immunoregulatory effects. These immunoregulatory molecules augment the functions of many other cells, including B cells, T cells and macrophages (T-cell help). A response to an antigen directed by CD4+ T cells may also elicit macrophage activation and killing of the microorganism expressing that antigen. Activation of macrophages by CD4+ T cells is critically dependent on the production of IFN- $\gamma$ .

The activation and proliferation of T cells occur under the influence of cytokines and other regulatory molecules, including co-stimulatory molecules such as the ligand of the B-cell membrane molecule CD40 (CD40L). Proliferating B cells differentiate into plasma cells, which secrete immunoglobulins with antibody activity against the initiating antigen. Nine isotypes of immunoglobulin can be produced, each of which has a different function.

### IMMUNOGLOBULINS AND ANTIBODIES

Immunoglobulin M (IgM) is a large pentameric molecule, which is particularly effective as a bacterial agglutinator and activator of the complement system, and has its major effect within the circulation. IgA<sub>1</sub> and IgA<sub>2</sub> are produced at secretory surfaces, such as the mucosa of

the gut and respiratory tract, and also in the breast, where IgA is a major constituent of the colostrum and provides secretory antibody to the gut of the neonate. IgE antibodies are also produced at mucosal surfaces where they form an important part of the immune response against parasitic infections. Antibodies of the IgG<sub>1</sub> and IgG<sub>3</sub> subclass are particularly effective at activating the complement system and binding to Fc receptors on phagocytic cells. IgG<sub>2</sub> antibodies are mainly active against polysaccharide antigens, such as those present in bacterial cell walls. The functions of IgG<sub>4</sub> antibodies are unclear.

### SECONDARY ANTIBODY FUNCTION

The elimination of a microorganism by antibodies usually requires the activation of a secondary effector mechanism, of which there are several. Antibodies complexed with antigens activate the complement system through the classical pathway. The complement system may also be activated directly by components of microorganisms through the alternative pathway or MBL pathway. Activation of the complement system results in the generation of biologically active molecules, such as C3b, which is an important opsonin, and the activation of the membrane attack complex (MAC), which lyses bacterial cell walls. Like C3b, antibodies of the IgM, IgG<sub>1</sub> and IgG<sub>3</sub> isotype are also important opsonins. These molecules, when bound to the surface of a microorganism, facilitate their opsonisation and phagocytosis. These effects of complement and antibody are mediated through complement receptors (CRs) and receptors for the Fc portion of the immunoglobulin molecules (Fc receptors) on the surface of phagocytic cells such as neutrophils and macrophages.

### DIVERSITY OF IMMUNE RESPONSES

The type of immune response produced against a microorganism varies according to the nature of the infecting organism. Thus, virus-infected cells elicit a cytotoxic CD8+ T-cell response; intracellular pathogens such as mycobacteria and protozoa elicit a CD4+ T-cell response, which results in macrophage activation; encapsulated bacteria elicit an opsonising antibody response; and some bacteria such as *Neisseria* spp. elicit a complement-activating antibody response, which lyses the cell wall of the bacterium. The nature of the immune response is regulated by cytokines, which provide T-cell help (Th) in the course of an immune response. Thus, IL-2, IL-12 and IFN- $\gamma$  production induces a predominantly cellular immune response (Th1), whereas the production of IL-4 and IL-13 induces a predominantly antibody-mediated immune response (Th2).

### IMMUNE DEFECTS UNDERLYING IMMUNODEFICIENCY DISORDERS

Defects of the immune system may give rise to immunodeficiency disorders, which are generally of five types: antibody

deficiency, complement deficiency, cellular immunodeficiency, combined immunodeficiency (T cells, B cells and NK cells) and phagocyte dysfunction.

### ANTIBODY DEFICIENCY

A deficient systemic antibody response most commonly results in a lack of opsonising antibody, and a propensity to infections with encapsulated bacteria such as pneumococci or *Haemophilus influenzae*. Recurrent respiratory tract infections including sinusitis are therefore the most common complication of this type of immune defect. Chronic echovirus infections of the nervous system and infection with some mycoplasmas may also occur in patients with severe primary immunoglobulin deficiency (agammaglobulinaemia).

Deficient secretory antibody responses are common in patients with IgA deficiency, but most affected individuals are able to produce compensatory secretory IgM or IgG antibody responses and do not suffer from infections.

### CELLULAR IMMUNODEFICIENCY

Impairment of cell-mediated immune responses leads to an increased propensity to infection with microorganisms which are normally controlled by cellular immune responses (Table 59.2). These microorganisms are often pathogens that replicate intracellularly (intracellular pathogens) and cause persistent (latent) infections that reactivate when the cellular immune response against them becomes ineffective.

### COMPLEMENT COMPONENT DEFICIENCY

Complement-mediated lysis of bacterial cell walls is a critical mechanism in the immune response against certain

bacteria, especially *Neisseria* spp. and related bacteria such as *Moraxella* spp. and *Acinetobacter* spp. Deficiency of complement components, particularly MAC components (C5–C9), may therefore result in infection with these bacteria. C3b is an important opsonin and C3 deficiency will often impair phagocytosis of bacteria. Deficiency of classical pathway components may also result in impaired antibody responses.

### PHAGOCYTE DEFECTS

Depletion or functional impairment of phagocytes results in an increased propensity to bacterial and fungal infections, particularly infection with *Staphylococcus aureus*, Gram-negative enteric bacteria, *Candida* spp. and *Aspergillus* spp. Fungal and yeast infections are often systemic in patients with severe neutropenia, indicating the importance of phagocytes in the systemic immune response against these microorganisms.

Phagocytosis of a bacterium or fungus by a neutrophil leukocyte or macrophage is dependent on chemotactic attraction of phagocytes to the site of infection, their adhesion to endothelial cells via adhesion molecules such as integrins, binding to opsonins on the microorganism, ingestion and intracellular killing. Intracellular killing involves both oxidative and non-oxidative mechanisms. Primary or acquired defects of phagocytes may result in localised pyogenic infections or pneumonia. However, in the neutropenic patient, localised infections may show little inflammatory reaction and overwhelming systemic infections are common.

**Table 59.2** Microorganisms that most commonly cause disease in patients with cellular immunodeficiency

Mycobacteria	<i>Mycobacterium tuberculosis</i> Non-tuberculous mycobacteria
Bacteria	<i>Salmonella</i> spp. <i>Shigella</i> spp. <i>Listeria monocytogenes</i>
Fungi and yeasts	<i>Candida</i> spp. (mucosal infections) <i>Pneumocystis jiroveci</i> Cryptococci <i>Aspergillus</i> spp.
Protozoa	<i>Toxoplasma gondii</i> Cryptosporidia
Viruses	Herpes simplex viruses Cytomegalovirus Varicella-zoster virus Epstein–Barr virus Molluscum contagiosum virus JC virus (cause of progressive multifocal leukoencephalopathy)

### IMMUNODEFICIENCY DISORDERS

Immunodeficiency disorders are classified as primary or acquired. Primary immunodeficiency disorders are the result of a developmental anomaly or a genetically determined defect of the immune system. Genetically determined defects are usually of two types:

1. the consequence of an absent or non-functional gene product, which is critical for the normal development or function of a component of the immune system
2. aberrant regulation of lymphocyte differentiation, which is probably determined by the products of several genes and possibly by environmental factors

Immunodeficiency disorders caused by the latter type of defect usually present later in life than congenital immunodeficiency caused by a non-functioning gene product.

Acquired immunodeficiency disorders are more common than primary immunodeficiency disorders and may present at any time after early childhood. Most result from an immune defect that is a consequence of a disease process, infection or complication of a therapeutic procedure such as splenectomy, immunosuppressant therapy or haemopoietic stem cell transplantation (HSCT).

IgG, immunoglobulin G; NBT, nitroblue tetrazolium.

Diagnosis of an immunodeficiency disorder in a patient with an abnormal propensity to infections is dependent on the demonstration of an immune defect, as indicated in Table 59.3.

## ANTIBODY DEFICIENCY

### PRIMARY ANTIBODY DEFICIENCY DISORDERS

Failure of B-cell production or the presence of immature B cells due to a defect of differentiation is the cause of most primary antibody deficiency disorders.<sup>1</sup> B cells are absent from blood and secondary lymphoid tissues in patients with X-linked agammaglobulinaemia (XLA) because mutations of the *Btk* gene on the X-chromosome result in the absence of a B-cell tyrosine kinase necessary for the maturation of pre-B cells to B cells in the bone marrow. In the hyper-IgM immunodeficiency syndrome, B cells are able to differentiate into plasma cells secreting IgM, but not IgG or IgA. The X-linked form of this condition results from mutations in the gene encoding CD40L, which is critical in delivering a T-cell signal to differentiating B cells.

Common variable immunodeficiency (CVID) and IgA deficiency appear to be the consequence of immunoregulatory defects which result in impaired B-cell differentiation. Severe immunoglobulin deficiency (hypogammaglobulinaemia) and systemic antibody deficiency are characteristic of CVID, whereas most individuals with IgA deficiency are asymptomatic. Those IgA-deficient patients who suffer from recurrent infections often have a defect of systemic antibody responses, which commonly manifests as deficiency of an IgG subclass and/or impairment of antibody responses to polysaccharide antigens.<sup>2</sup>

The immunoregulatory defect underlying CVID and IgA deficiency sometimes results in an increased propensity to autoimmunity, which can include the production of anti-IgA antibodies. These antibodies may be a cause of anaphylactoid reactions to blood products containing IgA.

### ACQUIRED ANTIBODY DEFICIENCY DISORDERS

B-cell chronic lymphocytic leukaemia or lymphoma and myeloma are commonly associated with reduced synthesis of normal immunoglobulins, which may result in immunoglobulin and antibody deficiency resulting in bacterial infections.<sup>3</sup> A thymoma is a rare cause of immunoglobulin and antibody deficiency, and should be considered in a patient presenting with primary immunoglobulin deficiency after the age of 40.<sup>4</sup> Impaired production of antibodies against polysaccharide antigens contributes to the susceptibility of asplenic patients to infection with encapsulated bacteria, such as pneumococci and meningococci, particularly in patients who had haematological malignancy.<sup>5</sup>

Drugs occasionally affect B-cell differentiation and cause immunoglobulin deficiency, particularly IgA deficiency. The most common offender is phenytoin. Most patients do not have antibody deficiency severe enough to cause infections. Intensive plasmapheresis may also cause severe immunoglobulin deficiency if immunoglobulin replacement is not used.

### TREATMENT OF ANTIBODY DEFICIENCY DISORDERS

Infections can be prevented by regular infusions of intravenous immunoglobulin (IVIg) in patients with primary or acquired antibody deficiency. The usual dose is 300–500 mg/kg given monthly. Acute infections should be treated with appropriate antibiotics. The use of IVIg as an adjunct in the management of sepsis, particularly pneumococcal infections, has been suggested. In the absence of documented antibody deficiency there is no evidence to support this practice.

## CELLULAR IMMUNODEFICIENCY

### PRIMARY CELLULAR IMMUNODEFICIENCY

Complete or partial absence of the thymus gland resulting in depletion of T cells from blood and lymphoid tissue is the characteristic immunological abnormality in children with the Di George syndrome.<sup>6</sup> Infections of the type listed in Table 59.2 occur from birth onwards. A less severe defect of cellular immunity is present in patients with chronic mucocutaneous candidiasis. This usually occurs in patients with the autoimmune polyendocrinopathy–candidiasis–ectodermal dystrophy syndrome (APECED) syndrome, which results from a disorder of T-cell-processing in the thymus.<sup>7</sup>

### ACQUIRED CELLULAR IMMUNODEFICIENCY

Acquired defects of cellular immunity are by far the most common cause of cellular immunodeficiency. Infection of

cells of the immune system by human immunodeficiency viruses (HIVs) 1 and 2 is the most common (see Chapter 60). Less commonly, Hodgkin's disease, T-cell lymphomas and sarcoidosis may also be complicated by opportunistic infections occurring as a consequence of cellular immunodeficiency. A thymoma is a rare cause of chronic mucocutaneous candidiasis which, like thymoma and immunoglobulin deficiency, occurs later in life.<sup>4</sup>

Suppression of cellular immune responses is an intended effect of many immunosuppressant drugs used to treat allograft rejection, graft-versus-host disease (GvHD), autoimmune diseases and vasculitis. However, opportunistic infections may be a complication of this type of immunodeficiency, and may cause severe morbidity and death.

#### **TREATMENT OF CELLULAR IMMUNODEFICIENCY DISORDERS**

Since most infections complicating cellular immunodeficiency are reactivated latent infections, an important aspect of management is prevention of infection by the use of prophylactic antimicrobial drugs, as exemplified by HIV-induced immunodeficiency.<sup>8</sup> In circumstances of acquired cellular immunodeficiency it is essential to take into account the severity and duration of immunodeficiency. It is possible to predict the likelihood of infection and the likely pathogens by determining the degree of cellular immunodeficiency. This allows for appropriate decisions to be made regarding investigations, treatment and prophylaxis.

Acquired cellular immunodeficiency may be corrected, at least temporarily, by removing its cause (e.g. by suppressing HIV infection or ceasing immunosuppressive therapy). Thymus transplantation may be effective in children with thymus aplasia.

#### **COMPLEMENT COMPONENT DEFICIENCY**

Deficiency of complement components is an uncommon but often overlooked cause of recurrent bacterial infections.

##### **PRIMARY COMPLEMENT DEFICIENCY**

Congenital deficiency of C3 is extremely rare and usually causes a propensity to severe pyogenic infections. Deficiency of MAC components (C5–9) is more common, and should be considered in patients with meningococcal infections, particularly when the infections are recurrent.<sup>9</sup> Deficiency of classical pathway components (C1, C2, C4) may also result in an increased propensity to infection with meningococci and some other bacteria, but most affected individuals do not experience recurrent infections.

##### **ACQUIRED COMPLEMENT DEFICIENCY**

Disease processes that cause persistent activation of the complement system may cause depletion of complement components, particularly classical pathway components. This can result in infections with *Neisseria* spp. or related bacteria, and sometimes overwhelming septicaemia when the complement deficiency is severe. Systemic lupus erythematosus, myeloma and chronic atrioventricular shunt infections are rare causes of complement component deficiency.

#### **MANAGEMENT OF PATIENTS WITH COMPLEMENT DEFICIENCY**

An awareness of the possibility of complement deficiency is the most important aspect of management. Replacement therapy is not available. If a complement component deficiency is identified, screening of family members should be considered.

#### **PHAGOCYTE DISORDERS**

##### **PRIMARY DISORDERS OF PHAGOCYTOSIS**

Congenital neutropenias are rare. Defects of phagocyte function usually affect chemotaxis, adhesion or intracellular killing, either alone or in combination. The best-characterised defect of phagocyte adherence results from a congenital absence of the  $\beta$ -subunit of CD18 integrins in patients with leukocyte adhesion deficiency syndrome type 1.<sup>10</sup> Defects of intracellular killing are usually caused by a deficiency of microbicidal enzymes. In chronic granulomatous disease (CGD), deficiency of a phagosome enzyme (NADPH oxidase) results in ineffective oxidative killing mechanisms.<sup>11</sup> CGD usually presents in childhood but may present in adults, even as late as the seventh decade.<sup>12</sup> It should be considered in patients with recurrent abscesses or suppurative lymphadenitis, and in patients with pneumonia caused by *Staphylococcus aureus* or *Aspergillus* spp. infection.

##### **ACQUIRED DISORDERS OF PHAGOCYTOSIS**

Severe neutropenia may be complicated by bacterial or fungal infections. There are many causes of neutropenia, including autoimmune neutropenia, drug therapy and haematological diseases such as cyclic neutropenia, myelodysplastic syndromes and aplastic anaemia. Cytotoxic chemotherapy, used to treat various malignancies, commonly causes neutropenia, which is often complicated by severe bacterial and fungal infections.

##### **MANAGEMENT OF PHAGOCYTE DISORDERS**

Acquired neutropenia may be corrected by removing the underlying cause and/or use of granulocyte colony-stimulating factor (G-CSF). Febrile neutropenia requires investigation for the source of sepsis and empirical antibiotics. If fever persists antifungals should be added. IFN- $\gamma$  therapy may be effective in patients with CGD.

#### **COMBINED IMMUNODEFICIENCY DISORDERS**

Several immunodeficiency disorders result from a combination of immune defects. Some combinations of congenital immune defects are so severe that death is a common occurrence, unless the defect can be corrected. Such conditions are classified as severe combined immune deficiency (SCID) syndromes.

##### **PRIMARY COMBINED IMMUNODEFICIENCY**

There are many primary combined immunodeficiency syndromes, which present in early childhood.<sup>13</sup> Some

are still classified descriptively, but the molecular defects have now been demonstrated for many of them. For example, defective expression of MHC class II molecules, adenosine deaminase (ADA) deficiency, and deficiency of the common  $\gamma$ -chain of the receptor for several interleukins (IL-2, 4, 7, 9, 15, 21) all result in a deficiency and/or functional impairment of B cells, T cells and sometimes NK cells. Deficiency of the interleukin receptor common  $\gamma$ -chain results from mutations of its gene on the X-chromosome and is the underlying defect of X-linked SCID.

#### TREATMENT OF PRIMARY COMBINED IMMUNODEFICIENCY

HSCT is the treatment of choice for many types of primary SCID, though enzyme replacement therapy can be effective in ADA deficiency and gene replacement therapy has been used to treat X-linked SCID. Antibody replacement with IVIg therapy and prophylaxis for opportunistic infections are also important in primary SCID.

#### ACQUIRED COMBINED IMMUNODEFICIENCY

Combined immune defects are a characteristic of several acquired immunodeficiency disorders.

##### Haemopoietic stem cell transplantation

Combined immune defects may result in severe infections in patients who have received an HSCT.<sup>14</sup> Following transplantation, the recipient's immune system is reconstituted with donor cells. A degree of immunocompetence is passively transferred from the donor to recipient by antigen-specific lymphocytes, but as this and any residual immunocompetence of the recipient declines, an immunodeficient state exists until the donor immune system is established. Consequently, both antibody-mediated and cell-mediated immunity are deficient in the first 3–4 months after transplantation and may remain deficient for a longer period of time in patients with GVHD. This combined immune defect is often compounded by neutropenia and/or the effects of corticosteroid or immunosuppressant therapy for GVHD. Defective antibody responses may persist for several years after transplantation, particularly antibody responses against polysaccharide antigens.

##### Critical illness

Many patients who are critically ill as a result of surgery, trauma, thermal injury or overwhelming sepsis also have acquired immune defects.<sup>15</sup> These defects include abnormalities of cellular immunity, immunoglobulin deficiency and impaired neutrophil function. They appear to be associated with an increased propensity to infections and arise from abnormalities that are complex and multifactorial. Impairment of cell-mediated immune responses usually manifests as decreased T-cell proliferation and impaired delayed-type hypersensitivity responses, and probably results from a combination of factors, including the effects of anaesthetic drugs, blood transfusion, negative nitrogen balance and serum suppressor factors,

including cytokines such as TNF. Phagocyte defects are mostly due to impairment of neutrophil chemotaxis by serum factors, and impaired intracellular killing. Deficiency of serum immunoglobulins also occurs, especially IgG deficiency, and may be associated with antibody deficiency. Serum leakage is a factor in patients with thermal injuries, and reduced synthesis and increased catabolism of immunoglobulins occur in many critically ill patients.

The correction of immune defects in critically ill patients has been intensely investigated, but no effective treatment regimen has been defined. General measures such as adequate nutrition, achieving a positive nitrogen balance and excision of thermally injured tissue are effective. Biological response modifiers, cytokine and mediator inhibitors, and IVIg therapy have all been evaluated. The number of acute infections, particularly pneumonia, can be reduced by the use of IVIg therapy, but patient survival is not increased. G-CSF levels are increased during critical illnesses and correlate with the severity of illness. Administration of G-CSF has been shown to be safe in intensive care patients with no apparent increases in acute respiratory distress syndrome or multiple-organ dysfunction. However there is no current evidence that the administration of G-CSF improves outcome and until further evidence is presented, G-CSF is not indicated in the treatment of critically ill intensive care unit patients.

##### Asplenia and hyposplenism

The spleen is an important part of the immune system's response to infections, particularly blood stream infections. The most important splenic functions in this context are removal of opsonised microorganisms from the blood by splenic macrophages and production of an early antibody response to the polysaccharide antigens of encapsulated bacteria by IgM memory B cells (also known as mantle-zone B cells). In those people in whom the spleen is removed or does not function, best-practice guidelines recommend lifelong education, vaccination and appropriate use of antibiotics. The risk of severe life-threatening infection related to splenectomy alone is in the order of 1 in 500 per annum with 50% mortality. The most common organisms identified with overwhelming postsplenectomy infection (OPSI) include encapsulated bacteria, such as pneumococcus, *Haemophilus influenzae* and meningococcus, for which vaccines are available. Other bacteria, which are sometimes important, include group A *Streptococcus*, *Capnocytophaga canimorsus* following dog bites, *Salmonella*, *Enterococcus* and *Bacteroides*.

Pneumococcus, *Haemophilus influenzae* and meningococcus vaccines including regular boosters and annual influenza vaccine are recommended. This is consistent with US guidelines and broadly with UK guidelines, which make the last bacterial vaccine optional. Second, chemoprophylaxis with penicillin for at least 2 years after splenectomy, if the patient is not allergic, should be considered.

### SUMMARY: APPROACH TO THE IMMUNODEFICIENT PATIENT

1. Determine: (a) type of immunodeficiency; (b) degree of immunodeficiency; and (c) duration of immunodeficiency.
2. Predict: (a) the likelihood of infection; and (b) the type of infection.
3. Commence: (a) empirical; and (b) prophylactic therapy.
4. Targeted diagnostic tests.

# HIV and the acquired immunodeficiency syndrome

Steve Wesselingh and Martyn A H French

## HIV REPLICATION

Human immunodeficiency viruses (HIVs) 1 and 2 are retroviruses of the Lentivirus group. Like other lentiviruses, they exhibit tropism for cells of the immune system and cause immunological disorders, particularly immunodeficiency. Infection of immune cells in the nervous system may also cause neurological disease. Entry of HIV into cells of the immune system is via cell surface receptors. The major receptor is the CD4 molecule but the chemokine receptors CCR5 and CXCR4 play an important role as co-receptors. Inside the cell, the viral RNA is reverse-transcribed into DNA by a viral reverse transcriptase enzyme, and the DNA is integrated into the DNA of the host cell as proviral DNA by a viral integrase enzyme. The proviral DNA remains there until the cell is activated, when it is transcribed into RNA, which provides the template for assembly of new HIVs under the control of viral enzymes such as proteases. Budding of new virus from the cell is followed by infection of new cells and a repeat of the replication cycle.

## PRIMARY HIV INFECTION

Initial infection by HIV-1 is associated with a primary HIV infection syndrome (also known as a seroconversion illness) in 50–70% of patients. This syndrome is similar to infectious mononucleosis, being characterised by fever, lymphadenopathy, headache, photophobia, fatigue and myalgia. However, mucocutaneous lesions, neurological disease and even transient immunodeficiency may also occur and, when present, this differentiates it from infectious mononucleosis. It may take a number of weeks for HIV antibody (detected by enzyme-linked immunosorbent assay (ELISA)) to become positive during seroconversion; however the level of plasma HIV RNA is very high. The diagnostic test of choice during this period is the measurement of HIV viral load utilising HIV RNA RT/PCR (reverse transcription of HIV RNA and amplification by polymerase chain reaction). HIV RNA peaks at a median of 10 days.<sup>1</sup>

## CHRONIC HIV INFECTION

The viraemia associated with primary HIV infection is controlled by a cellular and antibody-mediated immune response, which results in resolution of symptoms. However, even though the great majority of people become asymptomatic, HIV replication continues to take place. This results in activation of the immune system, depletion of CD4+ T cells and immunodeficiency, especially cellular immunodeficiency. These abnormalities develop at different rates in different individuals. In untreated patients the median time to develop the acquired immunodeficiency syndrome (AIDS) after acquiring HIV infection is 9 years. However, about 5% of HIV-infected individuals have no abnormalities after 15 years and are referred to as long-term non-progressors.

Early in the course of chronic HIV infection, virus is present in lymphoid tissues where it is bound to follicular dendritic cells. There is a persistent immune response against the HIV but, as this fails, viral replication increases and the viral load increases and other cells become infected, including macrophages, microglial cells of the nervous system and CD4+ T cells.

Chronic HIV infection may cause weight loss, fevers and diarrhoea, though such symptoms are more likely to be caused by an opportunistic infection in immunodeficient patients. Effects of worsening HIV infection are an immunodeficiency syndrome, which results in the development of opportunistic infections, tumours and neurological disease. Neurological disease is a consequence of HIV infection of macrophages and microglial cells in the central and peripheral nervous system.

## DIAGNOSIS

A diagnosis of HIV infection can usually be made by demonstrating anti-HIV antibodies in the patient's serum. However, the serological diagnosis of HIV infection can sometimes be problematic. A small minority of individuals who are not infected by HIV have serum antibodies which are reactive with some HIV proteins, and

give false-positive results with some ELISAs. Many laboratories use two different types of ELISA to identify such sera. To ensure that HIV infection is not incorrectly diagnosed, an antibody test should only be considered positive if antibody is also detected according to defined criteria, using a confirmatory antibody test such as a Western blot immunoassay.<sup>2</sup> Anti-HIV antibodies may be absent from the serum of patients with primary HIV infection. They are usually detectable by 2–6 weeks after infection, and almost always detectable by 12 weeks. After this time, absence of HIV antibodies excludes HIV infection in all but the most advanced cases of AIDS, or in a patient with an antibody deficiency disorder.

### VIROLOGICAL MONITORING

It could be argued that HIV has been one of the major driving forces in the development of modern virology. For the first time HIV viral load monitoring has enabled the clinician to predict outcome, and monitor therapy during a viral infection.

### HIV VIRAL LOAD MEASUREMENT

The major advance in viral diagnostics has been the development of polymerase chain reaction (PCR) and the application of this to the detection and quantification of viral nucleic acid in body fluids. Measurement of the blood 'HIV load' can be done by quantitating HIV RNA in plasma. Knowledge of the HIV load is useful in prognostication and essential when making decisions to commence and optimise therapy<sup>3</sup> (Figure 60.1).

### GENOTYPING HIV TO DETECT DRUG RESISTANCE MUTATIONS

Drug susceptibility testing of HIV from a clinical specimen is performed in order to detect mutations in the genome of HIV that predict failure of individual antiviral therapeutic agents. The predominant genotype from an individual's plasma or cerebrospinal fluid sample is determined by sequencing the reverse transcriptase and protease genes of complementary DNA (cDNA) obtained following RT/PCR. This information is used to assist the clinician and patient in the choice of an antiretroviral drug combination with the best chance of successful suppression of HIV replication, especially where resistance is suspected, i.e. in a failing regimen.<sup>4</sup>

### IMMUNOLOGICAL MONITORING

Immunodeficiency and neurological disease caused by HIV infection usually develop gradually over months to years. It is important to monitor their severity to determine when to commence therapy, and when the patient is susceptible to various disease manifestations.

The blood CD4+ T-cell count or percentage is the best indicator of the severity of HIV-induced immunodeficiency and, therefore, of the patient's susceptibility to opportunistic infections. Measurement of the blood CD4+ T-cell count or percentage is therefore critical in determining if the symptoms of an HIV-infected patient are likely to be caused by an opportunistic infection, and if so, what type of infection (Figure 60.2; and see text below).<sup>5</sup>

## MANAGEMENT OF THE HIV-INFECTED PATIENT

The impact of combination antiretroviral therapy on the morbidity and mortality associated with HIV infection has been dramatic. The HIV Outpatient Study demonstrated a stepwise reduction in opportunistic infections and mortality with increasing intensity of antiretroviral therapy.<sup>6</sup> In Australia, a comparison of cohorts before and after the introduction of combination antiretroviral therapy documented the effectiveness of these agents in reducing the risk of progression to AIDS and death.<sup>7</sup> This reflects similar epidemiological studies conducted in Switzerland,<sup>8</sup> France<sup>9</sup> and the USA.<sup>10</sup> A 70–80% reduction in mortality over 5 years has been the norm. AIDS-defining illnesses in Australia now occur predominantly in those without a past diagnosis of HIV infection.

Six classes of antiretroviral drugs are currently in use (Table 60.1). Fusion inhibitors block fusion of the virus with the cell membrane and CCR5 inhibitors block binding of CCR5-tropic strains of virus with CCR5, a co-receptor for HIV. Reverse transcriptase inhibitors are of three types. Firstly, nucleoside analogues and nucleotide analogues act by substituting for natural nucleosides or nucleotides during HIV replication, thereby inhibiting DNA chain elongation and the effects of the reverse transcriptase enzyme. Secondly, non-nucleoside reverse transcriptase inhibitors inhibit the reverse transcriptase enzyme by a different mechanism. Thirdly, integrase inhibitors block integration of viral DNA into host DNA and protease inhibitors inhibit the viral protease. All antiretroviral drugs have a limited duration of efficacy if used alone because HIV eventually

develops resistance to them. The use of drug combinations is much more effective than single drugs, partly because drug resistance develops more slowly. Adherence to antiretroviral therapy is critical for the success of treatment.

## DRUG TOXICITY

With decreased rates of HIV morbidity and mortality, attention has now become focused on the toxicities of treatments. Adverse effects of antiretroviral drugs are common, and are a cause of significant morbidity and even mortality.

Recently, nucleoside analogue reverse transcriptase inhibitors (NRTIs) have been implicated in the development of syndromes that include fatigue, fat wasting, lactic acidosis and peripheral neuropathy. It has been suggested that these symptoms may be due to an inhibition of mitochondrial DNA (mtDNA) synthesis.<sup>11,12</sup> Pancreatitis has occurred uncommonly with ddI (5–7%) and d4T (1–2%).

The most common adverse effect of NNRTIs is a skin rash. This occurs in up to 25% of subjects started on nevirapine and can range from a mild rash to Stevens–Johnson syndrome. Combination antiretroviral therapy is associated with a syndrome characterised by redistribution of fat (lipodystrophy) and fat atrophy (lipoatrophy). The biological mechanism responsible for the development of this syndrome is still unclear,<sup>13</sup> although protease inhibitors in association with d4T have been implicated.

The use of antiretroviral therapy is also associated with hepatotoxicity in about 10% of patients.<sup>14</sup> Co-infection with hepatitis C virus is one risk factor for hepatotoxicity and at least some cases are probably a type of immune

restoration disease.<sup>15</sup> Restoration of immune responses against pathogens also appears to be a cause of other types of inflammatory disease after the use of combination antiretroviral therapy.<sup>16,17</sup>

**HIV-INDUCED IMMUNODEFICIENCY**

Patients who are not treated with antiretroviral therapy or whose antiretroviral therapy is ineffective, for whatever reason, often become immunodeficient. Both CD4<sup>+</sup> T-cell depletion and the effects of other immune defects lead to the development of an immunodeficiency syndrome. This syndrome is characterised by impaired cellular immunity

and an increased propensity to opportunistic infections. In addition, some patients have impaired antibody responses and phagocyte dysfunction, which results in infections with encapsulated bacteria. As mentioned previously, during chronic HIV infection there is a strong relationship between the degree of immunodeficiency and susceptibility to opportunistic infections. The CD4<sup>+</sup> T-cell count (or percentage) predicts the likely pathogens and is a guide to the need for prophylactic antimicrobials (see Figure 60.2).

**MILD IMMUNODEFICIENCY (CD4 T-CELL COUNT > 200/ml, 20%)**

Infectious complications of cellular immunodeficiency may occur when there is relatively mild impairment of cellular immune responses (CD4<sup>+</sup> T-cell counts of 200–500/ml). Mucocutaneous infections occur most commonly (Table 60.2) but infections with bacteria such as *Campylobacter jejuni*, *Salmonella* spp. or *Shigella* spp. are a cause of diarrhoea, and occasionally bacteraemia. Bacteraemic pneumococcal disease is also more common in this group. Most of these infections are not restricted to patients with HIV infection, and are therefore not considered to be AIDS-defining opportunistic infections. However, when they present atypically, are severe or are recurrent, they may be the first indication of underlying HIV-induced immunodeficiency. In contrast to the other infections, oral hairy leukoplakia (due to Epstein–Barr virus infection of epithelial cells) is almost always indicative of HIV infection.

**MODERATE IMMUNODEFICIENCY (CD4 T-CELL COUNT 50–200/UL, 10–20%)**

Cellular immunodeficiency which is severe enough to result in an increased propensity to systemic opportunistic infections is usually associated with a CD4 T-cell count of < 200/ml. Such infections are considered to be indicative of the presence of AIDS. Infection with many different microorganisms may occur, including infection with unusual microorganisms. Only the most common are described here.

**Table 60.2** Mucocutaneous opportunistic infections in patients with human immunodeficiency virus (HIV)-induced immunodeficiency

Herpes zoster (varicella-zoster virus infection)
Mucosal candidiasis
Oral hairy leukoplakia (Epstein–Barr virus infection)
Seborrhoeic dermatitis ( <i>Pityrosporon</i> spp. yeast infection)
Molluscum contagiosum (poxvirus infection)
Genital and cutaneous warts (human papillomavirus infection)
Fungal infections of the skin and nails
Recurrent mucocutaneous herpes simplex virus infections
Folliculitis ( <i>Staphylococcus aureus</i> , <i>Pityrosporon</i> spp.)

**PNEUMOCYSTIS JIROVECI PNEUMONITIS**

Infection of the lungs by *Pneumocystis jiroveci* causes an interstitial pneumonitis. Patients with this condition usually have a history of subacute progressive dyspnoea, cough, fever and weight loss. Examination often reveals basal pulmonary crackles. The chest X-ray usually shows interstitial infiltrates but is occasionally normal. Other findings which would support a diagnosis of *P. jiroveci* pneumonitis (PJP) are hypoxaemia, an increased serum lactate dehydrogenase (LDH) concentration, diffuse uptake of radiolabelled gallium into the lungs on a gallium scan, ground-glass pulmonary opacities on a high-resolution computed tomographic (CT) scan of the lungs, and detection of *Pneumocystis* by smear or DNA by PCR in induced sputum specimens. A definitive diagnosis can be made by demonstrating *Pneumocystis* cysts in an induced sputum specimen, bronchoalveolar lavage fluid or a transbronchial biopsy.<sup>18</sup>

PJP is treated with co-trimoxazole (trimethoprim-sulfamethoxazole), given orally or intravenously depending on disease severity. However, many patients develop a hypersensitivity reaction to co-trimoxazole which is usually mild and transient but, if systemic and severe, alternative medications, including oral dapsone and trimethoprim or intravenous pentamidine, can be used with equal efficacy. Steroid therapy should also be used if the  $P_{aO_2}$  is  $< 70$  mmHg (9.3 kPa)<sup>19</sup> with an  $F_{iO_2}$  of 0.21.

*Pneumocystis* infection can be prevented by prophylactic medications, which should be offered to all patients with a CD4 T-cell count of  $< 200$ /ml. The most effective drug is co-trimoxazole. Alternatives for patients who are sensitive to co-trimoxazole include dapsone (with or without pyrimethamine) or inhaled pentamidine.<sup>20</sup>

**OESOPHAGEAL CANDIDIASIS**

*Candida* infection of the oesophageal mucosa presents with odynophagia and dysphagia. The occurrence of such symptoms in association with oral candidiasis is usually sufficient to make a presumptive diagnosis of oesophageal candidiasis and to start treatment. Endoscopy is required for a definitive diagnosis. Treatment is usually with an azole, such as fluconazole. However, in patients with severe immunodeficiency, resistance to azoles is not uncommon and treatment with intravenous amphotericin may be required.

**CRYPTOCOCCAL MENINGITIS**

Meningitis is the most common manifestation of infection with *Cryptococcus neoformans* in patients with AIDS. It usually presents with headache and fever, but sometimes confusion or behavioural abnormalities are the predominant abnormalities. Neck stiffness is often minimal or absent. Cerebrospinal fluid examination may reveal little evidence of inflammation, particularly in the most severe cases, but cryptococcal antigen is virtually always present in both serum and cerebrospinal fluid and cultures for cryptococci are positive.<sup>21</sup> Most patients also

have cryptococcal antigen in their serum. Intravenous amphotericin is the treatment of choice, and must be followed by suppressive therapy or oral fluconazole, until immune reconstitution is achieved with antiretroviral therapy, to prevent relapses.<sup>22</sup>

**TOXOPLASMA ENCEPHALITIS**

Reactivation of *Toxoplasma gondii* infection most commonly presents as a focal encephalitis. This may cause headaches, fever, focal neurological deficits, convulsions and even coma. One or more brain lesions may be present. They usually produce ring-enhancing lesions with surrounding oedema on a contrast brain CT scan, and can occur in many sites, with a predilection for the basal ganglia. Serological evidence of previous *Toxoplasma* infection is present in virtually all patients, and absence of serum *Toxoplasma* antibody is strongly against the diagnosis. Treatment is with intravenous sulfadiazine or clindamycin and oral pyrimethamine. Hypersensitivity reactions to sulfadiazine and clindamycin are common, and an alternative drug regimen may be necessary. A brain CT scan should be repeated after 2–3 weeks of therapy, and an alternative diagnosis considered if there has been no resolution of the lesions. Cerebral lymphoma can produce very similar lesions to *Toxoplasma* encephalitis. A brain biopsy is often necessary to make the diagnosis.<sup>23</sup>

**SEVERE IMMUNODEFICIENCY (CD4 T CELLS  $< 50$ /UL, 10%)****CYTOMEGALOVIRUS (CMV) DISEASE**

CMV disease most often occurs in patients with very severe immunodeficiency (CD4 T-cell count  $< 50$ /ml). The most common site for reactivation of CMV infection is the retina. CMV retinitis usually presents with unilateral blurred vision, visual field loss or 'floaters'. Diagnosis is by funduscopy and should be confirmed by an ophthalmologist. Treatment is with intravenous ganciclovir or foscarnet or oral valganciclovir, followed by suppressive therapy to prevent relapses until there is immune reconstitution following the use of combination antiretroviral therapy.

CMV infection less commonly presents with disease of other organs, particularly the oesophagus, bile ducts or colon. Biopsy of affected tissue is necessary to make a definitive diagnosis. High or increasing CMV viral load in blood provides support for a diagnosis of CMV infection. In addition, CMV load can be utilised to monitor the response to therapy and early identification of resistance.

**CRYPTOSPORIDIOSIS**

Infection of the gastrointestinal tract by *Cryptosporidium parvum* causes a severe and intractable secretory diarrhoea, which is often associated with a malabsorption syndrome. It can also cause cholangitis. Diagnosis is by demonstrating *Cryptosporidium* oocysts in faeces and/or a rectal or

duodenal biopsy. There is no satisfactory treatment, but nitroimidazole is of use in some patients. Resolution is common following successful antiretroviral therapy.

#### MYCOBACTERIUM AVIUM COMPLEX (MAC) INFECTION

Infection with MAC is usually disseminated and affects blood leukocytes, liver, spleen and lymph nodes, and the gastrointestinal tract. This infection often results in weight loss, fatigue, fevers, anaemia and diarrhoea. The diagnosis is usually made by culturing MAC from blood, but sometimes stool microscopy and culture or biopsy of affected tissues are necessary. Treatment with multiple-drug therapy is often successful. Commonly used drugs are clarithromycin, rifabutin and ethambutol. Suppressive therapy should be continued until there is immune reconstitution following the use of combination antiretroviral therapy.<sup>24</sup> An unusual painful necrotising lymphadenopathy following initiation of antiretroviral therapy has been identified as MAC immune restoration disease.<sup>16,17</sup>

#### AIDS-RELATED NEOPLASMS

Certain neoplasms are a characteristic complication of cellular immunodeficiency, including HIV-induced immunodeficiency. ‘Opportunistic’ virus infections resulting from the immunodeficiency are involved in the pathogenesis of these neoplasms.

Kaposi’s sarcoma (KS) is an angioproliferative tumour which originates from vascular endothelium, and is a complication of human herpesvirus-8 (HHV-8) infection. It usually presents as skin lesions, which have a reddish-brown colour. They vary in extent from one or two small papules to numerous bulbous lesions. The mucosal surface of the gastrointestinal tract, lymph nodes and, rarely, internal organs may also be involved. A clinical diagnosis of KS can be confirmed by biopsy of a lesion. KS may present at any degree of immunodeficiency but occurs most often, and is more severe, in patients with moderate to severe immunodeficiency. New antimitotic agents plus antiretroviral therapy have resulted in KS essentially disappearing as a clinical problem in treated individuals.

Lymphomas are also a complication of HIV-induced immunodeficiency. The great majority are B-cell lymphomas (non-Hodgkin’s), and reactivation of Epstein–Barr virus infection is implicated in the pathogenesis of many cases. Primary cerebral lymphoma or extracerebral lymphoma, which often has extranodal involvement, is common in patients with severe immunodeficiency. These lymphomas are usually high-grade with poor prognosis (stage 3/4, CD4 < 100, median survival 44 weeks).<sup>25</sup>

Cervical intraepithelial neoplasia is more common in women with HIV infection. This is presumably because human papillomavirus infection is more likely to be present in women with HIV infection, and the cellular immunodeficiency permits human papillomavirus replication. As a consequence, the incidence of cervical carcinoma appears to be increased in HIV-infected women. Anal neoplasia is also increased in males.

#### HIV-RELATED NEUROLOGICAL DISEASE

In addition to the opportunistic infections of the nervous system discussed above, HIV infection of macrophages and microglial cells in the nervous system often results in neurological disease by incompletely understood mechanisms. Encephalopathy, myelopathy and peripheral neuropathy are all possible. In a small number of patients, the neurological disease is more problematic than the immunodeficiency. The encephalopathy usually develops insidiously in individuals with advanced immunodeficiency and eventually results in cognitive, motor and behavioural abnormalities. Myelopathy, which is now rare, results in an ataxic spastic paraparesis.<sup>26</sup>

Investigation of HIV patients with space-occupying cerebral lesions requires analysis of serology, cerebrospinal fluid and neuro-imaging investigations. Analysis of cerebrospinal fluid includes PCR for Epstein–Barr virus (indicative of lymphoma), herpes simplex virus, CMV, varicella-zoster virus (viral encephalitis), JC virus (indicative of progressive multifocal leukoencephalopathy), toxoplasmosis and *Mycobacterium tuberculosis*.<sup>27</sup>

#### HIV/AIDS AND ADMISSION TO THE INTENSIVE CARE UNIT (ICU)

HIV infection remains an incurable condition but is controllable by antiretroviral therapy for long periods of time. The prognosis has improved significantly over the past 10 years, with mathematical models indicating a median survival of 30 years. The admission of a patient with AIDS to an ICU is therefore often indicated.<sup>28,29</sup>

The most common indications are:

- respiratory failure complicating *Pneumocystis carinii* pneumonia or other infective pulmonary conditions
- coma or convulsions complicating opportunistic infections or tumours of the brain
- non-HIV-related conditions, such as self-poisoning and postoperative management

Respiratory failure complicating PJP has been the most common reason for admitting an HIV-infected patient to an ICU. Survival following ventilation for PJP was poor in the early 1980s, but improved with treatment advances. In recent years, survival has worsened again in some cohorts, particularly for patients with a CD4 T-cell count of < 50/ml and for those who develop pneumothorax as a result of barotrauma. The poor outcome in recent years may reflect the fact that patients are living longer because of improved therapy, and are hence often more immunodeficient when PJP develops. A first episode of PJP, a CD4 T-cell count of > 50/ml and no previous antiretroviral therapy are all favourable factors for survival. Furthermore, ventilation may be avoided by the use of continuous positive airways pressure (CPAP) or bilevel positive airways pressure (BPAP), thereby reducing the risks of a pneumothorax, airway obstruction and nosocomial infection. Prolonged illness antedating

ICU admission, low serum albumin and few options for antiretroviral therapy should be considered when assessing predictors of survival.

Drug–drug interactions are of particular importance, especially when ART includes protease inhibitors or efavirenz (metabolised via P450 hepatic enzyme system). Web-based guidelines are very useful ([www.HIV-druginteractions.org](http://www.HIV-druginteractions.org)) when prescribing antimicrobials, antiemetics and lipid-lowering drugs.

### NEEDLESTICK INJURIES AND POSTEXPOSURE PROPHYLAXIS

Patients with unrecognised HIV infection or AIDS may also be admitted to an ICU with the first manifestation of HIV disease. It is therefore important for all ICU staff to practise stringent infection control procedures at all times.

HIV transmission from needlesticks occurs at a rate of approximately 0.3%, and from mucosal exposure at a rate of approximately 0.009%. There have been no reported seroconversions after skin exposure. The major risk factors for infection after a needlestick injury are: (1) deep injury; (2) visible blood on device; (3) needle placement in a vein or artery; and (4) a source patient with late-stage HIV/AIDS (high viral load).

There is evidence that antiretroviral prophylaxis is associated with a reduction in transmission rates. On the basis of this, antiretroviral prophylaxis guidelines have been published.<sup>30</sup> A protocol for dealing with blood and body fluid exposure should therefore be developed for every health-care institution.

# Severe sepsis

A Raffaele De Gaudio

The incidence of sepsis has increased steadily over the last three decades, at least in part because of ageing western populations.<sup>1</sup> Nearly 15% of patients in intensive care have severe sepsis and two-thirds of them have septic shock.<sup>2,3</sup> Despite our increased understanding, improved support and more powerful antibiotic therapy, severe sepsis is consistently reported as a leading cause of death in non-cardiac intensive care units (ICUs). Mortality remains high<sup>3,4</sup> and severe sepsis claims far more lives than the common diseases of western countries such as acute myocardial infarction, stroke and trauma.<sup>1,4</sup>

## DEFINITION

In 1991 the American College of Chest Physicians and Society of Critical Care Medicine convened a consensus conference with the goal of providing a uniform definition for sepsis and its sequelae, using common clinical findings such as alteration in body temperature, tachycardia, tachypnoea and abnormalities in the white blood cell count that were identifiable at the bedside or early in the clinical process.<sup>5</sup> They proposed to differentiate systemic inflammation from the inflammatory response itself, and advocated a model in which *sepsis* is defined as infection in association with a state of systemically activated inflammation (Table 61.1). To differentiate illness severity further, *severe sepsis* was defined as sepsis with organ dysfunction and *septic shock* as sepsis with haemodynamic collapse.<sup>5</sup>

These consensus definitions delineate gradations of mortality risk, but they do not adequately stratify patients into homogeneous groups with respect to the underlying pathophysiology or potential to respond to therapy. They define concepts, but do not identify patients with a single disease.<sup>6,7</sup> For these reasons, a new consensus conference held in 2001 presented a new framework of consensus definitions and a staging system. This system, called *PIRO* (Table 61.2), includes domains for *predisposition* (premorbid illness), *insult/infection* (site, bacteriology of infection, severity of other insults such as trauma), *response* (hypotension, severity of illness measures such as such as Acute Physiology, Age and Chronic Health Evaluation – APACHE), and *organ dysfunction* (aggregate organ dysfunction scores such as multiple-organ

dysfunction syndrome and Sequential Organ Failure Assessment – SOFA).<sup>6,7</sup>

## PATHOGENESIS

Severe sepsis and septic shock evolve from a systemic inflammatory and coagulation response to a documented infection. Gram-negative bacilli (mainly *Escherichia coli*, *Klebsiella* spp. and *Pseudomonas aeruginosa*) and Gram-positive cocci (mainly staphylococci and streptococci) are the pathogens most commonly associated with the development of sepsis, although fungi, viruses and parasites cause the syndrome. Fungi, mostly *Candida*, account for only 5% of all cases of severe sepsis.<sup>7,8</sup>

The pathophysiology of bacterial sepsis is initiated by the outer-membrane components of both Gram-negative organisms (lipopolysaccharide, lipid A, flagellin and peptidoglycan) and Gram-positive organisms (teichoic acid, lipoteichoic acid, peptidoglycan). These outer-membrane components and other cell wall components are able to bind to the CD14 receptor, a protein anchored in the outer leaflet of the surface of monocytes. Recently, some coreceptors called Toll-like receptors were identified and it was demonstrated that bacterial components also interact with them. Ten members of the Toll-like receptor family have been identified, each of which shows a degree of specificity for pathogenic microorganisms and cellular products (e.g. TLR2 for peptidoglycan, lipoteichoic acid or TLR4 for lipopolysaccharide).<sup>7,8</sup>

Binding of Toll-like receptors activates intracellular signalling pathways that trigger transcription factors, such as nuclear factor- $\kappa$ B, which in turn control the expression of immune response genes, resulting in the release of cytokines (Figure 61.1). They secrete either cytokines with inflammatory properties (including tumour necrosis factor- $\alpha$  (TNF- $\alpha$ ), interleukin-1 (IL-1), IL-2, IL-6) or cytokines with anti-inflammatory properties (IL-4 and IL-10).<sup>7,8</sup>

A network of inflammatory mediators activates leukocytes, promotes leukocyte–vascular endothelium adhesion and induces endothelial damage.<sup>6</sup> This endothelial damage, in turn, leads to tissue factor expression and activation of the tissue factor-dependent clotting cascade with subsequent formation of thrombin, so that microaggregates of fibrin,

**Table 61.1** Sepsis definitions from the 1991 American College of Chest Physician and Society of Critical Care Medicine Consensus Conference<sup>5</sup>

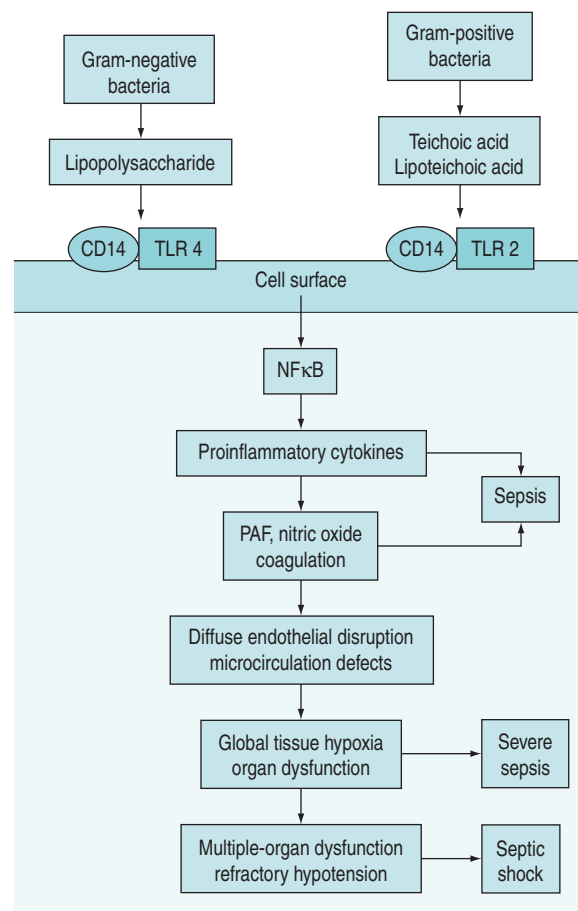

Systemic inflammatory response syndrome (SIRS)	At least two among the following: Temperature < 36°C or > 38°C Heart rate > 90 beats/min Respiratory rate > 20 breaths/min or PaCO <sub>2</sub> < 32 mmHg or mechanically ventilated Leukocyte count < 4000/μl or > 12 000/μl or > 10% immature band forms
Sepsis	SIRS + confirmed or presumed infection
Severe sepsis	Sepsis + organ hypoperfusion or dysfunction
Septic shock	Sepsis with refractory hypotension (systolic arterial blood pressure < 90 mmHg, mean arterial pressure < 70 mmHg) or vasopressor dependency after adequate volume resuscitation

**Table 61.2** The PIRO sepsis staging system<sup>6</sup>

Predisposition	Previous illness with reduced probability of short-term survival Age Genetic polymorphisms in components of inflammatory response
Insult/infection	Culture and sensitivity of infecting pathogens Disease amenable to source control Gene transcript profiles
Response	Systemic inflammatory response syndrome (SIRS) Sepsis Severe sepsis Septic shock Markers of activated inflammation (C-reactive protein, procalcitonin, interleukin-6) Markers of impaired host responsiveness (human leukocyte antigen (HLA)-DR) Detection of therapy target (protein C, tumour necrosis factor, platelet-activating factor)
Organ dysfunction	Number of failing organs Composite scores

platelets, neutrophils and red blood cells impair capillary blood flow, thereby decreasing oxygen and nutrient delivery.<sup>6-8</sup>

In particular, early inflammatory cytokines increase the expression of the enzyme-inducible nitric oxide synthase (iNOS) in endothelial cells; increased synthesis of the potent vasodilator nitric oxide leads to a decrease in

**Figure 61.1** Pathogenesis of bacterial sepsis.

systemic vascular resistance characteristic of shock. Inflammatory cytokines such as TNF also contribute to disruption of the tight junctions between endothelial cells, resulting in increased permeability to plasma proteins and fluid with generalised tissue oedema.<sup>7,9</sup> IL-6 alters hepatocyte protein synthesis, inducing the synthesis of acute-phase reactants and promoting anaemia. The acute-phase response also results in downregulation of the production of albumin and anticoagulant proteins such as protein C.<sup>7,9</sup> Microcirculatory dysfunction plays a key role in the development of organ dysfunction in septic patients.<sup>10</sup> As a result of the vicious cycle of inflammation and coagulation, cardiovascular insufficiency (due to the myocardial-depressant effect of TNF, vasodilation and capillary leak) and multiple-organ failure occur, often leading to death (see Figure 61.1).

## DIAGNOSIS

The initial presentation of severe sepsis and septic shock is often non-specific and its severity is cryptic. Diagnosis

**Table 61.3** Diagnosis of sepsis-associated organ dysfunctions

Cardiovascular	Systolic arterial blood pressure < 90 mmHg Decrease in systolic blood pressure > 40 mmHg Mean arterial blood pressure < 70 mmHg Decreased capillary refill or mottling
Respiratory	$P_{aO_2}/F_{iO_2} < 300$
Renal	Creatinine increase > 60 $\mu\text{mol/l}$ from baseline Creatinine increase > 60 $\mu\text{mol/l}$ within last 24 hours Urine output < 0.5 ml/kg per hour for 2 hours despite fluid resuscitation
Coagulation	Activated partial thromboplastin time > 60 seconds International normalised ratio > 1.5 Platelets < 100 000/ $\mu\text{l}$
Liver	Bilirubin > 70 mmol/l
Acid–base	Lactate > 2.1 mmol/l

requires the presence of a presumed or known site of infection, evidence of a systemic inflammatory response syndrome and acute sepsis-associated organ dysfunction (Table 61.3).

Clinical signs include fever or hypothermia, tachycardia, tachypnoea, mental status changes and signs of peripheral vasodilation, that are manifestations of the systemic inflammatory response syndrome.

Laboratory and invasive haemodynamic measurements include:

1. increased cardiac output with normal or low systemic vascular resistance
2. increased oxygen consumption (low  $ScvO_2$ )
3. leukocytosis or leukopenia
4. lactic acidosis
5. impaired renal or liver function

### PULMONARY DYSFUNCTION

Detection of sepsis is facilitated by the nearly universal presence of tachypnoea and hypoxaemia. Pulmonary dysfunction requires a high-volume ventilation, precisely when compliance of the lungs is diminished, airway resistance is increased and muscle efficiency is impaired. Respiratory failure often progresses rapidly; sustained high respiratory rate is usually a sign of impending ventilatory collapse, even if arterial oxygen levels are normal.

### CARDIOVASCULAR FAILURE

Cardiovascular failure is caused by an inadequate supply or inappropriate use of metabolic substrate. There is increasing evidence that sepsis is accompanied by a hypermetabolic state, with enhanced glycolysis and hyperlactataemia

that do not necessarily indicate tissue hypoxia.<sup>11</sup> Hypotension is frequently the result of low systemic vascular resistance. Shock is typically defined as a systolic pressure lower than 90 mmHg that is unresponsive to fluids or that requires vasoactive drugs.

### RENAL DYSFUNCTION

Oliguria is related to hypotension. Anuria is rare. Volume deficit correction reverses oliguria but does not always prevent moderate increases in the serum creatinine level. Renal failure requiring dialysis occurs in about 5% of patients.

### LIVER DYSFUNCTION

The liver is a mechanical and immunologic filter for portal blood and may be a major source of cytokines. An increase in aminotransferase and bilirubin levels is common,<sup>12</sup> but hepatic failure is rare.

### COAGULATION ABNORMALITIES

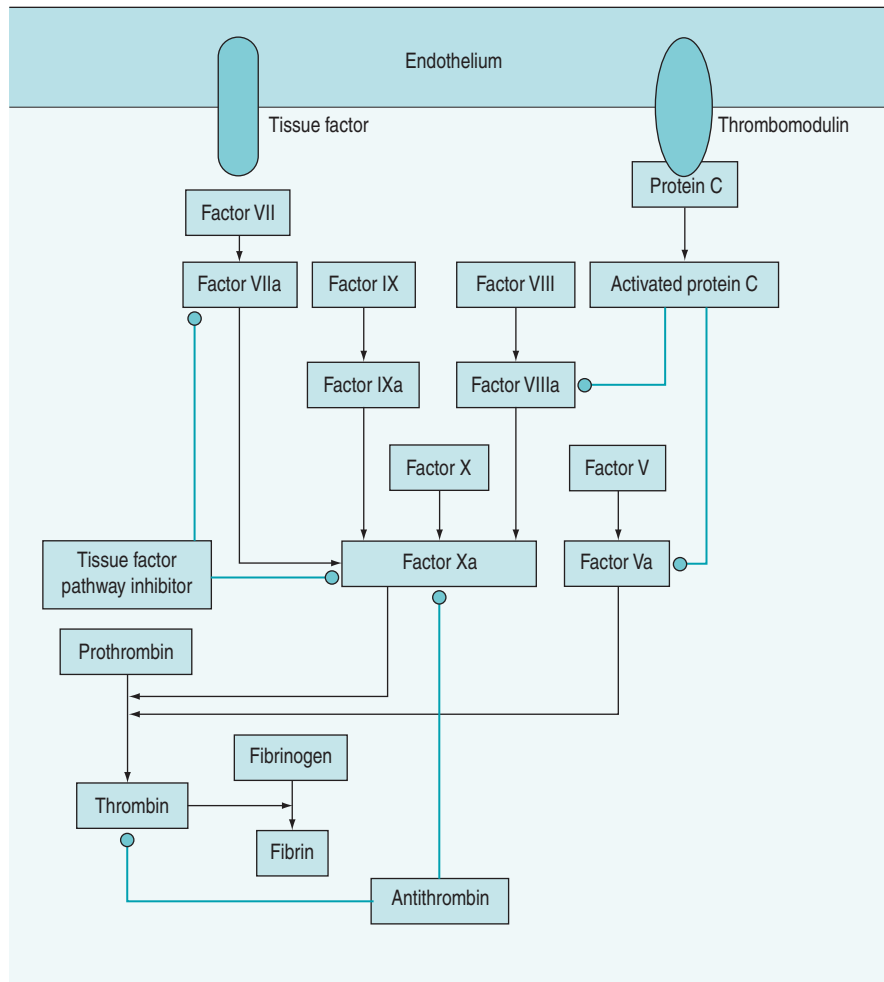

Subclinical coagulopathy, with a mild elevation of the prothrombin or partial thromboplastin time, or a moderate reduction in platelet count or an increase in plasma fibrinogen degradation and D-dimer levels may occur. Coagulopathy is caused by deficiencies of the coagulation system proteins (antithrombin III, protein C, tissue factor pathway inhibitor and the kinin system) (Figure 61.2). Simultaneous activation of coagulation by inflammatory cytokines and reduced production of anticoagulant proteins contribute to disseminated intravascular coagulation.<sup>12</sup>

### SEPSIS-ASSOCIATED ENCEPHALOPATHY

A diffuse cerebral dysfunction is often present in sepsis and may ensue even before signs of other organ failure. It is better defined as ‘sepsis-associated encephalopathy’ (SAE), in order to stress the absence of direct infection of the central nervous system. The main sign of SAE is an altered mental status. Electroencephalography is the most sensitive diagnostic test, and allows the grading of the severity of cerebral dysfunction that is related to outcome. SAE is potentially reversible, but always worsens the prognosis. The pathophysiology of SAE is still not completely understood, and it is probably multifactorial. Indeed, brain dysfunction in sepsis may be related to microorganism toxin activity, to the effects of inflammatory mediators, to metabolic alterations and to abnormalities in cerebral circulation.<sup>13,14</sup>

### BIOLOGICAL MARKERS

More than 80 biological markers of sepsis have been proposed for diagnosis and prognosis (including C-reactive protein, IL-6, procalcitonin). At the moment lack of availability, non-standardised assays and cut-off values limit their practical use.<sup>12</sup>

**Figure 61.2** Coagulation cascade and its inhibition by activated protein C, antithrombin and tissue factor pathway inhibitor.

## TREATMENT

Timely and proper care of the patient with severe sepsis is essential and includes: (1) treatment of the infection with source control and antimicrobial agents; (2) supportive measures such as fluid therapy and vasoactive agents; and (3) adjuvant therapies (Table 61.4).

During the past few years, several randomised controlled trials in patients with severe sepsis and septic shock have demonstrated significant reductions in mortality rates with new applied therapies. Concurrently, antimicrobial resistance to several agents has emerged and changed considerations about empirical therapy. Advances in imaging and non-invasive interventional techniques have also led to new diagnostic and therapeutic strategies for early source control. Some of the new approaches to management of severe sepsis appear to be time-dependent, suggesting a 'golden hour' and a 'silver day' perspective on the management of this syndrome.<sup>15</sup>

## SURVIVING SEPSIS CAMPAIGN

In order to improve the standard of care offered to patients with sepsis, the Society of Critical Care Medicine, the European Intensive Care Society and the International Sepsis Forum launched the Surviving Sepsis Campaign (SSC) with a founding statement that became known as the 'Barcelona declaration'.<sup>16</sup> All aspects of management of the patient with severe sepsis were covered and recommendations or bundles, depending on the available level of evidence, were developed for each category<sup>16</sup> (Table 61.5).

However, at the moment, there is no evidence that their beneficial effects are synergistic.<sup>17,18</sup>

## SOURCE CONTROL OF INFECTION

Adequate source control of infection is as important as appropriate antimicrobial therapy. All patients presenting with the clinical syndrome of sepsis should be evaluated for

**Table 61.4** Management of severe sepsis/septic shock

Monitoring of heart rate, blood pressure, pulse oximetry and urine output
Investigation of the infection source
Laboratory tests for organ dysfunction and global tissue hypoxia (lactate)
Empiric broad-spectrum antibiotics
Central venous access and early goal-directed therapy in patients with lactate > 4 mmol/l or systolic arterial pressure < 90 mmHg even after 20–40 ml/kg fluid challenge
Source control (abscess drainage, tissue debridement, prosthesis removal)
Fluid therapy, vasoactive and inotrope drugs
Consider adjuvant therapies
Additional general treatment components

**Table 61.5** Issues considered by the Surviving Sepsis Campaign Guidelines<sup>16</sup>

Diagnosis
Initial resuscitation
Antibiotic therapy
Fluid therapy
Vasopressors
Inotropic therapy
Steroids
Activated protein C
Blood product administration
Mechanical ventilation
Sedation/analgesia
Glucose control
Renal replacement
Bicarbonate therapy
Deep-vein thrombosis prophylaxis
Stress ulcer prophylaxis
Consideration regarding limitation of life support

the possible presence of a focus of infection amenable to treatment by source control measures. A source of infection should be rapidly sought by integration of the clinical history, physical examination and results of focused diagnostic tests and imaging examinations.<sup>7</sup> Advances in diagnostic or interventional radiology and surgical procedure have revolutionised the management of many intra-abdominal infections: Specifically, the diagnostic impact of abdominal computed tomography (CT) scan has been significant in patients with multiple potential causes of their acute abdominal pain or sepsis of unknown origin.<sup>15</sup>

Source control includes removal of infected foreign bodies (such as intravascular catheters, vascular graft); incision and drainage (open or percutaneous) of abscesses or fluid collections; the debridement of infected necrotic tissue and the definitive management of anatomical derangements that permit ongoing microbial contamination. For patients with necrotising fasciitis mortality and extent of tissue loss are directly related to the rapidity of surgical intervention.<sup>7</sup>

## ANTIMICROBIAL THERAPY

The site of infection and causative organisms are often unknown. Appropriate antimicrobial therapy must be administered empirically in these cases, guided by knowledge of the most common site of infection and most common infecting organisms. Specimens for culture and sensitivity testing should be obtained before empiric wide-spectrum antibiotic therapy is started.

If cultures do not support a diagnosis of infection as the cause of a systemic inflammatory response within 3 days, systemic antibiotics should be discontinued to reduce the risk of superinfection with resistant species, and the patient re-evaluated.

Observational studies suggest a significant reduction in mortality when antibiotics are administered within 4 and 8 hours of hospital admission.<sup>19</sup> Current SSC recommendations are to administer antibiotics within 1 hour of sepsis diagnosis.<sup>16</sup> Specific antibiotic strategies may be found in Chapter 64.

## EARLY HAEMODYNAMIC RESUSCITATION (FIRST 6 HOURS)

Haemodynamic resuscitation to normal physiological parameters has been trialled as early goal-directed therapy (EGDT), which revealed a statistically significant mortality reduction of 16.5%.<sup>20</sup> EGDT aims to restore the balance between oxygen supply and demand within the first 6 hours. The strategy involves obtaining adequate oxygen delivery by optimisation of intravascular volume (preload) with the use of: (1) central venous pressure (CVP) monitoring; (2) blood pressure (afterload) with mean arterial pressure monitoring; (3) contractility monitoring to avoid tachycardia; and (d) restoration of the balance between systemic oxygen delivery and oxygen demand to resolve global tissue hypoxia (guided by  $ScvO_2$ ).<sup>15,21,22</sup> A low  $ScvO_2$  (< 70%), coupled with an elevated lactate level, suggests a mismatch between systemic oxygen delivery and oxygen consumption of the tissues. When a low  $ScvO_2$  is identified, therapies to augment the components of oxygen delivery are recommended to restore the balance between systemic oxygen delivery and consumption (oxygen-carrying capacity, arterial oxygen saturation and cardiac output).  $ScvO_2$  can be measured intermittently from venous gas samples taken from the distal port of a standard central venous catheter.<sup>23</sup> At the moment, EGDT appears to decrease ICU pulmonary artery catheter utilisation.<sup>23,24</sup> In any case, the pulmonary artery catheter remains effective as a measurement site, although outcome benefit from its use remains to be demonstrated.<sup>23,24</sup>

Resuscitation goals proposed in SSC<sup>16</sup> include: central venous pressure of 8–12 mmHg, mean arterial pressure  $\geq$  65 mmHg, urine output  $\geq$  0.5 ml/kg per hour, central venous (superior vena cava) oxygen saturation  $\geq$  70% or mixed venous  $\geq$  65%.

## FLUID THERAPY

Initial resuscitation efforts should incorporate intravenous fluid therapy. The first goal of volume therapy of

sepsis is repletion of the patient's intravascular volume. The selection of crystalloid versus colloid solutions has been vigorously debated. At the moment no randomised controlled trial or systemic review has definitively shown a benefit in the critically ill septic patient for the use of colloid or crystalloid fluid.<sup>25,26</sup> A larger volume of crystalloids (2–3 times) is usually required. A smaller volume of colloid will produce a similar improvement in volume status, but these fluids are more expensive and may alter blood coagulation. Intravenous fluid therapy should begin with 1000 ml crystalloid fluid challenge or 500 ml colloids over 30 min.<sup>16</sup> Rapid and repeated 500-ml boluses of either crystalloid or colloid fluid may be necessary up to an initial resuscitation volume of 20–40 ml/kg body weight.<sup>15,21</sup>

#### VASOACTIVE AGENTS AND INOTROPES

Organ perfusion cannot be maintained with fluids alone. Vasoactive agents (Table 61.6) should be administered when hypotension is persistent or mean arterial blood pressure is less than 65 mmHg, after a crystalloid challenge of 20–40 ml/kg.<sup>15,21</sup> However, existing evidence does not clearly support the superiority of one vasopressor over another.<sup>27</sup> Both noradrenaline (norepinephrine) and dopamine have been advocated as first-line vasopressor agents in cases of sepsis,<sup>15,21</sup> although some prefer norepinephrine.<sup>28</sup> Norepinephrine and phenylephrine, agents with more alpha-agonist effects, may be preferable for patients with tachycardia or ischaemic cardiac diseases. The combination of noradrenaline plus low-dose dobutamine has been shown to prevent gastric mucosal perfusion in comparison with adrenaline (epinephrine) or dopamine.<sup>28,29</sup>

Inotropic support with dobutamine may treat the myocardial depression, improving contractility.<sup>15</sup> When hypotension persists, a vasopressin deficiency may be considered. Exogenously administered vasopressin in physiologic replacement doses may act synergistically with other vasopressor agents.<sup>18,23</sup> The SSC<sup>16</sup> recommends vasopressin infusion for refractory shock and in limited doses.

#### ADMINISTRATION OF ERYTHROCYTES

The patient's oxygen-carrying capacity may be augmented by the administration of packed erythrocytes to achieve a haematocrit above 30%, with a more restrictive transfusion strategy in the convalescent phase of the disease.<sup>16,30</sup>

#### DECREASING OXYGEN CONSUMPTION

Strategies to minimise oxygen demand should consider: intubation, analgo-sedation, control of fever with antipyretic, mechanical ventilation to reduce the work of breathing and oxygen consumption by respiratory muscles.<sup>21</sup>

#### ADJUVANT THERAPIES

Several additional therapies initiated early after identification of severe sepsis can improve the patient's outcome, and reduce the mortality rate. At the moment there is no consensus in these issues.

#### ACTIVATED PROTEIN C (APC)

During sepsis the APC pathway serves as a major system for controlling thrombosis, inhibiting thrombin formation, limiting inflammatory responses and potentially decreasing endothelial cell apoptosis. Recombinant APC (rhAPC) could also improve microcirculatory blood flow in septic patients, as recently measured in vivo.<sup>10</sup> There are concerns about the effects of rhAPC, although it has been shown to yield a 6.1% absolute reduction in 28-day all-cause mortality when administered to a heterogeneous group of patients with severe sepsis (Protein C Worldwide Evaluation in Severe Sepsis (PROWESS) trial).<sup>31</sup> This was supported by the open-label extended evaluation of recombinant human protein C (ENHANCE study).<sup>32</sup> However, a second large randomised controlled trial that compared rhAPC with placebo in patients with less severe sepsis was terminated early, when there appeared to be no mortality benefit for this patient population (Administration of Drotrecogin alfa (activated) in Early Stage Severe Sepsis (ADDRESS) trial).<sup>33</sup>

**Table 61.6** Vasopressors and inotropes used for severe sepsis/septic shock

Agent	Receptor pharmacology				Cardiovascular effect		Dose
	$\alpha_1$	$\beta_1$	$\beta_2$	Dopaminergic	CO	SVR	
Dopamine	0	+	0	++	+	+	0.5–2 $\mu\text{g}/\text{kg}$ per min
	+	++	0	++	+	+	5–10 $\mu\text{g}/\text{kg}$ per min
	++	++	0	++	+	++	10–20 $\mu\text{g}/\text{kg}$ per min
Dobutamine	0/+	+++ +	++	0	++	-	2.5–20 $\mu\text{g}/\text{kg}$ per min
Adrenaline (epinephrine)	+++	+++	++	0	++	0/+	1–10 $\mu\text{g}/\text{min}$
Noradrenaline (norepinephrine)	+++	++	0	0	0/+	++	0.5–1.5 $\mu\text{g}/\text{kg}$ per min
Phenylephrine	+++	0	0	0	0/+	++	1–10 $\mu\text{g}/\text{kg}/\text{min}$

CO, cardiac output; SVR, systemic vascular resistance.

The SSC recommends rhAPC in patients at high risk of death (APACHE II  $\geq$  25), sepsis-induced multiple-organ failure, septic shock or sepsis-induced acute respiratory distress syndrome (ARDS) and with no absolute contraindication related to bleeding risk or relative contraindication that outweighs the potential benefit of rhAPC.<sup>16</sup> This may not seem the most reliable method for choosing patients because the use of this drug has not been validated in this context, and there are numerous variables in the calculation of the APACHE II score, including age.<sup>18</sup> Further studies are necessary to optimise the use of this drug; many uncertainties remain and it must also be taken into account that the drug is expensive, carries an elevated risk of bleeding and that its introduction was accompanied by more than the usual amount of scientific debate.<sup>7,34,35</sup>

### STEROIDS

Steroid administration in severe sepsis and septic shock remains controversial. The SSC recommends the use of intravenous corticosteroids in patients with septic shock who, despite adequate fluid replacement, require vasopressor therapy to maintain blood pressure.<sup>16</sup>

The use of large doses of methylprednisolone has not been shown to be beneficial.<sup>36</sup> Recently, the concept of inadequate adrenal reserve, or relative adrenal insufficiency (RAI), has led to the consideration of administering moderate doses of steroids. The administration of low doses of hydrocortisone (200–300 mg/day for 7 days) plus fludrocortisone (50  $\mu$ g orally per day for 7 days) to patients with septic shock decreased their requirements for vasopressors and lowered their mortality rate.<sup>37–39</sup> In other studies RAI was diagnosed using the 250- $\mu$ g adrenocorticotrophin test to identify patients who would benefit more from steroid administration.<sup>37–39</sup>

Recently, in a multicentre, randomised, double-blind, placebo-controlled trial on about 500 patients, hydrocortisone did not improve survival or reversal of septic shock, either overall or in patients who did not have a response to corticotrophin.<sup>40</sup>

### TIGHT BLOOD GLUCOSE CONTROL

When conservative glycaemic control was compared with tight control in a multicentre randomised clinical trial, tight control led to a significant reduction in mortality and improved morbidity at 1 year.<sup>41</sup> Other advantages included shorter intensive care stay, a reduced risk of renal failure and a much lower incidence of critical-illness polyneuropathy. The study involved cardiac surgery patients. A recent trial by the same group in medical critically ill patients showed no significant difference.<sup>42</sup> As it is not clear if slightly less stringent control has the same advantages, it is necessary to carry out meticulous monitoring of blood glucose in order to prevent the risk of hypoglycaemia, particularly in unstable septic patients.

Insulin has anti-inflammatory effects that may contribute to its beneficial action in sepsis. Other characteristics of insulin (i.e. prevention of apoptosis) that may be

responsible for its most important therapeutic effect in these patients should also be considered.

### PROTECTIVE LUNG STRATEGIES

High tidal volumes coupled with high plateau pressures should be avoided in those patients who develop acute lung injury (ALI) or ARDS as a consequence of severe sepsis.<sup>43</sup> Mechanical ventilation with large tidal volume can stretch lung tissue to excess (volume trauma), exacerbating the inflammatory response and leading to ALI. In one study patients with ALI or ARDS were randomised to receive ventilation with tidal volumes of 12 ml/kg predicted body weight (control) or 6 ml/kg predicted body weight (treatment), with plateau pressure maintained at  $<$  30 cm H<sub>2</sub>O. An absolute reduction of 9.9% in 28-day mortality was demonstrated in the low tidal volume group,<sup>44</sup> with fewer days on ventilatory support and lower levels of circulating IL-6.

### EXTRACORPOREAL BLOOD PURIFICATION TECHNIQUES

These techniques may hold promise for the treatment of sepsis.<sup>45</sup> At the moment definitive studies have yet to be performed. Dialysis does improve survival among patients with sepsis who have established renal insufficiency. It is not certain that dialysis, plasmapheresis or plasma exchange will improve outcomes in patients with sepsis who do not have renal failure. Studies in animals and humans examining this issue have been inconclusive. There is also a potential for harm, since this therapy could remove beneficial compounds or molecules as well.<sup>46</sup>

### ADDITIONAL GENERAL TREATMENT COMPONENTS

Additional components in the care of severe sepsis include:

1. adequate early nutrition that is best accomplished via the enteral route, to avoid catheter-related blood stream infections and to maintain gut mucosa integrity
2. deep-venous thrombosis prevention that can be accomplished with the use of subcutaneous heparin or continuous use of pneumatic compression stockings
3. gastric ulcer prophylaxis that may be accomplished with sucralfate, an H<sub>2</sub>-receptor antagonist or a proton pump inhibitor
4. prevention of nosocomial infection (adopting selective antimicrobial decontamination of digestive tract,<sup>47</sup> removing catheters)

### OUTCOME

The overall hospital mortality rate for patients with severe sepsis is high. Since this disease is reversible, prompt recognition and resuscitation are key to optimising outcome. Studies focused on novel targets, mechanism of action and combination therapy may also improve outcome.<sup>48</sup>

# Nosocomial infection

Neil Soni

Nosocomial or hospital-acquired infections are a major problem in hospitals, affecting up to 9% of inpatients at any one time. Intensive care units (ICUs) represent 2–10% of hospital beds, but are responsible for 25% of all nosocomial blood stream and pulmonary infections. In the European Prevalence of Infection in Intensive Care (EPIC) snapshot of prevalence the infection rate in ICU was 20.62%.<sup>1</sup> Nosocomial infection is, at least in theory, a preventable cause of morbidity and mortality (Table 62.1).

## EPIDEMIOLOGY

The prevalence of nosocomial infection is reported as being between 3 and 12% in most institutions but varies considerably between different sites within each institution.<sup>2</sup> The vulnerability of the patient population, the nature of interventions and cross-infection are but three of many factors. This is seen clearly if one compares the range between ophthalmology and critical care – 0–23%.<sup>3</sup>

The site of infection varies with location so that, whereas the urinary tract and the chest are common throughout the hospital, within the ICU surgical wound infection, pneumonia and blood stream infection are far more common (8–12%).

The impact of nosocomial infection is impressive. Ventilator-associated pneumonia (VAP) is common, has significant morbidity with increased length of stay, associated costs and a twofold increase in mortality.<sup>4</sup> It has been suggested that blood stream infections, surgical wound infections and nosocomial pneumonia result in 14, 12 and 13 attributable extra hospital days respectively.<sup>5</sup> Catheter-related blood stream infection (CRBSI) was also associated with major morbidity although, curiously, not necessarily mortality.<sup>6</sup> The mortality rates directly due to these infections are hard to separate from the mortality attributed to the presenting severity of illness, which in its own right may have predisposed to infection. What is clear is that nosocomial infection is associated with increased mortality, and huge financial and resource costs.<sup>2</sup>

## THE MECHANISMS INVOLVED IN NOSOCOMIAL INFECTION

A range of factors come together to enable nosocomial infection to occur. Some may be risk factors in their own right whereas other may simply represent an identifier of a sicker and therefore more vulnerable population (Table 62.2).

### HOST

The vulnerability of a potential host will be determined by several factors:

- the acute illness or problem that required ICU admission
- the chronic health status and underlying disease. Conditions such as diabetes predispose to infective problems
- the status of their immunocompetence, which may involve medications, such as steroids
- the integrity of natural defences, such as the skin and mucous membranes. This may be disrupted by burns, surgery or by breakdown of tissues such as pressure areas. The presence of invasive devices (e.g. endotracheal tube, intravenous devices) provides a conduit past the natural defences
- antibiotics given to the patient which may encourage emergence of particular strains or resistant organisms
- blood transfusion has been suggested as a risk factor<sup>7</sup>

### ENVIRONMENT

Local environmental pressures play their part. The combination of antibiotics, in particular multiple antibiotics, and cross-infection predisposes a vulnerable population to pseudomembranous colitis from *Clostridium difficile* toxin.<sup>8</sup> Epidemiological patterns, such as the prevalence of *Enterococcus faecalis* as a common pathogen in the surgical population, may be linked to widespread cephalosporin usage. Much of the multiresistance problem probably originates from antibiotic pressures.<sup>9</sup> Cross-infection is the biggest single problem in intensive care and transmission is by various means, but still the most common is by hands.<sup>10</sup>

**Table 62.1** Principles of diagnosis of nosocomial infections

- Diagnosis of infection usually requires the combination of both clinical findings and the results of diagnostic tests
- Clinical diagnosis of infection from direct observation at surgery, endoscopy or other diagnostic procedure is an acceptable criterion for an infection
- It must be hospital-acquired. There must be no evidence that the infection was present or incubating at the time of hospital admission. Infection acquired in hospital, but only evident after hospital discharge, also fulfils the criteria
- Usually no specific time during or after hospitalisation is given to determine whether an infection is nosocomial or community-acquired. Each infection is examined for evidence that links it to hospitalisation (this is a matter of controversy)

**Table 62.2** Risk factors for nosocomial infection**Patient**

Severity of illness  
 Underlying diseases  
 Nutritional state  
 Immunosuppression  
 Open wounds  
 Invasive devices  
 Multiple procedures  
 Prolonged stay  
 Ventilation  
 Multiple or prolonged antibiotics  
 Blood transfusion

**Environment**

Changes in procedures or protocols  
 Multiple changes in staff; new staff  
 Poor aseptic practice – poor hand-washing  
 Patient-to-patient: busy, crowded unit, staff shortages

**The organism**

Resistance  
 Resilience in terms of survival  
 Formation of slime or ability to adhere  
 Pathogenicity  
 Prevalence

**ORGANISM**

The host usually lives in synergistic or symbiotic tranquility with a huge range of organisms (Table 62.3). Antibiotics suppress many normal organisms and allow the emergence and overgrowth of a usually insignificant organism or resistant organism of the same type. For example, an intrinsic organism such as *Candida* will flourish in the presence of broad-spectrum antibiotics and this overgrowth may result in symptomatic or even invasive candidiasis. Cephalosporin use may encourage the intrinsically resistant but quiescent enterococci to emerge as a dominant and problematic organism.

**Table 62.3** Common commensals that may cause infection in a vulnerable host

Site	Common commensal organisms
Skin	<i>Staphylococcus epidermidis</i> , streptococci, <i>Corynebacterium</i> (diphtheroids), <i>Candida</i>
Throat	<i>Streptococcus viridans</i> , diphtheroids
Mouth	<i>Streptococcus viridans</i> , <i>Moraxella catarrhalis</i> , <i>Actinomyces</i> , spirochaetes
Respiratory tract	<i>Streptococcus viridans</i> , <i>Moraxella</i> , diphtheroids, micrococci
Vagina	Lactobacilli, diphtheroids, streptococci, yeast
Intestines	<i>Bacteroides</i> , anaerobic streptococci, <i>Clostridium perfringens</i> , <i>Escherichia coli</i> , <i>Klebsiella</i> , <i>Proteus</i> , enterococci

Extrinsic organisms may be introduced from the environment, from other patients, from staff or from surfaces. These may be organisms which are thriving in that environment because of local pressures (e.g. antibiotics), or from poor hygiene. Examples include *Acinetobacter* and, of course, meticillin-resistant *Staphylococcus aureus* (MRSA). On admission, patients will be carrying a range of organisms that have the potential to cause problems, but during their stay they are likely to acquire a new ecology from their surroundings. In a hospital that ecology may be quite hostile, with multiresistance being common.

The individual characteristics of the organism are important. These include their resilience in the local environment, the ease of transmission and the individual pathogenicity. This clearly interacts with the vulnerability of the host, as some usually innocuous organisms, such as *Candida* or *Serratia marcescens*, will only cause problems in vulnerable hosts whereas others, such as some strains of *Staphylococcus aureus*, *Acinetobacter* or *Clostridium difficile*, may be intrinsically more virulent.

**THE ORGANISMS**

A vast range of organisms can cause nosocomial infection (Table 62.4). It must be emphasised that each hospital and each ICU will have its own local ecology and knowing this ecology is important. Regional, national and international surveys give indications of general trends but this does not supplant local knowledge.

Nosocomial infection is dynamic in that it is influenced by many environmental factors, the type of patient, type of surgery or illness, the antibiotic usage profile and many other variables. This dynamism is illustrated by the Gram-positive infections of the 1950s and 1960s, giving way to the Gram-negative infections of the 1970s and, while the multiresistant Gram-positive organisms are a major anxiety currently, they are already being superseded by super-resistant organisms, such as *Stenotrophomonas* and *Acinetobacter*. The ease of transmission or development of resistance is a key factor in the current explosion in multiresistance.

**Table 62.4** Organisms responsible for the majority of nosocomial infections

Methicillin-resistant <i>Staphylococcus aureus</i> (MRSA)
Coagulase-negative <i>Staphylococcus</i> (CNS)
<i>Enterococcus</i> spp. ( <i>E. faecalis</i> , <i>E. faecium</i> )
<i>Pseudomonas aeruginosa</i>
<i>Acinetobacter baumannii</i>
<i>Stenotrophomonas maltophilia</i>
<i>Enterobacter</i> spp.
<i>Klebsiella</i> spp.
<i>Escherichia coli</i>
<i>Serratia marcescens</i>
<i>Proteus</i> spp.
<i>Candida</i> spp. ( <i>C. albicans</i> , <i>C. glabrata</i> , <i>C. krusei</i> )

Other organisms may be a problem in the severely immunocompromised, such as those with acquired immunodeficiency syndrome (AIDS; see Chapter 60)

The combination of sick patients and widespread use of potent antibiotics selects out problematic organisms and, as this epitomises intensive care practice, it is in ICU where multiresistance is common.

The organisms causing nosocomial infection may be endogenous or exogenous. Illness and antibiotics may both encourage the emergence and overgrowth of endogenous organisms that were normally suppressed and hence ecological change takes place in the skin, nasopharynx and gut. Alternatively the same factors influence colonisation with exogenous organisms from the environment. Cross-infection plays a significant role, as does the size of the local reservoir of exogenous organisms. The colonising organisms are well placed to invade or be introduced by invasive procedures, by devices or simply through areas of injury. Infection follows.

### MULTIRESISTANT ORGANISMS

Many of the organisms that cause nosocomial infection are characterised by multiresistance. There are several mechanisms involved in resistance and in its spread. Enzymes, such as the  $\beta$ -lactamases, render a large array of antibiotics useless. Class I  $\beta$ -lactamase is effective against some  $\beta$ -lactam-containing antibiotics but extended-spectrum  $\beta$ -lactamases (ESBL), which incorporate enzymes, such as TEM-24, will produce cross-resistance to multiple classes of antibiotics, including fluoroquinolones and aminoglycosides. Resistance may be produced by a combination of mechanisms, such as in *Pseudomonas aeruginosa*, where the resistance is due to a combination of derepression of protein efflux systems, cephalosporinases and derepression of AmpC enzyme.

Resistance is acquired in a variety of ways. Mutation of any gene occurs at a rate of one cell in  $10^7$  and, if this cell is then presented with antibiotics that it can survive, it will become a dominant cell, reproducing at a rate of  $10^9$  overnight. An example of this might be the development of AmpC  $\beta$ -lactamase in *Enterobacter*, when patients are treated with third-generation cephalosporins. A similar

**Table 62.5** The influence of extended-spectrum  $\beta$ -lactamases (ESBL) on resistance in *Klebsiella*

Antibiotics	ESBL-negative (% resistant)	ESBL-positive (% resistant)
Gentamicin	8	76
Amikacin	3	52
Ciprofloxacin	3	31
All the above	0	5

(Reproduced from Livermore DM, Yuan M. Antibiotic resistance and production of extended-spectrum beta-lactamases amongst *Klebsiella* spp. from intensive care units in Europe. *J Antimicrob Chemother* 1996; **38**: 409–24.)

example is the loss of porin OprD in *P. aeruginosa* in the presence of imipenem.

The big problem, particularly with ESBL, is that they can spread by plasmid transmission which is very rapid. The enzyme production is encoded chromosomally within an organism, and can then be transferred between bacteria by plasmids. Transposons transfer genes between plasmids. Examples of this include:

1. SHV-1 plasmid  $\beta$ -lactamase from *Klebsiella*
2. plasmid AmpC  $\beta$ -lactamases from *Citrobacter*
3. aminoglycoside-modifying enzymes from aminoglycoside-producing streptomycetes

The phenomenon of induction is also seen. This is the process whereby the presence of an antibiotic appears to 'induce' or speed up the production of the relevant enzyme so that the organism rapidly becomes resistant.

Staphylococcal resistance to methicillin occurs due to an altered penicillin-binding protein, which has low affinity for all  $\beta$ -lactam agents. It is linked to a *MecA* gene. This gene does not develop readily and spread of methicillin resistance is by vector transmission, not de novo production of resistance<sup>7</sup> (Table 62.5).

### SOME COMMON ORGANISMS

See Table 62.4 for organisms responsible for the majority of nosocomial infections.

#### *Escherichia Coli*

*E. coli* was one of the first organisms to become multiresistant. The spread of its resistance is a model of how the problem develops in different environments. Currently in Europe, about 4% of *E. coli* is resistant to ceftazidime but in Turkey this figure is 26%. The trend towards an increase in resistance seems to correspond with the use of quinolones.<sup>11</sup>

#### *Enterobacter species, cloacae and Aerogenes*

Part of the normal intestinal flora, these species tend to develop ESBL relatively easily, making them multiresistant to a wide range of antibiotics, including ceftazidime. The prevalence of resistance in many western ICUs is running at about 35% and rising. This organism has been

implicated in cross-colonisation in ICU and the relevant enzymes, including TEM-24, impart cross-resistance to multiple classes of antibiotics. Prompt recognition and treatment are usually effective.<sup>12</sup>

### **Klebsiella**

*Klebsiella* has become increasingly resistant with the acquisition of ESBL, and can be multiresistant. The incidence is incredibly variable between countries.

### **Pseudomonas**

*Pseudomonas* are versatile opportunistic pathogens common in the critically ill; they may colonise patients with chronic lung disease. Resistance is able to develop in a range of ways and produces a very broad spectrum of resistance, making it potentially very difficult to treat and resulting in the increased popularity of combination therapy.<sup>13</sup> It is associated with adverse outcome in the critically ill.<sup>14</sup>

### **Stenotrophomonas Maltophilia**

This is an increasingly common and troublesome environmental organism. It is often resistant to  $\beta$ -lactam antibiotics, quinolones and to aminoglycosides. It also produces a carbapenamase, which makes it resistant to carbapenems.

### **Acinetobacter Baumannii**

*Acinetobacter baumannii* is an increasing and major problem. It survives even in dry environments and, despite its name, spreads and cross-infects readily (*a cineto*: without movement). They are multiresistant and, although they were sensitive to carbapenems, they are increasingly resistant even to these agents, presumably through gene exchange. They become rapidly resistant and the profile of resistance is unpredictable but can be extremely broad, with some organisms recently only sensitive to colistin.<sup>15</sup>

### **Coagulase-Negative Staphylococci (CNS)**

CNS are low-virulence organisms, but are increasingly causing nosocomial infection. Their resilience may be in part due to the production of biofilm. Frequently methicillin-resistant, they are also resistant to multiple classes of antibiotics, but are usually sensitive to glycopeptides. As glycopeptide resistance patterns alter, newer agents, such as quinupristin, dalbapristin and linezolid, will have a role.

### **Staphylococcus Aureus**

This is a virulent pathogen causing a wide range of infections. Methicillin resistance started in the early 1960s, and although rates between countries and ICUs vary considerably, there has been an inexorable rise in its prevalence in most countries. It is easily identified. It both colonises and infects, but is relatively easily treated with glycopeptides. More recent reports of occasional glycopeptide-resistant organisms are therefore a major source of concern. It has been a model of the failure of some infection control methods. It is being increasingly assessed in terms of suppressibility with a selective decontamination of the digestive tract (SDD)-style approach to elimination.<sup>16</sup>

### **Enterococcus Faecalis and Faecium**

These organisms emerged with increased third-generation cephalosporin use. *E. faecalis* is more commonly isolated and may still be sensitive to ampicillin but more than 30% are resistant to aminoglycosides. This contrasts with *E. faecium*, which has a resistance rate of 7% to vancomycin (and rising), 53% to ampicillin and 30% to aminoglycosides. Glycopeptide resistance is increasing and vancomycin-resistant enterococcus (VRE), unheard of 10 years ago, is now being regularly identified.<sup>17</sup>

### **Tuberculosis**

Not normally seen as a nosocomial infection, this has the potential to become a nosocomial problem. As numbers increase and infected patients are not recognised on admission, there is the possibility of rapid spread to both other patients and staff. In particular multiresistant tuberculosis is on the increase. At present there are occasional outbreaks but these could easily increase.

### **Clostridium difficile**

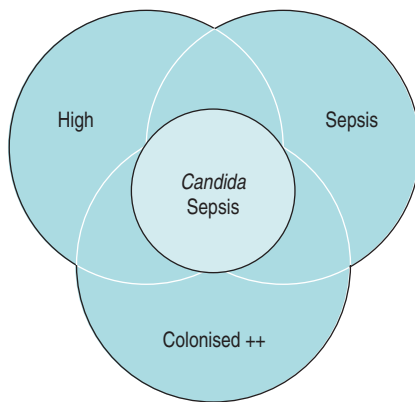

This originally emerged as an organism that became a problem after certain antibiotics, including clindamycin. It is now clear that in the critically ill it often emerges after almost any broad-spectrum antibiotics, although usually after several courses and some considerable time. Probably as important is the observation of case clusters, indicating that cross-infection is important. The organism produces a toxin that causes pseudomembranous colitis, but paradoxically, testing for the toxin provides a rapid diagnostic pathway that can facilitate early treatment. Aggressive pseudomembranous colitis is a potentially catastrophic disease and, although it usually settles on metronidazole or vancomycin orally, not only is recurrence common but it can also progress to severe colitis and necessitates radical surgery such as colectomy.<sup>18</sup> Surgery carries a high mortality rate, quoted at 11% for total colectomy, and very high mortality for less aggressive surgery such as hemicolectomy in the presence of toxic megacolon.<sup>19</sup>

### **Candida Sepsis**

*Candida* sepsis is almost always a nosocomial problem, probably endogenous in origin, and related to overgrowth secondary to antibiotic pressures. Occasionally clusters of more unusual *Candida* such as *C. glabrata* or *C. krusei* are seen in the ICU, suggesting cross-infection. The prevalence of species is defined by each unit but *C. albicans* is most common. There is some evidence to suggest that the widespread use of azoles may have influenced the relative increase in *C. glabrata* and *C. krusei* species. Definitive diagnosis is by blood culture but presumptive diagnosis is suggested by the triad of clinical infection, a high-risk patient and *Candida* at more than two sites. Antifungal treatment should depend on the sensitivity of the species involved.

In the next decade, three organisms will dominate nosocomial infection and one, MRSA, will provide a historical perspective. The organisms are *Stenotrophomonas*

**Figure 62.1** Diagnostic triad of *Candida* sepsis.

and *Acinetobacter*, which are rapidly becoming more common and less easy to treat. The third, although in relatively small numbers, relates to the rising incidence of multiresistant tuberculosis, which not only has potential but is already providing infection control challenges in the critically ill (Figure 62.1).

## COLONISATION AND INFECTION

Many organisms both colonise and infect, but differentiating between colonisation and infection is difficult. In essence the presence of the organism may not indicate infection and, in complex patients with multiple colonisations and infection, determining which the culprit is may be difficult or even impossible. As a consequence, treatment is often based on probability or the weight of evidence, rather than certainty.

MRSA colonises very readily and causes infection in a significant proportion of cases but is often easily identified and treated. VRE is still relatively uncommon. It does colonise, although the incidence of overt infection appears low, at present, but is difficult to treat when it occurs. *Acinetobacter* colonises and infects very readily, may take days to identify and is difficult to treat.<sup>20</sup>

## SITES OF INFECTION

The main sites of nosocomial infection are the chest, wounds and intravenous lines. Urinary tract infection, often quoted as common, seems to be seen rarely in the critically ill.

## NOSOCOMIAL PNEUMONIA

Nosocomial pneumonia is a common problem in the critically ill, particularly in ventilated patients, with an incidence of 15–30%.<sup>21–23</sup>

### Aetiology

There are several possible mechanisms, including aspiration from the nasopharynx, local spread or haematogenous

spread of infection. Some 45% of healthy adults aspirate in their sleep. In the sick the nasopharynx colonises rapidly with a wide range of organisms, usually Gram-negatives, and aspiration is encouraged by the unconscious state, the presence of a nasogastric tube or by endotracheal intubation. Pneumonia will develop in up to 25% of colonised patients, compared with a 3% incidence in non-colonised patients. It may also be related to the colonisation of the upper gastrointestinal tract, which may in turn colonise the nasopharynx.

Factors that are likely to encourage colonisation of the pharyngeal areas with organisms include antibiotics and nasogastric tubes. Also implicated are alterations in the host defences in the pharynx, changes in the local pH, the amount of surface mucin and impairment of other local immune defence mechanisms.

Patient factors predisposing to nosocomial pneumonia include acute severity of illness; chronic illness, especially chronic lung disease; diabetes; immunosuppression; advanced age; recent surgery to thorax or abdomen; intubation; and bronchoscopy. Environmental factors include broad-spectrum and prolonged use of antibiotics; potential pathogens in the vicinity; bacterial properties such as ability to adhere to surfaces; cross-infection; 24-hour ventilator tubing changes; and foreign bodies such as nasogastric tubes. Intubated and ventilated patients have a higher rate of nosocomial infection than patients receiving non-invasive ventilation. However, this may be due to different patient populations with different underlying problems and background morbidity.<sup>24</sup> The role of neutralisation by H<sub>2</sub> antagonists and proton pump inhibitors is still debated.<sup>25–27</sup>

### Diagnosis

The general criteria for diagnosis are general signs of infection; clinical signs of a chest infection; purulent sputum; radiological evidence, such as new pulmonary infiltrates; and positive cultures, from sputum or blood.<sup>21,23,28,29</sup> These produce a non-specific diagnosis. Expectored sputum is difficult to assess, but should contain < 25 polymorphs and > 10 squamous epithelial cells per low-power field. In ICU it is more usual to provide samples from the endotracheal tube and then to use quantitative techniques. This can be achieved with protected brush specimens (PBS) bronchoalveolar lavage (BAL) and protected BAL. These are difficult and time-consuming and it appears that non-bronchoscopic techniques such as blind tracheal aspirates through the endotracheal tube are both practical and reasonably effective from a clinical – if not a research – viewpoint<sup>23,30</sup> (Table 62.6).

### The Organisms

Aerobic Gram-negatives predominate, including *Pseudomonas aeruginosa*, *Enterobacter* spp., *Klebsiella*, *Escherichia coli*, *Serratia marcescens* and *Proteus*; between them, these account for about 70% of infections. Staphylococci, in particular MRSA, account for a small but significant number of nosocomial pneumonias. Early-onset VAP,

**Table 62.6** Principles for the diagnosis of nosocomial pneumonia

Crackles on auscultation or dullness to percussion on physical examination of the chest and any of the following:

- New onset of purulent sputum
- Organism isolated from blood cultures
- Isolation of pathogen from specimen obtained by transtracheal aspirate, bronchial brushing or biopsy
- Chest radiography examination shows no or progressive infiltration, consolidation, cavitation or pleural effusion
- Isolation of virus or detection of virus antigen in respiratory secretions
- Diagnostic single antibody titre (IgM) or fourfold increase in paired serum samples (IgG) for pathogen
- Histopathological evidence of pneumonia

IgM, immunoglobulin M.

between 48 hours and 5 days, may be due to community pathogens, such as methicillin-sensitive *Staphylococcus aureus*, *Streptococcus pneumoniae* and *Haemophilus influenzae*, as well as Gram-negative enteric bacilli (GNEB). This has been described as early endogenous infection. In contrast, later onset, after 5–7 days, involves more resistant species such as MRSA, *Pseudomonas aeruginosa*, *Acinetobacter baumannii* and *Stenotrophomonas maltophilia*.<sup>31,32</sup> This has been called secondary endogenous and exogenous infection.

### Prevention

Prevention is by methods that reduce aspiration, cross-infection and contamination of respiratory devices.<sup>29</sup> Several recommended methods are:

- hand-washing
- limiting antibiotic use
- changing ventilator circuits at longer intervals – 1 week
- orotracheal, rather than nasotracheal intubation
- removing nasogastric tube
- semirecumbent position – this reduces aspiration
- avoiding muscle relaxants
- avoiding reintubation
- using non-invasive ventilation, where possible

Other more controversial methods include:

- antibiotic prophylaxis after intubation
- continuous suctioning of subglottic secretions
- early enteral nutrition: benefits of the colonisation of the gastrointestinal tract might be offset by problems with nasogastric tubes and nasopharyngeal colonisation
- the use of heat moisture exchangers
- closed suctioning: with some limited evidence it reduces VAP

### Treatment

The use of inappropriate or inadequate antibiotics leads to an increased mortality, so current trends are towards

initial broad-spectrum antibiotics followed by reassessment and de-escalation.<sup>33,34</sup> The principle is that an empirical broad-spectrum approach will cover the relevant organisms but once the specific organism is identified the antibiotics can be rationalised to focus on that organism; this is clearly harder to apply in practice than in theory. As the spectrum of resistance grows it is highly likely that it will be increasingly difficult to apply this broad-spectrum empiric treatment, especially with late-onset VAP. Surveillance of current colonisation, awareness of an individual ICU's ecology and targeted treatment will replace empiric regimens. At present, combination therapy is recommended, but there is little evidence to support it over monotherapy.<sup>23,33,35–37</sup>

Another area of interest is duration of treatment with antibiotics. Many regimens are traditional rather than evidence-based and may result in unnecessarily prolonged treatment. There is a trend to reducing courses. For VAP an 8-day course may be adequate.<sup>30</sup> There has not yet been a move towards using a clinical or bacterial response to treatment as an indicator for the duration of treatment, although it may be on the horizon.

The attributable mortality with nosocomial pneumonia is difficult to determine because patients requiring ventilation often have a high intrinsic mortality. Rates of 30% have been quoted: pneumonia accounts for 60% of deaths from nosocomial infections. In addition, nosocomial pneumonia increases length of stay by 12–23 days.<sup>4,38,39</sup>

## WOUND INFECTION

Wound infections are common and represent 20% of all nosocomial infection. The organisms involved may be those introduced at the time or from later contamination.

### RISK FACTORS

- The procedure itself and the level of contamination prior to or during surgery. In clean elective surgery the incidence should be less than 10%, but where contamination may occur (e.g. bowel surgery) it may be as high as 15%. In contaminated procedures, the rate rises to around 20%, and where infection already exists it may be 40% or higher.
- The surgeon's technical ability<sup>40</sup>
- Host factors: see Table 62.2
- The use of antibiotic prophylaxis
- Duration of stay in ICU

### THE ORGANISMS

The organisms are frequently determined by the type of surgery and procedure. Skin commensals are common, such as staphylococci or streptococci, and are usually early infections. These are characterised by fever, pain and redness around the site. With streptococcal infection this

may be quite confluent. Gram-negative organisms may also cause infection. Drainage is important.

### PREVENTION

Clean theatres, good operating technique and thorough asepsis, both in the theatre and postoperatively, are important.

### ANTIBIOTIC PROPHYLAXIS

This is a difficult and contentious area. The unnecessary use of broad-spectrum antibiotics should be avoided, but there are some areas of surgery where prophylaxis has a proven place. If there is no risk of infection with a clean procedure there is no place for antibiotics. If contamination is either seen or likely to occur, the use of antibiotics is to provide cover for the spillage. There may be other circumstances where the patient is particularly vulnerable to bacteraemia, such as with valve disease or where the consequences of infection would be disastrous. Effective prophylaxis requires an antibiotic:

- which covers the most likely organisms
- to be given prior to contamination
- at peak dosage at the time of contamination

A single dose should suffice, although a second dose is recommended if the procedure extends beyond 3 hours. Prolonged administration:

- increases the chance of antibiotic resistance
- unnecessarily exposes the patient to adverse effects from the drugs
- encourages colonisation with resistant organisms
- ensures that if a late infection occurs it will be with an organism resistant to the prophylaxis

In many circumstances the evidence supporting prophylaxis is minimal, and frequently the antibiotics used are inappropriate to the perceived risk. Local factors, including the local ecology, will determine specific requirements. With grafts, mesh or prostheses the morbidity from infection is so great as to justify using prophylaxis even if the evidence is marginal (Table 62.7).

### LINE SEPSIS

The use of intravascular devices in hospital practice is ubiquitous. There is both a significant morbidity, resulting in prolongation of hospital stay, and an attributable mortality associated with their use due to infection.<sup>41–43</sup>

### PERIPHERAL LINES

The use of peripheral lines is commonly associated with phlebitis, which may be chemical but is frequently a precursor of infection. Usually peripheral lines should only be in situ for less than 72 hours.

**Table 62.7** Surgical prophylaxis

Type of surgery	
Abdominal wall	Insertion of mesh. Staphylococcal or streptococcal cover. In the groin, Gram-negative cover may be needed
Cardiac	Protection of valves and grafts. Staphylococci may be resistant
Vascular	Protection of grafts. Staphylococci are a major consideration. If the groin is involved, it may require Gram-negative cover
Orthopaedic	Prostheses. Staphylococci are an increasing problem
Biliary upper GI	Usually Gram-negative and anaerobic cover, with an awareness of resistant enterococci
Colorectal	Protection against faecal flora. Cephalosporins and metronidazole have been popular but predispose to developing enterococci such as <i>Enterococcus faecalis</i> or <i>E. faecium</i> , which may be multiresistant
Gynaecological	Conventionally broad-spectrum involving cephalosporins or, currently, augmentin. Metronidazole is also favoured
Urological	Protection from instrumentation of the urinary tract, Gram-negative cover. Awareness of any existing infection

GI, gastrointestinal.

### ARTERIAL LINES

Curiously, arterial lines seem to become colonised and infected less frequently than other peripheral devices. Nevertheless they do become colonised and should be regularly changed. Complications include infected radial aneurysms or thrombosis.

### PULMONARY ARTERY CATHETERS

The introducers are a potential source of infection, as is the part of the catheter in the introducer. They are frequently left in situ when they should have been removed earlier.

### CENTRAL VENOUS CATHETERS

Colonisation of catheters is common and it is likely that this is a precursor of infection. Colonisation rates are in the order of 5–40%, determined in part by the risk factors involved (see below). Infection rates are approximately 10% of the colonised catheters.<sup>44</sup>

### DEFINITIONS

1. Colonised catheter: growth of > 15 colony-forming units (semiquantitative) or 10<sup>5</sup> (quantitative) from a

**Table 62.8** Risk factors for catheter infection**Host risk factors**

Site: subclavian is a lower risk than internal jugular and femoral  
Catheter material: antibacterial catheters may reduce infection, antiseptic catheters reduce colonisation

Number of lumens: multilumen catheters increase the infection risk<sup>30</sup>

Number of administrations through the lines

Dressing type: frequency of changes

**Skin preparation**

Experience of technique of personnel

Occurrence of bacteraemia

Tunnelling: often used for long-term access but the data are contentious<sup>31</sup>

proximal or distal catheter segment in the absence of accompanying clinical symptoms and signs.

2. CR-BSI: isolation of the same organism from the catheter segment (see above) as from a peripheral blood culture in a patient with signs of infection and in the absence of another source. In the absence of laboratory corroboration of infection then effervescence of infection after removal of the catheter may be taken as circumstantial evidence.

Extrinsic mechanisms associated with developing catheter sepsis include infection from the skin and insertion site; contamination from the hub and then internally spread; and contamination of drugs or fluids administered through the catheter. Bacteraemia seeding to catheter is an intrinsic mechanism.

The actual mechanics by which the organisms colonise the catheter is important. Some organisms, such as CNS, produce a polysaccharide film of 'slime' that develops on the catheter while the host's proteins such as fibronectin may also provide a matrix in which the organism can adhere, and which may provide a protective barrier against both white cells and antibiotics. Polyvinyl chloride or polythene is more prone to this film developing than some other materials such as silicone (Table 62.8).

**THE ORGANISMS**

The organisms involved in catheter sepsis are many and varied. There is a 25% incidence of CNS, which are increasingly recognised as pathogens. *Staphylococcus aureus* and MRSA are prevalent. There may be seeding, resulting in vertebral osteomyelitis and a variably reported incidence of endocarditis. Enterococci are increasingly seen. Occasionally fungi are found and may again be associated with seeding to the eyes or heart.

**TREATMENT OF CATHETER INFECTION**

The most important aspect of treatment is a high index of suspicion that leads to removal of the device if infection is present either locally or systemically.<sup>42</sup> Although fever

and bacteraemia are likely to resolve rapidly after removal of the line, appropriate antibiotics are indicated. The recommended duration of treatment varies: 5–7 days for CNS, 10–14 days for *S. aureus*, Gram-negative organisms and fungi, and 4–6 weeks if there is evidence of endocarditis, infected thrombus or osteomyelitis, or clinical line sepsis is still present after 3 days.<sup>42</sup> Lines removed should be cultured. If an infection is present it is best to avoid replacing the central venous catheter if possible for a few days. In situations where it is uncertain if the line is implicated in infection, some advocate replacing a new line over a wire. If the removed catheter is subsequently shown to be infected, then it must be removed.

The situation is slightly different with Broviac or Hickman catheters. Occasionally administration of antibiotics through the catheter will eradicate the infection and save the line. Unfortunately, it is not always successful: the risk of failure should be balanced against the value of the line. Some medical catastrophes have been the consequence of persisting with infected Hickman lines.

**PREVENTION**

Important issues include adequate hand-washing; adequate skin disinfection; insertion under aseptic conditions; intravenous team to insert and manage lines; anchoring of lines to prevent excessive movement; closed systems with limited interruptions to the lines; application of sterile dressings to the insertion site; and daily inspection of catheter site. Replacement of intravenous administration sets at 72 hours is optimal. Stopcocks may be essential, but are portals of infection. Local antiseptics are advocated for site care, but there is little difference between gauze and transparent dressings, although efforts to reduce local humidity at the site may be important.<sup>45–47</sup>

Techniques of unproven benefit include antiseptic cream at insertion site; routine changes of dressings at frequent intervals; occlusive antimicrobial dressings; in-line filters; tunnelling of central venous catheters; and routine flushing of long-term central venous catheters.

**METHODS OF INFECTION CONTROL**

Each hospital has an infection control team that can employ techniques to reduce infection (Table 62.9).

The most important aspects of preventing nosocomial infection and facilitating infection control are simple

**Table 62.9** Roles of infection control teams

Surveillance and investigation of infection outbreaks
Education of staff
Review of antibiotic utilisation
Review of antibiotic resistance patterns
Review of infection control procedures and policies

hygiene, such as hand-washing, and being aware that the problem exists. There are several ways in which the issue of nosocomial infection can be addressed. These include surveillance, screening, isolation, eradication and strategic planning.<sup>48</sup>

### SURVEILLANCE

Routine culture of both patients and environment provides information on the organisms currently prevalent, and is a useful tool in guiding management when infection occurs. It also provides information on cross-infection rates. Using 'typing' techniques, individual organisms can be tracked, and this is of particular importance in following outbreaks.

### SCREENING

This tries to prevent multiresistance by identifying patients carrying high-risk organisms. In the critically ill, to be effective it requires isolating the patient until cultures are available. It is clearly of benefit with rare or very threatening infection, such as the haemorrhagic fevers, but cumbersome and ineffectual with an organism as prevalent as MRSA. Future problems with *Acinetobacter* may need re-evaluation of its role.

### ISOLATION

Although physical barriers undoubtedly reduce cross-contamination, isolation may be hazardous as it often indicates lower-intensity care. The relative risks need to be addressed.

### ERADICATION

This requires the use of potent antibiotics ± antiseptics to eliminate the organism, which may be colonising rather than infecting. It exposes potent therapeutic agents and facilitates the development of resistance or the emergence of more resistant strains. It is therefore a hazardous undertaking in strategic terms.

### STRATEGIC PLANNING

There are two elements. One is enforcing hygienic practice, which is simple, cheap and very effective. The other is looking towards means of reducing both nosocomial infection and the emergence of resistance. This is essentially the planned use of antibiotics.

Currently the same agents are used in agriculture, the community and in hospital, which provides vast potential for the emergence of resistance. In human practice the widespread use of potent agents in the community will impinge on hospitals. In hospitals focused antibiotic use in one area will be undermined by generalised use in another. There should be controls across the boundaries of these areas of use.

On an individual basis the approach to management must change. In the past, empiric treatment on the basis

of likely organisms led to the use of very-broad-spectrum antibiotics. It is already clear that in an individual who has been in hospital for any period of time, using any antibiotic is likely to miss some resistant strains. Narrow-spectrum targeted treatment will cease to be an option and will become a necessity. Prolonged broad-spectrum antibiotic management aimed at dealing with any eventuality will be replaced by short-duration specific and effective regimens.

### SELECTIVE DECONTAMINATION OF THE DIGESTIVE TRACT

SDD is based on the idea that overgrowth of colonising organisms in the gut predisposes to nosocomial infection so that reducing or eliminating the reservoir of organisms from the nasopharynx and from the gastrointestinal tract will prevent infection. To achieve this, oral non-absorbable antibiotics, such as polymyxin, tobramycin, gentamicin, neomycin and nystatin, are applied to the oropharynx and administered through nasogastric tubes. Parenteral antibiotics have been added to some regimens. Although the positive results outweigh the negative ones, the uptake of this technique has been limited.<sup>31,49,50</sup> Concerns over generating resistance have not been substantiated nor completely refuted.<sup>51–53</sup>

A new controversial but interesting application has been in attempting to eliminate multiresistant organisms such as MRSA with an MRSA-targeted regimen, which is claimed to eradicate MRSA.<sup>16</sup> It remains a controversial area.

# Severe soft-tissue infections

Hugo Sax and Didier Pittet

The skin is the largest organ and acts as an excellent barrier against infection. It consists of the epidermis and dermis and resides on fibrous connective tissue, the superficial and deep fasciae (Figure 63.1). The fascial cleft, with nerves, arteries, veins, lymphatic and adipose tissue, lies between these fascial planes. Normal skin flora includes *Corynebacterium* spp., coagulase-negative staphylococci, *Micrococcus* spp., *Lactobacillus* and, rarely, *Staphylococcus aureus*. Colonisation by Gram-negative bacteria occurs in hospital patients; once altered, skin flora includes a higher proportion of *S. aureus* which ultimately becomes pathogenic.

These colonising microorganisms seldom cause skin and soft-tissue infections, but serious infections can occur if: there is a break in the skin because of traumatic lesion or maceration; soft tissues are ischaemic and non-viable; colonising bacteria are particularly virulent; or the patient is immunocompromised (Figure 63.2).<sup>1–9</sup> Conditions predisposing to infection include diabetes mellitus, cirrhosis, malnutrition, major trauma, advanced age, renal failure, steroid use, collagen vascular disease and malignancies.<sup>1–10</sup> Differentiation between soft-tissue infections can be difficult and one unified management approach to severe forms is appropriate.<sup>11–13</sup> Management decisions are further based on likely causative organism, depth of infection and clinical severity.<sup>8</sup>

Soft-tissue infections are usually caused by bacterial entry through skin lesions or perforation of adjacent intestinal structures. Skin lesions can on occasion be the manifestations of systemic infection; examples of this are bacteraemia by meningococci, staphylococci, *Pseudomonas aeruginosa*, *Candida* spp., and bacterial endocarditis.<sup>3</sup> These will not be specifically addressed here.

## CLASSIFICATION

The bacteriology and subtypes of severe soft-tissue infections have not changed significantly over the last century.<sup>8,14–16</sup> Community-acquired methicillin-resistant *Staphylococcus aureus* (MRSA), however, can be seen as an emerging cause of severe tissue infection with a high prevalence in certain parts of the world.<sup>17–19</sup> The classification of soft-tissue infections can be confusing, partly because individual organisms can cause different clinical

syndromes. Consequently, there are a wealth of terms often referring to the same diseases (e.g. Meleney's gangrene, haemolytic streptococcal gangrene and progressive bacterial synergistic gangrene).<sup>14</sup> Classification by the anatomical structure involved is more logical, but it has to be borne in mind that some conditions involve several soft-tissue levels and that some cases may evolve from a minor entity to a more severe form with more diffuse anatomical involvement (see Figure 63.1).

## IMPETIGO

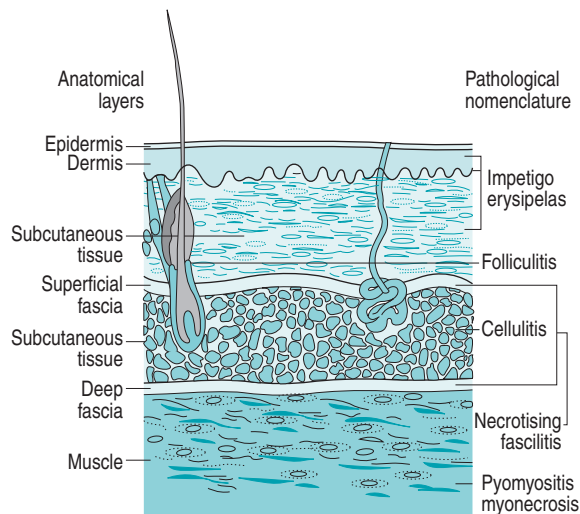

Impetigo,<sup>1–3</sup> more common in children, is a superficial skin infection caused by group A streptococci, *Staphylococcus aureus*, or both. Mild infections can be managed with topical antibiotics; more serious infections need a first-generation cephalosporin. A penicillinase-resistant penicillin is mostly chosen in severe empirical conditions (e.g. dicloxacillin).<sup>20</sup> Increasing resistance in streptococci and staphylococci might prohibit the use of erythromycin, which has been the alternative in the penicillin-allergic patient. For community-acquired MRSA, co-trimoxazole is an alternative.

## FOLLICULITIS

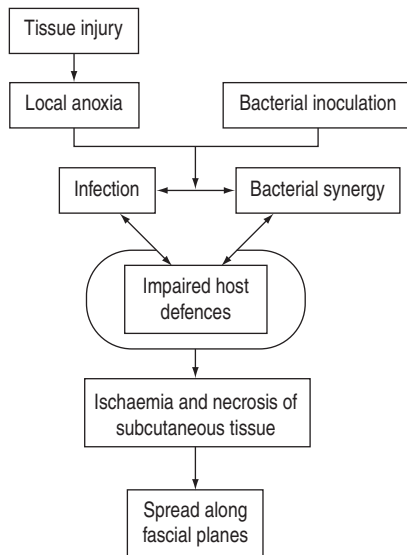

This is an infection arising in hair follicles and apocrine glands.<sup>2,3</sup> *S. aureus* is the usual causative organism. Topical antibiotic treatment is usually all that is required. When confluent, folliculitis can evolve to furunculosis and may need surgical drainage as sole effective therapy. If accompanied by cellulitis and/or sepsis, antibiotics are added (see section on cellulitis). Repeated folliculitis raises the possibility of chronic granulomatous disease, an inherited immunodeficiency syndrome based on granulocyte malfunction.<sup>21</sup> Affected individuals are at risk for severe soft-tissue infections, sometimes with rare pathogens such as *Aspergillus* spp.

## ERYSIPELAS

This superficial dermal infection is largely caused by group A streptococci and also by other streptococci and *Staphylococcus aureus*.<sup>1–3,8,9</sup> The prominent lymphatic blockade results in a painful bright red patch with a raised

**Figure 63.1** Anatomy of skin and nomenclature of skin and deep-tissue infections.

**Figure 63.2** Pathogenesis of severe soft-tissue infections.

sharp border, which clearly demarcates the infection from normal surrounding skin. Fever and chills often precede the skin eruption. Predisposing conditions include ulcers, venous stasis, diabetes, alcoholism and paraparesis. High-dose penicillin is still the drug of choice in the absence of underlying disease and the possibility to observe the evolution of the lesion. Severe infections in diabetic patients require a third-generation cephalosporin, piperacillin-tazobactam or a carbapenem. If mobilisation is premature, signs recur and treatment failure may falsely be suspected. However, recurrent erysipelas does occur with persistent lymphoedema.

## CELLULITIS

Cellulitis<sup>1,2,3,5-9,22</sup> is an acute spreading infection of the skin extending below the superficial fascia, usually involving only the upper part of the subcutaneous tissue. It can occur at any body site, but is most frequent in the lower extremities and in the face. There is less lymphatic involvement so the borders of the infection are often not well defined and differentiation between cellulitis and erysipelas is sometimes difficult. Fever, malaise and rigors are common. It is more common in patients with tissue oedema. Cellulitis is most commonly due to *Streptococcus pyogenes*, but other Gram-positive and negative organisms can also cause this condition according to location and exposure history.<sup>9</sup>

Typically, *S. pyogenes* cellulitis may appear hours after surgical intervention with fast progression of the erythematous zone over a large surface and can be accompanied by bacteraemia and sepsis. Many of these organisms may produce gas, hence crepitus is sometimes present (Table 63.1).

Other forms of cellulitis present with necrosis (gangrene) include anaerobic infections with *Clostridium* spp. or non-clostridial anaerobes sometimes mixed with Gram-negative pathogens that are facultative anaerobes. This latter condition may be hard to distinguish from deeper forms of infection such as necrotising fasciitis and myositis and may be crepitant. Immediate assessment by magnetic resonance imaging (MRI) and surgical exploration determines fascial and muscular involvement and allows for adequate debridement. Potent empirical therapy must include all possible pathogens because of the impossibility of deducing bacterial aetiology and depth from the initial clinical presentation. For antimicrobial therapy, see under necrotising fasciitis, below.

Periorbital cellulitis is a medical emergency. It needs immediate clinical and then radiological assessment to distinguish the periorbital from the more severe orbital cellulitis. Clinical signs for the latter include visual disturbance because of optical nerve involvement. Definite diagnosis can only be established by computed tomography (CT). External facial cellulitis may involve the venous system draining into the sinus venosus and, thus, lead to thrombosis. The aetiology includes a wider range of bacteria: *Streptococcus pneumoniae*, *Haemophilus influenzae*, *Moraxella catarrhalis*, *Staphylococcus aureus*, group A streptococci and anaerobes.

**Table 63.1** Infective causes of soft-tissue crepitus

Cellulitis	Usually anaerobic organisms, clostridial and non-clostridial
Bursitis	Gram-negative organisms
Necrotising fasciitis	Usually type I (mixed infections, Gram-negative organisms)
Myonecrosis	Clostridial organisms
Infected vascular gangrene	Any organism

A severe and fulminant form of cellulitis with hemorrhagic bullous lesions can be caused by marine bacteria of the *Vibrio* spp., mostly with a history of contact with sea-water or raw fish.<sup>23</sup> After fresh-water exposure of wounds<sup>24</sup> or application of medical leeches,<sup>25</sup> *Aeromonas hydrophilia* is a possible aetiology.

### TREATMENT

Appropriate microbiological tests are undertaken prior to starting antibiotics. Any skin abrasion or sites that drain are swabbed for Gram stain and culture. Needle aspiration, skin biopsy and blood cultures produce only a 25% positive yield.<sup>1</sup> Treatment involves site elevation and high-dose oxacillin or a first-generation cephalosporin. If there is a possibility of MRSA, vancomycin is indicated instead. In severe cases, the addition of clindamycin is beneficial because of its antitoxic effect and enhanced intracellular activity.<sup>26</sup> If Gram-negative rods are suspected or identified (e.g. an immunocompromised patient or involvement of intestinal tract lesions), a third-generation cephalosporin should be considered. In a patient with prolonged hospitalisation or in penetrating foot infections, a cephalosporin with anti-*Pseudomonas* activity is preferred. If *Vibrio* spp. are suspected or isolated, doxycycline may be added. In the absence of controlled studies, some authors recommend ceftazidime<sup>27,28</sup> in addition to tetracyclines because of the high mortality of 50%.<sup>23</sup>

Pyoderma gangrenosum has a similar appearance, but a completely different aetiology and therapeutic management. It is a rare idiopathic, inflammatory, ulcerative disease of undetermined cause that is more frequent in patients with ulcerative colitis and rheumatoid arthritis and presents as deep ulcers with undermined borders, usually on the lower extremities or abdomen. It is often triggered by surgical intervention and only secondarily colonised with skin flora. Treatment is conservative and includes steroid medication.<sup>29</sup>

### NECROTISING FASCIITIS

Necrotising fasciitis<sup>1,2,3,5-8,10-13,30-35</sup> is a deeper infection of the skin with extensive undermining of surrounding tissues. Interest in this fulminant infection has recently increased.<sup>14,30,36</sup> The World Health Organization reports only 160 cases since 1989, but the incidence in the USA is about 100 cases annually and recently there has been an increased incidence of group A streptococcal fasciitis in Europe.<sup>14,30</sup>

It usually occurs on the extremities, perineum and abdominal wall. Involvement of male genitalia is known as Fournier's gangrene.<sup>15</sup> Two types are described, depending on causative organisms.<sup>33</sup> Type I are mixed infections usually caused by Gram-positive and negative aerobe and anaerobe bacteria or *Vibrio* spp. Type II infections are caused by group A streptococci (occasionally

with *Staphylococcus aureus*). Secondary infections with zygomycetes may occur.<sup>32,34</sup> There is no difference in the clinical course, morbidity and mortality between the two types of infection.

### CLINICAL PRESENTATION

A history of minor trauma is common and necrotising fasciitis can complicate surgery and varicella infections.<sup>30,37</sup> Predisposing factors include cirrhosis, diabetes and other immunocompromised states. Necrotising fasciitis begins as an area of cellulitis that typically fails to improve on antibiotics and quickly spreads. Pathophysiological sequelae of sepsis result in microthrombi and impaired, leading to gangrene. Pain is a predominant feature and frequently out of keeping with other presenting symptoms and signs. Sometimes no external sign is apparent and increasing pain may even be the only initial symptom. Fever, rigors and shock are common.<sup>30</sup> Half of the cases of necrotising fasciitis present together with a streptococcal toxic-shock syndrome.<sup>20</sup> Manifestations of the systemic inflammatory response syndrome are evident and multiple-organ dysfunction develops in most cases. Bullae may form, and late lesions may resemble deep burns that are painfree because of the necrosis of nerve fibres. Reduced skin surface sensitivity and elevated creatine phosphokinase may suggest fascial involvement. Crepitus may be present (see Table 63.1). The normally adherent fascia may be easily peeled off the underlying muscle bed.

Retroperitoneal necrotising fasciitis is particularly vicious, with a high mortality due partly to the difficulty in diagnosis.<sup>38</sup> Abdominal or perineal trauma or sepsis is always the predisposing event. Diagnosis can only be made at laparotomy for the presenting acute abdomen. Broad-spectrum antibiotic therapy and aggressive surgery (repeated debridement of all necrotic tissue) with planned 'relook' laparotomies are strongly suggested.

Necrotising fasciitis concerning the face, eyelid or lip are rather of type II, whereas that of the neck is more often of type I and associated with a fourfold mortality compared to the facial form.<sup>39</sup>

### MANAGEMENT

Because of rapid progression, early diagnosis and treatment are crucial for the prognosis. Two major diagnostic tools are appropriate. We recommend that a highly experienced surgeon in the treatment of necrotising fasciitis be involved as early as possible with surgical incision, probing of fascial consistency and histological diagnosis on a frozen-section specimen of doubtful fascia intraoperatively.<sup>40</sup> The other mainstay of diagnosis is MRI. Recently, a score has been proposed to discriminate between necrotising and non-necrotising severe soft-tissue infections based on a set of six laboratory results.<sup>41</sup>

A complete microbiological investigation is of the utmost importance. This includes sampling for culture by needle aspiration of any crepitant area and blood cultures. Treatment with antibiotics alone is usually inadequate. Immediate extensive surgical removal of necrotic and damaged tissues is essential.<sup>11,12,30–32,34</sup> Planned surgery at 24-hour intervals to debride spreading necrotic tissue is necessary until the necrotic process stops. If extremities are involved, amputation may be life-saving.

Initial antibiotic therapy includes a carbapenem or a third-generation cephalosporin plus clindamycin while awaiting Gram stain and culture results. Clindamycin 600 mg intravenously 6-hourly is added because of toxin inhibition and anaerobic activity.<sup>26</sup> If fungi (e.g. mucormycosis) are isolated, amphotericin B 0.5 mg/kg per day intravenously should be given for at least 2 weeks.<sup>32,34</sup> As in cellulitis, *Vibrio* spp. are treated with both a third-generation cephalosporin and tetracycline.<sup>27</sup>

Supportive care, especially organ support, is also fundamental treatment, and is discussed in other chapters. Hyperbaric oxygen therapy has no proven benefit and is likely to delay surgical intervention. Mortality from necrotising fasciitis is high, and survival appears improved when surgery is undertaken early.

### PYOMYOSITIS AND MYONECROSIS

Muscles are remarkably resistant to infection so bacterial infections are rare. Pyomyositis is a focal infection usually caused by *Staphylococcus aureus*. Myonecrosis is caused by *Clostridium* spp. or various other bacteria when it evolves from cellulitis.<sup>1,2,4–7,11,12,31,32,35,42–44</sup> Bacteria might act synergistically and often produce various toxins (Figure 63.2).<sup>4,32</sup> As infection is likely to be mixed, differentiation of pyomyositis and myonecrosis is bacteriological, and only important for antibiotic choices.

### PYOMYOSITIS

Pyomyositis is more common in the tropics. The causative organism in over 90% of cases is *S. aureus*, with others being *Streptococcus pyogenes*, *Escherichia coli* and *S. pneumoniae*. Pyomyositis often follows blunt trauma to torso, thigh or buttock muscles. Spontaneous staphylococcal muscle abscesses may occasionally occur.<sup>2</sup> Initial presentation is with aching muscles which feel indurated on examination. If untreated, the muscles become erythematous and boggy and are eventually destroyed. Spontaneous drainage of debris and pus does not occur. Instead, there is contiguous spread to surrounding tissues and metastatic spread to the chest (e.g. empyemas) and heart (e.g. endocarditis and pericarditis).

Investigations include needle biopsy (for Gram stain of the aspirate), ultrasound (for localised muscle oedema) and, more recently, MRI.<sup>2</sup> Large increases in serum creatine phosphokinase may be indicative of the degree of muscle involvement.<sup>44</sup> Antibiotic therapy with a penicillinase-resistant penicillin or a first-generation

cephalosporin may be successful in the early stages. More often, though, the condition is not recognised early because of diagnostic difficulties and extensive surgical drainage becomes necessary for a favourable outcome.<sup>44</sup> Even after disfiguring muscle destruction, functional prognosis is good.

### MYONECROSIS

The bacterial infection of muscles by clostridial organisms (usually *Clostridium perfringens* or *C. septicum*) has been called gas gangrene as crepitus may occur. However, other causes of skin crepitus are just as common (see Table 63.1). Predisposing causes are contaminated wounds (e.g. in trauma and septic abortions) and surgery in immunocompromised patients.

Onset is often abrupt, with involved areas being very painful and swollen. The patient presents with signs of severe sepsis. If a wound is present, there is usually a profuse serosanguineous discharge of sweet odour. Later, the skin becomes red, yellow, green or black. Bullae and crepitus may form.

A Gram stain revealing Gram-positive rods of *Clostridium* is diagnostic. Treatment of myonecrosis involves prompt, extensive surgical debridement of all infected tissue and antibiotics (i.e. high-dose penicillin plus clindamycin).<sup>2</sup> At surgery, the muscle is pale or brick-coloured and does not bleed. Hyperbaric oxygen has its proponents<sup>45,46</sup> and may be beneficial in conjunction with good supportive care. However, there is no prospective evidence to support the use of hyperbaric oxygen.<sup>47</sup>

## SPECIAL AREAS OF SOFT-TISSUE INFECTION

### NECK INFECTIONS

Since the advent of antibiotics, oropharyngeal infections are no longer major causes of neck infections.<sup>48–50</sup> Dental infection and regional trauma are now more common causes. Neck infections include Ludwig's angina, retropharyngeal abscesses, parapharyngeal abscesses and necrotising cervical fasciitis. Ludwig's angina is a submandibular-space infection. There is deep and tender swelling of the submandibular and submaxillary area, with swelling of the floor of the mouth and elevation of the tongue.

Causative organisms are the usual mouth commensals, Gram-negative rods and *Staphylococcus aureus*. Pain and odynophagia are almost always the presenting symptoms. Local swelling is usually present. Trismus and dental pathology are common. Systemic inflammatory signs occur in about two-thirds of patients.

Neck X-rays usually demonstrate some abnormality. CT or MRI will define anatomy and may help to decide on a course of conservative, expectant therapy.<sup>50</sup> Oesophagoscopy should be performed on all retropharyngeal abscesses, as foreign-body ingestion is a possible predisposing event.

**Table 63.2** Pathogens and presumptive antibiotic therapy in severe soft-tissue infections\*

Disease	Suspected pathogens	Initial antibiotic choice*	Remarks†
Impetigo	<i>Staphylococcus aureus</i> , group A streptococci	First-generation cephalosporin, clindamycin, oral amoxicillin/clavulanate, dicloxacillin	Check for local resistance of streptococci against clindamycin
Folliculitis	<i>Staphylococcus aureus</i> , <i>Candida</i> spp., <i>Pseudomonas aeruginosa</i> , <i>Pityrosporum ovale</i>		Local therapy usually sufficient, antibiotic treatment only with cellulitis (see cellulitis). Surgical drainage if large and fluctuant
Erysipelas	Group A streptococci (occasionally, group B, C, G or <i>Staphylococcus aureus</i> )	Penicillin G or amoxicillin still drugs of choice (if no underlying disease and possible to observe), first-generation cephalosporin	Severe infections in diabetic patients: third-generation cephalosporin, piperacillin/tazobactam or carbapenem
Cellulitis	Group A streptococci, <i>Staphylococcus aureus</i> ; rarely, various other organisms	Oxacillin, first-generation cephalosporin, clindamycin (for severe penicillin allergy)	Resistance in <i>Streptococcus pyogenes</i> and <i>Staphylococcus aureus</i> against clindamycin exists. Vancomycin in case of high likelihood of MRSA
Necrotising fasciitis	Type I: anaerobic species ( <i>Bacteroides</i> , <i>Peptostreptococcus</i> spp.), together with facultative anaerobes, non-A streptococci, Enterobacteriaceae ( <i>Escherichia coli</i> , <i>Enterobacter</i> , <i>Klebsiella</i> , etc.) Type II: group A streptococci alone or with <i>Staphylococcus aureus</i>	Carbapenem if polymicrobial, high-dose penicilline plus clindamycin if <i>Streptococcus</i> or <i>Clostridium</i> , vancomycin if MRSA	Surgical debridement absolutely essential. Empirical therapy must cover for all pathogens. Add vancomycin if MRSA likely
Pyomyositis	<i>Staphylococcus aureus</i> , group A streptococci (rarely), Gram-negative bacilli (very rarely), anaerobic bacteria other than <i>Clostridium</i>	Oxacillin, or first-generation cephalosporin	Surgical drainage essential
Myonecrosis	<i>Clostridium perfringens</i> , other clostridia	High-dose penicillin plus clindamycin	Surgical exploration and debridement crucial with open wound healing; hyperbaric oxygen debated. If extending from cellulitis/necrotising fasciitis, see those sections

MRSA, methicillin-resistant *Staphylococcus aureus*.

\*Once causative pathogen(s) has(ve) been identified, antibiotic choice can be modified and spectrum narrowed.

†Be aware of local endemicity of community- or hospital-acquired MRSA. Co-trimoxazole is a good choice in most community-acquired low-grade infections; for all other cases use vancomycin.

Airway control must take top priority in any neck swelling. Antibiotics, in doses similar to necrotising fasciitis, should incorporate cover for Gram-positive cocci and Gram-negative rods. Penicillin or clindamycin plus gentamicin, or a third-generation cephalosporin plus metronidazole, are suitable. Some abscesses may be treated conservatively, especially those in children.<sup>50</sup> However, early surgical drainage remains the mainstay of management for large neck abscesses that impinge on airway

patency, or deep infections that pursue a fulminant course.

Retrotonsillar abscess may evolve to Lemierre's syndrome, an infection with anaerobic bacteria, mostly *Fusobacterium necrophorum*, that gain access to the jugular vein and lead to metastatic infections in the liver, lung and brain. Because of possible involvement of anaerobes that produce beta-lactamase, a beta-lactamase-resisting beta-lactam antibiotic should be used.<sup>51</sup>

# Principles of antibiotic use

Jeffrey Lipman

The intensive care unit (ICU) is always the area of any hospital associated with the greatest use of antibiotics. Much of this high usage is unavoidable, but the clinician working in the ICU must realise that there is an essential consequence of this use. Antibiotic use which should eliminate susceptible organisms promotes (over)growth of other, non-susceptible organisms, especially fungi. As far as bacteria are concerned, antibiotics confer enormous selective advantage to resistant strains, and therefore these strains will congregate where their advantage is greatest, in the ICU. Resistance (and fungal overgrowth) is a direct consequence of usage, and every course of inappropriate antibiotics should be avoided to help reduce the burden of resistance.

Antibiotic stewardship<sup>1</sup> has been suggested as a new strategy to help limit resistance. This involves selecting an appropriate drug and optimising its dose and duration to cure an infection while minimising toxicity and conditions for selection of resistant bacterial strains. Inadequate doses of even the 'correct' antibiotic may lead to survival of initially susceptible organisms.<sup>2,3</sup> For the optimal use of antibiotics not only should antibiotic pharmacokinetics be understood, but there should be clear and rational principles on which each specific antibiotic prescription in the ICU is based. Also, it is probably better to have portions of the ICU population receive different classes of antibiotics at the same time.

Although this chapter will provide basic principles for most of the antibiotic classes commonly used in the ICU, some important antimicrobial agents will not be specifically addressed here, namely macrolides, clindamycin and the antifungal agents.

## GENERAL PRINCIPLES<sup>4-8</sup>

1. All appropriate microbiological specimens, including blood cultures, should be obtained before commencing antibiotic therapy. An immediate Gram-stained report may indicate the appropriate antibiotic to use; otherwise a 'best-guess' choice is made, which is dependent on the clinical situation. This important and common clinical phenomenon involves trying to predict the infecting organism(s).
2. Blood cultures should be taken from a venepuncture site, after adequate skin antisepsis, and not from an intravenous or arterial catheter. Two separate sets of 20 ml (for adults) should be taken, the timing of which is less important.<sup>9</sup> Depending on what system is used, probably 10 ml should be placed into two different blood culture bottles.
3. Once a decision is made to administer antibiotics, they should be administered **without delay**.
4. The decision for empiric therapy, i.e. cover for the most 'likely' organisms causing any specific infection, must include various factors such as the site of the infecting organism (respiratory tract pathogens differ from those of abdominal infections), community versus hospital-associated infection; recent previous antibiotic prescription; ward versus ICU-acquired infection and knowledge of the organisms commonly grown in patients in any specific area. This latter point is where ward/unit surveillance becomes important.<sup>10,11</sup>
5. Whilst there should be an attempt to use a narrow-spectrum antibiotic whenever practicable, appropriate therapy, particularly for empirical choice for nosocomial sepsis, mandates initial broad-spectrum antibiotics, even a combination, until culture results are back,<sup>12</sup> at which time de-escalation should be embarked upon (see below). Inappropriate and/or delayed correct antibiotic use in the ICU has been shown to have an impact on morbidity and mortality<sup>12,13</sup> (Table 64.1).
6. Monotherapy with a single agent effective against the expected organisms aims to decrease the risk of drug antagonism, reaction or toxicity.<sup>14,15</sup> Monotherapy often costs less than multiple antibiotic usage.
7. The clinical response to treatment already given should always be considered, when bacteriological results suggest a change in antibiotics.
8. A standard 2-week course of antibiotics is unnecessary and probably harmful. There is a move to use shorter courses for pneumonia<sup>16,17</sup> (see Table 64.1).
9. In consultation with infectious disease specialists, additional tests such as antibiotic minimum inhibitory concentration (MIC), antibiotic assay, serum bactericidal activity and synergy tests of antibiotic combinations may be useful in serious infections (e.g. endocarditis and infections in immunocompromised

**Table 64.1** New paradigm of treatment for nosocomial sepsis

Old	New
Start with penicillin	Get it right first time (broad-spectrum)
Cost-efficient low dose	Hit hard up front
Low doses = fewer side-effects	Low dose → resistance
Long courses ≥ 2 weeks	Seldom longer than 7 days

patients). Sensitivity tests should be interpreted carefully. In vitro sensitivity does not equate with clinical effectiveness; in vitro resistance generally predicts clinical ineffectiveness.

- Consultations with the laboratory staff and infectious diseases/clinical microbiology specialists are always useful and should be mandatory in serious infections (e.g. meningococcal sepsis, meticillin-resistant staphylococci and multiresistant Enterobacteriaceae).
- The pharmacokinetics and pharmacodynamics (e.g. penetration into relevant tissues) as well as the spectrum of activity of the antibiotic must be considered. Antibiotic pharmacokinetic principles should determine the dosage and frequency of antibiotic regimens (see below).
- Adequate drug doses should be given. The intravenous route is preferable in critically ill patients, but other routes should be considered when appropriate (e.g. rectal metronidazole<sup>18</sup>).
- Serum levels of potentially toxic antibiotics should be monitored, especially if hepatic or renal dysfunction is present.
- Prophylactic use of antibiotics should be limited to certain situations, should cover organisms that can potentially cause infections in that specific group of patients (e.g. organisms causing skin and soft-tissue infections differ from those implicated in intra-abdominal infections) and should be given at the appropriate timing (see below).
- General signs of infection are signs of systemic inflammation. Although bacterial infection is likely, non-bacterial infection and non-infective causes should also be considered. High procalcitonin and C-reactive protein levels may be discriminatory for infection,<sup>19</sup> as are interleukin-6 levels, although these are difficult to measure.
- Antibiotic guidelines are only one aspect of infection control.<sup>20</sup> Hand-washing and hand hygiene in

general are vital and fundamental aspects of infection control.<sup>20</sup> Identification and elimination of reservoirs of infection, blocking transmission of infection, barrier nursing, interrupting progression from colonisation to infection and eliminating risk factors such as invasive devices are also important.

### COMMON ERRORS WHEN USING ANTIBIOTICS

- Administration of antibiotics before microbiological specimens are obtained.
- Inadequate quantity and poor quality of blood cultures.
- Extended use of antibiotics after eradication of infection (e.g. a 2-week course for ventilation associated pneumonia<sup>16</sup>).
- Antibiotic 'surfing' (i.e. switch from one combination to another) when patient is not improving without delving into the cause of persistent inflammatory response.
- Inadequate and delayed therapy and/or incorrect dosing of antibiotics.
- Failure to predict adequately 'resident' microbial flora and therefore inability to choose correctly empiric antibiotics for nosocomial infections, i.e. no adequate surveillance data.
- Failure to recognise toxic effects of antibiotics, particularly when polypharmacy is used.
- Use of combination therapy, irrespective of infection.

### SPECIFIC ISSUES

#### PHARMACOKINETIC PRINCIPLES

The goal of antimicrobial prescription is to achieve effective active drug concentrations (a combination of dose and duration) at the site of infection whilst avoiding, or at least minimising, toxicity.

The various antibiotic classes have different 'kill characteristics' and therefore should be dosed differently<sup>21</sup> (Table 64.2).

#### **β-LACTAMS (ALL PENICILLINS AND CEPHALOSPORINS, MONOBACTAMS)<sup>22,23</sup>**

- Studies of β-lactam antibiotics on Gram-negative bacilli show a bactericidal activity that is relatively slow, time-dependent and maximal at relatively low

**Table 64.2** Pharmacodynamic properties of selected antibiotics

Antibiotics	Aminoglycosides	Fluoroquinolones	β-lactams Carbapenems Glycopeptides?
PD kill characteristics	Concentration-dependent	Concentration-dependent with time dependence	Time-dependent
Optimal PK parameter	$C_{max}$ :MIC	AUC:MIC	$T > MIC$

PD, pharmacodynamic; PK, pharmacokinetic;  $C_{max}$ , peak serum concentration; MIC, minimum inhibitory concentration; AUC, area under concentration–time curve;  $T > MIC$ , time above MIC.

concentrations. Bacterial killing is almost entirely related to the time that levels in tissue and plasma exceed a certain threshold. The maximum time plasma  $\beta$ -lactams levels should be allowed to fall below MIC is 40% of the dosing interval.

- $\beta$ -lactam antibiotics lack a significant postantibiotic effect (PAE), particularly against Gram-negative organisms, and it is not necessary to achieve very high peak plasma concentrations. PAE is the continued suppression of bacterial growth despite zero serum concentration of antibiotic. It is suggested that concentrations of any  $\beta$ -lactam should be maintained at about 4–5 times MIC for long periods, as maximum killing of bacteria in vitro occurs at this level. If antibiotic concentrations fall below this threshold in the in vitro models, bacterial growth is immediately resumed.
- Thus, it is important for the efficacy of  $\beta$ -lactams that the dosing regime maintains adequate plasma levels for as long as possible during the dosing interval. It is not surprising, then, that dosing regimes of  $\beta$ -lactam antibiotics are being re-evaluated to keep plasma levels above certain thresholds of MICs of Gram-negative organisms for longer periods of the dosing interval.<sup>24,25</sup>

#### CARBAPENEMS

- Similarly to  $\beta$ -lactams, the carbapenems also have time-dependent kill characteristics but have some PAE.
- Prolonged infusions (over 3 hours) have been utilised to improve time above MIC.<sup>25,26</sup>
- In vitro data suggest low concentrations may predispose to development of resistant organisms.<sup>2</sup>

#### AMINOGLYCOSIDES (THE BEST PHARMACOKINETICALLY STUDIED OF THE ANTIBIOTIC CLASSES)<sup>22,23</sup>

- The above contrasts with the kill characteristic of the aminoglycosides, which is concentration-dependent. Experimentally, a high peak concentration of an aminoglycoside antibiotic provides a better, faster killing effect on standard bacterial inocula.
- All aminoglycosides exhibit a significant PAE. The duration of this effect is variable, but the higher the previous peak, the longer the PAE. This phenomenon allows drug concentration to fall significantly below MIC of the pathogen without allowing regrowth of bacteria and hence not compromising antibacterial efficacy. The phenomenon of PAE is much more prevalent in aminoglycosides than other antibiotics and more pronounced with Gram-negative bacilli than with other bacteria.
- These principles allow for single daily doses of aminoglycosides (also termed extended interval dosing). Combining various meta-analyses involving thousands of patients, once-daily administration was found to be more efficacious, with reduced toxicity, higher peak/MIC ratios, further prolonged PAE and reduced administration costs.

- With renal dysfunction<sup>27</sup> the dose should be altered according to creatinine clearance. If  $\geq 60$  ml/min, give 5–7 mg/kg daily; if 59–40 ml/min, the same dose at an interval of 36 hours; 39–20 ml/min, increase the dosing interval to 48 hours.

#### QUINOLONES<sup>22,23</sup>

- In contrast ciprofloxacin has a combination of both the above (concentration-dependent and time-dependent effects) as well as some PAE.
- Although one suggested ‘target’ parameter for a good clinical bactericidal effect is a high peak, the most validated parameter is the area under the inhibitor curve (AUC), i.e. AUC/MIC: values  $>125$  translate into better clinical cures.
- There is general concern about the emergence of resistance related to inappropriately low doses of ciprofloxacin<sup>3</sup> (see Table 64.1).

#### GLYCOPEPTIDES<sup>22,23</sup>

- Vancomycin induces a PAE and a postantibiotic sub-MIC effect. These combined effects suggest that bacterial regrowth will not occur for prolonged periods following a fall in drug concentrations to levels below the MIC.
- Continuous infusions of vancomycin may have some advantages.

Aminoglycosides and glycopeptides distribute well into fluids of the extravascular, extracellular space, and less well into tissues. This has two important implications. Firstly these agents should not be first-line agents for, nor monotherapy for, solid-organ infections (lung, kidney, liver). Secondly, in situations where extravascular fluid shifts are significant, such as in situations of ‘third-space losses’ of abdominal sepsis and in severe burns, the volume of distribution of these drugs is significantly affected. Hence for any serum level required a larger dose may have to be administered. The volume of distribution of the quinolones (very large) suggests that penetration is excellent into most tissues and hence these drugs are good for solid-organ infections. Similarly  $\beta$ -lactams as a group (including carbapenems) all have reasonable tissue penetration.

#### ANTIBIOTIC PROPHYLAXIS<sup>4,6,7,28</sup>

The main indications for prophylaxis are:

- When surgery involves incision through an area of colonisation or normal commensal flora and a resultant potential infection has morbidity or mortality.
- When a procedure (e.g. catheterisation, instrumentation, intubation, dental work) potentially produces a bacteraemia in the presence of an immunocompromised patient or when the potential bacteraemia occurs in the presence of an abnormal heart valve or a prosthesis.

Basic principles of choice of prophylactic regimen should include:

1. The organisms colonising the area through which the incision is made should be covered (Gram-positives if skin is breached, Gram-negatives and anaerobes if bowel is opened).
2. A similar case should be made for colonising organisms through the area breached by catheterisation or instrumentation (Gram-negatives for bladder catheterisation, Gram-positives and anaerobes for dental procedures).
3. If prevalence of a resistant organism in a specific area is high (e.g. methicillin-resistant *Staphylococcus aureus* (MRSA) in burns units), then those organisms should be covered by the prophylactic regimen.

#### TIMING AND DURATION OF PROPHYLAXIS

1. Optimal blood levels of antibiotic(s) are needed when the occurrence of the potential bacteraemia occurs, i.e. for surgery, optimal timing of the antibiotic should be at, or just prior to, induction of anaesthesia and skin incision.<sup>28</sup>
2. For prolonged procedures where bacteraemias are still a potential occurrence a second dose of antibiotic(s) may be considered.
3. There is no extra benefit of postoperative antibiotic prophylaxis.

#### DOSES

Comments on dosing regimens are provided below. Doses suggested below are intravenous, for a 70-kg adult with *normal* renal function. All these drugs accumulate with renal dysfunction and modified doses should be used accordingly.

1. Doses for  $\beta$ -lactams vary with each different drug *but* recent emphasis supports lower boluses with more frequent administration, i.e. 4-hourly versus 8-hourly or bd versus daily. Continuous infusions may become the standard of practice.<sup>25</sup>
2. Aminoglycosides: tobramycin and gentamicin 7 mg/kg as a loading dose on the first day, followed by 5 mg/kg per day. Amikacin 20 mg/kg as the loading dose followed by 15 mg/kg per day. These doses are the same for adults and children, neonates excluded.
3. Quinolones: ciprofloxacin *at least* 400 mg bd (up to tds).
4. Glycopeptide: vancomycin at least 2 g/day either as continuous infusion or in divided doses (40 mg/kg per day for children).
5. Carbapenems: meropenem or imipenem: 3 g/day in at least three divided doses.

#### SURVEILLANCE

Some type of simple laboratory-oriented surveillance which primarily collects data and resistance patterns of microbiological isolates is important. There are a few

international projects,<sup>11</sup> but each unit should have access to its own such data as there is increasing prevalence of resistant organisms in ICUs. This is complicated even further by different units having differing resistance patterns.<sup>10</sup> Empiric antibiotic therapy must take these factors into account. Some form of surveillance that provides units with their own microbiological data, updatable quarterly or biannually, is therefore beneficial in helping choose empiric and prophylactic regimens that are applicable to any specific unit.<sup>10</sup>

#### MULTIRESISTANT ORGANISMS

Although this chapter is on antibiotics, the point must be made that without good, efficient and effective infection control policies in all areas treating critically ill patients, the spread of multiresistant organisms would be rampant and the control thereof useless.<sup>20</sup> Part of these policies should involve attention to good hand hygiene and the use of antiseptic soaps and alcohol-based hand rubs.<sup>20</sup> Hands are still the most documented and incriminated mode of transmission of infection. In this regard a decrement in nursing numbers has also been incriminated in outbreaks of infections, possibly due to the time it takes to wash adequately between procedures.<sup>20</sup>

1. Multiresistant streptococci and vancomycin-resistant enterococci (VRE), although not common in all countries, are an increasing worldwide problem, as is community-acquired MRSA.
2. The prevalence of MRSA is wider, with many ICUs having this organism almost endemic. Community-acquired MRSA is becoming a huge problem, largely because of identification and initial treatment.<sup>29</sup> It differs from the hospital-associated strain in that it is far less multidrug-resistant, but nevertheless it is oxacillin-resistant.
3. New agents are available for treatment of resistant Gram-positive infections.<sup>30</sup>
4. Antibiotic resistance is agent-specific. Often resistance is claimed to be against third-generation cephalosporins, but this is largely to ceftazidime (particularly the extended-spectrum beta-lactamases of *Klebsiella pneumoniae*, *Escherichia coli* and some Enterobacteriaceae).
5. Worrying Gram-negative organisms are *Klebsiella pneumoniae*, *Pseudomonas aeruginosa*, *Acinetobacter baumannii* spp. and *Stenotrophomonas maltophilia* (the latter specifically, for which trimethoprim may need to be used). A common feature of these organisms is intrinsic resistance to multiple antibiotics. *P. aeruginosa* and *Acinetobacter* complex (also named *A. baumannii*) have become particular problems. Sulbactam and polymixin B or colistin have been used for these problem organisms.<sup>31</sup>
6. Since the carbapenems there are no new agents for multiresistant Gram-negative organisms,<sup>1</sup> although tigecycline has recently been launched.

### MONOTHERAPY VERSUS COMBINATION THERAPY<sup>14,15</sup>

1. Much of the work in this area was performed before the clinical introduction of the carbapenems, penicillin/betalactamase combinations and fourth-generation cephalosporins. It seems that newer single agents are adequate apart possibly for resistant pseudomonal infections.<sup>12</sup>
2. There is no clear evidence supporting the claim that combination antimicrobial therapy prevents emergence of resistance.<sup>14</sup>
3. However combination therapy is often suggested for endocarditis and some pseudomonal infections.<sup>12</sup> When combination therapy is used, preference should be given to the combination therapy of two different classes of antibiotics and then classes that act synergistically. The combination of two  $\beta$ -lactam antibiotics should not be used.

### BROAD-SPECTRUM INITIAL COVER WITH DE-ESCALATION<sup>32</sup> (SEE TABLE 64.1)

In view of the morbidity and mortality of delayed appropriate therapy for nosocomial sepsis,<sup>12,13,32</sup> particularly pneumonias, patients with risk factors for infection with resistant pathogens should initially receive broad-spectrum antibiotics, possibly even combination therapy,<sup>12,32</sup> and, as soon as the pathogen and the susceptibilities are available, treatment should be simplified to a more targeted one – so-called ‘de-escalation’ therapy.<sup>32</sup> In the limited studies to date, de-escalation has led to less antibiotic usage, shorter durations of therapy, fewer episodes of secondary pneumonia and reduced mortality, without increasing the frequency of antibiotic resistance.

### TIME TO ANTIBIOTICS AS A QUALITY INDICATOR

Recent data suggests that a delay of even hours of appropriate antibiotic administration increases morbidity and mortality.<sup>33</sup> A delay in antibiotic administration has therefore become an important negative factor in patient outcomes. Similar to the concept of “time to lysis”, antibiotic administration from the time of recognition of infection may in future become a quality indicator of infection management.

# Tropical diseases

Ramachandran Sivakumar and Michael E Pelly

Once an exotic and esoteric topic, modern travel and the quest for unusual holidays has the potential to bring tropical diseases to every ICU. This chapter covers some important diseases, which are common in the tropical belt.

## MALARIA

### EPIDEMIOLOGY AND PATHOGENESIS

It is estimated that four species of *Plasmodium* (*vivax*, *malariae*, *ovale* and *falciparum*) cause 300–500 million infections per year. Most of the 1–3 million deaths per year due to malaria are caused by *Plasmodium falciparum* and the majority of deaths are in children under 5 years in sub-Saharan Africa. Malaria is also widely prevalent in the Indian subcontinent and South-East Asia. It is transmitted from human to human by the bite of infected female *Anopheles* mosquitoes. After development in the liver, there is invasion of red cells by parasites, which is followed by their multiplication, and rupture of the red cells. The cycle is then repeated in red cells. In *vivax* and *ovale* infections, development to dormant forms can occur in the liver, which may lead to relapse.

### CLINICAL FEATURES

#### UNCOMPLICATED MALARIA

Initial symptoms of malaria are non-specific and similar to a viral illness. Classic symptoms of fever, aches, and headache are usually, but not always, present. Other features such as diarrhoea, vomiting, cough, and abdominal pain, may confuse the unwary. Unusual presentations are more common in children and may be missed. Classical rigors or fevers occurring on specific days (tertian or quartan) are usually absent in early falciparum infection. Clinical signs may be unhelpful although hepatosplenomegaly may be present fairly early.

#### SEVERE MALARIA

##### Risk factors for severe malaria

- Children under 5 years in endemic regions
- Adults and children in areas of low endemicity
- Non-immune travellers to endemic areas

#### Definition

The diagnosis of severe malaria requires the presence of one or more of the following with no other confirmed cause occurring in a patient with asexual *Plasmodium falciparum* parasitaemia:<sup>1</sup>

- impaired conscious state
- multiple convulsions
- respiratory distress
- pulmonary oedema
- circulatory collapse
- abnormal bleeding
- jaundice
- haemoglobinuria
- severe anaemia

The incubation period is at least 7 days. The usual range is 9–14 days but this may be longer. Anaemia, jaundice, renal dysfunction, haemostatic abnormalities, thrombocytopenia, pulmonary oedema, shock, hypoglycaemia, and severe metabolic acidosis are common in severe malaria. Several of the above coexist or may develop in rapid succession. Cough, convulsions, and hypoglycaemia are more common in children. Jaundice is common, but hepatic failure is uncommon. The acidosis of malaria is multifactorial and probably very similar to other forms of sepsis involving tissue hypoxia, liver dysfunction, and impaired renal handling of bicarbonate.

The differential diagnosis of malaria includes:

- meningitis, typhoid fever, septicaemia
- severe influenza, dengue and other arboviral infections
- haemorrhagic fevers
- hepatitis, leptospirosis
- rickettsial diseases, e.g. scrub typhus
- relapsing fever (*Borrelia recurrentis*)
- febrile convulsions in children

Pregnancy increases the risk of development of severe malaria. During pregnancy both maternal and fetal morbidity and mortality are increased.

Poor prognostic indicators include age under 3 years, cerebral malaria, circulatory collapse and organ dysfunction. Laboratory evidence of poor prognosis includes hyperparasitaemia (> 250 000/μl or > 5%), peripheral schizontaemia, severe anaemia (PCV < 15% or Hb < 50 g/l), raised

blood urea > 60 mg/dl and serum creatinine > 265 µmol/l (> 3.0 mg/dl), raised venous lactate (> 5 mmol/l), raised CSF lactate (> 6 mmol/l), low CSF glucose and a very high concentration of TNF-α.

### Cerebral malaria

Cerebral malaria may be the most common non-traumatic encephalopathy worldwide. The term is restricted to the syndrome in which altered consciousness due to malaria could not be attributed to convulsions, sedatives, hypoglycaemia or to a non-malarial cause. It is distinguished from the postictal state if unconsciousness persists for more than 30 minutes after a convulsion.

Clinical, histopathological and laboratory studies have suggested two potential mechanisms:

- mechanical hypothesis – cytoadherence of parasitised erythrocytes
- cytotoxic hypothesis – neuronal injury by malarial toxin and excessive cytokine production.

Cerebral malaria has few specific features, but there are differences in clinical presentation between African children and non-immune adults.<sup>2</sup>

Clinical findings include:

- coma
- convulsions
- raised intracranial pressure
- hypoglycaemia
- acidosis
- abnormalities of tone and posture (the commonest being symmetrical pyramidal signs)
- retinopathy – retinal haemorrhages, cotton wool spots, papilloedema, retinal whitening and retinal vessel abnormalities, all of which are more common in children.

### DIAGNOSIS

Microscopy of thick and thin films remains the gold standard for both the diagnosis and to follow the efficacy of treatment. In the non-immune patient there is a close association between parasite levels and complications; however, severe complications can occur in patients with low counts.

Rapid diagnostic tests (RDTs) which detect specific antigens (proteins) produced by malaria parasites are useful in diagnosis. Current tests are based on the detection of histidine-rich protein 2 (HRP2) (which is specific for *P. falciparum*), pan-specific or species-specific parasite lactate dehydrogenase (pLDH), or other pan-specific antigens such as aldolase. Many commercial assays are available. Some tests detect only one species (*P. falciparum*), while others detect one or more of the other three species. RDTs do not give information about the parasite load and their sensitivity and specificity decrease at low parasitaemia. Hence, it is important to seek microbiological advice regarding the RDTs used locally.

Polymerase chain reaction (PCR) tests based on detecting malarial DNA are more sensitive than microscopy but are expensive and do not give estimates of parasite load.

### TREATMENT OF MALARIA<sup>3</sup>

WHO has recently issued new guidelines for the treatment of malaria.

#### FALCIPARUM MALARIA (TABLE 65.1)

To counter the threat of resistance of *P. falciparum* to monotherapies, and to improve treatment outcome, combinations of antimalarials are now recommended by WHO for the treatment of falciparum malaria. Antimalarial combination therapy is the simultaneous use of two or more blood schizontocidal drugs with independent modes of action. Artemisin-based combination therapy (ACT) is the recommended treatment for uncomplicated falciparum malaria.

One of the following ACTs is currently recommended: artesunate + amodiaquine, artesunate + sulfadoxine-pyrimethamine, artesunate + mefloquine, or artemether-lumefantrine. The choice of ACT in a country or region will be based on the level of resistance of the partner medicine in the combination.

#### Severe falciparum malaria (Table 65.2)

Two classes of drug are currently available for the parenteral treatment of severe malaria: the cinchona alkaloids (quinine and quinidine) and the artemisinin derivatives (artesunate, artemether and artemotil). Recent evidence<sup>4,5</sup> suggests superior efficacy of artesunate over quinine in adults. The dosage of artemisinin derivatives does not need adjustment in vital organ dysfunction.

Following initial parenteral treatment, once the patient can tolerate it, current practice is to switch to oral therapy and complete a full 7 days of treatment. In non-pregnant

**Table 65.1** WHO recommendations for treatment of uncomplicated *P. falciparum* malaria

#### Artesunate + amodiaquine

4 mg/kg of artesunate and 10 mg base/kg of amodiaquine given once a day for 3 days

#### Artesunate + sulfadoxine-pyrimethamine

4 mg/kg of artesunate given once a day for 3 days and a single administration of sulfadoxine-pyrimethamine (25/1.25 mg base/kg body weight) on day 1

#### Artesunate + mefloquine

4 mg/kg of artesunate given once a day for 3 days and 25 mg base/kg of mefloquine, usually split over 2 or 3 days

#### Artemether-lumefantrine

Are available as co-formulated tablets containing 20 mg of artemether and 120 mg of lumefantrine. The recommended treatment for persons weighing more than 34 kg is 4 tablets twice a day for 3 days

**Table 65.2** WHO recommendations for treatment of severe *P. falciparum* malaria**Artesunate**

2.4 mg/kg i.v. or i.m. given on admission (time = 0), then at 12 hours and 24 hours, then once a day is recommended in low transmission areas or outside malaria endemic areas. If artesunate is not available, quinine i.v. should be used.

For children in high transmission areas, one of the following antimalarial medicines is recommended as there is insufficient evidence to recommend any of these antimalarial medicines over another for severe malaria:

- artesunate 2.4 mg/kg i.v. or i.m. given on admission (time = 0), then at 12 hours and 24 hours, then once a day
- artemether 3.2 mg/kg i.m. given on admission then 1.6 mg/kg body weight per day
- quinine 20 mg salt/kg on admission (i.v. infusion or divided i.m. injection), then 10 mg/kg every 8 hours; infusion rate should not exceed 5 mg salt/kg per hour

adults, doxycycline (3.5 mg/kg per day) is added to quinine, artesunate or artemether and should also be given for 7 days. During pregnancy or in children, clindamycin is used instead of doxycycline.

In patients with features of severe malaria, a mixed infection with *falciparum* should be assumed even if only a benign species is identified in the film. Occasionally, severe malaria can occur with *vivax* species. If the clinical suspicion is high, a therapeutic trial of antimalarial treatment is justified, even if the film is negative.

Severe malaria leads to severe septic shock, and the principles of management are the same including resuscitation and provision of supportive treatment. These patients are at risk of acute lung injury but do need adequate fluid resuscitation. Convulsions must be actively treated. Complications should be managed as they present. The threshold for dialysis should be low. Pneumonia and bacterial septicæmia are also common, and should be recognised and treated.

Exchange blood transfusion (EBT) has been used in severe malaria. However, recent WHO guidelines<sup>3</sup> do not recommend EBT, and note the lack of consensus on indications, benefits and dangers involved, or on practical details such as the volume of blood that should be exchanged. Traditional indications for EBT if pathogen-free compatible blood is available are:

- parasitaemia > 30%, even in the absence of clinical complications
- parasitaemia > 10% in the presence of severe disease, especially cerebral malaria, acute renal failure, ARDS, jaundice and severe anaemia and/or poor prognostic factors (e.g. elderly patient, late stage parasites (schizonts) in the peripheral blood)
- parasitaemia > 10% and failure to respond to optimal chemotherapy after 12–24 hours

**Table 65.3** WHO recommendations for treatment of *P. vivax*, *ovale* and *malariae* malaria**Uncomplicated *P. vivax* malaria**

Chloroquine 25 mg base/kg divided over 3 days, combined with primaquine 0.25 mg base/kg, taken with food once daily for 14 days is the treatment of choice for chloroquine-sensitive infections. In Oceania and Southeast Asia the dose of primaquine should be 0.5 mg/kg.

Amodiaquine (30 mg base/kg divided over 3 days as 10 mg/kg single daily doses) combined with primaquine should be given for chloroquine-resistant *vivax* malaria.

**Complicated *P. vivax* malaria**

Treatment is the same as severe *P. falciparum* malaria.

***P. ovale* and *malariae* malaria**

Treatment is the same as uncomplicated *vivax* malaria but without primaquine for *malariae*.

**OTHER FORMS OF MALARIA**

Treatment of other forms of malaria is outlined in Table 65.3.

**PROGNOSIS**

Data are largely derived from endemic areas where presentation with convulsions, acidosis or hypoglycaemia is associated with a poorer outcome. Mortality in an artesunate-treated severe falciparum malaria group in one trial<sup>5</sup> was still high (15% vs. 22% in quinine-treated patients). In cerebral malaria, mortality is around 20%. The prognosis of cerebral malaria is frequently determined by the management of other complications such as renal failure and acidosis, but neurological sequelae are increasingly recognised.

**TUBERCULOSIS****EPIDEMIOLOGY**

Tuberculosis continues to be a devastating disease worldwide, with an estimated 8 million new cases and 2.6–2.9 million deaths annually. Medical conditions which predispose to tuberculosis include HIV infection, silicosis, diabetes, chronic renal failure/haemodialysis, malnutrition, solid organ transplant, gastrectomy, jejunoileal bypass, injection and inhalational drug abuse, alcoholism, chronic pulmonary disease and prolonged steroid use. Social factors such as institutional living conditions (nursing homes, homeless shelters, prisons), urban dwelling and poverty are associated with an increased risk of tuberculosis.

**PATHOGENESIS**

Tuberculosis (TB) is usually caused by *Mycobacterium tuberculosis* and four others (*M. bovis*, *M. africanum*, *M. microti* and *M. canetti*) grouped in the Mycobacterium

complex. The genus *Mycobacterium* consists of many different species, all of which appear similar on acid-fast staining.

Inhalation of tubercle bacilli leads to one of four possible outcomes: immediate clearance of the organism, primary or progressive primary disease, chronic or latent infection, and reactivation disease. Latent infection refers to the presence of tuberculous infection (positive tuberculin reaction) without the disease.

The majority of primary TB infections are asymptomatic; clinical pneumonia occurs in 5–10% of adults with a higher incidence in children and those suffering from HIV infection. *M. tuberculosis* microfoci that have remained dormant after primary infection may undergo reactivation resulting in secondary TB, often referred to as reactivation disease. This is responsible for 90% of TB in patients not infected with HIV.

### CLINICAL SPECTRUM

The manifestations of TB are protean and TB should be considered in the differential diagnosis of all patients with fever of unknown origin, night sweats, or unexplained weight loss. Besides the lungs, it can also involve the central nervous system, peritoneum, pericardium, gastrointestinal and genitourinary tract, bone and joints, lymph nodes and skin. Occasionally it can be disseminated in the form of miliary tuberculosis.

### PULMONARY TUBERCULOSIS

Typically, reactivation disease starts in the apex of one or both lungs, leading to chronic inflammation and fibrosis. Pulmonary TB is often asymptomatic initially, though cough, dyspnoea and haemoptysis are useful clues. Hilar lymphadenopathy is the most common pulmonary presentation in children. It may occasionally present very late as extensive disease in both lungs with severe lung damage including cavitation, and pneumothoraces.

Sputum, induced sputum, bronchial washings and transbronchial biopsy of infiltrates should be performed to isolate the organism. Computed tomography (CT) is more sensitive than chest radiography for detection of infiltrates, cavities, lymphadenopathy, miliary disease, bronchiectasis, bronchial stenosis, bronchopleural fistula and pleural effusion.

### *Tuberculous pleural effusion*

Pleural TB may result in pleural effusion, pleural empyema with or without bronchopleural fistula. Thoracentesis and pleural biopsy should be performed. Positive cultures are found in less than 25% of cases. Pleural biopsy shows granulomatous inflammation in approximately 60% of patients. However, when culture of three biopsy specimens is combined with histological examination, the diagnosis can be made in up to 90% of cases. Pleuroscopy-guided biopsies increase the yield in pleural sampling.

The pleural fluid should be examined for total protein and glucose content, WBC count and differential, and fluid pH. Raised adenosine deaminase (ADA) levels have been found to be useful in the diagnosis, with levels more than 70 U/l in pleural fluid strongly favouring tuberculous aetiology and levels less than 40 U/l making it less likely; ADA also has a good negative predictive value. However, ADA assay should not be considered as an alternative to biopsy and culture.<sup>6</sup> Raised  $\gamma$ -interferon has also been found to be useful. The clinical utility of PCR testing in tuberculous pleural effusion is limited.<sup>7</sup>

### TUBERCULOUS MENINGITIS

Tuberculous meningitis<sup>8</sup> remains the most serious relevant manifestation of TB to the intensive care physician. Tuberculous meningitis results from haematogenous spread. There is a thick gelatinous exudate around the sylvian fissures, basal cisterns, brainstem and cerebellum.

The majority of patients with TB meningitis have had recent contact with TB, followed by a prodrome of vague ill-health lasting 2–8 weeks. Later, signs and symptoms of meningeal irritation appear. Cranial nerve palsies occur in 20–25% of patients and papilloedema may be present. Choroidal tubercles are rare but almost pathognomonic. Visual loss due to optic nerve involvement may occasionally be the presenting feature. There may be focal neurological deficit such as hemiplegia; extrapyramidal movements and seizures are other manifestations. As the disease progresses, cerebral dysfunction sets in and the mortality approaches 50%.

Diagnostic algorithms have been suggested but they are unlikely to provide sufficient assurance to confidently exclude other diagnoses.<sup>9,10</sup> The key is a high degree of clinical suspicion, especially in the critically ill. In one study, TB meningitis was considered as a diagnosis in only 36% of cases and only 6% received immediate treatment.<sup>11</sup>

Definitive diagnosis of TB meningitis depends upon the detection of the organism in CSF, either by smear examination or by bacterial culture. The yield from smear is variable, but generally low. Culture of the CSF for the organisms is not invariably positive. Raised ADA level is not specific.

The sensitivity and specificity of a commercial nucleic acid amplification assay for the diagnosis of TB meningitis are 56% and 98% respectively.<sup>12</sup> Careful bacteriology is as good as, or better than, the commercial nucleic acid amplification assays, but molecular methods may be more useful when antituberculous drugs have already been commenced. However, the diagnosis of TB meningitis cannot be excluded by these tests, even if both are negative.<sup>8</sup>

CT or magnetic resonance imaging (MRI) of the brain, which are sensitive but not specific, may reveal thickening and intense enhancement of meninges, especially in basilar regions. Hydrocephalus and tuberculomas may also be present. Infarcts due to either vasculitis or mechanical strangulation of the vessels by the surrounding exudates are detected in up to 40%. The radiological differential

diagnosis includes cryptococcal meningitis, cytomegalovirus encephalitis, sarcoidosis, meningeal metastases and lymphoma.

### TUBERCULOUS EMERGENCIES

- Massive haemoptysis
- Respiratory failure
- Pericardial tamponade
- Small intestinal obstruction
- Tuberculous meningitis
- Status epilepticus due to tuberculomas

### DIAGNOSIS OF TUBERCULOSIS

Once considered, isolate the patient and sample all potential sites for acid fast staining and culture. Pleural, peritoneal, pericardial and other fluids must be cultured and analysed for differential cell count, protein, glucose and ADA. Histological examination for granulomatous infection is useful in bronchial, pleural, peritoneal and skeletal tissues. Peritoneal biopsies are best obtained via laparoscopy. Newer culture media have reduced the time for culture to 2 weeks.

Nucleic acid amplification (NAA) tests amplify target nucleic acid regions that uniquely identify the *M. tuberculosis* complex, and are available as commercial kits or in-house assays. They can be applied to clinical specimens within hours. Based on current evidence, NAA tests cannot replace conventional diagnostic approaches using microscopy and culture.

The current status of NAA tests is summarised below:

- NAA tests, in general, have high specificity and positive predictive value; they are useful in ruling in rather than ruling out TB.
- A positive NAA test in smear-positive patients can differentiate *M. tuberculosis* from non-tuberculous mycobacteria (NTM); treatment can then be started.
- The interpretation of a smear-positive/NAA-negative test is controversial.
- Treatment can be started in smear-negative/NAA-positive patients with a high clinical suspicion, particularly when prompt treatment is imperative.
- If clinical suspicion is high, TB is not excluded by both a negative smear and NAA.
- NAA results may remain positive for months. This method should be used only for initial diagnosis and not follow-up.

Serodiagnosis of tuberculosis, despite remaining a poor confirmatory tool in areas of low incidence, may be useful in exclusion of disease.

Drug susceptibility tests should be performed on initial isolates from all patients in order to identify an effective antituberculous regimen, and may have to be repeated if the patient remains culture positive after 3 months.

### TREATMENT OF TUBERCULOSIS

Local guidelines are of paramount importance and advice should be sought. The commonest regimen used is isoniazid (5 mg/kg) and rifampicin (10 mg/kg) for 6 months with the addition of pyrazinamide (15–30 mg/kg) and ethambutol (5–25 mg/kg) for the first 2 months. It has been suggested that instead of ethambutol, prothionamide is preferable as a fourth drug in tuberculous meningitis. Steroids are generally recommended in tuberculous meningitis<sup>13,14</sup> and pericardial tuberculosis.

### DRUG-RESISTANT TUBERCULOSIS

This is an increasing problem. Multidrug-resistant tuberculosis (defined as resistance to two or more of the first-line antituberculous drugs, usually isoniazid and rifampicin) can be primary (no prior antituberculous therapy) or secondary (development of resistance during or after chemotherapy).

Diagnosis depends upon collection of adequate specimens for culture prior to the initiation of antituberculous therapy. In critically ill patients, rapid diagnosis of drug resistance is of paramount importance. With the improvements in the culture methods and the availability of newer techniques, including phage-based assays, rapid identification of resistance is possible.<sup>15</sup> When resistance is present to two or more first-line agents, parenteral aminoglycoside (streptomycin, amikacin, etc.) and fluoroquinolones are generally added. Specialist microbiological advice should be sought.

### TYPHOID FEVER

Typhoid fever is caused by *Salmonella typhi* and less commonly by paratyphi A, B and C. Even non-typhoidal salmonellae have occasionally been isolated.<sup>16</sup> Typhoid fever, common in South and South-East Asia, is almost exclusively caused by fecal–oral spread. In the developed world, cases are either seen in international travellers or occasionally caused by infected food.

### CLINICAL FEATURES

The incubation period is 5–21 days. Typhoid presents non-specifically with fever, chills, abdominal pain and constitutional symptoms. Constipation may be more frequent than diarrhoea. Hepatosplenomegaly, erythematous macular rash (30%) and relative bradycardia may be present. Relative bradycardia is not specific for enteric fever but is a useful clue.<sup>17</sup>

### COMPLICATIONS

- Shock
- Intestinal perforation
- Gastrointestinal haemorrhage
- Jaundice and encephalopathy<sup>18</sup>
- Neuropsychiatric manifestations

- Septic arthritis, pericarditis, etc.
- Obstetric complications in pregnant women

### DIAGNOSIS<sup>19</sup>

Anaemia, leukopenia/leukocytosis and deranged liver function are common. Blood cultures are positive in up to 80% of cases, and are the investigation of choice; 10–15 ml yields higher success than smaller volumes.<sup>20</sup> Though culturing urine, stool, rose spots and duodenal contents is useful, bone marrow culture is the most sensitive, and its yield remains unchanged up to 5 days after commencement of treatment.<sup>21</sup>

Serodiagnosis using Widal tests has limited clinical value. Commercial serological tests such as Typhidot-M and Tubex, which detect IgM antibodies against different *S. typhi* antigens, have a higher sensitivity and specificity.<sup>22</sup> Nested PCR is very promising in the diagnosis of typhoid fever.

### TREATMENT<sup>23</sup>

In both uncomplicated and complicated typhoid fever, the treatment of choice is the fluoroquinolones (ciprofloxacin or ofloxacin 15 mg/kg for 5–7 days in uncomplicated and 10–14 days in complicated infections). In fluoroquinolone-resistant cases, azithromycin, cefixime or ceftriaxone can be used. There is some concern in using fluoroquinolones in children as they have been shown to cause cartilage toxicity in immature animals, but this appears largely unfounded in clinical trials.<sup>24,25</sup>

Dexamethasone reduces mortality in severe typhoid fever: delirium, obtundation, stupor, coma, or shock.<sup>26</sup> Ileal perforation, which may occur late, classically in the third week of febrile illness, requires prompt surgical intervention, and segmental resection has been recommended as the procedure of choice.<sup>27,28</sup>

### CHOLERA

Cholera is caused by enterotoxin-producing *Vibrio cholerae*.<sup>29</sup> The incubation period varies from 12 hours to several days. The clinical case:infection ratio is about 1:10. It starts abruptly with painless watery diarrhoea associated with vomiting and painful muscle cramps. Vomiting may be the first symptom before diarrhoea.

Stool examination shows neither leukocytes nor erythrocytes. Dark field microscopy examination may reveal rapidly motile, comma-shaped bacilli in fresh stool. Commercial assays detecting O antigen in stool samples, which take less than 5 minutes, are now available and are as sensitive and specific as stool culture. Aggressive rehydration is the mainstay of treatment; very large quantities of fluid may be needed. Adjunctive antimicrobial therapy is effective in shortening the duration of diarrhoea. Single dose doxycycline (300 mg) or single dose ciprofloxacin (1 g) is very effective, but azithromycin has recently been shown to be superior.<sup>30</sup>

### LEPTOSPIROSIS

This is caused by *Leptospira interrogans*. It occurs due to exposure to contaminated water. The disease has an incubation period of 7–10 days with a range of 2–20 days. It has two phases: the septicaemic phase and the immune phase. Clinical features include conjunctival suffusion or haemorrhages (useful diagnostic clue), uveitis, severe muscle tenderness, non-oliguric renal failure, hypokalaemia, hepatic dysfunction, pulmonary haemorrhage, ARDS, myocarditis, rhabdomyolysis, thrombocytopenia, DIC, haemorrhage into the skin and internal organs, and digital gangrene. Weil's syndrome is characterised by hepatorenal dysfunction, bleeding diathesis and pulmonary involvement.

Diagnosis is made with isolation of the organism by culture (blood, urine, CSF) or serology using the gold standard microscopic agglutination test (MAT). Both culture and serology should be attempted if available, and local microbiological advice should be sought. Treatment is with penicillin G or ceftriaxone. In penicillin-allergic patients, doxycycline can be used.

### DENGUE FEVER

#### EPIDEMIOLOGY AND PATHOGENESIS

It is estimated 100 million cases of dengue fever and 250 000 cases of dengue haemorrhagic fever occur each year throughout the world.<sup>31</sup> The causative agent is a flavivirus with four distinct serogroups, and it is transmitted by the bite of *Aedes* mosquitoes. Two patterns of transmission have been recognised: epidemic due to isolated introduction of dengue to a region, usually due to a single serotype, and hyperendemic, referring to the continuous circulation of multiple dengue virus serotypes.

Following a mosquito bite, viraemia begins and usually lasts up to 7 days. Infection with one of the four serotypes (primary infection) provides life-long immunity against that serotype but not against the other serotypes (secondary infection). Epidemiological studies have suggested that the risk of severe disease (dengue haemorrhagic fever/dengue shock syndrome) is significantly higher in secondary than primary infection.

#### CLINICAL FEATURES

The clinical presentation varies from mild febrile illness to severe haemorrhagic fever. Most infections are asymptomatic. WHO classifies dengue infection as undifferentiated fever, dengue fever (DF) and dengue haemorrhagic fever (DHF)/dengue shock syndrome (DSS).

Dengue fever has an incubation period of 3–14 days and is characterised by the sudden onset of fever, severe headache, retro-orbital pain on moving the eyes, and fatigue. It is often associated with severe myalgia and

arthralgia (breakbone fever). Maculopapular rash, flushed facies and injected conjunctiva are common. Haemorrhagic manifestations can occur in DF and should not be confused with DHF.

Dengue haemorrhagic fever occurs primarily in children < 10 years and is characterised by plasma leakage syndrome and haemoconcentration (20% or greater rise in haematocrit), pleural effusion or ascites. The diagnosis is made if the following symptoms and signs are present: bleeding, a platelet count < 100 000 per mm<sup>3</sup> and plasma leakage. Haemorrhagic manifestations without evidence of plasma leakage do not constitute DHF. The mechanism underlying the profound capillary leak in DHF but not in DF is poorly understood. It is important to watch for the onset of DHF which typically occurs 4–7 days after the onset of the disease, approximately at the time of defervescence. Decrease in platelet count and rise in haematocrit are useful clues.<sup>32</sup>

Dengue shock syndrome is characterised by profound hypotension and shock.

### DIAGNOSIS

Dengue should be suspected in all febrile patients who live in, or have returned from, endemic areas in the preceding 2 weeks. Leukopenia, thrombocytopenia with a positive tourniquet test, and raised AST are frequently seen; the former two tests have the highest sensitivity (about 90%) for the diagnosis of early dengue.<sup>32</sup> A positive tourniquet test cannot differentiate DHF from DF.

IgM immunoassay allows rapid confirmation of the diagnosis. If it is negative, particularly in the first 6 days of the illness, the diagnosis should not be ruled out. Acute and convalescent sera should be analysed by haemagglutination assay or IgG immunoassay for a fourfold rise in titre. Virus isolation and reverse transcriptase PCR (RT-PCR) are available but are usually not used in the clinical setting.

### TREATMENT

Supportive therapy for shock, especially appropriate and prompt fluid replacement, can reduce mortality. WHO guidelines on fluid management are available.<sup>33</sup> In DSS, steroids have not been shown to be useful.<sup>34</sup> Once capillary leakage abates, fluid overload and pulmonary oedema can become problematic.

### HANTA VIRUS

Hantaviruses are rodent viruses distributed worldwide, with over 150 000 cases being registered annually. There are two major clinical syndromes: hantavirus cardiopulmonary syndrome (HCPS) and haemorrhagic fever with renal syndrome (HFRS). Both are acquired by exposure to aerosols of rodent excreta.

### HANTAVIRUS CARDIOPULMONARY SYNDROME

The incubation period is about 3 weeks. There are two phases: the prodromal phase is characterised by a relatively mild febrile illness, typically lasting 3–5 days, and the cardiopulmonary phase is characterised by severe, rapidly progressive respiratory failure. In the latter phase, acute pulmonary oedema due to increased capillary permeability occurs. Progress from the prodromal to cardiopulmonary phase is dramatic. In severe cases, significant myocardial depression also occurs, resulting in low cardiac output and hypotension. Acute renal failure can occur. The combination of thrombocytopenia, myelocytosis, haemoconcentration, lack of significant toxic granulation in neutrophils, and more than 10% of lymphocytes with immunoblastic morphological features is highly sensitive and specific. Enzyme-linked immunosorbent assay (ELISA) for IgM and IgG antibodies is useful in the diagnosis. Hantavirus can also be detected by tissue RT-PCR. Immunohistochemical staining of tissue reveals hantaviral antigen. Treatment is mainly supportive with intravenous fluids, inotropes, mechanical ventilation, extracorporeal membrane oxygenation and blood products. Intravenous ribavirin is probably ineffective in the treatment of HCPS in the cardiopulmonary stage.<sup>35</sup>

### HAEMORRHAGIC FEVER WITH RENAL SYNDROME

This is characterised by fever, renal failure and haemorrhagic manifestations. The disease has five progressive stages: febrile, hypotensive, oliguric, diuretic, and convalescent. Non-specific constitutional symptoms are followed by shock, oliguria, DIC and haemorrhagic manifestations. Diagnosis is made using ELISA for IgG and IGM antibodies. Treatment is supportive, including renal support. Ribavirin has been found to be useful.<sup>36</sup>

### ARBOVIRAL ENCEPHALITIS

Viruses transmitted to human beings by the bites of arthropods (especially mosquitoes and ticks) are major causes of encephalitis worldwide. Although different viruses can cause encephalitis, an antigenically related group of flaviviruses accounts for a major proportion of cases. These include mosquito-borne diseases such as Japanese encephalitis, West Nile virus encephalitis, St Louis encephalitis, Murray Valley encephalitis<sup>37</sup> and tick-borne encephalitis. Viral encephalitis is characterised by a triad of fever, headache and altered level of consciousness. Other common clinical findings include disorientation, behavioural and speech disturbances, and focal or diffuse neurological signs such as hemiparesis or seizures. The incubation period is usually 5–15 days. Other manifestations include recurrent seizures, including status epilepticus, a flaccid paralysis resembling that of poliomyelitis, and parkinsonian-type movement disorders. Flavivirus encephalitis is usually diagnosed by IgM capture ELISA.

Treatment is supportive. Interferon- $\alpha$ , ribavirin and intravenous immunoglobulin have all been tried with mixed success.

## VIRAL HAEMORRHAGIC FEVERS (VHF)

### EPIDEMIOLOGY

Lassa virus, Rift valley fever, Congo–Crimean haemorrhagic fever, haemorrhagic fever with renal syndrome, Marburg and Ebola viruses, yellow fever and dengue haemorrhagic fever are some of the most important viral haemorrhagic fevers. Increased vascular permeability is the primary defect. Petechial haemorrhages are usually associated with fever and myalgias. Later, frank mucous membrane haemorrhage may occur, with accompanying hypotension, shock and circulatory collapse. Multisystem organ failure can occur. There is a wide variation in the relative severity of the clinical presentation.

At least four of the haemorrhagic fevers – Lassa fever (LF), Ebola virus, Marburg virus and Congo–Crimean haemorrhagic fever (CCHF) – are capable of person-to-person transmission through close contact with infected blood and other body secretions. Epidemiological studies of VHF in humans indicate that, although possible, the airborne route does not readily transmit infection from person to person.

### CLINICAL FEATURES

The patient will have either been in an endemic area or been in contact with someone from an endemic area. Viral haemorrhagic fevers<sup>38</sup> generally have an abrupt onset with an incubation period < 10 days. The incubation period can be up to 21 days. They present as acute febrile illnesses with a prodrome that often includes severe headache, dizziness, flushing, conjunctival injection, myalgia, lumbar pain and prostration. Gastrointestinal symptoms with nausea, vomiting, abdominal pain and diarrhoea may occur.

Leukopenia or leukocytosis, thrombocytopenia and elevated serum aminotransferases may be evident early in the disease; a petechial rash may appear on days 3–10. Coagulation profiles become progressively more abnormal, and overt haemorrhagic features of the disease (ecchymoses, epistaxis, gingival bleeding, melaena, haematuria, etc.) may supervene from day 5 onward, or sometimes even earlier. Multiple organ failure supervenes and death may ensue. Clinical improvement becomes apparent towards the end of the second week of illness in patients who survive.

### DIAGNOSIS

A high index of suspicion is needed and VHF should be suspected in the following circumstances:

- Unexplained fever in patients who have visited areas where VHF are endemic, within 3 weeks of becoming

ill. The likelihood is greater if they have camped in the bush, slept on the ground or in rural farms, or had any bites or contact with sick animals.

- Febrile medical and nursing staff in the endemic areas and laboratory workers who handle VHF viruses.
- Febrile contacts.

Tests on samples present an extreme biohazard risk. The diagnosis may be made by isolating virus from blood or body fluids, positive IgM antibody or by showing a four-fold rise in antibody titre. Detection of characteristic virions by electron microscopy establishes the diagnosis of Marburg and Ebola viruses. If needed for infection control, electron microscopy of tissues (especially liver) at autopsy is confirmatory.

### TREATMENT

Therapy is essentially supportive for a severe shock state. Haemorrhage is managed by replacement of blood, platelets and clotting factors as indicated. Ribavirin is useful in treating LF and CCHF. Ribavirin may reduce mortality by 10-fold if treatment is begun within 6 days of onset. A 30 mg/kg i.v. loading dose is followed by 15 mg/kg every 6 hours for 4 days and then 7.5 mg/kg every 8 hours for another 6 days.

### PRECAUTIONS

In most countries these diseases must be notified immediately. In addition to universal blood and body fluid precautions, airborne isolation, including use of goggles, high-efficiency masks, a negative pressure room with no air circulation, and positive pressure filtered air respirators have all been recommended, as is surveillance of contacts. If applicable, to prevent further mosquito transmission, patients should be isolated in well-screened rooms sprayed with residual insecticides.

# Severe and multiple trauma

James A Judson

Trauma can be defined as physical injury from mechanical energy. It is usually categorised as blunt or penetrating. In Western countries, severe blunt trauma is common, caused by road crashes, falls and, less frequently, blows and assault. Severe penetrating trauma, usually from stabblings and gunshots, is less common except in larger cities of the USA,<sup>1,2</sup> South Africa and war zones. Blunt trauma is often more difficult to treat than penetrating trauma. Assessment is more difficult, because injuries are frequently internal, multiple and not obvious initially. The risk of missing serious injuries can only be lessened by a systematic approach and repeated assessments.<sup>3-5</sup>

## ASSESSMENT AND PRIORITIES

### TRIAGE

An important first step is triage – sorting patients with acute life-threatening injuries and complications from those whose lives are not in danger. The severity of total body injury is related to the number of separate injuries present, and to the severity of individual injuries. Assessment can be made either at the scene of injury or on arrival at hospital. As in any emergency, assessment, diagnosis and treatment need to be concurrent. There is limited time for detailed histories, examinations, investigations or well-considered diagnoses before starting emergency care. Most patients with severe injury can be distinguished early by the following:

- *Depressed consciousness* in the trauma patient can be related to brain injury, hypoxaemia, shock, alcohol or other ingested drugs, or precipitating neurological or cardiac events. Frequently, a combination of factors is present, and the precise extent of physical brain injury is not known initially. Initial treatment in any case is determined by the level of consciousness rather than its exact cause.
- *Breathing difficulties* are common in patients with trauma to the head, face, neck and chest. If rapid or distressed breathing is present, airway obstruction, laryngeal injury, pulmonary aspiration and lung or chest wall injury (especially pneumothorax and lung contusion) must be considered.

- *Shock* is almost always hypovolaemic from blood loss, but other types of shock occasionally occur in trauma (see below).

### PRIORITIES

A trauma patient often has multiple problems requiring attention. Determining priorities is not always easy. In general, the priorities are to:

- *Support life*: the patient is kept alive with resuscitative techniques, while the various injuries and complications are attended to
- *Locate and control bleeding*, which may be varied (see below)
- *Prevent brainstem compression* and spinal cord damage
- Diagnose and treat all other injuries and complications

## BASIC TREATMENT PRINCIPLES

A systematic approach to managing severe and multiple trauma is important. Effective programmes developed by the American College of Surgeons are now well established.<sup>6</sup> A number of basic treatment principles apply to all severe trauma patients.

### EMERGENCY ASSESSMENT (PRIMARY SURVEY)

The following must be recognised and treated before anything else:

- *A – Airway obstruction*: suggested by noisy (or silent) breathing, with paradoxical chest movements and breathing distress, and inadequate airway protection from impaired gag reflexes in patients with depressed consciousness.
- *B – Breathing difficulty*: suggested by tachypnoea, abnormal pattern of breathing, cyanosis or mental confusion.
- *C – Circulatory shock*: manifested by cold peripheries with delayed capillary refill, rapid weak pulse or low blood pressure (see below).

### OXYGEN AND VENTILATORY THERAPY

High-flow oxygen by mask is given to all trauma patients. However, patients with severe trauma frequently require ventilatory support. A restless uncooperative patient should be intubated under a rapid sequence induction to facilitate resuscitation.

### BLOOD CROSSMATCH AND TESTS

Six units of red cells should be crossmatched urgently, but it is impossible to predict the amount of blood that will be required. Blood is concurrently sent for baseline haematological and biochemical tests, including blood ethanol level. Blood ethanol is clinically useful in assessing individual patients with depressed consciousness, quite apart from epidemiological and preventive medicine,<sup>7</sup> and legal considerations.

### FLUID RESUSCITATION

Resuscitation fluids are given (see below). If necessary, two or three large 14- or 16-gauge i.v. cannulae are inserted in upper limb, external jugular or femoral veins.

### ANALGESIA

Analgesia is easily overlooked. Opioid agents should be titrated i.v., and not given i.m. or subcutaneously. Large doses may be needed.

### URINE OUTPUT

A urinary catheter is inserted unless a ruptured urethra is suspected (because of blood at the urinary meatus, severe fractured pelvis or abnormal prostate position on rectal examination), in which case a suprapubic catheter is indicated. Urine output monitoring is an important guide to resuscitation.

### OTHER INJURIES

All injuries should be evaluated.

### CLINICAL EVALUATION OF INJURIES (SECONDARY SURVEY)

Injuries are easily missed in an emergency, especially when one injury is obvious. A secondary, and even a tertiary, survey should be performed.<sup>5</sup> The back and the front of the patient should be examined. Special attention is paid to regions with external lacerations, contusions and abrasions. All body regions are examined systematically.

### HEAD

Neurological observations are made. The ears and nose are inspected for cerebrospinal fluid and blood, and the scalp is examined thoroughly.

### FACE

Bleeding into the airway should be excluded, and the face and jaws tested for abnormal mobility.

### SPINE

A cervical spine fracture or dislocation is assumed in all patients with depressed consciousness until proved otherwise. Signs of spinal cord injury should be sought (e.g. warm dilated peripheries from loss of vasomotor tone, diaphragmatic breathing, paralysis, priapism and loss of anal tone). The thoracic and lumbar spine should be inspected and palpated.

### THORAX

Fractured ribs in themselves are not usually life-threatening but haemothorax, pneumothorax, lung contusion and chest wall instability (flail chest) will require attention if present. Less common but very serious injuries can occur to the heart and great vessels (see Chapter 69).

### ABDOMEN

The spleen, liver and mesenteries are often damaged. Retroperitoneal haemorrhage is common. Injuries to the pancreas, duodenum and other hollow viscera are less frequent, and may be missed until signs of peritonitis occur. Renal injury with retroperitoneal haemorrhage is suggested by haematuria and loin pain (see Chapter 71).

### PELVIS

Pelvic fractures may be difficult to detect clinically, especially in the unconscious patient. Blood loss may be massive, particularly with posterior fractures involving sacroiliac dislocation. Ruptured bladder and ruptured urethra may occur with anterior fractures.

### EXTREMITIES

A litre or more of blood may be lost into a fractured femur. Long bone fractures are more serious when they are open, comminuted or displaced, or if associated with nerve or arterial damage.

### EXTERNAL

Contusions may be extensive and serious, especially in falls from heights, and may be overlooked if the victim's back is not examined. Road crash victims may sustain serious burns or abrasions.

### SHOCK IN THE TRAUMA PATIENT

The earliest, most constant and reliable signs of shock are seen in the peripheral circulation. A patient with cold, pale peripheries has shock until proved otherwise. Tachycardia is not always present and hypotension is a late sign of shock. The commonest form of shock in trauma is hypovolaemic shock.

**HYPOVOLAEMIC SHOCK**

If the neck veins are empty, hypovolaemic shock should be inferred. Possible sites of blood loss causing shock are:

- *External loss*, which is obvious clinically from blood-soaked clothing and pooled blood.
- *Major fractures*, which are obvious clinically by deformity, swelling, crepitus, pain and tenderness (e.g. femurs) or seen on a plain X-ray (e.g. pelvis).
- *Pleural cavity*, detected on urgent chest X-ray. Intra-pleural drains will reveal the amount and rate of blood loss.
- *Peritoneal cavity*, detected by laparotomy, diagnostic peritoneal lavage, computed tomography (CT) scan or ultrasound. Clinical examination of the abdomen can be misleading when the patient is intoxicated, has depressed consciousness or has multiple injuries. A single clinical examination is of limited value: changes over time are more important.
- *Retroperitoneum*, detected at laparotomy or by CT scan, or inferred when all the above are negative, especially in the presence of pelvic or lumbar spine fracture.

**CARDIOGENIC SHOCK**

If the trauma patient with shock has distended neck veins, possible causes are tension pneumothorax, concurrent myocardial infarction, cardiac tamponade or myocardial contusion.

**NEUROLOGICAL SHOCK**

Patients with paraplegia or tetraplegia from spinal cord injury may have low blood pressure with warm dilated peripheries accompanied by lax anal tone and by priapism in the male (see Chapter 70). This is a diagnosis of exclusion and all causes of hypovolaemic shock (see above) must be sought.

**SEPTIC SHOCK**

Occasionally, patients with pulmonary aspiration may develop septic shock. This is unlikely to confuse the initial trauma assessment soon after injury, but may require consideration some hours or a day or two later.

**ABDOMINAL ULTRASOUND**

Technological advances in ultrasound scanning and the increasing availability of FAST (focused assessment with sonography for trauma) scanning in emergency departments make this modality attractive in trauma, and it is becoming increasingly used. However:

- It is operator-dependent
- It may have an unacceptably high false-negative rate
- There is a small but important false-positive rate for intra-abdominal bleeding<sup>8</sup>
- It is unable to diagnose ruptured bowel
- It is not good for bleeding in the pelvis

Its main usefulness is probably in the unstable patient when it is positive, to indicate the need for laparotomy without the necessity to proceed to diagnostic peritoneal lavage (DPL).<sup>9</sup> FAST scans performed by enthusiastic amateurs in emergency departments without a treatment algorithm can be misleading and therefore worse than useless.

**DIAGNOSTIC PERITONEAL LAVAGE**

Diagnostic peritoneal lavage is indicated to diagnose intra-abdominal bleeding

- In shocked patients who are not proceeding straight to laparotomy
- In patients without shock when repeated clinical examination of the abdomen for 6 hours is not possible because of sedation or anaesthesia

Caution is needed with pregnancy, previous abdominal surgery or massive pelvic injury. Isotonic saline 1 l (or 10 ml/kg) is instilled into the peritoneal cavity, after drainage of the stomach and bladder. The presence of more than 10 ml frank blood on catheter aspiration necessitates immediate laparotomy; otherwise a lavage fluid specimen should be examined for red and white cell counts and amylase concentration. A red cell count over 100 000 per mm<sup>3</sup>, white cell count over 500 per mm<sup>3</sup>, or an increased amylase concentration suggests bleeding or viscus injury, and laparotomy should be undertaken immediately. These absolute figures are debatable and lower values are accepted in penetrating trauma.<sup>6,10</sup> Peritoneal lavages inevitably result in some false-positive laparotomies. However, in severe trauma, morbidity of a non-therapeutic laparotomy (i.e. no definitive surgery) is small compared with the dire consequences of missing significant intra-abdominal injury.<sup>11</sup>

**CT ABDOMEN**

Abdominal CT is not indicated in shock, but can be useful in the stable patient. Improved availability of CT scanning, and technological advances with reduced scanning times and better definition, is increasingly favouring CT abdomen over DPL in patients who are sufficiently stable to tolerate the procedure safely. It needs to be performed quickly and safely, with gastric and i.v. contrast, and interpreted by radiologists experienced in trauma. Visualisation of abdominal and pelvic organs and haemorrhage is excellent,<sup>12,13</sup> but results can be misleading and disastrous with poor technique.<sup>4</sup>

**FLUID RESUSCITATION****FLUIDS**

Almost all patients who are hypotensive or noticeably vasoconstricted will need blood transfusion. However, as cross-matched blood is not immediately available, other fluids

are used first. Uncrossmatched group O Rh-negative blood is occasionally indicated in the exsanguinating patient, but in general transfusion of large quantities of blood is wasteful while bleeding is uncontrolled. The place of hypertonic fluids in trauma resuscitation is unresolved.

Isotonic saline or a balanced salt solution should be the first fluid infused. Shocked patients may need 2–3 l in the first few minutes. One litre bags or bottles and giving sets with in-line pumps should be used on all i.v. lines. If fluid resuscitation is likely to be extensive, warmed fluids and rapid infusion devices should be used. Albumin solutions (and probably other colloid resuscitation fluids) are contraindicated in trauma patients, since the SAFE study, conducted in ICU patients, showed higher mortality in patients given albumin, in the predetermined trauma subgroup, particularly in those with traumatic brain injury.<sup>14</sup> By 20–30 minutes crossmatched red cells should be available. Platelets and fresh frozen plasma are reserved for documented or suspected coagulopathy (i.e. dilutional coagulopathy from fluids deficient in haemostatic factors, and disseminated intravascular coagulopathy (DIC) from prolonged shock).

All resuscitation fluids have a high sodium concentration, similar to that of extracellular fluid. Glucose 5% and glucose–saline solutions are not effective resuscitation fluids. Few trauma patients actually require them in the first day.

#### LIMITED FLUID RESUSCITATION

In penetrating trauma, there is some evidence that extensive fluid resuscitation prior to haemostasis may be detrimental, presumably because of higher blood pressure, displacement of blood clot and dilution of coagulation factors.<sup>15</sup>

In blunt trauma, there is no such evidence. Furthermore, it is not appropriate to generalise the evidence from penetrating trauma to blunt trauma because these two types of trauma are quite different. In penetrating trauma, the bleeding is often from single arteries without extensive tissue injury, and complete haemostasis can often be easily achieved.

In contrast, in blunt trauma, the bleeding is often venous as well as arterial, with capillary oozing into the soft tissues which may continue for hours. It can often not be controlled, or can be only partly controlled, by operative surgery, interventional radiology or reduction and fixation of fractures. Accordingly, fluid resuscitation in the face of continuing blood loss is an important part of the treatment of circulatory shock in blunt trauma (see section on Inadequate resuscitation). Nevertheless, fluid resuscitation is not an alternative to haemostasis and must not be used as an excuse for delaying haemostasis in blunt trauma.

Furthermore, traumatic brain injury is often present in blunt trauma, which frequently involves several body regions. Hypotension is disastrous to an already injured brain, and must not be prolonged by deliberate under-resuscitation (see Chapter 67, section on Traumatic brain injury – Emergency treatment).<sup>16–18</sup>

#### URINE OUTPUT

Hourly urine output is a useful guide to resuscitation from shock. Minimal acceptable urine output is 0.5 ml/kg per hour, but 1–2 ml/kg per hour is more adequate. Furosemide has no place in initial resuscitation. Apart from adequate resuscitation, diuresis can be due to ethanol, mannitol, dopamine, nephrogenic or neurogenic diabetes insipidus, or non-oliguric renal failure. Polyuria may mask early recognition of acute renal failure.

#### INADEQUATE RESUSCITATION

Patients in shock have depleted interstitial fluid as well as circulating blood volume, and need trauma resuscitation fluid volumes greater than the actual volume of blood lost. With blunt injury, volume losses often continue for 24–48 hours. Prolonged shock from delayed and inadequate resuscitation leads to renal failure, acute respiratory distress syndrome (ARDS), sepsis, DIC and multiple organ dysfunction.<sup>19,20</sup>

#### PULMONARY OEDEMA

Pulmonary oedema during resuscitation may be related to fluid overload, direct lung trauma, aspiration of gastric contents, pulmonary responses to non-thoracic trauma and reactions to resuscitation fluids. They can all cause leaky capillaries and produce non-cardiogenic pulmonary oedema.

#### RADIOLOGY FOR TRAUMA PATIENTS

Patients with depressed consciousness, breathing difficulties or unstable circulation should be X-rayed in the emergency department, and not sent to a radiology department remote from skilled resuscitation facilities. Conversely, extensive imaging examinations of shocked patients in the emergency department are unacceptable. Only three examinations should be requested in the emergency department.

#### CHEST

This is the only X-ray ever justified in an unresuscitated patient. A supine film is usually sufficient. An erect film is better for showing intrapleural air or fluid, ruptured diaphragm, free abdominal gas and for defining an abnormal mediastinum, but is often impractical in shock or suspected spinal injury. It can be done later if feasible. An obvious pneumothorax does not require a chest X-ray before insertion of an intercostal drain.

#### LATERAL CERVICAL SPINE

This should be performed in all patients with head injury or multiple injuries because cervical spine fractures are often missed. With head or facial injuries, a cervical

fracture should be assumed initially and a cervical collar applied. The lateral cervical spine X-ray can be taken later. It is only an initial screening examination for cervical spine fractures and does not 'clear' the spine.

### PELVIS

Unexplained blood loss can be due to a missed pelvic fracture. A dislocated hip can be missed in multiple injuries. A pelvic X-ray is not needed in awake patients with no pelvic abnormalities.

### OTHER RADIOLOGICAL INVESTIGATIONS

Other X-rays should be performed after adequate resuscitation in the radiology department, operating room or intensive care unit (ICU):

- *Skull*: plain skull X-rays do not guide immediate treatment. A CT scan of the brain is a more useful urgent investigation.
- *Extremities*: X-rays of the extremities to assess bony injuries are not urgent unless there is vascular injury. Therefore, these films should not be taken in the emergency department for diagnosis, unless the patient is going directly to the operating room for fracture fixation.
- *Spine*: X-rays of thoracic or lumbosacral spine are seldom indicated in the emergency department.
- *Abdomen*: a plain abdominal X-ray is of limited value in the initial evaluation of trauma.
- *CT abdomen*: this can be valuable to evaluate a patient who is haemodynamically sufficiently stable to tolerate the procedure safely (see above).
- *CT head*: this is vital in the treatment of traumatic brain injuries.
- *CT neck*: The most reliable way to exclude or delineate cervical spine injuries is by a CT neck scan,<sup>4,21</sup> which can conveniently be done when the patient is going to the CT scanner for other examinations.
- *CT thorax*: apart from diagnosis of aortic injury, CT thorax is of limited value in the trauma patient. Visualisation of thoracic structures is excellent but it seldom discovers important undiagnosed injuries which affect patient treatment.<sup>22</sup> If aortic injury is suspected, multislice CT is the current definitive diagnostic test. The use of aortic stent grafts for this injury, in locations where this technology is available, means that CT is not only the best diagnostic test, but necessary for preoperative planning.<sup>23</sup> Aortography is no longer the definitive diagnostic test for traumatic aortic rupture.
- *Urethrography* is used when urethral injury is suspected. Properly done CT abdomen may well demonstrate bladder injury, otherwise *cystography* is used.
- *Interventional radiology*: percutaneous transcatheter embolisation is therapeutic rather than diagnostic. It can provide life-saving haemostasis in massive retroperitoneal haemorrhage associated with pelvic

fracture.<sup>24</sup> The logistics of managing such haemodynamically unstable patients in the radiology department are formidable.

### THE EXSANGUINATING PATIENT

With exsanguination secondary to penetrating thoracic injury, there is a place for Emergency Room thoracotomy, but this approach has little place in blunt trauma.<sup>25</sup> The exsanguinating blunt trauma patient needs rapid intubation, volume resuscitation, bilateral intrapleural drains or thoracostomies, chest and pelvic X-ray, and a rapid trip to the operating room if it seems likely that the bleeding is in the thorax or abdomen.

### TRAUMATIC BRAIN INJURY (SEE CHAPTER 67)

Injuries to the head region are common, but those requiring urgent cranial operations are less so. Traumatic brain injury may initially be obvious amongst multiple injuries, but may not be the most important injury. Conversely, traumatic brain injury may seem unimportant initially. Traumatic brain injury is a major determinant of outcome in critically injured patients.

### EMERGENCY TREATMENT

Resuscitation measures, as in the Emergency assessment (primary survey) section above, are undertaken. Victims with one or both dilated unreactive pupils, or a rapidly deteriorating level of consciousness not due to hypoxia or shock, should be given mannitol 1 g/kg i.v. to relieve brainstem compression, until definitive diagnosis and treatment can be arranged. Mannitol should be given only if the patient has been adequately volume resuscitated as it may add to hypovolaemia. There is much interest in hypertonic saline, particularly in head trauma, and concentrated salt may eventually turn out to be a better agent than mannitol in this setting because it does not produce hypovolaemia.<sup>26,27</sup>

Shocked trauma patients with or without traumatic brain injuries require the same crystalloid resuscitation fluids. Treatment of shock and maintenance of cerebral perfusion are vital, as hypotension is disastrous to an already damaged brain.<sup>16-18</sup> Contrary to common belief, sodium-containing fluids are not inherently dangerous in traumatic brain injury. However, after adequate resuscitation, further sodium administration is usually not indicated. Excessive (free) water is potentially dangerous, as it can lead to hypo-osmolar brain swelling.<sup>28</sup>

### NEUROLOGICAL EVALUATION

Factors such as hypoxaemia, shock, alcohol, analgesics, anaesthetic agents, muscle relaxants and other drugs depress consciousness and confound neurological signs. Clinical neurological evaluation includes the Glasgow Coma Scale (GCS)<sup>29,30</sup> and a search for lateralising signs.

CT scanning is indicated in all patients who will not obey verbal commands, especially if they are rendered neurologically inaccessible by sedative and relaxant agents. Lateralising motor or pupillary signs with a deteriorating level of consciousness are indications for immediate CT scanning (or, if unavailable, emergency burr holes). In an unstable patient, a laparotomy for intra-abdominal haemorrhage should take priority over a head CT scan.<sup>31</sup>

### SEVERITY AND MORBIDITY OF TRAUMA

Severity of injury is measured by the abbreviated injury scale (AIS), updated over the years, most recently in 2005.<sup>32–34</sup> AIS divides the body into six regions: head and neck, face, thorax, abdomen, pelvis and extremities, and external. Specific injuries in each body region are coded on a scale of 1 (minor), 2 (moderate), 3 (serious, not life-threatening), 4 (severe, life-threatening, survival probable), 5 (critical, survival uncertain) and 6 (unsurvivable). The AIS was designed for motor vehicle injuries, but has been validated for blunt and penetrating trauma. It can provide a basis for research, education, audit and allocation of resources.

Severity of trauma is related not just to the severity of individual injuries, but also to the combined effects of multiple injuries. Multiple injuries are graded by the injury severity score (ISS), which is an empirical system based on the AIS grades for the three worst body regions.<sup>35,36</sup> ISS gives a score between 0 and 75 for total body injury; 16 or more indicates major trauma. Death with an ISS below 24 should be rare. Above an ISS of 25, there is a stepwise increase in mortality, with very high rates over 50.<sup>37,38</sup>

AIS and ISS study mostly the anatomy of injury. Other factors influence trauma mortality and morbidity, including age, pre-existing health, degree of physiological derangement, standard of prehospital and early hospital care and complications. Degree of physiological derangement can be measured by the revised trauma score,<sup>39</sup> which is computed from the coded values of GCS, systolic blood pressure and respiratory rate, usually at admission to the emergency department. The TRISS severity index is based on the revised trauma score, ISS, and patient age.<sup>40</sup> It correlates well with outcome, and has been used to compile survival norms for blunt and penetrating trauma.<sup>37,38</sup> Physiological scoring systems such as APACHE (acute physiology, age and chronic health evaluation) do not work well for trauma patients (see Chapter 3).<sup>41,42</sup> Preinjury illness (comorbidity) has a profound effect on trauma outcome.<sup>43</sup>

Shock influences trauma mortality and morbidity. The 'golden hour' is a catchy concept based on the observation that the longer the patient is in shock, the higher the probability of immediate or delayed complications. However, the specific timeframe of an hour has no real validity. Complications of shock include renal failure,

acute respiratory distress syndrome, sepsis, liver failure and multiorgan dysfunction.<sup>19,20,44</sup> Acute oliguric renal failure on the first day after trauma is now rare, but non-oliguric renal failure is often seen 2–4 days later, caused by the shock and delayed or inadequate resuscitation. It is often heralded by polyuria, which is misinterpreted as a sign of adequate resuscitation.

### EPIDEMIOLOGY OF INJURIES

Only a minority of victims of severe trauma reach hospital alive.<sup>45,46</sup> The majority of deaths are immediate (within minutes) at the scene of injury. Some deaths are early (within hours) in the emergency department or the operating room, and a few are late (after days or weeks) and occur in the ICU or ward.<sup>47</sup> Those in the ICU are mostly from severe head injury within a few days and, less commonly, multiorgan dysfunction later.

Of trauma admissions to hospital, only a minority have severe or multiple trauma.<sup>48</sup> In order of frequency, life-threatening injuries involve the head, abdomen and chest (Table 66.1), and are often multiple. The hospital services which this small number of severely injured patients use out of proportion to their numbers are major surgery, intensive care, radiography and CT scanning.<sup>48</sup> Major trauma outcome studies in the USA,<sup>37</sup> the UK<sup>38</sup> and Australia<sup>49</sup> offer valuable epidemiological data. The USA study found that the mortality of direct admissions is strongly related to serious head injury.

### ORGANISATION OF TRAUMA CARE

Many of the problems of trauma care are organisational. Problems faced by health authorities are the provision of advanced care at the scene of injury, rapid

**Table 66.1** Percentage of ICU trauma patients with grades of injury in different body regions

	AIS ≥4	AIS = 3	AIS = 1 or 2	AIS = 0
Head and neck	64	9	10	18
Face	2	11	8	79
Thorax	10	17	6	67
Abdomen	16	6	2	77
Extremities	1	33	10	56
External	0	<1	64	36

Data on 3965 adult trauma patients (excluding burns) in the DCCM, Auckland Hospital, 1988–2006. Abbreviated injury scale (AIS-80) codes:<sup>31</sup> 0 = no injury; 1 = minor; 2 = moderate; 3 = serious; not life-threatening; 4 = severe; life-threatening, survival probable; 5 = critical; survival uncertain; 6 = unsurvivable. In tertiary referral centres, these figures will vary with the mix of local and referred patients.<sup>50</sup>

transportation to hospital, policies on which hospitals should receive trauma patients, systems for rapid evaluation and decision-making in hospitals, and rapid, safe patient transfer between hospitals. If survival from major trauma is to be maximised, prehospital and hospital care must be coordinated.

Regionalisation of trauma care has become an accepted concept.<sup>2,51</sup> Trauma centres are designated hospitals which meet certain requirements. Main prerequisites are rapidly available experienced surgeons, anaesthetists and neurosurgeons, and a minimum number of patients seen annually for staff expertise. Regionalisation involves the concept of ambulances bypassing non-designated hospitals.<sup>2</sup> Helicopters are used increasingly to speed patient transportation.<sup>52</sup> Trauma teams are teams of surgeons and intensivists or anaesthetists who immediately attend the trauma victim on arrival at hospital.<sup>2-4,44</sup>

Trauma registries and databases are important tools in organising and improving trauma care. The UK major trauma outcome study<sup>38</sup> showed that the doctors in charge of resuscitation were often junior, delays in performing urgent operations were common, and the number of preventable deaths was significant. A hospital may not see enough trauma patients to justify a trauma team or supply adequate experience for its staff, and may not have all the facilities required by trauma patients. Transfer to a trauma hospital may be desirable, but geography and limited transport facilities may make such transfers hazardous.

In Western countries, trauma is a leading cause of death and disability under the age of 38 years.<sup>37</sup> Reduction of mortality and morbidity depends on public education, new legislations, on-site advanced care, rapid evacuation (see Chapter 4), hospital trauma expertise and coordination of services.<sup>53,54</sup>

# Severe head injury

John A Myburgh

Despite improvements in resuscitation and vital organ support, the management of patients with traumatic brain injury in the intensive care unit (ICU) presents a challenge to all members of the critical care team. As head injury is associated with a high mortality and morbidity, the benefits of intensive treatment and care may not become apparent until months or years later during rehabilitation after injury.

## EPIDEMIOLOGY

Traumatic brain injury has been termed a 'silent global epidemic'. It accounts for up to 30% of all trauma-related deaths and is the leading cause of death in young males in developed countries. The impact of mechanisation in developing countries has resulted in a sharp increase in the incidence and mortality from vehicular trauma.

In addition to this high mortality, the cost of survivors in these societies in emotional, social and financial terms is substantial as the effects of the original injury may persist for many years.

## AETIOLOGY

Vehicular trauma, industrial accidents, falls and assaults account for the majority of head injury, with marked variations in patterns of injury across the world. For example, in Australasia, the incidence of head injury due to vehicular trauma is decreasing due to the success of preventive strategies such as restraint devices, speed control and stricter drink-driving legislation.<sup>1</sup>

## DEMOGRAPHICS

The numbers of patients with traumatic brain injury presenting to hospitals vary widely in accordance with hospital admission policies and capabilities. Typical figures of all-cause head injury admissions in developed countries range from 200 to 300 per 100 000 patients.

Age and gender-specific data typically show two peaks: one in the second and third decades, with a male:female ratio of 2:1; the latter in the seventh to ninth decades with a more equivalent gender ratio.

## PATTERNS OF INJURY

Traumatic brain injury represents a range of injury from mild head injury that may fully recover to severe injury associated with high mortality or high levels of disability.

Injury may be either blunt or penetrating, with the latter associated with a higher mortality.

Although the majority of head injuries (70–80%) are minor, a significant proportion of these patients may have poor functional outcomes due to secondary brain insults, missed injuries and comorbidities. Of the 20–30% who constitute moderate to severe head injury, approximately 10% of these are dead on admission whilst the remainder will usually require admission to the ICU for management in the first 7–10 days.

## PATHOPHYSIOLOGY

Brain injury is a heterogenous pathophysiological process. It encompasses a spectrum of injury that includes the degree of brain damage at the time of injury (primary injury) in addition to insults that occur during the post-injury phase (secondary injury). These processes are depicted in Figure 67.1.

Both primary and secondary injuries are associated with the development of variable degrees of intracranial inflammation and disruption of cerebrovascular autoregulation.

An understanding of these processes is essential in order to quantify the severity of injury, direct appropriate management strategies and interpret information from clinical monitoring systems.

## PRIMARY BRAIN INJURY

The severity of primary injury is determined by the degree of neuronal damage or death at the time of impact. This is a major determinant of outcome from traumatic brain injury and, with the exception of surgically evacuable mass lesions, is usually irreversible.

Primary brain injuries include all types of injury to the brain parenchyma and vasculature. Primary injuries that are associated with adverse outcome include traumatic subarachnoid haemorrhage and non-evacuable mass lesions, particularly in critical parts of the brain such as the posterior fossa.

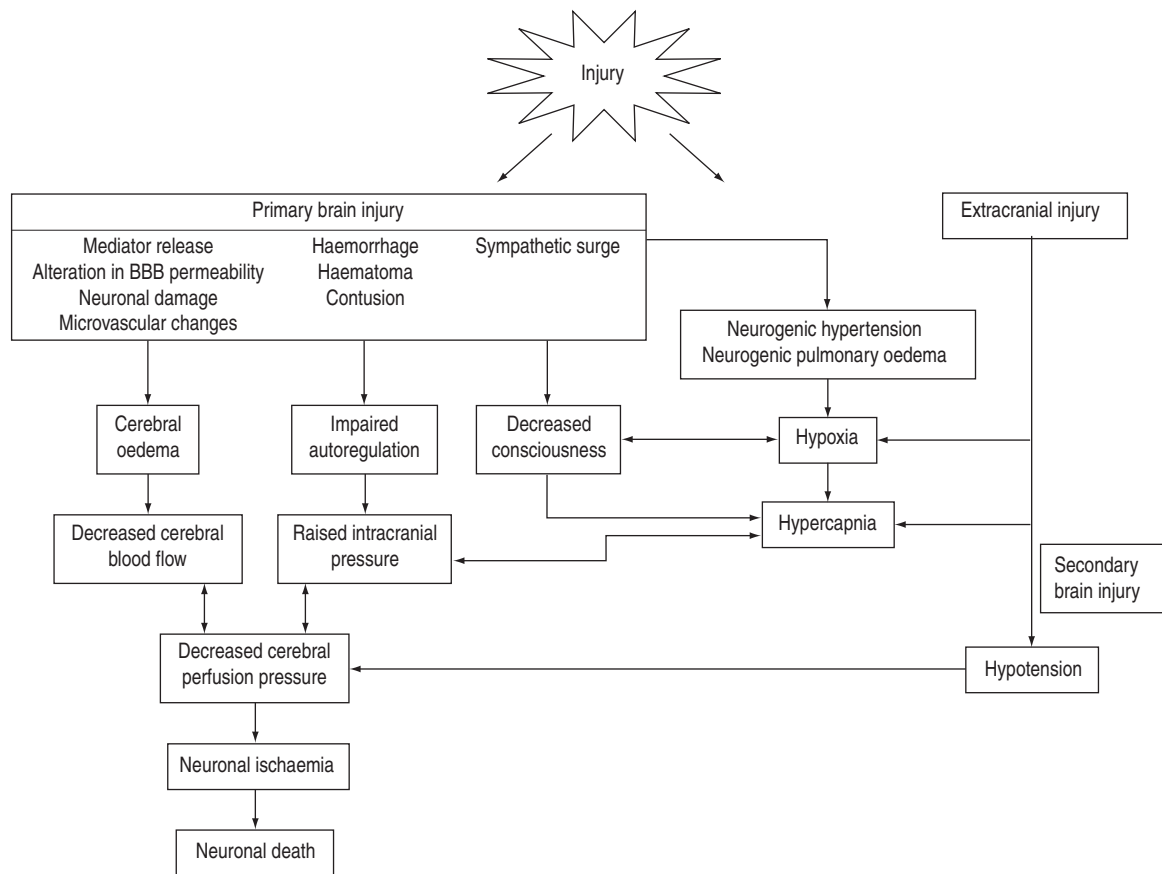

Figure 67.1 Pathophysiology of traumatic brain injury.

## SECONDARY BRAIN INJURY

Secondary brain insults are characterised by a reduction in cerebral substrate utilisation, particularly oxygen (Table 67.1). Of these insults, hypotension (defined as a systolic blood pressure of < 90 mmHg), hypoxia (oxygen saturation < 90% or  $P_{aO_2}$  < 50 mmHg), hypoglycaemia, hyperpyrexia (temperature > 39°C) and prolonged hypocapnia ( $P_{aCO_2}$  < 30 mmHg) have been shown to independently worsen survival following traumatic brain injury.

Secondary insults may occur during initial resuscitation, transport both between and within hospitals, during anaesthesia and surgery, and subsequently in the ICU. These insults may initiate or propagate pathophysiological processes which may fatally damage neurones already rendered susceptible by the primary injury. Consequently, a vicious circle of secondary brain damage may develop with adverse outcomes.

## INTRACRANIAL INFLAMMATION

As the brain is enclosed within the rigid skull and dura, small increases in intracranial volume result in sharp

increases in intracranial pressure (Monro–Kelly doctrine). Consequently, the brain is a poorly compliant organ that has a limited capacity to accommodate pathological increases in intracranial pressure.

Traumatic brain injury invokes an inflammatory response characterised by the release of cytokines, free

Table 67.1 Secondary brain insults following traumatic brain injury that are associated with increased morbidity and mortality

Systemic	Intracranial
Hypoxia	Seizure
Hypotension	Delayed haematoma
Hypocapnia	Subarachnoid haemorrhage
Hypercapnia	Vasospasm
Hyperthermia	Hydrocephalus
Hypoglycaemia	Neuroinfection

Hyponatraemia	
Hypernatraemia	
Hyperosmolality	
Infection	

radicals, excitatory amino acids and other mediators. The consequence of this response is disruption and alteration in the permeability of the blood–brain barrier, glial swelling and alterations in regional and global cerebral blood flow. The extent of this inflammatory process is an important determinant of intracranial pressure that may persist for some time following injury. Furthermore, alteration in blood–brain permeability may render the cerebral circulation susceptible to the effects of drugs that do not normally cross, such as osmotic diuretics and exogenous catecholamines.

### CEREBRAL BLOOD FLOW AND AUTOREGULATION

Normally, cerebral blood flow is maintained at a constant rate in the presence of changing perfusion pressures by myogenic and metabolic autoregulation. These homeostatic mechanisms are impaired following head injury due to neuronal damage and intracranial inflammation. Distinct patterns of cerebral blood flow have been described following head injury that have direct clinical relevance with regard to management<sup>2</sup> (Figure 67.2).

#### THE HYPOPERFUSION PHASE

Cerebral blood flow is reduced by extrinsic and intrinsic mechanisms in the first 72 hours following injury, with resultant global and regional ischaemia. Because myogenic autoregulation is markedly impaired during this period, cerebral blood flow in the hypoperfusion phase is directly dependent on systemic blood pressure. Resultant neuronal ischaemia may result in ‘cytotoxic’ cerebral oedema and increased intracranial pressure.

In order to maintain cerebral perfusion, systemic blood pressure must be maintained during this phase so that cerebral perfusion pressure (defined as the difference between mean arterial pressure and intracranial pressure) is maintained between 60 and 70 mmHg.<sup>3</sup>

#### THE HYPERAEMIC PHASE

Following the initial hypoperfusion phase, autoregulatory mechanisms may start to recover with improved cerebral blood flow.

During this phase, intracranial inflammation and/or effects of medical therapies directed at maintaining adequate cerebral perfusion pressure may result in cerebral hyperaemia and increased intracranial pressure. The consequences of hyperaemia, inflammation and altered blood–brain permeability result in ‘vasogenic’ cerebral oedema.

This hyperaemic phase may persist for up to 7–10 days post injury and occurs in 25–30% patients. As there is restoration or increased cerebral blood flow during this phase, a range of cerebral perfusion pressure is recommended (50–70 mmHg).<sup>4</sup>

#### THE VASOSPASTIC PHASE

In a small cohort of patients (10–15%), particularly those with severe primary and secondary injuries or those with significant traumatic subarachnoid haemorrhage, a vasospastic phase characterised by typical cerebral blood flow patterns may persist. This phase represents a complex of cerebral hypoperfusion due to arterial vasospasm, posttraumatic hypometabolism and impaired autoregulation.<sup>5</sup>

**Figure 67.2** Conceptual changes in cerebral blood flow and intracranial pressure (ICP) over time following traumatic brain injury: (a) cytotoxic oedema; (b) vasogenic oedema; (c) cerebral blood flow. CPP, cerebral perfusion pressure; MAP, mean arterial pressure.

## RESUSCITATION

### INITIAL ASSESSMENT

The resuscitation of head-injured patients should follow the principles outlined in the Advanced Trauma Life Support (ATLS®) guidelines for the early management of severe trauma.<sup>6</sup>

The initial emphasis is directed at assessing and controlling the airway, ensuring adequate oxygenation and ventilation, establishing adequate intravenous access and correcting haemodynamic inadequacy. Neurological assessment and brain-specific treatment should only follow once cardiorespiratory stability has occurred. Given the direct association between hypotension and hypoxia and adverse outcomes in traumatic brain injury, this is an absolute priority.

With respect to head-injured patients, the following principles in the initial assessment apply.<sup>7,8</sup>

#### AIRWAY

All patients with severe head injury (traumatic coma), marked agitation or significant extracranial trauma require early oral endotracheal intubation.

Depending on the skill of the operator and available facilities, this should be performed using a rapid sequence induction with cricoid pressure and in-line immobilisation of the cervical spine.

All head-injured patients should be assumed to have a potential cervical spine injury, and should be immobilised in a rigid collar until that possibility is definitively excluded.

#### BREATHING (= VENTILATION)

Patients should be ventilated in 100% oxygen using 6–10 ml/kg tidal volumes until blood gas analysis is available.

Oxygenation should be maintained at at least 100 mmHg (13 kPa) and the ventilator adjusted to achieve a normal arterial carbon dioxide tension (35–40 mmHg; 4.5–5.0 kPa).

Non-depolarising muscle relaxants and narcotics such as fentanyl may facilitate ventilation in the immediate post-intubation period in combative patients.

Empirical hyperventilation during initial resuscitation is not indicated until adequate oxygenation, haemodynamic stability and urgent computed tomography have been achieved.<sup>9</sup>

#### CIRCULATION (= CONTROL OF SHOCK)

Prompt restoration of circulating blood volume and restoration of a euvoaemic state is critical.<sup>10</sup>

An emerging body of evidence recommends the use of crystalloids, specifically normal saline, for fluid resuscitation of patients with traumatic brain injury. The use of albumin for fluid resuscitation is associated with increased mortality and should be avoided.<sup>11</sup> Hypertonic saline may have a role as a small-volume resuscitation fluid that is useful in expanding intravascular volume, with additional beneficial effects on cerebral blood flow and reduction of

cerebral oedema,<sup>12</sup> although there is no evidence of reduced mortality when used in the prehospital period.<sup>13</sup>

Early arterial monitoring for accurate measurement of mean arterial pressure and central venous catheter placement for providing a guide to volume replacement and administration of blood and drugs is essential. The placement of these lines must not delay volume resuscitation.

Inotropes, such as adrenaline (epinephrine) or noradrenaline (norepinephrine), or vasopressors such as phenylephrine or metaraminol, may be used to defend blood pressure once correction of hypovolaemia is underway or achieved.<sup>4</sup> This may be necessary if sedatives or narcotics are coadministered.

The use of military antishock trousers (MAST suit) in traumatic brain injury is not recommended.

#### DISABILITY (= NEUROLOGICAL ASSESSMENT)

Assessment of neurological function following injury is important to quantify the severity of neurotrauma and to provide prognostic information. The level of function may be influenced by associated injuries, hypoxia, hypotension and/or drug or alcohol intoxication. Similarly, recording the mechanism of injury is important, as high velocity injuries are associated with a greater degree of neuronal damage. It is important to review ambulance and emergency personnel and records in order to obtain the most accurate information.

#### Level of consciousness

The ATLS® recommends an initial assessment during initial resuscitation based on the response to stimulation: Awake, Verbal, Pain, Unresponsive (AVPU). This provides a rapid and practical grading of function with severe head injuries defined as those who respond to pain only or who are unresponsive.

The Glasgow Coma Scale (GCS) has an established place in the management of traumatic brain injury and is the most widely accepted and understood scale.<sup>14</sup> Whilst originally described as a prognostic index, it provides an overall assessment of neurological function, derived from three parameters: eye opening, verbal response and motor response (Table 67.2).

The best responses in the GCS components should be recorded following cardiorespiratory resuscitation and prior to surgical intervention in order to provide prognostic information. A GCS of 14–15 indicates a mild injury, 9–13 a moderate injury and 3–8 is classified as severe. In the severely injured, such as intubated patients or those with ocular or facial trauma, the motor response is the most useful.

#### Pupillary responses

Pupil size and reactivity are important when consciousness is impaired. Whilst not part of the GCS, pupillary function should always be assessed and recorded at the same time as the GCS, particularly prior to the administration of narcotics, sedatives or muscle relaxants.

**Table 67.2** The Glasgow Coma Scale.<sup>14</sup> The best response following non-surgical resuscitation is scored

Best eyes open score		Best verbal response		Best motor response	
Spontaneously	4	Orientated, adequate	5	Obeys spoken command	6
On spoken command	3	Disorientated, confused	4	Localized pain	5
To pain	2	Inappropriate words	3	Flexion withdrawal	4
No response	1	Incomprehensible	2	Abnormal flexion	3
		No response	1	Extension	2
				No response	1
		<i>Intubated patients:</i>			
		Appears able to converse	5		
		Questionable ability to converse	3		
		Unresponsive	1		

In the absence of traumatic mydriasis, abnormalities of pupil size and reactivity may indicate compression of the third cranial nerve, suggesting raised intracranial pressure or impending herniation, particularly when associated with lateralising motor signs and depressed consciousness.

Papilloedema is uncommon in the acute phase of head injuries.

#### Motor function

In addition to the motor response of the GCS, decerebrate or decorticate posturing, hemiparesis or lateralising signs, paraparesis and quadriparesis (given the high association with spinal injuries with traumatic brain injury) should be documented concurrently with the GCS and pupillary responses.

### SECONDARY SURVEY

Once the initial assessment is complete and resuscitation underway, a thorough secondary survey adopting a 'top-to-toe' approach is mandatory. This is outlined in the ATLS® approach to the traumatised patient.<sup>6</sup>

The principles outlined in the initial assessment form the basis for prioritising interventions in the secondary survey in traumatic brain injury. Extracranial causes of hypoxia such as pulmonary contusion or haemo/pneumothorax must be excluded and promptly treated. Haemorrhage – both externally from fractures or lacerations and internally from major vascular disruption or visceral injuries – must be aggressively treated until circulatory stability is achieved. There is no place for 'permissive hypotension' in head-injured patients as has been advocated in selected cases of penetrating trauma.

Target mean arterial pressure should be estimated in the context of the patient's premorbid blood pressure. Higher pressures may be necessary in hypertensive or elderly patients. The early use of inotropes such as adrenaline or noradrenaline may be necessary to achieve this.

An approach of 'damage-control surgery' is now advocated in head-injured patients to minimise secondary insults. In the initial 24–48 hours following injury, only life- or limb-threatening injuries should be addressed, following which patients are transferred to the ICU for

stabilisation and monitoring. Thereafter, semi-urgent surgery such as fixation of closed fractures or delayed plastic repairs may be done. Patients with severe head injury undergoing prolonged emergency surgery should ideally have intracranial pressure monitoring placed as soon as possible.

Routine X-rays of the chest, pelvis and cervical spine and baseline blood tests (including blood alcohol level in appropriate cases) are part of the secondary survey.

### BRAIN-SPECIFIC RESUSCITATION

The place of interventions and therapies specifically directed at reducing intracranial pressure has been extensively reviewed in evidence-based guidelines for the management of severe head injury. Whilst there is little evidence for the role of some therapies such as empirical hyperventilation and osmotherapy during resuscitation, they continue to be widely used in clinical practice.

#### HYPERVENTILATION

Ventilation-induced reductions in  $P_{aCO_2}$  result in marked reductions in cerebral blood flow and consequently in intracranial pressure. However, as cerebral blood flow may be reduced during the initial period following injury, further reductions in cerebral perfusion will result if hyperventilation is used during this phase (Figure 67.2).

Hyperventilation is associated with reductions in cerebral oxygenation, particularly in areas of neuronal damage, potentially exacerbating cerebral hypoxia. The combination of induced cerebral ischaemia in the damaged brain therefore offsets any theoretical benefit of reducing intracranial pressure. Consequently, empirical hyperventilation is not indicated during initial resuscitation when cerebral blood flow is compromised.

However, hyperventilation remains a potent non-surgical clinical tool of reducing intracranial pressure. In the resuscitated head-injured patient with unequivocal clinical signs of raised intracranial pressure or impending tentorial herniation (pupillary dilatation, lateralising signs or a witnessed neurological deterioration), hyperventilation is an option.

Reductions of  $P_{aCO_2}$  to levels  $\leq 30$  mmHg (4 kPa) may be therefore considered prior to urgent imaging or surgery for evacuation of a mass lesion.<sup>9</sup>

### OSMOTHERAPY

Osmotically active agents, such as mannitol, are widely used in the treatment of traumatic brain injury. Theoretically, mannitol is administered to increase plasma osmolality in order to cause net efflux of fluid from areas of damaged, oedematous brain, with resultant reduction in intracranial pressure. An intact blood–brain barrier is necessary for this to occur. Following intravenous administration of mannitol, an immediate plasma expanding effect that reduces haematocrit and viscosity ensues, which temporarily increases cerebral blood flow. Subsequent reductions in intracranial pressure probably result from restoration in cerebral perfusion pressure and rheological changes in cerebral blood flow, rather than specific cerebral dehydration.

Osmotherapy is associated with a number of potentially adverse effects. Mannitol exerts an osmotic effect over a narrow range of plasma osmolality (290–330 mosm/l) above which theoretically beneficial effects may be negated. Mannitol will induce an osmolal gap between measured and calculated osmolality, so that regular measurements of serum osmolality are necessary to monitor the amount administered. This gap may be further increased by alcohol that is frequently present in the acute period. Mannitol will enter the brain where the blood–brain barrier is damaged, thereby potentially increasing cerebral oedema by increasing brain osmolality. Mannitol is a potent osmotic diuretic that may compromise haemodynamic stability by inducing an inappropriate diuresis in a hypovolaemic patient. Consequently, systemic hypotension may ensue which may cause further cerebral ischaemia or subsequent organ dysfunction such as acute renal failure. This effect may be exacerbated by the concomitant administration of catecholamines in order to defend systemic blood pressure.

Given the high risk with minimal benefit during resuscitation, the routine use of mannitol is not recommended in the absence of raised intracranial pressure and in patients where cerebral blood flow is compromised.<sup>15</sup>

Similarly to hyperventilation, mannitol is considered as an option only in resuscitated patients with unequivocal signs of raised intracranial pressure prior to imaging or evacuation of a mass lesion. Although doses are frequently quoted as 0.25–1.0 g/kg, lower doses are equally as effective as higher doses in terms of improving cerebral perfusion and are associated with a lower incidence of side-effects.

Hypertonic saline (3% solution) exerts similar osmotic plasma expanding effects to mannitol. These solutions do not exert an osmolal gap so that serum sodium reflects serum osmolality allowing easier titration. These solutions have been advocated as ‘small-volume resuscitation fluids’ that may be very effective in restoring systemic and cerebral

perfusion in the acute phase following injury. In addition to reducing intracranial pressure, these solutions would appear to be superior to mannitol for resuscitation.<sup>16</sup>

### EMERGENCY SURGICAL DECOMPRESSION (‘BURR HOLES’)

The advent of better equipped in-field resuscitation, medical retrieval, imaging and innovations such as teleradiology and telemedicine has largely superseded the need to perform urgent craniotomy in head-injured patients. In most instances, patients are resuscitated, stabilised and imaged with CT scans prior to any surgical intervention. This may involve transfer to a specialised trauma centre. CT scanning provides accurate information and directs the surgeon to a mass lesion that needs evacuation under optimal circumstances.

In remote communities without immediate access to CT scanning, surgical evacuation may be lifesaving in patients with a clear history of an expanding mass lesion such as an extradural or subdural haematoma. These include patients with low velocity injuries to the temporal region and an associated skull fracture that have clinical signs of intracranial herniation or a witnessed deterioration.

## IMAGING

### X-RAYS

All head-injured patients receive the routine ‘trauma series’ of X-rays, namely chest, pelvis and cervical spine (lateral, anteroposterior and peg views), although the last may be superseded by high resolution CT scan of the entire cervical spine.<sup>17</sup>

Skull X-rays have essentially been superseded by CT scanning and their routine use in the emergency evaluation of head-injured patients has been questioned.

### COMPUTED TOMOGRAPHY (CT SCAN)

CT scanning is the most informative radiological technique in the evaluation of the acute head injury and is now standard in virtually all patients following head injury. CT scanning invariably requires moving the patient to a radiological suite. This must only be done once initial assessment and resuscitation are complete and the patient is stable enough to be transported by appropriately trained and equipped personnel.

The following patients should undergo CT head scan following traumatic brain injury:

- All patients with a history of loss of consciousness or traumatic coma.
- Combative patients where clinical assessment is masked by associated alcohol, drugs or extracranial injuries. These patients may require endotracheal intubation, sedation and ventilation to facilitate completion of CT scanning.

**Table 67.3** Classification of CT scan appearance following traumatic brain injury.<sup>16</sup> Examples are shown in Figure 67.3a

Category	Definition
Diffuse injury (DI) I	No visible intracranial pathology seen on CT scan
DI II (diffuse injury)	Cisterns are present with midline shift 0–5 mm and/or Lesion densities present No high or mixed density > 25 mm May include bony fragments and foreign bodies
DI III (swelling)	Cisterns are compressed or absent with midline shift 0–5 mm No high or mixed density > 25 mm
DI IV (shift)	Midline shift > 5 mm No high or mixed density > 25 mm
Evacuated mass lesion	Any lesion surgically evacuated
Non-evacuated mass lesion	High or mixed density lesion > 25 mm, not surgically evacuated

Technological advances in imaging now enable quick, high resolution digital images of the brain parenchyma and bony compartments. The most important role of CT scanning is prompt detection of mass lesion such as extradural or subdural haematomas. Thereafter, the degree of brain injury may be quantified by radiological criteria (Table 67.3 and Figure 67.3a).<sup>18</sup>

These criteria are important for:

1. providing an index of injury severity
2. providing criteria for intracranial pressure monitoring
3. comparing the progression of injuries with subsequent scans
4. providing an index for prognosis

These criteria should be recorded following each CT scan, particularly when patients are transferred to secondary or tertiary centres. Examples of typical injuries appear in Figure 67.3a and 67.3b.

The presence of traumatic subarachnoid haemorrhage should be recorded. This is an important index of severity of injury and is relevant for prognostication.<sup>19</sup>

### CEREBRAL ANGIOGRAPHY

Cerebral angiography should be considered when a vascular injury, such as carotid artery dissection, is suspected in head-injured patients. This may be indicated by a large isodense lesion on CT scan or when the patient's clinical condition is not consistent with the CT findings (e.g. a dense hemiparesis in the absence of a mass lesion).

### MAGNETIC RESONANCE IMAGING

Magnetic resonance imaging (MRI) provides accurate detail of parenchymal damage, specifically small collections and non-haemorrhagic contusions. However, the information provided is not significantly better than that obtained from CT scanning to warrant routine use of MRI in the acute phase of injury. In addition, the placement and monitoring of an acute traumatised patient in an MRI scanner poses an additional risk that is not justified by the information provided.

MRI may have an important role in prognostication at a later stage in management, particularly in mild and moderate head injury.

### INTERHOSPITAL TRANSFER

All severely head-injured patients should be managed in a specialised neurotrauma centre in close collaboration with intensive care physicians and neurosurgeons.<sup>20</sup> This may involve intra- or interhospital transportation. This is a potentially hazardous exercise and has the potential to adversely affect outcome by causing secondary insults. Consequently, appropriately skilled and equipped personnel should only do this once resuscitation, stabilisation and initial imaging are completed.

A full primary and secondary survey and review of all documentation and investigation is required following transfer to a secondary or tertiary centre.

### INTENSIVE CARE MANAGEMENT

There is no standard or uniform method of managing traumatic brain injury in the ICU. Most practices are determined by local preferences and experience, caseload and resources. The Brain Trauma Foundation of the American Association of Neurological Surgeons<sup>21</sup> and the European Brain Injury Consortium<sup>22</sup> have published evidence-based management guidelines for the management of severe brain injury. These publications provide very few standards by which to direct therapy and the majority of issues addressed are presented either as management guidelines or options.

Although management of head injury in the ICU will be considered in two sections – supportive therapy and brain-specific therapy – these occur simultaneously. The principles of management focus on the integration of all monitoring information in the context of the underlying injury so that secondary brain injury is prevented.

### SUPPORTIVE THERAPY

Following initial resuscitation, good intensive care management forms the basis of head injury management and is regarded as a continuum of care. This takes priority over brain-specific therapies, which to date remain inconclusive in their efficacy.

**Figure 67.3a** Computed tomographic classification of diffuse axonal injury (Table 67.3).<sup>33</sup> Panel (a) Diffuse injury II; Panel (b) Diffuse injury III; Panel (c) Diffuse injury IV.

#### **HAEMODYNAMIC MANAGEMENT**

##### **Monitoring**

Accurate measurement of systemic blood pressure is essential and should be measured via an arterial catheter referenced to the aortic root. A large artery such as the

femoral artery should be considered in haemodynamically unstable patients as radial or dorsalis pedis arterial catheters may underestimate true systemic pressure in shocked patients. Given the importance of maintaining adequate systemic pressures, non-invasive measurement of blood

pressure is not recommended during the acute phase of monitoring.<sup>10</sup>

Therapy should be titrated to mean arterial pressure in accordance with the patient's pre-morbid blood pressure – i.e. in older patients, higher mean arterial pressure (e.g. 80 mmHg) may be necessary.

Volume status should be assessed using clinical criteria, central venous pressure monitoring and hourly urine output.

Pulmonary artery catheterisation for the measurement of cardiac output and pulmonary artery pressures is rarely indicated in head-injured patients and is not recommended on current evidence.

### Fluid management

The attainment of a euvoelaemic state is essential throughout intensive care management. This is determined by standard measurements such as serum sodium and osmolality, urea and creatinine, pulse rate, right atrial and mean arterial pressure and urine output.

Resuscitative fluids depend on local preferences, as there is no evidence to recommend crystalloids over colloids.

Optimal rheology for the cerebral circulation requires a haematocrit of approximately 30%: patients should be transfused if actively bleeding or to maintain a haemoglobin between 8.5 and 10 g/l.

Maintenance fluids should be directed at maintaining a normal osmolality. As a general principle, glucose-containing solutions are not recommended; however, these may be required (i.e. as 5% dextrose in water) if patients become hyperosmolar (> 320 mosm/l).

### Inotropic therapy

Inotropes such as adrenaline, noradrenaline or dopamine are frequently used to augment mean arterial pressure to attain an adequate cerebral perfusion pressure. These should only be commenced once volume resuscitation is actively underway or complete. The early use of inotropes is increasingly being advocated during resuscitation as an important strategy during the hypoperfusion phase.<sup>4</sup>

There are no conclusive trials to recommend one inotrope over another or combination of inotropes. Adrenaline, noradrenaline and dopamine are equally effective in augmenting cerebral perfusion pressure. The degree by which these agents directly affect the cerebral circulation following head injury is unknown, although there is some evidence suggesting that dopamine has both direct cerebrovascular and adverse neuroendocrine effects.<sup>23,24</sup>

Adrenaline is widely used as an initial inotropic agent in doses titrated to achieve a desired mean or cerebral perfusion pressure. Whilst effective, it may be associated with metabolic side-effects such as hyperlactataemia and hyperglycaemia, which may complicate metabolic management. For this reason, noradrenaline is currently regarded by many as the initial agent of choice for patients with traumatic brain injury.<sup>25</sup>

Doses may range widely and high doses may be required to attain a desired cerebral perfusion pressure, particularly if cerebral perfusion pressures are targeted for > 72 hours. It is important to prescribe inotropes in the context of the underlying injury. Lower cerebral perfusion pressure targets (i.e. 50–70 mmHg), and therefore doses of inotropes, may be necessary if patients develop cerebral hyperaemia. Titration of inotropes may require an index of cerebral blood flow such as jugular venous saturation monitoring during this phase.

### Neurogenic hypertension

Neurogenic hypertension is common in the latter phases following injury (> 5 days) and is usually centrally mediated. It may be associated with ECG changes and/or supraventricular arrhythmias. It is usually self-limiting and correlates with the severity of injury. Treatment depends on the severity of the problem:  $\beta$ -blockers or centrally acting agents such as clonidine are usually effective; vasodilators are relatively contraindicated.

## RESPIRATORY THERAPY

### Monitoring

Continuous measurement of arterial oxygen saturation is essential.

Continuous measurement of end-tidal carbon dioxide is frequently performed, although the reliability is questionable and should be intermittently checked with arterial blood gases.

Monitoring of ventilatory parameters should be consistent with standard approaches and includes measurement of tidal volumes, respiratory rates, and inspiratory and expiratory airway pressures.

### Ventilation

The majority of patients with severe head injury will require mechanical ventilation to ensure adequate oxygenation and to maintain an arterial carbon dioxide tension between 36 and 40 mmHg (4.8–5.3 kPa).

The principles of optimal ventilation, humidification and weaning are addressed elsewhere. Strategies such as 'permissive hypercapnia' that are advocated for selected patients with acute lung injury or acute respiratory distress syndrome do not have a role in head-injured patients due to the requirement to maintain normocapnia.

Positive end-expiratory pressure (PEEP) is recommended at low levels (5–10 cmH<sub>2</sub>O) to maintain functional residual capacity and oxygenation. Higher levels may compromise blood pressure, particularly in hypovolaemic patients, and should be used with caution. High levels of PEEP (> 15 cmH<sub>2</sub>O) may compromise cerebral venous return but adverse effects on intracranial pressure are uncommon.

Weaning from ventilation should commence once intracranial pathology has stabilised – resolution of cerebral oedema on CT scan, control of intracranial hypertension and adequate cerebral perfusion pressures.

Trials of extubation should be carefully considered so that subsequent hypoxic episodes do not occur, as these are potent secondary insults.

Patients with slow recovery of adequate consciousness should be considered for early tracheostomy, either percutaneously or surgically.

### **Neurogenic pulmonary oedema**

This is a dramatic clinical syndrome that occurs in most patients with severe head injury and correlates with severity of injury. The underlying pathophysiological process is complex, but is primarily related to centrally mediated sympathetic overactivity. It is characterised by sudden onset of clinical pulmonary oedema, hypoxia, low filling pressures, poor lung compliance and bilateral lung infiltrates, usually within 2–8 hours following injury.

The process is usually self-limiting and treatment is primarily supportive, aimed at ensuring adequate oxygenation and ventilation. This usually requires endotracheal intubation and mechanical ventilation with the administration of PEEP. Ablation of sympathetic overactivity is effectively done with adequate sedation;  $\beta$ -blockade is usually unnecessary. Diuretics are effective but must be titrated against the volume status of the patient so that cerebral perfusion pressure is not compromised.<sup>26</sup>

The development of pulmonary oedema in patients with cardiac disease should be regarded as cardiogenic until proven otherwise.

### **Nosocomial pneumonia**

Head-injured patients who require prolonged ventilation are at increased risk of nosocomial pneumonia. This is associated with secondary brain injury and an increased mortality.<sup>27</sup> Risk factors include barbiturate and hypothermia therapy. Diagnosis and treatment are discussed elsewhere.

### **SEDATION, ANALGESIA AND MUSCLE RELAXANTS**

There are no standards for sedation and analgesia in head injured patients – protocols will depend on local preferences and resources. The level of sedation and analgesia required for head-injured patients depends on the degree of traumatic coma, haemodynamic stability, intracranial pressure and systemic effects of the head injury itself.

During the resuscitation phase, where cerebral hypoperfusion is common, sedation should be titrated to cause the least effect on systemic blood pressure. During this period, short-acting narcotics such as fentanyl are useful, particularly if patients have associated extracranial injuries. These agents have relatively little adverse effect on haemodynamics and have the additional benefit of tempering systemic sympathetic surges that frequently occur after injury. As narcotics affect pupillary responses, these must be documented before administration, and CT scan should be performed soon afterwards to define baseline intracranial pathology. Short-term muscle relaxants such as vecuronium are useful during this phase to control combative patients following intubation, ventilation and sedation.

During the intensive care phase, the requirements for sedation are different. Sedation should be titrated to have the patient sedated as lightly as possible to allow clinical assessment of neurological function and to facilitate mechanical ventilation. The level of sedation will depend on haemodynamic stability and the degree of intracranial pressure. Infusions of narcotics and benzodiazepines (e.g. morphine and midazolam) are useful in providing moderate to deep levels of sedation and are effective in controlling surges of intracranial pressure. However, these agents may accumulate, resulting in a delay in return of consciousness or, if used for prolonged periods, may be associated with an emergence delirium state.

The use of propofol as a sole sedating agent has become popular.<sup>28</sup> It provides deep levels of sedation, which is effective in controlling systemic sympathetic swings and rises in intracranial pressure. It is rapidly reversible on cessation allowing prompt assessment of neurological status and does not accumulate. In addition, pupillary responses are not directly affected. Propofol should be used with caution in haemodynamically unstable patients, as it is a potent negative inotrope. The prolonged use of propofol is associated with tachyphylaxis and significant caloric loading from the lipid vector. Concerns have been raised about myocardial depression and sudden cardiac death, particularly if large doses are administered.<sup>29</sup>

The routine use of muscle relaxants is not recommended either to facilitate sedation or to control raised intracranial pressure. The prolonged use of these agents is associated with adverse outcome in traumatic brain injury and prolonged use of non-depolarising muscle relaxants is associated with polyneuromyopathies.

### **BODY POSITION**

Patients should be nursed at 30–45° head elevation to facilitate ventilation, improve oxygenation, and reduce the risk of aspiration. The head should be kept in a neutral position.<sup>30</sup>

### **PHYSIOTHERAPY**

Physiotherapy has an important role to play in the removal of lung secretions, prevention of contractures and venous thrombosis. Patients with raised intracranial pressure may require boluses of sedation before chest physiotherapy to prevent acute rises in intracranial pressure.

### **METABOLIC MANAGEMENT**

Routine measurement of biochemistry is essential with the aim of keeping all parameters within normal limits. The syndrome of inappropriate antidiuretic hormone secretion (SIADH) and diabetes insipidus may occur following head injury. Management is discussed elsewhere.

Hyperglycaemia is common following severe head injury and is usually centrally mediated and transient. Blood sugar levels should be maintained within normal limits with insulin infusions. The role of 'tight' glycaemic control (i.e. 4.0–6.0 mmol/l) in patients with traumatic

brain injury has not been determined and as hypoglycaemia is a recognised secondary insult, normal blood sugar levels (i.e. 8.0–10.0 mmol/l) are recommended.

Core temperature should be routinely monitored as hyperthermia has been identified as a cause of secondary injury. However, the real incidence of hyperpyrexia secondary brain damage may be underestimated as a temperature gradient of 1–2°C between core and brain temperature has been demonstrated and efforts should be directed at maintaining core temperature at 37.5°C.

### **NUTRITION**

The caloric needs of head-injured patients must be addressed as soon as possible following resuscitation. Early enteral feeding is recommended.<sup>31</sup>

Placement of a nasogastric and/or enteral feeding tubes in head-injured patients is usually via the oral route until an anterior cranial fossa (fractured cribriform plate) is excluded. Thereafter, post-pyloric tubes, via the oral, nasal or percutaneous route, are recommended as gastroparesis is common following head injury.

### **STRESS ULCER PROPHYLAXIS**

The incidence of gastric erosions and ‘stress ulceration’ has markedly decreased with better resuscitation and early enteral feeding. Head-injured patients are at no more risk than other critically ill patients for developing stress ulceration.

H<sub>2</sub> antagonists, such as ranitidine, should be used in ventilated patients until enteral feeding is established, following which they may be ceased.

Patients with a previous history of peptic ulceration should remain on antacid therapy for the duration of the intensive care stay.

### **THROMBOPROPHYLAXIS**

Head-injured patients, particularly those requiring prolonged ventilation and sedation, or with extracranial injuries, are at increased risk for developing thromboembolism. The use of anticoagulants such as fractionated or low molecular weight heparins is contraindicated in patients with intracranial haemorrhage. Consequently, the role of thromboprophylactic agents in head injury is difficult and there are no standards for their use.<sup>32</sup>

As a general rule, anticoagulants should not be used in head-injured patients with any evidence of destructive intracranial pathology or haemorrhage, until there is resolution of these processes on CT scan.

Non-pharmacological methods of thromboprophylaxis such as elastic stockings or pneumatic calf compressors are unproven, but provide a reasonable alternative. Frequent surveillance using Doppler ultrasound of the iliofemoral veins in high-risk patients, such as those with pelvic fractures, should be performed. Patients who develop deep-vein thromboses and who cannot be anticoagulated should be considered for inferior vena caval filters. The use of anticoagulants in head-injured patients with proven pulmonary embolism will depend on the relative risk to the patients’ life.

### **ANTIBIOTICS**

These should be used sparingly and in accordance with accepted microbiological principles. Prophylactic antibiotics should only be prescribed to cover insertion of intracranial pressure monitors and are not recommended for basal skull fractures.<sup>33</sup> Frequent cultures of leaking or draining cerebrospinal fluid should be taken and infection treated specifically.

### **BRAIN-SPECIFIC MONITORING**

The most accurate assessment of brain function following traumatic brain injury is a full clinical neurological examination in the absence of drugs or sedatives. However, this is often not possible for the majority of head-injured patients managed in the ICU.

Ideally, neuromonitoring should provide accurate and integrated information about intracranial pressure–volume relationships (elastance), patterns and adequacy of cerebral perfusion, and an assessment of cerebral function. No such monitor exists, although each of these parameters may be monitored in various ways with variable levels of accuracy and clinical utility.

### **CLINICAL ASSESSMENT**

Regular assessments of GCS, pupillary signs and motor responses (see above) should be made and recorded in the ICU flow chart. Concomitant sedation may influence the level of consciousness and this should be recorded. Initially, these assessments are recorded hourly, but this may change as patients become more stable.

A witnessed deterioration in GCS, especially the motor response, or the development of new lateralising signs should be regarded as life-threatening intracranial hypertension or tentorial herniation until proven otherwise.

### **INTRACRANIAL ELASTANCE**

#### **Intracranial pressure monitoring**

The recognition that raised intracranial pressure is associated with adverse outcome led to the measurement of this parameter in order to quantify the degree of injury and to assess the response to treatments directed at reducing intracranial pressure.

The Brain Trauma Foundation guidelines recommend intracranial pressure monitoring in patients with traumatic coma (severe head injury: GCS = 8 following non-surgical resuscitation)<sup>34</sup> with either:

- abnormal CT scan:
  - diffuse injury II–IV (Table 67.3) or
  - high or mixed density lesions > 25 mm
- normal CT scan with two or more of the following features.
  - age > 40 years
  - unilateral or bilateral motor posturing
  - significant extracranial trauma with systolic hypotension (< 90 mmHg)

Coagulopathy is a contraindication to intracranial pressure monitoring. Measurement of intracranial pressure<sup>35</sup> with an intraventricular catheter is the most accurate and clinically useful method. It has the advantages of zero calibration, cerebrospinal fluid drainage for raised intracranial pressure and allows dynamic testing of pressure–volume relationships. Disadvantages include technical difficulty with insertion, particularly in patients with cerebral oedema and compression of the lateral ventricles, and an increased incidence of infection.

Solid state systems such as fiberoptic (e.g. Camino<sup>®</sup>) or strain gauge tipped catheters (e.g. Codman<sup>®</sup>) may be placed intraparenchymally or intraventricularly. These systems transduce intracranial pressure to provide high fidelity waveforms. They are small calibre and although requiring a small craniotomy (burr hole) for insertion, may be inserted at the bedside. Disadvantages include inability to perform zero calibration after insertion and baseline drift that may be clinically significant after 5 days.

Fluid-filled subdural catheters have been used for many years. However, these are no longer recommended due to the development of more accurate solid state systems. Subdural pressures do not accurately reflect global intracranial pressure, particularly in the presence of a craniectomy. Pressure readings may also be affected by local clot formation within the catheter.

Measurements are used to calculate cerebral perfusion pressure: mean arterial pressure minus intracranial pressure. For this calculation, both measurements should be referenced to the external auditory meatus (equivalent to the circle of Willis).

Intracranial pressure monitoring should be continued until the patient can be assessed clinically, intracranial pressure has stabilised (< 20–25 cmH<sub>2</sub>O) and cerebral oedema has resolved on CT scan. This occurs in the majority of patients within 7 days. Patients with refractory intracranial hypertension may require monitoring for longer periods, although this may be complicated by drift (with solid state systems), infection (with intraventricular catheters) or occlusion (subdural catheters). In this situation, intracranial pressure monitors may need to be replaced or removed and patients assessed by serial CT scan or clinically.

### CEREBRAL BLOOD FLOW

Currently, there is no method of routinely measuring cerebral blood flow at the bedside. Technological advances such as mapping with labelled xenon under computed tomography and laser Doppler flowmetry provide useful imaging of regional and cerebral blood flow. However, these techniques are intermittent, labour intensive and limited to research-based units.

A number of qualitative measurement techniques are available that provide an indirect assessment of cerebral blood flow that may be useful, particularly when used in conjunction with other modalities such as intracranial pressure monitoring and CT scanning. Interpretation of

these measurements must be taken within the clinical context, particularly the time course of the underlying injury (Figure 67.2).

### Jugular bulb oximetry

Measurement of oxygen saturation in the jugular bulb by the retrograde placement of a fiberoptic catheter provides an indirect assessment of cerebral perfusion. Low jugular venous saturations (< 55%) may be indicative of cerebral hypoperfusion due to systemic hypotension or hypocapnia. High levels of jugular venous saturation (> 85%) may be indicative of cerebral hyperaemia or inadequate neuronal metabolism, such as occurs during the hyperaemic phase or during the evolution of brain death. Both low and high jugular venous saturation are associated with adverse outcomes.<sup>36</sup>

There are insufficient data to provide evidence-based indications for the routine use of jugular bulb oximetry. Its use is limited to experienced units when an index of cerebral blood flow is required during adjunctive therapies in patients with intracranial hypertension – for example, cerebral perfusion pressure augmentation with catecholamines, barbiturate coma, hyperventilation or hypothermia.

### Transcranial Doppler

Transcranial Doppler ultrasonography with a 2 MHz pulsed Doppler probe allows non-invasive, intermittent or continuous assessment of the velocity of blood flow through large cerebral vessels. Insonation through a naturally occurring acoustic window such as the trans-temporal approach allows insonation of the anterior, middle and posterior cerebral arteries, terminal internal carotid artery and anterior and posterior communicating arteries.<sup>37</sup>

Measured indices of flow include systolic, mean and diastolic flow velocities. Distinct patterns associated with normal, hyperaemic, vasospastic and absent flow are recognised. Derived indices such as the Gosling pulsatility index (systolic/diastolic difference divided by the mean velocity) and Lindegaard ratio (between middle cerebral artery to extracranial internal carotid artery) may assist in differentiating these flow patterns.

Despite increasing use of transcranial Doppler to diagnose posttraumatic hyperaemia and vasospasm, there are insufficient data to provide evidence-based indications for the routine use of transcranial Doppler.

Continuous measurements and trends of transcranial Doppler provide a better assessment of flow/velocity patterns than intermittent or daily measurements. The technique is operator-dependent and there may be significant variations in velocity patterns during the course of the injury. Consequently, interpretation of intermittent measurements should be made in conjunction with other variables such as CT scan appearance, intracranial pressure and, where applicable, jugular venous saturation.

## CEREBRAL FUNCTION AND METABOLISM

### Electroencephalography

Electroencephalography has been used for many years to assess seizure activity that may be masked by sedatives or muscle relaxants and to provide an objective estimate of the degree of electrical neuronal depression with barbiturate therapy. Whilst seizures may not be clinically apparent in a proportion of patients, and may constitute an important secondary insult, the accuracy and reliability of electroencephalography in ICUs is questionable due to outside electrical interference from monitors and ventilators.<sup>38</sup>

The development of bispectral index (BIS monitoring) as a measurement of depth of anaesthesia has led to the suggestion that this may be an alternative to the use of electroencephalography with barbiturate or sedative therapy in traumatic brain injury. Bispectral index has not been validated in this context and cannot be recommended as a titration end-point.<sup>39</sup>

Other forms of electroencephalography such as processed electroencephalography and integrated cerebral function monitors have a limited role in head-injured patients due to the amount of data generated and the need for skilled personnel to acquire and interpret the data.

### Evoked potentials

Measurement of evoked potentials, assessing the integrity of sensory and motor pathways, may provide diagnostic and prognostic information; however, because of the complexity of the technique, it is not recommended for general use.<sup>40</sup> The reliance of one variable, such as evoked potentials, to predict outcome from traumatic brain injury is not recommended.

### Neuronal function

Research developments in microprobe technology have resulted in specific electrodes that may be placed into the brain parenchyma to measure brain oxygen, pH and carbon dioxide tensions. These may be individual electrodes or combined with other sensors such as pressure monitors to form multimodal tissue monitors.

Cerebral microdialysis is a technique that measures brain extracellular fluid metabolites. Dialysate is obtained through a microdialysis catheter inserted through the same burr hole as an intracranial pressure monitor to measure concentration and fluxes of markers of intracranial inflammation (e.g. lactate, pyruvate and purines).<sup>41</sup>

Whilst these systems provide highly specific information about the biochemical milieu of focal areas of brain tissue, their clinical utility is limited to research centres.

## BRAIN INJURY SURVEILLANCE

Serial assessment of the anatomical injury is an essential part of monitoring head injury. This is done by serial CT scanning at frequent intervals depending on the neurological status of the patient.

Any patient who develops an unexplained neurological deterioration or significant validated deviation of monitored parameters should have a CT scan so that new or delayed intracranial mass lesions are identified.

CT scans should be assessed and scored according to the classification outlined in Table 67.3. The progression or resolution of axonal injury, cerebral oedema, contusion and haemorrhages should be recorded. Other parameters such as intracranial pressure and jugular venous saturation should be interpreted in accordance with the CT scan appearance.

However, as CT scanning requires transport of the patient to a radiology suite, this should only be done by experienced personnel when the patient is stable.

## BRAIN-SPECIFIC THERAPY

Treatment options directed at ameliorating brain injury are limited. Despite intensive research into defining the pathological processes in primary injury, studies analysing therapies designed to modulate intracranial inflammation have not been successful. These include aminosteroids, calcium channel blockade and *N*-methyl-D-aspartic acid (NMDA) antagonists.<sup>42</sup>

Brain-specific or 'targeted' therapy is directed at maintaining cerebral perfusion pressure and minimising intracranial pressure. Whilst there is an inherent relationship between these two principles, priorities are different depending on the time course of the underlying injury. This is important as strategies directed at one may have adverse effects in the other (Figure 67.2).

### DEFENCE OF CEREBRAL PERFUSION PRESSURE

The pathophysiological principles outlined on p. 765 are important in defining strategies to optimise cerebral perfusion pressure following injury. Whilst the Brain Trauma Foundation guidelines recommend a cerebral perfusion pressure of 60–70 mmHg, this figure may not be applicable over the entire time course following injury.<sup>3</sup>

This requires a change from a 'set and forget' philosophy to one of 'titration against time' in order to prescribe desirable therapeutic targets.

### Hypoperfusion phase (0–72 hours)

Cerebral hypoperfusion is present in the majority of patients with severe head injury (GCS = 8). During this phase, augmentation of cerebral perfusion pressure is paramount and should be done by maintaining adequate haemodynamic function.

The principles outlined above on 'Haemodynamic management' become the mainstay of defence of cerebral perfusion pressure. This phase should be regarded as an extension of resuscitation and supportive treatment. During this period, a cerebral perfusion pressure of at least 60 mmHg is recommended. In addition to reduced cerebral blood flow, intracranial pressure may be increased by mass lesions or 'cytotoxic' cerebral oedema. The latter will usually respond to restoration of cerebral perfusion pressure.

During this phase, medical therapies directed at raised intracranial pressure such as osmotherapy or hyperventilation should only be used if cerebral perfusion pressure is maintained at an appropriate level and the patient is adequately monitored.

Assessment of adequacy of the response to augmentation of cerebral perfusion pressure is made by intracranial pressure trends, CT scan appearance and, where possible, neurological assessment. If patients appear to have stabilised, sedation may be reduced with the aim of extubation.

#### **Hyperaemic phase (3–7 days)**

Approximately 25–30% of patients will develop clinical signs of cerebral hyperaemia, characterised by raised intracranial pressure, persistent cerebral oedema on CT scan and possibly confirmed by high jugular venous saturations.<sup>43</sup> This may be due to vasogenic cerebral oedema caused by intracranial inflammation or by catecholamine infusions often used to augment cerebral perfusion pressure.

The diagnosis of catecholamine-induced cerebral hyperaemia is difficult. This should be suspected in patients who require progressively increasing doses of catecholamines (e.g. > 20 µg/min of adrenaline or noradrenaline) to attain a prescribed cerebral perfusion pressure of 60 mmHg. This phenomenon is due to tachyphylaxis to prolonged catecholamine infusions and may be responsible for iatrogenically increasing intracranial pressure.

If CT appearance is unchanged, cerebral perfusion pressure targets may be lowered in order to use lower doses of inotropes. This exercise may be facilitated by jugular venous saturation monitoring or transcranial Doppler to provide an index of adequate cerebral blood flow for the lower cerebral perfusion pressure.

If patients continue to have raised intracranial pressure, strategies directed at reducing intracranial pressure should be considered.

#### **REDUCTION OF INTRACRANIAL PRESSURE**

In the absence of intracranial mass lesions, raised intracranial pressure is usually an indicator of severity of the underlying injury and represents exhausted intracranial elastance.

The most effective methods of reducing raised intracranial pressure are mechanical interventions such as removal of mass lesions, drainage of cerebrospinal fluid or decompressive craniectomy.

A number of medical strategies directed at reducing intracranial pressure have been used for many years. Despite widespread use and firmly held beliefs, there is little evidence to support the routine use of these therapies.<sup>44</sup>

Intracranial pressure should be maintained at < 25 cmH<sub>2</sub>O.<sup>45</sup> Trends of intracranial pressure are equally as important and should be assessed within the context of cerebral perfusion pressure and the methods used to defend it.

#### **Surgical evacuation of mass lesions**

The prompt detection and evacuation of mass lesions causing raised intracranial pressure is the most effective method of relieving intracranial hypertension. Although the majority of these lesions will be present immediately after injury and will be treated during the resuscitative phase, approximately 10% patients will develop delayed intracranial haematomas. These are detected by sudden unexplained rises in intracranial pressure or by CT scan surveillance.

Close liaison and coordination with neurosurgeons is essential.

#### **Cerebrospinal fluid drainage**

Drainage of cerebrospinal fluid through an intraventricular catheter is an effective method of reducing intracranial pressure. If present, these catheters should be placed 5–10 cm above the head and opened for drainage every 1–4 hours.

#### **Decompressive craniectomy**

Wide, bilateral, frontoparietal craniectomies are increasingly being advocated to reduce intracranial pressure in patients with refractory intracranial hypertension. Whilst there are numerous case series demonstrating dramatic improvements, there are no conclusive outcome-based trials to make firm recommendations.<sup>46</sup>

Recent experience in paediatric patients is encouraging and the role of pre-emptive decompressive craniectomy in high-risk patients is yet to be determined.<sup>47</sup>

#### **Osmotherapy**

The rationale and role of osmotherapy using mannitol or hypertonic solution is addressed on p. 780. The same principles during resuscitation apply during intensive care management.

Mannitol or hypertonic saline should only be used in patients with validated intracranial hypertension who are euvoaemic, haemodynamically stable, with a serum osmolality < 320 mosm/l.

There is no evidence that osmotherapy or induced dehydration improves outcome or is more effective in cytotoxic than vasogenic cerebral oedema.<sup>15</sup>

#### **Hyperventilation**

The role of hyperventilation during intensive care management is limited to the indications outlined on p. 780.

The routine prolonged use of hyperventilation in head-injured patients is associated with a worse outcome than patients ventilated to normocapnia. This is probably due to reductions of cerebral blood flow and secondary brain ischaemia.

Current evidence-based guidelines do not recommend the use of routine hyperventilation.<sup>9</sup>

#### **Hypothermia**

Induced hypothermia has been used for many years to reduce cerebral metabolism and thereby raised intracranial pressure. A sound theoretical benefit exists in experimental models where hypothermia is induced immediately

following injury with prompt reduction in raised intracranial pressure. However, these benefits have not translated into improved outcomes in a number of clinical trials.<sup>48</sup>

Induced hypothermia (to temperatures of 30–33°C) is associated with prolonged ventilation and increased susceptibility to nosocomial infection, and may be associated with increased morbidity and mortality in head-injured patients.

Currently, hypothermia is regarded as a 'second tier' option in patients with refractory intracranial hypertension, but on current evidence, cannot be recommended.

### **Barbiturate coma**

The role of barbiturates in traumatic brain injury is similar to hypothermia. Despite experimental evidence that barbiturates reduce cerebral metabolism and reduce intracranial pressure, no definitive studies have shown a benefit in clinical trials. Barbiturates have invariably been used in patients with refractory intracranial hypertension where a positive outcome was unlikely, making interpretation of these trials difficult.

Titration of barbiturate coma to burst suppression on an electroencephalograph is suggested as a reasonable end-point. However, this is often difficult to obtain and measure.

Barbiturates may cause hypotension and reduce cerebral blood flow, potentially exacerbating secondary insults in patients with cerebral oligaemia. Prolonged use of barbiturates will delay awakening and predispose the patient to nosocomial infection.

Barbiturates are a 'second tier' option in patients with refractory intracranial hypertension and not recommended on current evidence.<sup>49</sup>

### **Steroids**

Steroids have been advocated for many years to ameliorate intracranial inflammation, thereby reducing intracranial pressure. A large international study has provided conclusive evidence that steroids may be associated with adverse outcomes in traumatic brain injury, and therefore have no place in management.<sup>50,51</sup>

### **Cerebral blood volume regulation**

Following resuscitation and stabilisation, a strategy reducing cerebral perfusion pressure to > 50 mmHg using colloids,  $\beta$ -blockade, clonidine and dihydroergotamine may be effective in minimising secondary cerebral hyperaemia and vasogenic oedema. This strategy requires a measurement of cerebral blood flow to demonstrate adequate cerebral perfusion.<sup>52</sup>

### **CEREBRAL VASOSPASM**

Posttraumatic cerebral vasospasm occurs in approximately 10–15% of patients. It is associated with a high morbidity and mortality. It is frequently present in patients with traumatic subarachnoid haemorrhage and is a marker of severity of injury.

Cerebral angiography and transcranial Doppler are frequently used to diagnose vasospasm, although false positives and negatives exist with both techniques and the true incidence of clinically significant vasospasm is uncertain.

Treatment options remain limited. Calcium antagonists, such as nimodipine, have not been shown to be effective in traumatic subarachnoid haemorrhage. Strategies that have been used in aneurysmal subarachnoid haemorrhage such as 'triple H' therapy (induced hypertension, hypervolaemia and haemodilution) or chemical angioplasty have not been evaluated in traumatic subarachnoid haemorrhage and are not recommended.<sup>5</sup>

### **SEIZURE PROPHYLAXIS**

Seizures are infrequent following traumatic brain injury and usually present at the time of injury. These should be treated with anticonvulsants (e.g. diazepam, midazolam) when they occur. Subsequent prophylaxis with phenytoin is recommended only in patients with destructive parenchymal lesions on CT scan and continued for 10 days following injury. Short-term seizure prophylaxis does not prevent late onset posttraumatic epilepsy.<sup>53</sup>

## **OUTCOME AND PROGNOSIS**

Patient factors that determine outcome from traumatic brain injury include severity of primary and secondary injuries, low GCS on presentation,<sup>54</sup> advanced age (> 60 years)<sup>55</sup> and comorbidities. Prediction of outcome is difficult and must be made with circumspection as significant functional improvements, particularly in young patients, may occur over time.

There are patients in whom the prognosis is clearly very poor or hopeless. A proportion of these patients will become brain dead and may be considered for organ donation. This is discussed elsewhere. In other patients, it may be appropriate to withdraw active treatment. This increasingly complex process requires time, careful consideration and consensus with all members of the health care and relatives.

Outcomes from traumatic brain injury are difficult to quantify. Whilst mortality is an easy end-point to measure, functional outcome is an equally important measurement, as the effects of traumatic brain injury on psychosocial recovery and duration of rehabilitation often take extended periods of time.

The future challenge facing the intensive care management of traumatic brain injury is to determine whether standards of practice and innovations improve mortality and functional survival. There is a responsibility to ensure that accurate outcome data are collected both at institution and regional levels. This will define the epidemiology and provide the basis for future studies.

# Maxillofacial and upper-airway injuries

Cyrus Edibam

## MAXILLOFACIAL INJURIES

Life-threatening haemorrhage and airway obstruction are common complications accompanying severe blunt or penetrating maxillofacial and neck injury. Injuries may be isolated or part of multisystem trauma. Up to 20% of people with facial injury will have life-threatening associated injuries: 15% with closed head injury, 3.5% with airway obstruction and 1.5% with pulmonary contusion and/or aspiration.<sup>1–3</sup> Urgent skilled airway management and awareness of other commonly associated injuries to the brain, cervical spine, thorax and oesophagus are paramount in preventing adverse outcomes. This chapter outlines the basic anatomy, pathology, complications and common pitfalls in the emergency management of maxillofacial, upper-airway and non-bony neck trauma.

## EPIDEMIOLOGY

Maxillofacial trauma occurs most frequently in the 20–25 years age group, decreasing in frequency either side of this age group. It is three to five times more likely to occur in males than in females. Blunt injury is by far the commonest mechanism, accounting for nearly 97% of all maxillofacial injuries.<sup>4</sup> Motor vehicle accidents (MVAs) account for nearly three-quarters of blunt injuries, with falls, physical assault, contact sports and industrial accidents accounting for the remainder. Legislative changes and preventative measures involving drink-driving, seat-belt and airbag use have seen a reduction in the incidence of MVA-related maxillofacial injury.<sup>5,6</sup> In multiple trauma patients with an injury severity score (ISS) > 12, maxillofacial injury occurs in up to 17%, with a corresponding mortality rate of 13%.<sup>4</sup>

## ANATOMICAL ASPECTS

Fractures, haemorrhage, soft-tissue damage and oedema are the commonest manifestations of blunt facial trauma. The severity of facial injury is directly related to the velocity of force applied.<sup>7</sup> Common fractures of facial bones are maxilla (23%), orbital region (22%), zygoma (16%), nasal bones (15%), mandible (13%), teeth (8%), alveolar ridge (2%) and temporomandibular joint (TMJ) 1%.<sup>4</sup>

## MANDIBULAR FRACTURES

The mandible is a unique, horseshoe-shaped bone that is tubular and weakest where the cortices are thinnest; most fractures occur at vulnerable points, regardless of the point of impact.<sup>8</sup> Common sites are the ramus (condylar neck and angle of the mandible) and body at the level of the first or second molar. Multiple fractures are common (64%),<sup>8</sup> with body of mandible fractures often being accompanied by fractures of the opposite angle or neck, due to transmitted forces. Mandibular fragments are often distracted due to the action of the lower jaw muscles. Respiratory obstruction may occur after bilateral mandibular angle or body fractures due to the posterior displacement of the tongue – the ‘Andy Gump’ fracture.<sup>9,10</sup>

## MIDFACIAL FRACTURES

The bones of the middle third of the face are relatively thin and poorly reinforced. Fracture dislocations occur through the bones and suture lines and the facial skeleton acts as a compressible energy-absorbing mass that gives on impact. The series of compartments (nasal cavity, paranasal sinuses and orbits) within the bony framework collapse progressively, absorbing energy and protecting the brain, spinal cord and other vital structures.<sup>11</sup> Multiple complex facial fractures usually result and isolated facial bone fractures are rare. Le Fort described three great lines of weakness in the facial skeleton and thus derived the Le Fort classification of fractures<sup>12</sup> (Figure 68.1). Le Fort fractures are perpendicular to the three main vertical buttresses of the facial skeleton – the nasomaxillary, zygomaticomaxillary and pterygomaxillary ‘pillars’. Le Fort fractures rarely occur in their pure form with mixed patterns prevailing (e.g. right hemifacial Le Fort I and left hemifacial Le Fort II). Airway obstruction from posterior movement of the soft palate against the tongue and the posterior pharyngeal wall may occur. Oral secretions, blood, bone and tooth debris and pharyngeal wall haematomas may worsen airway compromise.

## LE FORT I (ALSO KNOWN AS GUERIN'S FRACTURE)

This fracture involves only the maxilla at the level of the nasal fossa. It follows a horizontal plane at the level of the nose. The fracture separates the palate from the

**Figure 68.1** Le Fort classification of facial fractures.

remainder of the facial skeleton (i.e. palate–facial disjunction) and is usually caused by direct low-maxillary blows or by a lateral blow to the maxilla.

#### **LE FORT II**

This is the most common midface fracture.<sup>13</sup> The maxilla, nasal bones and medial aspect of the orbit are involved which results in a freely mobile, pyramidal-shaped portion of the maxilla (i.e. pyramidal disjunction). The fracture line extends from the lower nasal bridge through the medial wall of the orbit, and crosses the zygomaticomaxillary process. It is caused by direct blows to the mid-alveolar area, or by lateral impacts and inferior blows to the mandible when the mouth is closed.

#### **LE FORT III**

This is known as craniofacial disjunction because the fracture line runs parallel to the base of the skull, separating the midfacial skeleton from the cranium. The fracture extends through the upper nasal bridge and most of the orbit and across the zygomatic arch. It involves the ethmoid bone, and thus may transect the cribriform plate at the base of the skull.<sup>13,14</sup> These fractures result from superiorly directed blows to the nasal bones.<sup>13</sup>

#### **TEMPOROMANDIBULAR JOINT**

Mechanical TMJ impairment may result from condylar or zygomatic arch fractures and can prevent jaw opening even after muscle relaxants have been administered.<sup>15</sup>

#### **ZYGOMATIC, ORBITAL AND NASAL FRACTURES**

Zygomatic fractures are uncommon, but its attachments to the maxilla, frontal and temporal bones are vulnerable and may be disrupted. When the zygoma is displaced, disruption of the lateral wall and floor of the orbit may

ensue. Orbital injury is commonly associated with mid-face trauma. The severity of injury in the orbital region varies from oedema and ecchymosis of the periosteal soft tissue to subconjunctival haemorrhage and loss of visual acuity or ocular rupture. Blinding injuries reported with facial fractures occur in 3–12% and most are secondary to globe perforation rather than optic nerve injury.<sup>16</sup> Orbital blowout fractures occur when pressure is directly applied to the eye, and is hydraulically transmitted via the globe to the interior bony structures. The weaker inferior wall usually fractures, causing enophthalmos, diplopia, impaired eye movement and infraorbital hypoesthesia. Nasal fractures are common, with epistaxis and septal haematoma being the prime concerns.

#### **SOFT-TISSUE INJURIES**

Abrasions, contusions, lacerations to the tongue, palate, pharynx, cheek, eyelids, nasolacrimal duct, ear, parotid gland and facial nerve can occur. Oedema evolving over 24–48 hours can be massive and cause gross distortion of soft-tissue structures. Patency of an initially unobstructed airway may become compromised during this period.

#### **HAEMORRHAGE**

Haemorrhage following blunt maxillofacial injury is extremely common. Life-threatening bleeding is fortunately rare. Various series have reported the incidence to be between 1 and 10%.<sup>1,17–19</sup> Most severe haemorrhage is associated with midfacial fractures although soft-tissue lacerations alone can cause significant blood loss. Swallowing of large quantities of blood may conceal haemorrhage and predispose to aspiration.<sup>20</sup>

The origin of bleeding in facial trauma is complicated, as the vascular supply is derived from both the internal and external carotid arteries, with anastomoses occurring between them as well as between both halves of the face. The internal maxillary artery, especially the intraosseous branches, is the main source of bleeding in facial injury, because the artery passes within the common Le Fort fracture borders.<sup>16</sup> The comminuted nature of maxillary fractures makes the detection of an exact site of vessel damage nearly impossible.<sup>16</sup> Branches of the internal carotid artery such as the lacrimal and zygomatic branches, as well as the anterior and posterior ethmoidal arteries, may contribute to bleeding.

#### **ASSOCIATED INJURIES**

More than half of all patients with maxillofacial injuries will have other injuries and these are listed below.

#### **Basilar skull fracture**

The anterior cranial fossa is often involved in craniofacial injuries. Fractures involving the frontal bone, frontal sinus, nasoethmoid complex or fronto-orbital complex result in bone defects in the skull base and can cause dural tears with resultant leakage of cerebrospinal fluid (CSF). CSF fistulae occur in 10–30% of basilar skull fractures.<sup>21</sup> The clinical finding of CSF rhinorrhoea is not diagnostic

for anterior cranial fossa lesions, as this represents only the site of exiting CSF. The origin may be from a temporal bone fracture, because CSF from the middle ear discharges into the nose via the Eustachian tube. A middle cranial fossa defect can produce rhinorrhoea through the sphenoid sinus. The vast majority of fistulae present within 1 week of injury. Meningitis in patients with mid-face fractures is uncommon, despite the fact that approximately 36% of patients sustaining Le Fort fractures with anterior cranial fossa fractures have CSF leaks.<sup>22,23</sup>

Pulsating exophthalmos and the presence of an orbital bruit may lead to the diagnosis of a carotido-cavernous fistula, which may develop following fractures involving the skull base and orbit.

### Head and cervical spine injury

The incidence of head injury in those with maxillofacial trauma has been variably reported to be between 15% for severe head injury, increasing to 80% if all grades of head injuries are included.<sup>1,4,24</sup> Cervical spine injury has been reported in up to 11% of patients.

The association between maxillofacial and cervical spine injury depends on the mechanism of injury. Falls and motor vehicle accident victims are more likely to have cervical injury than sporting or personal assault victims.<sup>25</sup> Cervical spine fracture occurs with mandibular injury in 3%<sup>16</sup> and is attributed to forces exerted directly or indirectly from the facial skeleton to the neck. C1/C2 and C5–C7 are at particular risk.

### Other injuries

Thoracic (9–40%) and abdominal (5–40%) trauma and limb fractures (30%) are other common coexistent injuries.<sup>24,26</sup> Traumatic occlusion of the internal carotid artery (ICA) is a rare complication of maxillofacial trauma occurring in less than 0.5% of patients presenting with blunt maxillofacial injury.<sup>27,28</sup> It is usually recognised when a patient develops an unexplained neurological deficit, most often hemiplegia, subsequent to trauma or surgery of the head, face or neck. Assessment of the carotid circulation by CT angiography is a useful investigation if carotid injury is suspected.

### ASSESSMENT OF INJURY

The obvious priorities are airway management and control of haemorrhage and identifying other life-threatening injuries. These are discussed later in detail. Once the patient is stable, formal assessment of the facial injuries can proceed.

### HISTORY

Evaluation of facial fractures begins with a history of the injury. The mechanism of injury is important in order to assess the likelihood of other injuries.

### EXAMINATION

Physical examination includes inspection of the deformity, presence of enophthalmos, asymmetry, dental malocclusion,

nasal septal deviation or haematoma, CSF rhinorrhoea and the extent of jaw opening. Other signs associated with basal skull fracture should also be noted (haemotympanum, Battle's sign, raccoon eyes). Tenderness and mobility on bimanual palpation of the alveolar process and the infraorbital rim or frontozygomatic suture indicates the presence of a complex midfacial fracture. Naso-orbito-ethmoid instability can also be established by bimanual palpation. Visual acuity (in the conscious patient), corneal integrity and pupillary reflexes as well as eye movements (failure of upward movements in orbital blowout fracture) should be assessed early and thoroughly. Facial nerve function should also be assessed if possible. The presence of a bruit over the orbit may indicate a carotido-cavernous fistula.

### INVESTIGATION

Radiographic studies include a posterior–anterior, lateral oblique, stereo Water's view, stereo Caldwell's view and Panorex views. However, use of CT scanning, especially with the three-dimensional reconstructive ability, is now the preferred and most accurate method of imaging. In addition to bony distortion, fluid in the paranasal sinuses, optic nerve integrity and soft-tissue distortion, the brain, upper cervical spine and other body areas can be visualised concurrently. Other investigations such as colour Doppler ultrasound studies, CT angiography or standard angiography of the great vessels in the neck may be required in cases of possible carotid dissection or carotido-cavernous fistulae. Nasal discharge should be tested to determine the presence of a CSF fistula. Assay for  $\beta$ -2 transferrin is more valuable than the traditional glucose assay for CSF leak detection.<sup>29</sup>

### AIRWAY MANAGEMENT

Airway management in maxillofacial injury is potentially complex due to multiple concurrent compromising factors (Table 68.1).

### IMMEDIATE PRIORITIES

- Assess and monitor for signs of airway obstruction
- Clear airway, assist respiration
- Definitive airway intervention

As swelling and oedema are progressive in the initial hours after injury, even an unobstructed airway may become compromised. Careful close monitoring in an intensive care unit (ICU) or high-dependency unit (HDU) is essential. Maintaining the head-up position and the use of humidified oxygen may lessen the likelihood of later airway compromise. Sudden obstruction may occur with clot dislodgement and inhalation. Signs of partial obstruction include noisy breathing, stridor, intercostal, supraclavicular recession and restlessness.

Occasionally, patients may assume positions that lessen airway obstruction (e.g. sitting forward or even prone).<sup>30</sup> Simple measures such as suction and clearing the airway and insertion of an oropharyngeal airway may suffice.

Table 68.1 Airway problems in maxillofacial trauma

General problems	Management
Haemorrhage/debris Impaired laryngoscopy Aspiration risk from blood swallowing Clot inhalation/obstruction Teeth, bone fragments	Suction, volume replacement Head down Definitive control of haemorrhage (see text)
Oedema soft tissue haematomas Increases over 48 hours Mask fit can be poor	Monitor airway closely Head up 30° Maintain spontaneous ventilation during airway manipulation; laryngeal mask ventilation
Specific problems	
Bilateral mandibular body/angle fractures Posterior displacement of tongue	Anterior traction on tongue or jaw, towel clip or suture through tongue and elevate
TMJ impairment Mandibular condyle, zygomatic arch Mouth opening limited	Nasotracheal intubation (blind/fibreoptic) or surgical airway may be required (see text)
Midfacial fracture Mask seal poor Soft palate collapses against pharynx	Anterior traction on mobile segment
Basilar skull Nasotracheal intubation contraindicated Pneumocephalus from mask ventilation	Avoid nasal intubation
Cervical spine injury	Orotracheal intubation with in-line stabilisation; fibreoptic intubation; surgical airway

In midfacial injuries, anterior digital traction on the mobile mid-segment may relieve obstruction. In bilateral mandibular fractures of the angle or body, a towel clip or suture through the tongue may allow anterior traction on the unsupported tongue and relieve obstruction.

Bag and mask ventilation may be difficult due to distorted anatomy, and this should be borne in mind when a decision to intubate is made. Failure of these simple manoeuvres necessitates definitive airway management

#### TECHNIQUES (FIGURE 68.2)

Facilities to perform a surgical airway must be available prior to elective intubation. The chosen technique for securing the airway depends on the presence of airway obstruction and the likelihood of difficult direct laryngoscopy (extent of jaw opening, gross anatomical distortion and swelling, operator experience). In a combative patient or if urgent intubation is necessary, then a rapid sequence induction can be used if airway difficulty is not anticipated. If direct laryngoscopy is likely to be difficult or impossible, then spontaneous respiration must be maintained and intubation carried out under local anaesthesia.

Analgesia can be achieved with a combination of sprayed or nebulised lidocaine (4%) to the posterior pharynx as well as a transcrioid injection of 2–4 ml lidocaine (2%). Adjunctive superior laryngeal and glossopharyngeal nerve blocks can be used.<sup>31,32</sup> The oro-tracheal route for intubation is the route of choice in the presence of basal skull fracture.

If cervical spine injury is present or suspected, in-line stabilisation is mandatory. A variety of intubation techniques can be used – for example, direct laryngoscopy, fibreoptic guided laryngoscopy (oral/nasal), use of a light wand stylet, blind nasal and retrograde intubation techniques.<sup>33,34</sup> The operator should use the technique with which he/she is most comfortable. Excessive bleeding may render fibreoptic techniques useless.

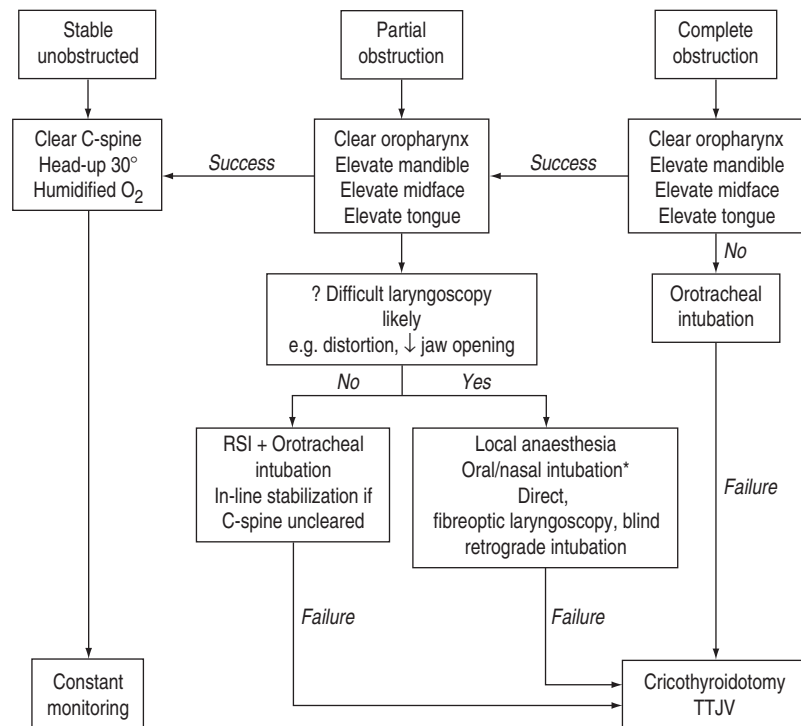

Failure to intubate in the presence of airway obstruction necessitates emergency cricothyroidotomy. Tracheostomy may be required in those likely to need prolonged ventilatory support (e.g. multiple facial fractures combined with a head injury), and is best performed as a semi-elective procedure in the operating room.<sup>16</sup>

#### MANAGEMENT OF HAEMORRHAGE

Topical vasoconstrictors may not be effective with ongoing nasal haemorrhage. Anterior nasopharyngeal packs are sometimes effective at reducing blood loss. Foley catheters passed into the posterior nasopharynx with the balloons filled with air may stem blood loss, especially if anterior traction is applied.<sup>20</sup> Plastic or maxillofacial surgical opinion should be sought regarding operative reduction and stabilisation of fractures and direct ligation of bleeding vessels if haemorrhage is persistent. External carotid ligation and angiographic embolisation can be used as a last resort.

**Figure 68.2** An airway management algorithm for maxillofacial trauma. C-spine, cervical spine; RSI, rapid sequence induction; TTJV, transtracheal jet ventilation. \*Nasotracheal route contraindicated in basilar skull fracture.

## DEFINITIVE MANAGEMENT

Definitive surgery is generally delayed 4–10 days to allow swelling to subside. The timing of surgery may be further delayed if a severe head injury coexists. Early surgery may be warranted if orbital injury with optic nerve compromise is present. The use of high dose steroids in optic nerve compression is controversial and good data do not exist regarding its efficacy.<sup>16</sup> Irrigation and debridement of open wounds, closure of facial lacerations and removal of foreign bodies must be undertaken as soon as is practicable, preferably within 24 hours.

The use of prophylactic antibiotics in the presence of basilar skull fracture and CSF leak is controversial and local protocols should be followed.<sup>21</sup> Persistent CSF leaks (> 2 weeks) or those complicated by meningitis or pneumocephalus are repaired surgically.<sup>21</sup> Appropriate tetanus prophylaxis must be given.

The use of modern internal fixation techniques have reduced the need for intermaxillary fixation following elective facial fracture repair, with only unstable comminuted fractures requiring this form of fixation. Submental intubation during fracture repair is now being used as an alternative to tracheostomy.<sup>35</sup>

## INJURIES TO THE LARYNX AND TRACHEA

Direct trauma to the airway is rare, accounting for less than 1% of traumatic injury seen in most major centres.<sup>15,36</sup> The

bony protection afforded to the airway by the sternum and mandible and death from asphyxia at the accident scene account for the rarity of the injury. Laryngotracheal injury can be classified as blunt or penetrating. Failure to recognise these injuries, their complications and specific pitfalls in airway management can lead to death.<sup>37,38</sup>

## MECHANISM OF INJURY

### BLUNT INJURY

Common causes include motor vehicle accidents where the extended neck impacts with the steering wheel or dashboard. The ‘clothesline injury’ occurs when a cyclist or horse rider collides with a cable or wire causing direct injury to the upper airway. Assaults and strangulation account for the remainder of blunt injuries. Direct blows are more likely to injure the cartilages of the larynx while flexion/extension injuries are most commonly associated with tracheal tears and laryngotracheal transection.<sup>37</sup> The larynx above the cricoid cartilage is injured in 35%, manifesting as oedema, contusions, haematomas, lacerations, avulsion and fracture dislocation, most commonly of the thyroid and arytenoid cartilages.

The cricoid cartilage itself is injured in 15%, which may cause recurrent laryngeal nerve dysfunction.<sup>36</sup> The cervical trachea is injured in 45%.<sup>38</sup> Tracheal transection most often occurs at the junction between the cricoid cartilage and trachea.<sup>39</sup> Oedema fluid and air dissecting within submucosal layers of the larynx and trachea may cause

airway obstruction. Air in the soft tissues can cause epiglottic emphysema and narrowing of the supraglottic airway.<sup>40</sup> Straining, talking and coughing may worsen the oedema.

### PENETRATING INJURY

Penetrating injuries usually result from stab or gunshot wounds. The anterior triangle of the neck is the most common site of entry. The cervical trachea is most commonly involved in stab wounds. The larynx is injured in about one-third of those with upper-airway injuries.<sup>38</sup>

### ASSOCIATED INJURIES

Common associations with blunt laryngotracheal injury include cervical spine, head injury and multisystem trauma. Of those with penetrating neck trauma, major vascular injuries (carotid, jugular, subclavian, vertebral arteries) occur in 25–50%, pharyngeal or oesophageal injury in 30%, neural injury (spinal cord, brachial plexus) in 12% and apical thoracic injury in 10%.<sup>7</sup>

### ASSESSMENT OF INJURY

Definitive investigation and management depend on the airway status and presence of associated injury. The degree of injury is not readily assessable on the basis of any one clinical symptom or sign (Table 68.2) and delayed diagnosis is common. Plain radiography (CXR, cervical spine) is performed in all cases. CT scanning demonstrates fractures of cartilages, haematomas and other injuries and is used in stable patients with laryngeal tenderness, endolaryngeal oedema and small haematomas. When obvious signs of injury are not present and there is a satisfactory airway, fiberoptic laryngotracheoscopy under local anaesthesia can demonstrate vocal cord dysfunction, integrity of the cartilaginous framework and

**Table 68.2** Clinical features in laryngotracheal injury

#### Symptoms

- Respiratory distress
- Hoarseness
- Dysphonia
- Cough
- Stridor, noisy breathing
- Dysphagia

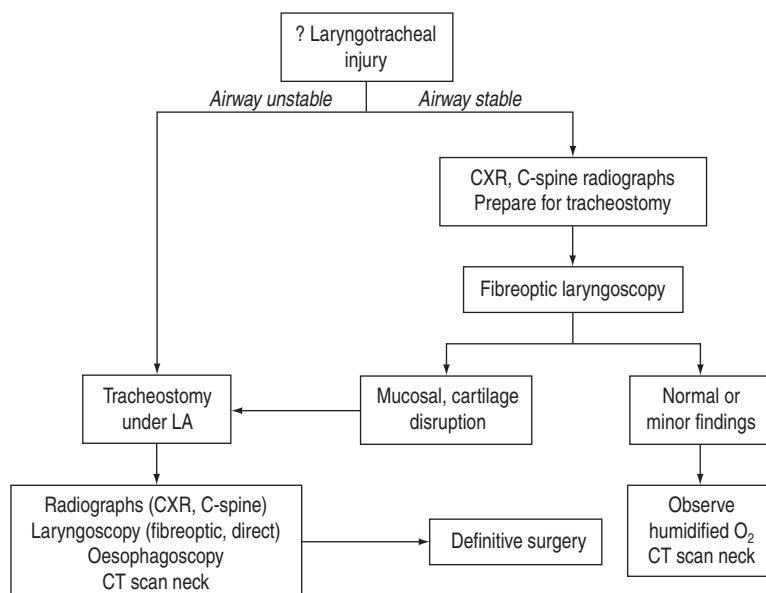

#### Signs

- Abnormal laryngeal contour

  - Vocal paralysis
  - Mucosal or cartilage disruption
  - Haematoma
  - Laceration

laryngeal mucosa. Rigid laryngoscopy can be used when adequate visualisation is not achieved with the former. Pharyngo-oesophagoscopy, contrast studies, open exploration and angiography may be required to exclude aerodigestive tract and major vascular injuries.

**Figure 68.3** Airway assessment and management algorithm for laryngotracheal trauma. CXR, chest X-ray; C-spine, cervical spine; CT, computed tomography; LA, local anaesthesia.

## AIRWAY MANAGEMENT

Major complications from airway manipulation can occur after laryngotracheal trauma. Blind intubation can lead to complete airway obstruction due to creation of false passages and mucosal disruption.<sup>15</sup> Cricoid pressure can lead to laryngotracheal separation and is contraindicated. Positive pressure ventilation can rapidly worsen air leaks and wherever possible the patient should maintain spontaneous respiration until a tube has been placed distal to the site of injury. Cricothyroidotomy is not recommended as it may compound laryngeal injury. Gaping airway wounds can be intubated under direct vision pending subsequent surgery.<sup>38</sup> The optimal mode of intubation is thus tracheostomy under local anaesthesia (Figure 68.3). Excessive movement of the cervical spine during airway manipulation should be avoided in cases of blunt trauma.

# Chest injuries

Ubbo F Wiersema

## CHEST INJURIES

The majority of chest injuries in Australasia result from blunt trauma due to motor vehicle crashes. Less frequent causes include falls and penetrating injuries from stab or gunshot wounds. Associated extrathoracic injuries are common. Chest injuries account for a quarter of all trauma deaths. Immediate death from blunt chest trauma is usually due to blunt rupture of the thoracic aorta, heart or major vessel. Patients who survive the immediate post-trauma period may still have life-threatening injuries that require timely intervention. Most patients can be managed with simple measures, including intercostal tube drainage, analgesia, oxygen therapy and mechanical ventilation. Thoracotomy is infrequently required.<sup>1,2</sup>

A systematic team approach to immediate assessment and resuscitation is important. This is followed by a detailed secondary survey and appropriate further investigations to identify all injuries and determine patient disposition.

## IMMEDIATE MANAGEMENT

During the primary survey a rapid assessment of the respiratory, circulatory and neurological status of the patient is made (Table 69.1). Airway patency is ensured, oxygen administered by facemask and ventilation assessed. Obvious external bleeding is controlled. Two large bore intravenous cannulae are sited, blood samples taken for crossmatch, haematology and biochemistry tests, and intravenous fluids commenced. Intravenous opioid analgesia is given as repeated small boluses, titrated to effect. There are four critical chest injuries that should be sought during the primary survey for which immediate intervention may be life saving:

- tension pneumothorax
- open (sucking) pneumothorax
- massive haemothorax
- pericardial tamponade

In addition, the clinical features of flail chest should be sought as these will no longer be apparent if positive-pressure ventilation is instituted (see below). A chest radiograph is integral to the initial assessment and should be performed promptly. Subcostal ultrasonography of the

heart as part of the focused assessment with sonography for trauma (FAST) should be performed with penetrating chest trauma, or if there is haemodynamic instability.<sup>3</sup> An ECG is important in the assessment for blunt cardiac injury (see below).<sup>4</sup>

Endotracheal intubation and mechanical ventilation are indicated for the patient with a compromised airway, severe head injury, or gross hypoventilation and/or hypoxaemia not attributable to pneumothorax. Haemodynamic instability should be anticipated (Table 69.2). Emergency cricothyroidotomy or tracheostomy is only rarely required when an airway obstruction cannot be bypassed by translaryngeal intubation. A nasogastric tube (or orogastric, if facial injuries are suspected) should be inserted to decompress the stomach after endotracheal intubation.

## PNEUMOTHORAX

Pneumothorax visible on the initial chest radiograph should be treated with insertion of an intercostal tube connected to an underwater seal drainage system (Figure 69.1). A single-bottle drainage system without suction is usually adequate. Low-pressure suction (20 cmH<sub>2</sub>O) is applied if the pneumothorax fails to fully resolve, or if there is associated haemothorax (Figure 69.2). A three-bottle system (or commercially available three-in-one system) allows more accurate control of suction (Figure 69.3). Presumptive antibiotics are not indicated.<sup>5</sup>

*Tension pneumothorax* results from progressive accumulation of air in the pleural space, leading to vena caval compression and cardiopulmonary decompensation. Clinically, tension pneumothorax is characterised by:

- tachypnoea and tachycardia
- hyperinflated chest
- contralateral tracheal deviation
- hyperresonance to percussion
- reduced breath sounds
- hypotension and jugular venous distension

If tension pneumothorax is suspected clinically an intercostal tube should be inserted immediately, prior to the chest radiograph. Needle thoracostomy with a large bore cannula inserted into the second intercostal space in the

Severe blunt cardiac injury

midclavicular line may be used to drain air more rapidly for patients in extremis. However, this is rarely necessary and may puncture the lung, fail to reach the pleural space, or kink when the needle is removed from within the cannula. Whether successful or not, needle thoracostomy must be followed by formal intercostal tube drainage.

*Open pneumothorax* occurs when a chest wall defect allows direct communication of a pneumothorax with the exterior, usually after penetrating trauma. Tension can develop if air can enter but not exit through the defect. Treatment involves application of an occlusive, non-adherent, square dressing sealed along three edges over the wound after sterile skin preparation. This allows air to escape but not to enter through the wound, but should be followed by intercostal tube insertion at a site not immediately adjacent to the wound.

*Simple pneumothorax* may develop tension at any stage, especially with positive-pressure ventilation (Table 69.2). A small pneumothorax may be missed on the initial chest radiograph. In the supine position pleural air collects anteroinferiorly and is demonstrated radiologically by a deep sulcus sign or increased radiolucency of one side of the chest compared to the other (Figure 69.4).<sup>6</sup>

*Occult pneumothorax* is defined as visible on chest CT (or upper slices of an abdominal CT) but not plain radiograph.<sup>7</sup> Drainage is not mandatory, but should be considered if prolonged surgery is anticipated, there is significant cardiorespiratory compromise or interhospital transport is necessary. With a conservative approach the patient should be carefully monitored for deterioration from expansion of the pneumothorax.<sup>7</sup>

**Figure 69.1** Intercostal tube insertion. After sterile preparation and drape, 1% lidocaine is infiltrated in the mid-axillary line at the level of the nipple. A 2–3 cm transverse skin incision is made. Dissection is performed by blunt forceps down to the pleura, passing just superior to the rib surface to avoid injury to neurovascular structures. A gloved finger is used to confirm separation of lung from chest wall. A large bore (32 French) intercostal tube is inserted without a trocar and directed anteriorly for pneumothorax or posteriorly for haemothorax. Curved forceps clamped to the tip of the tube can be used to guide the tube through the chest wall. The tube is immediately connected to an underwater seal drainage system (Figures 69.2 and 69.3) and checked for satisfactory drainage and tidal rise and fall in fluid level with respiration. Non-absorbable sutures are used to seal the skin incision around the tube and secure the tube. The intrathoracic position of the tube is checked with a chest radiograph.

*Subcutaneous emphysema* over the chest wall in a patient with blunt chest trauma is almost always associated with pneumothorax, but should raise suspicion of other injuries (Table 69.3). The pneumothorax may not be visible on the plain chest radiograph, either because it is obscured by the emphysema or because it has largely decompressed into subcutaneous tissues. An intercostal tube should be inserted.

**Figure 69.2** Single-bottle drainage system for haemopneumothorax. Air drainage will become more difficult if there is also fluid drainage, raising the fluid level in the bottle (dashed line) and increasing the depth of immersion of the hollow rod. This can be overcome by applying low pressure suction (20 cmH<sub>2</sub>O). Arrows indicate direction of airflow.

**Figure 69.3** Three-bottle chest drainage system. The first bottle (connected to the intercostal tube) is a fluid collection chamber, the second functions as a one-way valve (underwater seal), and the third (connected to wall suction) limits the amount of suction applied. The level of suction is set by adjusting the depth of the atmospheric vent whilst ensuring that it bubbles continuously. Commercially available drainage systems function on the same principles as the three-bottle system. Arrows indicate direction of airflow.

If there is no associated fluid collection the chest tube can be removed once the pneumothorax is no longer visible on chest radiograph and there has been no air drained for at least 24 hours. Persistent air leak and incomplete drainage of a pneumothorax after intercostal tube insertion should prompt investigation for tracheo-bronchial injury. However, the depth of the tube within the pleural space and tubing connections should be checked to ensure that extraneous air is not being inadvertently entrained. Incomplete drainage with no air leak is usually due to tube malplacement.

**Figure 69.4** (a) Moderate-sized left pneumothorax on supine chest radiograph. The visceral pleura is visible at the lung apex (curved arrow). Hyperlucency is visible in the left lower chest (straight arrows). (b) Supine chest radiograph of right-sided deep sulcus sign (arrows). Miller LA. Chest wall, lung, and pleural space trauma. *Radiol Clin North Am* 2006; **44**: 213–224, viii.

### HAEMOTHORAX

Haemothorax visible on chest radiography should be drained as completely as possible (Figure 69.1). The tube can be removed once radiographic clearance is achieved, with < 100 ml/24 hours drainage. A small haemothorax (< 300 ml) (visible on ultrasound or CT) may initially be managed conservatively, but should be drained if it enlarges.

*Massive haemothorax*, defined as > 1500 ml, causes life-threatening circulatory compromise from

**Table 69.3** Causes of pneumothorax, subcutaneous emphysema and/or pneumomediastinum

Lung puncture
Tracheobronchial injury
Oesophageal injury
Facial or pharyngeal injury
Abdominal or retroperitoneal injury (air tracking up)

hypovolaemia and vena caval compression as well as hypoxaemia. This requires immediate tube drainage. If the amount of ongoing bleeding following initial drainage is low, the patient remains haemodynamically stable after initial resuscitation, and the blood is venous in appearance, the patient can be managed with close observation. Ongoing bleeding of > 200 ml/h, or > 600 ml over 6 hours (massive haemothorax equivalent), is an indication to proceed to thoracotomy.

### PERICARDIAL TAMPONADE

Pericardial tamponade should be suspected in any patient with a gunshot wound to the chest or stab wound to the precordium. It occurs rarely with blunt trauma, but should be suspected if there is hypotension out of proportion to blood loss, and distended neck veins. Pulsus paradoxus may be detected in the spontaneously breathing patient. The differential diagnosis includes tension pneumothorax (most likely) and cardiogenic shock from severe blunt cardiac injury or delayed and inadequate resuscitation. Pericardial fluid can be detected with ultrasound (FAST scan).<sup>3</sup> Cardiac structures are imaged via a subcostal view using a low-frequency transducer (3.5 MHz) to provide good tissue depth penetration. Echocardiography, or operative subxiphoid window, can be used if diagnostic uncertainty remains.

Haemodynamically unstable patients should undergo thoracotomy.<sup>8</sup> Subxiphoid pericardiectomy can be performed in selected stable patients, but may require conversion to open thoracotomy. Needle pericardiocentesis is rarely effective in the acute setting, but may have a role in the drainage of delayed pericardial effusions following stab wounds.<sup>8</sup>

### CARDIAC ARREST AND EMERGENCY THORACOTOMY

External cardiac massage is invariably unsuccessful in the trauma setting. Indeed, cardiac compression may cause further injury to intrathoracic structures and obstruct access to the patient for more potentially useful interventions such as (bilateral) intercostal tube insertion. For patients with witnessed loss of vital signs after penetrating chest trauma, emergency thoracotomy should be considered if suitably experienced medical personnel are available.<sup>8</sup> This is rarely successful for blunt trauma. The standard approach is a left-sided anterolateral

thoracotomy. This allows access to the thoracic cavity for specific interventions:<sup>8</sup>

- Release of pericardial tamponade
- Control of intrathoracic bleeding
- Control of massive air embolism or bronchopleural fistula
- Cross-clamping of the descending aorta
- Internal cardiac massage

These temporising (damage control) measures are followed by transfer to the operating room for completion of surgery:<sup>9</sup>

- Definitive repair of cardiac injury
- Pulmonary tractotomy, wedge resection, or lobectomy/pneumonectomy for lung injury
- Repair or grafting of vascular injury

Postoperatively the patient is admitted to the intensive care unit (ICU) for rewarming, correction of coagulopathy and resuscitation.

### SPECIFIC INJURIES

Specific chest injuries should be systematically excluded. Imaging techniques play an important role. Choice of investigation is influenced by clinical findings. The degree of haemodynamic and respiratory instability will determine whether the patient can be moved to an imaging facility. Local availability of equipment and clinician expertise may limit the options available. Extrathoracic injuries will often determine investigation and management priorities. With the advent of rapid high-resolution CT scanners, routine chest CT has become increasingly popular, particularly in patients who require abdominal or head CT.<sup>10</sup> Endotracheal intubation and mechanical ventilation may be required to facilitate investigations (e.g. the combative trauma patient with ethanol intoxication).

### BLUNT AORTIC INJURY

Blunt aortic injury usually occurs at the junction between the mobile arch and fixed descending aorta, just distal to the origin of the left subclavian artery, as a result of severe deceleration injury. Less frequently, the ascending aorta or arch vessels are injured by direct trauma. Blunt aortic injuries may be divided into:<sup>11</sup>

- *significant* aortic injury, with disruption of the intima and full thickness of the media. There is a high risk of rupture
- *minimal* aortic injury, with laceration limited to the intima and inner media. Radiologically this manifests as an intimal flap < 1 cm with minimal periaortic haematoma. There is a low risk of rupture

Most patients with blunt aortic injury die at the scene from complete aortic wall transection or associated

**Table 69.4** Chest radiograph signs of blunt aortic injury

Signs of periaortic haematoma	Indirect signs
Widened mediastinum (> 8 cm)	Left haemothorax
Obscured aortic knuckle	Left pleural cap
Opacification of aortopulmonary window	Fractured first or second ribs
Deviation of trachea, left main bronchus or nasogastric tube	
Thickened paratracheal stripe	

injuries. Of those that reach hospital, 90% will have a significant injury.<sup>11</sup> Clinical signs include unequal upper limb pulses, pseudocoarctation or interscapular murmur, but these are rarely detected.<sup>12</sup> Aortic injury should be suspected if the mechanism of injury is suggestive of rapid deceleration, such as high speed (greater than 90 km/h) motor vehicle or motorcycle crashes, or a pedestrian hit by a vehicle.<sup>13</sup>

Historically, chest radiography has been the screening test (to detect mediastinal haematoma) and aortic angiography the diagnostic test for blunt aortic injury.<sup>12,14</sup> More recently, CT and echocardiography have been introduced for screening and diagnostic purposes.<sup>15</sup>

- *Chest radiograph* features of blunt aortic injury are caused by distortion of normal mediastinal contour by periaortic haemorrhage. A widened mediastinum (> 8 cm at the level of the aortic knuckle) is the principal finding (Table 69.4).<sup>12,16</sup> A good quality erect chest radiograph has a high sensitivity (> 90%), but low positive predictive value for aortic injury. Historically, this has resulted in a large number of negative aortograms.<sup>12,13</sup> Furthermore, a supine chest radiograph accentuates mediastinal width and in the acute trauma setting is often of lower quality. Measurement of left mediastinal width (> 6 cm), or left mediastinal width to mediastinal width ratio (> 0.6), may improve specificity.<sup>16</sup>
- *Single slice helical chest CT* may demonstrate direct signs of aortic injury. However, more commonly aortic injury manifests indirectly with periaortic haematoma, and a further diagnostic test is required.<sup>13</sup> Nevertheless, by differentiating periaortic haematoma from other types of mediastinal haematoma, and excluding other causes of an abnormal mediastinal contour, helical CT provides a useful screening test. Routine chest CT has thus been advocated for haemodynamically stable patients with a high-risk mechanism of injury, especially if other CT scans are planned.<sup>13,17</sup> *Multirow detector chest CT* (with more than 16 detectors) provides sufficient resolution in multiple planes for CT to be used as the sole diagnostic test. However, the diagnostic role of CT for branch vessel injuries remains undefined (Table 69.5).<sup>18</sup>
- *Transoesophageal echocardiography* is rapid and portable, making it suitable for examination of the unstable

**Table 69.5** Signs of aortic branch vessel injury

Supraclavicular haematoma
Pulse discrepancy in arms
Brachial plexus palsy or stroke
Widened upper mediastinum on chest radiograph

patient (who is intubated). It provides high diagnostic accuracy for aortic injury and also allows examination for blunt cardiac injury.<sup>19,20</sup> However, imaging of the distal aorta, proximal arch and major branches is limited. Thus, if signs of mediastinal haematoma are detected, but an aortic injury not identified, further diagnostic testing is warranted.<sup>19</sup> It is contraindicated if an upper-airway or oesophageal injury is suspected.

- *Aortic angiography* is relatively time consuming and requires transfer of the patient to the angiography room, making it potentially hazardous in the unstable patient. However, it is the preferred diagnostic test if branch vessel injury is suspected (Table 69.5)<sup>18</sup> or if uncertainty remains after other diagnostic imaging.<sup>14</sup> It is also necessary for endoluminal stent placement, and may be required for operative planning.

Significant aortic injury requires prompt surgical or endoluminal stent repair.<sup>21</sup> However, this should not take priority over other life-saving operations (e.g. craniotomy or laparotomy).<sup>12</sup> Surgical options include direct repair (clamp and sew) or techniques that maintain distal aortic perfusion.<sup>14</sup> The latter reduce the risk of postoperative paraplegia from spinal cord ischaemia, but often require systemic heparinisation, which may exacerbate bleeding from other injuries.<sup>15</sup> Surgery should be deferred, sometimes indefinitely, if severe associated injuries or comorbidities make the operative risk unacceptably high.<sup>12,22</sup> In such cases endoluminal stent repair may still be feasible.<sup>21</sup> Conservative management includes antihypertensive therapy ( $\beta$ -blockers  $\pm$  vasodilators) and serial imaging to assess for expanding pseudoaneurysm that will require intervention. Minimal aortic injury may also be managed expectantly.<sup>11,15,20</sup>

## BLUNT CARDIAC INJURY

Blunt cardiac injury results from compression of the heart between the sternum and the spine, abrupt pressure changes within cardiac chambers or deceleration shear injury. A wide spectrum of injuries has been described, but may be classified according to the clinical sequelae and need for intervention:<sup>4</sup>

- *Minor ECG and cardiac enzyme abnormalities*: Sinus tachycardia and premature beats are common, but usually resolve within 24 hours without intervention.
- *Complex arrhythmias*: This may cause heart failure, or persistent hypotension, and may warrant antiarrhythmic therapy.

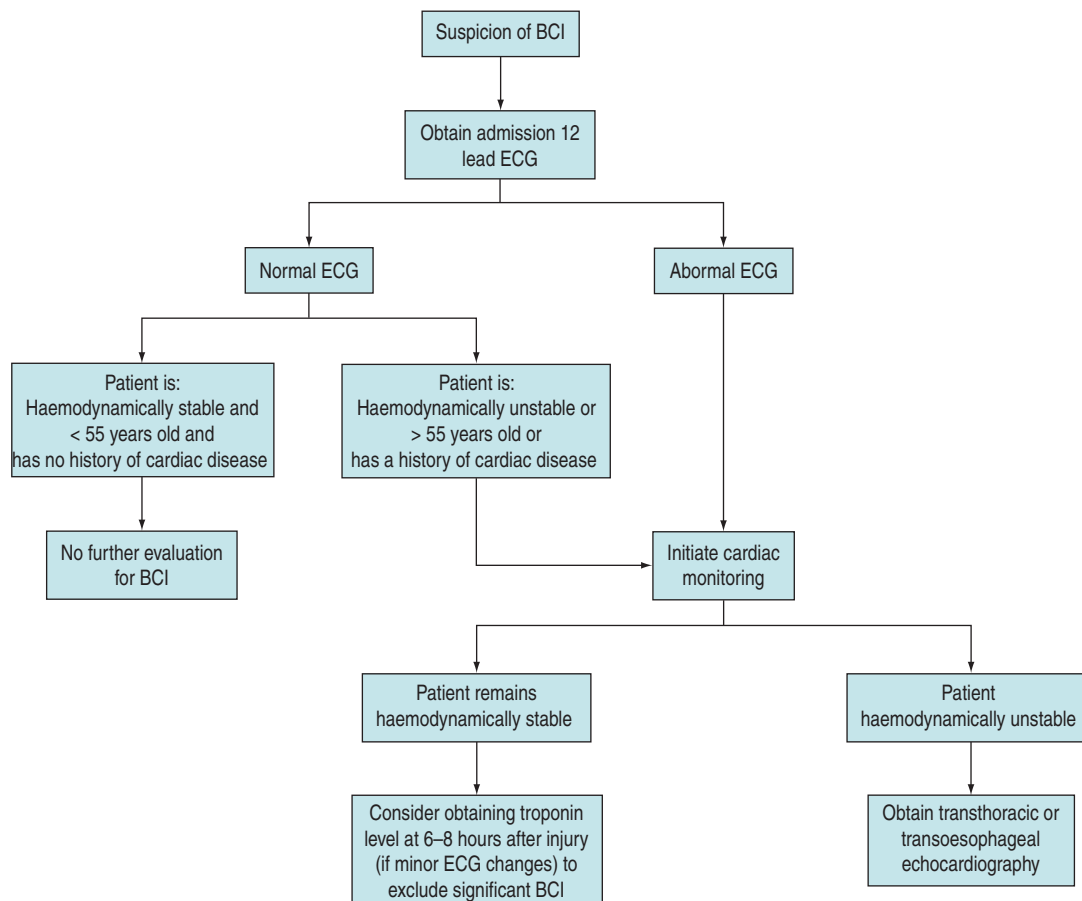

- *Free wall rupture*: This is usually fatal, but atrial rupture may present with haemopericardium  $\pm$  tamponade. Immediate drainage and repair is required.
- *Heart failure* may develop from gross myocardial injury, septal rupture (causing left-to-right shunt) or valvular injury (causing regurgitation). The latter may not manifest until weeks later. Septal rupture and severe valvular injury require surgery. Myocardial dysfunction may require inotropic support.
- *Coronary artery injury*: This is very rare and ST elevation on ECG is more likely to be due to a primary myocardial infarction.

All patients should have an ECG on admission (Figure 69.5). If this is normal and the patient is young, haemodynamically stable, and has no history of cardiac disease, the risk of significant injury is very low and no further cardiac evaluation is required. Other patients should be monitored for late sequelae of significant cardiac injury (arrhythmia or heart failure).<sup>4</sup> Patients who remain haemodynamically stable, with only minor ECG changes, and who have a normal troponin level at 6–8 hours post injury, have a

low risk of cardiac complications.<sup>4,23</sup> Echocardiography is indicated for patients with hypotension unexplained by other injuries, heart failure, or persistent arrhythmias.<sup>4</sup> Undisplaced sternal fracture does not of itself warrant cardiac evaluation.<sup>24</sup>

### TRACHEOBRONCHIAL INJURY

Blunt rupture of the trachea or bronchi results from crush injury or rapid deceleration with shearing of the airway between a fixed trachea and mobile lungs. The proximal right main bronchus is the most common site of injury.<sup>25</sup> Large injuries present with respiratory distress, subcutaneous emphysema and haemoptysis (Table 69.3).<sup>26</sup> The chest radiograph demonstrates pneumothorax and mediastinal emphysema. Dramatic deterioration may follow the institution of positive-pressure ventilation (Table 69.2). With smaller injuries, initial findings are often overshadowed by associated injuries with delay in diagnosis. Persistent pneumothorax with a large air leak, or recurrent

**Figure 69.5** Algorithm for evaluation of patients suspected of having blunt cardiac injury (BCI). (Modified from Schultz JM, Trunkey DD. Blunt cardiac injury. *Crit Care Clin* 2004; **20**: 57–70.)

pneumothoraces and pulmonary collapse, should prompt further investigation. Flexible bronchoscopy confirms the diagnosis and identifies the level of injury. Treatment is usually primary repair, although non-operative management has been described.<sup>27</sup> Late complications of either approach include postobstructive pneumonia, empyema or bronchiectasis.<sup>25</sup>

With penetrating trauma the cervical trachea is most commonly injured. Immediate management involves tracheal intubation (preferably with flexible bronchoscopy) with the cuff positioned distal to the tear to ablate the air leak. With a large neck wound the endotracheal tube can be passed directly through the wound in emergency situations.

### DIAPHRAGMATIC RUPTURE AND DIAPHRAGMATIC PARESIS

The usual mechanism of diaphragmatic rupture is gross abdominal compression from direct vehicular intrusion. The risk of rupture is higher with lateral impact collisions, but not seat belt use.<sup>28</sup> Associated injuries are very common.<sup>28</sup> Rupture of the left hemidiaphragm is more common, because the right hemidiaphragm is congenitally stronger and protected by the liver.

Symptoms (dyspnoea and chest pain) are non-specific. Rarely bowel sounds are audible on chest auscultation. Diagnostic chest radiograph findings are herniation of bowel into the thoracic cavity and nasogastric tube above the left hemidiaphragm. Indirect signs include an elevated or distorted diaphragmatic outline, or pleural effusion, but these may be obscured by adjacent pulmonary pathology, phrenic nerve injury or with positive-pressure ventilation.<sup>29</sup> The low diagnostic accuracy of chest radiography often results in delayed diagnosis unless further imaging is performed. Multidetector CT has high diagnostic accuracy, but magnetic resonance imaging or video thorascopy may be required if uncertainty persists.<sup>29–31</sup> Prompt operative repair is important to prevent bowel incarceration or perforation. The choice of surgical approach (laparotomy or thoracotomy) is dictated by associated injuries.

Traumatic phrenic nerve palsy, or postoperative diaphragmatic dysfunction, may go unrecognised whilst the patient is on mandatory positive-pressure ventilation. With the transition to spontaneous ventilation, paradoxical abdominal and chest wall movement, reduced vital capacity, and difficulty weaning from ventilatory support become evident.

### OE SOPHAGEAL INJURY

Rupture of the oesophagus from blunt trauma is rare. Penetrating trauma usually causes injury to the cervical portion of the oesophagus. Oesophageal injury may also result from attempted endotracheal intubation or gastric tube insertion during resuscitation of the trauma patient.<sup>32</sup> Clinical features include chest

pain, dysphagia, pain on swallowing and subcutaneous emphysema (Table 69.3). Chest radiograph findings include pneumothorax and/or hydrothorax, mediastinal emphysema or widened mediastinum.<sup>26</sup> Prompt diagnosis by oesophagoscopy or gastrograffin swallow is important. Treatment is immediate surgical repair.<sup>32</sup> Delayed recognition or repair (more than 12 hours post injury) leads to septic shock from mediastinal contamination. Extensive irrigation and drainage are then required, but postoperative complications are common.<sup>32</sup>

### PULMONARY INJURY

Pulmonary contusion is characterised by interstitial haemorrhage and oedema, with a secondary inflammatory reaction. Clinically, there is increased work of breathing, impaired gas exchange and sometimes haemoptysis. The chest radiograph demonstrates patchy interstitial infiltrates or consolidation not confined to anatomical segments. Gas exchange and radiographic findings may initially be unremarkable, with deterioration over the first 24–48 hours.<sup>2,6</sup> CT is more sensitive at detecting contusion, and quantification of lung volume affected predicts risk of acute respiratory distress syndrome (ARDS).<sup>33</sup> In the absence of complications (ARDS, pneumonia or aspiration), clinical and radiological recovery can be expected within 3–5 days.<sup>6,33</sup>

Treatment is supportive with humidified oxygen therapy, and encouragement of deep breathing and coughing in the spontaneously breathing patient. Non-invasive ventilation can be used in selected patients if gas exchange is poor. Intubation and mechanical ventilation are indicated for refractory hypoxaemia, or if intubation is required for non-pulmonary reasons. Routine corticosteroids are not indicated. Antibiotics should be reserved for superimposed pneumonia.<sup>2</sup>

Pulmonary laceration occurs when disruption of lung architecture, with formation of an air- or blood-filled cavity, occurs after blunt or penetrating trauma.<sup>6</sup> On chest radiography lacerations are often initially obscured by adjacent contusion, but typically take many weeks to resolve, and may be complicated by abscess formation or bronchopleural fistula.<sup>6</sup>

### BONY INJURIES

Half of all rib fractures are missed on plain chest radiography, but should be suspected if there is localised tenderness over the chest wall. Good analgesia to prevent pulmonary complications from sputum retention is essential.<sup>34</sup> This risk may not be clinically apparent initially, but deterioration in respiratory status over the next few days should be anticipated, especially in the elderly, smokers or patients with pre-existing pulmonary disease. First and second rib fractures, scapula fracture and sternoclavicular dislocation are markers of high-energy trauma.<sup>6</sup>

Most sternal fractures occur in restrained occupants involved in frontal impact vehicular crashes. Associated

**Figure 69.6** Types of flail chest. (Modified from Wanek S, Mayberry JC. Blunt thoracic trauma: flail chest, pulmonary contusion, and blast injury. *Crit Care Clin* 2004; **20**: 71–81.)

thoracolumbar spine fractures are common.<sup>24</sup> Blunt cardiac injury should be suspected with displaced sternal fractures.<sup>24</sup>

### FLAIL CHEST

Fracture of at least four consecutive ribs in two or more places results in a flail segment with paradoxical movement of the chest wall during tidal breathing (Figure 69.6).<sup>2</sup> Associated pulmonary contusion is often present. Younger patients with no other major injuries, no pulmonary comorbidities, and good analgesia can often be managed with non-invasive ventilation or oxygen therapy alone.<sup>35</sup> Deteriorating gas exchange and sputum retention are indications for intubation and mechanical ventilation. Prolonged ventilatory support is often not necessary in patients whose associated injuries and comorbidities are not severe. Surgical stabilisation has been advocated for severe flail to reduce the duration of ventilation.<sup>36</sup>

### EXTRAPLEURAL HAEMATOMA

Traumatic extrapleural haemorrhage arises when chest wall bleeding does not enter the pleural space.<sup>37</sup> Chest radiography shows a parietal shadow that does not cause blunting of the costophrenic angle or shift with gravity. A large haematoma should be evacuated with a chest tube or by thoracotomy.

### SYSTEMIC AIR EMBOLISM

This is more frequent with penetrating injuries and is immediately life threatening. The typical presentation is circulatory collapse after institution of positive-pressure ventilation, when the pulmonary airspace pressure exceeds pulmonary venous pressure (Table 69.2). Focal

neurological changes in the absence of head injury also suggest the diagnosis. Characteristic head CT findings have been described.<sup>38</sup>

When suspected, maintenance of spontaneous ventilation is preferred. If positive-pressure ventilation is necessary, an  $FiO_2$  of 1.0 should be used, with ventilatory pressures and volumes reduced to a minimum. Selective lung ventilation, using a double lumen endotracheal tube or bronchial blocker, and/or high frequency ventilation, should be considered.<sup>8</sup> However, urgent thoracotomy, with hilar clamping or lung isolation, is usually indicated.<sup>8</sup> Hyperbaric oxygen therapy has been used to treat cerebral air embolism, but is often impractical.<sup>38</sup>

### COMPLICATIONS AND ICU MANAGEMENT

On admission to ICU, rewarming, correction of coagulopathy and ongoing fluid resuscitation are often required. Pericardial tamponade and persistent air leak should be anticipated in post-thoracotomy patients.<sup>9</sup> A restrictive approach to fluid therapy is indicated for patients who have undergone lung surgery. However, care should be taken to ensure adequate fluid resuscitation. A judicious transfusion policy should be employed with all patients.<sup>39</sup>

As with other critically ill or injured patients, prophylactic measures against thromboembolism<sup>40</sup> and upper gastrointestinal stress ulceration should be used. Adequate nutrition is important to ameliorate the hypermetabolic and catabolic metabolic changes, reduce the incidence of sepsis, and improve outcome. Nutrition should be instituted early, preferably via the enteral route. Nasogastric feeding may be limited by gastric stasis, in which case nasojejunal feeding is usually successful.

### ACUTE RESPIRATORY FAILURE AND MECHANICAL VENTILATION

Respiratory complications are common. When acute lung injury occurs early after trauma, common causes are pulmonary contusion, aspiration, massive transfusion and prolonged shock or delayed resuscitation with severe systemic inflammatory response. Aspiration with persistent lobar collapse is an indication for bronchoscopy to exclude bronchial obstruction from particulate obstruction. When lung injury develops several days later, sepsis – of either pulmonary or non-pulmonary origin – is a more likely cause.

The approach to mechanical ventilation for intubated patients follows the same principles as with other critically ill patients:

- Patients with acute lung injury/ARDS should be ventilated with a lung-protective strategy.<sup>41</sup> However, high PEEP and permissive hypercapnia are contraindicated if there is associated head injury.

- Patients with pneumothorax or tracheobronchial injury should be managed with low PEEP, low peak airway pressures, and early transition to spontaneous ventilation if possible.
- Patients with flail chest may benefit from the splinting effect of moderate levels of PEEP.
- Failure to wean from mechanical ventilation should raise suspicion of fluid overload, diaphragmatic injury, cardiac dysfunction or flail.

### SPUTUM RETENTION

Sputum retention leads to progressive pulmonary collapse, with impaired gas exchange, increased work of breathing and increased risk of infection. Smokers, or patients with pre-existing respiratory disease, are particularly at risk. In the spontaneously breathing patient, good analgesia without excessive sedation is required to allow the patient to breathe deeply and cough adequately. In the intubated/ventilated patient, humidification, tracheal suctioning and regular position changes are important. In unintubated patients with an inadequate cough, but no other indication for ventilation, a minitracheostomy may avoid the need for conventional intubation.

### ANALGESIA

Adequate analgesia is essential for deep breathing and effective coughing, which, if achieved, will reduce the likelihood that endotracheal intubation is needed for less severely injured patients. Analgesia also facilitates chest physiotherapy and early mobilisation, reducing pulmonary morbidity. The choice of analgesia depends on the severity of illness and may vary over time. Options include:<sup>34</sup>

- *Intravenous morphine* by frequent small boluses or continuous infusion. This is the mainstay of analgesia for severely injured patients who are intubated and ventilated. Patient-controlled analgesia (PCA) using morphine can be used for cooperative unintubated patients.
- *Thoracic epidural infusion* of combined opioid and local anaesthetic agent (e.g. fentanyl 2 µg/ml + bupivacaine 0.125% at 5–15 ml/h). This is the preferred option for unintubated patients, particularly the elderly, if four or more ribs are fractured, or if there are cardiopulmonary comorbidities. It may also be used to facilitate successful extubation of ventilated patients who still have significant analgesia requirements
- *Intercostal nerve block*. This can be used if only a few lower ribs are fractured. Either a single large bolus (20 ml of 0.5% bupivacaine) can be injected into one intercostal space, or smaller amounts can be injected at multiple levels. Repeated injections may be required.
- *Paravertebral block*. This is rarely used unless thoracic surgery is performed.

- *Non-steroidal anti-inflammatory agents*. These should only be used in fully resuscitated patients with normal renal function and no other contraindications.
- *Paracetamol* given regularly except in the presence of hepatic dysfunction.

### PNEUMONIA

Sepsis is the principal cause of late death after major trauma. Breach of the skin surface barrier, devitalised tissues, and the presence of invasive drains and catheters make the trauma patient especially prone to bacterial invasion. In the chest-injured patient, pulmonary contusion, emergency intubation, shock, blood transfusion and the presence of extrathoracic injuries increase the risk of nosocomial pneumonia.<sup>42</sup>

Early-onset pneumonia (within the first few days of hospitalisation) may result from aspiration at the time of injury, particularly after head injury. Common pathogens are *Haemophilus influenzae*, Pneumococcus and anaerobes. Late-onset nosocomial pneumonia is more likely to be due to aerobic Gram-negative bacilli and *Staphylococcus aureus*.

The diagnosis of pneumonia is suspected if there are new or progressive infiltrates on the chest radiograph and deterioration in respiratory status. However, new infiltrates may also be caused by pulmonary contusion, pleural fluid collections, atelectasis, aspiration and pulmonary oedema. Infection is supported by the presence of purulent sputum, new fever and leukocytosis. Confirmation depends on culture of tracheal aspirate or bronchoscopic samples.<sup>43</sup> Antibiotic therapy should be targeted at causative organisms. Prompt empiric antibiotics should be started in unstable patients, with re-evaluation at 48–72 hours.

Preventative measures include careful hand cleansing, reduced duration of intubation and ventilation, semirecumbent position, enteral nutrition, avoidance of excessive sedation or hyperglycaemia, and avoidance of prolonged prophylactic antibiotics.<sup>43</sup> The role of selective decontamination of the digestive tract remains controversial.

### RETAINED HAEMOTHORAX AND EMPYEMA

Haemothorax that is not adequately drained within a few days becomes clotted and unable to drain via intercostal tube. The clot becomes organised and fibrosed with progressive pleural thickening (fibrothorax). This results in loss of lung volume, impaired pulmonary compliance and increased risk of empyema formation. Retained haemothorax should be evaluated by ultrasound or CT. Small haemothoraces (< 300 ml) in clinically stable patients where the pleural cavity has not been violated may be observed. However, in the presence of respiratory compromise, suspected empyema or retained haemothorax over 500 ml, further drainage is required. This should be performed within 5–7 days, before the development of fibrothorax or empyema.

If the initial chest tube is poorly positioned or blocked, a second tube may be placed through a different skin incision, preferably under ultrasound or CT guidance. In the absence of a bleeding diathesis or empyema formation, early evacuation of retained haemothorax (within a few days of the initial haemothorax) can be attempted with intrapleural administration of a thrombolytic agent. Streptokinase 250 000 units, or urokinase 100 000 units, in 100 ml saline is instilled into the intercostal tube for 4 hours each day until resolution of haemothorax with minimal further drain losses.<sup>44</sup> Alternatively, video-assisted thoracoscopic surgery (VATS) may be used in haemodynamically stable patients who can tolerate single lung ventilation.<sup>30,31</sup> Failure of these techniques, or empyema formation, requires formal thoracotomy ± decortication.

### FAT EMBOLISM SYNDROME

Fat embolism invariably occurs in patients with long bone fractures.<sup>45</sup> Although fat embolism syndrome (with pulmonary, neurological and cutaneous sequelae) is uncommon, oxygen desaturation occurs frequently, and may be more severe and prolonged in patients with parenchymal lung injury.<sup>46</sup> Treatment is supportive, but early resuscitation and fracture stabilisation are important preventative measures.<sup>45</sup> Early (< 24 hours) intramedullary nailing is the fixation method of choice, resulting in fewer orthopaedic complications than other fixation methods, and fewer pulmonary complications than delayed surgery.<sup>47</sup> However, internal fixation may provoke further fat embolism, require a longer operative time, and result in more blood loss than external fixation.<sup>47</sup> Thus, in severely chest-injured patients, temporary stabilisation using external fixation, with intramedullary nailing several days later, is preferred.<sup>47</sup>

### PROGNOSIS

Reported mortality rates for chest-injured patients vary greatly, reflecting the severity of chest injury and associated extrathoracic injuries. Initial physiological markers that predict adverse outcome are low Glasgow Coma Scale score, hypotension and high respiratory rate. In patients with severe blunt trauma, mortality is significantly higher with bilateral than unilateral chest injuries, and depends more on the extent of parenchymal lung injury than the extent of chest wall injury.<sup>48</sup> Older age correlates strongly with worse outcome, even though the elderly are more likely to suffer rib fractures than parenchymal lung injury.<sup>48</sup> In the elderly, the risk of death or pneumonia increases with each additional rib fractured. In younger patients, better physiological reserve means that outcome is only significantly worsened if four or more ribs are fractured.<sup>34,49</sup> Obese patients (BMI > 30) are likely to suffer more complications during hospitalisation than non-obese patients.<sup>50</sup>

# Spinal injuries

Geoff A Gutteridge

There are few injuries that have a more devastating impact on both the patient and their family than spinal cord injuries (SCI). The physical, psychological and functional sequelae of permanent disability are immense. In addition, the economic cost to the individual and to society, with the loss of productivity and costs of hospitalisation, rehabilitation and ongoing care, are enormous.

## AETIOLOGY

The incidence of SCI in developed countries is 12–53 new cases per million population per year (excluding deaths before reaching hospital).<sup>1</sup> There is some variation in the incidence and causes in different countries. About 80% of SCI are male, usually in the 15–35 years age group.

SCI are due mainly to motor car, motor bike and bicycle accidents (50%), falls (15–20%) and sporting injuries (10–25%).<sup>1</sup> Alcohol ingestion is frequently an associated factor. Work-related injuries account for 10–25%, and physical violence for 10–20% of SCI, especially from gunshot injury in the USA. Sporting and recreational injuries appear to be increasing (but with fewer now due to diving), and there is an increasing incidence of SCI in the elderly, especially from falls.<sup>2</sup> Ischaemic SCI is occasionally due to aortic injury or cross clamping. Pre-existing spinal pathology predisposes to SCI, including osteoarthritis, spinal canal stenosis, ankylosing spondylitis, rheumatoid arthritis and congenital abnormalities.

Fifty-five per cent of SCI are cervical (most at the C4–6 levels), with thoracic, thoracolumbar and lumbosacral injuries each being 15% of SCI. Forty-five per cent of SCI are complete and 55% incomplete. Between 20 and 60% of patients with SCI have significant associated injuries such as head and chest injuries.<sup>1</sup>

## PATHOGENESIS

### SPINAL INJURY

#### CERVICAL SPINE

Injury to the cervical spine has been classified several ways<sup>3–5</sup> relating to the mechanism of injury using the

two-column concept. Differences appear to be due to the fact that compression of the anterior column is associated with distraction of the posterior column, and vice-versa. Injuries may be grouped according to the predominant mechanism of injury (Table 70.1) with these mechanisms having characteristic radiological patterns.

#### THORACOLUMBAR SPINE

The classification of Denis<sup>6</sup> using the three-column concept of the spine has been widely adopted. Major injuries are classified as in Table 70.2.

### SPINAL CORD INJURY

Trauma to the spinal cord results in immediate primary and delayed secondary injury processes.

#### PRIMARY INJURY

Direct mechanical injury may produce focal compression, laceration or traction injury to the cord. Actual transection is unusual. Ischaemic injury may result from interference to the segmental spinal arterial supply.

#### SECONDARY INJURY

An understanding of secondary injury mechanisms has come from experimental SCI in animals.<sup>1,7</sup> Local hypoperfusion and ischaemia begin at the site of injury, extending progressively over hours from the site of injury in both directions. There is loss of spinal cord autoregulation, complicated by arterial hypotension with high SCI. Apart from ischaemia, other mechanisms may contribute to the secondary injury. These include the release of free radicals, eicosanoids, calcium, proteases, phospholipases and excitotoxic neurotransmitters (e.g. glutamate).

Petechial haemorrhages begin in the grey matter, progress over hours and may result in significant haemorrhage into the cord. There is oedema, cellular chromatolysis and vacuolation, and ultimately neuronal necrosis. Apoptosis, especially of oligodendrocytes, also occurs.<sup>1</sup> In the white matter vasogenic oedema, axonal degeneration and demyelination follow. Infiltration of polymorphs occurs in the haemorrhagic areas. Late coagulative necrosis and cavitation subsequently take place.

### CLINICAL PRESENTATION

Spinal and spinal cord injuries should be suspected after severe trauma or head injuries, if there are motor or sensory symptoms or signs, or the patient reports neck or back pain.

### NEUROLOGICAL ASSESSMENT

A detailed neurological examination is essential, including motor function, sensory function (spinothalamic and dorsal column) and reflexes, as well as anal motor function, sensation and reflexes. The vital capacity should be measured. This neurological examination provides the most useful information with respect to assessment of the SCI and to prognosis. However, it may be difficult to conduct on presentation due to head or other injuries, pain, alcohol or the administration of analgesic or other drugs.

In an alert patient SCI may be obvious with limb paralysis or weakness, numbness and absence of reflexes.

With a complete SCI there is muscle paralysis, with somatic and visceral sensory loss below a discrete segmental level. *Spinal shock* is usually present, with the additional features of muscle flaccidity, absence of tendon reflexes, vaso- and venodilatation, loss of bladder function and paralytic ileus. This term refers to a form of neurogenic 'shock' with temporary loss of somatic and autonomic reflex activity below the neurological level of injury. It usually lasts for 1–3 weeks before the recovery of distal reflex activity in the isolated cord segment.

### TERMINOLOGY

The terminology for SCI has now been standardised.<sup>8</sup>

- *Tetraplegia* (preferred to quadriplegia) refers to impairment or loss of motor and/or sensory function in the cervical segments of the spinal cord due to damage of the neural elements within the spinal canal.

**Table 70.3** American Spinal Injury Association (ASIA) impairment scale

<b>A</b>	Complete: No sensory or motor function is preserved in the sacral segments S4–S5
<b>B</b>	Incomplete: Sensory but not motor function is preserved below the neurological level and includes the sacral segments S4–S5
<b>C</b>	Incomplete: Motor function is preserved below the neurological level, and more than half of key muscles below the neurological level have a muscle grade less than 3
<b>D</b>	Incomplete: Motor function is preserved below the neurological level, and at least half of key muscles below the neurological level have a muscle grade greater than or equal to 3
<b>E</b>	Normal: Sensory and motor function is normal

- *Paraplegia* refers to impairment or loss in the thoracic, lumbar or sacral segments of the cord, as well as conus and cauda equina injuries within the spinal canal.
- *Neurological level* is reported as the most caudal cord segment with normal motor and sensory function on both sides. As differences often exist it is preferred to describe the individual motor and sensory levels on each side (as the most caudal segments with normal motor and sensory function, respectively). In this context, normal motor function refers to a motor grade of 3, with all cephalad motor levels being grade 5.
- *Skeletal level* refers to the level with the greatest vertebral damage on X-ray.
- *Complete* injury refers to the absence of motor and sensory function in the lowest sacral segment.<sup>9</sup> A *zone of partial preservation* exists if there is partial innervation of motor and sensory segments below the neurological level. This term is only used in complete SCI. If partial innervation of motor and sensory function is found below the neurological level *and* includes the lowest sacral segment (with anal sensation and voluntary external anal sphincter contraction) the injury is defined as *incomplete*. Grading of complete and incomplete SCI utilises the ASIA impairment scale<sup>8</sup> (Table 70.3).

### INCOMPLETE SCI

Incomplete SCI tend to occur in characteristic syndromes.<sup>10</sup>

- The *central cord syndrome* is the most common, usually resulting from hyperextension injury to the neck, often in the elderly with a narrow spinal canal. There is disproportionate paralysis in the arms compared with the legs, and variable sensory loss.
- The *anterior cord syndrome* has extensive bilateral paralysis with loss of pain and temperature sensation, but preservation of sensory function in the posterior white columns.
- The *Brown-Sequard syndrome* is due to damage to one side of the spinal cord with loss of ipsilateral motor and

proprioceptive function, as well as contralateral pain and temperature sensation. It usually results from penetrating injury.

- The *conus medullaris syndrome* is due to T12/L1 injury with damage to lumbar and sacral cord segments producing extensive paralysis in the legs of both upper and lower motor neurone type.
- The *Cauda equina syndrome* results from skeletal injuries below L1 with damage to the lumbosacral nerve roots resulting in lower motor neurone paralysis, and bladder and bowel areflexia.
- Spinal cord injury without radiological abnormality (SCIWORA) occurs mainly in children, but is now very uncommon with magnetic resonance imaging (MRI).

#### UNCONSCIOUS OR UNCOOPERATIVE PATIENTS

The neurological examination may be difficult if the patient is unconscious or uncooperative. In this case a number of signs may be helpful in drawing attention to a SCI as in Table 70.4. Confirmation of SCI may be established by MRI or somatosensory-evoked potentials (SSEP).

#### SPINE

Alert patients will report neck or back pain and tenderness with spinal injuries. A palpable gap may be felt between the spinous processes of thoracolumbar vertebrae. However, a spinal injury is readily overlooked in association with head or other major injuries, or alcohol ingestion.

#### ASSOCIATED INJURIES

##### CERVICAL SPINE INJURY/TETRAPLEGIA

Overall with major trauma the incidence of cervical spine injury (CSI) is 1–3%.<sup>11</sup> However, 2–10% of patients with head injuries have a CSI. The more severe the head injury, the more likely is CSI to be present. Patients with head injuries should be assumed to have a CSI until proved otherwise. Of patients with a cervical SCI, 25% have some degree of head injury, with 2–3% having a severe injury.<sup>1,12</sup>

**Table 70.4** Signs of SCI in unconscious or uncooperative patients

Response to pain above, but not below a suspected level
Flaccid areflexia in the arms and/or legs
Elbow flexion with the inability to extend suggestive of cervical SCI
Paradoxical pattern of breathing with indrawing of upper chest on inspiration (in the absence of upper respiratory tract obstruction or chest injury)
Inappropriate vasodilatation (in association with hypothermia, or in the legs but not the arms with thoracolumbar SCI)
Unexplained bradycardia, hypotension
Priapism
Loss of anal tone and reflexes

##### THORACOLUMBAR SPINE INJURY/PARAPLEGIA

Chest injuries are often present and are difficult to assess with the inability to take an erect chest X-ray, and the presence of a mediastinal haematoma associated with the vertebral injury. Contrast-enhanced helical CT of the chest may be used to assess other chest injuries, and to exclude an aortic injury,<sup>13</sup> although aortography may be preferred for this purpose.

Abdominal injuries are difficult to diagnose if there is a SCI. However, they should be suspected if there is excessive hypotension, referred shoulder pain, or free gas or fluid seen on X-ray of the spine or chest. Abdominal CT, diagnostic peritoneal lavage or ultrasound may be used to delineate these injuries.<sup>14</sup>

#### IMAGING

##### PLAIN X-RAYS (FIGURE 70.1)

Plain X-rays remain the primary screening method for suspected spinal injuries in symptomatic patients, except in unconscious or multitrauma patients. However, the absence of a detectable abnormality does not exclude a spinal injury. Lesions may not be seen if the views are inadequate or of poor technical quality, or the observer is inexperienced. Even without these limitations, plain X-rays of the neck frequently miss fractures and subluxations,<sup>15,16</sup> and a high index of suspicion should be maintained. Adequate views of the entire cervical spine from the base of the skull down to and including the C7–T1 junction should always be obtained. Abnormalities of the prevertebral soft tissues are often present and indicative of subtle injuries.<sup>4</sup>

With the cervical spine the three-view trauma series is standard in most hospitals (Table 70.5). This consists of lateral, anteroposterior (AP) and odontoid (open mouth) views. A five-view series with supine oblique views has been recommended as improving the diagnostic yield,<sup>17</sup> but other studies show no difference in the detection rate. Lateral and AP views are standard screening views for the thoracolumbar spine.

##### COMPUTED TOMOGRAPHY (CT) SCANNING

The sensitivity of CT scanning is much greater than plain X-rays in the detection of spinal injuries,<sup>15</sup> especially with the newer multidetector CT machines. CT scanning now has an essential role in the detection and evaluation of spinal injuries, as well as the exclusion of injuries with spinal clearance.<sup>18</sup>

Indications for CT scanning have been regarded as:

- inadequate plain X-rays
- high clinical suspicion of injury despite normal plain X-rays, e.g. ongoing or persistent neck pain or tenderness, or the development of neurological symptoms or signs
- suspicious plain X-ray findings

**Figure 70.1** Plain lateral X-ray of the cervical spine showing a C5/6 dislocation.

- abnormal plain X-rays: further investigation of fracture, subluxation or dislocation seen on plain X-rays. Additional fractures are frequently found in the same, adjacent or distant vertebrae
- evaluation of the spinal canal

**Table 70.5** Basic examination of plain X-rays of cervical spine

Must include occipital condyles to C7–T1 junction  
Lateral is the most important view and will show most injuries

Soft tissues:

Prevertebral soft tissue shadow
---------------------------------

However, CT scanning should now be undertaken in all suspected or proven spinal injuries. If patients are unconscious or have suffered severe or multiple trauma, CT scanning should be undertaken as the first line imaging, without screening plain X-rays, for the evaluation of cervical and thoracolumbar injuries.<sup>2,19</sup> Sagittal and coronal reconstructions should be routinely obtained. CT scanning of the spine should be coordinated with CT of other regions if needed. CT myelography has now been replaced by MRI, but may be indicated if MRI is not available or is contraindicated.

### MAGNETIC RESONANCE IMAGING (MRI) (FIGURE 70.2)

MRI allows visualisation of soft tissues including ligaments, intervertebral discs and the spinal cord itself where it may show the site, extent and nature of the SCI.<sup>4</sup> However, it involves a prolonged study with physical isolation of the patient in a difficult environment. Nevertheless, it provides important information in evaluation of the neurological deficit, assessment of prognosis and in the planning of surgical management of SCI. MRI is urgent if there is an unexplained neurological deficit, discordance between the skeletal and neurological levels of injury or worsening neurological status.

**Figure 70.2** T2 weighted MRI of the same patient as in Figure 70.1 showing severe spinal cord damage.

### CLEARANCE OF THE CERVICAL SPINE

Although familiarity with common injuries is desirable, in view of the severe consequences of a missed spinal injury, clearance of the spine must only be undertaken by a suitably experienced specialist after adequate imaging. Neurological deterioration with missed spinal injuries still occurs, usually as a result of insufficient imaging.<sup>20</sup>

The Canadian C-spine rule<sup>21,22</sup> now provides guidelines for the need for imaging in alert, stable trauma patients in an emergency department setting, but this would not frequently apply to patients in the intensive care unit (ICU). Clearance of the cervical spine in unconscious ICU patients remains controversial with no standardised approach.<sup>23</sup> The best approach would seem to be fine-cut helical multidetector CT scanning with reconstructions,<sup>18</sup> reserving the further use of MRI for selected

cases such as those with a high-velocity mechanism of injury or high injury severity score, rather than using flexion/extension imaging to detect unstable ligamentous injuries.<sup>16,24,25</sup>

Early clearance of CSI is desirable to allow early removal of the cervical collar with its associated problems of pressure sores, difficult access for airway management and insertion of central venous lines, and increased intracranial pressure with head injuries.<sup>26</sup>

### MANAGEMENT

The main principles in the early management of a spinal injury relate to the prevention of secondary injury and the provision of optimum conditions for neurological recovery. Emphasis should be on resuscitation measures and immobilisation, together with good protocols for clearance of the spine.

### PREHOSPITAL MANAGEMENT

It should be assumed that all severe trauma patients have a spinal injury until proven otherwise. If a SCI is obvious, basic trauma assessment and resuscitation principles still apply.

### RESPIRATION AND CIRCULATION

An adequate airway must be established by clearance of foreign material, jaw thrust and an oro- or nasopharyngeal airway if necessary. Adequate ventilation must be ensured with the provision of supplementary oxygen by facemask. Immediate endotracheal intubation and artificial ventilation may be required.

Hypotension may be due to a high SCI and will need some plasma volume expansion to correct relative hypovolaemia, but excessive volume expansion should be avoided. Hypovolaemia may also be due to other injuries.

### IMMOBILISATION

If a CSI is suspected, the patient may have to be extricated from the scene of the accident. Manual stabilisation of the head in a neutral position is used with four people lifting and one controlling the head and neck. The neck is immobilised in a rigid, hard collar that should be applied without neck movement. The patient is placed supine on a rigid spine board with straps and occipital padding.<sup>26</sup> Sandbags should be placed on either side of the head, and the head secured with the application of broad tape across the forehead. With a suspected thoracolumbar spinal injury (TLSI) the patient is again lifted as a single unit or log rolled as necessary.

### HYPOTHERMIA

Prevention of hypothermia in the field is important with SCI.

## EMERGENCY MANAGEMENT

The initial management of spinal injuries follows the usual trauma triage principles with a primary survey, resuscitation and a careful secondary survey. The measures previously mentioned for establishing an adequate airway, and for providing adequate ventilation and circulation should be continued to minimise any further spinal cord insult.

After stabilisation, definitive X-rays and CT are undertaken whilst maintaining spinal immobilisation. A cervical collar does not provide rigid immobilisation and manual stabilisation is still necessary with patient transfers.<sup>27</sup> The prevention of hypothermia is a continuing issue in both the emergency and radiology departments. Morphine analgesia is likely to be required for pain at the spinal fracture site and/or other injury.

With SCI, a nasogastric tube should be inserted to prevent aspiration of gastric content and bowel distension from the associated ileus. A urinary catheter should also be inserted to monitor the urine output and prevent overdistension of the bladder. Attention to the skin, taking care to prevent pressure areas, is important. If high-dose corticosteroids are to be used they should be started within 8 hours from the time of SCI (see pharmacological treatment). If stable, early transport to a definitive care facility such as a multidisciplinary SCI referral centre is recommended. This approach has been shown to result in fewer complications and a reduced hospital length of stay.<sup>2</sup> Initially, patients (especially tetraplegics) should be admitted to the ICU for the detection and management of respiratory and cardiovascular problems.<sup>28</sup>

## HOSPITAL/ICU MANAGEMENT

### RESPIRATORY

#### *Respiratory dysfunction*

Respiratory dysfunction is a major cause of morbidity after SCI, especially in tetraplegics.<sup>29,30</sup>

**Tetraplegia** The diaphragm is innervated by the C3–5 segments. With a C5 SCI the diaphragm is intact but about 50% still need short-term mechanical ventilation (MV). With a C4 SCI there is partial loss of diaphragmatic innervation, and nearly all need short-term MV. With a C3 SCI most of the diaphragmatic innervation is lost, and all need initial MV, with about 50% requiring permanent MV.<sup>29</sup> Scalene muscle weakness and intercostal muscle paralysis lead to a paradoxical pattern of breathing, and abdominal muscle paralysis produces an inability to cough.

The vital capacity (VC) is markedly reduced and is usually 1.0–1.5 l on presentation. In C5–6 complete SCI the VC is decreased to 31% of predicted during the first week, and with C4 lesions to 24%.<sup>31</sup> It often undergoes a further decrease due to atelectasis, and sometimes from ascent of the neurological level. However, there is usually a significant increase in VC by 3–5 weeks after injury, reaching values of 44–51% of predicted by 3 months.<sup>31</sup>

This is thought to be due to stiffening of the ligaments and joints of the rib cage, and the return of intercostal muscle tone preventing indrawing of the chest wall by the diaphragm. The VC and tidal volume are dependent on posture and surprisingly are greatest when supine due to the more cephalad position of the diaphragm.<sup>30,32</sup> Hypoxaemia is very common in the early phase.

**Paraplegia** The diaphragm is intact, but there is paralysis of the intercostal and abdominal muscles dependent on the neurological level of the SCI. The VC is reduced but is usually adequate, and there is variable impairment of the cough mechanism.

#### *Respiratory management*

The aims of respiratory management are to prevent hypoxaemia, and the development of respiratory complications and failure. Humidified oxygen should be provided by facemask. A regimen of 2-hourly postural change is instituted on a turning bed, or with log rolling, to prevent atelectasis. An intensive physiotherapy regimen is started with 4-hourly deep breathing using non-invasive ventilatory support by mouthpiece, with bronchodilators if necessary. Assisted coughing (where the physiotherapist pushes on the abdomen synchronous with glottic closure as the patient attempts to cough) may be used to clear sputum. Serial evaluation of respiratory rate, oxygenation, vital capacity and chest X-ray is necessary.

#### *Respiratory complications*

Respiratory complications are frequent and the major reason for SCI patients to be admitted to the ICU. They are dependent on the level of the SCI, the presence of underlying respiratory disease, age and associated injuries. Respiratory complications are the leading early cause of death after SCI, with most attributed to pneumonia.

These complications consist of atelectasis, sputum retention, pneumonia and acute respiratory failure (ARF). There is also the risk of aspiration of mouth secretions and gastric content, acute respiratory distress syndrome (ARDS), acute pulmonary oedema and pulmonary embolism. Indications for intubation and MV include an inability to clear secretions, progressive atelectasis or pneumonia, or frank ARF. Intubation and MV should also be undertaken for associated head or chest injuries, or if the VC falls below 12–15 ml/kg.

**Endotracheal intubation with CSI** The options are awake fibreoptic nasotracheal intubation or orotracheal intubation under general anaesthesia. No particular approach has been shown to be superior, and either is acceptable depending on individual circumstances. Factors determining the choice include the urgency of the situation, the skill and training of medical staff, the availability of equipment, the conscious state of the patient and the associated injuries.<sup>11</sup>

Awake nasotracheal intubation with topical anaesthesia allows continuous neurological assessment, but should only be attempted with an alert cooperative patient. It is contraindicated if urgent intubation is required, or if there is coagulopathy, nasal obstruction or basal skull fracture. Blind intubation often requires multiple attempts, and has a significant complication and failure rate. Fiberoptic intubation is a more acceptable technique for those with appropriate training, although desaturation during the procedure is common.

Orotracheal intubation under anaesthesia is a safe technique, despite the greater potential for neck movement, and there is no evidence to suggest that neurological outcome is worse.<sup>11,33</sup> Preparation should be made for a rapid sequence induction and a difficult intubation. The anterior part of the collar is removed to allow adequate mouth opening, manual stabilisation of the head is performed without traction, and cricoid pressure is applied. Intravenous atropine is given, followed by the induction agent and muscle relaxant. Suxamethonium should be avoided between 10 days and 7 months after SCI to prevent severe hyperkalaemia.<sup>34</sup> Rocuronium is then the preferred relaxant.

After intubation, MV is instituted using larger tidal volumes and an I:E ratio of at least 1:2. Persistent and/or recurrent atelectasis remains a problem, with the added risk of nosocomial ventilator-associated pneumonia.

**Tracheostomy** Once intubated, tracheostomy is usually necessary. It improves comfort and communication, and facilitates weaning from MV and discharge from the ICU. Percutaneous tracheostomy may be used after internal fixation of the cervical spine, but often the neck cannot be extended into the optimal position. Surgical tracheostomy is preferred and is ideally performed in the ICU.

**Weaning from MV** With high tetraplegics weaning can be very prolonged, difficult and is frequently complicated by recurrent atelectasis. Weaning is usually started after resolution of any pulmonary pathology, in the supine position and having a VC of at least 10 ml/kg. No method of weaning has been shown to be superior. Weaning is most conveniently begun by conversion to pressure support ventilation, ideally with flow triggering. Incremental reduction in the pressure support level is carried out as tolerated, before conversion to a T-piece or tracheostomy shield. Alternatively, T-piece trials may be used from the outset, but need much more psychological support to prevent patient anxiety and loss of confidence. Nearly all C4 or lower tetraplegics, and about 50% of C3 tetraplegics can be weaned from MV given time.<sup>29</sup> When weaned, patients may be discharged from the ICU, but tracheostomy decannulation should be delayed until it is clear that the patient is coping off MV, atelectasis does not recur, sputum production is minimal and aspiration is not occurring.

C1–3 tetraplegics who cannot be weaned are usually managed with permanent MV via a home ventilator. Some of these patients may be suitable for phrenic nerve pacing.<sup>35</sup> Other tetraplegics with very limited ventilatory reserve are likely to require nocturnal ventilatory support.

## CARDIOVASCULAR

### Cardiovascular dysfunction

With tetraplegia there is loss of supraspinal sympathetic control of the heart and peripheral vasculature, with unopposed vagal activity. In the early phase of spinal shock there is also loss of autonomic reflex activity in the isolated cord segment. These changes lead to sinus bradycardia and arterial hypotension associated with systemic vaso- and venodilatation. Similar problems are seen in paraplegia, especially with SCI above T6. Patients are sensitive to further hypotension with postural change, blood or fluid loss, and intermittent positive-pressure ventilation (IPPV).

### Cardiovascular management

Monitoring should include ECG, arterial blood pressure (BP), subclavian or femoral central venous pressure (CVP) and urine output. Some plasma volume expansion is necessary to correct a degree of relative hypovolaemia. Previously mean arterial pressures (MAP) of 60–70 mmHg have been tolerated if the urine output was adequate (> 0.5 ml/kg per hour). However, animal evidence strongly suggests that hypotension after SCI contributes to secondary ischaemic injury of the cord. Clinical studies of BP elevation suggest improved neurological outcomes without adverse effects.<sup>36</sup> Consensus guidelines now recommend prompt correction of hypotension, and maintenance of MAP at 85–90 mmHg with vasopressors for the first 7 days after SCI.<sup>37</sup>

### Cardiovascular complications

**Venous thromboembolism** Venous thromboembolism has a 40% incidence without prophylaxis, with pulmonary embolism accounting for up to 15% of deaths in the first year after SCI. Consensus guidelines<sup>38</sup> for prevention recommend intermittent pneumatic compression or electrical calf muscle stimulation, plus enoxaparin 30 mg twice daily or adjusted dose unfractionated heparin (to a high normal activated partial thromboplastin time) starting within 72 hours and continued for 8–12 weeks depending on risk factors. If high risk and anticoagulation fails or is contraindicated, an inferior vena caval filter should be inserted.

**Bradycardia, asystole** Due to disruption of sympathetic pathways and unopposed vagal activity these problems are extremely common after high SCI. With severe cervical SCI the incidence of persistent bradycardia was 100% and transient marked bradycardia (heart rate < 45 per min) 71%, with cardiac arrest occurring in 16% of patients. These arrhythmias peaked in the first week and resolved 2–6 weeks after injury.<sup>39</sup> Tracheal suction in the presence of hypoxia appears to be a cause of cardiac arrest preventable with atropine.

**Acute pulmonary oedema** This is now less common, but does occur with misguided attempts to correct hypotension with excessive volume expansion, in the absence of CVP monitoring.

**Autonomic hyperreflexia** This is not a problem in the early phase. It begins within 6 months of SCI after recovery from spinal shock, and is usually only significant with SCI above the T6 level.<sup>40</sup> In response to an afferent stimulus below the neurological level there is excessive paroxysmal autonomic reflex activity. The stimulus is often bladder or bowel distension, but may be cutaneous stimulation or surgery. The massive sympathetic efferent response causes intense vasoconstriction that produces severe hypertension, with the risk of seizures and cerebral haemorrhage. Baroreceptor-mediated bradycardia may occur with reflex vasodilatation above the neurological level in paraplegics. Treatment consists of preventing or removing the stimulus, placing the patient in an upright posture and, if necessary, short-acting i.v. antihypertensive drugs such as nitroprusside.

### NEUROLOGICAL

Drug treatment strategies are aimed to reduce secondary injury mechanisms, and to allow recovery of damaged neurones. Encouraging results have been achieved with animal experiments but only minimal improvement in human SCI using corticosteroids. In the NASCIS 2 trial,<sup>41</sup> methylprednisolone – if started within 8 hours of SCI (30 mg/kg bolus followed by 5.4 mg/kg per hour for 23 hours) – resulted in mildly improved motor and sensory scores at 6 months and 1 year. A further trial, NASCIS 3,<sup>42</sup> showed some improvement in motor score and functional outcome if methylprednisolone started within 3–8 hours of SCI was given for 48 hours rather than 24 hours. However, this was associated with more sepsis and pneumonia. The administration of methylprednisolone has been widely, but not universally, accepted. Criticism of these studies has followed from reanalysis of the NASCIS data<sup>43</sup> and systematic review of all published studies.<sup>44</sup> An attempt to set guidelines<sup>45</sup> concluded that methylprednisolone for 24 or 48 hours was only an option for treatment of acute SCI, and that it should only be undertaken with the knowledge that evidence suggesting harmful side-effects was more consistent than suggestion of clinical benefit. No additional evidence has been forthcoming and the controversy remains.<sup>46,47</sup>

In human studies, GM-1 ganglioside, tirilazad, naloxone and nimodipine have shown no benefit.

Muscle spasticity is a late problem not seen in the acute phase in ICU. It develops after resolution of spinal shock.

### SKELETAL

The principles of management include adequate reduction, maintenance of position, and immobilisation until stability has been achieved. There are both conservative and surgical options to management of injury to the spine.

Conservative measures for CSI include closed reduction, traction in head tongs or a halo, collars or the application of a halo-thoracic brace. For TLSI postural realignment may be used. However, some of these techniques require prolonged periods of immobilisation in bed. Mechanical turning beds facilitate this approach. Some

believe that most spinal injuries, and especially TLSI, should be treated without surgery.<sup>27</sup>

Surgical techniques utilise open reduction and internal fixation to provide sufficient stability to allow early mobilisation. External supports such as a collar or brace may be added. Surgery is now utilised more frequently with the aim of achieving early stability and pain control, earlier mobilisation and rehabilitation, less muscle wasting, fewer hospital complications and earlier time for hospital discharge. If surgery is undertaken it is probably best performed at the earliest opportunity that other injuries and complications allow. In a multicentre study in North America, surgery was performed on 65% of acute SCI with little agreement as to timing.<sup>48</sup> Although claims have been made for fewer complications with earlier mobilisation and hospital discharge, there is no clear evidence in favour of surgical management.

With regard to the SCI itself, animal studies have consistently shown improved neurological outcomes with early surgical decompression of the spinal cord.<sup>49</sup> A recent systematic review of human studies concluded that early (< 24 hours) decompression produced better outcomes than delayed decompression or conservative treatment, especially for incomplete SCI with neurological deterioration.<sup>50</sup> However, there is no conclusive evidence of benefit of early decompression of the spinal cord in clinical practice, and this aspect also remains controversial.<sup>49</sup>

Physiotherapy measures are needed to preserve a full range of movement in paralysed joints and to prevent contractures.

### TEMPERATURE

With high SCI the loss of sympathetic nerve function and an inability to shiver leads to poikilothermia. Regular temperature monitoring is needed together with an approach to prevent hypothermia.

### GASTROINTESTINAL

A range of GI problems are associated with SCI. Paralytic ileus and acute gastric dilatation are frequent problems in the first few days. A nasogastric tube should be inserted immediately to protect against aspiration and respiratory impairment from abdominal distension. It may then be used for early enteral nutrition once these problems have resolved. Stress ulceration with GI bleeding has an incidence of 3–5%.<sup>41</sup> H<sub>2</sub> antagonists or proton pump inhibitors should be used for prevention. Acute acalculous cholecystitis, pancreatitis and the superior mesenteric artery syndrome are uncommon. Constipation and faecal impaction readily develop after a number of days. A preventative bowel regimen consisting of faecal softeners, suppositories and laxatives should be started early.

### URINARY

After SCI there is paralysis of the bladder detrusor and urinary retention with the risk of bladder overdistension. A urethral catheter should be inserted early and placed on continuous drainage. Bladder training techniques with intermittent catheterisation are delayed until the patient

is stable and has been discharged from the ICU. Bacterial colonisation of the urine is accepted while catheterised.

### SKIN

Pressure sores readily develop and may cause considerable morbidity, prolonged hospitalisation and need extensive plastic surgery for closure. They must be prevented by meticulous attention to 2-hourly postural change, the use of pneumatic pressure mattresses or pillows, and to the protection of bony pressure points.

### METABOLIC

Hyponatraemia has been reported to be common after complete and severe incomplete SCI.<sup>51</sup> Immobility after SCI leads to calcium mobilisation from bone, hypercalciuria and occasionally hypercalcaemia. Atrophy of denervated muscle, muscle wasting, weight loss and negative nitrogen balance are marked. Enteral nutrition should meet caloric needs (preferably estimated by indirect calorimetry) but nitrogen loss has to be accepted.<sup>52</sup>

### PAIN

Pain is common after SCI. Pain may result from vertebral fractures or the gut. Neuropathic pain may occur at, or below the level of SCI. Intravenous opioids, ketamine, lidocaine and gabapentin are effective for neuropathic pain.<sup>53</sup>

### PSYCHOLOGICAL

Prolonged supportive care is necessary for both patients and their families to deal with depression, and to help them accept and adapt to neurological disability. After intubation or tracheostomy tetraplegics have great difficulty with communication, as they are unable to write or use an alphabet board. Lip reading is utilised until a speaking tracheostomy tube can be used or a one-way speaking valve can be attached to the tracheostomy tube.

### OUTCOME

After the acute care phase SCI patients undergo extensive periods of rehabilitation to maximise their functional ability before returning to the community.

### NEUROLOGICAL RECOVERY

The prognosis for neurological recovery is best judged by neurological examination 72 hours post SCI. Most complete tetraplegics regain one motor level and do not recover functional lower limb movement. Incomplete SCI have much more recovery, and more than 50% of incomplete tetraplegics become ambulatory.<sup>54,55</sup> Significant spinal cord haemorrhage seen on MRI indicates a very low probability of motor recovery, but if < 4 mm the prognosis is better.<sup>56</sup>

### SURVIVAL

Hospital survival after SCI is now more than 90%, with increasing life expectancy in the longer term. Long-term survival studies have shown a higher mortality risk with a higher neurological level, complete SCI, older age and earlier year of injury.<sup>57</sup> Most deaths are now due to respiratory and heart disease, with a decreasing proportion due to urinary complications.

# Abdominal and pelvic injuries

Colin McArthur

Although important abdominal injuries are present in only 16–27% of hospital trauma admissions,<sup>1</sup> abdominal and pelvic injuries can represent up to 60% of missed diagnoses in preventable trauma deaths.<sup>2</sup> Most abdominal and pelvic injuries are caused by blunt trauma; penetrating aetiologies account for 6–21% of cases, depending on the society concerned.<sup>1,3</sup> Important considerations with abdominal and pelvic injuries are:

- potential for severe haemorrhage
- difficulties in diagnosing visceral injury
- severity of associated injuries (e.g. chest and head)
- complications, especially sepsis

## MECHANISMS OF INJURY

### BLUNT INJURIES

Road crashes account for most abdominal and pelvic blunt injuries. Injuries may also result from falls, assaults and industrial accidents.<sup>1</sup> Associated injuries are frequent, involving the thorax (most common), head and extremities. Seat belts and airbags reduce mortality in motor vehicle crashes (mainly by limiting brain injury), but are associated with more lower body injuries. Abdominal and pelvic injuries are more likely with vehicular side-on collisions, and when crashes result in a deformed steering wheel.<sup>4</sup>

### PENETRATING INJURIES

Stab and gunshot wounds account for most penetrating injuries to the abdomen.

### STAB AND LACERATION WOUNDS

Entry sites do not accurately predict the nature of deeper injury. Penetration of the thoracic cavity should be suspected with upper abdominal wounds; conversely, lower chest wounds may involve abdominal structures. Selective management of haemodynamically stable patients using investigation algorithms that accurately predict intra-abdominal injury has superseded mandatory laparotomy.<sup>5</sup>

### GUNSHOT WOUNDS

Injuries depend on missile calibre, and its velocity and trajectory. Intra-abdominal, thoracic and multiple organ injuries and mortality are substantially greater than with stab wounds. Laparotomy should be performed in all cases with haemodynamic instability, peritonitis or a clinically unevaluable abdomen. A non-operative approach for solid organ injury<sup>6</sup> carries the risk of missed bowel injury.

## INITIAL TREATMENT AND INVESTIGATIONS

### RESUSCITATION

Ensuring adequacy of airway, ventilation and oxygenation are immediate priorities. However, circulatory resuscitation should not delay surgery for uncontrolled haemorrhage.<sup>7</sup> End-points for replacement of blood volume are controversial.<sup>8</sup> If rapid surgical haemostasis is provided in penetrating trauma, delaying or limiting fluid resuscitation before surgery may improve outcome.<sup>9</sup> Pneumatic antishock garments provide no benefit.<sup>7,10</sup>

### CLINICAL ASSESSMENT

A full clinical examination (including the back) by experienced clinicians is most important. The mechanism of injury may direct attention to particular anatomical areas.<sup>4</sup>

- Contusions, external wounds and their relationship to underlying viscera are noted
- Abdominal distension, tenderness and peritonism are sought but auscultation for bowel sounds is not useful
- The rectum is examined for prostatic position, anal tone, blood or other evidence of injury
- Gastric aspirate and urine are inspected for blood

Isolated penetrating injuries present few diagnostic problems, but the decision to explore the abdomen can be difficult. Blunt abdominal trauma is often part of multiple injuries, and is more difficult to diagnose clinically, except when abdominal signs are obvious.

Nevertheless, in conscious patients, serial assessments can accurately identify those with significant intra-abdominal pathology. In the presence of impaired consciousness,

intellectual disability or spinal, chest or pelvic injury, clinical assessment is unreliable. Other more visually spectacular injuries may also divert attention from the abdomen.

Laparotomy is indicated on clinical grounds when there is:

- shock with signs of intra-abdominal haemorrhage (e.g. peritonism or increasing distension)
- evisceration or peritonism without shock in penetrating trauma

In all other situations where clinical examination is inadequate, further investigations must be undertaken.<sup>11</sup>

### PLAIN X-RAYS

A chest X-ray (preferably erect) is essential. It may demonstrate free intraperitoneal gas, herniation of abdominal contents through a ruptured diaphragm, or other abnormalities. Plain films of the abdomen are of no benefit. An anteroposterior pelvic X-ray is indicated for all victims of blunt trauma, except conscious patients with normal pelvis on examination.<sup>12</sup>

### INVESTIGATIONS FOR OCCULT ABDOMINAL INJURY

#### ULTRASONOGRAPHY

Focused abdominal sonography for trauma (FAST) can be performed rapidly in the resuscitation room without compromising ongoing treatment. It requires significant training to achieve acceptable accuracy,<sup>13</sup> and although highly specific, its sensitivity of around 85%<sup>14</sup> is less than that of peritoneal lavage or CT in detecting free intra-abdominal fluid following either blunt<sup>15,16</sup> or penetrating<sup>17</sup> trauma. FAST can also identify pericardial fluid, but not hollow viscus injury or the nature of solid organ injury.<sup>16</sup> FAST may reduce the need for other investigations,<sup>18</sup> but the small but important false-negative rate must be considered in determining its role in abdominal assessment algorithms.

#### PERITONEAL LAVAGE

Diagnostic peritoneal lavage (DPL)<sup>19</sup> is indicated in blunt trauma when there is haemodynamic instability or uncertain clinical findings, and in penetrating trauma when peritoneal breach is suspected.

Open and closed (percutaneous guidewire) methods are both satisfactory.<sup>20</sup>

DPL is unjustified when an indication for laparotomy already exists. It is relatively contraindicated in pregnancy, significant obesity and previous abdominal surgery.

If required in these situations (or with pelvic fractures), the supraumbilical open method should be considered. DPL undertaken early remains reliable in the presence of pelvic fractures.<sup>21</sup> DPL detects intraperitoneal injury with up to 98% accuracy,<sup>19</sup> but its high sensitivity can result in a significant non-therapeutic laparotomy rate. Cell counts of lavage effluent are more accurate than

**Table 71.1** Criteria for positive diagnostic peritoneal lavage

Clinical		
Initial aspiration of > 10 ml frank blood		
Egress of lavage fluid via chest tube or urinary catheter		
Bile or vegetable material in lavage fluid		
Laboratory		
	Blunt injury	Penetrating injury
Red cells		
Definite	> 100 × 10 <sup>9</sup> /l	> 20 × 10 <sup>9</sup> /l
Indeterminate	50–100 × 10 <sup>9</sup> /l	5–20 × 10 <sup>9</sup> /l
White cells	> 0.5 × 10 <sup>9</sup> /l	0.5 × 10 <sup>9</sup> /l
Amylase	> 20 IU/l	> 20 IU/l
Alkaline phosphatase	> 10 IU/l	> 10 IU/l

qualitative methods, but hollow viscus injury is difficult to detect. Generally accepted criteria for a positive DPL are shown in Table 71.1.

#### COMPUTED TOMOGRAPHY (CT)

CT requires a still patient, a high-resolution scanner and experienced interpretation to match the sensitivity of peritoneal lavage. The value of enteral contrast is controversial.<sup>22</sup> Cuts from the top of the diaphragm to the symphysis pubis following i.v. contrast are required. CT is particularly useful to assess the retroperitoneum and pelvic fractures, and to delineate the nature of abdominal injury (thus guiding non-operative management of some solid organ injuries). It may not detect all hollow viscus trauma, but multidetector row CT is more specific and sensitive for bowel injury.<sup>23</sup> Magnetic resonance imaging offers no advantage over CT in evaluating acute abdominal trauma, and poses significant logistical problems.

The safety of undertaking CT in acute trauma depends on the degree of cardiorespiratory stability relative to the speed of scanning and access to resuscitation support.

#### CHOICE OF INVESTIGATION

- FAST is non-invasive, rapid and reasonably accurate when used by trained staff. It can screen for haemoperitoneum but negative studies should be followed by another investigation<sup>15,16</sup>
- DPL is invasive, takes some time and is accurate in identifying intraperitoneal bleeding or contamination, but may miss diaphragmatic injuries and does not examine the retroperitoneum. It is an alternative to FAST in unstable patients with blunt trauma, and stable patients with anterior stab wounds
- CT is non-invasive, time-consuming, accurate, and has a primary role in defining the location and magnitude of intra-abdominal injuries in stable patients with blunt trauma or penetrating trauma to the flank or back
- FAST, DPL and CT are complementary,<sup>24</sup> and should all be available. If CT is unavailable, DPL rather than FAST is indicated in the stable patient with blunt trauma in whom clinical examination is inadequate

### LAPAROSCOPY

Diagnostic laparoscopy may be useful in the haemodynamically stable patient. It is good at visualising the diaphragm and identifying a need for laparotomy, but may miss specific organ injuries, particularly of the bowel. Laparoscopy appears best suited for the evaluation of equivocal penetrating wounds.<sup>25</sup>

### ANGIOGRAPHY

Selective angiography and embolisation are valuable in detecting and treating the source of major haemorrhage from spleen, liver, pelvis and retroperitoneal structures.

### LAPAROTOMY

Laparotomy can be regarded as both therapeutic and diagnostic. Intra-abdominal injury may be detected by means discussed above, but often only laparotomy can accurately diagnose specific injuries. In severe and multiple trauma, the morbidity of a negative laparotomy is insignificant compared to the dire consequences of not diagnosing and treating a serious injury.

Operative treatment of more severe injuries with difficult haemostasis can cause a lethal triad of hypothermia, acidosis and coagulopathy. A 'damage control' laparotomy<sup>26</sup> with control of haemorrhage and contamination, intraperitoneal packing, elective re-exploration and removal of packs 24–48 hours later should be performed.

- Angiography should be considered and may be required for inaccessible arterial bleeding
- Temporary prosthetic closure is often required to avoid elevated intra-abdominal pressure
- Survival is better when the decision to terminate the initial procedure is made earlier

## SPECIFIC INJURIES

### SPLEEN

The spleen is the organ most frequently injured by blunt trauma. Injuries vary from a small subcapsular haematoma to hilar devascularisation or shattered spleen, but are rarely fatal with good medical care.<sup>27</sup> Diagnosis may be delayed in mild trauma. When associated chest or neurological injuries are severe, minor splenic injury may not initially be detected unless further investigation is undertaken. Fractures of the lower left ribs are a common association. Minor trauma may cause splenic injury when the spleen is enlarged (e.g. from malaria, lymphomas and haemolytic anaemias).

Immediate splenectomy is indicated in patients with splenic avulsion, fragmentation or rupture, extensive hilar injuries, failure of haemostasis, peritoneal contamination from gastrointestinal injury or rupture of diseased spleen.<sup>27</sup> However, overwhelming infection by

encapsulated organisms, such as *Pneumococcus*, can occur early or late (even years) after splenectomy in 0–2% of individuals. It is a particular risk following splenectomy in children and young adults. Polyvalent pneumococcal vaccine (*Pneumovax*) and haemophilus and meningococcal vaccines should be administered following splenectomy.<sup>28</sup>

If associated abdominal injuries have been excluded, a non-operative approach can give splenic salvage rates of over 80%. Arterial embolisation can further reduce the need for laparotomy.<sup>29</sup> Failure rates are higher with higher grade injuries.<sup>28</sup>

Other treatment alternatives include operative procedures to conserve splenic tissue (e.g. topical haemostatic agents, suture repair, absorbable mesh, partial splenectomy and splenic artery ligation). Benefits of splenectomy with autotransplantation of splenic tissue are unproven.

### LIVER

The liver is the second most commonly injured organ after blunt abdominal trauma, and has been the most frequently missed injury in deaths from trauma.<sup>2</sup> Diagnosis is made by laparotomy in unstable patients, or CT in stable patients. Injuries range from small subcapsular haematomas to major parenchymal disruption and laceration of hepatic veins or even hepatic avulsion.

CT assessment enables most patients to be managed without operation. Patients should be haemodynamically stable, have associated major abdominal injuries excluded, and be assessed repeatedly. Follow-up CT scans can show the resolution of injury, which typically takes 2–3 months. CT-guided percutaneous drainage, endoscopic retrograde cholangiopancreatogram (ERCP) and angioembolisation can treat the complications of a non-operative approach such as bile leak, haemobilia, necrosis, abscess and delayed haemorrhage.<sup>28</sup>

If surgery is required, early determination of indications for a damage control approach is important. Perihepatic packing gives best haemostasis. Angiography may identify and treat uncontrolled arterial bleeding. Early complications of liver injury relate to the effects of hypoperfusion or massive blood transfusion. Late complications are usually associated with sepsis.<sup>30</sup>

### GASTROINTESTINAL TRACT (GIT)

Injury to the GIT is more common following penetrating than blunt trauma. The very high likelihood of bowel injury in abdominal gunshot wounds should mandate laparotomy. Laparoscopy can be used to identify those with stab wounds for laparotomy when peritoneal violation cannot be excluded. Posterior stab wounds may damage retroperitoneal structures. CT examination with contrast enema may identify colonic injury better than clinical assessment or DPL.<sup>5</sup>

Blunt abdominal injuries to stomach, duodenum, small intestine, colon and their mesenteries are difficult to evaluate. Physical signs may be absent initially.

FAST or DPL may provide a general indication for laparotomy, but are not accurate in diagnosing isolated bowel trauma (especially of the duodenum) because of its retroperitoneal location.

CT is a sensitive indicator of free intraperitoneal air, but signs of duodenal perforation or haematoma are subtle, even with enteral contrast. Consequently, duodenal injury is often missed. A high index of suspicion should be maintained in patients with persistent abdominal pain and tenderness.<sup>31</sup>

Bleeding from mesenteric vessels is often self-limiting and may not require surgical control. However, vessel damage can cause ischaemia and infarction, and may require resection of affected bowel. Uncomplicated blunt or penetrating bowel injury can usually be managed by primary repair and anastomosis rather than colostomy.<sup>32</sup> A faecal diversion procedure with delayed repair is indicated in significant peritoneal contamination.

### PANCREAS

Blunt injuries to the pancreas require considerable force and are often associated with duodenal, liver and splenic trauma. CT is the most useful investigation. Acute hyperamylasaemia does not predict pancreatic or hollow viscus injury.<sup>33</sup>

Minor injuries require simple drainage and haemostasis. Severe injuries to the body and tail of the pancreas are best managed by distal pancreatectomy. Severe injuries involving the proximal pancreas and duodenum with intact ampulla and common bile duct can be treated by drainage alone if associated duodenal injury is simple to repair. Pancreaticoduodenectomy is required if there is disruption of the ampullary–biliary–pancreatic union or major devitalisation. Complications such as pancreatitis, fistula, abscess and pseudocyst are common.<sup>34,35</sup>

### KIDNEY AND URINARY TRACT

Blunt injury to the urinary tract is more common than penetrating injury. Identification and treatment of other major injuries often take precedence. Gross haematuria should be investigated; CT is the examination of choice. Urinary extravasation may be missed unless a repeat scan 10–20 minutes after contrast injection is performed. Unless there is unexplained shock, microscopic haematuria does not require further investigation. Renovascular pedicle or ureteric injuries may not cause any haematuria. Most renal injuries resolve with expectant management. Lacerations involving the collecting system or injury to the renal pedicle usually require operative intervention, although restoration of renal function following long warm ischaemic times is unusual. If major renal injury is discovered at emergency laparotomy, intraoperative i.v. urography is prudent to ensure contralateral function and will identify urinary extravasation. Angioembolisation may be useful in controlling renal haemorrhage.<sup>36</sup>

Bladder rupture is commonly associated with pelvic fractures. Over 95% of patients have macroscopic haematuria.

Retrograde cystography is the investigation of choice because CT has a high false-negative rate. Intraperitoneal bladder rupture requires operative repair and urinary drainage. Patients with sterile urine and extraperitoneal rupture can be managed with catheter drainage alone.<sup>37</sup>

Urethral trauma is caused by direct blunt injury, or occurs in association with pelvic injury. It should be suspected if there is blood at the urinary meatus, perineal injury or abnormal position of the prostate on rectal examination in the male. In the absence of these findings, cautious urethral catheterisation is appropriate. Treatment of urethral trauma is suprapubic drainage and subsequent definitive repair.

### DIAPHRAGM

Diaphragmatic injury occurs in fewer than 5% of cases of blunt injury, is left-sided in 80% of cases, and is commonly associated with injuries to abdominal organs. It should also be suspected in penetrating trauma below the fifth rib. Diagnosis can be difficult, especially in the presence of positive-pressure ventilation, and may become evident only after ventilatory support is discontinued.

- Chest X-rays are commonly abnormal but often with non-specific findings
- DPL is insensitive for isolated diaphragmatic injuries
- Laparoscopy and thoracoscopy provide good views of the diaphragm

Spontaneous healing does not occur, and all defects should be repaired. The risk of associated injuries in acute cases mandates an abdominal approach.<sup>38</sup>

### BONY PELVIS AND PERINEUM

Pelvic fractures are primarily caused by vehicular trauma or falls. Associated injuries to the bladder, urethra and intra-abdominal organs are common. Injuries may be life-threatening initially from major haemorrhage, or later from sepsis. Significant morbidity can result from damage to pelvic nerves, urethra or the structural integrity of the pelvis. Pelvic injury is suggested by pain on movement, structural instability, gross haematuria or peri-pelvic ecchymosis. Rectal examination is mandatory to identify rectal injury and prostatic position.

Radiography can confirm bony injury, but CT is required to identify associated intra-abdominal injuries (in the haemodynamically stable) and can assist in planning operative stabilisation. FAST has a significant false-negative rate with major pelvic fractures.<sup>39</sup>

Patients with haemodynamic instability and pelvic fractures must have intra-abdominal haemorrhage excluded. Early open supraumbilical DPL or FAST are the investigations of choice. If grossly positive, laparotomy should precede external fixation or angiography. If DPL is positive by cell count alone or FAST negative, the risk of life-threatening intra-abdominal haemorrhage is relatively

low, and achieving haemostasis for pelvic bleeding becomes the priority; CT and/or laparotomy should follow if the patient is still unstable.

- Emergency measures to improve tamponade by reducing pelvic volume (pelvic binding or C-clamp) and prompt angiography and selective embolisation can significantly reduce mortality<sup>40</sup>
- External fixation of the pelvis can control venous and small arteriolar bleeding near fracture sites, and will also reduce the volume of an open pelvis
- Bleeding from large vessels such as the aorta, common and external iliac arteries, and common femoral artery requires surgical control

Pelvic fractures range from simple fractures of individual bones requiring bed rest alone to complex fractures. Early operative stabilisation of complex pelvic fractures is preferred in the intensive care unit (ICU), as it facilitates respiratory care, pain control and early mobilisation. Compound pelvic fractures involving the perineum, rectum or vagina require aggressive surgery (including diversion of the faecal stream) to avoid high mortality.

### RETROPERITONEAL HAEMATOMA

Retroperitoneal haematoma is frequent following blunt trauma, and is commonly caused by injury to the lumbar spine, bony pelvis, bladder or kidney or, less commonly, to the pancreas, duodenum or major vascular structures. Diagnosis may be inferred by excluding other sites of major blood loss, or presumed by signs of underlying organ injury.

CT is the most useful investigation in the stable patient.

A central haematoma should be explored with proximal vascular control, because of the risk of pancreatic, duodenal or major vascular injury. A lateral or pelvic haematoma should not be explored, unless there is evidence of major arterial injury, intraperitoneal bladder rupture or colonic injury.<sup>41</sup>

### TRAUMA IN PREGNANCY

Women injured during pregnancy pose problems of altered physiology, risk to the gravid uterus and fetus, and conflict of priorities between mother and fetus.

- High-flow oxygen must be given until maternal hypoxaemia, hypovolaemia and fetal distress have been excluded
- Reduced respiratory reserve demands earlier intervention
- Maternal compensation for blood loss is at the expense of uteroplacental blood flow
- Mothers should be positioned to avoid aortocaval compression
- Secondary survey must include a vaginal examination
- Intravenous access should be in the upper limbs

- Transfusions should be Rhesus compatible
- All Rhesus-negative mothers should receive immune globulin, because of the immunological risk of even minor fetomaternal haemorrhage<sup>42</sup>

Only X-rays that may significantly alter therapy should be taken (with appropriate shielding), especially if under 20 weeks' gestation.

Ultrasound is the preferred investigation as it is safe and can accurately detect free intra-abdominal fluid, confirm gestation and fetal well-being, and identify placental abnormalities. DPL is safe if performed by the open method above the fundus. CT may miss injuries due to abdominal crowding.

Retroperitoneal haemorrhage is more common in pregnant patients. Placental abruption may conceal significant blood loss. Treatment may be expectant or by caesarean section, depending on the condition of the mother and fetus. Uterine rupture is unusual and will often require hysterectomy. Rarely, perimortem caesarean section may be indicated in a dead or dying mother, to attempt to save the fetus.

Placental abruption, fetal distress and fetal loss are rare following blunt injury, but premature uterine contractions are common.

Continuous cardiotocography (indicated at viable gestations) is the most sensitive test to detect obstetric complications, but is required for only 4 hours unless abnormalities are noted.<sup>42</sup> Kleihauer–Betke tests to identify fetomaternal haemorrhage are not predictive of fetal or maternal morbidity.

### HAEMORRHAGE

Patients with haemorrhage from abdominal and pelvic injuries can suffer the same complications of shock and massive transfusion as any patient with severe haemorrhage. Dilutional coagulopathy is common following resuscitation with fluids deficient in haemostatic factors. Patients resuscitated with crystalloids, colloids and red cells often require platelet and fresh frozen plasma transfusions. Disseminated intravascular coagulation occurs infrequently in trauma, usually when shock has been prolonged.

### SEPSIS

Intra-abdominal sepsis remains an important preventable cause of death after trauma. Predisposing factors include:

- peritoneal contamination from GIT injury
- external wounds
- invasive procedures
- delayed diagnosis of hollow viscus injuries
- splenectomy
- devitalised tissue

Early diagnosis and effective lavage and drainage procedures may reduce the incidence of intra-abdominal sepsis.

Prophylactic antibiotics for 24 hours are satisfactory for penetrating injuries. Intra-abdominal sepsis should be excluded if unexplained fever and/or neutrophil leucocytosis or multiple organ failure develops. Septic shock may represent a second shock insult to the trauma patient, leading to multiorgan dysfunction.

### GASTROINTESTINAL FAILURE

GIT failure in various forms, ranging from stress ulceration and delayed gastric emptying to paralytic ileus, is a frequent occurrence. Prophylaxis against stress ulceration may be indicated. Enteral nutrition is associated with a lower incidence of sepsis following trauma.<sup>43</sup> Feeding through a jejunostomy tube placed during surgery or radiologically in the ICU is usually feasible. Parenteral nutrition may be necessary in patients with severe bowel or retroperitoneal injuries.

### RAISED INTRA-ABDOMINAL PRESSURE

Abdominal distension with raised intra-abdominal pressure may be seen in the critically injured as a consequence of haemorrhage, bowel oedema, ileus or surgical packs. This can have severe adverse effects on respiratory, cardiovascular and renal function.<sup>44</sup> Alleviation is by abdominal decompression using interposed synthetic mesh<sup>45</sup> or by leaving the abdomen open, with or without visceral packing. The abdomen is subsequently closed by staged repair as the distension resolves.

# Near drowning

Cyrus Edibam

## DEFINITIONS

The American Heart Association Guidelines for Resuscitation<sup>1</sup> suggest that the term ‘submersion victim’ be used to describe a person who experiences some swimming-related stress that is sufficient to require support in the field plus transportation to an emergency facility for further observation and treatment. ‘Drowning’ refers to death within 24 hours following a submersion event and the term ‘near drowning’ should no longer be used.

## EPIDEMIOLOGY

Drowning causes over 400 000 deaths worldwide.<sup>2</sup> Of these, 4000 are reported from the USA (approximately 1.5 deaths per 100 000 population),<sup>3</sup> 500 from Australia<sup>4</sup> and 700 from the UK.<sup>5</sup> The incidence of non-fatal submersion events has been estimated to be 2–20 times more common than drowning.<sup>6</sup> More than half of all submersion events occur in children less than 5 years old, the majority being 1–2 years old.<sup>7,8</sup> Males predominate, with peaks at 5 and 20 years of age. Private swimming pools and natural water bodies close to home present the greatest risk to young children.<sup>8</sup> Other sites include bathtubs, fish tanks, buckets, toilets and washing machines. Adolescent drowning tends to occur in rivers, lakes, canals and beaches.<sup>9</sup> Lack of adult supervision is almost always to blame for toddler accidents; however, child abuse must also be considered. Alcohol and drug intoxication is associated with up to 40% of adolescent drowning.<sup>10</sup> Other risk factors include epilepsy (18%), trauma (16%) and cardiopulmonary disease (14%).<sup>11</sup> Hyperventilation prior to underwater swimming suppresses the physiological response to rising carbon dioxide tension, allowing hypoxia to ensue with consequent loss of consciousness and water breathing.<sup>12</sup>

## PATHOPHYSIOLOGY

Voluntary apnoea and reflex responses occur upon submersion. The *diving response* is characterised by apnoea, marked generalised vasoconstriction and bradycardia in response to cold-water stimulus of the ophthalmic

division of the trigeminal nerve. Blood is thus shunted preferentially to the brain and heart. In infants the response may be marked,<sup>13</sup> but only 15% of fully clothed adults show a significant response. Although the diving reflex appears to play a powerful role in oxygen conservation in animals, its role in humans is unknown but may be protective.<sup>14</sup>

At some point after submersion involuntary inspiration occurs which leads to aspiration of water and often vomitus. Laryngeal spasm may occur which may explain the approximate 15% incidence of *dry drowning*, where little or no fluid is found in the lungs.<sup>15,16</sup> Gasping then occurs and water aspiration continues. Up to 22 ml/kg of water has been estimated to be the maximal survivable inhaled water volume.<sup>17</sup> This is followed by a phase of secondary apnoea and loss of consciousness. Hypoxaemic death ensues if the person is not retrieved and resuscitated. Acute lung injury (ALI) – often termed *secondary drowning*, the pathophysiology of which is discussed elsewhere in the book – occurs in up to 72% of symptomatic survivors.<sup>18</sup> Multiple organ dysfunction and cerebral damage may become evident in those that survive to hospital.

## SALT VS FRESH WATER ASPIRATION

The differences between salt and fresh water drowning should be downplayed.<sup>1</sup> On the basis of animal studies it was thought that hypertonic seawater aspiration would draw plasma volume into the pulmonary interstitial space, leading to hypovolaemia, hypernatraemia and haemoconcentration. Similarly, aspiration of hypotonic fresh water was thought to lead to the passage of large volumes into the blood stream, leading to hypervolaemia, dilutional hyponatraemia, haemolysis and haemoglobinuria.

Modell *et al.*<sup>19</sup> showed that volumes of water normally aspirated rarely translate into clinically meaningful syndromes. Orłowski and colleagues<sup>20</sup> showed little difference in observed cardiovascular effects in a canine model using six solutions of differing tonicity. They concluded that the cardiovascular effects seen with drowning and aspiration of water are not dependent on the tonicity of the aspirated fluid, but are the direct result of anoxia. Of 91 patients seen with severe submersion, no patient had serious electrolyte abnormalities or

haemolysis. In another series, only 15% of retrieved but unresuscitatable patients had any of the expected electrolyte changes.<sup>17</sup> Generally, most patients with ALI/pulmonary oedema will be hypovolaemic by the time they reach hospital.<sup>12</sup> No clinically detectable difference in the patterns of lung injury is seen between salt and fresh water drowning; both types reduce pulmonary surfactant quantity and function.<sup>21</sup>

### WATER CONTAMINANTS

The incidence of pneumonia complicating submersion injury may be greater than 15% in those who survive long enough.<sup>18</sup> Rivers, lakes and coastal waters are greater reservoirs for microbes than well-kept swimming pools. In fresh water, Gram-negative bacteria predominate along with anaerobes and *Staphylococcus* spp., fungi, algal and protozoan species. *Aeromonas* spp. are ubiquitous water-borne bacteria and can be responsible for severe pneumonia.<sup>22</sup>

Chemicals in polluted water (e.g. kerosene<sup>23</sup>), chlorine<sup>24</sup> and particulate matter (e.g. sand<sup>25</sup>) can cause severe pulmonary dysfunction.

### TEMPERATURE

Victims of submersion may develop primary or secondary hypothermia. If submersion occurs in icy water (<5°C) hypothermia may develop rapidly and provide some protection against hypoxia. Surface cooling is unlikely to produce adequate protective hypothermia before hypoxia ensues.<sup>14</sup> Most survivors of prolonged submersion almost always involve small children in icy water and it has been postulated that protective core cooling occurs rapidly due to cold-water aspiration, ingestion and absorption, though the mechanisms remain controversial.<sup>26</sup>

Of more importance in cold-water submersion are the detrimental 'cold-shock' responses.<sup>27</sup> These responses include a 'gasp' followed by uncontrollable hyperventilation and reduction in maximal breath-hold times, vasoconstriction, tachycardia, hypertension and increased myocardial oxygen consumption. These responses may lead to motor dyscoordination and swimming failure as well as cardiac arrhythmias, hence even strong swimmers may drown quickly in icy waters.

### MANAGEMENT

#### BASIC LIFE SUPPORT

Prompt retrieval from the water is essential as is immediate on-site resuscitation. Expired air resuscitation and external cardiac compression should be applied immediately after retrieval. If trauma is suspected, especially in diving and surfing accidents, head and spinal injuries are assumed and due caution in stabilising the cervical spine

during airway manipulation and transport is required. The Heimlich manoeuvre is no longer recommended in the management of submersion injury as the volume of aspirated water removed at the time of attempt is small and the risk of gastric aspiration is great.<sup>1</sup> Rewarming should be commenced immediately with the use of blankets and further heat loss should be avoided. When experienced personnel arrive, bag and mask ventilation and advanced cardiac life support is initiated.

### INITIAL HOSPITAL MANAGEMENT

Resuscitation continues on arrival to hospital. Endotracheal intubation and mechanical ventilation is instituted if hypoxaemia is severe despite high-flow oxygen or assisted bag and mask respiration. Ventilatory failure, characterised by increasing respiratory distress and rising carbon dioxide levels, and the presence of an impaired conscious level or severe agitation may also necessitate intubation. Insertion of a nasogastric tube to decompress the stomach should be performed if possible but may be difficult in a hypoxic agitated patient. Attempts to actively rewarm the patient are initiated as soon as possible.

### ASSESSMENT

#### HISTORY

Attempts should be made to elucidate the time and the duration of submersion, the presence of polluted water and likely contaminants, delay in resuscitation attempts and the likelihood of alcohol ingestion, drug use, pre-existing medical conditions and coexisting trauma.

#### EXAMINATION

A thorough secondary survey is carried out, concentrating on cardiorespiratory examination in particular, looking for signs of respiratory distress, wheeze, crepitations and peripheral circulatory insufficiency. Neurological status should also be assessed. Clinical deterioration in those with minor symptoms and signs can occur and the patient should be reassessed at frequent intervals.

#### INVESTIGATIONS

These depend on the clinical circumstances and could include:

- arterial blood gases/lactate level
- plasma biochemistry/serum osmolality: electrolyte abnormalities are unlikely in sea or fresh water drowning. CK should be measured as rhabdomyolysis has been reported<sup>28</sup>
- haematology: tests for haemolysis, e.g. total haemoglobin (tHb), free Hb and myoglobin concentrations in the plasma and urine
- toxicological assays for drug and alcohol levels should be considered
- chest X-ray, 12 lead ECG
- microbiology: tracheal aspirates or sputum for Gram stain, microscopy and culture

- trauma imaging: cervical and/or thoracolumbar spine views; CT head if head injury is suspected or the patient is comatose. Imaging of other body areas is dependent upon the clinical likelihood of injury

### ADMISSION CRITERIA

Asymptomatic patients with no clinical findings on cardio-respiratory examination and a normal chest radiograph and blood gas are unlikely to develop ALI and pneumonia and thus do not require hospital admission.<sup>18,29</sup> All other patients should be admitted to a high-dependency area or intensive care unit for continuous monitoring and rewarming.

### RESPIRATORY SUPPORT

Severe agitation or coma mandates intubation and mechanical ventilation; otherwise oxygenation is initially maintained with high-flow oxygen or continuous positive airway pressure (CPAP) by tight fitting facemask. Superimposed ventilatory failure may be managed with non-invasive inspiratory pressure assistance in addition to CPAP (often termed bilevel positive airway pressure or non-invasive pressure support). The use of intravenous and inhaled bronchodilators may reduce airflow resistance and the work of breathing. Selective pulmonary vasodilators such as inhaled nitric oxide or inhaled prostacyclin may be useful in severe refractory hypoxaemia. In severe cases, extracorporeal membrane oxygenation has been used in some centres.<sup>30</sup>

### CARDIOVASCULAR SUPPORT

Patients with ALI are often hypovolaemic regardless of the type of water ingestion. Cautious volume expansion and the use of catecholamine infusion may improve cardiac output and blood pressure. Fluid replacement with isotonic fluids is aimed at restoring adequate end-organ perfusion without compromising respiratory function. The use of a central venous or pulmonary artery catheter may be necessary to achieve these goals. In cases where severe circulatory insufficiency or cardiac arrest is associated with severe hypothermia, cardiopulmonary bypass has been used successfully.<sup>31</sup>

### CEREBRAL PROTECTION

Recent data show a better neurological outcome with induced hypothermia (32–34°C) after cardiac arrest due to ventricular fibrillation.<sup>32</sup> Although no specific data for the cerebral protective effects of hypothermia exist for patients suffering hypoxic brain injury associated with submersion, the data would suggest that comatose drowning victims should not be actively rewarmed above 34°C.

No other specific cerebral protective measures have proven efficacy in post anoxic encephalopathy associated with drowning.<sup>33</sup> Maintenance of an adequate cerebral

perfusion pressure (mean arterial pressure >90 mmHg in adults, 60–70 mmHg in children) is the most important goal of therapy. Prevention of cerebral venous and thus intracranial hypertension can be achieved by neutral neck positioning, avoiding occlusive endotracheal tube ties and head-up positioning. Avoiding hypocapnia ( $P_{aCO_2}$  <30 mmHg), reducing cerebral metabolic rate with sedation, preventing hypoglycaemia and hyperthermia, and the use of anticonvulsants in those with documented seizures are simple measures to prevent secondary cerebral injury.

### OTHER THERAPIES

There is no role for prophylactic corticosteroid therapy in the prevention of acute lung injury after submersion.<sup>12</sup> Prophylactic antibiotic therapy is unproven and the decision to commence therapy is made on the degree of water contamination, need for mechanical ventilation and severity of respiratory failure in each case.<sup>18</sup> Baseline microbiological studies should be sent prior to commencement of therapy.

### PROGNOSIS

Mortality rate for those surviving more than 24 hours was 24% in a recent large series,<sup>18</sup> with three quarters succumbing in the early stages after injury. Moderate to severe brain damage is reported in 33% of survivors.<sup>8</sup> The outcome in children is similar, with 30% having selective deficits and 3% with persistent vegetative state.<sup>34</sup> No difference in mortality between fresh and salt water submersion has been documented.<sup>11</sup> Lower core temperatures appear to be associated with a better prognosis, except if this occurs after rescue. However, hypothermia in warm water immersion and severe hypothermia (<30°C) in cold water immersion is indicative of prolonged immersion and poor outcome.<sup>27</sup> Table 72.1 lists some factors associated with death or severe neurological impairment. None of these predictors is infallible and survival with normal cerebral function has been noted despite the presence of some or all of these factors.<sup>12</sup>

**Table 72.1** Predictors of death or severe neurological impairment after submersion

#### At site of immersion:

- Immersion duration > 10 minutes<sup>35</sup>
- Delay in commencement of CPR > 10 minutes<sup>8</sup>

#### In the emergency department

- Asystole on arrival<sup>36</sup> or CPR duration > 25 minutes
- Fixed dilated pupils<sup>37</sup> and Glasgow Coma Score < 5<sup>38</sup>
- Fixed dilated pupils and arterial pH < 7.0<sup>39</sup>

#### In the ICU

- No spontaneous, purposeful movements and abnormal brainstem function 24 hours after immersion
- Abnormal CT scan within 36 hours of submersion

# Burns

David P Mackie

The last half of the twentieth century witnessed a sustained improvement in the survival of patients suffering thermal injury. Arguably, the single most important development has been the establishment of centralised burn care which made possible advances in fluid resuscitation, life support techniques and the prevention of infection. With optimal care, children and young adults with burns of more than 80% of total body surface area (TBSA) now stand a reasonable chance of survival.<sup>1</sup>

Improvements in survival have gradually led to a shift of emphasis in burn care towards qualitative aspects, such as rehabilitation and quality of life. The complexity of care has led to the concept of the multidisciplinary burn team, in which all aspects of care are coordinated in an integrated approach to clinical management.<sup>1</sup>

## PATHOPHYSIOLOGY

### LOCAL EFFECTS

Thermal injury produces complex local and systemic responses. The local inflammatory response results in vasodilatation and an increase in vascular permeability. The changes are immediate and combine to produce extravasation of fluid and plasma protein at the site of injury. In extensive burns, oedema becomes generalised. The greatest rate of oedema formation occurs in the first few hours, but further extravasation occurs up to 24 hours post burn.<sup>2</sup> The total amount of oedema formed depends on the extent of injury and the volume and rate of fluid administration. Without fluid replacement, hypovolaemic shock occurs, limiting the extent of extravasation. On the other hand, excessive fluid administration will produce excessive oedema. By 24 hours post burn, oedema formation is largely complete and vascular integrity restored.

The process of deepening of the burn wound beyond the area of heat necrosis following injury is at least partly due to microvascular stasis. Events occurring within minutes and hours of injury that contribute to stasis include microthrombus formation, neutrophil adherence, fibrin deposition and endothelial swelling. Diverse agents, including antioxidants and anti-inflammatory drugs, have been shown to attenuate this process in experimental

settings, but none is yet established in clinical practice. Empirically, it is assumed that maintenance of good tissue oxygenation, avoidance of overresuscitation and prevention of wound dehydration all contribute to wound healing by preventing undue extension of necrosis in the wound bed.

### CIRCULATORY EFFECTS

Circulatory effects of burn injury become significant in burns of over 15% TBSA. Changes are rapid and the magnitude is roughly proportional to the extent of burn injury. Cardiac output is reduced immediately following injury. Secretion of adrenaline (epinephrine), noradrenaline (norepinephrine), vasopressin and angiotensin cause an increase in systemic and pulmonary vascular resistance. Circulating levels of agents with myocardial depressant properties, such as interleukin-1 and TNF- $\alpha$ , are increased following burn injury, but developing hypovolaemia and increased blood viscosity may be equally important.<sup>3</sup>

Cardiac output recovers gradually during the second post-burn day, reaching supranormal levels by day 3 as the hypermetabolic response to burn injury becomes manifest. Circulatory dynamics are complicated by resorption of oedema fluid and by continuing evaporative fluid loss from the wounds. Prolonged elevation of renin/angiotensin and antidiuretic hormone (ADH) has been well documented and circulating blood volume may remain subnormal into the second week post burn.<sup>4</sup>

### METABOLIC EFFECTS

The hypermetabolic state, which ensues from around the third post-burn day until the wounds are substantially healed, is a manifestation of the systemic inflammatory response syndrome. The state is partly sustained by evaporative and radiant heat loss through the wounds, and energy expenditure can be reduced by increasing the ambient temperature and by the use of occlusive dressings.<sup>5,6</sup> Other factors known to influence the metabolic rate include pain, fear and anxiety. There is also a suggestion that bacterial colonisation may aggravate hypermetabolism.<sup>7,8</sup> Burn patients often develop moderate pyrexia, even when all microbial cultures are negative.

### PHARMACOLOGICAL EFFECTS

The pharmacokinetics and pharmacodynamics of many drugs are markedly altered in burn patients. During the first 24 hours, when the cardiac output is depressed, absorption and distribution of administered drugs are delayed. Thereafter, increased cardiac output leads to accelerated drug absorption and distribution, while oedema fluid acts as an ill-defined third space. At the same time, renal blood flow and creatinine clearance are increased, particularly in younger patients. Drugs excreted via this route, such as the quinolone and aminoglycoside antibiotics, may therefore fail to reach effective levels at conventional dosages.<sup>9</sup> On the other hand, toxic levels may ensue if renal failure supervenes. If possible, therefore, antibiotic administration should be guided by measurement of plasma concentrations.

Serum albumin levels are low in burn patients, and drugs bound to this protein, including some benzodiazepines, will show increased bioavailability. On the other hand,  $\alpha_1$ -glycoprotein levels, which bind fentanyl, are increased. Detoxification via redox pathways, such as cytochrome P-450, is depressed, lengthening the half-life of drugs such as diazepam.<sup>10</sup> Accumulation of benzodiazepine derivatives may be increased.

The pharmacodynamics of muscle relaxants are significantly altered due to an increase in peri-junctional acetylcholine receptors.<sup>11</sup> Patients become relatively insensitive to non-depolarising agents, while administration of succinylcholine may give rise to excessive release of potassium, and cardiac arrest.

The burn wound is a significant route of drug absorption as well as drug loss. For example, the topical sulfonamide agent, mafenide, may cause metabolic acidosis through inhibition of renal carbonic anhydrase; deafness has been reported following the topical use of gentamicin.

### CLINICAL MANAGEMENT

#### FIRST AID

Immediate aid comprises stopping the burn process, followed by the removal of clothing and cooling the wound, preferably with tepid, running water, for 10–20 minutes. This provides pain relief and may prevent deepening of the wound.<sup>12</sup> Hypothermia should be avoided. Oxygen should be given, if available, and patients with burns to head and neck should be kept in a semi-upright position. Burn injury can only be assessed properly in hospital conditions, and priority should be given to early evacuation of the victim.

#### GENERAL MANAGEMENT: 0–24 HOURS

On admission, a careful history should be taken of the circumstances of the injury, and to elucidate past medical history. The patient should be undressed, weighed, and carefully examined to exclude additional traumatic injury.

**Figure 73.1** Rule of nine to estimate body surface area burns in adults.

The extent and depth of injury is assessed with the aid of printed Lund and Browder charts, or by using the 'rule of nines' (Figure 73.1). The rule of nines is modified for children (Figure 73.2). A nasogastric tube and urinary catheter should be inserted in patients requiring resuscitation therapy. Escharotomies may be required for circular burns of the trunk and limbs.

#### FLUID THERAPY: 0–24 HOURS

Fluid therapy is required for injuries exceeding 15% of body surface area (10% in children and the elderly), preferably via a wide-bore peripheral i.v. cannula (preferably not in a burned area). The aim is to provide sufficient salt and water to preserve normal organ function, while minimising oedema formation. Excessive fluid administration increases the risk of circulatory overload in the days following the resuscitation period. Potentially fatal complications of excessive fluid administration include the abdominal compartment syndrome in adults<sup>13</sup> and the occurrence of cerebral oedema in children.<sup>14</sup> An increasing tendency in recent years to overresuscitate burn patients has been signalled.<sup>15,16</sup> In contrast to other traumatic injuries, burn hypovolaemia is gradual, obligatory and predictable. Aggressive fluid administration will not restore the circulating volume<sup>17</sup> and in the absence of frank shock, bolus fluids should not be given.

Various resuscitation formulae have been published in the past to guide initial fluid therapy. These formulae are entirely experience-based and many are of historical interest only, but all comprise a fluid intake of 2–4 ml/kg

**Figure 73.2** Surface area percentages by age.

Age	<1 year	1 year	5 years	10 years	15 years	Adult
Area A = $\frac{1}{2}$ of head (%)	9.5	8.5	6.5	5.5	4.5	3.5
Area B = $\frac{1}{2}$ of one thigh (%)	2.75	3.25	4.0	4.25	4.5	4.75
Area C = $\frac{1}{2}$ of one leg (%)	2.5	2.5	2.75	3.0	3.25	3.5

body weight per % burn in 24 hours, and a sodium intake of approximately 0.5 mmol/kg per % burn.<sup>18</sup> These findings have led some to employ resuscitation regimens based on the administration of hypertonic sodium solutions, which require a smaller volume of fluid. However, the solute load may be excessive, requiring extra water administration in subsequent days, with an increased risk of fluid overload. The use of isotonic saline solutions is therefore preferred by those without experience of burns resuscitation.

The most widely used resuscitation formula for adults is based on the Parkland Formula, which has been adopted by major training programmes, such as the Advanced Trauma Life Support and the Emergency Medicine for Severe Burns:

4 ml Ringer-Lactate solution  $\times$  kg body weight  $\times$  % TBSA burn in the first 24 hours, of which half should be given in the first 8 hours *post burn* and the other half in the next 16 hours

The formula thus incorporates a faster rate of administration if initial treatment has been delayed.

Children require extra fluid to compensate for basal needs. For children under 30 kg, the resuscitation formula of Carvajal<sup>19</sup> is useful:

Fluid requirement (ml) : 0–24 hours post burn =  
 $(2000 \times \text{TBSA}) + (5000 \times \text{TBSAB})$

where TBSA is the total body surface area ( $\text{m}^2$ ) and TBSAB is total body surface area burned ( $\text{m}^2$ ). Again half of the calculated amount is given in the first 8 hours.

These formulae are to be regarded as guidelines only. The actual amount of fluid given depends on the clinical condition and the actual amount of fluid administered can vary widely from that predicted. Adequacy of resuscitation is monitored by vital signs and a targeted urine output of 0.5–1 ml/kg per hour in adults and 1–2 ml/kg per hour in children. Other indicators include warm extremities and return of gut peristalsis. Fluid intake may be adjusted to maintain urine output at the desired range. Requirements are increased in the presence of mechanical ventilation, additional traumatic injury and dehydration (e.g. fire-fighters).

Invasive monitoring is not essential in uncomplicated burns and the results may be misleading, as central pressures are invariably low. Hypoalbuminaemia develops rapidly and may be extreme. The extent to which burn patients will tolerate hypoalbuminaemia is unknown and clinical studies into best practice are awaited. In our unit at present, albumin is given to maintain serum albumin above 15 g/l, commencing 12 hours post burn when capillary integrity has been largely restored.

Thirst is common, but unrestricted oral fluids will increase oedema formation. Controlled quantities of nutritional liquids are recommended to protect gut integrity.<sup>20</sup>

In patients with extensive injuries, tube feeding at a low rate can be commenced within a few hours of injury.

### FLUID THERAPY AFTER 24 HOURS

During the second 24 hours, enteral nutritional intake is increased, while the total rate of fluid administration is gradually reduced. At the end of the second day, fluid intake should allow for generous urine production, while compensating for evaporative losses through the wounds.

The actual fluid loss through wounds varies widely, and depends on the type of burn and topical wound treatment. A useful formula to obtain a rough estimate for insensible fluid loss is:

$$(25 + \% \text{ body surface burn}) \times \text{m}^2 \text{ body surface area} \\ = \text{evaporative fluid loss (ml/h)}$$

Electrolyte disturbance is common following burn injury and requires treatment. Hypernatraemia is often a sign of hypovolaemia, confirmed if urine sodium is low. The condition is perilous, especially in the first week post burn, as oliguria and renal failure may develop unexpectedly. The amount of free water given should be increased gradually, particularly in the elderly, to avoid fluid overload. Patients who are in fluid balance may require sodium supplementation to compensate for solute loss in wound exudates.

### HAEMOGLOBINUREA/MYOGLOBINUREA

Tissue injury from deep burns, particularly electrical injury, causes the release of myoglobin and haemoglobin from damaged cells. Diagnosis is made on observing discoloration of the urine, from faint pink in mild cases to almost black. Fluid administration should be increased; additional measures such as mannitol (12.5 g/l resuscitation fluid) to encourage diuresis, and bicarbonate to alkalise the urine pH and increase the rate of pigment excretion may be considered.

### PAIN THERAPY

During the first 24 hours, pain management is best achieved by incremental doses of i.v. morphine, or equivalent opiate. Thereafter, the pain suffered by burn patients may be divided into background pain, which is continuous, and procedural pain caused by interventions.<sup>21</sup> The recurring ordeal of dressing changes, physiotherapy exercises and surgical procedures generates apprehension and anxiety, which compound distress.

Regular pain therapy is required to counter background pain, topped up by extra analgesics prior to procedures. In recent years, the advent of slow-release oral opiate medication has greatly improved the administration of analgesia. Procedural pain is best treated with continuous i.v. morphine or fentanyl, with titrated incremental boluses as required. Patient-controlled analgesia is effective, although modification of the control button

may be necessary for those with bandaged hands. Ketamine in subanaesthetic doses is extremely useful for procedural pain in children. The influence of anxiety and depression on pain perception suggests additional avenues of therapy.<sup>22</sup> Non-pharmacological interventions, such as hypnosis and other distraction techniques, are an effective adjunct in susceptible patients.<sup>23</sup> Many burn patients may develop posttraumatic distress syndrome, and the emergence of symptoms may require additional support. Above all, an attitude of reassurance and understanding by all carers is indispensable.

### NUTRITION

The hypermetabolic response is roughly proportional to the extent of injury. In young adults and children with extensive burns, energy expenditure may be doubled. In addition, protein and substantial amounts of trace elements, such as zinc, copper and selenium are lost in wound exudate.<sup>24</sup>

There is no doubt that burn patients require additional calories and proteins, but traditional formulae for calculating requirements produce overestimates in the context of current burn care.<sup>25</sup> In the absence of direct metabolic measurements we currently use an empirical formula for estimating caloric intake:

$$\text{Caloric requirement} = \text{REE} + (\text{REE} \times \% \text{ TBSA burn} / 100)$$

where REE is the resting energy expenditure calculated from the Harris and Benedict equation.

Patients with extensive burns will require tube feeds, which are generally well tolerated. If gastric emptying is problematic, a post-pyloric tube is usually effective. A high-protein proprietary feed is usually adequate, but should be supplemented by extra trace elements and vitamins. The possible benefit of glutamine supplements in burns has recently been reviewed.<sup>26</sup> Adequacy of feeding is best assessed by monitoring body weight. Adjunctive therapy aimed at promoting anabolism includes the use of insulin to maintain normoglycaemia, the administration of oxandrolone (10 mg twice daily for adults),<sup>27</sup> and the use of  $\beta$ -blockers to control tachycardia and extensive catabolism.<sup>28</sup>

### WOUND HEALING

Treatment of extensive, full-thickness burn wounds by early excision and grafting has been firmly linked to survival.<sup>29</sup> Wound excision should be completed within the first week, before bacterial colonisation and neovascular infiltration of the wound bed develop. These operations are therefore urgent. Successfully grafted wounds will heal within 5 weeks, reducing the time available for bacterial infection to develop, and shortening the period of physiological disturbance. Wounds covered with widely meshed autografts lose large amounts of fluid, unless protected by a semipermeable layer, such as allograft skin. Autograft donor sites are a further source of fluid loss.

For wounds treated conservatively, the main effort is devoted to the prevention of infection. Topical antimicrobial agents are commonly used, but may have potential side-effects (Table 73.1). These compounds change the appearance of the wound and should never be applied until expert wound inspection is complete. A number of biosynthetic materials are currently available, which are designed to improve cosmetic and functional outcome. Despite the use of antiseptic dressings or biosynthetic coverings there is still a risk of microbial infection developing and unexplained signs of sepsis may necessitate urgent wound revision.

**Table 73.1** Commonly used topical antimicrobial agents

Agent	Comments
Silver sulfadiazine (SSD)	The most widely used agent with broad spectrum cover. Hypersensitivity (rarely) and transient leucopenia have been reported
Cerium nitrate 0.5%	Often added to SSD, and forms a stable eschar. It is reported to bind 'burn toxins'. Methaemoglobinaemia has been reported
Silver nitrate 0.5%	Applied as a soak, and is especially effective against <i>Pseudomonas</i> . However, it may increase sodium loss, and potentially can cause methaemoglobinaemia
Mafenide acetate 5–10%	Effective but short-lived antimicrobial, requiring repeated application. It has good penetration, and its side-effects (pain and metabolic acidosis) are less evident with 5% solution
Chlorhexidine	Aqueous solution (0.2%) or 1% gel provides broad spectrum cover, but is rapidly inactivated, and may cause local pain, and rarely causes hypersensitivity
Nitrofurazone	In polyethylene glycol (PEG) solution it is effective against <i>S. aureus</i> , but resistance develops early. Side-effects include hypersensitivity (common), hyperosmolarity, and renal failure due to PEG absorption has been reported
Povidone iodine	In PEG solution provides broad spectrum cover, but is rapidly inactivated. It prevents wound maceration. Side-effects include occasional hypersensitivity, renal dysfunction due to excessive PEG, metabolic acidosis and rarely dysfunction
Antibiotics	Have been used in solutions, creams, gels and sprays, but selection and development of resistant strains is inevitable, with a risk of systemic toxicity through absorption. Their usage is generally discouraged

## PREVENTION OF WOUND INFECTION

Bacterial infection is still the most common cause of death in burns. Depression of the immune system is well documented.<sup>30</sup> At the same time, the burn wound presents a favourable medium for bacterial growth.

### BACTERIOLOGICAL SURVEILLANCE

Routine bacteriological surveillance of burn patients (at least twice weekly) is essential. The growth of pathogens from wound swabs may reflect growing resistance to topical wound therapy, indicating a need for change. When infection is suspected, the choice of an appropriate antibiotic will be governed by prior knowledge of the colonising micro-organisms and their antibiograms. In addition, the effectiveness of prophylactic measures can only be assessed by regular monitoring of the microflora present within the burns unit.

### PATIENT ISOLATION

In an effort to reduce wound colonisation and contamination from cross-infection, barrier nursing of patients with extensive injuries is mandatory. The importance of isolation measures has been stressed,<sup>31</sup> but a significant proportion of patients still become colonised by micro-organisms from endogenous reservoirs, which cannot be controlled by barrier nursing alone.<sup>32,33</sup> Positive experiences have been reported with selective decontamination of the digestive tract,<sup>8,34</sup> but large scale prospective trials have not been performed.

### THE GASTROINTESTINAL TRACT

Loss of gut integrity following burn injury has been well demonstrated.<sup>35</sup> In addition to reactive damage following reperfusion of the ischaemic gut, mediators derived from the burn wound itself may also be involved.<sup>36</sup> Clinical strategies aimed at protecting the gastrointestinal tract include optimal fluid therapy during the first hours following injury to prevent mesenteric hypoperfusion, and the institution of early enteral nutrition, which can be safely commenced within a few hours of injury.<sup>20</sup> Diets enriched with glutamine may contribute to the maintenance of gut integrity.<sup>26,37</sup> Whatever the merits of each approach, all are secondary to the maintenance of effective hygienic policies in all aspects of patient care.

### WOUND SEPSIS

Local effects include disruption of wound healing and deepening of the injury.

Systemic effects are often insidious. Prodromal signs are common and may include gastrointestinal stasis, increasing positive fluid balance, increasing insulin resistance and increasing pyrexia. As sepsis progresses, clinical deterioration becomes manifest: tachypnoea, circulatory instability, thrombocytopenia and oliguria may herald the onset of multiorgan failure. Leukocyte counts and C-reactive protein elevation are affected by the systemic inflammatory response syndrome (SIRS) and are unreliable indicators in the absence of clinical signs and symptoms. Blood cultures are indicated if sepsis is suspected.

### ANTIBIOTIC THERAPY

This is chosen on the basis of bacteriological surveillance data, and should be given early, if possible. Fluid therapy in burn patients is complicated by evaporative fluid loss, which may increase if the wound surface degenerates. Supportive therapy for (multi-) organ failure should be implemented as indicated.

The causes of sepsis will persist until wound coverage is achieved and operative wound treatment should not be postponed. Although mortality is appreciable, experience has repeatedly shown that the prognosis is by no means hopeless.

### INHALATION INJURY

The term inhalation injury includes three distinct types of injury which often, but not always, occur together. The presence of inhalation injury may increase resuscitation fluid requirements in patients with extensive cutaneous burns.

### HEAT INJURY TO THE UPPER AIRWAY

Burns due to the inhalation of hot gases (steam excepted) rarely extend beyond the larynx. The development of mucosal and facial oedema can cause respiratory obstruction, particularly in children.

### DIAGNOSIS

Facial burn, singed nasal hairs, visible burn to oropharynx, and hoarseness are typical features.

### TREATMENT

If the condition is suspected, early endotracheal intubation is safest, before the procedure is rendered hazardous by oedema formation.

### EFFECTS OF SMOKE ON THE RESPIRATORY SYSTEM

Many of the chemicals that are contained in smoke are highly reactive and produce damage to the tracheobronchial tree. Detachment of epithelial cells and the development of tracheobronchial oedema cause airway narrowing and cast formation. Small airway closure leads to hypoxaemia and respiratory failure. Later, bronchorrhoea and mucosal sloughing may cause atelectasis and provide a focus for infection. In the absence of a cutaneous injury the clinical course is usually benign. However, the presence of an extensive skin burn increases the likelihood of acute respiratory distress syndrome (ARDS); respiratory infection may follow.

### DIAGNOSIS

There is a history of exposure in a confined space, cough, breathlessness, wheeze, stridor, hypoxaemia, and soot particles in the pharynx. Diagnosis is confirmed by bronchoscopy, which may reveal soot in the bronchial tree, mucosal injury and tracheobronchial oedema.

### TREATMENT

Mild cases may be treated by high-flow oxygen administration by mask. The mainstay of treatment in severe cases is intubation and ventilatory support with positive end-expiratory pressure (PEEP) to maintain small-airway patency. Regular bronchial toilet is recommended to clear debris and to prevent respiratory infection. Endotracheal tubes may become blocked with detritus. As small-airway obstruction is common, ventilation pressures may be adversely affected. Various strategies, such as high-frequency ventilation, have been advocated to minimise the risks of barotrauma.

Prolonged respiratory assistance may be necessary. The added respiratory requirements of the hypermetabolic state combined with inevitable loss of muscle mass frequently frustrate early weaning efforts.

### INHALATION OF TOXIC GASES

Of the many toxic compounds<sup>38</sup> in smoke (Table 73.2), carbon monoxide (CO) deserves special mention. The affinity of CO for haemoglobin is 240 times that of oxygen. The loss of oxygen transport capacity is dependent on the concentration of inhaled CO and the duration of exposure. In addition, CO binds to cytochrome systems, inhibiting cellular oxidative processes. The half-life of COHb is 4 hours when breathing air, compared with 45 minutes when breathing 100% oxygen.

### DIAGNOSIS

Carbon monoxide poisoning should be suspected in all cases of exposure to combustion products in a closed space. The classic cherry red appearance of the CO victim is seldom evident; early signs may be mistaken for inebriation. Symptoms range from a throbbing headache in mild exposure (10–25% COHb) to weakness, dizziness, confusion and nausea (25–40% COHb), progressing to collapse, unconsciousness and convulsions (40–60% COHb). Death is increasingly likely at COHb concentrations of >60%. Patients exposed to high levels of CO may exhibit signs of cardiac instability. Signs of cerebral irritability may persist for days or weeks following apparent recovery.

### TREATMENT

Administration of the highest concentration of oxygen available, as soon as possible after exposure. Loss of consciousness is an indication for oxygen delivery via an endotracheal tube. The use of hyperbaric oxygen, if immediately available, seems logical, but additional benefit has not been proven.

### HYDROGEN CYANIDE TOXICITY

Hydrogen cyanide (HCN) toxicity frequently occurs in conjunction with CO inhalation. Inhaled concentrations of 200 ppm are rapidly fatal and HCN may account for many deaths at fire accident scenes.<sup>39</sup> Conventional treatment is as for CO intoxication. Removal by chelating agents, such

Table 73.2 Common inhaled toxic gases

Gas	Source	Effect
Carbon monoxide	Organic matter	Tissue hypoxia, lipid peroxidation
Carbon dioxide	Organic matter	Narcosis, tachycardia, hypertension
Nitrogen dioxide	Wallpaper, wood	Bronchial irritation, dizziness, pulmonary oedema
Hydrogen chloride	Plastics	Severe mucosal irritation
Hydrogen cyanide	Wood, silk, nylons, polyurethane	Headache, coma, acidosis
Benzene	Petrol, plastics	Mucosal irritation, coma
Ammonia	Nylon	Mucosal damage, extensive lung injury
Aldehyde	Wood, cotton, paper	Mucosal irritation

as hydroxycobalamin or by the administration of sodium thiosulphate is also possible, but treatment would have to be immediate, based on a presumptive diagnosis, and is therefore not generally recommended.

### FUTURE PROSPECTS

The outlook for young patients with extensive burn injuries, treated under optimal conditions, is now such that little further progress may be expected in terms of survival alone. Mortality among the elderly does, however, remain high. The major thrust of research is currently directed at improving functional and cosmetic outcome following burns. While the most visible efforts concern the development of techniques and materials to improve the quality of wound healing, advances in the field of intensive care are also relevant: strategies aimed at preventing ventilator-associated morbidity are equally applicable to burn patients, who often require prolonged ventilatory support; new insights into the inflammatory responses may improve the general condition of burn patients, increasing resistance to infection and improving tissue repair. There is growing interest in the psychological effects of thermal trauma, which includes new approaches to the management of pain and mental distress.

In the past, the establishment of burn centres has been largely opportunistic, often depending on the dedication of individual specialists. As the provision of medical services undergoes increasing scrutiny, the organisation of burn care in many countries may be subject to reorganisation. It is of the utmost importance that specialists involved in the field of burn care become actively engaged in this process, in order to guarantee continued quality of care for their population.

# Thermal disorders

Anwar Hussein

Body temperature is normally very tightly controlled by a balance between heat production and heat loss, through a complex feedback mechanism involving the thermoregulatory centre in the hypothalamus. In the intensive care unit (ICU), fever (pyrexia) is usually due to resetting of the thermoregulatory set-point at a higher level by activation of heat-conserving mechanisms, whereas hyperthermia is due to failure of effector mechanisms to maintain body temperature at the normal set-point.

Although the pathogenesis of hyperthermia varies between different aetiologies, the complications are similar:

- metabolic acidosis
- hyperkalaemia
- rhabdomyolysis
- renal failure
- disseminated intravascular coagulation (DIC)
- liver failure
- death

## THERMOREGULATION

Control of body temperature, like most complex biological systems, is maintained by a complicated system of sensors and controls. The target set-point varies by  $<1^{\circ}\text{C}$  per day on a circadian basis, and by  $<1/2^{\circ}\text{C}$  monthly in women. However, at any given time the core temperature is within a few tenths of  $1^{\circ}\text{C}$  of the set-point.

The three major components of the thermoregulatory system are:

- afferent input
- central control
- effector responses

Temperature is sensed by A- $\delta$  fibres (most cold signals) and unmyelinated C fibres (most warm signals). These sensors are distributed throughout the body but the largest contribution is from the thermal core (deep abdominal and thoracic tissues, and neuraxis).

Signals from these sensors ascend via the spinothalamic tracts in the anterior spinal cord to the thermoregulatory centre located in the preoptic region of the hypothalamus near the floor of the third ventricle. This region contains

heat-sensitive neurones but also receives neural input from other thermoreceptors. The preoptic region receives afferent information from peripheral thermoreceptors, determines the thermoregulatory set-point and coordinates appropriate responses.

Temperature is then regulated by a variety of central structures that compare integrated thermal inputs from skin, neuraxis and deep tissues with reference temperatures for each thermoregulatory response.

The most important effector response in humans against extreme environments is behavioural, and outweighs autonomic changes. At extremes of age, hypothalamic temperature regulation is impaired and less effective.

Humoral mediators from the circulation act to alter temperature primarily via the organum vasculosum of the lamina terminalis (OVLT), an area of fenestrated capillaries in the hypothalamus that permits cytokine access to neuronal receptors. Cytokines appear to be the endogenous pyrogens, with interleukin-6 (IL-6) and prostaglandin- $\text{E}_2$  ( $\text{PGE}_2$ ) being a final common pathway. In addition to elevating body temperature, several cytokines also reduce the thermoregulatory set-point, and are known as endogenous cryogens.<sup>1</sup>

Patients in the ICU are likely to have disturbance of both heat production and heat loss. Heat is produced as a result of metabolic activity and energy expenditure. Inflammation or infection as part of an acute phase response results in an increase in body temperature and energy expenditure. Pyrexia in turn results in an increased metabolic rate; however, reducing activity with sedation and muscle relaxation reduces energy expenditure.

Regulation of heat loss, which is the predominant effector of thermoregulation, is usually disturbed in the ICU population. Patients are usually nursed semi-naked, bed-bathed frequently, sedated and sometimes paralysed, and infused with drugs and fluids at ambient temperature. This effect is particularly pronounced during renal replacement therapy. Peripheral blood flow may be affected by vasopressors and the ability to shiver abolished by muscle relaxants. Behavioural defences may be compromised by sedative use. All of these effects play a variable part and, together with the method of temperature measurement, should be considered when evaluating fever in the ICU.

### FEVER IN THE ICU

Fever is defined by a *regulated* hyperthermia, that is, it is a regulated elevation in the preoptic set-point temperature. Endogenous pyrogens as well as other mediators inhibit warm-sensitive neurones that normally facilitate heat loss and suppress heat production. This elevates the set-point temperature for all thermoregulatory responses and activates cold defences such as vasoconstriction and shivering, which decrease heat loss and increase metabolic heat production respectively. The set-point temperature returns to normal when pyrogen concentrations decrease, triggering heat loss by vasodilatation and sweating.<sup>2</sup>

Fever may reflect a wide variety of pathological processes including infection, inflammation, trauma, malignancy and connective tissue diseases (Table 74.1), necessitating a systematic and comprehensive diagnostic approach.<sup>3</sup> It is often assumed that a patient presenting with a fever should be treated, regardless of the presence or absence of other symptoms. However, the evidence that anti-fever treatments lead to an improvement in morbidity or mortality, or even patient comfort, is lacking.<sup>4</sup>

The development of fever in response to infection may be a protective adaptive response, and appears to be a phylogenetically preserved evolutionary response because of its survival value.<sup>5</sup> In mammalian models, increasing body temperature results in enhanced resistance to infection. In humans, retrospective clinical trials have shown a positive correlation between maximum temperature on the day of bacteraemia and increased survival in patients with Gram-negative bacteraemia and spontaneous bacterial peritonitis.<sup>6</sup> Also, septic patients with hypothermia have a poorer outcome than those who develop fever, although this causality is less clear. Both local and systemic hyperthermia has been used to facilitate cancer treatment. The protective effects of fever result from increased immune and cytokine functions.<sup>7–10</sup>

Temperature elevation has been shown to enhance:

- antibody production
- neutrophil and macrophage mobility and function
- cytokine production
- T-lymphocyte activity
- reduction of serum iron, which is required for bacterial growth

In addition, elevated temperatures inhibit some pathogens, such as *Streptococcus pneumoniae*.<sup>11</sup>

Moderate fever is a common occurrence in ICU patients, but approximately half of these are non-infectious in origin.<sup>12–14</sup> The presence of fever frequently results in the performance of diagnostic tests and exposes the patient to unnecessary invasive procedures and inappropriate use of antibiotics.<sup>15</sup>

Whilst very high fevers (> 40°C) are dangerous, it is less clear whether moderate elevation of body temperature is detrimental and, indeed, may be protective.<sup>4</sup>

Table 74.1 Causes of fever in the ICU

System	Infectious aetiology	Non-infectious aetiology
Cardiovascular	Endocarditis Catheter-related infection Pacemaker infection	Myocardial infarction Deep-vein thrombosis Pericarditis
Respiratory	Pneumonia Empyema Sinusitis	Atelectasis Chemical pneumonitis Pulmonary emboli
Alimentary	Abdominal abscess Biliary infection Peritonitis Diverticulitis Viral hepatitis Antibiotic-related colitis	Inflammatory bowel disease Acalculous cholecystitis Pancreatitis Ischaemic colitis Non-viral hepatitis Gastrointestinal haemorrhage
Renal	Pyelonephritis Urinary tract infection	
Central nervous	Meningitis Encephalitis	Cerebral haemorrhage/infarct Seizures
Rheumatological	Septic arthritis Osteomyelitis Gout	Connective tissue disease Vasculitis
Endocrine		Adrenocortical insufficiency Alcohol and drug withdrawal Hyperthyroidism
Skin/soft tissue	Cellulitis Decubitus ulcer Wound infections	Burns Intramuscular injections Haematoma
Other	Parotitis Pharyngitis Otitis media	Drug fever Transfusion reaction Neoplasms

Moreover, artificially lowering the temperature of a febrile patient may mask the signs of infection and make diagnosis and monitoring more difficult. Any decision to adopt anti-fever measures, physical or pharmacological, must take into consideration the variable response by this patient population. Antipyretics may be ineffective.

The usual concern about external cooling measures inducing peripheral vasoconstriction, reducing heat loss and making the pyrexia worse by shivering and hypermetabolism, may not be observed in sedated ICU patients.<sup>16</sup> The most likely cause for this response is the drugs used to maintain sedation.<sup>17,18</sup>

Pyrexia is associated with a number of deleterious physiological effects. Cardiac output, oxygen consumption, carbon dioxide production and energy expenditure are all increased, particularly in the presence of shivering. Oxygen consumption is increased on average by 10%/°C.<sup>2</sup> These changes are poorly tolerated by patients with limited cardiorespiratory reserve, and this group of patients would probably derive benefit from cooling measures. Other patient groups that require special consideration include those with immunosuppression, prosthetic implants and acute brain injury. Recent trials of therapeutic moderate hypothermia and traumatic brain injury indicate that hypothermia is a complicated treatment that is likely to benefit only a subgroup of patients with traumatic brain injury.<sup>19–21</sup>

## HEAT STROKE

A diagnosis of heat stroke is suggested when hyperthermia is associated with neurological abnormalities after exposure to high ambient temperature and/or vigorous exercise. Rectal temperature is usually greater than 42°C. Two distinct forms are recognised, and the spectrum of injury includes milder forms of thermal injury often termed heat stress.

Exertional heat stroke is a consequence of prolonged, intense exercise in warm humid environments, often seen in athletes and military recruits. Classic heat stroke is commonly seen in sedentary, elderly patients with underlying illnesses during heat waves. Factors predisposing to heat stroke are listed in Table 74.2. About 80% of heat stroke deaths occur in people aged 50 years and older, because of the diminished ability of the older body to compensate for increased core temperatures. Heat stroke is estimated to be the cause of approximately 1700 deaths each year in the USA.<sup>22</sup> The European heat wave of 2003 was responsible for > 14 000 excess deaths within 2 weeks in France alone, of which a third were attributed to heat stroke, hyperthermia or dehydration.<sup>23,24</sup> A high mortality rate of > 62% was reported for this cohort, which is higher than that for leading killers in ICUs such as acute respiratory distress syndrome (ARDS) and septic shock.<sup>25</sup> Furthermore, there is a late mortality contributed by survivors who have sustained neurological injury. A study of former heat stroke patients suggests that susceptible individuals have a poorer physiological response to heat stress in terms of core temperature, heart rate and sweat response.

There are two autonomic responses to heat stress: sweating and active precapillary vasodilatation. Sweating is extremely effective and can dissipate up to 10 times

**Table 74.2** Predisposing factors to heat stroke

<b>Age</b>	Elderly
<b>Environmental</b>	High ambient temperature and humidity Heat waves Poor ventilation
<b>Behavioural</b>	Lack of acclimatisation Salt and water deprivation Obesity
<b>Underlying conditions</b>	Infection/fever Diabetes Malnutrition Alcoholism Hyperthyroidism Impaired sweat production Healed burns Ectodermal dysplasia Impaired sweating Cardiovascular disease Fatigue Potassium deficiency
<b>Drugs</b>	Anticholinergics Antiparkinsonians Antihistamines Butyrophenones Phenothiazines Tricyclics Diuretics Sympathomimetics

the basal metabolic rate, provided that environmental conditions such as ambient temperature, humidity and wind speed are optimal. The resemblance between heat illness and the effects of antimuscarinic drugs, which produce a central anticholinergic syndrome, is explained by the postganglionic, cholinergic sympathetic innervation of sweat glands. Vascular responses to heat stress include vasodilatation of peripheral vascular beds and vasoconstriction of splanchnic and renal beds. During severe heat stress, blood flow through the top millimetre of skin can be equal to the entire resting cardiac output.

## PATHOGENESIS

The pathogenesis of multiple organ failure in heat stroke is complex. Although direct cellular damage from increased temperature constitutes the initiating insult,<sup>26</sup> the precise sequence of injury and responsible mediators are poorly understood. At the cellular level, thermal injury results in increased membrane permeability, which in turn stimulates membrane enzymes such as Na<sup>+</sup>K<sup>+</sup>-ATPase to maintain membrane integrity. This ATP-consuming enzyme activity is also responsible for nerve impulse conduction, which is

markedly curtailed when ATP is depleted. This results in tissue oedema, reduced oxygen extraction and neuronal injury. High temperatures ameliorate ATP synthesis leading to fatigue.

Recent evidence suggests that the pathways for tissue injury in heat stroke share many features with that of sepsis, endotoxaemia and systemic inflammation. Increased levels of circulating endotoxin and cytokines have been identified in patients with heat stroke.<sup>27,28</sup> The use of anti-endotoxin antibodies in primate models of heat stroke suggests that endotoxin at least in part mediates the tissue injury associated with hyperthermia. There was also a significant correlation between plasma IL-6 concentration and the severity of heat stroke. Since this cytokine is known to modulate the hypothalamic set-point, the ramifications of such a response in an already hyperthermic patient are obvious.

Activation of coagulation factors<sup>29</sup> and release of endothelin and adhesion molecules<sup>30,31</sup> from activated or injured endothelium have also been demonstrated in heat stroke. These recent observations lead to the speculation that certain mediators that are implicated in the pathogenesis of acute organ injury are also elevated in heat stress, but become intense when heat stroke develops and are not normalised upon cooling.

### CLINICAL PRESENTATION

Heat stroke induces multiple organ failure and the clinical presentation reflects this. The first clinical signs may be neurological, and include restlessness, delirium, pupillary abnormalities, seizures and coma. Brainstem reflexes may be lost in the presence of brainstem-evoked potentials. There may be focal pathology including cerebellar injury, which may remain permanent. Lumbar puncture may show increased protein, xanthochromia and lymphocytic pleocytosis.

The signs of distributive shock, with a hyperdynamic haemodynamic profile not dissimilar to that of sepsis, are present in a large number of patients. The marked hyperventilation results in respiratory alkalosis, and hypoxaemic respiratory failure may be due to cardiac failure or acute lung injury.

Dehydration follows excessive insensible losses although sweating is generally absent in the terminal stages of classic heat stroke, leaving a hot, dry skin. Hypovolaemia is a consequence of dehydration and fluid redistribution, and results in reduced organ perfusion. A severe metabolic (lactic) acidosis is present. The major biochemical abnormalities include hyperglycaemia, hypophosphataemia, and raised serum enzymes and acute phase proteins (Table 74.3). Haematological findings include leukocytosis, thrombocytopenia, and activation of coagulation and fibrinolysis.

Exertional heat stroke differs slightly in that additional findings include rhabdomyolysis and acute renal failure that is associated with hyperkalaemia, hyperphosphataemia and hypocalcaemia (Table 74.3).

**Table 74.3** Biochemical differences between classic and exertional heat stroke

	Classic heat stroke	Exertional heat stroke
Arterial gases	Mixed respiratory alkalosis	Severe metabolic acidosis
Serum electrolytes	Na <sup>+</sup> , Mg <sup>2+</sup> , Ca <sup>2+</sup> are usually normal	Hyperkalaemia Hypocalcaemia Hyperphosphataemia
Blood glucose	Hyperglycaemia	Hypoglycaemia
Creatinine kinase	Moderately increased	Markedly increased
Hepatic enzymes	Markedly increased	Moderately increased
Acute phase proteins	Markedly increased	Moderately increased

### MANAGEMENT

Heat stroke is a medical emergency. The principal therapeutic objectives are rapid cooling to below 40°C and support of vital organ systems. Heat is dissipated by:

- conduction (immersion in ice-cold water or packed ice)
- evaporation (repeated wetting of skin with tepid water and fanning the patient at room temperature and low humidity)

Evaporation is considerably more effective. Pharmacological treatment with antipyretic agents, or dantrolene,<sup>32</sup> is ineffective. Prevention of vasoconstriction and shivering by overcooling is important because of the danger of subsequent rebound hyperthermia. Core and skin temperature monitoring is useful, but measurement of rectal temperature should be avoided because it lags considerably during cooling. Cooling can be stopped when core temperature reaches below 39°C. However, despite cooling, about 25% of patients experience failure of one or more organ systems.

Fluid and electrolyte imbalance, and acid-base disturbances must be corrected cautiously with appropriate fluids tailored to the individual and guided by measurements of filling pressure, serum electrolytes and haematocrit.

The mechanism of acute renal failure is multifactorial but rhabdomyolysis is the major component. Early institution of alkaline diuresis and mannitol may obviate the need for renal replacement therapy.

Oxygen therapy and controlled ventilation may be indicated, and anticonvulsants required. Prophylactic antibiotics and steroids are not recommended. Blood glucose must be controlled aggressively. Finally, any underlying illness should be sought and treated accordingly.

## OUTCOME

The largest study reported of heat stroke patients in intensive care suggests an alarmingly high mortality of > 60%,<sup>23</sup> although this diminishes substantially with early recognition and aggressive treatment. The incidence of permanent neurological deficit remains at 7–15%. Variables associated independently with reduced hospital survival include:

- high core temperature
- high simplified acute physiology score (SAPS) II score
- having heat stroke at home
- prolonged prothrombin time
- vasoactive therapy within 24 hours
- admission to ICU lacking air conditioning

## DRUG-INDUCED HYPERTHERMIAS

In contrast to fever, the thermoregulatory set-point during hyperthermia remains unchanged at normothermic levels; however, body temperature increases in an uncontrolled fashion and overrides the ability of effector mechanisms to dissipate heat. Although a raised body temperature is not necessarily due to increased heat production but rather due to an imbalance between heat production and loss, most hyperthermias result as a consequence of net heat gain. Hyperthermia can result in dangerously high core temperatures by two mechanisms:

- excessive exogenous heat exposure
- excessive endogenous heat production

The numerous causes of hyperthermia are listed in Table 74.4. This section will review the relatively common causes of drug-induced hyperthermias, including malignant hyperthermia, neuroleptic malignant syndrome, and the sympathomimetic and anticholinergic syndromes.

## MALIGNANT HYPERTHERMIA

Malignant hyperthermia (MH) is a rare pharmacogenetic myopathy usually manifested when a susceptible individual is exposed to anaesthetic triggering agents. It is characterised by an intense hypermetabolic state and skeletal muscle rigidity upon exposure to volatile anaesthetics and depolarising muscle relaxants. In extreme cases, body temperature may exceed 42°C and the arterial pH reach 6.8, and can be rapidly fatal. The incidence of an MH reaction during general anaesthesia varies between 1/60 000 when succinylcholine is used, and 1/250 000 when only volatile agents are used. It is more frequent in children (1/15 000), with more than 50% of cases occurring before the age of 15 years.

## PATHOGENESIS

Skeletal muscle is the principal tissue involved in an MH reaction. The primary defect is thought to be in the

Table 74.4 Causes of hyperthermia

<b>Disorders of excessive heat production</b>	Exertional hyperthermia Heat stroke (exertional) Malignant hyperthermia Neuroleptic malignant syndrome Lethal catatonia Thyrotoxicosis Pheochromocytoma Salicylate intoxication Sympathomimetic drug abuse Delirium tremens Seizures Tetanus

<b>Disorders of hypothalamic function</b>	Cerebrovascular accidents Encephalitis Trauma Granulomatous diseases Neuroleptic malignant syndrome

sarcolemma, and in particular the calcium release channel also termed the ryanodine receptor (RYR1). In MH, exposure of skeletal muscle to triggering agents depolarises the muscle hypersensitively to release massive amounts of calcium ions from the sarcoplasmic reticulum (SR), thus vastly increasing its cytoplasmic concentration. It is believed that the altered kinetics of the ryanodine receptor is due to exaggerated release of calcium by small increases in cytoplasmic calcium concentration (calcium-induced calcium release), as well as a decrease in inhibitory effects of high calcium concentrations. ATP-dependent membrane pumps (Ca<sup>2+</sup>-ATPase) attempt to return the calcium back to the SR, resulting in a sustained glycolytic and aerobic metabolism. Recovery of calcium by the SR is often incomplete, causing prolonged excitation–contraction coupling and leading to muscle rigidity. Muscle contractures impede blood flow and perturb nutrient supply and waste removal from this hypermetabolic reaction. Eventually, oxidative phosphorylation is uncoupled, metabolism becomes anaerobic, and a severe lactic and respiratory acidosis develops. As muscle constitutes about 40% of body mass and is a major source of body heat, increased activity results in hyperthermia.

Membrane phospholipase A<sub>2</sub> is also activated by calcium, leading to an increase in mitochondrial and sarcoplasmic permeability, with further loss of calcium regulation and release of intracellular contents (potassium [K<sup>+</sup>], calcium [Ca<sup>2+</sup>], creatinine kinase (CK) and myoglobin) into the circulation.

### CLINICAL PRESENTATION

The earliest sign of an impending MH crisis is an unexplained rise in end-tidal CO<sub>2</sub> and heart rate, and not necessarily an increase in body temperature. This classic crisis of acute fulminant MH with its multiplicity of marked metabolic and muscle anomalies and sympathetic stimulation is unmistakable, but now rare. The pattern of presentation has altered since its first description in 1960, as anaesthetic techniques and succinylcholine use have changed.

The more gradual appearance of signs following exposure to triggering agents may be more difficult to diagnose as the signs may be subtle, non-specific and have variable intensity, incidence and temporal association (Table 74.5).<sup>33</sup> Apart from the classic crisis, other forms of MH – including smouldering, recurring, delayed and abortive – may also occur. Other conditions that may mimic MH include inadequate levels of anaesthesia or analgesia, sepsis, ischaemia or anaphylaxis. Early diagnosis is important as immediate treatment is associated with improved outcome. Masseter muscle spasm (MMS) has been associated with MH.<sup>34</sup> When MMS is the only presenting sign, the incidence of MH susceptibility is likely to be low. However, this incidence is increased if MMS is associated with other muscle or metabolic signs.

Halothane is the most potent of the contemporary volatile anaesthetic agents at inducing sustained contractures in isolated muscle strips from MH patients, and has formed the basis of diagnostic testing for MH for 30 years. There may be a difference amongst the volatile anaesthetics in their relative potency to trigger an MH reaction. Succinylcholine will cause an increase in the calcium concentration in the cytosol of normal muscle, and

it appears that this release of calcium is exaggerated in MH muscle. Non-depolarising muscle relaxants are generally accepted to be safe in MH. A list of safe and implicated drugs is shown in Table 74.6.

Several neuromuscular and musculoskeletal abnormalities such as scoliosis, strabismus, muscular dystrophy and central core disease have been associated with MH susceptibility but definitive evidence for this association is lacking. Patients with neuroleptic malignant syndrome are not considered at risk of developing MH under general anaesthesia.

MH susceptibility has been diagnosed for the last 30 years on the basis of abnormal in vitro contractures to separate exposures to halothane and caffeine performed on freshly biopsied muscle strips. Recently, a ryanodine contracture test has been shown to be more specific and may be of additional value.

**Table 74.6** Drug use in malignant hyperthermia

Contraindicated drugs	Safe drugs
Halothane	Nitrous oxide
Enflurane	Barbiturates
Isoflurane	Propofol
Desflurane	Etomidate
Sevoflurane	Ketamine
Succinylcholine	Opiates
Verapamil	Amide/ester local anaesthetics
Nifedipine	Noradrenaline (norepinephrine)
Diltiazem	Adrenaline (epinephrine)
	Dopamine
	Dobutamine

**Table 74.5** Clinical features of malignant hyperthermia

Timing	Clinical signs	Changes in monitored variables	Biochemical changes
Acute	Sustained jaw rigidity after succinylcholine Tachypnoea Rapid exhaustion of soda lime Hot soda lime canister High pulse rate Irregular pulse	Increased minute ventilation Rising end-tidal CO <sub>2</sub> Tachycardia Ventricular ectopics Peaked T waves on ECG	Increased <i>Paco</i> <sub>2</sub> Decreased pH Increased [K <sup>+</sup> ]
Intermediate	Patient hot to touch Cyanosis Dark blood in wound Irregular pulse	Rising core body temperature Falling <i>Spo</i> <sub>2</sub> Ventricular ectopics Peaked T waves on ECG	Decreased <i>Pao</i> <sub>2</sub> Increased [K <sup>+</sup> ]
Late	Generalised muscle rigidity Prolonged bleeding Dark urine Oliguria Irregular pulse Death	Ventricular ectopics Peaked T waves on ECG	Increased creatine kinase Myoglobinuria Increased [K <sup>+</sup> ]

Adapted from Hopkins PM. Malignant hyperthermia: advances in clinical management and diagnosis. *BJA* 2000; **85**: 118–28.

**MOLECULAR GENETICS OF MH**

MH is a heterogenetic disorder that is autosomal dominant with variable penetration and expression. Recent advances in molecular genetics have supported the concept for a role of the *RYR1* gene in the pathogenesis of MH. The *RYR1* gene is found at position 13.1 on chromosome 19 q and codes for the ryanodine receptor that regulates calcium transport across the calcium release channel. However, only 50% of MH families show genetic linkage to the *RYR1* gene, and more than 17 mutations at this locus have been described so far. The mutation does not always segregate with in vitro contracture testing within a family. Furthermore, *RYR1* linkage is not found in some MH families. Although all known mutations share the final common pathway of excessive calcium release from the SR, the genetic diversity of this disease precludes DNA-based diagnosis at present.

**MANAGEMENT**

Once a diagnosis of MH is suspected, and other diagnoses excluded, treatment should be based as follows:

- Stop all anaesthetic triggering drugs, increase fresh gas flow to purge the anaesthetic machine, and substitute a new breathing circuit. Valuable time should not be lost changing the machine and is no longer recommended. Increase ventilation to two to three times the minute volume to aid removal of CO<sub>2</sub>.
- Abandon surgery if possible, or continue using safe drugs (Table 74.6).
- Administer intravenous dantrolene, which is the only specific therapy, at an initial dose of 2.5 mg/kg and repeat at 5–10-minute intervals until the drug reverses the metabolic derangements of MH (maximum dose 10 mg/kg). Dantrolene acts by inhibition of SR calcium release but without affecting uptake. It may be repeated at 1–2 mg/kg 4-hourly for 1–3 days and then given orally if still required.
- Arrhythmias not responsive to correction of acidosis and hyperkalaemia should be treated in the conventional manner. However, calcium antagonists are contraindicated as these drugs interact with high-dose dantrolene to cause severe hyperkalaemia and cardiovascular collapse.
- Cool the patient using simple measures such as tepid sponging, fanning and cool intravenous fluids in order to avoid vasoconstriction, which impedes heat loss. Occasionally, more aggressive cooling methods may be required.
- Frequent blood samples should be taken for analysis of blood gases, potassium, creatinine kinase, myoglobin and coagulation. Treat hyperkalaemia and acidosis early and aggressively.
- Measure urine output for impending signs of acute renal failure. Diuresis with mannitol or furosemide may be considered in addition to fluids to attempt to prevent myoglobin precipitation in renal tubules. Mannitol doses should incorporate that contained in dantrolene preparations.

- Continue monitoring closely in the post acute phase according to signs and severity. Renal protection therapy and control of coagulopathy are desirable.
- Consider alternative diagnoses if there is no response to dantrolene, e.g. other myopathies, sepsis, thyrotoxic storm, pheochromocytoma.
- After recovery, patients and relatives should be referred to an MH screening centre.

**OUTCOME**

The mortality rate from MH has declined from 70% in the 1960s to less than 10% worldwide. This vast improvement is attributed to increased awareness and understanding by anaesthetists, improved monitoring techniques (especially capnography and pulse oximetry) and the availability and early use of intravenous dantrolene. Late recognition of MH may result in a poor outcome despite treatment with dantrolene.

**NEUROLEPTIC MALIGNANT SYNDROME**

The neuroleptic malignant syndrome (NMS) is a relatively rare but potentially fatal idiosyncratic reaction to neuroleptic drugs that is not dose related. Many features of this syndrome remain controversial as several other medical conditions generate similar symptoms, but characteristic findings include:

- encephalopathy
- muscle rigidity
- hyperthermia
- autonomic dysfunction

The incidence is estimated to vary between 0.07 and 2.2%. All ages are affected but males are disproportionately represented in some studies.

**PATHOGENESIS**

The pathophysiology of NMS remains unclear. Two mechanisms – a neuroleptic-induced perturbation of central thermo- and neuroregulatory mechanisms and an abnormal reaction of skeletal muscle – have been proposed.

Hypothalamic thermoregulation involves noradrenergic, serotonergic, cholinergic and central dopaminergic pathways. Neuroleptic blockade of dopamine receptors in the hypothalamus leads to disturbances in thermoregulation and heat dissipation. In addition, blockade of dopamine receptors in the basal ganglia is thought to cause muscle hypertonicity and contraction, leading to further heat production. Drugs linked to NMS appear to share the ability to antagonise dopamine receptors (primarily D<sub>2</sub> receptors) or to lower synaptic dopamine levels. Recent work suggests that glutaminergic excitatory amino acids may influence central dopamine activity and be more important in the development of NMS.

A common pathogenesis of NMS and MH has been suggested by virtue of similar clinical features (hyperthermia, rigidity, raised serum muscle enzymes), abnormal in vitro contracture tests and, interestingly, successful treatment

with dantrolene in both. However, conflicting results have been reported regarding the prevalence of MH susceptibility among NMS patients. Neuroleptic agents induce muscle contracture *in vitro*; however, no difference was found in response to four neuroleptic drugs between muscle from NMS patients and normal individuals.<sup>35</sup>

Although biochemical studies suggest the involvement of genetic factors in the pathogenesis of NMS, the molecular basis remains elusive. There does not appear to be an association between NMS and the mutations in the *RYR1* gene associated with MH.

### CLINICAL PRESENTATION

The presentation and course of NMS can be quite variable; it may take a relatively benign and self-limiting course, or it may be fulminant and fatal, although the latter is rare. NMS usually develops within 2–4 weeks of starting antipsychotic therapy but the majority of the cases develop within the first week. The main symptoms that indicate a high probability of NMS include:

- hyperthermia
- muscle rigidity
- elevated serum creatinine kinase
- autonomic instability

A predictable progression of symptoms may be identified in many patients with NMS where mental status changes and rigidity precede hyperthermia and autonomic dysfunction:<sup>36</sup>

- temperature elevation can be mild or severe, but is rarely greater than 42 °C as seen in heat stroke
- muscle rigidity is characterised by a ‘lead pipe’ increase in tone that may result in decreased chest wall compliance and hypoventilation
- extrapyramidal symptoms may also be present
- autonomic instability is demonstrated by labile hypertension (hypotension is rare), tachycardia and sweating
- altered consciousness is typically of the form of delirium and agitation that may progress to stupor and coma

Other clinical features of lesser frequency include dysarthria, dysphagia, chorea, mutism and seizures. Elevated serum creatinine kinase is now considered to be a major feature of NMS. Other non-specific laboratory abnormalities include leukocytosis, mildly elevated hepatic enzymes, and secondary electrolyte disturbances including hypocalcaemia, hypomagnesaemia and hypophosphataemia. Urine analysis often reveals proteinuria and myoglobinuria from rhabdomyolysis. The electroencephalograph (EEG) may show diffuse slowing. CT scans of the brain as well as examination of cerebrospinal fluid is usually normal in NMS.

All classes of neuroleptic medications have been implicated in NMS including butyrophenones, phenothiazines, thioxanthenes and benzamides, as well as newer drugs such as clozapine and risperidone. Haloperidol and fluphenazine are the most frequently reported

agents. Other agents that block dopamine receptors or inhibit dopamine release have been associated with NMS including metoclopramide, reserpine and  $\alpha$ -methyl-paratyrosine. Discontinuation of anti-parkinsonian drugs (leading to a relative decrease in dopamine levels) has also been associated with NMS.

Risk factors include organic brain disease, functional psychoses, dehydration and rapid loading of antipsychotics.

Complications include:

- acute renal failure from rhabdomyolysis
- respiratory failure from hypoventilation and aspiration pneumonia
- cardiovascular collapse
- irreversible neurological injury may result from extreme temperatures

The differential diagnosis of NMS includes all disorders that can present with a combination of hyperthermia, rigidity and encephalopathy. These include CNS infections, cerebral masses, tetanus, heat stress, MH, catatonia and drug toxicities (lithium, atropine and monoamine oxidase inhibitors).

Neuroleptic-induced heat stroke is differentiated from NMS by its faster onset, absence of extrapyramidal signs and sweating (anticholinergic properties of neuroleptics), and a history of physical exertion and exposure to a hostile environment. Like NMS, lethal catatonia can present with hyperthermia, akinesia and muscle rigidity. The importance of distinguishing the catatonias from NMS lies in the differential treatment. Benzodiazepines are usually required for the former.

### SEROTONERGIC SYNDROME

Drugs that enhance serotonergic neurotransmission or lead to a relative increase in synaptic levels of serotonin can result in a toxic state that resembles features of NMS. These drugs include selective serotonin reuptake inhibitors (SSRIs), monoamine oxidase inhibitors (MAOIs) and tricyclic antidepressants (TCAs), either alone or in combination. Serotonin syndrome may complicate the administration of drugs frequently used in anaesthetic practice, including pethidine and tramadol, in combination with the above drugs. This syndrome is a toxic effect that appears to be due to hyperstimulation of 5-HT<sub>1A</sub> receptors in the brain and spinal cord. This is differentiated from NMS, which is an idiosyncratic response to antipsychotics and not serotonergic drugs.

Clinical features of the serotonergic syndrome include encephalopathy, hyperreflexia, nausea and vomiting, and autonomic instability. Sweating and mild increases in temperature are evident in 50% of cases. Rhabdomyolysis, hyperkalaemia, renal failure, DIC and seizures are all rare but reported findings. The serotonergic syndrome is usually self-limited, and resolves uneventfully once the offending drug has been withdrawn. However, rarely severe forms require more aggressive supportive therapy analogous to the treatment of NMS. Specific treatments including the use of serotonin antagonists have been

proposed; however, these cannot be recommended at present due to lack of well-designed studies.

### MANAGEMENT

Management of mild forms of NMS may only require early recognition, withdrawal of all neuroleptic, dopamine-depleting or dopamine-antagonist medication, and general supportive therapy. Cessation of all psychotropic drugs should be considered. Rarely, severe cases require aggressive treatment of fluid/electrolyte and acid-base balance as well as cardiorespiratory function. Because acute renal failure is the most frequent complication of NMS, therapy must be directed at renal protection from myoglobin injury. The hyperthermic patient should be cooled as described previously in this chapter. Haemodialysis may be required for renal failure, but is not useful for clearing neuroleptic drugs as these are protein-bound and therefore too large to dialyse.

The benefit of adding specific pharmacotherapies in addition to supportive measures is unclear, but potential use cannot be excluded. Treatments with bromocriptine (a dopamine agonist) and dantrolene have led to a faster resolution of symptoms than with supportive therapy alone.<sup>37</sup> However, the place of dantrolene in the treatment of NMS is less well defined. Bromocriptine seems to be well tolerated by psychotic patients despite being a strong central dopamine agonist. The drug is effective within 24 h, with a reduction in rigidity followed by resolution of temperature and normalisation of blood pressure. Similarly, amantadine, as well as a combination of levodopa-carbidopa, has also been reported to be effective. Anticholinergic drugs have little effect on muscle rigidity or hyperthermia. Non-specific adjuncts, such as the use of benzodiazepines, have been reported to be useful in agitated patients. Electroconvulsive therapy (ECT) may be of value in selected patients, e.g. those with refractory NMS, those who remain catatonic or those with ECT-responsive psychotic symptoms.

### OUTCOME

A mortality of 22% prior to 1980 has been halved since 1984. This reduction has occurred largely due to early diagnosis, supportive therapy and advances in critical care medicine, rather than a consequence of therapy with either dantrolene or dopamine agonists. Renal failure increases the mortality rate to approximately 50%; however, prognosis remains good in survivors.

## SYMPATHOMIMETIC AND ANTICHOLINERGIC SYNDROMES

### SYMPATHOMIMETIC POISONING

Mild to severe hyperthermia may be associated with all centrally acting sympathomimetics. These drugs produce their clinical effects by increasing synaptic concentrations of noradrenaline (norepinephrine), dopamine and serotonin.

Cocaine predominantly blocks the presynaptic uptake of noradrenaline, although neurotransmission of dopamine and serotonin is also affected. Amphetamines and related drugs augment the release of noradrenaline, dopamine and serotonin from presynaptic nerve terminals and inhibit their uptake from the synapse. Some amphetamine metabolites also inhibit monoamine oxidase.

Central thermoregulatory disturbances from sympathomimetics may arise from complex interactions of these neurotransmitters in the brainstem and hypothalamus. The syndrome of hyperthermia associated with sympathomimetic poisoning bears similarity to that of heat stroke, MH, NMS and serotonin syndrome. This may reflect the final common pathway associated with the consequences of severe hyperthermia. Sympathomimetics such as MDMA ('ecstasy') have been shown to induce marked hyperthermia through central mechanisms involving 5-HT<sub>2</sub> receptors, with subsequent rhabdomyolysis, DIC and multiorgan failure.<sup>38</sup> Hyperkinetic muscle action, motor excitability and seizures may contribute to the rise in core temperature. Furthermore, elevated levels of both cocaine and amphetamine result in peripheral vasoconstriction, thus impairing heat dissipation. Mortality appears to be related to the extent and duration of hyperthermia.

Therapy involves rapid cooling measures as outlined previously, together with support of failing organ systems. Benzodiazepines may relieve myotonic and hyperkinetic thermogenesis. However, patients who remain agitated and non-compliant should be paralysed and ventilated to permit institution of aggressive cooling measures. In moderately severe hyperthermia, dantrolene therapy has been described to improve outcome by enabling rapid muscle relaxation and control of temperature. However, the basis of its utility in this setting has not been established.

### ANTICHOLINERGIC POISONING

The central and peripheral symptoms of anticholinergic syndrome result from the blockade of muscarinic acetylcholinergic receptors. Central toxicity results in:

- confusion
- tremor
- hallucinations
- myoclonus
- agitation

whereas peripheral signs of toxicity include:

- dry mucous membranes
- mydriasis
- blurred vision
- tachycardia
- urinary retention

Muscular hyperactivity from agitation, restlessness and convulsions in combination with impaired sweating may

result in hyperthermia and rhabdomyolysis. Excessive temperatures can lead to multiorgan failure as described for other types of heat illness.

### HYPOTHERMIA

Hypothermia is defined as a core body temperature below 35 °C. In the UK, hypothermia accounts for 1% of winter admissions, particularly amongst the elderly population. The leading causes of hypothermia in the USA are exposure due to alcoholism, drug addiction, mental illness, or accidents involving immersion in cold water. The mortality rate from accidental hypothermia varies according to its severity, but averages 21% when core temperature is decreased to 28–32°C.<sup>39</sup> However, a core temperature of 32 °C or less in trauma victims is associated with a mortality rate near 100%, and any hypothermia is considered a poor prognostic sign.<sup>40,41</sup>

Hypothermia is traditionally classified as:

- mild (temperature 32–35°C)
- moderate (temperature 28–32°C)
- severe (temperature below 28°C)

Significant hypothermia in terms of severity and duration results in multiple systemic derangements that ultimately lead to impaired tissue oxygenation. The major defence against cold stress is behavioural adaptation. However, autonomic thermoregulatory responses orchestrated by the hypothalamus are also activated to prevent heat loss and generate heat production. These include:

- peripheral vasoconstriction
- shivering
- increase in metabolism.

The four physical mechanisms of heat loss from the body surfaces are conduction, convection, radiation and evaporation.

Hypothermia may be induced deliberately for therapeutic purposes, e.g. cardiovascular surgery or neuroprotection, or it may be accidental. Primary accidental hypothermia occurs when an otherwise healthy individual experiences overwhelming cold stress, e.g. cold-water immersion. Secondary accidental hypothermia occurs despite mild environmental conditions and is due to illness or injury-induced perturbations in thermoregulation and heat production, e.g. drug intoxication or trauma.

The causes and predisposing conditions of hypothermia are listed in Table 74.7; however, the most frequent causes appear to be exposure, hypoglycaemia and the use of depressant drugs including alcohol. An impaired thermoregulatory system together with a reduced functional reserve makes the elderly more susceptible.

Administration of anaesthesia impairs the ability to maintain thermal homeostasis, decreases heat production and causes heat loss due to vasodilatation and exposure. General anaesthesia also alters the threshold for

**Table 74.7** Causes and predisposing conditions of hypothermia

<b>Age</b>	Extremes of age

thermoregulatory vasoconstriction and shivering in the non-paralysed patient.<sup>42</sup>

### PATHOGENESIS AND CLINICAL PRESENTATION

Hypothermia depresses all organ functions resulting in decreased cardiac function, shock, respiratory failure, confusion, muscle rigidity, renal failure and death. The cardiovascular response in hypothermia initially comprises an increase in heart rate, cardiac output and blood pressure in response to shivering and increased metabolic demand. Peripheral vasoconstriction is due to activation of the sympathetic nervous system as well as local cutaneous reflexes, resulting in shunting of peripheral blood to the central pool. With worsening hypothermia:

- progressive cardiovascular depression leads to a reduction in tissue perfusion
- cardiac output is halved at 28°C as a result of decreased heart rate and contractility
- conduction and pacemaker activity are reduced, and there is prolongation of PR, QRS and QT intervals as well as non-specific ST-T wave changes. The characteristic J or Osborn wave may be seen when core temperature is below 33°C

- atrial fibrillation and heart block are also common below this temperature. Ventricular fibrillation and asystole can occur below 28°C and 20°C respectively. Fibrillation may occur earlier if the myocardium is diseased or stimulated, either mechanically or pharmacologically

An initial increase in respiratory rate during hypothermia is followed by progressive depression of rate, vital capacity and minute volume. The cough reflex is abolished, exposing the patient to an increased risk of aspiration pneumonia. Bronchial secretions, atelectasis and pulmonary oedema may develop. Apnoea may occur below 24°C. The oxyhaemoglobin dissociation curve is shifted to the left, resulting in reduced oxygen delivery to the tissues, but this is partially balanced by a right shift due to the underlying acidosis.

Shivering occurs in the early phase of hypothermia and is characterised by intense heat and energy production from the metabolism of stored fuels. Non-shivering thermogenesis is probably only of importance in children. Metabolic processes slow by approximately 6%/°C, and the metabolic rate is reduced by half at 28°C.<sup>43</sup> A mixed respiratory and metabolic acidosis results from hypoventilation and reduced tissue perfusion, leading to lactate accumulation from anaerobic metabolism. Hepatic function is depressed, affecting most enzymatic and detoxifying processes. There is a high risk of developing pancreatitis.

There is generalised cerebral depression as the metabolism of the brain declines with a fall in core temperature. This adaptation is neuroprotective and may improve the chances of survival even after prolonged hypothermic arrest. Cerebral blood flow falls as a consequence of reduced cardiac output and increased blood viscosity at a rate of 7%/°C drop in temperature.<sup>44</sup> Confusion can cause illogical behaviour (e.g. aggression) and paradoxical undressing. Coma, pupillary dilatation, absence of tendon reflexes and rigidity are present below 28°C. Cerebral electrical activity ceases below 20°C.

Hypothermia causes an initial increase in catecholamine and cortisol release as a result of the stress response. There is a delayed increase in serum thyroxine levels. Below 30°C, pituitary and pancreatic functions, as well as catecholamine secretion, are blunted. Blood sugar concentration is increased as a result of increased glycogenolysis and insulin resistance.

Haemoconcentration develops as a consequence of hypovolaemia as well as fluid shifts between compartments. Hypothermia increases blood viscosity by 2%/°C. Splenic sequestration results in leukopenia and thrombocytopenia. Low temperature also interferes with the intrinsic coagulation cascade. In severe hypothermia, platelet dysfunction and DIC are common.

## MANAGEMENT

Once the diagnosis of hypothermia has been made, further heat loss must be prevented and rewarming started with close monitoring to avoid complications. Individual management should be modified according to aetiology and severity of hypothermia, as well as the functional reserve of the patient. Severe hypothermia, especially in the

immersion victim, can mimic death, with apnoea, cardiac standstill, coma, unreactive pupils, and a silent electrocardiogram and electroencephalogram. Successful resuscitation of such patients has been reported and death should not be assumed until resuscitation has failed in an adequately warmed patient (at least 35°C).<sup>45</sup>

General measures begin with removal of the patient from the cold environment as rapidly as possible. Rough handling must be avoided during transport as this may precipitate fatal arrhythmias in severe hypothermia. Also, transport in the upright position must be avoided because cerebral blood flow may be compromised due to orthostatic hypotension.

Recommendation for basic and advanced life support for hypothermic patients is according to the principles of Advanced Cardiorespiratory Life Support (ACLS). Aggressive rewarming should be continued during resuscitation until the core temperature is at least 35°C. A resuscitation protocol based on core temperature and cardiac monitoring may be used.<sup>46</sup> If core temperature is unknown or known to be above 28°C, cardiopulmonary resuscitation (CPR) should be instituted for apparent cardiac arrest. If the patient is known to be severely hypothermic (< 28°C) but maintains sinus rhythm, chest compression may precipitate ventricular fibrillation (VF) and may be best withheld.

Vascular cannulation may be difficult in the presence of intense vasoconstriction and a central catheter is inevitably required, taking precautions to avoid myocardial stimulation.

For the same reasons, a pulmonary artery catheter should be deferred until normothermia has been re-established. Hypotension should be treated with aggressive warm fluid therapy. Lactated Ringers should be avoided because the liver may not be able to metabolise lactate to bicarbonate.

Atrial arrhythmias, bradycardia or atrioventricular block generally do not require treatment with antiarrhythmic agents unless decompensated, and resolve on rewarming.

Electrical defibrillation may not be effective at body temperature below 30°C. Indeed, VF may resolve spontaneously upon rewarming.

Sodium bicarbonate should be avoided because of paradoxical intracellular acidosis, and severe alkalosis on rewarming may induce refractory VF and left shift of the oxyhaemoglobin dissociation curve, thereby reducing tissue oxygen uptake. Progressive cardiac depression during rewarming ('recovery shock', 'afterdrop') may be due to further cooling of blood as it redistributes from the core to the relatively colder periphery.<sup>47</sup>

The increased metabolic demand during rewarming requires oxygen therapy. Patients in coma or respiratory failure should be intubated and ventilated with warm gases. Drug administration during hypothermia may reach toxic levels after rewarming because of functionally prolonged half-lives, and therefore should be used sparingly. Insulin treatment should be delayed until the temperature is above 30°C. It should be administered in small doses because degradation is slow and accumulation may occur with rebound hypoglycaemia as the patient is warmed.

**REWARMING**

Various methods of rewarming have been employed depending upon the severity of the hypothermia (Table 74.8). Careful monitoring and supportive therapy are mandatory during rewarming.

Passive warming involves removing the patient from a cold environment and allowing to rewarm spontaneously in a warm room (30°C). It is best for patients with mild hypothermia who have no circulatory compromise. Rewarming is gradual at 0.5–1.0°C/h.

Patients with moderate or severe hypothermia should be treated with active rewarming, which consists of active external rewarming or active core rewarming. Patients with moderate hypothermia and no evidence of circulatory collapse can initially be treated with active external rewarming techniques. These include use of immersion, radiant heat, forced air and electric blankets. Convective (forced air) warming at 43°C has been shown to increase body temperature by 2–3°C/hour, and is extremely effective in both preventing and treating hypothermia, as well as preventing shivering in the postoperative period.<sup>48,49</sup>

Active core rewarming is best used for patients with moderate to severe hypothermia. Techniques include:

- airway rewarming
- gastrointestinal
- peritoneal or pleural cavity lavage
- extracorporeal rewarming
- cardiopulmonary bypass

Active core rewarming methods are extremely rapid but invasive, and the inherent risks should be considered in the management.

**Table 74.8** Rewarming methods

<b>Passive</b>	Warm environment >30°C (rate 0.5–1.0 °C/hour) Insulating cover (warm blanket)
<b>Active, external</b>	Conduction methods Warmed pads, blanket Convective methods (rate at 2–3°C/hour) Hot air blower (e.g. Bair Hugger) Radiant methods
<b>Active, core</b>	Humidified warm inspired gases (rate 0.5–1.5°C/hour) Warmed intravenous fluids Body cavity lavage (rate 2–3°C/hour) Gastric irrigation Pleural irrigation Peritoneal dialysis Extracorporeal methods Haemodialysis, continuous arteriovenous or venovenous rewarming (rate 5°C/hour) Cardiopulmonary bypass (rate up to 10°C/hour)

In airway rewarming, inspired gas is heated and humidified up to 40 °C, and delivered either through a facemask or an endotracheal tube. It insulates the respiratory tract and stops heat and moisture lost through breathing. The rate of rewarming is about 0.5–1.5 °C/h. Volume expansion with intravenous fluids warmed with heat exchangers or by microwave can also be used. However, this method is insufficient by itself as very large volumes would be required to achieve a significant rise in body temperature.

Peritoneal lavage with heated dialysate, and closed pleural irrigation using warm sterile saline (temperature 40–42°C) through large bore tubes may also be attempted.<sup>50,51</sup> These methods are equally effective in raising temperature (2–3°C/h), but impossible in patients with thoracoabdominal injuries.

Haemodialysis and continuous arteriovenous or venovenous rewarming techniques are extremely effective in raising body temperature (5 °C/h). The advantages of this technique include non-requirement of heparinisation if heparin-bonded tubing is used, rapid reversal of hypothermia, decreased total fluid requirements, decreased organ failure, decreased length of ICU stay and decreased early mortality.<sup>52</sup> Patients with severe cardiovascular dysfunction may not tolerate high arteriovenous fistula flows.

The best method for rewarming patients with severe hypothermia who have haemodynamic instability involves the use of cardiopulmonary bypass. Its advantages include the highest rewarming rate (up to 10°C/h), control of rewarming rate, oxygenation, fluid composition and haemodynamic support.<sup>53</sup> However, associated risks include heparinisation, haemolysis and air embolism.

Afterdrop is a phenomenon seen with rewarming where tissues that have been vasoconstricted and very cold start to become perfused again. Blood returning from these areas may be cold and will result in a late reduction in core temperature. This may be seen when core temperature is approaching normal and after active measures have been stopped.

**OUTCOME**

Poor prognostic factors include aetiology and severity of hypothermia, advanced age, comorbid states and cardiorespiratory arrest. Hypothermia associated with trauma or sepsis carries a high mortality.

# Electrical safety and injuries

Lester A H Critchley

Patients suffering from the consequences of electrocution and associated burns occasionally require intensive care unit (ICU) management. Patients and staff in the ICU are at risk of electrocution from faulty electrical equipment. The necessity of direct patient contact with electrical equipment increases this risk, and when therapy involves an invasive contact close to the heart, microshock is an additional hazard. Faulty electrical equipment can also result in power failures, fires and explosions. The use of mobile phones and related devices nearby patient equipment can lead to malfunctioning.

## PHYSICAL CONCEPTS

Electricity is produced by the movement of negatively charged electrons. A potential difference or voltage, measured in volts (V), exists between two points if the number or density of electrons is greater at one point. When these points are connected by a conductor, the potential difference will cause electrons or an electric current (I), measured in amperes (A), to flow. Resistance (R), measured in ohms (O), opposes this flow of electrons. Resistance is low in a conductor, because electrons can move freely from atom to atom. However, resistance is high in an insulator as electrons are unable to move freely. Voltage, current and resistance are related by Ohm's law:

$$V = I \times R$$

When an electric current flows through a resistance, it dissipates energy as heat. The heating effect per second, or power, is measured in Joules (J)/s or Watts (W):

$$\text{Power} = V \times I = I^2 \times R$$

When a current flows in one direction, such as produced by a battery, it is called a direct current. Electricity to homes, hospitals and factories is supplied as an alternating current which flows back and forth at a frequency, i.e. cycles per second or hertz (Hz). Voltage and frequency specifications vary worldwide. This may cause problems when electrical equipment, designed to be used in one region, is used elsewhere. Voltage specifications range from 100 V (i.e. Japan) to 240 V (i.e. Australia), with 220 V being most commonly supplied (i.e. UK, most of Europe and Asia). The frequency most commonly supplied is 50 Hz. North

America is a notable exception, where the specification is 110–120 V and 60 Hz.

A current flowing in a circuit produces electric and magnetic fields, which induce currents to flow in neighbouring circuits. When this results in a current flowing between the two circuits, it is called coupling. With capacitive coupling, high frequency currents are most easily passed, and the size of the current is greatest when the circuits are close. Inductive coupling can result from the strong magnetic fields produced by heavy duty electrical equipment, such as transformers, electric motors and magnetic resonance imaging machines. The most common problem associated with coupling is electrical interference or 'noise'. Monitoring equipment is designed to 'filter' out this noise. However, in certain circumstances, such as the use of high frequency surgical diathermy and magnetic resonance, sufficient amperage can be induced to cause microshock and burns.<sup>1,2</sup> Smaller electromagnetic fields emitted by hand-held devices, such as mobile phones, can affect the programming of microprocessors. Cases of patient equipment malfunctions have been reported.<sup>3</sup>

Static electricity has no free flow of electrons. Insulated objects can become highly charged, usually by repeated rubbing. The charge is dissipated by electrons jumping onto another neighbouring object of a different potential. 'Jumping' electrons ionise and heat the air through which they pass, causing a spark which may ignite an inflammable liquid or gas. Lightning is a type of static electrical discharge. Direct currents of 12 000–200 000 A and voltages in the millions are involved; however, flow lasts only a fraction of a second.<sup>4</sup>

## PHYSIOLOGICAL CONSIDERATIONS

For a current to flow through the body, the body must complete a circuit. Usually this involves the current flowing from its source to ground through the body. The pathological effects depend on the size of the current, and this depends on the voltage and electrical resistance of the body, most of which occurs in the skin. Dry skin has a resistance in excess of 100 000 O.<sup>5</sup> However, skin resistance is markedly reduced (to 1000 O)<sup>6</sup> if the skin is wet, or if a conductive jelly has been applied. Hence, from

Ohm's law, dry skin in contact with 240 V mains supply will result in a harmless 0.24 mA current flowing through the body, whereas moist or wet skin will result in a potentially lethal 240 mA current.

### ELECTROCUTION

Most cases of electrocution occur in the workplace (about 60%) or at home (about 30%), where misuse of extension cables is the main culprit.<sup>6</sup> Pathophysiological processes involved in true electrical injuries are poorly understood. The extent of injury depends on (i) the amount of current that passes through the body, (ii) the duration of the current, and (iii) the tissues traversed by the current (Table 75.1).

The extent of injury is most directly related to amperage. However, usually only the voltage involved is known. In general, lower voltages cause less injury, although voltages as low as 50 V have caused fatalities. An electric current passing through the body produces these main effects.

### TISSUE HEAT INJURY

Currents in excess of 1 A generate sufficient heat energy to cause burns to the skin and occult thermal injury to internal tissues and organs. Blood vessels and nervous tissue appear to be particularly susceptible.<sup>6</sup>

### DEPOLARISATION OF MUSCLE CELLS

An alternating current of 30–200 mA will cause ventricular fibrillation.<sup>7</sup> Currents in excess of 5 A cause sustained

**Table 75.1** Origin and pathophysiological effects of different levels of electrical injury

Current (A)	Source	Effects on victim
10–100 $\mu$ A	Earth leakage	Microshock (ventricular fibrillation)
300–400 $\mu$ A	Faulty equipment	Tingling (harmless)
> 1 mA	Faulty equipment	Pain (withdraw)
> 10 mA	Faulty equipment	Tetany (cannot let go)
> 100 mA	Faulty equipment	Macroshock (ventricular fibrillation)
> 1 A	Faulty equipment	Burns and tissue damage
> 1000 A	High tension injury	Severe burns and loss of limbs
> 12 000 A	Lightning	Coma, severe burns and loss of limbs

cardiac asystole, which is the principle used in defibrillation. Apart from ventricular fibrillation, other arrhythmias may occur. Myocardial damage is common and may result in ST and T-wave changes. Global left ventricular dysfunction may occur hours or days later, despite initial minimal ECG changes.<sup>8,9</sup> Myocardial infarction has also been reported.<sup>10</sup> Specific markers of myocardial injury, such as cardiac troponin, should be checked in all suspected cases of electrical injury to the heart.<sup>11</sup>

Tetanic contractions of skeletal muscle occur with currents in excess of 15–20 mA. The threshold is particularly low with alternating currents at the household frequency of 50–60 Hz. Tetanic contraction will prevent voluntary release of the source of electrocution, and violent muscle contractions may cause fractures of long bones and spinal vertebrae.<sup>6</sup>

### VASCULAR INJURIES

Blood vessels may become thrombosed and occluded as a result of the thermal injury. Compartment syndromes are seen secondary to tissue oedema, causing tissue ischaemia and necrosis. Affected limbs may even require amputation.<sup>12</sup>

### NEUROLOGICAL INJURIES

Neurological injuries may be central or peripheral, and immediate or late in onset. Monoparesis may occur in affected limbs, and the median nerve is particularly vulnerable.<sup>6,13</sup> Electrocution to the head may result in unconsciousness, paralysis of the respiratory centre, and late complications such as epilepsy, encephalopathy and parkinsonism.<sup>6,13</sup> Spinal cord damage resulting in paraplegia can result from a current traversing both arms.<sup>6,13</sup> Autonomic dysfunction may also occur, causing acute vasospasm or a late sympathetic dystrophy.<sup>6</sup>

### RENAL FAILURE

Acute renal failure may result from the myoglobinuria and toxins produced by extensive muscle necrosis.<sup>13</sup>

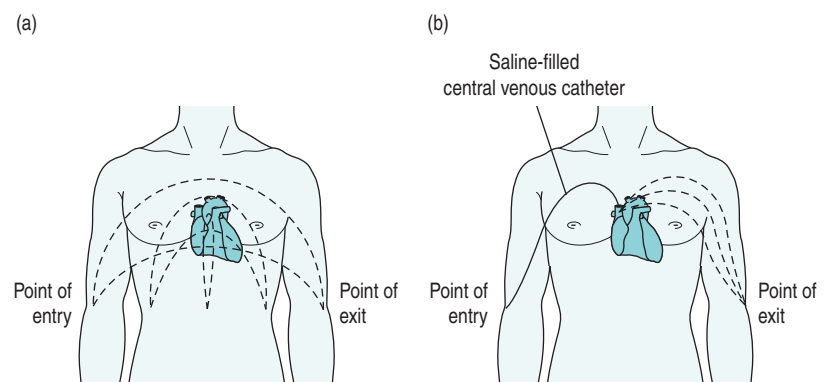

### OTHER INJURIES

Electrocution can cause the victim to fall or be thrown, and clothing to catch fire, resulting in associated injuries. High voltage injuries can rupture the eardrum.<sup>14</sup> Cataracts may later develop.<sup>13</sup>

### MICROSHOCK

The above domestic/industrial electrocution is known as macroshock, when current flowing through the intact skin and body passes through the heart. In the ICU, potential microshock electrocution exists. Microshock occurs when there is a direct current path to the heart muscle. The pathway may be provided by a saline-filled

**Figure 75.1** Microshock: (a) low current density at the heart; (b) high current density at the heart if there is a conducting pathway, such as a saline-filled catheter.

monitoring catheter, pulmonary artery catheter, or transvenous pacemaker wires. The current required to produce ventricular fibrillation in microshock is extremely small, in the order of 60 mA.<sup>15</sup> Currents of 1–2 mA are barely perceptible and produce tingling of the skin (Table 75.1). Hence a lethal microshock may be transmitted to a patient via a staff member who is unaware of the conducted current. Microshock can result from direct contact with faulty electrical equipment, stray currents from capacitive coupling or earth leakage. Such small currents are potentially lethal because a high current density is produced at the heart (Figure 75.1).

#### HIGH TENSION AND LIGHTNING INJURIES

High tension electricity (> 1000 V) involves voltage much greater than domestic supply, usually many thousands of volts. Tissue damage is mainly due to the generation of heat, as high amperage currents are involved. Witnesses have described tissues actually exploding.<sup>16</sup>

Lightning injury is a type of high tension injury. It is rare and its incidence depends upon geographic location. Victims can be thrown several feet as a result of violent muscular contractions. Electrical arcing of the air causes intense heat, resulting in superficial burns and clothes igniting. Characteristic entrance and exit site burns are seen, which have a spider-like appearance with redness and blistering. Victims are usually unconscious in the initial phase. However, many victims survive,<sup>4</sup> and good recovery has been reported despite initial hopeless neurological responsiveness (e.g. fixed dilated pupils).<sup>17</sup> Immediate death usually results from cardiorespiratory arrest; asystole is more common than ventricular fibrillation.<sup>4</sup>

#### MANAGEMENT OF ELECTRICAL INJURIES

Treatment of electrical injuries is mainly supportive and includes the following.

#### FIRST AID AND RESUSCITATION

It is imperative to make the immediate environment safe for rescuers. Power sources should be switched off and

wet areas avoided where possible. Instinctive attempts to grab the electrocuted victim must be avoided until it is safe to do so. Cardiopulmonary resuscitation is carried out when indicated, and continued even if the prognosis seems hopeless. The neck and spine should be protected from possible fractures.

#### INVESTIGATIONS

Investigations are indicated to detect damaged organs. They include ECG, echocardiography, CT of the head, EEG, X-rays of the spine and long bones, haemoglobin, serum electrolytes, creatine kinase and urine myoglobin to assess muscle damage, and nerve conduction studies. Arteriograms may help in the decision to amputate a limb.<sup>12</sup>

#### HOSPITAL AND ICU MANAGEMENT

Management is directed towards treatment of burns, ischaemic and necrotic tissue, and injured organs. The principle of treating electrical burns is complete excision because of the risks of acute renal failure and sepsis. Fasciotomies and amputations may be necessary. Tetanus toxoid and antibiotics, especially penicillin, are given if indicated.

#### ELECTRICAL HAZARDS IN ICU

The ICU has the potential to inflict both macroshock and microshock injuries to staff and patients. Potential sources of these electrical hazards are as follows.

#### MAJOR ELECTRICAL FAULTS

The casing and insulated wiring of electrical equipment protect against electric shock. Faulty wiring or components, and deterioration of internal insulation, can result in the casing becoming 'live'. Contact with live casing or wires can result in an electric current flowing through the victim to ground. The outcome largely depends on the resistance offered by the body to the current. If it is low, such as in a wet environment, sufficient current can flow to cause death.

## MICROSHOCK CURRENTS

### EARTH LEAKAGE CURRENTS

Within all pieces of electrical equipment, stray low amperage electrical currents exist that usually flow to earth, called earth leakage currents. They originate from current leaks across imperfect insulation of wires, capacitive and inductive coupling within the equipment, and coupling from electric and magnetic fields that exist in the working environment, such as the 50–60 Hz mains supply. Normally these currents are small and harmless, but they have the potential to cause microshock.

### PACING WIRES AND CENTRAL VENOUS LINES

In certain circumstances, sufficient current to cause microshock can be passed by capacitive and inductive coupling to intracardiac pacing wires and central venous lines. Ventricular fibrillation has resulted from capacitive coupling with thermistor wires in a pulmonary artery catheter.<sup>1</sup>

### DIFFERENT EARTH POTENTIALS

Inadequate or faulty earthing can result in separate earthing points being at different resting potentials. If contact is made between the two earthing points, sufficient current can flow to cause microshock.

### STAFF–PATIENT CONTACT

Small currents capable of causing microshock can be transmitted unknowingly to a patient by a staff member who simultaneously touches faulty electrical equipment and the patient. If this current returns to earth via an intracardiac connection, a high current density will pass through the heart resulting in microshock.

## INDUCTIVE CURRENTS

Inductive coupling from the strong magnetic fields produced by magnetic resonance imaging can cause overheating of wires and equipment. Severe burns have resulted from the use of pulse oximetry during magnetic resonance imaging, and specially designed wiring and probes are recommended.<sup>2</sup> Similar problems can exist with any intravascular device containing wires, such as a pulmonary artery catheter. More recently, problems have arisen from the interference caused by personal computers, mobile phones and related devices with patient equipment. Many hospitals have banned the use of such devices in areas where patients are treated.

## OTHER RELATED HAZARDS

Electrical equipment has the potential to cause other hazards such as thermal injury, fires and power failures. Preliminary critical incident reports suggest that power failures are the most commonly encountered incidents involving electricity in the ICU. Power failures can be disastrous, as many patients' lives depend on electrically driven 'life support' equipment. Because of frequent

work outside the ICU, the intensivist should also be aware of potential electrical hazards outside ICU.

## ELECTRICAL SAFETY STANDARDS

Most Western countries have standards of electrical safety that apply to the use of medical equipment. For example, Australian Standards (AS 3003 and AS 3200) set minimum requirements for Australian hospitals. AS 2500 covers the safe use of electricity in patient care areas.<sup>18</sup> Britain and Europe follow the International Electrotechnical Commission Code<sup>19,20</sup> and the USA follows the National Electric Code 1993.<sup>21</sup> These standards have not changed significantly over the last few decades and are now easily accessible on the internet. Hospitals should establish their own committees to ensure that adequate standards are applied. However, patient care areas differ in their safety requirements and commonly used classifications are listed below. The ICU should conform to (1b) and preferably (1c).

1. (a) *Unprotected areas*, where only routine electrical safety standards are applied.
- (b) *Body protected areas*, where the level of electrical safety is sufficient to minimise the risk of macroshock when the patient is in direct contact with electrical equipment and the skin impedance is reduced or bypassed.
- (c) *Cardiac protected areas*, where the level of electrical safety is sufficient to minimise the risk of direct microshock to the heart.
2. *Wet locations*, where spillage of water and physiological solutions, such as saline and blood, frequently occurs.
3. Until recently, standards existed for the safe use of inflammable anaesthetics agents.

## MEASURES TO PROTECT STAFF AND PATIENTS<sup>22,23</sup>

### EARTHING, FUSES AND CIRCUIT BREAKERS

Earthing reduces the risk of macroshock. The casing in most electrical equipment is connected to ground by a very low resistance wire. If a fault arises, the earth wire offers a low resistance path to ground. The high amperage current that results will blow the main fuse or circuit breaker, thus warning that a fault is present. Additional protection can be achieved by connecting all the earthing points in a patient care area together by a very low resistance wire. This reduces the risk of microshock occurring from earthing points at different potentials, and is commonly used in cardiac protected areas.

### POWER SUPPLY ISOLATION

#### MAINS ISOLATION

The power supply is isolated from earth using a mains isolation transformer. If contact is made with live faulty

circuitry, the risk of electric shock is reduced because stray currents no longer preferentially flow through patient or staff member to earth. Presence of stray earth leakage currents can be detected by using a line isolation monitor. This type of system is particularly useful in wet locations where the body may offer a very low resistance to earth.

### INTERNAL ISOLATION

The mains power supply is isolated from the patient connection by using transformers and photoelectric diodes. The casing is still earthed to protect against faulty circuitry. This method of protection is commonly used in ICU equipment.

### EARTH LEAKAGE CIRCUIT BREAKERS

These are devices that switch off the electrical supply if small currents are detected flowing to earth. They can be used to protect against microshock. A major disadvantage is that power supply to essential life-supporting equipment is switched off.

### EQUIPMENT CHECKS

The purchase of new equipment should be strictly controlled, and circuit diagrams should be provided. All new equipment should be checked for function and current leaks before use in the ICU. Preventative maintenance of equipment should be done regularly. Dated stickers should be used to show when the equipment was last checked. All faulty equipment must be removed from service, labelled appropriately, and recommissioned only after thorough checking.

### RESERVE POWER SUPPLIES AND ALARMS

All essential equipment should have a reserve power supply (usually a battery) and alarms that warn of power failure. All hospitals should provide an emergency back-up power supply in case of power cuts.

### PERSONNEL EDUCATION

Staff should be taught correct ways to handle electrical equipment. Equipment with frayed wires should never be used, plugs should never be tugged, trolleys should never be wheeled over power cords, and two pieces of equipment should never be handled simultaneously. Staff should also respond appropriately to alarms.

# Envenomation

James Tibballs

Envenomation by species of snakes, spiders, ticks, bees, ants, wasps, jellyfish, octopuses or cone shell snails may threaten life, while envenomation by other creatures may cause serious illness.<sup>1</sup> Although this chapter focuses on Australia, the principles of management are widely applicable elsewhere except for stings by scorpions which are not a significant health problem in Australia. Immediate advice on management may be obtained from the Australian Venom Research Unit (AVRU) advisory service on their 24-hour telephone number within Australia on 1300 760 451, from overseas on 61 3 8344 7753 or from their website at <http://www.avru.org>.

## SNAKES

### EPIDEMIOLOGY

Australia is habitat to a large number of venomous terrestrial and marine snakes (Families Elapidae and Hydrophiidae). The genera responsible for the majority of serious illness are Brown Snakes (*Pseudonaja*), Tiger Snakes (*Notechis*), Taipans (*Oxyuranus*), Black Snakes (*Pseudechis*) and Death Adders (*Acanthophis*).

The mean death rate in Australia from 1981 to 1999 was 2.6 per year<sup>1</sup> (~0.014/100 000), usually occurring because of massive envenomation, snake bite in remote locations, rapid collapse, or due to delayed or inadequate antivenom therapy. However, as many as 2000 people are bitten each year and of these at least 300 require antivenom treatment. This morbidity and mortality is far less than that observed in surrounding countries. Death and critical illness is due to (1) progressive paralysis leading to respiratory failure, (2) bleeding, or (3) renal failure occurring as a complication of rhabdomyolysis, disseminated intravascular coagulation (DIC), haemorrhage, haemolysis or to their combinations. Rapid collapse within minutes after a snake bite is due to anaphylaxis to venom or possibly due to the myocardial effects of DIC causing hypotension.

Snake bite is often 'accidental' when a snake is trodden upon or suddenly disturbed. However, many bites occur when humans deliberately interfere with snakes or handle them. The herpetologist or snake collector is at special risk. Not only do they invariably sustain bites in the course of their work<sup>2</sup> or hobby, but they are also at risk

of developing allergic reactions to venoms and to the antivenoms used in their treatment. Contact with exotic snakes has additional problems.

### SNAKE VENOMS

Venoms are complex mixtures of toxins, usually proteins, which kill the snake's prey and aid its digestion. Many are phospholipases. The main toxins cause paralysis, coagulopathy, rhabdomyolysis and haemolysis (Table 76.1). Coagulopathy may be due to a procoagulant effect by prothrombin activators (Factor Xa-like enzymes), with consumption of clotting factors, or due to a direct anticoagulant effect.

### SNAKE BITE AND ENVENOMATION

Although a bite may be observed, envenomation is less common because no venom or a variable amount of venom is injected. Bites are relatively painless and may be unnoticed. This is in marked contrast to many overseas crotalid and viperid snakes, where massive local reaction and necrosis are often a major feature as a result of proteolytic enzymes. Paired fang marks are usually evident but sometimes only scratches or single puncture wounds are found. In general, Australian snake venoms do not cause extensive damage to local tissues and are usually confined to mild swelling and bruising, and continued slight bleeding from the bite site.

### SYMPTOMS AND SIGNS OF ENVENOMATION

Not all possible symptoms and signs occur in a particular case: in some cases, one symptom or sign may dominate the clinical picture, and in other cases they may wax and wane (Table 76.2). These phenomena are explained by variations in toxin content of venoms of the same species in different geographical areas, and by variable absorption of different toxins.

The cause of transient hypotension soon after envenomation is obscure but it may be related to intravascular coagulation.<sup>3,4</sup> Prothrombin activators gain access to the circulation within a number of minutes after subcutaneous injection. There is often tachycardia and relatively minor ECG abnormalities. Other causes of hypotension such as direct cardiac toxicity remain unproven. Hypotension may be secondary to myocardial hypoxaemia.

**Table 76.1** Main components of Australian snake venoms

<b>Neurotoxins</b>
Presynaptic and postsynaptic neuromuscular blockers present in all dangerous venomous snakes. May cause paralysis
Postsynaptic blockers readily reversed by antivenom
Presynaptic blockers are more difficult to reverse, particularly if treatment is delayed
Some presynaptic blockers are also rhabdomyolysins
<b>Prothrombin activators</b>
Present in many important species
Cause disseminated intravascular coagulation with consumption of clotting factors including fibrinogen
Intrinsic fibrin(ogen)lysis generates fibrin(ogen) degradation products
Significant risk of haemorrhage
<b>Anticoagulants</b>
Present in a relatively small number of dangerous species
Prevent blood clotting without consumption of clotting factors
<b>Rhabdomyolysins</b>
Some presynaptic neurotoxins also cause lysis of skeletal and cardiac muscle
Apart from loss muscle of mass, may cause myoglobinuria and renal failure
<b>Haemolysins</b>
Present in a few species
Rarely a serious clinical effect

**Table 76.2** Progressive onset of major systemic symptoms and signs of untreated envenomation (in massive envenomation or in a child, a critical illness may develop in minutes rather than hours)

<b>&lt; 1 hour after bite</b>
Headache
Nausea, vomiting, abdominal pain
Transient hypotension associated with confusion or loss of consciousness
Coagulopathy (laboratory testing)
Regional lymphadenitis
<b>1–3 hours after bite</b>
Paresis/paralysis of cranial nerves, e.g. ptosis, double vision, external ophthalmoplegia, dysphonia, dysphagia, myopathic facies
Haemorrhage from mucosal surfaces and needle punctures
Tachycardia, hypotension
Tachypnoea, shallow tidal volume
<b>&gt; 3 hours after bite</b>
Paresis/paralysis of truncal and limb muscles
Paresis/paralysis of respiratory muscles (respiratory failure)
Peripheral circulatory failure (shock), hypoxaemia, cyanosis
Rhabdomyolysis
Dark urine (due to myoglobinuria or haemoglobin)
Renal failure

Tender or even painful regional lymph nodes are moderately common but are not per se an indication for antivenom therapy, since lymphadenitis also occurs with bites by mildly venomous snakes which do not cause serious systemic illness.

Occasionally intracranial haemorrhage occurs. In the case of untreated or massive envenomation, rhabdomyolysis may occur. This usually involves all skeletal musculature and sometimes cardiac muscle. The resultant myoglobinuria may cause renal failure. Direct nephrotoxicity has been suspected in a few cases of Brown Snake bites, but is as yet unproven.

A high intake of alcohol by adults before snake bite is common, and may make management quite difficult initially. Pre-existing treatment (e.g. warfarin therapy) or disease (e.g. gastrointestinal tract ulceration) may complicate management of coagulopathy.

### **SNAKE BITE IN CHILDREN**

Snake bite in young children presents additional problems. It is difficult to diagnose when a bite has not been observed. The symptoms of early envenomation may pass unsuspected and the signs, particularly cranial nerve effects, are difficult to elicit. Bite marks may be difficult to distinguish from the effects of everyday minor trauma. Lastly, the onset of the syndrome of envenomation is likely to be more rapid than in adults and the severity of envenomation more acute because of the relatively higher ratio of venom to body mass. Presentation may be cardiorespiratory failure.

### **IDENTIFICATION OF THE SNAKE**

Identification of the snake guides selection of the appropriate antivenom, and provides an insight into the expected syndrome. Administration of the wrong antivenom may endanger the victim's life because there may be very little neutralisation of venom. A venom detection kit can be used to identify the snake venom. If the snake cannot be identified, a specific antivenom, or a combination of monovalent antivenoms or polyvalent antivenom should be administered on a geographical basis (see Tables 76.3 and 76.4).

### **IDENTIFICATION BY VENOM DETECTION KIT TEST**

The venom detection kit (VDK) is an in vitro test for detection and identification of snake venom at the bite site, in urine, blood or other tissue in cases of snake bite in Australia and Papua New Guinea. It is an enzyme immunoassay using rabbit antibodies and chromogen and peroxide solutions. A positive result will indicate the type of antivenom to be administered. It detects venom from a range of snake genera including Tiger, Brown, Black, Death Adder and Taipan. Individual species of snake cannot be identified by the test and several genera may yield a positive result in a specified well. The incidences of false-positive and false-negative tests of the kit remain unknown, but are generally regarded as low. The test is

**Table 76.3** Antivenom and initial dosages when snake identified

Snake	Antivenom	Dose (units)
Common Brown Snake	Brown Snake	4000
Chappell Island Tiger Snake	Tiger Snake	12 000
Copperheads	Tiger Snake	3000–6000
Death Adders	Death Adder	6000
Dugite	Brown Snake	4000
Gwardar	Brown Snake	4000
Mulga (King Brown) Snake	Black Snake	18 000
Papuan Black Snake	Black Snake	18 000
Red-bellied Black Snake	Tiger Snake <i>or</i> Black Snake*	3000 18 000
Rough-scaled (Clarence River) Snake	Tiger Snake	3000
Sea-Snakes	Sea-Snake <i>or</i> Tiger Snake	1000 3000
Small-scaled (Fierce) Snake	Taipan	12 000
Taipans	Taipan	12 000
Tasmanian Tiger Snake	Tiger Snake	6000
Tiger Snake	Tiger Snake	3000

\*Smaller protein mass Tiger Snake antivenom preferable. Antivenom units per vial: Brown Snake 1000; Tiger Snake 3000; Black Snake 18 000; Taipan 12 000; Death Adder 6000; polyvalent 40 000.

Note: (1) If the victim on presentation is critically ill, 2–3 times these amounts should be given initially; (2) additional antivenom may be required in the course of management since absorption of venom may be delayed.

**Table 76.4** Antivenom and initial dosages when identity of snake uncertain

State	Antivenom	Dose (units)
Tasmania	Tiger Snake	6000
Victoria	Tiger Snake <i>and</i> Brown Snake	3000 4000
New South Wales and ACT; Queensland; South Australia; Western Australia; Northern Territory	Polyvalent	40 000
Papua New Guinea	Polyvalent	40 000

Note: (1) If the victim on presentation is critically ill, 2–3 times these amounts should be given initially; (2) additional antivenom may be required in the course of management since absorption of venom may be delayed.

very sensitive, able to detect venom in concentrations as low as 10 ng/ml, and can yield a visual qualitative result in test wells in approximately 25 minutes. On occasion, a positive test may be present but the patient is asymptomatic. A decision to administer antivenom should be made on clinical grounds. A very high concentration of venom in a sample may overwhelm the test and yield a spuriously negative result (Hook effect). If that possibility exists, a diluted sample should be re-tested.

#### IDENTIFICATION BY PHYSICAL CHARACTERISTICS

This can be misleading. Non-herpetologists should consult an identification guide<sup>1</sup> with reference to scale patterns to identify a specimen correctly if antivenom therapy is to be based on morphological characteristics alone.

#### IDENTIFICATION BY CLINICAL EFFECTS

The appearance of a bite site cannot be used to reliably identify the snake.

The constellation of symptoms and signs may be used to a limited degree in identification. For example, within the common genera, paralysis associated with procoagulopathy may be caused by a Tiger Snake, Taipan, Brown Snake, Rough-scaled Snake, *Hoplocephalus* spp. or Red-bellied Black Snake, but if rhabdomyolysis also occurs, a bite by a Brown Snake is improbable. Paralysis associated with anticoagulation may be caused by a Black Snake (other than a Red-bellied Black Snake), Copperhead or Death Adder, but if rhabdomyolysis occurs, a bite by a Death Adder is improbable. Paralysis with neither coagulopathy nor rhabdomyolysis may be caused by a Death Adder bite.

This information is of limited practical importance. It is essential to administer antivenom at the first opportunity when indicated, rather than wait until the full syndrome becomes apparent to enable an ‘educated clinical guess’ in selection of the appropriate antivenom.

#### MANAGEMENT OF SNAKE ENVENOMATION

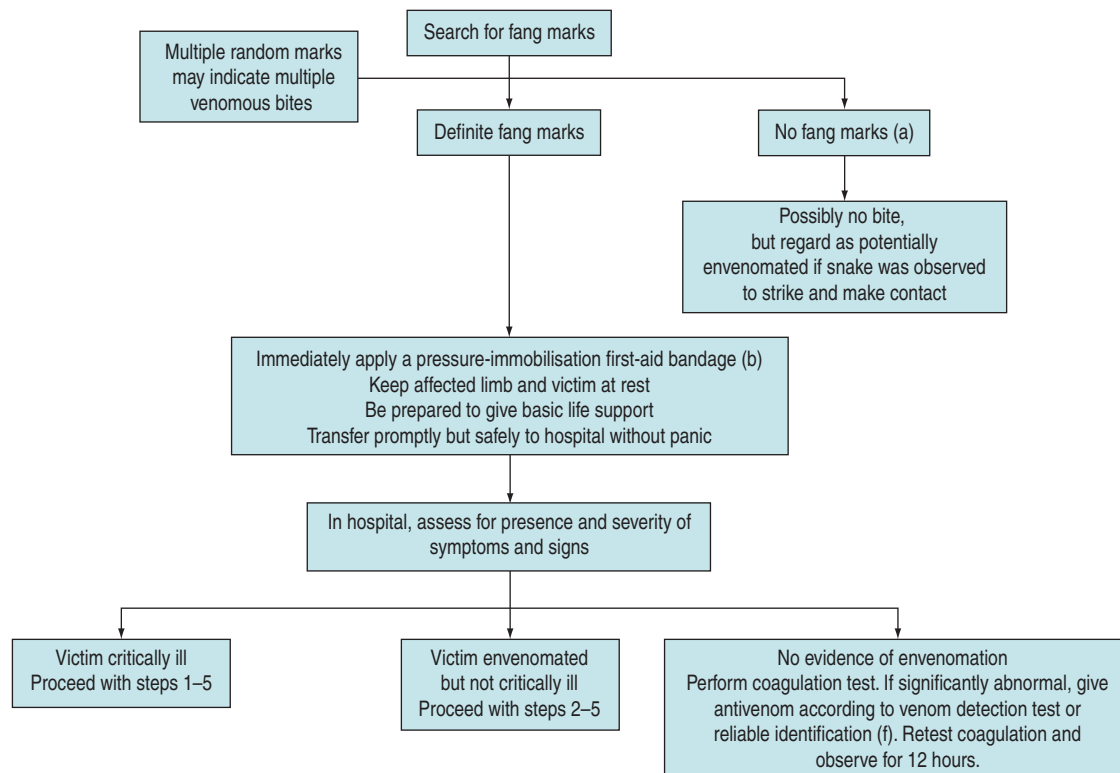

The essentials of management are:

- resuscitation: mechanical ventilation and restoration of blood pressure with intravenous fluids, inotropic and vasoactive agents as needed
- application of a pressure-immobilisation first-aid bandage
- administration of antivenom
- performance of investigations

From a practical point of view, one of three clinical situations arises after snake bite. A plan of management for each of these is summarised in Figure 76.1.

- Victim presents with a critical illness
- Victim envenomated but not critically ill
- Victim bitten but does not appear envenomated

When the envenomated victim is not critically ill, more time is available to identify the snake by investigations

1. Resuscitate (treat hypoxaemia and shock)  
Be prepared to intubate and mechanically ventilate. Admit to intensive care.
2. Apply pressure-immobilisation bandage. Do not remove if already applied (b)
3. Give antivenom intravenously (c,d,e,f,g)
  - Give monovalent if species reliably known or appropriate antivenom indicated by venom detection test.
  - In critically ill victim, don't wait for venom detection test result or if species cannot be determined; give according to geographic location:  
Victoria – Brown and Tiger Snake  
Tasmania – Tiger Snake  
Other states and territories – polyvalent
  - Titrate antivenom against clinical and coagulation status (NOTE: Death Adders don't cause significant coagulopathy).
4. Perform investigations
  - Bite swab for venom detection. (First-aid bandage may be cut to expose bite site, and then reinforced)
  - Blood for venom detection, coagulation, type and crossmatch blood (if bleeding), fibrin degradation products, full blood examination, enzymes, electrolytes, urea, creatinine
  - Urine for venom detection, red blood cells, haemoglobin, myoglobin.
5. Examine frequently to detect slow onset of paralysis (h), coagulopathy, rhabdomyolysis and renal failure.

#### Dangers and mistakes in management

- a. Fang marks not visible to naked eye.
- b. Premature release of bandage may result in sudden systemic envenomation. Leave in situ until victim reaches full medical facilities.  
If clinically envenomated, remove only after antivenom given.
- c. Erroneous identification of snake may cause wrong antivenom to be given. If in any doubt treat as unidentified.
- d. Antivenom without premedication. Anaphylaxis is not rare and may not respond to treatment.
- e. Insufficient antivenom. Titrate dose against clinical and coagulation status.
- f. Blood and coagulation factors (fresh frozen plasma, cryoprecipitate) not preceded by antivenom will worsen coagulopathy.
- g. Antivenom given without clinical or laboratory evidence of envenomation.
- h. Delayed onset of paralysis may be missed. Victim must be examined at least hourly.

Figure 76.1 Management of snake bite.

and to administer specific monovalent antivenom. A pressure-immobilisation bandage should be applied if not already in place, and not removed until antivenom has been administered.

When the victim has been bitten, but not apparently envenomated, admission to hospital is advisable with observation and examination hourly for at least 12 hours in the case of a child but less time for an adult. The syndrome of envenomation may be very slow in onset over numerous hours with an initial period free of symptoms. A test of coagulation should always be performed. If a coagulopathy is present, specific monovalent antivenom should be administered after identification of the species or as indicated by a VDK test. If only a mild coagulopathy is present it may be acceptable to withhold antivenom in the anticipation of spontaneous resolution but coagulation should be checked at intervals and the victim maintained under surveillance until coagulation is normal.

#### **THE PRESSURE-IMMOBILISATION TECHNIQUE OF FIRST AID**

Since at least 95% of snake bites occur on the arms or legs,<sup>1</sup> Sutherland's first-aid pressure-immobilisation technique<sup>5</sup> is applicable to the majority of cases. With this technique, a crêpe (or crêpe-like) bandage is applied from the fingers or toes up the limb as far as possible, encompassing the bite site. It should be as firm as required for a sprained ankle. Additional immobilisation is applied to the entire limb by a rigid splint, with the aim of immobilising the joints either side of the bite site.

Venom is usually deposited subcutaneously. The systemic spread of venom is largely dependent on its absorption by way of the lymphatics<sup>6</sup> or the small blood vessels. Application of a pressure less than arterial to the bitten area when combined with immobilisation of the limb effectively delays the movement of venom to the central circulation.<sup>5</sup> Although it is a first-aid technique designed for use in the field, it should be part of initial management in hospital since it halts further absorption of venom. There is some experimental<sup>1</sup> and anecdotal<sup>7</sup> evidence with Death Adder bites that the technique inactivates some venom at the bite site but prolonged application has not been subjected to a controlled study.

#### **Removal of the pressure-immobilisation bandage**

Removal may precipitate a sudden elevation in blood concentration of venom and collapse of the victim. On the other hand, first aid has not been proven to inactivate venom in humans. Its removal therefore should be dictated by the circumstance. When an asymptomatic snake-bite victim reaches hospital with the recommended first-aid measures in place, these should not be disturbed until antivenom, appropriate staff and equipment have been assembled. If the victim is symptomatic and antivenom is indicated, the first-aid measures should not be removed until after antivenom has been administered, and reapplied if the victim's condition deteriorates. A swab of the bite site may be obtained by removing the splint temporarily and then cutting a window in the

bandage. Thereafter the bandage should be made good and the splint reapplied.

#### **ANTIVENOM**

CSL Ltd (Parkville, Australia) produces highly purified equine monovalent antivenoms against the venoms of the main terrestrial snakes, including Tiger Snake, Brown Snake, Black Snake, Death Adder and Taipan. A polyvalent antivenom – a mixture of aliquots of all these – is also available. A sea-snake antivenom is also produced from horses immunised with Beaked Sea-Snake (*Enhydrina schistosa*) and Tiger Snake venom.

Antivenom should be administered according to the identity of the snake or, if unknown or doubtful, according to the result of a VDK test (Table 76.3). If neither of these criteria can be fulfilled, and if the situation warrants immediate antivenom therapy, the geographical location may be used as a guide, since the distribution of many species is known (Table 76.4). Polyvalent antivenom should not be used when a monovalent antivenom could be used appropriately. For bites by uncommon snakes, when antivenom is indicated, polyvalent antivenom, or a monovalent antivenom as indicated by a VDK test, should be chosen.

#### **Dose**

One vial of specific antivenom neutralises in vitro the average yield on 'milking' – a process whereby venom is harvested by inducing the snake to bite through a latex membrane. If the amount of venom injected at a bite is greater than the average yield on milking, one vial of antivenom will not be adequate therapy. In severe cases of envenomation, a number of vials of antivenom will need to be administered. Absorption of venom from a bite site(s) is a continuing process.

The initial doses of antivenom are given in Tables 76.3 and 76.4. The need for subsequent doses should be guided by the clinical response. After bites by species with coagulopathic effects the victim's coagulation status is a useful guide.

The dose of antivenom required varies because the amount of venom injected cannot be determined, and snakes may bite multiple times. Victims may present late after envenomation when toxins have already become bound to target tissues and cannot be easily neutralised. Some victims in this circumstance have required mechanical ventilation for many weeks despite large amounts of appropriate antivenom. A child requires more antivenom than an adult envenomated by the same amount of venom, and a victim in poor general health will likewise require more. Finally, antivenoms are manufactured against specific species and may have less neutralising ability against different species of the same genus or against unrelated species, even when the antivenom chosen is nonetheless appropriate.

#### **Administration**

The decision to administer antivenom must be based on clinical criteria of envenomation, not restricted to the result of a VDK test. A positive VDK test establishes the diagnosis

of envenomation and the choice of antivenom, but does not imply that antivenom should or should not be given.

However, if the victim is significantly envenomated, antivenom must be administered since there is no other effective treatment. Antivenom may be withheld if envenomation is so mild that spontaneous recovery may occur or the consequences of antivenom administration are likely to outweigh the benefit to be gained, e.g. in a herpetologist known to have allergy to antivenom.

Snake antivenoms must be given by the intravenous route, or in dire circumstances if a vein cannot be cannulated, by the intraosseous route in a child. The large volume of fluid and slow absorption render the intramuscular route useless in emergencies.

A test dose of antivenom to determine allergy should not be done. It is unreliable and a waste of precious time.

### Premedication

Antivenom should be preceded by premedication with subcutaneous adrenaline (epinephrine), approximately 0.25 mg for an adult and 0.005–0.01 mg/kg for a child, at least 5–10 minutes before commencement of infusion. In the moribund or critically ill victim, when it is essential to administer antivenom quickly, the epinephrine may be given intramuscularly or even intravenously in smaller doses. However, in general, epinephrine is not recommended by either of those routes because of the risk of intracerebral haemorrhage due to the combination of possible hypertension and coagulopathy. Although intracerebral haemorrhage has been recorded in the past in association with premedication, all such cases were accompanied by intravenous epinephrine, none with subcutaneous epinephrine. On the other hand, the incidence of adverse reactions (8–13%) to antivenom is sufficient to warrant premedication with epinephrine, which is the only medication proven effective in reducing the incidence of antivenom-induced reactions and their severity.<sup>8</sup>

It is not prudent to forgo premedication and elect to treat anaphylaxis if it occurs. Iatrogenic anaphylaxis has a high mortality despite vigorous and expert resuscitation.<sup>9</sup> If an adverse reaction to the first vial of antivenom has not occurred, subsequent vials do not need to be preceded by epinephrine. The reaction rate to polyvalent antivenom is higher than to monovalent antivenoms and should not be used when a monovalent antivenom or combinations will suffice.

The antihistamine, promethazine, is ineffective in this setting<sup>10</sup> and may cause obtundation and hypotension, both of which may exacerbate and confound a state of envenomation. It is not recommended. Other drugs such as steroids and aminophylline are also not useful in preventing anaphylaxis because their actions, apart from being unproven, are too slow in onset, but steroids are useful for preventing serum sickness.

### Infusion

The antivenom may be injected slowly into a running intravenous line or diluted in Hartmann's or other

crystalloid solution in approximately 1 in 10 volumes in a burette and administered over 15–30 minutes if the situation is not critical. This measure reduces the risk of an anaphylactoid reaction resulting from its binding with complement. For small children, if multiple vials are required, the dilution may be less to prevent excessive fluid administration. In emergencies the antivenom may be infused quickly in high concentration.

### Adverse reactions

Antivenom infusion should always be administered in a location equipped and staffed by personnel capable of managing anaphylaxis. Management of anaphylaxis is discussed in detail in Chapter 58. Intramuscular epinephrine is the key treatment in a dose of approximately 0.25–1.00 mg for adults and 10 µg/kg for children. Antivenom therapy should be discontinued temporarily and restarted when the victim's condition is stable.

Lesser degrees of immediate adverse reaction restricted to headache, chest discomfort, fine rash, arthralgia, myalgia, nausea, abdominal pain, vomiting, and pyrexia may be managed by temporary cessation of infusion and administration of steroids and antihistamine before recommencement.

A delayed hypersensitivity reaction, serum sickness, should be anticipated and patients warned of the symptoms and signs which usually appear several days to 2 weeks after antivenom administration. Severity may range from a faint rash and pyrexia to serious multisystem disease including lymphadenitis, polyarthralgia, urticaria, nephritis, neuropathy and vasculitis. The incidence of serum sickness appears to be greater with the use of multiple doses of monovalent antivenom and with polyvalent antivenom. Prophylactic treatment is a course of steroids, e.g. prednisolone 1 mg/kg per day for 5 days.

## INVESTIGATIONS AND MONITORING

Tests should be performed regularly, interpreted quickly and treated promptly to counter venom effects and its complications. Serial coagulation tests and tests of renal function are especially important. Absorption of venom from the bite site is a continuing process and management must anticipate unabsorbed venom. Apart from regular monitoring of vital signs and oxygenation, the following are specifically needed.

### BITE SITE

A swab for venom testing should be done. It has the highest likelihood of detecting venom provided the site has not been washed. The site may be squeezed to yield venom if it has been washed.

### URINE

Test the urine for venom that may be present when venom in blood has been bound by antivenom and is therefore undetectable. Urine should also be tested for blood and protein. If the urine is pigmented a distinction

should be made between haemoglobinuria and myoglobinuria, which is impossible with simple ward tests. Urine output should be recorded.

#### BLOOD

- Coagulation tests should include prothrombin time, activated thromboplastin time, serum fibrinogen and fibrin degradation products
- A full blood examination and blood film for haemoglobin level, evidence of haemolysis and platelet count. A mild elevation in white cell count is expected
- Electrolytes, urea, creatinine and creatine phosphokinase (isoenzymes and troponin are useful) to monitor rhabdomyolysis and possible renal compromise

#### ELECTROCARDIOGRAM

Sinus tachycardia, ventricular ectopy and ST segment and T-wave changes are not uncommon. These effects may be the direct result of venom toxins or from electrolyte disturbances caused by rhabdomyolysis or renal failure.

#### SECONDARY MANAGEMENT

##### COAGULATION FACTOR AND BLOOD TRANSFUSION

Although coagulopathy often resolves after several doses of antivenom it does not per se restore coagulation – it permits newly released or manufactured coagulation factors to act unopposed by venom. If coagulation is not restored after several doses of antivenom over several hours, it is prudent to administer fresh frozen plasma and to remeasure coagulation at intervals. Because regeneration of coagulation factors takes many hours, treatment of isolated coagulopathy entirely with antivenom while waiting for their regeneration exposes the patient to serious haemorrhage and implies overdosage with antivenom. Administration of coagulation factors should be preceded by antivenom to neutralise venom prothrombin activator. Platelets may be required but whole blood is rarely needed.

##### INTRAVENOUS FLUIDS, RHABDOMYOLYSIS AND RENAL PROTECTION

After acute resuscitation, administer intravenous fluids in sufficient volume to maintain urine output at about 40 ml/kg per day in an adult and 1–2 ml/kg per hour in a child to prevent tubular necrosis as a consequence of rhabdomyolysis. Life-threatening hyperkalaemia and hypocalcaemia may develop with rhabdomyolysis. Haemofiltration or dialysis may be required.

#### HEPARIN

Although this anticoagulant has prevented the action of prothrombin activators in animal models of envenomation, it does not improve established disseminated intravascular coagulation.<sup>11</sup> It is not recommended. Emphasis instead should be on treating the cause by neutralising venom with antivenom.

#### ANALGESIA AND SEDATION

Australian snake bite does not cause severe pain. However, sedation is required for the mechanically ventilated venom-paralysed victim and analgesia for rhabdomyolysis.

#### CARE OF THE BITE SITE

Usually no specific care is required. Occasionally the site may blister, bruise, ulcerate or necrose, particularly when a first-aid bandage has been in place for a considerable time or when the bite was by a member of the Black Snake genus, such as a Mulga Snake or Red-bellied Black Snake.

#### OTHER DRUGS

Antibiotics are not routinely required but should be considered as for any potentially contaminated wound. Sea-snake bites may cause Gram-negative infections. Tetanus prophylaxis should be reviewed.

#### SEA-SNAKE BITE

Some sea-snake venoms cause widespread damage to skeletal muscle with consequent myoglobinuria, neuromuscular paralysis or direct renal damage. Many have not been researched. The principles of treatment are essentially the same as for envenomation by terrestrial snakes. The venoms of significant species are neutralised with CSL Ltd Beaked Sea-Snake (*Enhydrina schistosa*) antivenom. If that preparation is not available, Tiger Snake or polyvalent antivenom should be used. Sea-snake bites are uncommon in Australia and no deaths have been recorded.

#### UNCOMMON AND EXOTIC SNAKE BITE

Zoo personnel, herpetologists and amateur collectors who catch, maintain or breed species of uncommon Australian snakes or who import or breed exotic (overseas) snakes are at risk, as are personnel in the Australian Quarantine and Inspection Service (AQIS). There are no specific antivenoms to the venoms of uncommon Australian snakes, but neutralisation is provided by polyvalent antivenom or by monovalent antivenom, as indicated by the VDK. Exotic snake antivenoms are maintained by Venom Supplies Ltd, Tanunda, South Australia (Tel: 08 8563 0001), Royal Melbourne Hospital (Tel: 03 9342 7000), Royal Adelaide Hospital (Tel: 08 8223 4000), Australian Reptile Park (Tel: 02 4340 1022) and by Taronga Zoo (Mosman, Tel: 02 9969 2777). The locations of antivenoms in Australia for treatment of bites by specific exotic snakes are maintained by AVRU at [http://www.avru.org/reference/reference\\_avhold.html](http://www.avru.org/reference/reference_avhold.html).

#### LONG-TERM EFFECTS OF SNAKE BITE

After appropriate treatment, recovery is expected but it may be slow, taking many weeks or months, particularly

from a critical illness or after delayed presentation with neurotoxicity and rhabdomyolysis. Isolated neurological or ophthalmic signs may persist. Long-term loss of taste or smell occurs occasionally.

## SPIDERS

Although several thousand species of spiders exist in Australia, only Funnel-web Spiders (genera *Atrax* and *Hadronyche*) and the Red-back Spider (*Latrodectus hasselti*) have caused death or significant systemic illness. All spiders have venom and a few, particularly the White-tailed Spider (*Lampona cylindrata*) and the Common Black House Spider (*Badumna insignis*), have caused severe local injury, although this occurs rarely.<sup>1,12,13</sup> Causes for ulcerated skin lesions other than spider bites should be sought.

### FUNNEL-WEB SPIDERS

Many species of the Funnel-web genera *Atrax* and *Hadronyche* inhabit Queensland, New South Wales, Victoria, Tasmania and South Australia but only spiders from New South Wales and southern Queensland have caused significant illness and death. These are large dark-coloured aggressive spiders. A systematic review involving 138 cases identified 77 cases of severe envenomation with 13 deaths, but none occurred after introduction of antivenom in 1981 and the vast majority (97%) responded to antivenom therapy.<sup>14</sup> All deaths were attributed to the Sydney Funnel-web Spider (*A. robustus*)<sup>1</sup> which inhabits an area within an approximate 160 km radius of Sydney and is inclined to roam after rainfall, enter houses and seek shelter among clothes or bedding, giving a painful bite when disturbed.

Severe envenomation is also caused by the southern tree (*H. cerberea*), northern tree (*H. formidabilis*), Port Macquarie (*H. sp. 14*), Toowoomba or Darling Downs (*H. infensa*) and Blue Mountains (*H. versuta*) species. In contrast to other spiders, male Funnel-web Spiders have more potent venom than female spiders.

Bites do not always result in envenomation, but envenomation may be rapidly fatal. The early features of the envenomation syndrome include nausea, vomiting, profuse sweating, salivation and abdominal pain. Life-threatening features are usually heralded by the appearance of muscle fasciculation at the bite site, which quickly involves distant muscle groups. Hypertension, tachyarrhythmias, vasoconstriction, hypersalivation and bronchorrhoea occur. The victim may lapse into coma, develop central hypoventilation and have difficulty maintaining an airway free of secretions. Finally, respiratory failure, pulmonary oedema and severe hypotension culminate in death. The syndrome may develop within several hours but it may be more rapid. Several children have died within 90 minutes of envenomation, and one died within 15 minutes. An active component in the venom is a

polypeptide which stimulates the release of acetylcholine at neuromuscular junctions and within the autonomic nervous system, and the release of catecholamines.

Treatment consists of the application of a pressure-immobilisation bandage, intravenous administration of antivenom and support of vital functions, which may include airway support, mechanical ventilation and intensive cardiovascular support.

### RED-BACK SPIDER

This spider is distributed throughout Australia and is found outdoors in household gardens in suburban and rural areas. Related species and similar effects of envenomation ('Latrodectism') occur in many parts of the world. Red-back Spider bite is the most common cause for antivenom administration in Australia at 300–400 per annum. The adult female is identified easily. Its body is about 1 cm in size and has a distinct red or orange dorsal stripe over its abdomen. When disturbed, it gives a pin prick-like bite. The bite site becomes inflamed and, during the following minutes to several hours, severe pain, exacerbated by movement, commences locally and may extend up the limb or radiate elsewhere. The pain may be accompanied by profuse sweating, headache, nausea, vomiting, abdominal pain, fever, hypertension, paraesthesias and rashes. In a small percentage of cases when treatment is delayed, progressive muscle paralysis may occur over many hours, requiring mechanical ventilation. Untreated, muscle weakness, spasm and arthralgia may persist for months after the bite. Death has not occurred since the introduction of an antivenom in 1956.

If the effects of a bite are trivial and confined to the bite site, antivenom may be withheld; otherwise, antivenom should be given intramuscularly. The antivenom may be given intravenously in cases of refractory pain but the risk of anaphylaxis may be higher than by the intramuscular route which is very low (< 0.5%). A premedication with promethazine is recommended and epinephrine should be at hand. In contrast to a bite from a snake or Funnel-web Spider, a bite from a Red-back Spider is not immediately life threatening. There is no proven effective first aid, but application of a cold pack or iced water may help relieve pain. Bites by *Steatoda* spp. (cupboard spiders) may cause a similar syndrome and can be treated effectively with Red-back Spider antivenom.<sup>15</sup>

### BOX JELLYFISH

This creature, *Chironex fleckeri*, is probably the most venomous in the world. It has caused at least 63 deaths in the waters off northern Australia.<sup>16</sup> It has a cuboid bell up to 30 cm in diameter. Numerous tentacles arise from the corners of the bell and trail several metres. It is semitransparent and difficult to see by anyone wading or swimming in shallow water. The tentacles are lined with millions of nematocysts which, on contact with skin, discharge

a threaded barb which pierces subcutaneous tissue, including small blood vessels. Contact with the tentacles causes severe pain and envenomation, from which death may occur within minutes. Death is probably due to both neurotoxic effects causing apnoea and direct cardiotoxicity, although the precise mode of action of the venom is unknown. In mechanically ventilated animals, fatal hypotension occurs rapidly on envenomation.<sup>17</sup> The skin which sustains the injury may heal with disfiguring scars.

First aid, which must be administered on the beach, consists of dousing the skin with acetic acid (vinegar) which inactivates undischarged nematocysts. Adherent tentacles can then be removed. Cardiopulmonary resuscitation may be required on the beach. An ovine antivenom is available but prevention is of paramount importance. Water must not be entered when this jellyfish is known to be close inshore. Wet suits, clothing and 'stinger suits' offer protection.

#### IRUKANDJI

Stings by the Irukandji, *Carukia barnesi*, and possibly by other jellyfish may cause a syndrome known as the Irukandji syndrome. The Irukandji is a small cubozoan jellyfish with a squarish bell a little more than 1 cm in diameter. Single tentacles trail from its corners. When submerged it is virtually impossible to see.

Its sting is mild and marked only by a small area of erythema. However, severe general illness may follow with abdominal cramps, hypertension, back pain, nausea and vomiting, limb cramps, chest tightness and marked distress.<sup>18</sup> Occasionally, cardiogenic pulmonary oedema has necessitated mechanical ventilation and inotropic therapy, while hypertension has caused two deaths by stroke. The mechanism is uncertain, but experimental studies in animals have shown that Irukandji extracts cause a hyperadrenergic syndrome secondary to massive release of catecholamines<sup>19</sup> which may explain at least in part the cause of heart failure. Pain relief is the most important feature of management in mild to moderate cases. In a series of 10 victims with 'Irukandji syndrome', intravenous magnesium salts provided pain relief and a reduction in blood pressure.<sup>20</sup> Antihypertensive therapy with phentolamine or a 'titratable' nitrate may be required in the initial phase of management.

#### AUSTRALIAN PARALYSIS TICK

This tick (*Ixodes holocyclus*) injects a toxin that causes flacid paralysis after some 3–5 days of feeding on humans. The onset of illness resembles that of Guillain-Barré syndrome. Prompt, careful and entire removal of tick(s) is necessary, followed by a period of observation to ensure that late onset paralysis does not occur. No antitoxin is available.

#### BEEES, WASPS AND ANTS

Anaphylactic reactions to bee and wasp stings cause approximately the same number of deaths in Australia each year as do snake bites at an average of 2.3 per annum.<sup>20</sup> The common European Honey Bee (*Apis mellifera*) is largely responsible. Jumper and Bull Ants (*Myrmecia* spp.) may also cause anaphylaxis. Persons who develop reactions to bites should seek immunotherapy and carry injectable epinephrine.

#### BLUE-RINGED OCTOPUSES

Several species of *Hapalochlaena* inhabit the Australian coastline. When handled, these octopuses bite and inject tetrodotoxin – a neurotoxin found in many different species of marine animals. It causes rapid onset of flaccid paralysis. Approximately a dozen deaths have been recorded. The required treatment is mechanical ventilation until spontaneous recovery occurs.

#### STINGING FISH

Numerous marine and fresh-water fish carry venom in glands attached to stinging spines. The most dangerous is the Stonefish (*Synanceia* spp.). When trodden upon, venom is injected. The immediate effect is extreme pain. Several deaths have been recorded, presumed due to the known depressive effects of the toxins on cardiovascular and neuromuscular function, and myotoxicity. An antivenom is available. Local or regional nerve blockade may be required for pain relief. Other stinging fish, such as the freshwater Bull-rout (*Notesthes robusta*) also cause excruciating pain when their spines are contacted. Immersion of the affected limb in warm-to-hot water provides pain relief.

#### VENOMOUS CONE SHELLS

From within their beautiful shells, many gastropod molluscs rapidly eject a venom-laden harpoon to almost instantaneously immobilise and kill prey. The numerous conotoxins, short proteins, stimulate or block neuronal and neuromuscular receptors, causing rapid death. A handful of human deaths have been recorded, when shells have been carelessly or unwittingly handled. There is no antivenom. Mechanical ventilation would be required until spontaneous recovery occurs.

# Blast injury and gunshot wounds: pathophysiology and principles of management

Stephen Brett

Widespread terrorist outrages in the recent past have once again served to emphasise that unpredictable events can suddenly deliver numbers of casualties to civilian hospitals, with unfamiliar patterns of injury. An understanding of the pathophysiology of blast injury, and the impact of such events on hospital function, will help medical staff make appropriate management decisions, often under difficult circumstances.<sup>1-4</sup>

## BLAST INJURY

### PHYSICS OF EXPLOSIONS<sup>5</sup>

An explosion is the almost instantaneous release of stored energy. The energy may come from, for example, pressurised gas, a nuclear reaction or stored chemical energy. Thus specific ‘explosives’ are not necessarily required. *Explosives* are materials that contain stored chemical energy that may be released rapidly. High-performance explosives release this energy by means of a chemical reaction which propagates through the explosive material faster than the speed of sound; thus the *detonation velocity* is of the order of 8 km/s compared with the speed of sound in air, 0.33 km/s.<sup>5</sup> This produces a supersonic shock front (blast wave) with a rapidly expanding cloud of gaseous reaction products which causes damage to structures and people in the vicinity. In effect, there is an extremely rapid increase in atmospheric pressure, ‘positive overpressure’, the duration of which is dependent on the magnitude of the explosive charge. This dies away exponentially and is followed by a *negative* pressure phase produced by gases forced away from the centre of the blast leaving a vacuum. Blast winds may subsequently move paradoxically towards the explosion as pressures equalise.

The blast wave carries with it energised environmental debris and device fragments. These are propelled substantial distances. In air, the blast wave intensity dies away rapidly with distance (with an inverse cube relationship) while debris travels further with the capacity to damage

and injure at much greater distances. This is reversed in an underwater blast. Water propagates the blast wave effectively but ‘drag’ reduces the range of debris and device fragments.

In addition to the kinetic energy released, heat and light energy are also produced, and can contribute to damage and injury. For a deliberate explosion, such as that produced by a military or terrorist device, the precise characteristics depend upon a number of factors including the size and nature of the container, the environment, and the dispositions of buildings and rooms.

### CLASSIFICATION OF BLAST INJURY

By convention blast injuries are classified according to which feature of the explosion was involved in wound generation.<sup>6,7</sup> In outline:

- *Primary injury*: caused by interaction of the blast wave and the body, particularly injuring the lungs, abdominal contents, the ears and contributing to traumatic amputation
- *Secondary injury*: produced by energised debris and weapon fragments – predominantly leading to penetrating and soft tissue injuries
- *Tertiary injury*: caused by displacement of the victim by the mass movement of air – ‘blast winds’; this group includes long bone fractures and head injury
- *Quaternary injury*: this is a miscellaneous group including crush injury from falling masonry (leading to renal failure) and flash burns

### EXPLOSIVE DEVICES (TABLE 77.1)

Conventional military anti-personnel devices rely on fragment generation to produce ‘secondary’ injuries. The device’s casing is designed to produce fragments, and may contain preformed fragments or notched wire to increase the fragment load. An 81 mm mortar round contains a small quantity (~1 kg) of high explosive; the blast

Table 77.1 Types of explosive devices

Conventional munitions: e.g. grenades, aerial bombs, mortar bombs, rockets	All types of blast injury may occur, but penetrating injuries from multiple fragments predominate. Primary fragments are derived from the munition; preformed within the shell or from the casing when the munition explodes. Other materials (building debris, vehicle components) energised by the blast form secondary fragments.
Terrorist devices: typically contain a few kilograms of explosive ( <i>NB</i> : Recent attacks have been larger, more sophisticated and specifically designed to maximise casualties)	Although the reported incidence of primary blast injuries varies from 1 to 76%, serious primary blast injury is uncommon and secondary and tertiary injuries predominate. Mortality is low unless the device is large, explodes in a confined space or there is structural collapse. Less than 50% of those presenting to hospital will require admission. <sup>2</sup>
Antipersonnel landmines: common in developing countries; indiscriminate in action	<p>Patterns of injury:</p> <ul style="list-style-type: none"> <li>• Traumatic amputation of foot or leg, due to standing on a buried 'point detonating' mine. Mine fragments, grass, soil, parts of shoe and foot are blown upwards with substantial proximal tissue damage and contamination.</li> <li>• More random distribution of penetrating injuries caused by fragment mine triggered near victim by a tripwire.</li> <li>• Severe upper limb and facial injuries due to handling of a mine.</li> </ul>
Enhanced-blast munitions, e.g. fuel-air or thermobaric explosives	Designed to injure by primary blast effect rather than by fragmentation. Used in recent conflict situations.

itself would only be lethal within 2–3 m, but the fragment cloud generated will seriously injure or kill within a radius of around 85 m. Improvised explosive devices (IED), built by terrorists, contain material (e.g. bolts, nails) to increase secondary injury. Larger devices, such as air-delivered free-fall bombs, missiles or artillery shells, contain sufficient explosive to produce secondary injury by throwing bricks, masonry debris and glass substantial distances. In addition, the blast may collapse physical structures such as walls and buildings.

Anti-personnel mines are broadly of two types:

- *buried mines* detonate and disrupt the foot and lower leg, blasting debris from the mine, the ground, footwear and device fragments up fascial planes towards the knee
- *above ground mines*, initiated by trip or command wires or electronic sensors, produce a preformed fragment load leading to secondary injury, with a high incidence of ocular damage

### PRIMARY BLAST INJURY

A blast wave passing through an individual behaves like an acoustic wave, giving up energy at interfaces between materials of differing acoustic quality, causing damage. Air-containing organs – the lungs, the gut and the ears – are particularly vulnerable.<sup>8,9</sup> Massive pressure pulses, causing body wall distortion, can tear solid organs from their vascular supplies. Recent work suggests that traumatic amputation is caused by shock wave-induced stress concentrations that fracture the long bones which are subsequently removed by flailing and blast wind effects.<sup>10</sup> This explains why amputations are generally not through joints.<sup>11</sup>

Primary blast injury (PBI) is unusual amongst survivors,<sup>12</sup> but very common in those killed immediately.<sup>13</sup>

The blast wave dies away rapidly with distance, but device fragments and energised debris travel and injure at greater distances. If a casualty is close enough to sustain primary injury there will be overwhelming secondary and tertiary damage. The majority of survivors from an explosion will have sustained secondary or tertiary injuries.<sup>12</sup> Military and terrorist devices are specifically designed to maximise casualties by the use of fragments.

Primary injury does sometimes occur and an understanding of mechanisms is useful in guiding management of such casualties. Survivors presenting with signs of one PBI (e.g. visceral perforation) must be assumed to have damage to other vulnerable regions and investigated accordingly. Casualties as close to the blast as other overwhelmingly injured fatalities must be investigated carefully for PBI. The absence of eardrum damage does not exclude PBI, as eardrum rupture depends on a number of factors, including critically the orientation of the head to the blast.

### THE LUNG

Immediate effects of severe blast exposure may include apnoea and bradycardia.<sup>9</sup> The blast wave produces disruption of the alveolar–capillary barrier leading to intra-alveolar haemorrhage that may be massive. This occurs in regions of the chest subjected most directly to the incident blast wave (not by a pressure pulse travelling down the trachea). The wave may 'echo' around the pleural cavity, exhibiting interference effects and injuring other regions at points of stress wave concentration. Such regions include the juxtamediastinal tissue and the diaphragmatic recesses. Pulmonary contusions are produced, with associated shunt and reduction in compliance, and pulmonary fat embolism has recently been described.<sup>14</sup> The surface of the lung may evolve bullae, which are mechanically weak and may rupture producing pneumothoraces. These may present early

**Table 77.2** Clinical features of blast lung

<b>Symptoms</b>	Dyspnoea Cough – dry to productive with frothy sputum; haemoptysis Chest pain or discomfort (typically retrosternal)
<b>Signs</b>	Cyanosis Torrential pulmonary haemorrhage Tachypnoea Reduced breath sounds, dullness to percussion Coarse crackles, wheeze Features of pneumothorax or haemopneumothorax. Subcutaneous emphysema. Retrosternal crunch (pneumomediastinum) Retinal artery air emboli

**Table 77.3** Radiological evidence of blast lung

Diffuse pulmonary opacities or 'infiltrates' (typically these develop within a few hours, become maximal at 24–48 hours and resolve over 7 days)
Pneumothorax/haemopneumothorax
Interstitial (peribronchial) emphysema
Subcutaneous emphysema
Pneumomediastinum
Pneumoperitoneum (usually secondary to perforation of an abdominal viscus, but tension pneumoperitoneum has been ascribed to blast lung)

or late, perhaps triggered by mechanical ventilation. Damage to hilar structures may be produced by severe and long duration overpressures; pulmonary artery and vein injuries are usually rapidly fatal. A variety of clinical features have been described and these are summarised in Table 77.2. Radiological features are outlined in Table 77.3.

Investigations obtained may depend on availability and prioritisation if the casualty burden is high. Chest X-ray (CXR), blood gas analysis and pulse oximetry monitoring are useful. CXR will provide data concerning pneumothorax, pneumomediastinum, subcutaneous and interstitial emphysema and subdiaphragmatic air from visceral perforation. The CXR is a poor modality for quantifying extent of contusion, for which computed tomography (CT) is better.<sup>15,16</sup> CT may be unavailable or overwhelmed with demand. In the majority of cases CT will not provide management-altering data. The priority is close clinical observation of conventional parameters to identify the drift toward respiratory failure.

The management of significant PBI is similar to that of any other pulmonary contusion with a number of corollaries from the pathology. PBI renders the lungs prone to development of pneumothorax, and importantly, significant air emboli may be created.<sup>17</sup> Historically, continuous positive airway pressure (CPAP) and mechanical ventilation were regarded as so hazardous as to be treatments of last resort. This was due to fear of creating or exacerbating air

embolism. Modern strategies based around modest gas exchange targets, with limited volume excursion and pressure change, has ameliorated these concerns.<sup>18,19</sup> A variety of non-conventional strategies including hyperbaric chambers, inhaled nitric oxide, high frequency jet ventilation and extracorporeal membrane oxygenation (ECMO) have been tried with varying success. The prognosis for pulmonary function in survivors is generally excellent.<sup>20</sup>

### THE ABDOMEN

The hollow viscera are at risk of primary blast injury, particularly in cases of immersion blast. Isolated PBI to the gut is unusual in air blast, and generally occurs in the presence of severe secondary and tertiary injuries. At high overpressures, immediate rupture of the gut wall occurs with bleeding and spillage of intraluminal contents into the peritoneal cavity. More commonly, and at lower overpressures, haemorrhage develops within the intestinal wall, ranging from small petechiae to confluent haematomas. These lesions are characterised by varying degrees of vascular damage and thus some will progress to necrosis of the gut wall and late perforation.<sup>21</sup>

With large numbers of casualties, surgical triage is difficult. Data derived from a pig model provide some guidance as to those contusions at greater risk of late perforation.<sup>22</sup> Bowel contusions > 15 mm diameter and colonic contusions > 20 mm diameter were at higher risk and warranted resection; smaller lesions could be treated conservatively. Circumferential lesions and those on the antimesenteric border were also associated with greater evidence of microvascular damage and perforation risk. Subcapsular haematomas, lacerations of solid organs, testicular rupture and retroperitoneal haematomas have all been described. These result from high blast loads and are likely to present early with abdominal signs and cardiovascular instability. In some patients the indications for exploratory laparotomy are obvious; in others PBI to the abdomen represents a diagnostic challenge, since it may be clinically silent until complications are advanced.

### THE EARS<sup>23</sup>

Damage to the ears includes sensorineural deafness, tympanic membrane rupture, injury to the ossicles and implantation cholesteatoma. These injuries are clearly not of major importance in the immediate management of the critically injured. Acute deafness may be very distressing to the victim, and impair assessment of conscious level. It may prevent gaining an accurate history of the circumstances of the blast that might assist in assessing risk of PBI. The absence of PBI to the ear has a poor negative predictive value for PBI to the lungs and gut.

### TRAUMATIC AMPUTATION

Common in mine injury, traumatic amputation is unusual in blast survivors. It is common in those who are killed immediately or die quickly.<sup>13</sup> The amputations do not generally occur through joints.<sup>10</sup> That situation is seen in ejecting fast jet pilots exposed to high wind speeds

(1100 km/h). The common sites are the upper third of the tibia, and the upper or lower third of the femur. Computer modelling and evidence from isolated animal limb studies<sup>10</sup> demonstrate that the blast wave generates stress concentrations at particular points in long bones, causing fractures before displacement occurs. Subsequently, blast wind-induced displacement removes the limb. The implication of this is that any survivors with traumatic amputation, not obviously due to fragment damage, must be regarded as at very high risk for PBI to the lungs and gut, even if not manifest immediately, and observed accordingly.

The surgical strategy is initially one of extensive debridement leaving only viable tissue. The resulting wound is loosely packed and allowed to drain, with planned secondary inspection and soft tissue closure after a few days.<sup>24</sup> Bone stock is preserved with the intention that a myoplastic stump can be organised at a later date, but the surgeon must acknowledge that this may be the final stump.<sup>25</sup> The vascular damage which occurs under these circumstances is severe, and heroic efforts to revascularise partially amputated limbs may be counterproductive; any venous anastomosis attempted is likely to be precarious, and may jeopardise survival due to prolonged shock.

#### SPECIAL CIRCUMSTANCES

Under certain circumstances a relatively high incidence of PBI may be encountered, for example if casualties are protected from fatal secondary injury by personal body armour or environmental structures. Alternatively, an explosion in a confining space may produce exacerbation of the overpressure experienced by an individual, by summation of incident blast energy and that reflected from rigid surfaces. Casualties at a distance from the explosion normally considered safe (for primary effects) for a 'free field' blast, might experience an enhanced blast effect and be at risk for PBI; survivors may have a high incidence of PBI. This has been well described for terrorist bombs in buses<sup>26</sup> and more recently trains.<sup>27</sup>

Conventional military devices exert their anti-personnel effects by secondary and tertiary action. Fuel-air weapons function by delivering a cloud of fuel vapour over or around a target which, once optimally mixed with air, is then detonated. These devices have a very low integral fragment load, but have an enhanced blast effect experienced throughout the fuel cloud that may cover a wide area; the thermal output is also substantial. Originally designed to assist in mine clearance, these weapons are ideal for attacking enemy troops in trenches or built-up areas.<sup>28</sup> The development of these weapons was initially difficult, but most of the technical problems have been overcome, and new generations have appeared. Such devices are reported to have been deployed in recent conflicts, and are available in air-delivered, artillery, tank-mounted and shoulder-launched variants. Now fairly widely available, this class of enhanced blast effect weapon is likely to become an increasing threat. Individuals caught in the centre of the vapour cloud are unlikely to

survive, but people at the margins can be predicted to have a high incidence of PBI, significant burns and injuries associated with collapse of buildings.

#### SECONDARY BLAST INJURY

Secondary injury can be due either to the effects of energised environmental debris, or to material integral to the explosive device itself. Environmental debris may include glass fragments or material from any vehicle used to deliver the device. Clearly a careful exposure and physical and radiological examination is required, bearing in mind that material penetrating one body cavity may travel some distance and produce damage in another. In the terrorist context, material removed, and indeed excised, and amputated tissue must be retained for forensic examination.

Surgical strategy hinges around the identification and removal of large pieces of foreign material, or those associated with, or likely to cause, neurovascular compromise.<sup>29</sup> Systematic removal of all minute fragments may cause more tissue destruction than might otherwise have occurred.<sup>30,31</sup>

Modern anti-personnel munitions (grenades, mortar rounds) are designed to incapacitate or kill by delivering high-energy small fragments into the target. Such weapons have caused the majority of wounds to military personnel in recent conflicts.<sup>32</sup> Preformed fragments often have a mass of 0.1–0.2 g and an initial velocity of ~1500 m/s. Because of irregular shape, velocity falls rapidly, but penetration can still occur at substantial distances. Soldiers in field conditions wear clothes contaminated with soil (and *Clostridia* spp.), and the skin is covered with faecal organisms and pyogenic *Streptococci* and *Staphylococci* spp.<sup>33</sup> High-energy fragments produce temporary cavities (see below) with negative intracavity pressure. Small fragments shred clothing and contaminated clothing fibres are driven or drawn into the wound. Wounds characterised by cavitation will have contamination distributed throughout a greater volume of tissue than might have been anticipated, or exhibited by lower energy wounds. The benefit of the early administration of antibiotics to prevent or retard the development of infection is well established.

Many of these wounds are to the limbs and these are small and multiple. The orthodox operative doctrine was derived from experiences in World War I where large fragments produced the majority of wounds. Newer weapons producing smaller wounds have caused a re-examination of this philosophy; selected wounds may be managed conservatively with cleansing, closed fracture management, antibiotics and observation, and criteria (Table 77.4) have been published.<sup>34–36</sup>

High-energy fragments can produce fractures, and can penetrate the body wall and injure the lungs or visceral structures. As the body wall is penetrated, the fragment energy is significantly reduced so that in survivors reaching hospital intracavity damage will tend to be localised.<sup>31</sup> Thus, mesenteric and gut perforations tend to be small and discrete. Small bowel wounds can generally be

**Table 77.4** Factors to be considered in the management of small fragment wounds

Risk factors for infection <sup>34</sup>	Criteria where non-operative management may be appropriate <sup>30,35,36</sup>
Prolonged time between wounding and presentation for treatment	Entry/exit wound < 1 cm
Lack of prior wound cleansing	No evidence of permanent cavitation within the wound
Wound size > 1 cm	No neurovascular compromise
Failure to comply with wound care instructions	No compartment syndrome
Low to medium energy transfer fractures	Stable fracture pattern
	No signs of infection
	Have been treated early with dressings and antibiotics

repaired primarily; the management of large bowel wounds remains controversial. There is an increasing enthusiasm for primary resection and repair with or without proximal diversion.<sup>37</sup> The pursuit of small fragments, which have transited the colon into the retroperitoneal tissues, may be counterproductive.<sup>38</sup>

Recent reports after terrorist incidents have highlighted that biological material from fellow victims, or even suicide bombers, may penetrate casualties and present a risk of viral transmission,<sup>39</sup> thus vaccination or post-exposure prophylaxis should be considered.

### TERTIARY BLAST INJURY

Head injuries, long bone, spinal and pelvic fractures and soft-tissue injuries can all be caused by casualties being displaced by the blast winds. Furthermore, limb flailing contributes to the pathogenesis of traumatic amputation. The management of such injuries follows conventional trauma doctrines.

### QUATERNARY BLAST INJURY

This classification includes injuries not otherwise classified, and includes superficial flash burns and crush injury from collapsing buildings. Depending on the exact explosives and physical circumstances, burn injuries may impose a substantial challenge, the combination of burns plus secondary injuries posing a very substantial infection risk.<sup>40,41</sup>

### MINES

It has been estimated that around 100 million anti-personnel mines are currently in the ground worldwide and a further 250 million are stockpiled. A mine explodes every 20 minutes, injuring or killing approximately 26 000 people per year, most commonly children and agricultural workers. Many of these people die before reaching medical assistance<sup>42</sup> (Table 77.5).

**Table 77.5** Classification of anti-personnel mine injury<sup>42</sup>

	Activation	Injury pattern
Pattern 1	Mine stepped on	Severe lower limb, perineal and genital injuries
Pattern 2	Device explodes near victim: activated by other victim or an above-ground mine	Less severe lower extremity injuries; injuries to head, chest and abdomen common
Pattern 3	Handling injury	Severe facial and upper limb injury

An anti-personnel mine is designed to incapacitate and maim rather than to kill – an exception being trip- or command-wire detonated above ground mines (e.g. ‘Claymore’ mines). A small quantity of explosive is detonated by pressure, and device fragments, soil and footwear remnants are forced upwards. The shock wave is concentrated in the tibia which fractures; the subsequent expansion of explosive products opens up tissue planes, causing substantial damage and contamination, and often completes the traumatic amputation. Limbs not amputated at first instance often require surgical amputation due to overwhelming soft-tissue damage. Damage to the contralateral limb is likely to be less severe, but meticulous attention must be paid to avoid complications leading to a second amputation. In addition, up to 5% of casualties suffer ocular injuries, and this figure is higher for handling injuries and above ground mines. Injuries to the perineum, the external genitalia and the rectum are all common. Many patients will require laparotomy for penetrating trauma.<sup>43,44</sup>

The wounds are heavily contaminated with soil organisms. The surgical strategy consists of:

- initial débridement – exposing and exploring all tissue planes
- removing devitalised tissue and foreign material
- subsequent delayed closure

Primary closure of wounds<sup>45</sup> and heroic limb salvage for limited posterior foot injuries<sup>46</sup> have been reported. Complication rates are likely to be high under all but the most ideal circumstances, and the expertise and facilities required to attempt this approach safely are not available to the vast majority of those injured.

### GUNSHOT WOUNDS

Small arms ammunition can be divided broadly into two types: rifle rounds, which are supersonic, and subsonic handgun or submachine gun rounds. This leads to a superficially attractive classification of gunshot wounds (GSW) into high- or low-velocity wounds. This has now been

superseded with the realisation that *energy transfer* is the important factor. The kinetic energy available is governed by the equation:

$$\text{Kinetic energy} = 1/2 \times \text{mass} \times \text{velocity}^2$$

High-velocity rounds have inherently more energy available. The amount of energy transferred is governed by a variety of factors, including:

- the resistance of the tissues penetrated
- direct impact on to bone
- whether the round penetrated point first or was unstable in flight

Thus, low-velocity wounds caused by handguns (or even shotguns) at close range may cause massive tissue

destruction, and occasionally high-velocity rounds may pass directly through a casualty causing very little damage.

### **PATHOLOGY AND MANAGEMENT OF GUNSHOT WOUNDS**

The phenomenon of *temporary cavitation* is generally a feature of high-velocity rounds.<sup>47</sup> The bullet penetrating a casualty is preceded by a shock wave which forces tissue away from its path, producing a temporary cavity, the diameter of which is many times that of the projectile itself (Figure 77.1). The cavity is instantly under negative pressure which draws environmental debris, clothing fragments and resident skin organisms into the casualty, via the entry wound. In addition, the tissue forming the walls and margins of the cavity is damaged and devitalised,

**Figure 77.1** High speed camera capturing (a) a rifle round penetrating a block of ballistic gelatin; the round is fired through simulated clothing. The round yaws and tumbles shortly after penetration (b), a temporary cavity forms (c), oscillates (d) and collapses (e). Cloth fragments that have been drawn in to the 'wound' are clearly visible (f).

forming a substrate for infection with the inoculating organisms. Shock wave and cavitation effects may be responsible for fractures not directly involved with the wound track.<sup>47–49</sup> Skeletal muscle is fairly elastic and tolerates cavitation reasonably well, whereas organs constrained by inelastic capsules or bony structures, such as the liver and brain, fare very badly.

Rounds may yaw and tumble prior to or after impact, leading to an unpredictable path through the victim; this is a particular feature of bullets from high-velocity smaller calibre rifles, known as assault rifles. Such injuries commonly involve more than one body cavity. Thus, extensive radiological studies must be performed prior to surgical exploration if at all possible. Occasionally, minute fragments of radio-opaque bullet debris may mark the path of the wound track.<sup>50</sup> The presence or absence, and size of any exit wound are an imperfect guide to the magnitude of wound trauma.<sup>47</sup> The behaviour of bullets is unpredictable, and attempting to predict this from knowledge of the weapon and firing distance may produce a misleading treatment plan.

The severity of fractures produced by direct impact on bone is governed largely by energy transfer. High-energy

weapons such as military and hunting rifles produce fractures with a high degree of comminution, whereas the majority of ballistic fractures due to handguns are minimally fragmented.<sup>51,52</sup>

Gunshot wounds become infected quickly due to the effects outlined above. Military surgical doctrine is for extensive wide local excision and delayed primary closure of limb wounds (Figure 77.2). This strategy evolved from conflicts during which both time of wounding to time of surgery intervals were long, and contamination with coliforms and soil organisms was likely. In civilian practice the wounding to treatment interval is usually short, and a less mutilating surgical strategy can sometimes be adopted.<sup>53</sup> Under certain circumstances upper limb wounds can be treated on an outpatient basis, with suitable wound cleansing, immobilisation and perhaps an antibiotic prescription.<sup>54–56</sup>

The majority of casualties surviving to hospital admission will require surgical exploration. The degree of debridement required will be governed by the operative findings and anatomy, rather than assumptions derived from knowledge of the weapon. Under certain circumstances, and with haemodynamically stable patients,

**Figure 77.2** (a) Rifle wound of the thigh with small entrance wound, (b) substantial damage to muscle visible at exploration, and (c) typical mass of devitalised, contaminated tissues removed. Both Figure 77.1 and 77.2 courtesy of Professor Jim Ryan, Leonard Cheshire Professor of Conflict Recovery, University College, London.

penetrating abdominal wounds may be evaluated laparoscopically, potentially avoiding a negative laparotomy.<sup>57,58</sup>

### ANTIBIOTIC CONSIDERATIONS

The combination of a wound, devitalised tissue and foreign material is ideal for the development of infection. Whether or not an infection develops depends on the quantity of bacteria and foreign material inoculated, and the time interval during which the bacteria can divide prior to wound irrigation, surgery or antibiotic administration.<sup>59,60</sup> Antibiotics can lengthen the safe period prior to establishment of infection if surgery is to be delayed.<sup>61</sup> The mainstay of treatment is surgery but during conflict this may not be available immediately and thus early dressing and antibiotics have an important role. As *Clostridia* spp. and  $\beta$ -haemolytic *Streptococci* have caused the majority of infective complications of war wounds, simple benzyl penicillin has been the most valuable first-line prophylactic and therapeutic agent, with strong evidence to support its continued use.<sup>33,59</sup> Ballistic fractures carry a significant risk of staphylococcal osteomyelitis and require flucloxacillin. In civilian circumstances the bacterial inoculum is orders of magnitude less. Thus, for simple limb gunshot wounds, if there is minimal inoculated material and the wound is attended to early, a far weaker argument for prophylactic use exists. The optimum duration of postoperative prophylaxis remains unclear;<sup>59</sup> evidence exists that even for penetrating hollow viscus injury, a short course may be adequate.<sup>62</sup>

### SUMMARY

Detailed descriptions of the surgical management of individual injuries are beyond the scope of this book. However, with an understanding of pathophysiology it should be possible to generate an appropriate management plan. These injuries are likely to provide clinical challenges for the foreseeable future.

# Biochemical terrorism

Munita Grover and Michael E Pelly

Biochemical terrorism is defined as the use of biological or chemical agents to intimidate, incapacitate or eradicate crops, livestock, civilian and military personnel.<sup>1</sup> It is well suited for attack by poorer nations against the rich, and is known as a poor man's atom bomb, or asymmetric method of attack. The large scale use of mustard and nerve gases in the Iran/Iraq war,<sup>2</sup> the dissemination of nerve gas sarin on the Tokyo underground,<sup>3</sup> and the discovery by UN inspectors in Iraq of SCUD missiles, rockets and aerial bombs primed with Botulinum and aflatoxins<sup>4,5</sup> have highlighted the need for planning.

## CHARACTERISTICS OF BIOLOGICAL WEAPONS (TABLES 78.1 AND 78.2)

Intended target effects are due either to infection with disease-causing micro-organisms and other replicative entities, including viruses, fungi and prions, or to the toxins they elaborate. Their effects depend on the ability to multiply in the person, animal or plant attacked.<sup>6</sup> Sequelae depend on host factors (state of nutrition, immunocompetence) and environment (sanitation, temperature, humidity, water quality, population density).<sup>7</sup>

## CLASSIFICATION

Although classification of biological weapons can be taxonomy based (e.g. bacterial/viral/fungal), it is also useful to examine particular features such as:

- *Infectivity*: proportion of persons exposed to a given dose that become infected. This reflects the capability of an agent to enter, survive and replicate
- *Virulence*: ratio of the number of clinical cases to the number of infected hosts. May differ for strains of the same pathogen.
- *Lethality*: ability of agent to cause death in an infected population
- *Pathogenicity*: ratio of number of clinical cases to the number of exposed persons, which reflects the capability of an agent to cause disease
- *Incubation period*: time elapsing between exposure to the agent and first signs and symptoms of disease
- *Contagiousness*: number of secondary cases following exposure to a primary case in relation to the total number exposed
- *Stability*: ability of an agent to survive the environment

Another useful classification system available is that from the Centers for Disease Control and Prevention (CDC) Atlanta:

### CATEGORY A

High-priority agents include organisms that pose a risk to national security because they can be easily disseminated or transmitted from person to person. They result in high mortality rates and have the potential for major public health impact, which might cause public panic and social disruption, and require special action for public health preparedness. Examples include anthrax, botulism, plague, smallpox, tularaemia and viral haemorrhagic fevers.

### CATEGORY B

Second highest priority agents include those that are moderately easy to disseminate. They result in moderate morbidity rates and low mortality rates, and require specific enhancements of CDC's diagnostic capacity and enhanced disease surveillance. Examples include brucellosis, salmonella, glanders, melioidosis, psittacosis, Q fever, ricin toxin, typhus, staphylococcal enterotoxin B and viral encephalitis.

## ROUTES OF DISSEMINATION

- Inhalational exposure using sprays or aerosols: Optimal particle size for alveolar deposition is 0.6–5 microns. Particles larger than this are filtered by the nose, and smaller particles are exhaled. This can be achieved using aerosol generators mounted on stationary objects or primed onto trucks, cars, boats, cruise missiles and planes. Environmental factors such as wind velocity, cloud cover, rainfall and humidity affect the efficiency of dissemination.<sup>7</sup>
- Cutaneous: Via wounds and mucous membranes.
- Ingestion via food and water: Hand to mouth contact is a suitable vehicle, for example the Rajneeshee cult successfully disseminated Salmonella via salads, infecting 750 people in 1984.

Table 78.1 Potential weapons

Biological diseases	Chemical agents
<i>Bacillus anthracis</i> (anthrax)	Blisters/vesicants
<i>Clostridium botulinum</i> toxin (botulism)	Distilled mustard (HD) Lewsite (L)
<i>Yersinia pestis</i> (plague)	Mustard gas (H)
<i>Variola major</i> (smallpox)	Nitrogen mustard (HN-2)
<i>Francisella tularensis</i> (tularemia)	Phosgene oxime (CX)
Viral haemorrhagic fever	Blood
<i>Coxiella burnetii</i> (Q fever)	Arsine (SA)
<i>Brucella melitensis</i> (brucellosis)	Cyanogen chloride (CK)
<i>Burkholderia mallei</i> (glanders)	Hydrogen chloride
Ricin toxin ( <i>Ricinus communis</i> – castor beans)	Hydrogen cyanide (AC)
Staphylococcus enterotoxin B	Choking/pulmonary damage
Niaph virus	Chlorine (CL)
Hantaviruses	Nitrogen oxide (NO) Phosgene (CG)
	Nerve
	Sarin (GF)
	Soman (GD)
	Tabun (GA)
	VX
	Incapacitating
	LSD
	Cannabinoids

Table 78.2 Criteria for a successful biological weapon<sup>6</sup>

<b>Assailant</b>
Has methods to treat own forces and population
<b>Target population</b>
Non-immune
Little or no access to immunisation or treatment
<b>Bioweapon</b>
Consistently produces disease/death
Highly contagious or infective in low doses
Short and predictable incubation period
Difficult to identify in target population
Suitable for mass production, storage and weaponisation
Stable during dissemination
Low persistence after delivery

### DETECTION OF A BIOTERRORIST EVENT (TABLE 78.3)

This may be obvious if large numbers of military personnel become ill with similar syndromes, but any release is likely to be a covert event. Furthermore, genetic engineering may result in altered pathogenicity, incubation periods, clinical effects and response to treatment or immunisation.

Table 78.3 Epidemiological evidence of an attack

Increasing incidence of disease in a normally healthy population
Higher incidence in subgroups, e.g. outdoor workers/shared ventilation
Increasing numbers seeking help with similar symptoms
Rise in endemic disease at an uncharacteristic time
Large numbers of rapidly fatal cases
Any patient with an uncommon disease which has bioterrorist potential
Large numbers of dying animals or fish, and unusual swarms of insects

### SPECIFIC AGENTS

#### ANTHRAX

Anthrax<sup>8</sup> is an acute infectious zoonosis caused by *Bacillus anthracis*, a Gram-positive, spore-forming bacillus. The infective dose is 8000–50 000 spores and routes of transmission include inhalation, ingestion and skin contact. Person-to-person transmission does not occur for the pulmonary form but secondary cutaneous lesions may occur after direct exposure to vesicle secretions. As spraying by aircraft is a potential threat to a large city, pulmonary exposure is the most likely route in a mass casualty situation.

#### CLINICAL FEATURES

##### Pulmonary exposure<sup>9,10</sup>

- Incubation period is 2–60 days
- Prodrome with flu-like symptoms
- Interim improvement followed by respiratory failure, cardiovascular collapse. Widened mediastinum on CXR, due to haemorrhagic mediastinitis and lymphadenopathy
- Gram-positive bacilli on blood cultures

##### Cutaneous exposure

- Incubation period is 1–7 days
- Mostly head, hands and forearms
- Pruritus, erythema, oedema and maculopapular lesions progress to depressed black eschars within 2–6 days. Eschars fall off without scarring

##### Gastrointestinal exposure

- Incubation period is 1–7 days
- Usually follows ingestion of infected meat
- Presents with abdominal pain, cramps, haematemesis and bloody diarrhoea, followed by toxemia and cardiovascular collapse
- Gram-positive blood cultures

##### Post exposure management<sup>11</sup>

- Universal precautions for medical personnel
- Warning to laboratory and coroners personnel regarding pathology specimens

- Contact infection control team
- Minimal handling of fomites
- Thorough decontamination with soap and water
- Disinfection of surfaces with 0.5% hypochlorite solution

### TREATMENT

Most strains used for bioterrorism will produce  $\beta$ -lactamases, and cephalosporinases were produced by the latest cases in the USA. Appropriate antibiotics include:

- ciprofloxacin: adults 500 mg b.d. for 8 weeks; children 20–30 mg/kg per day
- doxycycline: adults 100 mg b.d. for 8 weeks; children 5 mg/kg per day
- amoxicillin: in children and pregnant patients amoxicillin 40 mg/kg per day (max 500 mg t.d.s.) is appropriate if the organism is penicillin sensitive

Immunisation with anthrax vaccine consists of three doses at 0, 2 and 4 weeks. Prophylaxis of contacts should continue for 8 weeks and include immunisation if exposure is confirmed. Preventative immunisation using an inactivated cell-free vaccine is available but presently only administered to military personnel.

### BOTULISM

Botulism<sup>5</sup> is caused by *Clostridium botulinum*, an anaerobic Gram-positive bacillus that produces a neurotoxin. Seven forms of the toxin have been identified from A to G, but human botulism is due mainly to strains A, B and E. The neurotoxin contains a zinc protease that acts at the presynaptic terminal of the neuromuscular junction to prevent the fusion of vesicles of acetylcholine with the presynaptic membrane, therefore preventing release of acetylcholine and causing a flaccid paralysis. The LD<sub>50</sub> for type A is 0.001  $\mu$ g/kg.

Routes of exposure are either inhalation or ingestion, and there is an incubation period of 12–36 hours. Person-to-person transmission does not occur.

Clinical features include a responsive patient with no fever. There is a symmetric descending flaccid paralysis in a proximal to distal pattern without a sensory deficit. Cranial neuropathies (mainly bulbar) lead to diplopia, dysphagia, dysphonia and dysarthria. Respiratory dysfunction may occur due to upper-airway obstruction or muscle paralysis. The diagnosis is clinical, and confirmation is with the mouse bioassay in which mice are pre-treated with antitoxin and exposed to the patient's serum. A pentavalent toxoid vaccine is available for prevention, but routine immunisation is not recommended.

### TREATMENT

Patients should be monitored with frequent assessment of gag, cough reflexes, inspiratory force and vital capacity. Mechanical ventilation may be protracted, and may be punctuated by nosocomial infections requiring antibiotics.

Aminoglycosides and clindamycin are contraindicated because of their ability to increase blockade.<sup>12</sup> Administration of the trivalent (A, B, E) antitoxin should not be delayed while awaiting confirmation of the diagnosis. This horse serum has <9% hypersensitivity reactions, and <2% incidence of anaphylaxis. Skin testing is advisable.<sup>13</sup> A heptavalent antitoxin is under investigation. Passive administration of neutralising antibody minimises further damage.<sup>14</sup>

Treatment of children, pregnant women and immunocompromised patients should be no different; all have received equine antitoxin without short-term sequelae.

Prophylaxis of contacts involves close observation and, at the first sign of illness, treatment with antitoxin, neutralising antibody and administration of the pentavalent toxoid vaccine.

### SMALLPOX

Smallpox<sup>15</sup> is an acute viral illness caused by variola virus (orthopoxvirus). The last documented case was in Somalia in 1977. It is transmitted from person to person via the airborne route. The infective dose is 10–100 virions, with an incubation period of 7–17 days.

In a non-immune society, the impact would be devastating<sup>16</sup> as the person-to-person spread would be difficult to check, and many countries have very poor health structures with overcrowding in the cities. In addition, the impact of global travel would change the epidemic and allow it to move rapidly from continent to continent.

There are two other major factors that may change the profile of a predicted epidemic: the potential use of new antiviral agents against smallpox and the HIV epidemic. Predictions are difficult.

### CLINICAL FEATURES<sup>17</sup>

There is a flu-like prodrome with malaise, fever and headache. There is also a synchronously evolving maculopapular rash forming pustules over the head and extremities; the mouth and pharynx may also be affected. Multiorgan failure commonly complicates smallpox. Diagnosis is clinical with confirmation by identification of brick-shaped virions from vesicular fluid using electron microscopy.

### PREVENTION

Routine vaccination with vaccinia virus stopped in 1972. The immune status of vaccinated individuals is unclear, but if a single dose vaccine was administered it is assumed the subject is non-immune. A preventative vaccination programme is currently under review.

### TREATMENT

Vaccination within 4 days of exposure.<sup>18</sup> However, complications include:

- post-vaccinal encephalitis
- vaccinia gangrenosa
- eczema vaccinatum
- generalised vaccinia
- inadvertent inoculation

Five groups are considered high risk for these complications. These are pregnancy, HIV infection, chemotherapy, eczema and immune disorders.<sup>19</sup> In these cases, vaccinia immune globulin should be given simultaneously. Other treatments include:

- supportive care with isolation
- antibiotics for secondary bacterial infections
- cidofovir, a nucleoside DNA polymerase inhibitor, is under investigation but needs to be given i.v. and causes renal toxicity.<sup>20</sup>

## PLAGUE

Plague<sup>21</sup> is an acute bacterial disease caused by the Gram-negative *Yersinia pestis*, from the enterobacter species.<sup>22</sup> Although usually transmitted by fleas causing bubonic and septicemic plague, a bioterrorist event is likely to be airborne resulting in pneumonic plague. The infective dose is <100 organisms, and has an incubation period of 2–3 days. It is unlikely that spread would be person to person.

Plague presents with fever, haemoptysis, chest pain and dyspnoea. Gram-negative rods are found in mucopurulent sputum, and on Wright's, Giemsa or Wayson stain appear as bipolar rods with a safety pin appearance. The diagnosis can be confirmed on blood culture, and with fluorescent antibody testing. There is radiographic evidence of bronchopneumonia, and multi organ failure soon develops. Until 72 hours of antibiotic therapy have been completed, plague is communicable.

A formalin-killed vaccine exists but is ineffective and unavailable. Post exposure immunisation has no benefit.

## TREATMENT<sup>21</sup>

Once the diagnosis is considered, isolation and universal precautions should be instituted. Historically, streptomycin (1 g b.d. i.m.) reduced mortality to 5%, and gentamicin (5 mg/kg per day) has also been used successfully. Tetracycline and doxycycline (100 mg b.d.) have been used, but in Madagascar 13% of strains were resistant to doxycycline. Animal studies have demonstrated efficacy of fluoroquinolones including ciprofloxacin (400 mg b.d.), ofloxacin and levofloxacin. No human trials exist so far. Chloramphenicol (25 mg/kg q.i.d.) is recommended for plague meningitis.

## CHARACTERISTICS OF CHEMICAL AGENTS

The North Atlantic Treaty Organization definition of a chemical agent is a 'chemical substance which is intended for use in military operations to kill, seriously injure, or incapacitate people because of its physiological effects'.<sup>2</sup> In addition to physiological effects, these agents promote psychological warfare.<sup>23</sup>

## ROUTES OF DISSEMINATION

The principal hazard is inhalation of liquid, vapour, or droplets (0.6–5 microns). Delivery may be by artillery

shells, missiles or aerial bombing. In the Tokyo subway attack in 1995, terrorists left plastic bags on the subway filled with sarin after piercing them with umbrella tips. There were 3796 casualties and 12 deaths.<sup>3</sup>

Toxicity depends on the concentration and time of exposure, is measured in units of concentration and time (mg/min m<sup>3</sup>), known as the Haber product.<sup>7</sup> Most chemical agents are designed to penetrate the skin, respiratory epithelium and cornea, unlike biological agents. Penetration is promoted by thinner, more vascular, moister, hairy skin, and by high humidity, spills and aerosols.

## RICIN

Ricin is one of the most toxic biological agents known – a Category B bioterrorism agent and a Schedule number 1 chemical warfare agent. Ricin toxin can be extracted from castor beans, purified and treated to form a pellet, a white powder, or dissolved in water or weak acid to be released as a liquid. It is stable under ambient conditions. Particles of <5 microns have been used for aerosol dispersion in animal studies. Ricin particles can remain suspended in undisturbed air for several hours, and resuspension of settled ricin from disturbed surfaces also may occur.

## TRANSMISSION

Ricin would need to be dispersed in particles smaller than 5 microns to be used as an effective weapon by the airborne route. It is very difficult to prepare particles of this size. Routes of exposure include inhalation, parenteral (injection) ingestion, dermal contact (exposure risk is low, except where absorption is through non-intact skin or via a solvent carrier) or ocular contact. Although ricin may adhere to skin, person-to-person transmission through casual contact has not been reported. Despite the fact that ricin may adhere to clothing or be present on surfaces, there is low potential for transmission via contact with contaminated clothing or contaminated surfaces.

## RISK GROUPS

- There is worldwide distribution of castor plants. Ricin is produced when castor oil is made from castor beans, but the general public is not considered at risk for exposure
- Persons in or around castor oil processing plants. However, it would take a deliberate act to make ricin and use it as a poison
- Persons in the dispersal area of a ricin aerosol release
- Persons who are victims of parenteral injection with ricin
- Persons who ingest castor beans, or food or water contaminated with ricin
- It is not known whether certain populations are more vulnerable to the health effects of ricin exposure (e.g. children, pregnant women, the elderly, those with immunosuppression, or underlying respiratory or gastrointestinal tract disease); however, persons with pre-existing tissue irritation or damage who are exposed to ricin may sustain further injury and greater absorption of ricin toxin

**PATHOGENESIS**

- Ricin is a toxalbumin, a biological toxin whose mechanism of action is inhibition of protein synthesis in eukaryotic cells; cell death results from the absence of proteins
- The effects of ricin poisoning depend upon the amount of ricin exposure, the route of exposure and the person's premorbid condition
- Ingestion and mastication of three to six castor beans is the estimated fatal dose in adults. The fatal dose in children is not known, but is likely to be less
- Most cases of castor bean ingestion do not result in poisoning: ricin release requires mastication, and the degree of mastication is likely to be important in determining the extent of poisoning. Ricin is not as well absorbed through the gastrointestinal tract when compared to injection or inhalation
- Inhalation or injection of ricin would be expected to lead to a more rapid onset of symptoms of ricin poisoning and to a more rapid progression of poisoning compared to ingestion, given the same exposure amount

Data on inhalational exposure to ricin in humans are extremely limited, and systemic toxicity has not been described. Animal studies suggest that inhalation is one of the most lethal forms of ricin poisoning. Following severe ricin poisoning, damage to vital organs may be permanent or have lasting effects. No long-term effects are known to exist from ricin exposure that did not result in symptoms.

**LABORATORY DIAGNOSIS**

Non-specific laboratory findings in ricin poisoning include:

- metabolic acidosis
- impaired liver and renal function tests
- hematuria
- leukocytosis (two- to five-fold higher than normal value)

The presence of leukocytosis and/or abnormal liver and renal function tests may suggest ricin-associated illness in the correct clinical context but are not very specific. There are no specific clinically validated assays for detection of ricin that can be performed by the hospital/health care facility clinical laboratory, and no methods are available for the detection of ricin in biological fluids. However, tests for ricinine, an alkaloidal component of the castor bean plant, are being developed. The potential uses of tests for either ricin or ricinine in human biological samples would primarily be for purposes of confirming exposure or assessing the prevalence of exposure rather than diagnostic use.

Testing for ricin in environmental samples will most likely not be immediately available to assist in clinical decision-making. However, they may document the potential for exposure or affirm the exposure circumstances.

**LABORATORY TESTING**

Tests performed on ricin-suspicious samples include:

- time-resolved fluorescence immunoassay: antibody binds to ricin
- polymerase chain reaction: locates and makes copies of parts of the DNA contained in the castor bean plant. The search specifically identifies the DNA of the gene that produces the ricin protein

**TREATMENT**

As no antidote exists for ricin, exposure must be avoided if possible. Otherwise, all efforts must be directed to minimising exposure through decontamination. Supportive care is, in part, dictated by the route of exposure: inhalation, ingestion, skin or eye exposure, and includes measures such as ventilation, i.v. fluids, and treatment of seizure or hypotension.

**SARIN**

Sarin ( $C_4H_{10}FO_2P$ , isopropylmethylphosphofluoridate) is a colourless and odourless liquid at room temperature. It is volatile and incompatible with metals or concrete, which lead to production of hydrogen gas. Hydrolysis of sarin forms acids. It is thermally stable  $<49^\circ C$ , but clings to clothing and releases slowly for 30 minutes. Toxicity is through inhibition of the enzyme acetylcholinesterase.

The route of exposure determines which clinical features (Table 78.4) appear first.<sup>24</sup> Post inhalation respiratory and eye symptoms appear, whereas post cutaneous exposure diaphoresis and muscle fasciculation occur. Immediate first aid is to remove the patient from the area of danger to a well-ventilated area before removal of clothing and decontamination of the skin. This can be achieved using mists of water, or dilute sodium hypochlorite. Eyes are irrigated with water or normal saline.

**Table 78.4** Sarin toxicity

<b>Mild</b>	Rhinorrhitis Dyspnoea Miosis Blurred vision
<b>Moderate</b>	Diaphoresis Drooling Bronchospasm Nausea, vomiting, cramps Weakness Twitching Headache Confusion
<b>Severe</b>	Involuntary defecation/urination Convulsions Respiratory arrest Coma, death

Assessment follows airway, breathing and circulation. Patients with compromised airways, due either to direct effects or secondary to reduced level of consciousness, require intubation and positive-pressure ventilation. Aggressive suctioning may be needed for bronchial secretions.

#### TREATMENT

- Anticholinergics to antagonise the muscarinic effects, usually i.v. atropine in 2 mg doses, every 3–5 minutes, until the patient is atropinised. It may need to be continued for 24 hours at 2 mg/h<sup>2</sup>
- Oximes to reactivate the anticholinesterase enzyme at nicotinic sites, e.g. pralidoxime mesilate 30 mg/kg by slow i.v. injection, up to 2–4 g. This should be prompt, as dealkylation of the inhibited enzyme renders it resistant to reactivation
- Prophylactic anticonvulsants to prevent seizures. Diazepam 5 mg by any route has been shown to reduce morbidity in animal studies

#### MUSTARD GAS

Mustard gas (C<sub>4</sub>H<sub>8</sub>Cl<sub>2</sub>S, Bis-(2-Chloroethyl) sulphide) is a yellow oily liquid at room temperature. It has a faint garlic odour and evaporates to form a vapour that penetrates clothing. Although mortality is low, poisoning tends to incapacitate. It is a bifunctional alkylating agent that is carcinogenic (oral cavity, larynx, bronchus), and irritates skin and mucosa (Table 78.5). Mustard gas is also myelotoxic (pancytopenia) and teratogenic. Assessment is similar to sarin.<sup>25</sup>

#### TREATMENT

Patients with large burns are resuscitated as any other burn; however, fluid losses are transudates, so protein losses are less.<sup>26</sup> Pain control is important and frequently requires analgesics, such as morphine. Tense blisters are dressed with silver sulfadiazine. Mustard burns take at least 12 weeks to heal, but early excision and grafting does not reduce healing time.<sup>27,28</sup> Eye lesions usually heal in 2 weeks, and are aided by topical antibiotics and saline irrigation. Oxygen, antibiotics for secondary pneumonia, physiotherapy and ventilation are the mainstays of treatment for respiratory effects.

**Table 78.5** Features of mustard gas toxicity

<b>Eyes</b>	Lacrimation, conjunctivitis, photophobia
<b>Skin</b>	Erythema, blistering, partial to full-thickness burns
<b>Respiratory tract</b>	Rhinorrhoea, tracheobronchitis, bronchopneumonia
<b>Systemic</b>	Nausea, vomiting, diarrhoea, bradycardia, hypotension

# Pharmacokinetics, pharmacodynamics and drug monitoring in critical illness

Richard N Upton, John A Myburgh and Raymond G Morris

Pharmacokinetics (PK) is the study of the absorption, distribution, metabolism and elimination (ADME) of drugs, usually by measurement of drug concentrations in blood or plasma. Pharmacodynamics (PD) is the study of the effects of a drug on the body. The pharmacokinetics of a drug is one determinant of its pharmacodynamics. Pharmacokinetic-pharmacodynamic (PK-PD) analysis seeks to summarise the behaviour of a drug in the body, to understand the sources of variability in this behaviour, and to use this knowledge to design rational, and ideally individualised, dosing regimens. The aim of this chapter is to review some basic PK and PD principles, to introduce the concepts that an intensive care physician may encounter when reading a contemporary PK-PD paper, and to consider the influence of critical illness on the pharmacokinetics and pharmacodynamics of drugs used in intensive care.

## DOSE-RESPONSE RELATIONSHIPS

Most drugs exert their effects by binding to receptors<sup>1</sup> such as an enzyme or membrane ion channel. The binding to the receptor directly or indirectly triggers a chain of biological events leading to the observable effects of the drug. The magnitude of effect is a function of:

- the number of receptors present
- the willingness of a drug to associate with a receptor (receptor affinity)
- the presence of other compounds competing for the binding site on the receptor (agonists/antagonists)
- the concentration of the free (unbound) drug in the vicinity of the receptor

As the number of receptors present is finite, drugs have a maximum achievable effect. Classically, a plot of drug effect versus the logarithm of a wide range of doses will be described by a sigmoid-shaped dose-response curve (Figure 79.1). In practice, the range of doses used in patients is often narrower, and is confined to a smaller section of the dose-response curve.

Note that a drug effect can be plotted in individuals (e.g. mean arterial pressure vs. drug concentration)

or for a population of individuals (e.g. % of patients responding to increasing doses of an antihypertensive). The shape of dose-response curves is often defined by three parameters:

- the maximum possible effect ( $E_{\max}$ )
- the dose at which 50% of  $E_{\max}$  is achieved (the median effective dose, or  $ED_{50}$ )
- a parameter controlling the steepness of the linear section of the curve (sometimes called the Hill coefficient, Figure 79.1)

Analogous curves can often be drawn for each of the adverse or toxic effects of a drug. The ratio of the median toxic dose and the median effective dose is termed the therapeutic index. The smaller the therapeutic index of a drug, the greater the potential to do harm rather than good.

Any drug should be administered with a clear understanding of the expected benefits to the patient. While it is more difficult to cause drug toxicity by administering a drug with a high therapeutic index, careless use can result in treatment failure and unnecessary cost. Drugs with a low therapeutic index should be used with considerable caution, with the assistance of titration to measured drug effects, dose nomograms or measurements of drug concentrations (therapeutic monitoring).

## TITRATION

Many drugs used in intensive care have a relatively rapid onset of a directly measurable physiological effect (Table 79.1). They can therefore be used by a process of titration of dose versus effect to achieve the desired therapeutic outcome. While titration can be an empirical process, efficient titration strategies are guided by an understanding of the kinetics and dynamics of a drug. Important issues include an understanding of:

- the time required for the drug to achieve peak effect after intravenous bolus administration; multiple doses within this time period may result in 'overshoot' of effect

**Figure 79.1** The basic concepts of dose-response curves for the therapeutic and toxic effects of a hypothetical drug. Each curve can be described by the maximum effect ( $E_{\max}$ ) and the dose at which half of the maximum effect is achieved ( $ED_{50}$ ). The Hill coefficient ( $n$ ) controls the steepness of the linear section of the curve. When this is very steep, drugs have a threshold effect and behave in an 'on or off' manner.

- potential for drug accumulation with repeated bolus doses that may manifest as a stronger, longer action for subsequent doses
- potential range of dose sizes for titration
- optimisation of initiating, increasing or decreasing the rate of an intravenous infusion
- the effects of evolving pathophysiology and tolerance
- potential kinetic and dynamic interactions with co-administered drugs

Developing this understanding requires knowledge of some fundamental pharmacokinetic and pharmacodynamic concepts.

## PHARMACOKINETICS

Key pharmacokinetic concepts include volume of distribution ( $V$ ) and clearance ( $CL$ ). These can be applied to individual organs or to the whole body.

### VOLUME OF DISTRIBUTION IN AN ORGAN

A drug administered to a patient will directly or indirectly enter the blood and be distributed by the blood circulation around the body. Drug enters the organs of the body via the afferent arterial blood supply. Any given molecule can then either diffuse into the organ or leave via the

effluent venous blood (Figure 79.2). At steady state (when the arterial concentrations are constant and the net rates of diffusion into and out of the organ are equal), the total amount of drug in the organ ( $A$ ) will often be a fixed ratio of the afferent arterial concentration ( $C$ ). This ratio is known as an apparent volume of distribution ( $V$ ):

$$V = A/C = \text{mg}/(\text{mg/l}) = l \quad (1)$$

The process of normalising amount (e.g. mg) for concentration (e.g. mg/l) produces a constant with the units of volume (l).

A given organ is characterised by the size of defined 'physiological' spaces and its relative proportions of water, lipids and drug-binding sites (Figure 79.2). The important physiological spaces are:

- the *intravascular* space (about 3% of the total mass of the organ)
- the *interstitial* space (about one-third of total organ mass). It is separated from the intravascular space by the endothelium, which has pores of sufficient size to allow the passage of most drugs (transcapillary exchange) but not (effectively) plasma proteins
- the *intracellular* space (about two-thirds of total organ mass). It is separated from the interstitial space by the lipid barriers of the parenchymal cell membranes

Table 79.1 PK-PD summary for some commonly used drugs

Class	Family	Drug	Titrated index	PK summary	Possible changes in critical illness	Dose comment
Inotropes <sup>2</sup>	Catecholamines	Noradrenaline	MAP Filling pressures Indirect evidence of organ hypoperfusion	High systemic clearance (3 l/min) Low Vss (0.1 l/kg) $t_{1/2} = 2$ minutes <sup>3</sup>	Clearance to one-third normal $t_{1/2}$ to three times normal <sup>3</sup> CO dependent kinetics?	By titration Initial infusion 3–5 µg/min, 3–10 minutes to reach constant effect
		Adrenaline		Similar to noradrenaline	Similar to noradrenaline	
	Phosphodiesterase inhibitors	Milrinone		Mainly renal clearance (0.5 l/min) Moderate Vss (0.25 l/kg) $t_{1/2} = 1.5$ –2 hours <sup>4</sup>	Half-life increased to 20 hours in CHF + RF <sup>5</sup>	Loading dose needed Difficult to titrate 12.5–50 µg/kg i.v. over 20 minutes, then 0.375– 0.75 µg/kg per min Loading dose needed Actions persist long after last dose
Vasopressor		Levosimendan		Parent $t_{1/2} = 1$ hour Active metabolite $t_{1/2} = 80$ hours <sup>6</sup>		
Vasopressor	Catecholamines	Noradrenaline	MAP once hypovolaemia corrected	See above		See above
	Others	Phenylephrine		Low hepatic clearance (0.03 l/min) High Vss (5 l/kg) $t_{1/2} = 0.08$ and 0.8 hours <sup>7</sup>	Expect variable clearance and drug interactions	Beware MAO inhibitors Short-term use Loading dose needed, 100–180 µg/min then 40–60 µg/min Used in catecholamine resistance Threshold effect – do not titrate Infusion 0.04 units/min
		Vasopressin		Peptide High CL Low Vss $t_{1/2} = 8$ –15 minutes <sup>8</sup>		
Antihypertensives		GTN	MAP, ICP	Variable kinetics Very high CL (> CO) Low Vss $t_{1/2} = 2$ –3 minutes <sup>9</sup>	Expect CO dependent kinetics	Tolerance after 24 hours Infusion 0–20 mg/hour
		Sodium nitroprusside		Variable kinetics Very high CL (> CO) Low Vss $t_{1/2} = 2$ –3 minutes <sup>10</sup>	Expect CO dependent kinetics	Tolerance Potential cyanide toxicity Infusion 0–20 mg/hour
		Labetalol		High hepatic clearance (1.2 l/min) Very high Vss (3–11 l/kg) $t_{1/2} = 3$ –5 hours <sup>11</sup>	Expect CL to depend on CO and HBF	Loading dose needed Give bolus doses slowly Infusion 25–150 mg/hour

Continued

Table 79.1 PK-PD summary for some commonly used drugs—Continued

Class	Family	Drug	Titrated index	PK summary	Possible changes in critical illness	Dose comment
Antiarrhythmics	Bradyarrhythmias	Metoprolol		High hepatic clearance (polymorphic) High Vss (3 l/kg) $t_{1/2} = 3-7$ hours <sup>12</sup>	Expect CL to depend on CO and HBF	Usually repeat bolus doses, 1–5 mg slowly up to 15 mg
		Adrenaline	ECG	See above		See above, short-term emergency use Bolus 0.6 or 1.0 mg
	Supraventricular arrhythmias	Atropine		High renal and hepatic clearance (1.1 l/min) High Vss (4 l/kg) $t_{1/2} = 2$ and 222 minutes <sup>13</sup>		
		Adenosine		Very high systemic clearance (CL > CO) Low Vss $t_{1/2} < 2$ minutes <sup>14</sup>	Expect CO dependent kinetics	Increasing i.v. bolus (3, 6, 12, 18 mg) until desired effect Higher doses needed for peripheral vs. central venous lines
Respiratory	Ventricular arrhythmias	Verapamil		Initial redistribution after bolus Moderate hepatic clearance (0.5 l/min) High Vss (2.5 l/kg) $t_{1/2} = 0.2$ and 4 hours <sup>15</sup>	Little change with renal failure	Bolus 5 mg then 10 mg 10 minutes later if needed
		Amiodarone		Variable hepatic clearance (0.1–0.7 l/min) Variable Vss (0.01–2.11 l/kg) $t_{1/2} = 3-80$ hours <sup>16</sup>	Animal data suggest lower clearance in biliary stasis Renal failure affected total CL but not tissue levels <sup>17</sup>	5 mg/kg over 30–60 minutes, then 1200 mg over remainder of 24 hours Accumulates with chronic dosing giving long recovery times See above
		Amiodarone		See above		
Sedatives	Respiratory	Salbutamol	Respiratory status	Local effect, only R enantiomer active Mainly renal clearance (0.7 l/min) $t_{1/2} = 2$ hours <sup>18</sup> Variable pulmonary bioavailability		Nebulised, MDI or infusion (0.5–1 mg/hour)
		Propofol	Sedation-agitation score, possibly EEG Stopped daily for neurological assessment	Rapid redistribution after bolus High extrahepatic clearance (2.2 l/min) High Vss (4.5 l/kg) $t_{1/2} = 1.5, 30$ and 350 minutes <sup>19</sup>	CO dependent kinetics <sup>20</sup> Higher doses needed in hypercarbia <sup>21</sup>	Prolonged infusions risk hypertriglyceridaemia, Bolus doses given slowly, infusion starts at 30 mg/hour <sup>22</sup>

Table 79.1 PK-PD summary for some commonly used drugs—Continued

Class	Family	Drug	Titrated index	PK summary	Possible changes in critical illness	Dose comment
Renal		Furosemide	Urine output	Low renal and hepatic clearance (0.13 l/min) Low $V_{ss}$ (0.3 l/kg) $t_{1/2} = 1.25$ and 33 hours <sup>31</sup>	Dose adjustment in renal failure complex <sup>31</sup>	Possible tolerance Infusion 2.5–10 mg/hour
		Spironolactone		Kinetics of parent drug probably less relevant than that of active metabolites	Dose adjustment in renal failure complex Little effect of hepatic failure Metabolism increased with chronic dosing	Significant active metabolites Avoid or increase dose interval with renal failure or cirrhosis, 25–100 mg b.d.
Antibiotics		Many	Culture Clinical response	Wide range <sup>32</sup>	Drug dependent <sup>32</sup>	May require up to 48 hours for full effects of regimen

BBB, blood–brain barrier; CHF, congestive heart failure; CL, clearance; CO, cardiac output; GTN, glyceryl trinitrate; HBF, hepatic blood flow; ICP, intracranial pressure; MAO, monoamine oxidase; MAP, mean arterial pressure; MDI, metered dose inhaler; RF, renal failure;  $V_{ss}$ , volume of distribution at steady state.

**Figure 79.2** Processes governing drug entry into a tissue.

A drug may act on receptors in any of these spaces. The physicochemical properties of a drug dictate which physiological spaces are accessible to the drug. A drug can exist in blood in several forms: ionised or unionised (governed by the local pH and the pKa of the drug), and bound or unbound to plasma proteins.

- Only unbound (free) drug can diffuse into the interstitial space via capillary pores or via a paracellular route
- Only unbound, unionised drug can diffuse across cell membranes (transcellular route)

Consequently, drugs that are *highly bound* or *highly ionised* in blood generally have smaller distribution volumes in an organ. For example, the distribution volume of propofol in the brain is less than expected based on its high lipophilicity because it is highly bound in plasma. Paradoxically, highly lipophilic drugs in general do not penetrate tissues as extensively as moderately lipophilic compounds, as high lipophilicity is correlated with high binding in plasma.<sup>33</sup>

A distribution volume ( $V$ ) provides information about how much drug is in an organ at steady state, but provides no information about how quickly steady-state concentrations in the organ would be achieved. The fastest possible rate is when diffusion across the endothelium and cell membranes is significantly faster than organ blood flow ( $Q$ ). In this case, the uptake into the organ is 'flow-limited', and the half-life of organ equilibration is given by:

$$t_{1/2} = 0.693 \times V/Q \quad (2)$$

Note that if the distribution volume of an organ is relatively large or the organ blood flow is low, the time required for an organ to completely equilibrate (at least five times  $t_{1/2}$ ) with the blood can be quite long despite flow-limited kinetics.

When the diffusion rate across the endothelium and cell membranes is significantly less than organ blood flow ( $Q$ ), the uptake into the organ is 'membrane-limited' and less affected by changes in organ blood flow. Morphine shows membrane-limited uptake into the brain.<sup>34</sup>

### THE SPECIAL CASE OF THE BRAIN

Drug penetration into the brain is further restricted compared to that of other organs because of passive and active defence mechanisms collectively known as the blood–brain barrier (BBB). The passive component is the tight junctions of endothelial cells in the brain, which means that passage across the endothelium is solely by the transcellular route, and therefore restricted to lipophilic compounds. The active component is a range of transmembrane transporters. Some of these allow the uptake of endogenous compounds (e.g. amino acids and glucose). Of more pharmacological importance are a range of efflux transporters that actively pump drugs from the brain to the blood.<sup>35</sup> The clinical significance of these transporters is currently being defined, but may be particularly important for some drugs. For example, loperamide is a potent opioid, but has no central effects at normal doses because it is excluded from the brain by P-glycoprotein.<sup>36</sup> Similarly, the concentration of morphine in the brain is kept low by active transport. When the BBB is damaged, morphine concentrations in the brain are found to be higher.<sup>26</sup>

### CLEARANCE IN AN ORGAN

The liver and the kidney have the special (but not exclusive) role of removing drug from the body. The liver can either transport a drug from the blood into the bile or metabolise a drug into another chemical entity (metabolite). Metabolism can be Phase I (e.g. by oxidation or reduction by enzymes of the cytochrome P-450 (CYP) family, or hydrolysis by esterases) or Phase II (e.g. conjugation with another compound to form a glucuronide or sulphate). The kidney excretes drug by filtration, and potentially active secretion, into the urine. Usually metabolites are less active than their parent compound, are more polar and more readily excreted in bile or urine.

The rate ( $R$ ) that the liver or kidney can remove drug from the body is usually proportional to the concentration of drug in the blood ( $C$ ) (i.e. first-order kinetics). This proportionality constant is known as drug clearance ( $CL$ ):

$$CL = R/C = (\text{mg}/\text{min})/(\text{mg}/\text{l}) = \text{l}/\text{min} \quad (3)$$

The process of normalising rate (e.g. mg/min) for concentration (e.g. mg/l) produces a constant with the units of flow (l/min). For an organ, the clearance can be shown to be equal to the blood flow ( $Q$ ) through the organ multiplied by the extraction ratio of the drug across the organ ( $E$ ). If the liver, for example, completely removes all drug passing through it, then  $E = 1$  and the clearance of the drug is hepatic blood flow. If half the drug is removed,  $E = 0.5$  and the clearance is half the hepatic blood flow. Clearance can also be calculated for the whole body, where it represents the total rate of removal of the drug from the body.

### HEPATIC DRUG CLEARANCE

There are a number of factors that affect drug metabolism by the liver, but they can be classified by the extraction ratio of the drug across the liver: high ( $> 0.7$ ), intermediate or low ( $< 0.3$ ).

- *High extraction drugs:* There is a relative excess of the enzymes that metabolise a drug (i.e. a high intrinsic clearance). The rate-limiting step is supply of the drug to the liver, so hepatic clearance depends on hepatic blood flow (which is proportional to cardiac output<sup>37</sup>) and is unaffected by changes in the amount of active enzyme (and therefore enzyme inhibition or enzyme induction) and changes in free fraction of the drug.
- *Low extraction drugs:* There is a relative shortage of the enzymes that metabolise the drug (i.e. a low intrinsic clearance) and the rate-limiting step is the activity of the enzymes themselves. Hepatic clearance is independent of hepatic blood flow but is affected by enzyme inhibition or enzyme induction, other competing drugs, and changes in free fraction of the drug (the form accessible to the enzyme).

When the concentration of some drugs is relatively high (e.g. ethyl alcohol, phenytoin, high-dose barbiturates), the metabolic pathway becomes saturated, and the drug is slowly eliminated at a fixed rate (i.e. a zero-order process). A corollary is that small increases in a dose of a drug will cause marked sustained increases in plasma concentration during zero-order kinetics compared with administration during first-order elimination kinetics.

### RENAL DRUG CLEARANCE

Three processes govern the net clearance of a drug or metabolite by the kidneys: glomerular filtration, tubular secretion and tubular reabsorption. Filtration in the glomerulus normally allows the passage of the free but not protein-bound drug into the renal tubules. Therefore, drugs that are not subject to tubular secretion or reabsorption have a renal clearance that equals the glomerular filtration rate (normally 0.1 l/min). Drugs that are actively secreted into the tubules (usually charged molecules) can have higher renal clearances up to a theoretical maximum of renal blood flow (1.2 l/min). Drugs that are lipophilic and uncharged are filtered, but rapidly diffuse back across the tubule into the blood stream so that their net renal clearance is zero.

### HALF-LIFE IN THE BODY

For a given drug, each organ of the body has characteristic rates of distribution (equilibration half-life) or clearance (extraction). When these complex processes are summed together, however, the sum appears to reduce to changes in blood concentrations that can be described by one, two or three exponential functions, each with an associated half-life term. Half-lives can describe the rate

of decline of the blood drug concentration following a dose, or the rate of increase in concentration during an infusion. Half-life is defined as the time taken for the drug concentration in the blood to decrease (or increase) by 50%, and when only one half-life is evident it is related to distribution volume and clearance as follows:

$$t_{1/2} = 0.693 \times V/CL \quad (4)$$

In this case, clearance and distribution volume describe the apparent behaviour of the drug in the body as a whole. This volume and clearance can be used to calculate dose regimens for this special case.

- *Intravenous bolus dose:* Shortly after a bolus dose of  $A$  mg, the initial blood concentration will be:

$$A/V \quad (5)$$

It will decline to 50% of this concentration in one half-life, and to 6% of this concentration in four half-lives.

- *Intravenous infusion:* For a constant rate infusion of  $X$  mg/min, the final steady-state concentration during the infusion will be:

$$X/CL \quad (6)$$

It will reach 50% of this concentration in one half-life, and 94% of this concentration in four half-lives.

The distribution volume can sometimes provide information about the location of a drug in the body:<sup>38</sup> a drug that distributes only in the *intravascular space* (e.g. one that is tightly bound to plasma proteins, such as indocyanine green) will have a distribution volume of about 0.075 l/kg; a drug that distributes into the *extracellular space* (e.g. one that is charged and cannot cross cell membrane, such as furosemide) will have a distribution volume of about 0.21 l/kg; and a drug that distributes into the *total water space* (e.g. one that is uncharged, lipophilic but does not bind to proteins, such as antipyrine) will have a distribution volume of about 0.6 l/kg. Drugs with higher distribution volumes can be assumed to be bound in blood and/or tissues.

### INTERPRETING HALF-LIVES

Clinicians find the concept of half-life an attractive way to summarise the behaviour of a drug. Its simplicity is appealing, but some caution is required as a drug can have more than one half-life. For many drugs, half-lives can be found that represent initial mixing of the drug in blood, distribution, elimination and sometimes slow sequestration into tissues such as fat. The most relevant half-life(s) is the one that is dominant in determining a drug's duration of action. Thus, elimination half-life is of limited use if termination of drug effect is caused by redistribution after a bolus (e.g. propofol). The measured half-life of drug also depends on the design of the study (whether frequent early blood samples were taken), can be assay dependent (the terminal half-life of propofol

has increased with newer assay methods with lower detection limits) and varies between arterial and venous blood (rapid distribution half-lives are generally more apparent in arterial blood). Finally, the half-life of a drug is not a constant – it depends on the physiological and pathophysiological state of a patient and their drug history.

## PHARMACOKINETIC MODELS

It is feasible to describe the behaviour of drug in the body using the concepts of distribution volumes, clearances and half-lives. However, pharmacokineticists are often required to predict the consequences of dose changes on the concentrations and effects of a drug – this requires a mathematical representation (or model) of the behaviour of drug. A model is defined by a set of equations (representing the basic structure) and a set of parameter values for those equations (representing the behaviour of a specific drug).

There are three basic forms of pharmacokinetic models:

- *Compartmental models* are the most common and most traditional pharmacokinetic model, and assume that the body can be represented by a central compartment and possibly one or more peripheral compartments. While these models have proved serviceable in some areas of therapeutics, as they do not represent organ blood flow they therefore have some limitations in intensive care where patient physiology is labile.
- *Physiological models* represent the major organs of the body, with drug supply to and from the organs dictated by vascular anatomy and organ blood flow. While they have been developed for some important drugs, in particular for animals, they are consequently less common in the literature for humans (with some notable exceptions<sup>23</sup>) because they require a large amount of data for their development. They have the advantage of being able to predict the consequences of changes in both dose regimen and physiological status.
- *Recirculatory models* are an intermediate between compartment and physiological models. Recirculatory models can provide a simple conceptual framework for the important relationship between cardiac output, bolus injection rate and initial drug concentrations<sup>39</sup> that is lacking in compartmental models.

In a traditional pharmacokinetic analysis, the model is fitted to pooled data from a group of patients to estimate, for example, the mean clearance for the group (e.g.  $CL = 1.8$  l/min). In contrast, the population approach is a type of modelling that fits data from individual patients simultaneously.<sup>40</sup> It is possible to estimate not only the mean value of clearance but also its variability in the population (e.g.  $CL = 1.8 \pm 0.2$  l/min). The population pharmacokinetic approach is of particular relevance to intensive care, as it can accommodate wide inter- and intra-patient variability and does not require that all patients in a study have the same dose or blood sampling schedule.

## PRACTICAL APPLICATIONS

### BOLUS INJECTION RATE

Dose regimens specifying an intravenous bolus injection often do not state the time over which the bolus should be administered, and often subjective and highly variable descriptions such as ‘slow’ are used. However, the rate of injection of a bolus is often crucial in determining the magnitude of transient toxic effects. This is because rapid injections cause disproportionately high transient ‘first-pass’ concentrations in arterial blood and target organs. For example, if the peak arterial concentration after 100 mg of propofol injected over 20 seconds is 60 mg/l, it will be only 10 mg/l if it is injected over 2 minutes.<sup>39</sup> High arterial propofol concentrations are associated with adverse haemodynamic effects.<sup>41</sup> Figure 79.3 shows a conceptual hydraulic model which illustrates ways that rapid injections transiently ‘load’ the blood and target organs with drug.

The high ‘first-pass’ concentrations achieved after a bolus injection are also inversely affected by cardiac output, and particular caution is required in low cardiac output states. For example, if an injection of propofol over 20 seconds into a cardiac output of 5 l/min gave a peak arterial concentration of 60 mg/l, then for a cardiac output of 10 l/min the peak concentration would be 30 mg/l, and

for 2 l/min it would be 150 mg/l. The conceptual hydraulic model in Figure 79.3 can also be used to develop a mental picture of how cardiac output affects bolus kinetics. There are very few drugs for which intravenous injection over less than 2 minutes is indicated.

### REPEAT BOLUS OR INFUSION

Whilst drugs with relatively long half-lives and wide therapeutic indices can be given by repeat bolus administration, those with short half-lives and narrow therapeutic indices (e.g. catecholamines) can be given in a more predictable and titratable manner by infusion.

### LOADING DOSES

Drugs with relatively long half-lives (due to large distribution volumes and/or low clearance) can take a considerable amount of time (five times the half-life) to reach steady state once a constant rate infusion is initiated. A loading dose (either a bolus or a short period of higher infusion rate) can decrease the time required to reach steady state by adding additional drug that can compensate for the drug initially being ‘lost’ from the blood into peripheral distribution volumes (see Table 79.1 for drug-specific information on loading doses).

**Figure 79.3** A conceptual hydraulic model of the important factors governing drug disposition after i.v. bolus administration based on recirculatory principles. This example illustrates the case where a drug acts in a well-perfused target organ such as the heart or the brain but has a large volume of distribution. Three water tanks represent drug in the lung, important target organs and the ‘rest of the body’; in each tank *the height of the water is proportional to the drug concentration*. Pipes connect the tanks to represent the circulation; the diameters of the pipes are proportional to the blood flow to each organ. To impart recirculatory characteristics like the real circulation, one-way valves are fitted before and after each tank in the directions shown. Intravenous drug administration corresponds to adding to the lung tank; drug clearance is a ‘leak’ from the ‘body’ tank. The reader is asked to imagine the consequences of a rapid i.v. injection, e.g. pouring a bucket into the lung tank. It can be seen that there will be high levels of water in both the lung and target organ tank until the water has had the time to distribute into the body or be cleared; in vivo this would potentially manifest as transient toxic drug effects in the target organs. By slowing the ‘injection’ down and pouring more slowly, lower peak concentrations can be achieved.

### MAINTENANCE DOSE

Once steady state has been achieved, it is traditionally taught that the steady-state blood concentrations are a function only of dose rate and drug clearance (Eq 6). However, intensivists should be aware that haemodynamic status can also significantly affect the steady-state blood concentration due to the key role of cardiac output (Figure 79.3) and blood flow-dependent clearance.<sup>37</sup> For example, administering catecholamines during a constant rate infusion of propofol could rapidly increase the cardiac output and lower the propofol concentrations in the blood and brain sufficiently to cause emergence from anaesthesia.<sup>42</sup> This behaviour is particularly evident for high clearance drugs.<sup>39</sup>

### CHANGING INFUSION RATES

The immediate effect of changing the rate of drug infusion will depend on the half-life of the drug. For drugs with long half-lives (e.g. midazolam and morphine), an increase in dose requirements should be met by titrating small boluses to achieve the new state, and then increasing the infusion rate by an appropriate amount. Decreases in requirements should be met by switching off the infusion and then restarting at a lower rate after the new desired state has been reached. If severe illness causes the volume of distribution of a drug to be doubled, then its half-life will also be doubled. Severe illness may also decrease clearance of a drug; halving clearance will cause a similar doubling of half-life. Should both effects occur together, half-life will be increased four-fold, having a significant effect on the duration of action of a drug.

### OFFSET TIMES

It should be appreciated that the half-life for some drugs depends on the duration of the infusion. This is particularly evident for drugs with high distribution volumes and whose bolus kinetics are governed significantly by redistribution rather than clearance (e.g. fentanyl). For short infusions, the plasma half-life after the infusion will be less than the terminal elimination half-life. However, as the duration of infusion becomes sufficient to achieve steady state, the half-life upon stopping the infusion will increase until it equals the terminal elimination half-life.<sup>43</sup>

## ROUTES OF DRUG ADMINISTRATION

### ORAL

Traditionally the enteral route has been avoided in the critically ill because alterations in gut motility, blood flow, pH, function and first-pass metabolism by the liver contribute to variability in drug response. Gastric emptying is also impaired by many factors including anticholinergics, antacids, phenothiazines and opioids, inotropes (especially dopamine), traumatic brain injury and diabetes mellitus.

However, there is an increasing trend to resume pre-morbid oral medications as soon as possible after the

intercurrent illness has resolved or vital organ function has stabilised. Furthermore, some commonly used drugs have no suitable parenteral equivalents (e.g. statins, angiotensin-converting enzyme inhibitors, angiotensin II inhibitors, aspirin, digoxin, oral anticoagulants and some antibiotics such as fusidic acid and rifampicin). Consequently, the use of the oral route is becoming more common. One confounding issue is that critically ill patients are increasingly also fed via the enteral route.<sup>44</sup> Enteral feeding may reduce drug availability due to absorption of drug onto enteral feed components, nasogastric tubing or by reduced absorption due to the pH of the feed. Conversely, the administered drug has the potential to block the feeding tube.

### SUBCUTANEOUS AND INTRAMUSCULAR

Subcutaneous and i.m. injection may also be unpredictable because systemic transfer of drug is dependent on blood flow at the site of injection, which in turn depends on posture, activity, site of injection and degree of vasoconstriction or vasodilatation at that site.

### INTRAVENOUS

The i.v. route is used for speed, convenience, reliability, titratability and lack of enteral formulations of some drugs. Intravenous apparatus including glass, plastics and rubber may absorb drugs, decreasing the dose delivered (e.g. insulin, heparin, amiodarone). When several drugs are delivered through the same i.v. line, chemical incompatibility may also occur. This may be a result of pH effects altering solubility, solvent effects (e.g. precipitation of the propylene glycol used to dissolve some preparations of diazepam when diluted excessively) and cation-anion interactions causing precipitation or formation of less active, yet soluble complexes (e.g. thiopentone or calcium in combination with most other drugs). Although precipitation can be detected by visual inspection, lack of visual changes does not mean there has not been loss of potency (e.g. heparin and dopamine, insulin and total parenteral nutrition).<sup>45</sup>

When infusing drugs i.v., the method of administration can alter the amount of drug delivered dramatically. Simple infusions using a drip chamber to regulate flow are not adequate when infusing inotropes, and mechanical drop counters and peristaltic pumps may be erratic, especially if drug is not adequately diluted and the flow rate is low. Syringe pumps are the most accurate, but may also be unreliable at low flow rates (1–2 ml/h). As siphoning from or flushing of i.v. lines can also result in drug overdose, it is essential that anti-reflux valves are used when more than one infusion is running into a single i.v. site.

## PK-PD CHANGES IN CRITICAL ILLNESS

Critically ill patients often have multiple organ dysfunction, causing alterations in drug handling and effect in the body at all levels. The net effect of these multiple

changes is difficult to predict. Frequently, the main effect is to increase inter-patient variability in response, even if typical patient response is altered little. Intra-patient variability also occurs over brief periods of time in response to changes in a patient's condition.

### CIRCULATORY FAILURE

Circulatory failure causes a greater percentage of cardiac output to go to essential organs (e.g. heart and brain) and decreased blood flow to peripheral tissues (Table 79.2). The net effects are:

- Increased drug concentrations in the heart and brain (Figure 79.3)
- Decreased drug concentrations in the periphery
- Decreased renal blood flow and shunting of blood from cortical to juxtamedullary nephrons. Glomerular filtration rate and tubular excretion are decreased, decreasing extraction of drugs and metabolites
- Decreased liver blood flow. Hepatocellular function may be impaired, decreasing clearance of both highly extracted drugs due to failure of delivery to the liver, and of poorly extracted drugs due to failure of cellular metabolism

**Table 79.2** Distribution of cardiac output in healthy and critically ill patients

Organ	% Body weight	% Cardiac output	Change in % of cardiac output in critical illness
Lungs	2	100	Nil
Heart	0.5	5	+++
Brain	2	14	+++
Kidneys	0.5	23	---
Liver/splanchnic	10	28	---
Endocrine/bone marrow	2	6	--
Skin	6	9	--
Muscle	50	16	--
Fat	15	5	--
Other	12	5	--

In the critically ill, cardiac output may vary widely depending on therapy, and distribution will depend on the amount of peripheral vasoconstriction (e.g. from hypovolaemia) or vasodilatation (e.g. from systemic inflammatory response syndrome).

Mechanical ventilation may cause further decreases in liver blood flow by increasing intrathoracic pressure and therefore decreasing venous return.

The initial effect is a large decrease in distribution volumes and clearance of drugs. The effects are more profound on drugs that are usually rapidly distributed such as sedatives. Fluid and inotropic therapy may alter these effects over brief periods of time. With volume overload, there may be an increase in initial distribution volume but with a more prolonged distribution half-life.

### HEPATIC FAILURE

Hepatic failure may increase or decrease volume of distribution and total body clearance, and increase excretion half-life of hepatically metabolised drugs. Loading doses are often not greatly affected. In the critically ill, there is usually a decrease in liver blood flow and therefore the rate at which drugs are delivered to the liver for metabolism. Flow-dependent drugs include morphine, propofol, labetalol, metoprolol and atropine (Table 79.1). Vaso-pressors do not usually decrease liver blood flow because of increases in cardiac output.

There is a poor correlation between derangement of conventional tests of liver function and the degree of impairment of drug metabolism. In addition, the degree of impairment may vary widely over short periods of time. In the critically ill, metabolism of some drugs will almost cease, as indicated by a lack of formation of metabolites and very high plasma concentrations (e.g. midazolam<sup>46</sup>).

Hepatic failure tends to decrease the amount of drug bound because of accumulation of metabolites which compete for binding sites on protein. For example, elevated concentrations of bilirubin decrease protein binding of sulphonamides, tetracyclines, penicillins and cephalosporins. A decrease in protein binding will offset increases in volume of distribution when the drug is highly protein bound, such as most penicillins and erythromycin. For drugs with low protein binding, such as aminoglycosides, a decrease in protein binding will have little effect on free plasma concentrations.

### RENAL FAILURE

Renal drug clearance is reduced by renal failure, and distribution volumes will increase if there is significant fluid retention leading to increased half-lives of drugs cleared by the kidneys. Drug doses may be decreased to as little as 10% of normal. In the case of drugs that are metabolised by the liver and metabolites excreted by the kidneys, there may be accumulation of active metabolites (e.g. morphine-6-glucuronide). Renal failure usually affects glomerular function more than tubular function, so excretion of aminoglycosides which depend more on glomerular filtration are affected more than excretion of penicillins which are dependent on tubular function.

Creatinine clearance is usually a poor guide to renal function in the critically ill because there may be

alterations in the rate of formation of creatinine as well as its excretion by the kidneys. Algorithms for drug dose based on creatinine clearance may be similarly unreliable, particularly in critically ill patients. Accumulation of metabolic products may cause decreases in protein binding of drugs. For example, uraemia decreases binding of penicillins, sulphonamides and cephalosporins and in the case of phenytoin excretion is increased.

Renal replacement therapy drastically alters volumes and clearances of drugs. Effects vary with the mode of dialysis, the type of membrane in use and the drugs in question. For most modern membranes little information is available, but what is known has been reviewed.<sup>47</sup>

### SYSTEMIC INFLAMMATORY RESPONSE SYNDROME

In acute severe illness, such as sepsis and multiple organ failure, there is an increase in capillary permeability and total body water secondary to the increased capillary permeability and hypoalbuminaemia. This increases the volume of distribution of drugs, so that increased loading doses may be required to attain a satisfactory therapeutic concentration. Similar changes occur in patients with major burns, and this may be due to circulating cytokines. The volume of distribution may also change over short periods of time. When patients start to recover, serum concentrations may increase because of the decreasing volume of distribution of the drug (e.g. vancomycin<sup>48</sup>) as well as decrease because of resumption of normal metabolism and clearance (e.g. midazolam<sup>46</sup>). Circulatory, hepatic and renal failure may also add the characteristic changes already described, of decreased clearance or metabolism and accumulation of active metabolites.

### CHANGES IN RECEPTORS IN ACUTE ILLNESS

Drug receptors may change in the critically ill, affecting drug response. One cause of tolerance, which is a decreased drug effect for a given dose or plasma concentration, is altered receptor function. Catecholamines show an increase in receptor numbers in response to a lack of agonist (upregulation) and a decrease in receptor numbers in response to increased concentrations of agonist (downregulation). Drug affinity for receptors is also pH dependent. Acidosis decreases the affinity of catecholamines for their receptors, and is a significant problem when there is a pH < 7.1. Hypothermia also decreases drug affinity for receptors.

Proliferation of extrajunctional acetylcholine receptors on muscle after acute injuries such as burns and denervation can lead to hyperkalaemia following the use of suxamethonium.

### PROTEIN BINDING

For most drugs, it is the free (unbound) drug that can enter an organ and bind to receptors, be metabolised or be eliminated (Figure 79.2). Albumin is the dominant

binding protein in plasma, and the extent of binding is related in a non-linear manner to the concentration of albumin.<sup>49</sup> In most cases, the number of drug-binding sites available on albumin greatly exceeds the number of drug molecules, and the free drug concentration is proportional to the total drug concentration. Most acidic drugs, including all antibiotics, bind to albumin. Basic drugs, such as phenytoin and propranolol, bind mainly to  $\alpha_1$ -acid glycoprotein. During acute illness,  $\alpha_1$ -acid glycoprotein concentrations increase, with increased drug binding. Lipoproteins can bind highly lipophilic drugs such as propofol. It is also important to consider the dissociation rate of the drug-protein complex.<sup>50</sup> When this is slow, the binding is 'restrictive' (e.g. warfarin) and free drug concentrations are very important. When dissociation is fast, the binding is 'permissive' (e.g. propranolol) and free drug concentrations are less important for processes such as hepatic clearance where rapid dissociation from protein can supply drug to liver enzymes within one pass through the liver.

Changes in protein binding in critical illness can occur due to drug interactions at the protein binding site<sup>50</sup> or changes in the concentrations of binding protein. However, the net effect is drug dependent, and can be negligible if the free concentration determines both drug effect and drug clearance. Changes can be significant in some contexts. Midazolam (usually 96% protein bound) increases its effect in renal failure despite increased clearance, due to reduced protein binding.<sup>51</sup> Similarly, the anaesthetic effect of propofol increases during haemodilution due to increases in free propofol concentration, even though the total concentration is unchanged.<sup>52</sup>

### DRUG MONITORING

If no alternative is available, it may be necessary to use a drug with a narrow therapeutic index. When no direct clinical measure of clinical response is possible, plasma drug concentrations may be measured if there is a relationship between this concentration and pharmacological effects (efficacy and/or toxicity). Toxicity may be associated with peak drug concentration (e.g. seizures and arrhythmias from theophyllines) or with mean concentration (e.g. ototoxicity from aminoglycosides). Some drugs for which there are accepted therapeutic and/or toxic concentrations are shown in Table 79.3.

Drug assays usually measure total plasma concentration of the drug; however, it is the fraction not bound to proteins in plasma that is responsible for the pharmacological effect(s). These plasma protein levels do change during critical illness and so the unbound fraction can be different from that in relatively healthy persons, thus modifying the relationship between measured drug concentration and clinical effect. Regardless of measured concentration, evidence of clinical efficacy or toxicity

Table 79.3 Therapeutic drug monitoring in the critically ill

Drug	Therapeutic concentrations	Toxic effects and guidelines to dosage
<b>Antiarrhythmics</b>		
Digoxin	0.5–0.8 ng/ml in CHF patients <sup>53</sup>	Monitor ECG – dysrhythmia/conduction defects
<b>Antibiotics</b>		
Gentamicin	Peak 5–10 µg/ml, trough < 2	Renal and ototoxicity Once daily high dose Check trough (or extended dosing interval use trough < 0.5 µg/ml)
Amikacin	Peak 8–16 µg/ml, trough < 4	As above
Vancomycin	Peak 20–40 µg/ml, trough < 10	
<b>Anticonvulsants</b>		
Phenytoin	10–20 mg/l	Arrhythmias Check free concentration if uraemia/low albumin
<b>Theophyllines</b>		
Aminophylline	10–20 mg/l	> 25 mg/l

must be monitored regularly and the drug concentration used as a part of the clinical decision process with the view to individualising the patient's dosage to optimise beneficial response(s). Given these considerations, the relatively small expense of therapeutic drug monitoring must be weighed against the risks of toxicity or treatment failure.

#### DRUG BY DRUG SUMMARY

Table 79.1 summarises the kinetic properties of some drugs commonly used in intensive care. The reader is referred to other chapters in this book for detailed commentary on the use of specific drugs.

#### ACKNOWLEDGEMENTS

Updated and modified from the chapter in the previous edition by T G Short and G C Hood. Dose regimens in Table 79.1 are modified from the ICU Handbooks of the Royal Adelaide Hospital (2003) and Waikato Hospital (2004). Dose regimens are for illustration only and local guidelines should be consulted.

# Management of acute poisoning

Duncan L A Wyncoll

Acute poisoning remains one of the commonest medical emergencies, accounting for 5–10% of hospital medical admissions. Although in the majority of cases the drug ingestion is intentional, the in-hospital mortality remains low (< 0.5%).<sup>1</sup> There are specific antidotes available for a small number of poisons and drugs; however, in most intoxications, basic supportive care is the main requirement and recovery will follow. This chapter is a hands-on guide to the general management of acute poisoning and drug intoxication. Larger reference books should be sourced, or internet-based information services (e.g. Toxbase – <http://www.spib.axl.co.uk>) referred to, if specific detail is required.

Clinical toxicology remains an experience-based specialty; consequently, many recommendations are based on a small literature of case reports, rather than controlled clinical studies. In recent years, toxicological experts have produced position statements and clinical guidelines on certain aspects of care, and these will be referenced when possible.

## GENERAL PRINCIPLES

The general principles of the management of poisoned patients are diagnosis, clinical examination and resuscitation, investigations, drug manipulation, specific measures and continued supportive care. In the more acute situations, these actions often have to be carried out simultaneously.

## AIRWAY AND VENTILATION

In acute poisoned patients who are unconscious, dentures should be removed and the oropharynx cleared of food and vomit. Tracheal intubation and airway protection is almost always necessary when a patient tolerates insertion of an oropharyngeal airway. Inadequate spontaneous ventilation, determined clinically or by arterial blood gas (ABG) analysis, obviously requires ventilatory support. Venous access should be established, and circulatory assessment must be made. Basic observations, including blood pressure, pulse rate, peripheral perfusion and urine output, should be recorded. There are very few tricks or traps as to the use of invasive monitoring and inotropic drugs, and the principles are similar to those covered elsewhere in this book.

## CLINICAL EXAMINATION

A standard clinical examination should be carried out, looking particularly for needle marks or evidence of previous self-harm. The Glasgow Coma Scale, although designed for head-injured patients, is frequently used. However, descriptive documentation of the degree of impaired consciousness is much more valuable. When patients are unconscious and no history is available, the diagnosis depends upon excluding other common causes of coma (Table 80.1) and consideration of any circumstantial evidence. Specific attention should be paid to the temperature, pupil size, respiratory and heart rate, as these may help to restrict the list of potential toxins (Table 80.2).

## INVESTIGATIONS

Important initial investigations include:

- *Urinalysis*: with a sample kept for later analysis if required (rapid reaction dipsticks are available to screen for common drugs of abuse/recreational drugs; however, their reliability is questioned by some).
- *Basic biochemistry*: many drugs are dependent on renal elimination. Significant renal insufficiency may alter management.
- *ABG analysis*: Metabolic and/or respiratory acidosis is most common. Aspirin may initially cause a respiratory alkalosis. Metabolic alkaloses are unusual.
- *Anion gap* =  $([\text{Na}^+] + [\text{K}^+]) - ([\text{Cl}^-] + [\text{HCO}_3^-])$ : It is normally 10–14. Ethanol, methanol, ethylene glycol, metformin, cyanide, isoniazid or salicylates are the most frequent causes a high anion gap metabolic acidosis in clinical toxicology.
- *Osmolal gap*: this is the difference between the laboratory measured osmolality ( $O_m$ ) and the calculated osmolality ( $O_c$ ).  $O_c = 2(\text{Na}^+ + \text{K}^+) + \text{urea} + \text{glucose}$ . The osmolal gap is normally < 10. Causes of a raised osmolal gap are ethanol, methanol and ethylene glycol.
- *Chest X-ray*: inhalation of gastric contents is not uncommon.
- *Drug levels*: these are rarely helpful except in specific poisonings. They include paracetamol, salicylates, iron, digoxin and lithium.

**Table 80.2** Clinical effects of the common poisons

<b>Convulsions</b>	Tricyclics, isoniazid, lithium, amfetamines, theophylline, carbon monoxide, phenothiazines, cocaine
<b>Skin</b>	
Bullae	Barbiturates, tricyclics
Sweating	Salicylates, organophosphates, amfetamines, cocaine
<b>Pupils</b>	
Constricted	Opioids, organophosphates
Dilated	Hypoxia, hypothermia, tricyclics, phenothiazines, anticholinergics
<b>Temperature</b>	
Pyrexia	Anticholinergics, tricyclics, salicylates, amfetamines, cocaine
Hypothermia	Barbiturates, alcohol, opioids
<b>Cardiac rhythm</b>	
Bradycardia	Digoxin, $\beta$ -blockers, organophosphates
Tachycardia	Salicylates, theophylline, anticholinergics
Arrhythmias	Digoxin, phenothiazines, tricyclics, anticholinergics

## GUT DECONTAMINATION

### EMESIS

Ipecacuanha-induced emesis is no longer recommended for two reasons:<sup>2</sup> first, it is ineffective at removing significant quantities of poisons from the stomach and, second, it limits the use of activated charcoal.

### GASTRIC LAVAGE

Unless performed within 1 hour of drug ingestion, it is no longer recommended.<sup>3</sup> The joint American and European toxicologists' statement states that if performed after this time the amount of poison removed is insignificant, and lavage may only propel unabsorbed poison into the small intestine. However, this view has recently been questioned and is based on limited data.<sup>4</sup> Prior intubation is essential when laryngeal competence is absent or doubtful, especially because, in the majority of overdoses, pulmonary aspiration is more lethal than the ingested drug.

To perform gastric lavage, the patient should be positioned head-down on the left side, and then a large-bore tube (36–40 Fr) with large side holes is passed into the stomach. The tube is aspirated before lavage is started, then tepid water instilled and recovered completely before continuing. The lavage is repeated until the return is clear; stomach massage or gastroscopy may assist removal of coalesced drug masses. Sodium, water and heat balance are of major importance in children. Gastric lavage is contraindicated in ingestions of corrosives, caustics and acids as oesophageal or gastric perforation may occur. Inhalation of petrol, paraffin or white spirits can cause intense pneumonitis.

### ACTIVATED CHARCOAL

Activated charcoal (AC) remains the first-line treatment for most acute poisonings.<sup>5</sup> Owing to its large surface area and porous structure it is highly effective at adsorbing many toxins with few exceptions. Exceptions include elemental metals, pesticides, strong acids and alkalis, and cyanide. It should be given to all patients who present within 1 hour of ingestion, although it is also acceptable to administer it after 1 hour if it follows an overdose of a substance that slows gastric emptying (e.g. opioids, tricyclic antidepressants). Because of international guidelines recommending administration of AC within 1 hour, it is vital to identify rapidly those who present after a potentially serious overdose so that it can be given swiftly.<sup>6</sup>

Repeated doses of AC can increase the elimination of some drugs by interrupting their entero-enteric and enterohepatic circulation. Indications for repeated dose AC are shown in Table 80.3.<sup>7</sup> AC is given in 50 g doses for adults and 1 g/kg for children. It commonly causes vomiting; therefore consider giving an antiemetic prior to administration. Repeated doses are given at 4-hourly intervals.

### WHOLE BOWEL IRRIGATION

This is a newer method of gastric decontamination that is indicated for a limited number of poisons.<sup>8</sup> Whole bowel irrigation involves administration of non-absorbable polyethylene glycol solution to cause a liquid stool and reduce drug absorption by physically forcing contents rapidly through the gastrointestinal tract. Polyethylene glycol preparations are still occasionally used in surgical units for 'bowel preparation' prior to surgery. It may have a

**Table 80.3** Drug intoxications where multiple-dose activated charcoal may be beneficial

Carbamazepine
Theophylline
Digoxin
Quinine
Phenobarbital
Dapsone
Sustained-release preparations

role in treating large ingestions of drugs that are not absorbed by AC. Indications include large ingestions of iron or lithium, ingestion of drug-filled packets/condoms ('body packers'), and large ingestions of sustained-release or enteric-coated drugs (e.g. theophylline or calcium channel blockers). At present, efficacy is based on case reports alone.

### ENHANCING DRUG ELIMINATION

In the overwhelming majority of patients who present after an overdose, gut decontamination techniques and supportive care are all that is required. In a limited number of acute poisonings it may be necessary to consider methods to enhance elimination.

### URINARY ALKALINISATION

Urinary alkalisation (previously termed *forced alkaline diuresis*) may be useful for serious poisonings with:

- salicylates
- phenobarbital (with repeated dose AC)
- chlorpropamide
- methotrexate

Intravenous sodium bicarbonate (approximately 1.26%) is infused to maintain a neutral balance and attempt to achieve a urine pH of approximately  $\geq 7.5$ . The term 'urine alkalisation' emphasises that urine pH manipulation is the prime objective of treatment; the terms 'forced alkaline diuresis' and 'alkaline diuresis' should be discontinued. According to international position statements it should be considered the treatment of choice for moderate to severe salicylate poisoning.<sup>9</sup> Care must be taken to ensure the potassium does not fall rapidly.

### EXTRACORPOREAL TECHNIQUES

Numerous extracorporeal techniques are potentially available to aid drug removal in the poisoned patient. These include plasmapheresis, haemodialysis, haemofiltration, haemodiafiltration and haemoperfusion. There are limited data on drug clearance by these techniques in the literature and it is not possible to extrapolate from one system to the other. At present, knowledge of the principles of the methods and the kinetics of the drug involved is relied upon.

Extracorporeal techniques should only be considered when there are clinical features or markers of severe toxicity, failure to respond to full supportive care coupled with poisoning by a drug that can potentially be removed. Impairment of the normal route of elimination of the compound may also influence the decision. Use of extracorporeal techniques is probably only worthwhile if total body clearance is increased by at least 30%. Haemoperfusion is rarely performed in most intensive care units and intermittent haemodialysis is often confined to renal

units. Consequently, the use of continuous haemofiltration, with or without dialysis, using filtration rates of greater than 50–100 ml/kg per hour, is likely to be as equally effective as when an extracorporeal technique is indicated.

### CONTINUED SUPPORTIVE THERAPY

Self-poisoned patients do not always meet with the sympathies of the admitting medical team. Try to think of such patients as medical challenges, rather than merely instances of self-inflicted illness. Apart from specific measures that are described later, general care of the unconscious unstable patient should be continued. This includes monitoring of vital signs and provision of organ support when necessary. Attention should also be paid to fluid balance, correction of electrolytes, initiation of nutritional support, and prompt treatment of nosocomial infection.

Overall, in spite of the significant initial physiological disturbance, this group of patients usually has a good outcome.

### SPECIFIC THERAPY OF SOME COMMON OR DIFFICULT OVERDOSES

This section emphasises only those features that may aid clinical diagnosis or prognosis. Treatment suggestions are always intended to support those measures described under general principles. Some new and controversial therapies are mentioned.

### AMPHETAMINES (INCLUDING 'ECSTASY', MDMA)

#### CLINICAL FEATURES

Symptoms of mild overdose include sweating, dry mouth and anxiety. Although the majority of ecstasy patients are dehydrated, a proportion have hyponatraemia from drinking water to excess. More severe features include hypertonia, hyperreflexia, hallucinations and hypertension. Supraventricular dysrhythmias may follow with coma, convulsions and the risk of haemorrhagic stroke. A hyperthermic syndrome may develop with hyperpyrexia leading to rhabdomyolysis, metabolic acidosis, acute renal failure, disseminated intravascular coagulation (DIC) and multiple organ failure.<sup>10</sup>

#### TREATMENT

AC should be considered up to 1 hour post ingestion. Benzodiazepines are useful for agitated or psychotic patients and may have a central effect in reducing tachycardia, hypertension and hyperpyrexia. If benzodiazepines fail to control hypertension, other classes of antihypertensives should be started, such as  $\alpha$ -blockers, labetalol or direct vasodilators. Hypertonic saline may need to be considered in severe hyponatraemia. Hyperthermia should be

treated in the standard manner including administration of cold fluids. Dantrolene has been used in the treatment of ecstasy-related hyperpyrexia; however, it has been suggested that it treats the effects and not the cause, and that it may be better to direct treatment at the central mechanisms of thermoregulation.<sup>11</sup> Beyond this, there have been a few reports of the use of clozapine or olanzapine as a treatment for hyperpyrexia.

## BARBITURATES

### CLINICAL FEATURES

The central nervous, cardiovascular and respiratory systems are depressed. Cardiovascular depression is due to vasomotor centre depression and a toxic effect on myocardium and peripheral vessels. Hypotension and relative hypovolaemia may be significant.

### TREATMENT

Treatment is supportive; however, repeated dose AC and urinary alkalinisation should be considered.

## BENZODIAZEPINES

### CLINICAL FEATURES

Overdose is common, but clinical features are not usually severe unless complicated by other CNS depressant drugs (such as alcohol), pre-existing disease or the extremes of age. Toxicity commonly produces drowsiness, dysarthria, ataxia and nystagmus; however, agitation and confusion can occur.

### TREATMENT

AC can be given if patients present within 1 hour of ingestion, yet supportive treatment is usually all that is required. Flumazenil is a specific antagonist, but its brief duration of action limits its use to diagnostic purposes. Moreover, as flumazenil may cause other symptoms in patients who have ingested a cocktail of drugs (e.g. precipitation of fits in patients co-ingesting tricyclic antidepressants), its administration risks increasing morbidity and mortality.<sup>12</sup>

## β-BLOCKERS

### CLINICAL FEATURES

There is a wide variation in the individual response to β-blocker overdose. Those with cardiac disease are more at risk of complications. Hypotension and bradycardia predominate and are often refractory to standard resuscitation measures. The degree of heart block can range from a prolonged PR interval through to complete heart block and asystole. Cardiogenic shock and pulmonary oedema are not uncommon.<sup>13</sup>

### TREATMENT

AC should be considered up to 1 hour post ingestion and multiple-dose charcoal in patients who have ingested sustained-release preparations. The role of atropine is

not clear, although it is commonly used in patients who have bradycardia and hypotension. If symptomatic treatment fails, then other options such as glucagon (up to 10 mg i.v.), an adrenaline infusion or cardiac pacing are indicated. Although part of medical folklore, the evidence for glucagon is limited to animal studies.<sup>14</sup> It often comes as a dried powder with a phenol diluent, so if used, the glucagon powder should be dissolved in 5% dextrose, since the phenol diluent in large amounts is a myocardial depressant.

## BUTYROPHENONES (INCLUDING HALOPERIDOL)

### CLINICAL FEATURES

Drowsiness and extrapyramidal effects are most common. Rarely hypotension, QT prolongation, arrhythmias and convulsions develop.

### TREATMENT

AC should be considered up to 1 hour post ingestion, otherwise treatment is supportive. Extrapyramidal symptoms can be treated with procyclidine or benztropine. If ventricular arrhythmias do occur they are best treated with cardioversion; Class 1a antiarrhythmics are theoretically detrimental.

## CALCIUM CHANNEL BLOCKERS

### CLINICAL FEATURES

The cardiac effects of these drugs predominate in overdose, particularly hypotension and atrioventricular block, although reflex tachycardia occurs with nifedipine. Hypotension occurs due to peripheral vasodilatation and negative inotropy. Severe toxicity may occur in patients who initially appear well, when sustained-release preparations have been ingested.

### TREATMENT

AC should be considered up to 1 hour post ingestion and multiple-dose charcoal in patients who have ingested sustained-release preparations. Treatment remains supportive; however i.v. calcium chloride is often given in patients who remain hypotensive despite fluid administration.<sup>15</sup> Atropine is often used for bradycardia, and occasionally cardiac pacing may be necessary. In persistent low cardiac output states, phosphodiesterase inhibitors, levosimendan or high-dose insulin may need to be considered.<sup>16</sup>

## CANNABIS

### CLINICAL FEATURES

Overdose is unusual following smoking of cannabis; however, high doses can produce an acute paranoid psychosis. Ataxia, nystagmus, tachycardia and confusion have been reported after ingestion in children. In adults, i.v. abuse of the crude extract may cause abdominal pain, fever, hypotension, pulmonary oedema and DIC.

**TREATMENT**

Treatment is supportive and most patients only have mild symptoms. AC should be considered for children who have ingested cannabis.<sup>17</sup>

**CARBAMAZEPINE**

Absorption is slow and unpredictable; moreover, maximum serum concentrations may not be achieved until 72 hours after ingestion. Carbamazepine undergoes enterohepatic recirculation and is metabolised to an active metabolite.

**CLINICAL FEATURES**

Nystagmus, ataxia, tremor and fits are common but, in severe overdose, fluctuating coma and severe tachycardia or bradycardia may occur. Plasma concentrations of carbamazepine and the active metabolite can be measured, but they do not correlate well with toxicity.

**TREATMENT**

Gastric lavage should be used if a patient presents within 1 h of a massive overdose. Multiple-dose AC is indicated in large ingestions or symptomatic patients, and may help elimination even if initiated several hours after the overdose.

**CARBON MONOXIDE (CO)**

Haldane first described symptoms of CO toxicity in 1919 and the mechanisms of toxicity remain unclear. Smokers may have up to 10% of their haemoglobin bound to CO (i.e. carboxyhaemoglobin, COHb) without deleterious effects. During CO poisoning, oxygen delivery to the heart and brain is increased. There is no marker that reliably detects CO poisoning. Whilst coma and/or COHb levels > 40% always indicate serious poisoning, delayed deterioration can occur in their absence. Affinity of CO for haemoglobin is approximately 240 times that of oxygen.

**CLINICAL FEATURES**

Neurological signs vary from mild confusion through to seizures and coma. A history of loss of consciousness should always be sought and may be the only indicator of significant poisoning. ST segment changes may be present on electrocardiogram (ECG). In the absence of respiratory depression or aspiration,  $P_{aO_2}$  will be normal. It is essential that  $SaO_2$  is measured directly by a co-oximeter, and not calculated. Cherry-pink skin is only seen in textbooks; cyanosis is far more common.

**TREATMENT**

After basic resuscitative measures, high-flow oxygen (up to 100% if possible) should be administered and continued until the COHb level is less than 5%. This sometimes takes up to 24 hours. Hyperbaric oxygen (HBO), although often used, remains controversial. There have been eight randomised controlled trials of HBO versus normobaric oxygen. Unfortunately, many of these are of poor quality and it is not possible to show

any statistical benefit of HBO in reducing neurological sequelae at 1 month.<sup>18</sup> Considering the frequently encountered logistical difficulties in transferring an unconscious patient to an HBO centre, it cannot be recommended based on the data currently available.

**CHLOROQUINE****CLINICAL FEATURES**

Hypotension, hypokalaemia, convulsions, ventricular arrhythmias and sudden cardiac arrest may result from severe poisoning.

**TREATMENT**

AC should be considered up to 1 hour post ingestion. Vasopressors may be required until hypotension is reversed, together with diazepam for agitated patients. Hypokalaemia is common and may be protective in the early stage. It is self-correcting and consequently aggressive potassium replacement is not recommended.<sup>19</sup>

**COCAINE****CLINICAL FEATURES**

Features of severe intoxication include hyperreflexia, drowsiness and convulsions.<sup>20</sup> Severe hypertension may cause subarachnoid or intracerebral haemorrhage, and coronary artery spasm may result in myocardial infarction or ventricular arrhythmias; fatalities generally occur early. Hyperthermia associated with rhabdomyolysis, acute renal failure and DIC may also occur.

**TREATMENT**

The toxic dose is variable and depends upon tolerance, presence of other drugs and route of administration, but ingestion of > 1 g is potentially fatal. Blood pressure and ECG monitoring should be instituted early and AC administered within 1 hour of ingestion. Benzodiazepines are useful for agitated or psychotic patients and may have a central effect in reducing tachycardia, hypertension and hyperpyrexia. If benzodiazepines fail to control hypertension, other classes of antihypertensives should be started, such as  $\alpha$ -blockers, labetalol or direct vasodilators such as i.v. nitrates. The use of  $\beta$ -blockers is controversial and should be used with caution because of the risk of unopposed  $\alpha$ -stimulation. Hyperthermia should be treated in the standard manner including administration of cold fluids, physical cooling measures and in the presence of convulsions, sedation, paralysis and ventilation.

**CYANIDE****CLINICAL FEATURES**

Severe toxicity is rapidly fatal; however, features include coma, respiratory depression, hypotension and metabolic acidosis. More moderate features include brief loss of consciousness, convulsions and vomiting. Rescuers must ensure that they do not get contaminated themselves.

**TREATMENT**

Inhaled amyl nitrate and 100% oxygen may well have been given at the scene, since it is present in 'cyanide antidote kits'. Following this there are a number of options:

1. Patients with severe features need dicobalt edetate 300 mg i.v. over 1 minute, followed by 50 ml dextrose 50% i.v., with a further 300 mg if there is no response.
2. Patients with moderate features should be given sodium thiosulphate 12.5 g i.v.
3. Hydroxocobalamin i.v. can also be given, but suitable preparations are not always available.
4. Patients with a metabolic acidosis should be given sodium bicarbonate.

**DIGOXIN****CLINICAL FEATURES**

Toxicity may result from ingestion of greater than 2–3 mg, or more commonly from taking too high a daily dose and/or a reduction in renal elimination. Any cardiac arrhythmia may occur and adverse effects may be delayed for some hours. Severe poisoning can produce hyperkalaemia and hypotension.

**TREATMENT**

AC should be considered up to 1 hour post ingestion and multiple-dose charcoal may be effective by interrupting enterohepatic recirculation of the drug. A digoxin serum level may be helpful although it does not equate to the total body burden. Hyper/hypokalaemia and hypomagnesaemia should be corrected. Cardiac pacing may be necessary to control symptomatic bradyarrhythmias and amiodarone may be useful for tachyarrhythmias. DC shock should be avoided if possible, but when essential must be initiated at low energy levels. Digoxin-specific antibodies are indicated in severe hyperkalaemia resistant to basic treatment, bradycardia resistant to atropine, or ventricular arrhythmias; repeated dosing is sometimes required in chronic toxicity as tissue redistribution of digoxin from deeper stores occurs.<sup>21</sup>

**GAMMA-HYDROXYBUTYRIC ACID (GHB)****CLINICAL FEATURES**

In moderate to high ingestion (> 50 mg/kg), coma, convulsions, bradycardia, hypotension and severe respiratory depression can be seen, and other CNS depressant drugs potentiate the effects. Most patients who present to hospital merely require supportive care, and even those who present in coma are often awake within 2–4 h; very few require intensive care.<sup>22</sup>

**TREATMENT**

AC can be given for ingestions of > 20 mg/kg if within 1 hour of presentation. Most patients with symptoms should be admitted and observed until symptoms resolve, which is usually fairly quickly. Benzodiazepines are the drug of choice for convulsions.

**IRON****CLINICAL FEATURES**

The corrosive action on gastric mucosa results in vomiting, pain, haematemesis and melaena, and gastric perforation. Severe poisoning is reflected by plasma concentrations more than 90 µmol/l in children and 145 µmol/l in adults within 4 hours of ingestion.

**TREATMENT**

Desferrioxamine mesylate (an iron chelator) 5 g is left in the stomach after lavage. Simultaneously, 2 g is injected i.m. and an infusion of 15 mg/kg per hour (maximum 80 mg/kg) is commenced. Treatment is continued until serum concentration and clinical status are satisfactory.

**ISONIAZID****CLINICAL FEATURES**

Severe toxicity is characterised by coma, respiratory depression, hypotension and convulsions, and may result from doses > 80 mg/kg. Protracted convulsions can cause rhabdomyolysis and acute renal failure.

**TREATMENT**

Gastric lavage followed by AC should be considered for large ingestions seen within 1 hour. Convulsions should be controlled with diazepam and pyridoxine, which is a specific antidote for isoniazid poisoning. Pyridoxine should be given prophylactically for large ingestions as early as possible, since it may prevent the development of complications.

**LITHIUM****CLINICAL FEATURES**

Serum lithium levels > 1.5 mmol/l are toxic, with the main feature being varied neurological symptoms and signs. Severe poisoning may result in permanent neurological damage and nephrogenic diabetes insipidus.

**TREATMENT**

Serum concentrations > 3.5–4.0 mmol/l or patients with signs of severe toxicity generally require extracorporeal elimination techniques. Nevertheless, the majority of patients respond to general supportive measures.

**METHANOL AND ETHYLENE GLYCOL****CLINICAL FEATURES**

Methanol and ethylene glycol are relatively non-toxic, but their ingestion is a medical emergency, because of their metabolism (following a latent period of 12–18 hours) to formic acid and glycolic acid respectively. These toxic metabolites account for the metabolic acidosis, ocular toxicity, renal failure and mortality that are occasionally seen. Mild features include dizziness, drowsiness and abdominal pain. When treatment is delayed, metabolic

acidosis develops with drowsiness, coma and convulsions. The osmolal and the anion gap are increased.

#### TREATMENT

AC does not adsorb either methanol or ethylene glycol. The metabolic acidosis should be treated with sodium bicarbonate and the serum electrolytes measured. Ethanol prevents formation of the toxic metabolites and previously has been the most established treatment. However, ethanol dosing is complex, requires repeated monitoring and has adverse effects. The recent introduction of fomepizole (4-methylpyrazole), although expensive, has significantly simplified the treatment of ethylene glycol and methanol poisoning, and is now strongly recommended as first-line therapy in some national guidelines.<sup>23,24</sup> It has been shown to be safe and effective, with minimal adverse effects,<sup>25</sup> and potentially prevents the need for haemodialysis in patients presenting with visual disturbances or severe acidosis.<sup>26</sup> If the ethylene glycol blood concentration is > 20 mg/dl or if there is a good history of ethylene glycol/methanol ingestion with an osmolal gap > 10, then patients should receive a loading dose of 15 mg/kg, followed by 10 mg/kg every 12 hours for 48 hours.

Folinic acid should also be given since it enhances the metabolism of formic acid.

### MONOAMINE-OXIDASE INHIBITORS (MAOIs)

#### CLINICAL FEATURES

MAOIs cause an accumulation of amine neurotransmitters and are readily absorbed from the gastrointestinal tract and metabolised in the liver. Overdose results in neuromuscular excitation (muscle spasm, rigidity and opisthotonos) and sympathetic overactivity (tremor, tachycardia, hyperthermia, hypertension with fixed and dilated pupils).

#### TREATMENT

Management is similar to that of intoxication with amfetamines and cocaine (see above).

### NON-STEROIDAL ANTI-INFLAMMATORY DRUGS (NSAIDs)

#### CLINICAL FEATURES

NSAIDs are commonly ingested in overdose. Fortunately, however, serious problems, other than a bad attack of gastritis, are rare. Exceptions to this rule include mefenamic acid or large ingestions of ibuprofen where self-limiting convulsions and renal failure have been reported.<sup>27</sup> Patients who do not develop symptoms within 4 hours are unlikely to experience delayed toxicity.

#### TREATMENT

AC can be given for large ingestions (> 10 tablets) that are seen within 1 hour of the overdose. Seizures should

be treated with a benzodiazepine and an oral proton pump inhibitor may ease symptoms of gastrointestinal irritation.

### OPIOIDS

#### CLINICAL FEATURES

Overdose is characterised by pinpoint pupils, drowsiness, shallow breathing and ultimately respiratory failure.

#### TREATMENT

AC may be effective for oral ingestions, otherwise treatment is supportive. Naloxone 0.1–0.4 mg i.v. can be given by bolus; repeat doses may be required if there is an inadequate response. Intubation and mechanical ventilation are required if respiratory failure is not rapidly reversed by naloxone.

### PARACETAMOL

In normal adults, doses > 10 g may exceed the ability of hepatic glutathione to conjugate the toxic metabolite. Plasma concentrations > 200 mg/l at 4 hours or  $\geq$  50 mg/l at 12 hours (Figure 80.1) are usually associated with hepatic damage. Treatment should begin at lower levels for those considered to be high risk (see Table 80.4). While i.v. acetylcysteine administered more than 16 hours after ingestion may not prevent severe liver damage, it should still be given since outcome from paracetamol-induced fulminant hepatic failure is improved.<sup>28</sup> Although severe hepatic injury has a 10% mortality, the majority of patients recover within 1–2 weeks.

#### CLINICAL FEATURES

Nausea and vomiting may be the only features present in the first 24 hours.

#### TREATMENT

- Measure drug concentrations as described in general principles.
- Administer AC as soon as possible, even if more than 4 hours after overdose.<sup>29</sup>
- *N*-acetylcysteine 150 mg/kg in 200 ml 5% dextrose is infused over 15 minutes, followed by 50 mg/kg in 500 ml 5% dextrose over 4 hours and 100 mg/kg in 1 l 5% dextrose over 16 hours (total dose 300 mg/kg in 20 hours). Maximum protective effect is time-dependent. An ingestion–treatment interval of less than 10 hours gives the best results.
- In fulminant hepatic failure, the last dose (100 mg/kg in 1 l 5% dextrose over 16 hours) is repeated until the patient's INR is < 2.
- Expert opinion should be sought early on from a regional centre if liver failure is progressive since liver transplantation may become necessary.

**Figure 80.1** Treatment lines following paracetamol overdose in relation to time after ingestion and plasma levels. (Figure from Paracetamol Information Centre, London and the Welsh National Poisons Unit, Cardiff.)

Regular alcohol consumption
Regular use of enzyme-inducing drugs
Phenytoin, carbamazepine, phenobarbital, rifampicin
Conditions causing glutathione depletion
HIV, eating disorders, malnutrition and cystic fibrosis

## PARAQUAT

In adult humans the lethal dose is 3–6 g (i.e. 15–30 ml of 20% w/v liquid concentrate). The mortality rate in patients ingesting the liquid concentrate is about 45%.<sup>30</sup> The lung is the primary target organ, with the injury being enhanced by oxygen. Peak concentrations are achieved between 0.5 and 2.0 hours.

### CLINICAL FEATURES

Initial symptoms are gastrointestinal pain and vomiting with corrosive effects on the mouth, pharynx and oesophagus. Dyspnoea and pulmonary oedema follow within

24 hours, progressing to irreversible fibrosis and death. Cardiac, renal and hepatic dysfunctions are common.

### TREATMENT

AC should be given if the patient presents within 1 hour. Other than basic measures such as antiemetics, analgesics and fluid replacement, the efficacy of specific treatment options is not established. Palliative care is probably the best approach in patients with very high plasma and urinary levels.

## PHENYTOIN

### CLINICAL FEATURES

Absorption is slow and unpredictable; moreover, maximum serum concentrations may not be achieved until 72 hours after ingestion. After initial nausea and vomiting, neurological symptoms develop including drowsiness, dysarthria and ataxia, and may ultimately progress to seizures. Cardiovascular toxicity is rare unless the overdose has been given i.v.

### TREATMENT

Most patients require nothing more than supportive measures.

## SALICYLATES (ASPIRIN)

Moderate toxicity occurs with serum concentrations 500–750 mg/l (3600–5500 µmol/l) and severe toxicity with concentrations > 750 mg/l. Serum concentrations alone do not determine prognosis. The elimination half-life increases significantly with increasing concentrations. Small reductions in pH produce large increases in non-ionised salicylate, which then penetrates tissues.

### CLINICAL FEATURES

Tinnitus, deafness, diaphoresis, pyrexia, hypoglycaemia, haematemesis, hyperventilation and hypokalaemia may all occur. Coma, hyperpyrexia, pulmonary oedema and acidaemia are reported as more common in fatal cases, which present late.

### TREATMENT

Multiple-dose AC may be effective but is not established. Vitamin K and glucose are used to correct hypoprothrombinaemia and hypoglycaemia. Urinary alkalinisation (see above) will decrease the amount of non-ionised drug available to enter tissues, but is hazardous and should only be used for the most severely ill patients. Extracorporeal techniques are very effective in removing salicylates and correcting acid–base disturbance. Although indications for their use are yet to be defined, they should be considered for severe cases.<sup>31</sup>

## SELECTIVE SEROTONIN REUPTAKE INHIBITORS (SSRIs) or 5-HT Drugs

Drugs include citalopram, fluoxetine, fluvoxamine, paroxetine and sertraline. These drugs have increasingly

replaced the tricyclic antidepressants and generally appear to be much safer in overdose.

#### CLINICAL FEATURES

Drowsiness, tachycardia and mild hypertension are the commonest features. Seizures and coma can occur, as well as a serotonin syndrome in 14% cases.<sup>32</sup>

#### TREATMENT

AC should be considered up to 1 hour post ingestion, otherwise treatment is supportive. Benzodiazepines should be used to treat agitated or hyperthermic patients. There are case reports of cyproheptadine being used to treat severe toxicity with SSRIs.<sup>33</sup>

### THEOPHYLLINE

#### CLINICAL FEATURES

Acute theophylline poisoning is potentially very serious and severe poisoning carries a high mortality. Toxic effects such as agitation, tremor, nausea, vomiting and sinus tachycardia become evident at < 30 mg/l (167 µmol/l). Concentrations > 60 mg/l (333 µmol/l) in acute poisoning or > 40 mg/l (222 µmol/l) in chronic usage frequently result in seizures, malignant ventricular arrhythmias, severe hypotension and death.<sup>34</sup> A key feature is hypokalaemia, which predisposes to arrhythmias and rhabdomyolysis. Measuring plasma theophylline levels confirms the ingestion and may help in deciding elimination methods; in the majority of poisoned patients they do not aid management. Sustained-release preparations may result in delayed onset and prolonged toxicity.

#### TREATMENT

Gastric lavage is indicated for those who present early, but multiple-dose AC is highly effective. Electrolyte and acid-base disturbances should be corrected rapidly since this may be the only treatment required in many cases. Convulsions should be treated with benzodiazepines and cardiac arrhythmias with β-blockers in non-asthmatic patients. Extracorporeal elimination techniques may be indicated for severe cases. Whole bowel irrigation may be of use for sustained-release preparation overdoses.

### TRICYCLIC ANTIDEPRESSANTS (TCAs)

#### CLINICAL FEATURES

These drugs remain the leading cause of death from overdose in patients arriving at the emergency department alive and account for up to one half of all overdose-related adult intensive care admissions.<sup>35</sup> Features include anticholinergic effects such as warm dry skin, tachycardia, blurred vision, dilated pupils and urinary retention. Severe features include respiratory depression, reduced conscious level, cardiac arrhythmias, fits and hypotension. Arrhythmias may be predicted by a QRS duration > 100 ms on the ECG; a QRS duration of > 160 ms increases risk of seizures.<sup>36</sup> All forms of rhythm and

conduction disturbance have been described, and are not necessarily predicted by the ECG.<sup>37</sup> Amoxapine typically causes features of severe poisoning in the absence of QRS widening. Cardiac toxicity is due mainly to quinidine-like actions, slowing phase 0 depolarisation of the action potential. Other mechanisms include impaired automaticity, cholinergic blockade and inhibition of neuronal catecholamine uptake. Toxicity is worsened by acidemia, hypotension and hyperthermia.

#### TREATMENT

After supportive care as outlined above, including multiple-dose AC, continuous cardiac monitoring is essential. Increasing arterial pH to ≥ 7.45 significantly reduces the available free drug and this may be the best way to avoid TCA toxicity. Mild hyperventilation and 8.4% sodium bicarbonate in 50 mmol aliquots achieves this strategy and may improve outcome.<sup>38</sup> Bicarbonate should probably be given in all cases of QRS prolongation (even in the absence of metabolic acidosis), malignant arrhythmias, hypotension or metabolic acidosis. If arrhythmias occur, avoid Class 1a agents; lidocaine may be best. Benzodiazepines are the drug of choice for sedation, treatment of seizures and may prevent emergence delirium.

### VALPROATE

#### CLINICAL FEATURES

Most overdoses follow a benign course, with nausea, mild drowsiness and confusion. Coma can occur in large ingestions with cerebral oedema.

#### TREATMENT

Valproate levels are of little value, except to confirm the ingestion. There is poor correlation between depth of coma and free or total valproate levels. Supportive management is all that is usually required. Rapid absorption occurs and therefore gastric lavage or AC is of little benefit.

# Sedation, analgesia and muscle relaxation in the intensive care unit

Peter V van Heerden

Despite the widespread use of sedative and analgesic agents in the intensive care unit (ICU), the goals of sedation and analgesia are not well-established. Indications for the use of sedative agents include:

- to enable the critically ill patient to tolerate invasive and uncomfortable monitoring and treatment procedures
- to reduce oxygen consumption<sup>1</sup> by reducing patient arousal and activity
- to promote amnesia for events in the ICU

Sedatives may also be used as specific treatment for conditions such as epilepsy or tetanus. The delirious patient may require sedation to maintain safety of the patient and carers.

Combinations of opioids and benzodiazepines are commonly used to provide 'sedation' in the ICU. High doses of opioid analgesics may result in significant sedation in their own right and are synergistic with sedative agents such as benzodiazepines. The distinction between sedation and analgesia is therefore blurred, and makes the definition and attainment of clear sedation goals elusive.

Skilled use of analgesics in the modern ICU ensures that critically ill patients should no longer suffer pain. Pain management relies largely on the use of opioid analgesics, together with regional anaesthetic techniques. Poor management of sedation and analgesia in the critically ill patient may contribute to ongoing psychological morbidity, such as posttraumatic stress disorder.

## SEDATION

Sedation of patients in the ICU is an integral part care and compassion for the critically ill patient.

Sedative agents are used in an attempt to:

- allay anxiety over the patient's own illness, the welfare of relatives or the risk of death
- ensure adequate rest
- reduce the impact of unpleasant sensations, such as thirst

- reduce the distress of invasive treatment and monitoring, such as endotracheal intubation
- blunt awareness of the environment over which the patient has very little control and in which he/she may be unable to communicate

Attention to such details as avoiding potentially distressing situations, where possible, allowing adequate access to caring visitors maintaining of adequate communication with the patient and a positive outlook by the carers will satisfy many of these goals. Small comforts, such as ice chips by mouth, a comfortable mattress or relaxation audio tapes all help this process.

## LEVEL OF SEDATION

The level of sedation required will vary, depending on the indication, e.g. heavy sedation may be necessary during the control of status epilepticus, while a much lower level of sedation will be required to tolerate endotracheal intubation. Modern modes of mechanical ventilation do not demand heavy sedation in order to be comfortably tolerated. The aim of sedation should be clear to the treating team and the desired level of sedation should be determined and documented. Once sedation is instituted, the level of sedation should be regularly assessed. Protocol-based therapy reduces drug costs and enhances the quality of sedation and analgesia.<sup>2</sup> Failure to follow such a protocolised approach can result in significant problems, such as:<sup>3</sup>

- 'oversedation' with an increased risk of nosocomial pneumonia
- the need for more frequent neurological assessments including computed axial tomography (CT) scans
- prolonged stay in the ICU
- an increased incidence of psychological problems, such as posttraumatic stress disorder and depression

Level of sedation may be assessed by means of a number of measurement tools including:

- Scoring systems such as the Ramsay scale (see Table 81.1), which is a six-point scale that ranges from anxious and

Table 81.1 Ramsay scale

Level	Response
<b>Awake levels</b>	
1	Patient anxious and agitated or restless or both
2	Patient cooperative, orientated and tranquil
3	Patient responds to commands only
<b>Asleep levels</b>	
4	Brisk response to a light glabellar tap or loud auditory stimulus
5	Sluggish response to a light glabellar tap or loud auditory stimulus
6	No response to a light glabellar tap or loud auditory stimulus

agitated (level 1) to unresponsive (level 6), judged in response to a standardized stimulus (loud auditory stimulus or glabellar tap).<sup>3</sup> This scale has good interrater reliability and provides a numerical score, suitable for charting on the ICU observation chart and for descriptive purposes.

- Electroencephalography (EEG), which may be either 'raw' or 'processed' and is able to provide a measure of cerebral activity. This monitor is more suitable for assessing depth of anaesthesia and may be difficult to interpret in the encephalopathic patient. Newer, easy-to-use devices using integrated EEG are now appearing but their efficacy and role in the ICU have yet to be established. Use is also limited by practical considerations, such as interference due to movement artefact. To date these monitors have not enjoyed widespread use in the ICU, but may be useful for specific indications such as ensuring an isoelectric EEG trace in patients being treated for intracranial hypertension.
- Visual analogue scales, which are more suited to the assessment of pain (see below), or for use as a research tool.
- Evoked potentials.

Level of sedation may also be assessed by monitoring physiological parameters for signs of distress. A 'drug free' period every day, when sedative agents are completely withdrawn, is an excellent means of assessing level of sedation<sup>4</sup> – by taking note of the time for a patient to either wake up or rise to a predetermined level on the Ramsay scale.

### THE IDEAL SEDATIVE

There is no ideal sedative agent. Sedatives in the future may target specific aspects of sedation, such as hypnosis, anxiolysis or amnesia, without necessarily providing the whole spectrum of sedation for each patient. Currently a good sedative would address the following:

- hypnosis/sleep
- anxiolysis

- amnesia
- be anticonvulsant
- be non-cumulative
- be independent of renal or hepatic metabolic pathways
- not produce respiratory or cardiovascular depression
- have minimal interaction with other drugs
- be of modest cost
- have a rapid onset and short offset time
- have no prolonged effects on memory
- have no long-term psychological effects

### SEDATIVE AGENTS USED IN THE ICU

#### BENZODIAZEPINES

Benzodiazepines (BZAs), as a class, are probably the most widely used sedatives in ICUs. These agents provide hypnosis, amnesia and anxiolysis. They do not provide analgesia. BZAs are good anticonvulsant drugs and also provide some muscle relaxation. They act via BZA receptors, which are closely associated with GABA<sub>A</sub> receptors, resulting in intracellular influx of chloride when activated. These drugs may be given by mouth (PO), per rectum (PR) or intravenously (i.v.). Most commonly in the ICU they are administered by intermittent or continuous i.v. infusion, e.g. midazolam in 1 mg/ml dilution, titrated to effect.

Dosage of these agents is by titration and may vary widely depending on factors such as:

- prior exposure to BZA (increased tolerance)
- age and physiological reserve
- volume status (hypovolaemic patients are more sensitive)
- renal and hepatic dysfunction
- co-administered drugs (whether BZA is combined with an opioid)
- history of alcohol consumption (increased tolerance)

Although some BZAs (e.g. midazolam) are reported to be short-acting, water-soluble agents, there is still potential for accumulation of both parent compound and active metabolites in patients with hepatic and renal dysfunction. This may result in prolonged sedation and increased length of mechanical ventilation and ICU stay. In the critically ill, there may be extensive derangement of the pharmacokinetic profiles of BZAs. There is therefore some difficulty in predetermining suitable dosages of these agents. Typically, midazolam in doses of 0.02–0.2 mg/kg per hour may be suitable, with the level titrated to individual response. Longer acting agents, such as diazepam, may be given by intermittent i.v. injection, e.g. diazepam 5–10 mg i.v., as necessary.

BZAs are often combined with opioids in a compound 'sedative' infusion. This allows lower doses of BZA to be used, while capitalising on the opioid effects of respiratory and cough suppression, to facilitate mechanical ventilation.

Flumazenil, the specific BZA antagonist, may be used to reverse the effect of BZAs to reduce unwanted acute side-effects, such as severe hypotension or respiratory depression, or to allow acute neurological assessment of the sedated patient.

### INTRAVENOUS ANAESTHETIC AGENTS

#### Propofol

The i.v. anaesthetic agent propofol (2,6-di-isopropylphenol) is frequently used for sedation in the ICU. It is fast acting, very effective and has a rapid offset of action (due to its rapid metabolism to inactive metabolites in the liver). These features make it very suitable for use in patients requiring short-term sedation or for anaesthesia for procedures in the ICU. Although propofol has been shown to reduce time on mechanical ventilation compared with BZA (specifically midazolam) sedation, it has not been shown to reduce time in the ICU.<sup>5,6</sup> Caution is required in hypovolaemic patients or those with impaired myocardial function, as severe hypotension may result. Doses for ICU sedation are generally much lower than the 6–12 mg/kg per hour required for anaesthesia. The diluent in which propofol is delivered is lipid-rich and may have to be taken into account as a source of nutrition and indeed cause of hyperlipidaemia, depending on dosage and duration of therapy. Disodium edetate, present in the propofol solution, does not appear to be harmful in patients receiving long-term infusions of propofol.<sup>7</sup>

There has been some recent concern about the so-called ‘propofol infusion syndrome’ where particularly paediatric patients, but also adults, have developed severe heart failure (preceded by metabolic acidaemia, fatty infiltration of the liver and striated muscle damage) after prolonged high-dose infusions of propofol.<sup>8</sup> Caution should therefore be exercised when using propofol for prolonged periods.

#### Thiopentone

Thiopentone is reserved for specific indications, such as management of intractable intracranial hypertension (to reduce cerebral metabolism) or for the treatment of status epilepticus. It is not commonly used as a general sedative agent. Its use is limited by its long duration of action and long terminal half-life when used for prolonged infusions.

#### Ketamine

Ketamine acts by blocking *N*-methyl-D-aspartic acid (NMDA) receptors. It produces a sedative state known as ‘dissociative anaesthesia’, with the following characteristics:

- mild sedation
- amnesia
- analgesia
- reduced motor activity

The lack of respiratory and cardiovascular depression at lower doses makes this a very safe drug for use in the ICU. Limitations to its use include hallucinations and delirium during the recovery/withdrawal phase. These may be ameliorated by BZA administration. Ketamine may be used specifically for sedation in severe asthmatics (for its bronchodilator effect), in patients following head injury (for its effect at the NMDA receptor) or in patients where analgesia is difficult (e.g. extensive burns).

#### Etomidate

Etomidate is no longer used for ICU sedation due to its adrenocortical suppressant (immunosuppressant) action.

### MAJOR TRANQUILLIZERS

Butyrophenones (e.g. haloperidol) and phenothiazines (e.g. chlorpromazine) are very useful agents for the sedation of delirious patients in the ICU. They act via a range of receptors including dopaminergic (D<sub>1</sub> and D<sub>2</sub>),  $\alpha$ -adrenergic, histamine, serotonin and cholinergic receptors. Main actions include:

- reduced motor activity
- apathy and reduced initiative
- sedation and drowsiness
- reduced aggression
- antiemetic

Unwanted effects with these drugs are common and include:

- extrapyramidal effects (dystonia and tardive dyskinesia)
- endocrine effects (e.g. lactation)
- anticholinergic effects (e.g. blurred vision, dry mouth, urinary retention, constipation)
- hypotension
- neuroleptic malignant syndrome

The main advantage of major tranquillizers over large doses of minor tranquillizers is that they can be used to gain control in difficult situations (e.g. when delirious patients may be a risk to themselves or their carers) without a major risk of respiratory depression. These agents should not be used for long-term sedation, except where they are used for the specific treatment of psychosis. Typically, haloperidol, diluted to a 1 mg/ml solution, may be given by repeated i.v. injection in doses of 5–20 mg/hour until the delirious patient is approachable. Repeat dosages would then be titrated to allow easy arousal of the patient, with the patient otherwise calm. Haloperidol may also be given by mouth or by i.m. injection.

Olanzapine, a newer ‘atypical’ antipsychotic agent, is also a useful agent for the sedation of delirious patients when given in oral doses of 5–20 mg/day. It has a much lower side-effect profile than the more ‘typical’ antipsychotics, especially with respect to motor side-effects. Olanzapine may also be given as oral/sublingual wafers. This is a particularly useful route of administration in the uncooperative patient.

### VOLATILE ANAESTHETIC AGENTS

The widespread use of volatile anaesthetic agents for sedation in the ICU has been limited by:

- the cost of prolonged administration
- the more complex set-up required for the administration of these agents (vaporizer, scavenging apparatus, etc.)
- specific side-effects, e.g. ‘halothane’ hepatitis, accumulation of fluoride ions and consequent renal dysfunction (enflurane and isoflurane) and inactivation of methionine synthase and bone marrow depression (nitrous oxide)

Volatile agents are useful for short periods of anaesthesia during invasive procedures in the ICU. They may be used, with effect, for longer periods for sedation (up to a few days) in acute severe asthma, due to their bronchodilatory action. Short-term administrations of Entonox (50% nitrous oxide in oxygen) are still useful for analgesia and sedation during painful procedures (e.g. removal of intercostal catheters). This may be given by demand valve (controlled by the patient) or be administered by the medical staff.

### OPIOIDS

Although opioids are used primarily for their analgesic action in the ICU (see below), they also produce a degree of sedation. They therefore complement the effect of other sedatives used in the ICU, with which they are often given in combination.

### DEXMEDETOMIDINE

Dexmedetomidine is a novel highly selective  $\alpha_2$ -agonist, which has been shown to provide safe analgesia and sedation in the ICU when given as a single agent by i.v. infusion.<sup>9</sup>

Dosages are: loading dose of 1  $\mu\text{g}/\text{kg}$  over 10 min, followed by an infusion of 0.2–0.7  $\mu\text{g}/\text{kg}$  per hour.

Infusions longer than 24 hours are currently not recommended. Side-effects may be predicted from the mechanism of action and include hypotension, bradycardia, hypoxaemia and atrial fibrillation. More established  $\alpha_2$ -agonists, such as clonidine, may be used to enhance sedation and analgesia when BZA and opioids are used as the mainstay of sedation in the ICU.

## ANALGESIA

Pain management is an important priority in the care of critically ill patients.

Many patients present to the ICU with painful conditions or undergo painful procedures during their ICU stay. Pain has a number of adverse consequences:

- it produces anxiety
- it contributes to lack of sleep
- it worsens delirium
- it enhances the stress response – increases circulating catecholamine levels and oxygen consumption
- it results in respiratory embarrassment due to atelectasis and sputum retention
- it leads to immobility and venous and gut stasis

Pain management comprises a number of modalities in addition to analgesics and local and regional anaesthesia/analgesia, such as:

- a caring and supportive medical team that the patient can trust
- warm and comfortable surroundings
- attention to pressure areas (e.g. regular turning)
- the use of warm packs
- the use of simple analgesics as appropriate

- bowel and bladder care
- adequate hydration and amelioration of thirst (e.g. moistening the mouth)
- early tracheostomy where indicated to reduce the discomfort of endotracheal intubation
- splinting and early fixation of fractures.

When drug therapy is required to alleviate pain, the following groups of drugs are commonly used:

- opioid analgesics
- simple analgesics
- non-steroidal anti-inflammatory drugs (NSAIDs)
- novel agents, such as dexmedetomidine (see above) and tramadol
- local anaesthetic agents
- inhaled agents (see volatile anaesthetic agents above)
- ketamine (see above)
- ‘multimodality’ supplemental treatments such as acupuncture, acupressure, massage and transcutaneous electrical nerve stimulation (TENS)

### OPIOIDS

Opioids remain the mainstay of analgesia in the ICU. This group of drugs encompasses:

- morphine and its analogues (e.g. morphine, diamorphine, codeine)
- semisynthetic and synthetic agents
  - phenylpiperidine derivatives (e.g. pethidine, fentanyl)
  - methadone derivatives (e.g. methadone, dextro-propoxyphene)
  - benzomorphan derivatives (e.g. pentazocine)
  - thebaine derivatives (e.g. buprenorphine)

The effects of opioids are mediated via the three main opioid receptor subtypes  $\mu$ ,  $\kappa$  and  $\sigma$ . These G-protein coupled receptors inhibit adenylyl cyclase and effects include:

- analgesia (supraspinal, spinal and peripheral)
- sedation
- pupillary constriction
- respiratory depression and cough suppression
- euphoria or dysphoria
- reduced gastrointestinal motility
- physical dependence

Opioids are titrated to effect by intermittent injection (usually i.v. in the ICU) or by continuous infusion, which may be nurse controlled (nurse-controlled analgesia, NCA) or controlled by the patient (patient-controlled analgesia, PCA). A suitable regimen is a 1 mg/ml dilution of morphine given by continuous i.v. infusion, titrated to patient comfort. This is often combined with a BZA (e.g. midazolam) to produce a ‘sedative/analgesic’ infusion for use in very ill patients on mechanical ventilation (see sedation above). Opioids are also administered via the subarachnoid, extradural, transdermal and intranasal routes.

**Figure 81.1** Visual analogue score for the assessment of pain.<sup>3</sup>

The effect of analgesia in the clinical setting is judged by:

- patient response, if they are conscious, either verbally by describing the level of pain subjectively or by using a visual analogue score (Figure 81.1)<sup>3</sup> or other assessment, such as behavioural pain scales<sup>10</sup>
- physiological markers of distress, e.g. tachycardia, hypertension, diaphoresis, restlessness

These indicators should be assessed in the clinical context, i.e. is the pathophysiological process likely to be responsible for some, or considerable pain? Analgesia should be administered for a specific indication and to desired effect. Many factors lead to a wide variation in the experience of pain including:

- personality traits
- the previous experience of pain
- fear
- interpretation of events/disorientation/depersonalization
- age
- degree of tissue damage
- chronic disease and debility

In the critically ill, the use of opioids may be complicated by:

- wide interindividual responses to similar dosages, mandating titration of the analgesic, especially in debilitated and elderly patients
- severe hypotension following rapid administration, particularly in hypovolaemic patients. Fentanyl and sufentanil may offer advantages over morphine in terms of 'cardiostability'

- prolonged duration of action, due to accumulation of parent compound and metabolites (e.g. morphine and its major metabolites morphine-3-glucuronide and morphine-6-glucuronide) in the elderly and in patients with renal and hepatic dysfunction. Use of drugs with shorter half-lives (e.g. alfentanil) or which are less dependent on hepatic and renal pathways for metabolism and excretion (e.g. remifentanyl) can reduce this problem
- constipation, requiring careful attention to detail and the judicious use of prokinetic agents (e.g. metoclopramide, erythromycin) to overcome gastric stasis and enable enteral feeding, or prurients to aid evacuation
- the development of tolerance requiring increasing doses to achieve the same effect
- withdrawal symptoms on cessation/reduction of opioid medication. The 'abstinence syndrome' is characterized by:
  - irritability
  - tremor
  - aggression
  - fever
  - diaphoresis
  - piloerection
  - pupillary dilation
  - diarrhoea
  - insomnia

Early recognition of these symptoms of withdrawal is not always simple in the ICU patient and may be mistaken for sepsis or delirium. Treatment is by re-institution of and then slow withdrawal of the opioid, especially after prolonged periods of administration. Alternatively, symptoms may be controlled with a combination of long-acting opioid (e.g. methadone), BZA and  $\alpha_2$ -agonists (e.g. clonidine).

A knowledge of drug-related (as opposed to class-related) side-effects is important when using opioids other than morphine, e.g. the interaction between pethidine and the older monoamine oxidase inhibitors, the potential for seizures with high dose or prolonged use of pethidine, chest wall rigidity occasionally seen with high doses of fentanyl.

The specific opioid antagonist naloxone has little role to play in the ICU, except for the treatment of severe hypotension, unwanted sedation or respiratory depression following opioid usage. Rapid reversal of opioid effect for the purpose of neurological assessment may be another valid use of naloxone.

## PHARMACOKINETIC CONSIDERATIONS

The pharmacokinetics of analgesics and sedatives can be affected by such factors as:

- patient's fluid volume status
- capillary leak (changing volume of distribution)
- serum protein levels
- renal function
- hepatic function

- hepatic blood flow
- competition of combinations of drugs for carrier molecules, metabolic and excretory pathways

All of these factors make the rational choice of an appropriate drug in the appropriate dose difficult in the critically ill patient.

Use of simple analgesics or NSAIDs to treat pain will reduce the amount of opioid required.

### SIMPLE ANALGESICS

Paracetamol and other simple analgesics (e.g. salicylates) are particularly effective for:

- bone and joint pain
- soft tissue pain
- perioperative pain
- inflammatory conditions
- as part of multimodal analgesia, to reduce opioid requirements

These drugs are given by mouth, via a nasogastric tube, per rectum or i.v. to supplement analgesia in the critically ill (e.g. paracetamol 1–2 g 4–6-hourly). Use is limited by the risk of hepatic dysfunction if used in high dose or for prolonged periods.

### NSAIDs

The commonly used NSAIDs are carboxylic acids (e.g. indometacin, ibuprofen, mefenamic acid) or enolic acids (e.g. piroxicam). NSAIDs are useful for supplemental/multimodal analgesia in the ICU for the conditions listed for simple analgesics above. They are given by mouth, via a nasogastric tube, per rectum or by i.m. injection (e.g. indometacin 100 mg twice daily PR or ketorolac 10–15 mg 4–6-hourly i.m.) for pain and pyrexia. Side-effects include:

- renal dysfunction
- gastrointestinal haemorrhage
- increased bleeding tendency due to platelet inhibition

The newer cyclooxygenase 2 (COX-2) specific inhibitors, such as valdecoxib and its injectable precursor parecoxib, have a much lower side-effect profile than traditional NSAIDs. These drugs should be used only for short periods, due to recent evidence regarding increased cardiovascular morbidity associated with long-term use of the COX-2 inhibitors.<sup>11</sup>

### TRAMADOL

Tramadol is a more recent addition to the analgesic range. It acts via the  $\mu$  receptor, as well as by inhibiting the uptake of serotonin and noradrenaline (norepinephrine), with presynaptic stimulation of serotonin release, thereby enhancing the effects of the descending analgesia system. It is useful for moderate to severe pain in the postoperative patient in doses of 50–100 mg i.v., oral or i.m. 4–6-hourly to a maximum of 600 mg/day.

### LOCAL ANAESTHETICS – REGIONAL ANAESTHESIA/ANALGESIA

The use of local anaesthetic techniques in the critically ill patient is limited by:

- pain often emanating from multiple sources, and therefore not amenable to a single regional technique
- the requirement for ‘mandatory’ sedation/analgesia in order for the patient to tolerate endotracheal intubation, making a regional technique for another source of pain (e.g. laparotomy wound) superfluous
- the need to treat pain over a prolonged period, mandating either repetition of the regional block (e.g. intercostal nerve blocks for pain from an upper abdominal incision, or femoral nerve blocks for a fractured femur) or the placement of an indwelling catheter (e.g. epidural catheter). Indwelling catheters also have a defined safe duration of insertion (usually 3–4 days) before they need to be removed and replaced
- coagulopathy frequently seen in this group of patients, making procedures such as epidural injection less safe
- comorbidities (e.g. severe ischaemic heart disease) in the critically ill patient

When a regional technique is considered viable (e.g. thoracic epidural for the treatment of pain due to fractured ribs), then the following need to be considered:

- the procedure should be carried out by adequately trained personnel (usually with an anaesthesia background)
- regional techniques may be very time-consuming, requiring additional staff to properly position the patient and assist the proceduralist
- regional techniques may carry serious complication risks (e.g. subarachnoid injection of local anaesthetic or epidural haematoma during placement of epidural catheters, with serious haemodynamic, neurological and respiratory consequences)
- good preparation is paramount:
  - informed consent from patient or legal surrogate
  - recent normal coagulation profile, or correction of abnormal profile
  - the knowledge and ability to deal with complications (e.g. sudden hypotension)
  - experience with the drugs being used (typically a mixture of local anaesthetic, such as ropivacaine 0.2%, and an opioid, such as fentanyl 2  $\mu$ g/ml, are used for epidural infusion)
- adequate training of nursing staff to monitor the level of block, haemodynamic parameters and for possible complications

Within the context above, the following blocks may be useful in individual patients:

- femoral nerve block for lower limb injuries (10 ml of 7.5 mg/ml ropivacaine injected intermittently 8–12-hourly into the region of the femoral nerve immediately inferior to the inguinal ligament)

- intercostal nerve blocks for thoracic and upper abdominal injuries or wounds (2–3 ml of 7.5 mg/ml ropivacaine injected into the region of appropriate intercostal nerves – usually at three or four sites unilaterally or bilaterally)
- brachial plexus or i.v. regional anaesthesia for isolated upper limb injuries or procedures (e.g. fracture manipulation)
- epidural analgesia for thoracic and abdominal pain
- intrapleural analgesia/anaesthesia, applied either via a catheter placed for this purpose or via intercostal drains previously placed for treatment of pneumothorax

### MUSCLE RELAXANTS

The routine use of muscle relaxants for prolonged periods is a rare occurrence in the ICU since the advent of mechanical ventilators that provide assisted modes of ventilation (as opposed to mandatory modes used previously). Spontaneous assisted ventilation for almost all mechanically ventilated patients is now encouraged. Current indications for the use of muscle relaxants in the ICU include:

- to complement general anaesthesia for endotracheal intubation and initiation of mechanical ventilation or for short surgical procedures (e.g. tracheostomy)
- to facilitate the safe transport of patients and the acquisition of adequate radiographic images (e.g. CT or MRI)
- to facilitate mandatory mechanical ventilation when adequate sedation/analgesia alone is not adequate to achieve control, for example:
  - to increase chest wall compliance (e.g. in the severe asthmatic or to facilitate venous drainage in the patient with severe intracranial hypertension)
  - to facilitate precise control of respiratory parameters, such as airway pressure or  $P_{aCO_2}$  (e.g. permissive hypercapnia in patients with acute respiratory distress syndrome or normocapnia in patients with impaired cerebral autoregulation)
  - to reduce  $\dot{V}O_2$  in the severely hypoxaemic patient
- specific indications, such as treatment of muscle spasm in tetanus

Before muscle relaxants are used, patients should already be (or about to be commenced) on mechanical ventilation, there should be the expertise and equipment available to deal with ‘difficult intubation’ or accidental extubation, and patients should be sedated/anaesthetised to prevent the awareness of being paralysed while inadequately sedated. Muscle relaxants may be given by intermittent i.v. injection or by continuous i.v. infusion.

### CHOICE OF MUSCLE RELAXANT

Depolarising muscle relaxants are to be used with caution in the ICU patient who has:

- multiple injuries
- renal failure

- neurological problems (e.g. paraplegia)
- burns
- been immobilised for a prolonged period of time

The risk of severe hyperkalaemia following administration of suxamethonium in these settings is high. Rocuronium, a rapid-onset, non-depolarising muscle relaxant, may be a suitable alternative.

Non-depolarising agents are the most commonly used relaxants in the ICU. Their use may be complicated by:

- Accumulation of the parent compound or active metabolites in patients with hepatic or renal insufficiency. Atracurium and cisatracurium are useful agents in these patients due to their inactivation pathways being independent of the kidney and the liver. Accumulation of the epileptogenic metabolite laudanosine may be a problem with atracurium.
- Histamine release following usually rapid injection of certain of these agents (e.g. atracurium). Vecuronium has been shown to be very ‘cardiostable’.
- Protective reflexes (e.g. cough, gag, blink) are abolished and the patient is not able to move and posture him/herself. This requires increased vigilance and attention from the attendants.
- Neurological assessment of the paralysed patient is not possible and requires strict attention to detail to ensure the patient is adequately sedated while paralysed.
- Prolonged duration of action may result from:
  - patient factors, such as electrolyte disturbances (e.g. hypokalaemia, hypophosphataemia)
  - drug factors, such as myopathy associated with the use of steroidal relaxants (e.g. pancuronium, vecuronium), especially when used in conjunction with corticosteroids or aminoglycoside antibiotics.

When muscle relaxants are to be used, they should be used for a clearly defined indication, for as short a time as possible. In addition, the appropriate drug should be used and its use should be monitored regularly (e.g. train of four, post-tetanic count or double burst stimulation). Alternatively, muscle relaxants may be withheld at least once a day, until the return of muscle activity. This drug-free period may be combined with a sedation-free period every day in stable patients to allow adequate neurological assessment.

# Inotropes and vasopressors

John A Myburgh

The pharmacological support of the failing circulation is a fundamental part of critical care. The principal aim of these drugs is to restore inadequate systemic and regional perfusion to physiological levels.

## DEFINITIONS

Inotropic agents are defined as drugs that act on the heart by increasing the velocity and force of myocardial fibre shortening. The consequent increase in contractility results in increased cardiac output and blood pressure. Characteristics of the ideal inotrope are shown in Table 82.1.

Vasopressors are drugs that have a predominantly vasoconstrictive action on the peripheral vasculature, both arterial and venous. These drugs are used primarily to increase mean arterial pressure.

The distinction between these two groups of drugs is often confusing. Many of the commonly used agents such as the catecholamines have both inotropic and variable effects on the peripheral vasculature that include vasoconstriction, arteriolar vasodilatation and constriction.

Vasoregulatory agents may modulate the responsiveness of the peripheral vasculature to vasoactive drugs in pathological states such as sepsis. These agents include vasopressin and corticosteroids.

Given the overlap of pharmacodynamic effects of these drugs, the term 'vasoactive therapy' is a more appropriate description.

## THE FAILING CIRCULATION

### PHYSIOLOGY

Traditionally, cardiac output is discussed in terms of factors that govern cardiac function. These include preload, afterload, heart rate and rhythm, and contractility. Whilst this perspective is helpful in managing patients whose circulatory function is limited by cardiac disease, it is incomplete.

Cardiac output is controlled by the peripheral vasculature that is as energetic at returning blood to the heart as the heart is at pumping blood to the periphery<sup>1</sup> (Figure 82.1).

Blood is pumped down a pressure gradient that is determined by the force of myocardial ejection (contractility) and impedance to ventricular ejection (afterload). The resultant mean arterial pressure is the major 'afferent' determinant of regional perfusion pressure. Twenty per cent of the blood volume is contained in the arterial ('conducting') vessels. There is a marked drop in perfusion pressure and flow across the capillary beds to allow diffusion of substrates and oxygen. The difference between mean arterial pressure and the pressure in end capillaries ('efferent' perfusion pressure) determines regional, or organ-specific, perfusion pressure.

Blood enters the venous system and is returned to the heart via a pressure gradient determined by mean systemic pressure and right atrial pressure. The amount of blood returned to the heart determines the degree of ventricular filling prior to systole (preload), which subsequently determines stroke volume and cardiac output.

Under physiological conditions, the venous ('capacitance') system contains approximately 70% of the total blood volume which acts as a physiological reservoir ('unstressed' volume). Under conditions where circulatory demands increase, increased sympathetic tone will cause contraction of this reservoir. The resultant autotransfusion ('stressed' volume) may increase venous return by approximately 30% and subsequently cardiac output.<sup>2,3</sup>

Both the arterial and venous systems are integrated under complex neurohormonal influences. These include the adrenergic, renin-angiotensin-aldosterone, vasopressinergic and glucocorticoid systems in addition to local mediators such as nitric oxide, endothelin, endorphins and the eicosanoids.<sup>4</sup>

### PATHOPHYSIOLOGY

Circulatory dysfunction or failure may be considered in terms of the major determinants of cardiac output, although there is marked interdependence between these factors.

**Table 82.1** The ideal inotrope

Increases contractility
Increases mean arterial pressure
Increases cardiac output
Improves regional perfusion
No increase in myocardial oxygen consumption
Avoidance of tachycardia
Non-arrhythmogenic
Maintenance of diastolic blood pressure
Does not develop tolerance
Titrateable
Rapid onset
Rapid termination of action
Compatible with other drugs
Non-toxic
Cost effective

**HEART RATE FAILURE**

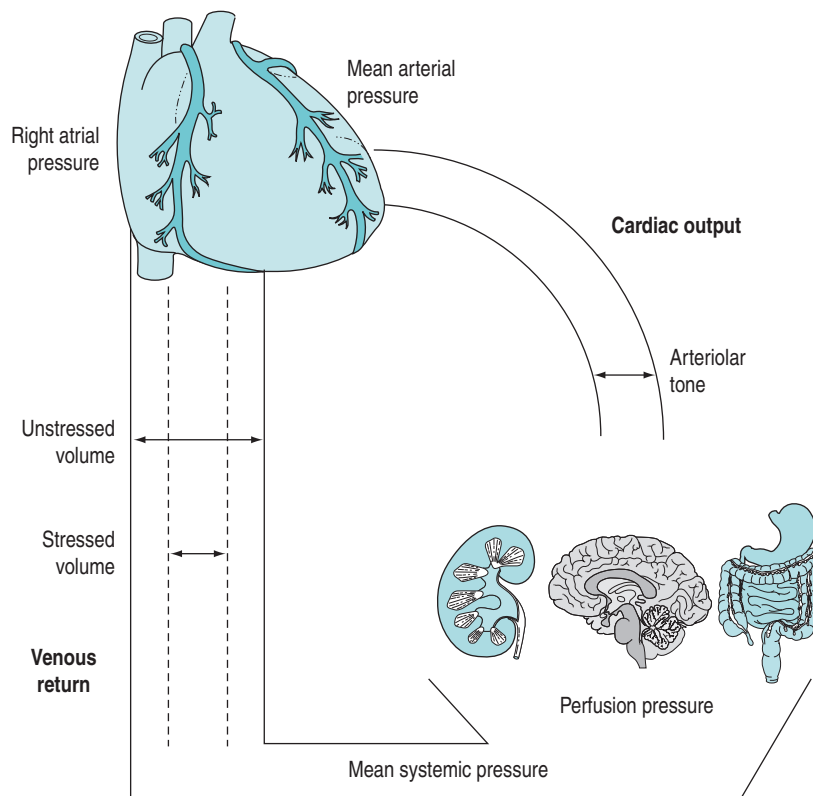

Profound bradycardia will reduce both cardiac output and mean arterial pressure if sympathetic tone is compromised. Inotropes will increase both rate and speed of conduction, in addition to augmenting peripheral venous return, thereby restoring cardiac output and mean arterial pressure.

Tachycardia is associated with decreased left coronary artery perfusion, due to reduction of diastolic time, during which coronary perfusion occurs. This may exacerbate myocardial ischaemia in patients with coronary artery disease, particularly if mean arterial pressure, specifically diastolic blood pressure, is compromised. Therefore, drugs that shorten diastolic time or compromise coronary perfusion should be used with caution in susceptible patients.

**PRELOAD FAILURE**

Loss of intravascular blood volume or extracellular fluid is the most common cause of inadequate ventricular preload. This is corrected with appropriate fluids to maintain and restore a euvolaemic state. Hypovolaemia must be recognised and treated as soon as possible, preferably before vasoactive therapy is used.

There are other determinants of ventricular preload and venous return. Factors such as loss of muscle tone, positive intrathoracic pressure, loss of atrial systole (atrial fibrillation) and ablation of sympathetic tone will also compromise preload by reducing venous return. Under these circumstances, volume replacement alone may be insufficient to maintain adequate preload and vasoactive therapy may be required to increase venous return.

**Figure 82.1** Schematic relationship of the determinants of cardiac output and venous return.

### MYOCARDIAL FAILURE

Myocardial or 'pump' failure may be divided into disorders of systolic ejection (systolic dysfunction) and diastolic filling (diastolic dysfunction).

Systolic dysfunction occurs as a result of reduced effective myocardial contractility. This may be due to primary myocardial factors such as ischaemia, infarction or cardiomyopathy. Myocardial depression of both right and left ventricular function may occur in severe sepsis or following prolonged infusions of catecholamines. Increased impedance to ventricular ejection (e.g. hypertensive states) or structural abnormalities (e.g. aortic stenosis or hypertrophic obstructive cardiomyopathy) may cause systolic dysfunction.

Diastolic dysfunction is characterised by reduced ventricular compliance or increased resistance to ventricular filling during diastole. It may be due to mechanical factors such as structural abnormalities of the ventricle (e.g. restrictive cardiomyopathy) or to impaired diastolic relaxation that occurs with myocardial ischaemia or severe sepsis. This results in elevated end-diastolic pressure and pulmonary venous congestion. Episodic or 'flash' pulmonary oedema is a common clinical sign of diastolic dysfunction.<sup>5</sup> Tachycardias that shorten diastolic time may exacerbate diastolic failure. Diastolic dysfunction frequently accompanies systolic failure, in both acute and chronic cardiac failure, particularly in elderly patients.

In the presence of systolic dysfunction, adequate stroke volume may be maintained by an increase in left ventricular end-diastolic volume (the Frank–Starling relationship), provided diastolic function is optimal. However, if the loss of effective myocardial mass is critical, the ventricle will be unable to maintain an adequate stroke volume and cardiac output will fall. In this situation, systolic dysfunction usually requires treatment with inotropic agents in order to augment stroke volume, thereby increasing cardiac output and mean arterial pressure.

### VASOREGULATORY FAILURE

Disruption or impairment of regulation of the peripheral vasculature may result in circulatory failure. This includes acute sympathetic denervation, such as high quadriplegia, epidural or total spinal anaesthesia ('spinal' shock); distributive failure such as anaphylaxis; or pathological 'vasoplegia' that occurs in severe sepsis.

These syndromes are characterised by reduced responsiveness of the peripheral circulation to endogenous or exogenous sympathetic stimulation. This results in pooling in the venous circulation due to the inability to provide a 'stressed' volume.<sup>4</sup>

Management of these conditions has traditionally focused on the arterial circulation with attempts to increase systemic vascular resistance, often regarded inaccurately as treatment of 'afterload failure'. This is a misnomer as the problem is predominantly impaired venous return, compounded to a lesser extent by pathological arteriolar vasodilatation.<sup>6</sup> Clearly, the effects of vasoregulatory

failure will be exacerbated by concomitant hypovolaemia. Fluid loading to restore effective intravascular volume is essential.

Vasoactive agents may have a role in restoring vasoregulatory tone once adequate volume has been established.

### CLASSIFICATION

The common ultimate cellular mechanism of action of these agents involves an influence on the release, utilisation or sequestration of intracellular calcium (Figure 82.2). These agents are divided into two main groups based on whether or not their actions depend upon increases in intracellular cyclic adenosine 3,5-monophosphate (cAMP) and are outlined in Table 82.2.

### CATECHOLAMINES

Sympathomimetic amines are the most frequently used vasoactive agents in the intensive care unit (ICU) and include the naturally occurring catecholamines dopamine, noradrenaline (norepinephrine) and adrenaline (epinephrine), and the synthetic substances dobutamine, isoprenaline and dopexamine.

### RECEPTOR BIOLOGY

#### PHYSIOLOGICAL

Agonists bind to populations of adrenergic receptors, largely divided into  $\alpha$  and  $\beta$  subgroups. Further subgroups of  $\alpha$ - ( $\alpha_{1A}$ ,  $\alpha_{1B}$ ,  $\alpha_{2A}$ ,  $\alpha_{2B}$ ,  $\alpha_{2C}$ ) and  $\beta$ -receptors ( $\beta_1$ ,  $\beta_2$ ,  $\beta_3$ ) have been identified.<sup>7</sup>

Signal transduction from agonist–receptor occupation to the effector cell is modulated by conformational changes in G proteins associated with these receptors. Under the additional influence of second messengers such as nitric oxide, endothelin and eicosanoids, these conformational changes promote the release of calcium from intracellular stores and increase membrane calcium permeability. Subsequent phosphorylation of substrate proteins via protein kinases act as third messengers to trigger a cascade of events which lead to specific cardiovascular effects.

$\beta$ -Receptor occupancy predominantly activates adenylyl cyclase to increase the conversion of adenosine triphosphate to cAMP.  $\alpha$ -Receptor occupancy acts independently of cAMP by activation of phospholipase C which increases inositol phosphates (IP<sub>3</sub> and IP<sub>4</sub>) and diacylglycerol.

This complex agonist–receptor–effector relationship is responsible for homeostatic mechanisms such as physiological responses to stress and autoregulation.

#### PATHOPHYSIOLOGICAL

The activity and function of this system is dynamic and may be markedly influenced by pathological states. This may

**Figure 82.2** Schematic representation of the action of inotropic drugs on intracellular calcium in myocytes. AMP, adenosine monophosphate; ATP, adenosine triphosphate; cAMP, cyclic AMP; GR, glucagon receptor; Gs, G protein complex; IP, inositol phosphate 3; PDE III, phosphodiesterase III; PIP<sub>2</sub>, phosphoinositol diphosphate.

Calcium sensitisers	
Levosimendan	
Glucagon	

result in qualitative changes in the agonist–receptor–effector organ relationship (desensitisation) where receptors no longer respond to physiological or pharmacological sympathetic stimulation to the same extent. Quantitative changes such as reduced receptor density, receptor sequestration and enzymatic uncoupling (downregulation) may also result in impaired responses.<sup>8</sup>

## BIOSYNTHESIS

The biosynthesis and chemical structures of the naturally occurring catecholamines are shown in Figure 82.3a.

Catecholamines consist of an aromatic ring attached to a terminal amine by a carbon chain. The configuration of each drug is important for determining affinity to respective receptors.

Dopamine is hydroxylated to form noradrenaline, which is the predominant peripheral sympathetic chemo-transmitter in humans, acting at all adrenergic receptors. The release of noradrenaline from sympathetic terminals is controlled by reuptake mechanisms mediated via α<sub>2</sub>-receptors and augmented by adrenaline released from the adrenal gland at times of stress. Noradrenaline is converted to form adrenaline that is subsequently metabolised in liver and lung.

All catecholamines have very short biological half-lives (1–2 minutes) and a steady state plasma concentration is achieved within 5–10 minutes after the start of a constant infusion. This allows rapid titration of drug to a clinical end-point such as mean arterial pressure.

Adrenaline and noradrenaline infusions produce blood concentrations similar to those produced endogenously in shock states, whereas dopamine infusions produce much higher concentrations than those naturally encountered. Dopamine may exert much of its effect by being converted to noradrenaline, thus bypassing the rate-limiting (tyrosine hydroxylase) step in catecholamine synthesis.

**Figure 82.3** (a) Biosynthesis of catecholamines in sympathetic terminals. \*Rate-limiting step by tyrosine hydroxylase. COMT, catechol-*O*-methyl transferase; PNMT, phenylethanolamine-*N*-methyltransferase. (b) Chemical structure of endogenous and synthetic catecholamines.

The synthetic catecholamines are derivatives of dopamine (Figure 82.3b). These agents are characterised by increased length of the carbon chain, which confers affinity for  $\beta$ -receptors. Dobutamine is a synthetic derivative of isoprenaline. These agents have relatively little affinity for  $\alpha$ -receptors due to the configuration of the terminal amine, which differs from the endogenous catecholamines.

Adrenaline, noradrenaline and isoprenaline all have hydroxyl groups on the  $\beta$ -carbon atom of the side chain, and this is associated with 100-fold greater potency than dopamine or dobutamine.

### SYSTEMIC EFFECTS

The systemic effects of any of these agents will vary greatly between patients and within individuals at different times. Adequacy of response is often unpredictable and depends on the aetiology of circulatory failure and systemic comorbidities. In some patients, dramatic responses to small doses may occur, whilst in others, large doses of inotropes may be required to support the failing circulation.

The classification of sympathomimetic agents into  $\alpha$ - and  $\beta$ -agonists, based on the above structure/function relationships, is only a crude predictor of systemic effects.

Adrenaline, noradrenaline and dopamine are all predominantly  $\beta$ -agonists at low doses, with increasing  $\alpha$ -effects becoming evident as the dose is increased.

The synthetic catecholamines are all predominantly  $\beta$ -agonists.

### CARDIOVASCULAR

The cardiovascular effects of the catecholamines under physiological conditions are shown in Table 82.3.

Noradrenaline, adrenaline and dopamine all tend to increase stroke volume, cardiac output and mean arterial pressure, with little change in heart rate and a low incidence of dysrhythmias. The effects on the peripheral vasculature are similar, with all agents increasing venous

return without significant changes in calculated systemic vascular resistance.

Isoprenaline increases cardiac output predominantly by increasing heart rate and by moderate inotropy. This occurs without a significant change in blood pressure due to predominant  $\beta_2$ -receptor induced veno- and vasodilatation.

The profile of dobutamine is similar to isoprenaline, although increases in heart rate are not as pronounced. Both of these agents may decrease mean arterial pressure, particularly in hypovolaemic patients, due to reduced venous return caused by venodilatation. The adverse effects of dobutamine and isoprenaline on heart rate and mean arterial pressure may compromise patients with ischaemic heart disease. However, the vasodilatory effects of dobutamine may be useful in selected patients with predominant systolic heart failure as a means of reducing afterload.

In the failing myocardium, particularly in patients with cardiac failure following cardiopulmonary bypass or septic shock, endogenous stores of noradrenaline are markedly reduced.<sup>9</sup> Furthermore, there may be significant desensitisation and downregulation of cardiac  $\beta$ -receptors. In these situations,  $\alpha_1$ - and  $\alpha_2$ -receptors have an important role in maintaining inotropy and peripheral vasoresponsiveness.<sup>10</sup> This may be expressed clinically as 'tolerance' or tachyphylaxis to catecholamines, particularly with predominantly  $\beta$ -agonists such as dobutamine. This phenomenon may explain the requirement for high doses of catecholamines in refractory shock states. Consequently, the role of  $\beta$ -agonists in patients with severe myocardial failure has been questioned.

Catecholamines have a significant effect on the venous circulation. These drugs primarily restore or maintain 'stressed volumes' of the capacitance vessels under pathological conditions, thereby maintaining or increasing cardiac output and mean arterial pressure. This is important in 'vasoplegic' states such as septic shock.<sup>11</sup>

**Table 82.3** Cardiovascular effect of catecholamines

Agent	$\beta_1$ -effects	$\beta_2$ -effects	$\alpha_1$ -effects	$\alpha_2$ -effects
	+ chronotropy + dromotropy + inotropy	+ inotropy vasodilatation bronchodilatation	+ inotropy vasoconstriction	+ inotropy vasoconstriction
Noradrenaline				
Adrenaline	$\beta$ -effects predominate at low dose; $\alpha$ -effects predominate at high dose			
Dopamine				
Dobutamine	+	+	(+)	-
Isoprenaline	+	(+)	-	-
Dopexamine	+	+	-	-

+ stimulation; (+) mild effect; - no effect.

In clinically used doses, intravenously administered catecholamines have minimal direct vasoconstrictive effects on conducting arterial vessels. Consequently, derived indices such as systemic vascular resistance do not reliably reflect the effect of catecholamines on the peripheral vasculature.

The development of peripheral gangrene in refractory septic shock has been attributed to catecholamine-induced vasoconstriction. There is little evidence to support this as the development of tissue gangrene in these situations primarily occurs as a consequence of intravascular thrombosis caused by sepsis-mediated coagulopathy.

### CEREBRAL

Under physiological conditions, catecholamines do not normally cross the blood–brain barrier. Cerebral blood flow is maintained at a constant rate over a range of perfusion pressure by cerebral autoregulation. Under conditions where the integrity of the blood–brain barrier is altered, such as following traumatic brain injury and aneurysmal subarachnoid haemorrhage, or where upper and lower autoregulatory thresholds are exceeded, exogenous catecholamines may directly enter the cerebral circulation.<sup>12</sup>

The degree by which these agents directly affect the cerebral circulation following head injury is unknown, although there is some evidence suggesting that dopamine has a direct effect causing increased cerebral blood flow and intracranial pressure.<sup>13</sup>

### RENAL

The kidney is an efficient autoregulator, maintaining constant glomerular filtration and renal blood flow by neurohumoral mechanisms such as the renin–angiotensin–aldosterone system. All catecholamines will increase renal blood flow to a similar extent because of increased cardiac output and mean arterial pressure with a resultant natriuresis. Catecholamine-mediated increases in renal blood flow do not affect glomerular filtration rate.

A direct natriuresis may also result from inhibition of cAMP in the renal tubules. This effect has been attributed primarily to low doses of dopamine (2 µg/kg per min), although this occurs to a similar extent with adrenaline, noradrenaline and dobutamine. The use of low dose “renal” dopamine has been shown to be ineffective in preventing renal dysfunction in susceptible patients.<sup>14</sup>

### SPLANCHNIC

Splanchnic autoregulation is not as robust as the brain and kidney. Perfusion is more dependent on mean arterial pressure and the duality of the mesenteric and portal systems. Concerns about catecholamine-induced splanchnic vasoconstriction with mesenteric and hepatic ischaemia have not been substantiated.<sup>15</sup>

Dopamine and dopexamine have been promoted as selective splanchnic vasodilators, but there are no conclusive studies indicating a significant benefit over noradrenaline or adrenaline. Many studies have used gastric

intramucosal pH (pHi), a surrogate measurement of splanchnic blood flow, as the primary end-point. However, as pHi remains an unvalidated measurement, the results of many of the comparative trials of the different sympathomimetics are inconclusive. All catecholamines are equally effective in increasing splanchnic perfusion by improving cardiac output and mean arterial pressure.

### METABOLIC

Catecholamine-mediated β-stimulation may result in hyperglycaemia, hypokalaemia and hypophosphataemia, which may need monitoring and correcting.

Adrenaline is associated with the development of hyperlactataemia and an acidaemia, due to activation of pyruvate dehydrogenase.<sup>16</sup> Whilst pH may fall to levels around 7.2, the acidosis is not associated with impaired tissue perfusion or cellular dysoxia. In most patients who are haemodynamically stable, this is a self-limiting phenomenon and is not associated with adverse outcomes.<sup>17</sup> This may become an issue in severe sepsis with the development of a metabolic acidosis.

## NON-CATECHOLAMINES

### PHOSPHODIESTERASE INHIBITORS

Phosphodiesterase inhibitors are compounds that cause non-receptor mediated competitive inhibition of phosphodiesterase isoenzymes (PDE), resulting in increased levels of cAMP (Figure 82.2). Importantly, cAMP also affects diastolic heart function through the regulation of phospholamban, the regulatory subunit of the calcium pump of the sarcoplasmic reticulum. This enhances the rate of calcium re-sequestration and thereby diastolic relaxation.

For cardiovascular tissue, inhibition of isoenzyme PDE III is responsible for the therapeutic effects. Cardiac effects are characterised by positive inotropy and improved diastolic relaxation. The latter is termed lusitropy and may be beneficial in patients with reduced ventricular compliance or predominant diastolic failure.<sup>18</sup>

These agents also cause potent vasodilatation with reductions in preload, venous return and afterload as well as a reduction in pulmonary vascular resistance. The term ‘inodilation’ has been used to describe this dual haemodynamic effect.

Tolerance is not a feature. These agents may have a place in the management of patients with β-receptor downregulation by causing intrinsic inotropic stimulation and by sensitising the myocardium to β-agonists. Other speculative actions include inhibition of platelet aggregation and reduction of postischaemic reperfusion injury.

Titration pharmacokinetics of phosphodiesterase inhibitors are markedly different from catecholamines. Drug half-lives may be prolonged and excretion is predominantly renal. Hypotension may result from vasodilatation, and combined use with catecholamines (e.g. noradrenaline or adrenaline) may be necessary and complementary to maintain mean arterial pressure.

Phosphodiesterase inhibitors that have been used in clinical practice include the bipyridine derivatives amrinone and milrinone, the imidazolones enoximone and piroximone, and the calcium sensitiser levosimendan. The cardiovascular effects are similar.

The oral form of amrinone is no longer used clinically due to a high incidence of thrombocytopenia, gastrointestinal and neurological side-effects. Milrinone and enoximone are more potent agents and are currently used in clinical practice, with the latter exhibiting more inotropic effects than vasodilatation. Enoximone is more rapidly metabolised, but the metabolite is active and its cardiovascular effects persist for some hours. There is evidence that prolonged use of these agents is associated with an increased mortality in patients with severe heart failure.

Levosimendan is a dose-dependent selective phosphodiesterase inhibitor with a unique action on myocardial calcium metabolism.<sup>19</sup> By increasing myofilament calcium sensitivity throughout the cardiac cycle by binding to cardiac troponin C, associated conformational changes induce improved inotropic and lusitropic function. Vasodilatation is also induced through ATP-sensitive potassium channels. Calcium-sensitive actions predominate at low doses, whilst PDE-inhibition effects predominate at higher doses. The half-life of levosimendan is shorter than older PDE III inhibitors (approximately 1 hour) and it may be given by infusion. Two large trials have demonstrated improved haemodynamic function compared to dobutamine in cardiogenic shock and myocardial infarction, and improved short-term mortality,<sup>20,21</sup> although definitive outcome-based results in critically ill patients are awaited.

## DIGOXIN

Digitalis glycosides have been used for the treatment of heart failure for 200 years and the vagotonic effects used to control the ventricular response in selected supraventricular tachyarrhythmias.

The effects of digoxin are largely mediated by an increase in intracellular calcium concentrations produced indirectly by inhibition of the Na<sup>+</sup>/K<sup>+</sup> membrane pump resulting in increased myocardial contractility (Figure 82.2). The effects on impulse conduction are mediated through change in both vagal and sympathetic tone, which may also increase venous return.

Digoxin has a narrow therapeutic index, is highly protein bound and is largely excreted unchanged in the urine. Alteration in renal function may prolong the normal half-life of about 35 hours to 5 days.

The role of digoxin in acute cardiac failure is questionable. It has minimal effects as an inotrope and evaluation of its efficacy is difficult. In the presence of high levels of sympathetic activity, the positive inotropic effect is negligible and there is usually a poor response in acute myocardial failure, myocarditis, advanced cardiomyopathy, shock states and cardiac tamponade.

The potential for toxicity in the critically ill patient is increased by hypokalaemia, hypomagnesaemia,

hypercalcaemia, hypoxia and acidosis. Toxicity is manifested by dysrhythmias that may assume any form including supraventricular tachyarrhythmias, bradycardia, ventricular ectopy and conduction block at any level.

Monitoring digoxin levels in critically ill patients is recommended, although interpretation of these levels is difficult. A concentration of 1–2 ng/ml represents an acceptable risk:benefit ratio, but concentrations of greater than 2 ng/ml may be associated with toxicity in some patients. However, correlation between blood concentrations, efficacy and toxic manifestations is poor. Clinical criteria remain the most reliable assessment of toxicity, but with the exception of dysrhythmias, may be difficult to elicit in ICU patients.

Drugs commonly used in the ICU, such as amiodarone, calcium channel blockers and erythromycin, demonstrate adverse drug interactions with digoxin. These may interfere with the radioimmune assay to reflect apparently increased digoxin blood concentrations. The place of digoxin in the critically ill patient is therefore limited due to unpredictable efficacy and toxicity. Careful titration of short-acting inotropes and drugs such as amiodarone for control of ventricular rate in supraventricular tachycardia in critically ill patients have largely superseded its use.

The role digoxin in chronic heart failure is well established, particularly in association with angiotensin-converting enzyme inhibitors.<sup>22</sup> These drugs may have a role in long-term intensive care patients with associated chronic cardiac failure. In critically ill patients, digoxin should only be administered by slow intravenous injection, as oral bioavailability varies considerably due to altered gastric motility or perfusion. A loading dose (1–1.5 mg in three or four divided doses, 4–6 hours apart) followed by a maintenance dose (0.125–0.5 mg/day) is a satisfactory regimen. Smaller doses should be used in the elderly, small patients, patients with renal, electrolyte and acid–base disturbances, and myxoedema.

Blood for assay should be taken at least 6 hours after an oral dose and 1 hour after an intravenous dose.

## GLUCAGON

Glucagon is a naturally occurring polypeptide that directly stimulates adenylyl cyclase via specific receptors to increase cAMP concentration in myocardial cells resulting in positive inotropy without producing myocardial excitability (Figure 82.2). Large doses are required to achieve this effect which is associated with a high incidence of metabolic side-effects.

No definitive cardiovascular role for this agent has been established apart from anecdotal reports of its use in severe  $\beta$ -blocker and tricyclic poisoning.

## THYROID HORMONE

Thyroid hormone is required for synthesis of contractile proteins and normal myocardial contraction. It is also a regulator of the synthesis of adrenergic receptors.

Low levels of thyroid hormone have been demonstrated in brain-dead organ donors, in patients with refractory cardiogenic shock, particularly following cardiopulmonary bypass, and secondary to myxoedema. Preliminary studies suggest that treatment with thyroid hormone in these patients may reduce the need for vasoactive therapy to achieve satisfactory haemodynamics.

### SELECTIVE VASOPRESSORS

Vascular responsiveness is mediated via adrenergic receptors:  $\alpha$ -mechanisms predominantly cause vasoconstriction;  $\beta$ -mechanisms, specifically  $\beta_2$ -receptors, mediate vasodilatation (Table 82.3).

Noradrenaline, adrenaline and dopamine have variable effects on the peripheral vasculature and should not be regarded principally as vasoconstrictors or vasopressors.

There are few selective 'vasoconstrictors' that predominantly have a role in vasodilated states such as regional (epidural) anaesthesia or selected patients with acute spinal injury. Their utility in critically ill patients remains limited and they have an unproven role in patients with catecholamine-resistant septic shock and cardiopulmonary resuscitation.

### PHENYLEPHRINE AND METARAMINOL

These agents are direct-acting  $\alpha_2$ -agonists that are selective vasoconstrictors, both venous and arterial, with minimal  $\beta$ -activity. They have similar pharmacokinetics to catecholamines and may be given by infusion. In patients with normal sympathetic tone, these drugs may cause reflex bradycardia, particularly following bolus administration.

### EPHEDRINE

Ephedrine is a synthetic, direct- and indirect-acting, non-catecholamine sympathomimetic that acts on both  $\alpha$ - and  $\beta$ -receptors. Duration of action is longer than equivalent doses of adrenaline and it is generally unsuitable as an infusion.

### VASOREGULATORY AGENTS

#### PATHOPHYSIOLOGY

In addition to adrenergic regulation, neurohumoral influences have a 'permissive' or regulatory role in maintaining vasomotor tone. These are mediated through the renin-aldosterone-angiotensin axis and local mediators such as vasopressin, corticosteroids, nitric oxide and endothelin.

The response of the whole neurohumoral system may become blunted in conditions such as severe sepsis, where qualitative and quantitative changes may occur. In this context, failure of vasomotor responsiveness may be considered as part of the multiple organ failure.

### VASOPRESSIN

Specific vasopressinergic receptors ( $V_1$ ,  $V_2$ ) have been identified in association with sympathetic terminals. Vasopressin is a naturally occurring peptide secreted by the posterior pituitary gland. Reduced serum levels of vasopressin have been demonstrated in septic shock and following cardiopulmonary bypass, suggesting an inflammatory-mediated mechanism. Levels are maintained during cardiogenic shock.

A proportion of patients with severe septic shock requiring high levels of catecholamines to support the circulation may respond to low doses of infused vasopressin (0.04 U/hour) significantly reducing doses of infused catecholamine. This phenomenon appears to be independent of any directly attributable vasopressor effect; rather it is a supplemental 'catecholamine sparing' strategy, particularly in patients with mild to moderate shock states.<sup>23</sup> The impact in severe shock or on mortality has not been substantiated in a large clinical trial (VASST Study).<sup>24</sup>

### STEROIDS

The role of steroid supplementation in circulatory failure has been studied for many years. Whilst immunosuppressive or anti-inflammatory doses have been shown to be ineffective, particularly in septic shock, replacement of 'stress response' doses (approximately 100–200 mg hydrocortisone per day) have been shown to improve vasore sponsiveness to catecholamine infusions in selected patients with refractory shock.

Patients who respond to low doses of steroids may have biochemical evidence of hypoadrenalism, although the diagnosis of this remains difficult to determine in critically ill patients.<sup>25</sup> Early studies of adrenal replacement therapy have suggested improvement in organ function and survival in 'non-responders' to adrenal stimulation with corticotropin.<sup>26</sup> although this effect has not been substantiated in a large randomised controlled trial (CORTICUS Study).<sup>27</sup>

### CLINICAL USES

Currently, there are no definitive studies comparing the efficacy of one inotrope (or combination of inotropes) over another in terms of improving survival.

### DRUG SELECTION

In most instances, individual experience and preference determine selection of inotrope(s).

On a pathobiological basis, exogenous catecholamines are essentially used to augment endogenous mechanisms that may be failing at a number of levels. In this context, vasoactive therapy should be regarded as 'cardiovascular neuroendocrine augmentation therapy'.

Noradrenaline or adrenaline may be considered as the first-line drug in most causes of circulatory failure. An emerging body of evidence confirms this statement (CATS and CAT Studies).<sup>28</sup>

Dopamine predominantly acts as a precursor of noradrenaline and may be used as an alternative to noradrenaline, although all of the endogenous catecholamines have similar pharmacodynamic profiles.

Prediction of the response of an individual to a catecholamine is problematic as marked inter- and intra-individual variability to the response of inotropic agents may occur.

The haemodynamic and metabolic response of an agent must be carefully monitored and evaluated. If there is not a satisfactory response, or if undesirable effects are obtained, the dose or agent should be changed.

## MONITORING

Accurate monitoring of the circulation is essential in patients with circulatory failure to assess baseline parameters and the response of vasoactive drugs.

Clinical assessment of the circulation remains the cornerstone of monitoring these patients and includes frequent assessment and recording of pulse rate and rhythm, blood pressure, adequacy of peripheral perfusion, skin turgor, level of consciousness and urine output.

The majority of patients with circulatory failure managed in the ICU require haemodynamic monitoring as clinical signs may be masked or influenced by sedation, ventilation or organ failure. This should provide accurate information about the state of the circulation and be interpreted within the context of the underlying pathophysiology.

The following principles are important in patients requiring vasoactive drugs.

### BLOOD PRESSURE

All patients receiving vasoactive drugs in all but trivial doses should have accurate monitoring of mean arterial pressure, ideally with an intra-arterial catheter referenced to the aortic root.

Adequacy of tissue perfusion correlates with mean arterial pressure. Accordingly, vasoactive drugs are titrated to achieve a mean arterial pressure that is commensurate with the patient's premorbid blood pressure.

Circulatory dysfunction is commonly defined as a mean arterial pressure  $\leq 50$  mmHg for 1 hour despite adequate fluid resuscitation, although this may vary between patients and will depend on the aetiology.

A large artery such as the femoral artery should be considered in haemodynamically unstable patients as radial or dorsalis pedis arterial catheters underestimate true systemic pressure in shocked patients.

The measurement of systolic and diastolic blood pressures may be inaccurate in haemodynamically unstable

patients, particularly if non-invasive devices are used. These devices tend to overread in hypotensive patients and underread in hypertensive patients.

### VOLUME STATUS

Right atrial pressure monitoring via a central venous catheter provides the best assessment of volume status.<sup>29</sup> Accuracy may be affected by tricuspid regurgitation or pulmonary hypertension.

Left atrial pressure may be measured via direct placement of a left atrial catheter, usually during cardiac surgery. Pulmonary artery occlusion pressure may be used as an indirect measurement of left atrial pressure. However, this measurement may be affected by respiratory artefact, positive airway pressure, tachycardia, hypovolaemia and poor ventricular compliance.

The response and trend to fluid loading and/or vasoactive drug provides more useful information than absolute values.

### CARDIAC OUTPUT

As cardiac output is the major determinant of mean arterial pressure, adequate pressure will usually indicate adequate flow (cardiac output). This relationship depends on the adequacy of venous return and level of afterload.

In selected patients with primary myocardial failure, an assessment of cardiac output is useful to quantify baseline function and to assess the response of the heart to drug therapy. Measurement of cardiac output may be done non-invasively using transthoracic or transoesophageal echocardiography or invasively using a pulmonary catheter, ideally using a continuous cardiac output display system, although the use of these catheters have decreased substantially.

Systemic vascular resistance is frequently calculated and used as a surrogate index of afterload. However, the clinical utility of systemic vascular resistance is limited to providing a crude estimate of global vascular tone, as it does not reflect afterload, arteriolar tone or venous return. Consequently, systemic vascular resistance should not be used as a criterion for selection of vasoactive drug or as a titratable end-point.

### TISSUE PERFUSION

Restoration of reduced tissue perfusion is a primary aim of inotropic therapy. This may be assessed clinically by improvements in urine output, serum urea and creatinine, reversal of metabolic acidosis and reduction in serum lactate.

Global indices of oxygenation such as systemic oxygen delivery ( $\dot{D}O_2$ ), oxygen consumption ( $\dot{V}O_2$ ) and oxygen extraction ratio ( $\dot{D}O_2/\dot{V}O_2$ ) have not been shown to correlate with tissue perfusion or adequacy of resuscitation. Measurement of regional tissue perfusion such as pHi (splanchnic) and jugular venous saturation (cerebral) are limited by poor specificity and are not used routinely.

### DOSAGES AND DRUG ADMINISTRATION

Vasoactive drugs, such as catecholamines or vasopressors, are administered by continuous infusion through a dedicated central venous catheter using drug delivery systems such as infusion pumps or syringe drivers.

Infusion lines should be free of injection portals and clearly marked with identifying labels.

Concentrations of infusions should be standardised in accordance with individual unit protocols. Suggested infusion concentrations are shown in Table 82.4.

These infusions in ml/hour approximate  $\mu\text{g}/\text{min}$ . Absolute doses with regard to body weight are not relevant; rather the titrated clinical effect. Vasoactive drugs are usually prescribed as a titration against a desired mean arterial pressure.

### SPECIFIC SITUATIONS

The following is a summary of the clinical uses of inotropes and vasopressors in common conditions of circulatory failure. Specific pharmacology and physiological effects are discussed above.

#### CARDIOPULMONARY RESUSCITATION

Adrenaline has been used for circulatory collapse at least since 1907. The International Liaison Committee on Resuscitation guidelines recommends adrenaline as first-line inotrope/vasopressor in cardiopulmonary resuscitation.<sup>30</sup> Doses are 1 mg intravenously every 3 minutes.

The use of 'high dose' adrenaline (5 mg), noradrenaline or phenylephrine in cardiopulmonary resuscitation has not been demonstrated to improve return of spontaneous circulation or survival.

Adrenaline is recommended as first-line therapy for 'medical pacing' for severe bradyarrhythmias that do not respond to atropine. Isoprenaline has traditionally been used for this purpose; however, its use has been superseded by adrenaline due to concerns about efficacy and lack of  $\alpha$ -adrenergic activity.

#### CARDIOGENIC SHOCK

Theoretically, catecholamine infusions may confer some advantages in cardiogenic shock, particularly in association with acute myocardial infarction. In patients with systolic heart failure, adrenaline, noradrenaline, dopamine and dobutamine have been shown to cause satisfactory short-term effects. This may allow the myocardium time to recover from post ischaemic 'stunning', particularly after revascularisation. However, no increased long-term survival due to their use has been demonstrated.<sup>31</sup>

The role of phosphodiesterase inhibitors (e.g. milrinone) and calcium sensitisers (e.g. levosimendan) in acute heart failure has yet to be determined, but they may have a potential role in patients with diastolic heart failure. Due to their non-adrenergic mechanism of action, these agents may be useful in patients who are 'resistant' to catecholamines.

**Table 82.4** Infusion concentrations of commonly used vasoactive drugs

Agent	Infusion concentration	Dose
Adrenaline	6 mg/100 ml 5% dextrose	Titrate ml/hour (= $\mu\text{g}/\text{min}$ )
Noradrenaline	6 mg/100 ml 5% dextrose	Titrate ml/hour (= $\mu\text{g}/\text{min}$ )
Dopamine	400 mg/100 ml 5% dextrose	Titrate ml/hour (~ $\mu\text{g}/\text{kg}$ per min)
Dobutamine	500 mg/100 ml 5% dextrose	Titrate ml/hour (~ $\mu\text{g}/\text{kg}$ per min)
Isoprenaline	6 mg/100 ml 5% dextrose	Titrate ml/hour (= $\mu\text{g}/\text{min}$ )
Milrinone	10 mg/100 ml 5% dextrose	Loading dose: 50 $\mu\text{g}/\text{kg}$ over 20 min Infusion: 0.5 $\mu\text{g}/\text{kg}$ per min
Levosimendan	25 mg/100 ml 5% dextrose	Loading dose: 24 $\mu\text{g}/\text{kg}$ over 10 min Infusion: 0.1 $\mu\text{g}/\text{kg}$ per min
Phenylephrine	10 mg/100 ml 5% dextrose	Titrate ml/hour (= 100 $\mu\text{g}/\text{hour}$ )
Metaraminol	100 mg/100 ml 5% dextrose	Titrate ml/hour (= mg/hour)
Ephedrine	300 mg/100 ml 5% dextrose	Titrate ml/hour (= 3 mg/hour)
Vasopressin	20 units/20 ml 5% dextrose	2.4 ml/hour (0.04 U/min)
Hydrocortisone	100 mg/100 ml 5% dextrose	Loading dose: 100 mg Infusion: 0.18 mg/kg per hour

### SEPARATION FROM CARDIOPULMONARY BYPASS

Numerous combinations of catecholamines have been used successfully to wean patients from cardiopulmonary bypass. However, there are no definitive studies demonstrating significant benefits of one catecholamine over another. Similarly, the question whether mechanical support devices, such as intra-aortic counterpulsation, offer a significant advantage over inotropes following cardiac surgery remains unanswered.

Adrenaline, noradrenaline and/or dopamine have been found to increase cardiac output with little increase in heart rate or afterload and are often regarded as first-line drugs. At higher doses ( $> 40 \mu\text{g}/\text{kg}$  per min), dopamine has been shown to cause more tachycardia than adrenaline and noradrenaline. Dobutamine may be associated with vasodilatation and hypotension.

There is no conclusive evidence that the catecholamines, including noradrenaline, cause vasospasm of arterial conduits in clinically used doses.

Phosphodiesterase inhibitors, such as milrinone and levosimendan, either as sole agents or in conjunction with adrenaline or noradrenaline, have been used with success. These may have a role following mitral valve replacement in patients with pulmonary hypertension or preoperative diastolic failure.<sup>32</sup>

Cardiopulmonary bypass may be associated with a systemic inflammatory response syndrome characterised by a hyperdynamic, vasodilated 'low systemic vascular resistance' state.<sup>33</sup> Noradrenaline is frequently advocated as a 'vasopressor' agent in this context to restore mean arterial pressure that may be reduced as a consequence. This condition is usually self-limiting with a nadir 8 hours post bypass. Although catecholamines may be required to achieve appropriate target mean arterial pressure and cardiac output, caution should be applied if high doses (e.g.  $> 30 \mu\text{g}/\text{min}$  noradrenaline) are required. This may be associated with tachyphylaxis and potentiation of catecholamine dependency.

### RIGHT VENTRICULAR FAILURE

Right ventricular infarction and major pulmonary embolism may be associated with acute right ventricular failure. Right ventricular depression may also occur in severe sepsis. Restoration of preload is critical in these conditions, as the failing right ventricle is particularly susceptible to reductions in preload.<sup>34</sup>

Inotropes such as noradrenaline and adrenaline are regarded as first-line drugs in these situations in order to maintain adequate mean arterial pressure so that right coronary artery perfusion, which occurs throughout the cardiac cycle, is maintained.

Concerns about pulmonary artery vasoconstriction and increased right ventricular afterload by noradrenaline and adrenaline appear to be unfounded. Consequently, the use of traditional vasodilators such as isoprenaline in acute right ventricular failure has been superseded by these drugs.

### SEPTIC SHOCK

The cardiovascular effects of the sepsis syndrome and septic shock are complex and range from a hyperdynamic, vasodilated state to one of increasing myocardial failure and paralysis of the peripheral vasculature (vasoplegia).<sup>35</sup> The latter represents inability of the venous circulation to respond to endogenous or exogenous catecholamines with resultant venous pooling.

Consequently, it is important to establish that the patient is not hypovolaemic before using a catecholamine infusion in septic shock, as 20% of patients will respond, at least initially, to intravascular volume expansion.

An increasing body of literature now recommends the use of catecholamines as first-line agents in the treatment of septic shock. The Surviving Sepsis Campaign guidelines<sup>36</sup> recommend either noradrenaline or dopamine be used as the first-line choice vasopressor/inotrope. The basis for this recommendation is weak as there is no high-quality evidence to recommend one catecholamine over another. Concerns about adverse metabolic and splanchnic side-effects of adrenaline are unsubstantiated, and there is an emerging body of evidence that noradrenaline and adrenaline are equally effective in treating septic shock (CAT Study: unpublished data). Furthermore, there is evidence that dopamine may be associated with adverse outcomes, possibly due to neuroendocrine<sup>37,38</sup> and immunological effects, and its use is being questioned in the absence of superiority to noradrenaline or adrenaline.

The efficacy of dobutamine as a sole agent or in combination with noradrenaline in septic shock is questionable and appears to add little to the efficacy of noradrenaline or adrenaline in terms of resolution of shock or mortality (CATS and CAT Studies).<sup>28</sup> Furthermore, the use of dobutamine to increase or augment oxygen delivery has been proven to be ineffective in septic shock.<sup>36</sup>

Doses required to achieve adequate mean arterial pressure in septic shock may vary: noradrenaline or adrenaline infusions (up to  $50 \mu\text{g}/\text{min}$ ) may be necessary. Patients who develop marked catecholamine dependency, in the absence of other acute remediable causes such as active infection, may respond to low doses of vasopressin or 'stress response' doses of hydrocortisone, although there is marked inter-individual variation in response to these drugs (see above).

### ANAPHYLAXIS

Adrenaline is the drug of choice for anaphylactic reactions and for life-threatening bronchospasm, as it blocks mediator release and specifically reverses end-organ effects (see Chapter 58).

A dose of 0.1 mg, as 1 ml of 1:10 000 solution, may be injected subcutaneously, intramuscularly or intravenously. Repeated doses or infusions of up to  $100 \mu\text{g}/\text{min}$  may be required. A strong slowing pulse indicates a pressor effect and provides a useful clinical end-point for the rate of infusion. This  $\alpha$ -agonist effect is probably also of

considerable importance in anaphylaxis, as deaths are frequently due to prolonged refractory hypotension caused by acute biventricular failure. Early intravenous fluid therapy is also important.

### RENAL PROTECTION

Augmentation of mean arterial pressure in order to prevent or ameliorate acute renal failure in critically ill patients is an important use of inotropes. In addition to ensuring adequate preload, catecholamines may be used to defend renal perfusion by maintaining mean arterial pressure at appropriate levels. This is important in hypertensive patients, where higher mean arterial pressure may be required to maintain renal perfusion, particularly when these patients develop intercurrent causes of circulatory failure.

'Renal' dose dopamine (2 µg/kg per min) has been advocated for many years as a renal protective agent by causing renal vasodilatation. However, this has not been substantiated in controlled clinical trials in susceptible patients<sup>14</sup> or as an adjunctive agent with other inotropes in septic shock. In addition, the prolonged use of low dose dopamine is associated with suppression of anterior and posterior pituitary hormonal secretion and impairment in T-cell function. Consequently, low dose dopamine is no longer recommended.

Equivalent renal protection has been demonstrated with dopamine, noradrenaline and dobutamine and it is likely that this effect relates primarily to defence of renal perfusion, rather than a specific renal effect.

### CEREBRAL PERFUSION PRESSURE

Augmentation of cerebral perfusion pressure is an important strategy in patients with pathological reductions in cerebral blood flow. This is well described following traumatic brain injury and aneurysmal subarachnoid haemorrhage and is discussed elsewhere in this volume. See Chapter 45 page 564. Catecholamine interactions on the cerebral vasculature are discussed above.

Noradrenaline, adrenaline, dopamine and phenylephrine have been used to augment cerebral perfusion pressure, although there is no conclusive evidence to recommend one drug over another.<sup>15</sup>

# Vasodilators and antihypertensives

John A Myburgh

Vasodilators are a generic group of drugs that are primarily used in the intensive care unit (ICU) for the management of acute hypertensive states and emergencies. In addition, they have an important role in the management of hypertension and cardiac failure.<sup>1</sup>

## PHYSIOLOGY

Blood pressure is controlled by a complex physiological neurohormonal system involving all components of the cardiovascular system.<sup>2,3</sup> Traditionally, clinical practice has focused on the arterial circulation as the major regulator of systemic pressure. The importance of venous circulation in determining mean arterial pressure and cardiac output is discussed in Chapter 82.

The role of the peripheral vasculature, including both arteriolar and venous systems, in the regulation of blood pressure may be conceptually regarded as a balance between vasodilatation and vasoconstriction<sup>3</sup> (Figure 83.1).

## CALCIUM FLUX

The concentration of intracellular ionised calcium is the primary determinant of vascular smooth muscle tone: increases lead to smooth muscle contraction, decreases cause relaxation. Control of calcium influx and efflux is determined by adrenergic receptor occupation and changes in membrane potential, mediated through voltage gated channels (see Chapter 82, Figure 82.2).

## ENDOTHELIAL SYSTEM

The endothelium has a central role in blood pressure homeostasis by secreting substances such as nitric oxide, prostacyclin and endothelin.<sup>3</sup> These substances are continuously released by the endothelium and are integral in regional autoregulation.<sup>4</sup>

Nitric oxide is synthesised from L-arginine by nitric oxide synthases. It is released under the influence of endothelial agonists such as noradrenaline (norepinephrine), acetylcholine and substance P and in response to mechanical factors such as endothelial shear forces and pulsatile flow. Nitric

oxide diffuses into underlying smooth muscle where it activates guanylate cyclase to increase cyclic guanosine monophosphate (cGMP). Subsequent phosphorylation results in relaxation of underlying smooth muscle and vasodilatation.

Prostacyclin is synthesised via the arachidonic pathway and has a minor role in the control of vascular tone.

Endothelin is an endothelium-derived vasoconstrictor peptide that is associated with increases in vascular smooth muscle intracellular calcium. It acts as endogenous ligand to regulate voltage-gated calcium channels, thereby producing vasoconstriction, usually in response to shear stresses, tissue hypoxia, angiotensin II and inflammatory mediators (e.g. interleukin-6 and nuclear factor  $\kappa$ B).

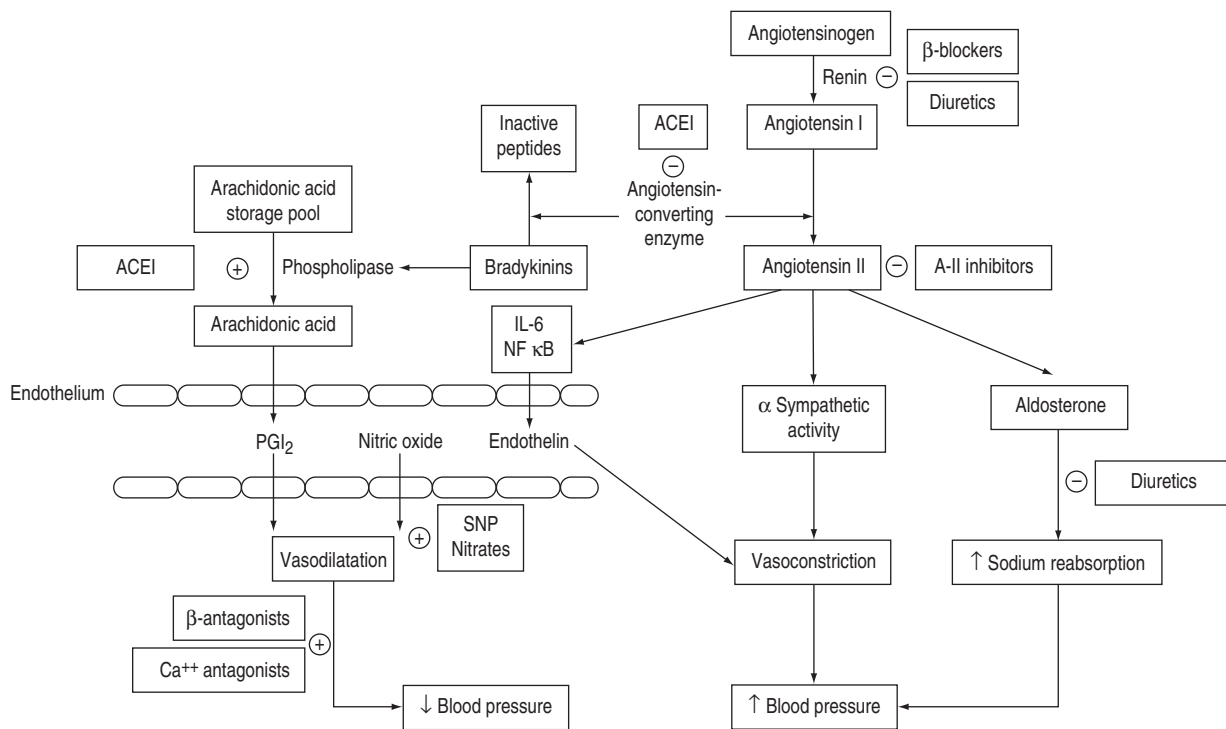

## RENIN-ANGIOTENSIN-ALDOSTERONE SYSTEM

Angiotensinogen is converted by renin to form angiotensin I, which is subsequently converted to angiotensin II by angiotensin-converting enzyme (ACE). Angiotensin II has a number of effects that are responsible for blood pressure homeostasis. These include release of aldosterone, direct activation of  $\alpha$ -adrenergic receptors on vascular smooth muscle and a direct effect in the endothelium. These effects are directed at defending blood pressure and are integral in the stress response. Angiotensin-converting enzyme is also responsible for the inactivation of bradykinins that have predominantly vasodilatory effects, coupled to arachidonic acid synthesis and generation of prostacyclin.

## ADRENERGIC SYSTEM

The sympathetic nervous system is integrally involved with all of the above systems, regulating vascular tone at central, ganglionic and local neural levels. Adrenergic stimulation of  $\beta$ -receptors is associated with vasodilatation;  $\alpha$ -receptor stimulation results in vasoconstriction. The vascular effects of the catecholamines and vasopressors are discussed in Chapter 82.

Adrenergic stimulation is the predominant system in regulating venous tone.<sup>5</sup> This is due to endothelial differences in veins resulting in less production of nitric oxide and reduced responsiveness to angiotensin II.

**Figure 83.1** Schematic diagram of the neurohormonal factors determining vasomotor tone. Mechanism of action of vasodilators is shown by (–) for inhibition, (+) for stimulation. ACEI, angiotensin-converting enzyme inhibitors; A-II, angiotensin II; IL, interleukin; NF, nuclear factor; PGI<sub>2</sub>, prostacyclin; SNP, sodium nitroprusside.

## PATHOPHYSIOLOGY

Hypertensive states develop as a result of impaired or abnormal homeostatic processes, causing an imbalance between vasoconstrictive and vasodilatory effects.

Essential hypertension is the most common cause of hypertension and is due to abnormal neurohormonal regulation, particularly exaggerated effects of renin-angiotensin activity.

Secondary causes of hypertension include structural abnormalities such as aortic stenosis or renal artery stenosis; endocrine conditions such as pheochromocytoma, Cushing's syndrome and pregnancy-induced hypertension; or central causes such as hypertensive encephalopathy or raised intracranial pressure.

## CALCIUM ANTAGONISTS

Calcium antagonists have numerous effects on the cardiovascular system, influencing heart rate conduction, myocardial contractility and vasomotor tone. Entry of calcium through voltage-gated calcium channels is a major determinant of arteriolar, but not venous, tone.<sup>6</sup>

There are three major groups of arterioselective calcium antagonists: dihydropyridines (e.g. nifedipine, nimodipine,

nifedipine and amlodipine), phenylalkylamines (e.g. verapamil) and benzothiazepines (e.g. diltiazem).

Magnesium is a physiological calcium antagonist, and is used therapeutically as magnesium sulphate.

## NIFEDIPINE

Nifedipine is a predominant arteriolar vasodilator, with minimal effect on venous capacitance vessels and no direct depressant effect on heart rate conduction.

It may be administered intravenously, orally or sublingually, and has a rapid onset of action (2–5 minutes) and duration of action of 20–30 minutes.

Nifedipine is frequently used to treat angina pectoris, especially that due to coronary artery vasospasm. Peripheral vasodilatation results in decreased systemic blood pressure, often associated with sympathetic stimulation resulting in increased cardiac output and heart rate that may counter the negative inotropic, chronotropic and dromotropic effects of nifedipine. Nevertheless, nifedipine may be associated with profound hypotension in patients with ventricular dysfunction, aortic stenosis and/or concomitant  $\beta$ -blockade. For this reason, the use of sublingual nifedipine as a method of treating hypertensive emergencies is no longer recommended.<sup>7</sup>

Nifedipine and related drugs may cause diuretic-resistant peripheral oedema that is due to redistribution of extracellular fluid rather than sodium and water retention.

### NIMODIPINE

Nimodipine is a highly lipid-soluble analogue of nifedipine. High lipid solubility facilitates entrance into the central nervous system where it causes selective cerebral arterial vasodilatation.

It may be used to attenuate cerebral arterial vasospasm following aneurysmal subarachnoid haemorrhage. Improved outcomes have been demonstrated in patients with Grade 1 and 2 subarachnoid haemorrhage.<sup>8</sup> Systemic hypotension may result from peripheral vasodilatation that may compromise cerebral blood flow in susceptible patients. Similarly, cerebral vasodilatation may increase intracranial pressure in patients with reduced intracranial elastance.

It may be given by intravenous infusion or enterally with equal effect.

### AMLODIPINE

Amlodipine is an oral preparation that has a similar pharmacodynamic profile to nifedipine. In addition to arteriolar vasodilatory and cardiac effects, amlodipine has been shown to exert specific anti-inflammatory effects in hypertension, diabetic nephropathy and in modulating high-density lipoprotein (HDL) in patients with hypercholesterolaemia.<sup>9</sup> These effects have seen amlodipine increasingly being used for treatment of hypertension in high-risk patients, and may have a role in stable critically ill patients with associated comorbidities.

### VERAPAMIL

The primary effect of verapamil is on the atrioventricular node and this drug is principally used as an antiarrhythmic for the treatment of supraventricular tachyarrhythmias. For this reason, concomitant therapy with  $\beta$ -blockers or digoxin is not recommended.

Verapamil is not as active as nifedipine in its effects on smooth muscle and therefore causes less pronounced decrease in systemic blood pressure and reflex sympathetic activity. It has a limited role as a vasodilator.<sup>10</sup>

### DILTIAZEM

Diltiazem has a similar cardiovascular profile to verapamil, although its vasodilatory properties are intermediate between nifedipine and verapamil. Diltiazem exerts minimal cardiodepressant effects and is unlikely to potentiate  $\beta$ -blockers.

### MAGNESIUM SULPHATE

Magnesium regulates intracellular calcium and potassium levels by activation of membrane pumps and competition

with calcium for transmembrane channels. Physiological effects are widespread, affecting cardiovascular, central and peripheral nervous systems and the musculoskeletal junction.<sup>11</sup>

It acts as a direct arteriolar and venous vasodilator causing reductions in blood pressure. Modulation of centrally mediated and peripheral sympathetic tone results in variable effects on cardiac output and heart rate.

Consequently, it has an established role in the treatment of pre-eclampsia and eclampsia,<sup>12</sup> perioperative management of pheochromocytoma<sup>13</sup> and treatment of autonomic dysfunction in tetanus.<sup>14</sup>

## DIRECT-ACTING VASODILATORS

These drugs act directly on vascular smooth muscle and exert their effects predominantly by increasing the concentration of endothelial nitric oxide. These drugs are also known as nitrovasodilators.<sup>15</sup>

### SODIUM NITROPRUSSIDE

Sodium nitroprusside is a non-selective vasodilator that causes relaxation of arterial and venous smooth muscle. It is comprised of a ferrous ion centre associated with five cyanide moieties and a nitrosyl group. The molecule is 44% cyanide by weight.

It is reconstituted from a powdered form. The solution is light-sensitive requiring protection from exposure to light by wrapping administration sets in aluminium foil. Prolonged exposure to light may be associated with an increase in release of hydrogen cyanide, although this is seldom clinically significant.

When infused intravenously, sodium nitroprusside interacts with oxyhaemoglobin, dissociating immediately to form methaemoglobin while releasing free cyanide and nitric oxide. The latter is responsible for the vasodilatory effect of sodium nitroprusside.

Onset of action is almost immediate with a transient duration, requiring continuous intravenous infusion to maintain a therapeutic effect.

Tachyphylaxis is common, particularly in younger patients. Large doses should not be used if the desired therapeutic effect is not attained, as this may be associated with toxicity.

Sodium nitroprusside produces direct venous and arterial vasodilatation, resulting in a prompt decrease in systemic blood pressure. The effect on cardiac output is variable. Decreases in right atrial pressure reflect pooling of blood in the venous system, which may decrease cardiac output. This may result in reflex tachycardia that may oppose the overall reduction in blood pressure. In patients with left ventricular failure, the effect on cardiac output will depend on initial left ventricular end-diastolic pressure. Sodium nitroprusside has unpredictable effects on calculated systemic vascular resistance. Homeostatic

mechanisms in preserving cardiac output may explain tachyphylaxis to prolonged infusions.

Sodium nitroprusside may increase myocardial ischaemia in patients with coronary artery disease by causing an intracoronary steal of blood flow away from ischaemic areas by arteriolar vasodilatation. Secondary tachycardia may also exacerbate myocardial ischaemia.

Due to its non-selectivity, sodium nitroprusside has direct effects on most vascular beds. In the cerebral circulation, sodium nitroprusside is a cerebral vasodilator, leading to increases in cerebral blood flow and blood volume. This may be critical in patients with increased intracranial pressure. Rapid and profound reductions in mean arterial pressure produced by sodium nitroprusside may exceed the autoregulatory capacity of the brain to maintain adequate cerebral blood flow.

Sodium nitroprusside is a pulmonary vasodilator and may attenuate hypoxic pulmonary vasoconstriction, resulting in increased intrapulmonary shunting and decreased arterial oxygen tension. This phenomenon may be exacerbated by associated hypotension.

The prolonged use of large doses of sodium nitroprusside may be associated with toxicity related to the production and cyanide and, to a lesser extent, methaemoglobin.<sup>16</sup>

Free cyanide produced by the dissociation of sodium nitroprusside reacts with methaemoglobin to form cyanmethaemoglobin, or is metabolised by rhodenase in the liver and kidneys to form thiocyanate. A healthy adult can eliminate cyanide at a rate equivalent to a sodium nitroprusside infusion of 2 µg/kg per min or up to 10 µg/kg per min for 10 minutes, although there is marked inter-individual variability.

Toxicity should be considered in patients who become resistant to sodium nitroprusside despite maximum infusion rates and who develop an unexplained lactic acidosis. In high doses, cyanide may cause seizures.

Treatment of suspected cyanide toxicity is cessation of the infusion and administration of 100% oxygen. Sodium thiosulphate (150 mg/kg) converts cyanide to thiocyanate, which is excreted renally. For severe cyanide toxicity, sodium nitrate may be infused (5 mg/kg) to produce methaemoglobin and subsequently cyanmethaemoglobin. Hydroxocobalamin, which binds cyanide to produce cyanocobalamin, may also be administered (25 mg/hour to maximum of 100 mg).

### GLYCERYL TRINITRATE

Glyceryl trinitrate is an organic nitrate that generates nitric oxide through a different mechanism from sodium nitroprusside.

The pharmacokinetics allows glyceryl trinitrate to be given by infusion, with a longer onset and duration of action than sodium nitroprusside. Glyceryl trinitrate may also be administered sublingually, orally or transdermally.

Tachyphylaxis is common with glyceryl trinitrate; doses should not be increased if patients no longer respond to standard doses. Glass bottles or polyethylene

administration sets are required as glyceryl trinitrate is absorbed into standard polyvinylchloride sets.

The effects on the peripheral vasculature are dose dependent, acting principally on venous capacitance vessels to produce venous pooling and decreased ventricular afterload. These are important mechanisms in patients with cardiac failure.

Glyceryl trinitrate primarily dilates larger conductance vessels of the coronary circulation, resulting in increased coronary blood flow to ischaemic subendocardial areas, thereby relieving angina pectoris. This is in contrast to sodium nitroprusside that may cause a coronary steal phenomenon.

Reductions in blood pressure are more dependent on blood volume than sodium nitroprusside. Precipitous falls in blood pressure may occur in hypovolaemic patients with small doses of glyceryl trinitrate. In euvoalaemic patients, reflex tachycardia is not as pronounced as with sodium nitroprusside. At higher doses, arteriolar vasodilatation occurs without significant changes in calculated systemic vascular resistance.

Glyceryl trinitrate is a cerebral vasodilator and should be used with caution in patients with reduced intracranial elastance. Headache due to this mechanism is a common side-effect in conscious patients.

### ISOSORBIDE DINITRATE

Isosorbide dinitrate is the most commonly administered oral nitrate for the prophylaxis of angina pectoris. It has a physiological effect that lasts up to 6 hours in doses of 60–120 mg. The mechanism of action is the same as glyceryl trinitrate. Hypotension may follow acute administration, but tolerance to this develops with chronic therapy.<sup>17</sup>

### HYDRALAZINE

Hydralazine is a potent, arterioselective, direct-acting vasodilator that acts via stimulation of cGMP and inhibition of smooth muscle myosin light chain kinase.

Following intravenous administration, hydralazine has a rapid onset of action, usually within 5–10 minutes. It may also be administered intramuscularly or orally. The drug is partially metabolised by acetylation, for which there is marked inter-individual variability (35% population are slow acetylators). Whilst this does not have much clinical significance regarding the antihypertensive effects, it is important with respect to toxicity.<sup>17</sup>

Hydralazine causes predominantly arteriolar vasodilatation that is widespread but not uniform. It is associated with direct and reflex sympathetic activity, so that cardiac output and heart rate are increased. Prolonged use of hydralazine stimulates renin release and is associated with sodium and water retention. Consequently, hydralazine is frequently administered with β-blockers and/or diuretics.

Chronic use of hydralazine may be associated with immunological side-effects including a lupus syndrome, vasculitis, haemolytic anaemia and rapidly progressive glomerulonephritis.

### DIAZOXIDE

Diazoxide is chemically related to the thiazide diuretics and is a potent, non-selective, direct-acting vasodilator. The mechanism of action is unclear, but it is a predominantly arteriolar vasodilator.<sup>18</sup> Diazoxide is administered intravenously or intramuscularly. It has a rapid onset (3–5 minutes) and prolonged duration of action (1–2 hours), often with precipitous reductions in blood pressure. Diazoxide has similar cardiovascular effects to hydralazine and is associated with significant reflex sympathetic stimulation, resulting in increased cardiac output and heart rate.

It is a useful drug in accelerated hypertension associated with acute renal failure such as glomerulonephritis and has been used in severe pregnancy-induced hypertension and eclampsia. Stimulation of catecholamine release prohibits the use of diazoxide in patients with phaeochromocytoma.

It is associated with metabolic side-effects such as hyperglycaemia and sodium and water retention.

## $\alpha$ -ADRENERGIC ANTAGONISTS

Several groups of compounds act as  $\alpha$ -adrenergic blockers with variable affinity for populations of  $\alpha$ -receptors. Physiology and pathophysiology may influence the responsiveness of the drug receptor–effector relationship. Receptor pathobiology is discussed in Chapter 82. Consequently, there may be marked inter- and intra-individual variability in the patient's response to these drugs.

There are six main groups of  $\alpha$ -receptor antagonists: imidazolines (e.g. phentolamine), haloalkylamines (e.g. phenoxybenzamine), prazosin,  $\beta$ -adrenergic antagonists with a receptor antagonism (labetalol, carvedilol), phenothiazines (chlorpromazine) and buyrophenones (haloperidol).

### PHENTOLAMINE

Phentolamine is a non-selective, competitive antagonist at  $\alpha_1$ - and  $\alpha_2$ -receptors. At low doses, phentolamine causes prejunctional inhibition of noradrenaline release (via  $\alpha_2$ -receptor inhibition). At higher doses, more complete  $\alpha$ -receptor blockade is achieved, with enhancement of effects of  $\beta$ -agonists due to increased local concentration of noradrenaline produced by  $\alpha_2$ -blockade (see Chapter 82, Figure 82.3a).

Phentolamine is administered intravenously and may be given intermittently or by infusion. Onset is rapid (within 2 minutes), with a duration of action of 10–15 minutes.

Arteriolar and venous vasodilatation reduces systemic blood pressure, without significant changes in calculated systemic vascular resistance. Effects on cardiac output are variable, and there is modest reflex sympathetic stimulation without significant increases in heart rate.

### PHENOXYBENZAMINE

Phenoxybenzamine is a non-selective, non-competitive,  $\alpha_1$ - and  $\alpha_2$ -receptor antagonist. Blockade is also produced on histamine, serotonin and acetylcholine muscarinic receptors. Reuptake of noradrenaline is blocked, thereby potentiating the effects of  $\beta$ -agonists.

Phenoxybenzamine is usually administered orally, but may also be given intravenously. It has a long onset of action and prolonged duration of action (3–4 days). It causes a gradual reduction in systemic blood pressure, without rapid reflex sympathetic activity.

Prolonged use is associated with increased  $\beta$ -adrenergic effects, predominantly increased heart rate, for which combination therapy with  $\beta$ -blockade is used. Phenoxybenzamine is primarily used in the management of phaeochromocytoma, either preoperatively or long term in inoperable patients. It may also be used to control autonomic hyperreflexia in patients with spinal cord transection.<sup>19</sup>

### PRAZOSIN

Prazosin is a relatively arterioselective, competitive,  $\alpha_1$ -receptor antagonist. It acts postjunctionally and therefore does not inhibit reuptake of noradrenaline. Consequently, it produces less tachycardia for a given reduction in systemic blood pressure.

It is administered orally and usually used for essential or renovascular (hyper-renaemia) hypertension. It is frequently used in combination with  $\beta$ -blockers and diuretics, particularly in patients with renal dysfunction.

### LABETALOL

Labetalol is specific competitive antagonist at  $\alpha_1$ -,  $\beta_1$ - and  $\beta_2$ -adrenergic receptors.  $\beta$ -Blockade effects predominate, with a blockade potency approximately 10% of prazosin. Labetalol has partial agonist effects on  $\beta_2$ -receptors. The ratio of  $\alpha_1$ : $\beta$ -receptor blockade is 1:4.

It is administered intravenously, has a rapid onset of action (5–10 minutes) with a duration of 2–6 hours. It may be given by infusion.

Systemic blood pressure and cardiac output are reduced by a combination of negative inotropy, arterial and venous vasodilatation. Reflex tachycardia is attenuated by  $\beta$ -blockade.

Side-effects such as bronchospasm and hyperkalaemia relate predominantly to  $\beta$ -blockade.

### CARVEDILOL

Carvedilol is a non-selective  $\beta$ -blocker with  $\alpha_1$ -antagonist activity. Most of the vasodilator activity relates to  $\alpha_1$ -antagonism, although at high concentrations it also blocks calcium entry. The ratio of  $\alpha_1$ : $\beta$ -receptor blockade is 1:10.

It is administered orally; no intravenous preparation is available.

Recent studies have demonstrated slowing of progression of congestive cardiac failure and improved mortality, particularly when used in conjunction with ACE inhibitors in patients with mild to moderate cardiac failure.<sup>20,21</sup> It may also be used in patients who cannot be treated with ACE inhibitors.

### HALOPERIDOL AND CHLORPROMAZINE

These drugs act as competitive  $\alpha$ -receptor antagonists causing non-selective vasodilatation and blockade of noradrenaline reuptake.

These drugs are primarily used as major tranquillisers or antipsychotics; their effect on the peripheral vasculature should be regarded as a side-effect, rather than a specific therapeutic action.

Reduction of systemic blood pressure is variable and may be precipitous, particularly in hypovolaemic patients with high sympathetic drive. These drugs may be useful in neurogenic hypertension, and are not regarded as first-line vasodilators.

### SYMPATHOMIMETICS

The peripheral vascular effects of  $\beta$ -adrenergic agonists such as adrenaline (epinephrine), noradrenaline, dopamine and the synthetic catecholamines dobutamine and isoprenaline are discussed in Chapter 82.

At low doses, adrenaline, noradrenaline and dopamine are predominantly  $\beta$ -agonists and cause both arterial and venous vasodilatation which may cause reductions in mean arterial pressure.

Dobutamine and isoprenaline are predominantly  $\beta$ -agonists and may cause decreases in mean arterial pressure, particularly in hypovolaemic patients or those with increased sympathetic drive. These agents may have a role in reducing left ventricular afterload in patients with systolic heart failure.

### ANGIOTENSIN-CONVERTING ENZYME INHIBITORS

Angiotensin converting enzyme (ACE) inhibition has become a cornerstone in the management of patients with hypertension, cardiac failure and ischaemic heart disease.<sup>22,23</sup> These drugs act by non-selective, competitive, irreversible inhibition to the angiotensin I binding site.

There are a very large number of ACE inhibitors on the market with very high penetration into the ambulant patient population. These drugs are administered orally; there are no routinely used parenteral preparations. Consequently, many critically ill patients admitted to the ICU may be taking ACE inhibitors. As a general rule, ACE inhibitors are stopped in most critically ill patients

until vital organ (specifically renal) function is stabilised and the patient can take orally or enterally. Thereafter, doses are gradually increased over time with close monitoring of renal function.

### PREPARATIONS

Captopril is the prototype and is still widely used. It is administered orally in increasing doses and intervals to a maximum dose of 50 mg 8 hourly. It may be administered sublingually in acute hypertension (5–25 mg), with an onset of action in 20–30 minutes, duration of 4 hours. There are no significant differences in the cardiovascular effects between captopril and other preparations. It is contraindicated in patients with bilateral renal artery stenosis and should be avoided in pregnancy.

Enalapril is a pro-drug, effective by hepatic metabolism to enalaprilat, producing a slower and more controlled action. It is administered orally in 5 mg increments to a total of 20 mg twice daily.

Lisinopril has the advantage of single daily dosing and may be useful in stable critically ill patients.

### CARDIOVASCULAR EFFECTS

The cardiovascular effects of ACE inhibition are widespread, with effects that influence the peripheral vasculature, cardiac performance, and salt and water homeostasis. Consequently, ACE inhibitors are not principally regarded as vasodilators, although they have both direct and indirect effects on the peripheral vasculature.

Increased production of endothelial vasodilators such as prostacyclin and decreased production of endothelin by angiotensin result in generalised venous and arteriolar vasodilatation. This occurs in the absence of reflex sympathetic activity or changes in heart rate, due to the modulation of adrenergic stimulation. Systemic blood pressure is reduced without changes in cardiac output or heart rate.

ACE inhibition is associated with improved myocardial performance following acute myocardial infarction due to left ventricular remodelling and improvement in neurohumoral activation. These drugs have been shown to improve survival following myocardial infarction in patients with left ventricular dysfunction.<sup>24</sup>

'First-dose hypotension' is described in patients receiving ACE inhibitors for the first time. This may occur particularly in patients who are salt and water depleted, or those who develop sensitivity to the drug. Drug sensitivity may also present as a sudden decrease in renal function following commencement of the drug (see below).

### RENOVASCULAR EFFECTS

ACE inhibitors may cause renal failure, particularly in patients with renovascular disease, hyperreninaemic hypertension and acute renal dysfunction. The renal effects of ACE inhibitors may be potentiated by diuretics, non-steroidal anti-inflammatory agents and  $\beta$ -blockers.

As a rule in intensive care patients, ACE inhibitors are started in suitable patients once renal function has stabilised and the patient no longer requires inotropic support.

### SIDE-EFFECTS AND TOXICITY

In addition to renal dysfunction, ACE inhibitors may be associated with a number of side-effects. The most common of these is cough, which is due to the increased production of kinins.<sup>25</sup>

Severe angioneurotic oedema causing upper-airway obstruction may occur with all ACE inhibitors, although this is less common with enalapril and lisinopril. This is due to increased activation of bradykinins. ACE inhibitors are contraindicated in patients with a history of hereditary or idiopathic angioneurotic oedema.<sup>26</sup>

Neutropenia and agranulocytosis are uncommon but potentially lethal side-effects in susceptible patients.

### ANGIOTENSIN RECEPTOR BLOCKERS

These are a newer class of antihypertensive drugs that cause irreversible, selective blockade of angiotensin II at AT<sub>1</sub> receptors.<sup>27,28</sup>

Losartan is the prototype, which has been followed by newer compounds such as irbesartan, valsartan and telmasartan. These drugs are oral preparations; there is no parenteral form.

The cardiovascular profile of angiotensin receptor blockers is similar to the ACE inhibitors, although definitive studies on long-term survival following acute myocardial infarction or in patients with cardiac failure have yet to be done.

The selective blockade of angiotensin II offers several possible advantages over ACE inhibitors. These drugs are long acting and may be given once daily; onset of action is slow, thereby avoiding first-dose hypotension; side-effects such as cough and angioneurotic oedema are less common.<sup>29</sup>

### CENTRALLY ACTING AGENTS

These agents modulate adrenergic stimulation at central nervous system and spinal cord level.

The vasomotor centre of the medulla mainly controls sympathetic pressor influences, although other brainstem, midbrain and spinal centres have a role.

Most central responses are mediated through  $\alpha_2$ -adrenergic receptors, which modulate the release and reuptake of noradrenaline, with subsequent effects on the peripheral vasculature and cardiac function.

### CLONIDINE

Clonidine is a centrally acting  $\alpha_2$ -agonist which stimulates inhibitory neurones in the vasomotor centre. This results

in a reduction in sympathetic outflow from the central nervous system and is associated with negative inotropy and reduction in heart rate. Systemic blood pressure is reduced by this mechanism, with associated arteriolar and venous vasodilatation. Clonidine has centrally acting analgesic properties, which make it a suitable drug in patients with postoperative hypertension.

Peripherally, it stimulates prejunctional  $\alpha_2$ -receptors, thereby decreasing noradrenaline release, but may also have an effect at postjunctional  $\alpha_1$ -receptors causing vasoconstriction. This may present as rebound hypertension following initial reduction of blood pressure, as there is variable duration of the central and peripheral effects.

Clonidine is administered by intravenous injection; it cannot be given by infusion. It has a rapid onset of action (5–10 minutes) and duration of action of 20–30 minutes. It has both central and peripheral effects.

### METHYLDOPA

Methyldopa has been used in the treatment of hypertension for 30 years. It acts as a centrally acting 'false' transmitter following metabolism to methylnoradrenaline and subsequent stimulation of  $\alpha_2$ -receptors, although the precise mechanism is not clear.

It has no direct effect on cardiac or renal function. Cardiac output is maintained without changes in heart rate. Consequently, it may arrest or improve hypertensive nephropathy. It has a limited role in hypertensive emergencies, but is useful in accelerated essential, renovascular and pregnancy-induced hypertension.

It is administered orally in doses of 250 mg to 2 g per day. An intravenous preparation is available.

### OTHER ANTIHYPERTENSIVE AGENTS

#### $\beta$ -ADRENERGIC ANTAGONISTS

$\beta$ -Blockers have been used for the treatment of hypertension for over 30 years and have an increasingly important role in the management of cardiac failure.<sup>30–32</sup>

In addition to decreasing heart rate and contractility,  $\beta$ -blockers have other neurohumoral effects that affect vascular tone. These relate to inhibition of renin release from juxtaglomerular cells (Figure 83.1) and prejunctional inhibition of noradrenaline that result in reduction in vascular tone and blood pressure. A central effect of  $\beta$ -blockers has also been proposed.

The mode of action has been described in terms of selectivity to blockade of  $\beta$ -adrenergic receptors –  $\beta_1$  and/or  $\beta_2$ . While this is an appropriate pharmacological distinction, the clinical activity of these drugs is not as predictable due to mixed populations of  $\beta_1$ - and  $\beta_2$ -receptors in most organs and variable receptor responsiveness in physiological and pathophysiological conditions. Consequently,

there is marked inter-individual variability in the response to these drugs. In high enough doses, whether intentionally or due to toxicity, all  $\beta$ -blockers will cause generalised antagonism with resultant therapeutic and toxic effects.

Lipid-soluble  $\beta$ -blockers include propranolol and metoprolol that are predominantly excreted by the liver; atenolol and sotalol are predominantly renally excreted, warranting caution with these drugs in patients with renal dysfunction.

$\beta$ -Blockers may be given orally or intravenously. As there is significant first-pass metabolism, doses for oral and intravenous administration are markedly different.

Esmolol is an intravenous  $\beta$ -blocker that is rapidly metabolised by red cell esterases. Its rapid onset of action and short duration allow infusion of drug, making it a useful drug in patients with acute hypertensive states associated with tachycardia. Labetalol and carvedilol are discussed above.

$\beta$ -Blockers are frequently used as adjuncts to vasodilators in the treatment of hypertensive emergencies and states, particularly where reflex tachycardia and sympathetic stimulation occurs (e.g. hydralazine, nifedipine and prazosin).

Side-effects and toxicity of  $\beta$ -blockers include bradycardia (which may be profound), hypotension, bronchoconstriction, aggravation of peripheral vascular ischaemia, hyperkalaemia and masking of the sympathetic response to hypoglycaemia.

## DIURETICS

As with  $\beta$ -blockers, diuretics have an established place in the management of hypertension. In addition to their effects on salt and water excretion and inhibition of aldosterone, direct vasodilatory effects are associated with diuretics such as furosemide and the thiazides.

These drugs have a rapid venodilatory action, which may be due to inhibition of a noradrenaline-activated chloride channel on veins. Reductions of blood pressure and right atrial pressure may occur following low doses, and may present before an associated diuresis.

All diuretics should be used with caution in patients with renal dysfunction and avoided until a euvolaemic state is achieved.

## DRUG SELECTION

The clinical use of vasodilators in intensive care is different from their use in ambulatory patients. In the critically ill patient, these drugs are primarily used to control acute rises in mean arterial pressure associated with sympathetic stimulation, or as specific treatment of hypertensive emergencies.<sup>33</sup>

The ideal vasodilator is therefore one that has a rapid and predictable onset of action, allows titration to achieve a desired systemic blood pressure, does not compromise cardiac output, does not cause significant reflex tachycardia and is non-toxic.

The selection of drug to treat hypertensive states will depend on the predominant cause of hypertension and the mechanism of action in the homeostatic pathway outlined in Figure 83.1.

There are no large studies investigating optimum therapy in patients presenting with hypertensive emergencies. These conditions occur in a heterogeneous group of patients and drug selection is essentially determined by the underlying pathophysiology, personal preference and experience.<sup>33</sup>

## MONITORING

The principles of haemodynamic monitoring in patients receiving vasoactive drugs is outlined in Chapter 82.

Patients with severe hypertension or those receiving infusions or doses of potent vasodilators such as sodium nitroprusside, glyceryl trinitrate, diazoxide or nifedipine should be monitored via an intra-arterial catheter.

The use of non-invasive measurement devices are not recommended in patients with hypertensive emergencies.

As peripheral vasodilators have significant effects on both the arterial and venous systems, measurement of volume status is important. In the majority of patients, establishing a euvolaemic state is essential before commencing a vasodilator.

## DOSAGES AND DRUG ADMINISTRATION

Vasodilators administered via infusion are delivered through a dedicated central venous catheter using infusion pumps or syringe drivers and titrated to achieve a target mean arterial pressure.

Infusion lines should be free of injection portals and clearly marked with identifying labels.

Concentrations of infusions should be standardised in accordance with individual unit protocols. Suggested infusion concentrations and common drug doses are shown in Table 83.1.

## SPECIFIC SITUATIONS

The following is a summary of the clinical uses of the above drugs in hypertensive states commonly encountered in the ICU. Specific pharmacology and physiological effects are discussed above.

## ACUTE HYPERTENSION

The most common cause of hypertension in intensive care patients is pain or agitation, particularly in postoperative patients. It is important that patients have adequate analgesia and sedation before antihypertensives or vasodilators are used.

Other common causes of hypertension include hypothermia, urinary retention, positional discomfort and omission of pre-admission antihypertensives, particularly  $\beta$ -blockers.

**Table 83.1** Dose and infusion concentrations of commonly used vasodilators and antihypertensives in intensive care

Agent	Infusion/Dose	Caution
Sodium nitroprusside	50 mg/250 ml 5% Dextrose; range 3–40 ml/hour	Cyanide toxicity (> total dose 0.5 mg/kg per 24 hours) Photodegradation Raised intracranial pressure Rebound hypotension Shunt and oxygen desaturation
Glyceryl trinitrate	30 mg/100 ml 5% Dextrose; range 2–25 ml/hour	Drug binding to polyvinylchloride Tachyphylaxis Raised intracranial pressure
Hydralazine	10–20 mg i.v. bolus 20–40 mg 6–8-hourly	Tachycardia Myocardial ischaemia
Diazoxide	50–100 mg i.v. boluses 15–30 mg/min infusion	Precipitous hypotension Hyperglycaemia
Trimetaphan	1–4 mg/min infusion	Mydriasis, ileus Bradycardia
Phentolamine	1–10 mg i.v. boluses 5–30 mg/hour infusion	Tachycardia
Phenoxybenzamine	Oral: 10 mg/day until postural hypotension i.v.: 1 mg/kg per day	Idiosyncratic hypotension
Prazosin	2–10 mg/day, 8-hourly	
Nifedipine	5–10 mg oral/sublingual	Precipitous hypotension
Amlodipine	5–10 mg oral b.d.	Caution in renal impairment
Captopril	6.25–50 mg orally, 8-hourly Acute hypertension: 6.5–25 mg sublingually p.r.n.	Caution in renovascular hypertension and renal failure Pregnancy Angioneurotic oedema
Enalapril	5–20 mg 8-hourly	
Enalaprilat	0.625–5 mg bolus	Caution in renal failure and hypovolaemia
Losartan	25–100 mg/day	Caution in renal failure
Clonidine	25 µg to 150 mg i.v. bolus	Acute, perioperative centrally mediated hypertension May cause rebound hypertension with chronic use
Atenolol	1–10 mg i.v. boluses 25–100 mg oral b.d.	Caution in poor left ventricular function, asthma Hyperkalaemia Potentiated in renal failure
Metoprolol		As for atenolol, safe in renal failure
Esmolol	Loading dose 0.5 mg/kg 10–40 mg/hour infusion	
Labetalol	20–80 mg i.v. boluses 0.5–4 mg/min infusion	
Magnesium sulphate	40–60 mg/kg loading (or 6 g) 2–4 g/hour infusion	Maintain serum magnesium > 1.5–2 mmol/l

The majority of instances of acute hypertension in the ICU will respond to simple measures addressing the above.<sup>34</sup>

Sustained hypertension may be treated acutely with incremental doses or infusions of short-acting drugs such as glyceryl trinitrate, sodium nitroprusside, phentolamine, hydralazine, nifedipine or clonidine. Infusions of vasodilators may be required if hypertension persists, or if the patient is unable to take longer acting oral agents such as prazosin or amlodipine. Hypertension associated with tachycardia may be treated with  $\beta$ -blockers.

### HYPERTENSIVE ENCEPHALOPATHY

Hypertensive encephalopathy is defined as an acute organic brain syndrome occurring as a result of failure of cerebrovascular autoregulation. There may be differences in the degree of hypertension that cause encephalopathy. It may present as confusion, visual disturbances, blindness, seizures or stroke. If not adequately treated, hypertensive encephalopathy may result in intracerebral haemorrhage, coma or death.<sup>35</sup>

Hypertensive encephalopathy may occur in patients with untreated or undertreated hypertension or in association with other diseases such as renal disease (e.g. glomerulonephritis, renovascular disease), thrombotic thrombocytopenic purpura, immunosuppressive therapy, collagen vascular diseases or eclampsia. Consequently, drug treatment will depend on the context in which it occurs.

The aim of drug therapy in these patients is to reduce blood pressure in a controlled, predictable and safe way. Acutely, short-acting, titratable parenteral drugs are suitable in emergency situations. Sodium nitroprusside can be used safely in most circumstances. Although sodium nitroprusside may increase intracranial pressure, associated reductions in mean arterial pressure offset this effect. Phentolamine is equally effective. Esmolol may be useful as an adjunctive agent.<sup>36</sup>

Other agents that are useful in controlling severe hypertension include hydralazine, diazoxide, nifedipine, clonidine and ACE inhibitors (although these must be used cautiously in patients with associated renal dysfunction). Combination therapy is usually required, although this should be done with caution to minimise additive effects with resultant hypotension.

Patients with hypertensive emergencies are frequently hypovolaemic due to excessive sympathetic stimulation. In the absence of left ventricular failure, judicious fluid replacement may reduce blood pressure and improve renal function, thereby minimising precipitous hypotension that may result following administration of some drugs. Diuretics are generally avoided in these conditions unless there is evidence of left ventricular failure.<sup>36</sup>

### ACUTE STROKE

Acute stroke syndromes frequently occur in the setting of severe hypertension. The reduction of mean arterial

pressure must be balanced by the maintenance of adequate cerebral perfusion pressure and cerebral blood flow. Ischaemic or infarcted brain is vulnerable to critical reductions in cerebral blood flow, while excessive mean arterial pressure may increase the risk of cerebral haemorrhage.<sup>37</sup>

Acutely, blood pressure should be maintained in a normal range until intracranial pathology has been identified by CT scan. Aggressive reduction in blood pressure is not recommended in patients with ischaemic stroke, whilst hypertension in patients with aneurysmal subarachnoid haemorrhage or intracranial haemorrhage may be managed by drugs outlined above.

### AORTIC DISSECTION

Aortic dissection is the most dramatic and most rapidly fatal complication of severe hypertension. Blood pressure should be decreased as rapidly as possible to normal or slightly hypotensive levels. Titrations are usually made to achieve systolic blood pressures of 100–110 mmHg or mean arterial pressure of 55–65 mmHg. This will depend on the patient's premorbid blood pressure and the accuracy of blood pressure measurement. It is important to maintain blood pressure at levels compatible with adequate cerebral and renal perfusion.<sup>38</sup>

This is best achieved initially by a combination of  $\beta$ -blockers (e.g. esmolol, labetalol or atenolol), then in combination with vasodilators such as sodium nitroprusside or glyceryl trinitrate. Tachycardia must be avoided as this is a significant determinant of aortic shear force that may exacerbate the dissection.

Aortic dissection distal to the left subclavian artery is managed conservatively with antihypertensive therapy. Proximal dissections are managed surgically after acute control of blood pressure.

### ACUTE MYOCARDIAL ISCHAEMIA

Myocardial ischaemia in the absence of obstructive coronary atherosclerosis may be precipitated by severe hypertension. This occurs by increased left ventricular wall stress, reduced preload, tachycardia and increased myocardial metabolic demand. Severe ischaemia may result in acute left ventricular failure.

Intravenous glyceryl trinitrate is useful in this situation and may be used in combination with  $\beta$ -blockers such as esmolol, labetalol or carvedilol.

ACE inhibitors may be used in the acute situation and may be required for longer term treatment.

### PHAECHROMOCYTOMA

Tumours of the adrenal medulla secrete catecholamines that result in initial paroxysmal, then sustained, severe hypertension. They may present to the ICU as a hypertensive emergency or perioperatively for surgical ablation.<sup>39</sup>

Acute hypertensive crises associated with phaeochromocytoma are managed with incremental doses or

infusions of phentolamine. Untreated patients may be significantly hypovolaemic and may require judicious volume replacement.  $\beta$ -Blockers should not be used in the acute stage as these will potentiate unopposed  $\alpha$ -adrenergic stimulation.

Phenoxybenzamine forms the mainstay of treatment and preparation for surgery. This is commenced in 20–30 mg increments and continued until blood pressure is controlled. Excessive  $\beta$ -adrenergic effects are treated with  $\beta$ -blockers after sufficient  $\alpha$ -blockade with phenoxybenzamine.<sup>19</sup>

Magnesium sulphate is useful in the perioperative management of pheochromocytoma. It is given by infusion at 2–4 g/hour.<sup>13</sup>

### RENAL FAILURE

Renal insufficiency may be a cause or consequence of a hypertensive emergency. Patients on haemodialysis (particularly those receiving erythropoietin therapy) and renal transplant patients (especially those receiving ciclosporin or corticosteroids) commonly present with severe hypertension. In patients with new onset renal failure accompanying severe hypertension, blood pressure must be controlled without potentiating renal dysfunction. Drugs such as calcium antagonists, phentolamine or prazosin may preserve renal blood flow and are appropriate in these patients. ACE inhibitors and diuretics should be used with caution until renal function has stabilised or improved.

Patients in the recovery phase of acute renal failure are usually hypertensive. This is a normal physiological response and should not be treated unless there is associated myocardial or cerebral ischaemia.<sup>40</sup>

### PRE-ECLAMPSIA AND ECLAMPSIA

In addition to delivery of the baby and placenta, parenteral magnesium sulphate is the treatment of choice to prevent the evolution of pre-eclampsia to eclampsia (seizures and deteriorating encephalopathy<sup>12</sup>). Other parenteral drugs that have been used for many years for pregnancy-induced hypertensive states include hydralazine, phentolamine, diazoxide and labetalol.<sup>41</sup>

ACE inhibitors and angiotensin receptor blockers are contraindicated in pregnancy. This is discussed in Chapter 55.

### DRUG INTERACTIONS

Severe rebound hypertension may result following abrupt cessation of antihypertensive treatment. Drugs associated with this discontinuation syndrome include clonidine, methyl dopa,  $\beta$ -blockers, guanethidine and diuretics. The degree of rebound depends on the rapidity of drug withdrawal, dosage, renovascular and cardiac function. Antihypertensives should be reintroduced according to the status of the patient and the degree of hypertension managed accordingly.

Interaction with monoamine oxidase inhibitors and drugs such as indirect sympathomimetics, narcotics and tyramine-containing foods may result in a hypertensive emergency. This is best managed acutely with  $\alpha$ - and/or  $\beta$ -blockers.

# Acid–base balance and disorders

Thomas J Morgan

## THEORETICAL CONSIDERATIONS

The structural integrity of intracellular enzymes is essential for survival. Proton activity at enzymatic sites of action in cytosol and organelles must be tightly controlled. In critical illness, with survival under threat, direct monitoring of any intracellular site remains an impractical ideal. Clinicians are obliged to track extracellular data, usually from tests on arterial blood, knowing that plasma pH exceeds intracellular pH by 0.6 pH units on average.

## WATER DISSOCIATION AND ACID–BASE

Stewart reminded us of the central role of water in aqueous acid–base equilibria.<sup>1</sup> Mammals are approximately 60% water. It follows that the behaviour of water is fundamental to our understanding of acid–base physiology. Water (simplistically) dissociates as follows:

By the Law of Mass Action, at any equilibrium  $[\text{H}^+][\text{OH}^-] = K_w [\text{H}_2\text{O}]$ , where  $K_w$  is the temperature-dependent dissociation constant. Water is a vast proton reservoir, its concentration several orders of magnitude greater than that of its two dissociation products (55.5 M vs. 160 nM at 37°C). When conditions favour proton release, for example with increased temperature, water dissociates and pH falls. With conditions less favourable, protons return to their source, and pH rises.

An advantage of its numeric predominance is that  $[\text{H}_2\text{O}]$  can be combined with  $K_w$  to form a new constant,  $K'_w$ . The equilibrium equation then simplifies to:

$$[\text{H}^+][\text{OH}^-] = K'_w \quad \text{Equation 84.1}$$

## pH AND ACID–BASE NEUTRALITY

The negative logarithm of the proton concentration, or more exactly proton ‘activity’, is termed pH. In aqueous solutions, neutrality occurs when  $[\text{H}^+] = [\text{OH}^-]$ , so that  $([\text{H}^+])^2 = K'_w$ . Thus neutral pH = 0.5 pK'<sub>w</sub>. At 37°C, neutral pH is 6.8, which is the normal mean intracellular

pH in health. The pH of the surrounding extracellular fluid, usually > 7.3, is relatively alkaline.

## THE $P_{\text{aCO}_2}$ /pH RELATIONSHIP – THE ACID–BASE ‘WINDOW’ FOR CLINICIANS

About 15 moles of CO<sub>2</sub> are generated daily by aerobic metabolism. CO<sub>2</sub> travels along a partial pressure gradient from its intracellular source ( $P_{\text{CO}_2} > 50$  mmHg) to the atmosphere ( $P_{\text{CO}_2} = 0.3$  mmHg). The primary exit point is the lungs, with transit facilitated by a large, perpetually refreshed blood–air interface. En route, CO<sub>2</sub> equilibrates with all aqueous environments. The  $P_{\text{CO}_2}$  in any body fluid is thus an equilibrium value, determined by the interplay between regional CO<sub>2</sub> production, regional blood flow, alveolar perfusion and alveolar ventilation.

Clinicians use the relationship between arterial  $P_{\text{CO}_2}$  ( $P_{\text{aCO}_2}$ ) and arterial pH as the acid–base assessment platform. This is appropriate, because the  $P_{\text{aCO}_2}$ /pH curve is a fundamental physiological property (Figure 84.1). Several factors determine the shape and position of this curve.

## THE $P_{\text{aCO}_2}$ /pH RELATIONSHIP IS DEFINED BY SEVERAL SIMULTANEOUS EQUATIONS

In body fluids, pH is a function of water dissociation modified by CO<sub>2</sub>, other weak acids and certain electrolytes. All equilibria obey the Laws of Mass Action and Mass Conservation, and must achieve overall electrical neutrality. Non-diffusible ions exert electrochemical forces across membranes, known as Gibbs Donnan effects, which influence the final acid–base result.

Therefore apart from Equation 1, several other equations must be satisfied simultaneously at any equilibrium. They relate to:

1. The interaction of carbon dioxide with water:

By applying the Law of Mass Action and substituting [dissolved CO<sub>2</sub>] for  $[\text{H}_2\text{CO}_3]$ , the following expression can be derived:

**Figure 84.1**  $P_{\text{CO}_2}$ /pH relationships. The solid line shows the normal in vivo  $P_{\text{aCO}_2}$ /pH relationship. The normal  $P_{\text{aCO}_2}$  range is between the filled circles. To the left of the circles there is an increasing acute respiratory alkalosis, and to the right an increasing acute respiratory acidosis. The interrupted curve represents the normal in vitro whole blood relationship, and the dotted curve is the same relationship for separated plasma. A point of commonality exists at  $P_{\text{CO}_2} = 40$  mmHg.

$$\text{pH} = 6.1 + \log_{10}([\text{HCO}_3^-]/\alpha P_{\text{CO}_2}) \quad \text{Equation 84.2}$$

This is the Henderson–Hasselbalch equation, where  $\alpha$  is the plasma  $\text{CO}_2$  solubility coefficient (0.03), and 6.1 is the pKa, the negative logarithm of the dissociation constant. The Henderson–Hasselbalch equation generates the plasma  $[\text{HCO}_3^-]$  in blood gas readouts.

2. Bicarbonate dissociation to carbonate. At equilibration:

3. Non-volatile weak acid dissociation. Fluid compartments have varying concentrations of non- $\text{CO}_2$  generating (non-volatile) molecules with weak acid properties. In other words, their overall negative charge alters in parallel with pH. In plasma, they consist mainly of albumin and to a lesser extent inorganic phosphate. In red cells haemoglobin predominates. Much smaller concentrations of non-volatile weak acid also appear in interstitial fluid, primarily as phosphate. For convenience, Stewart modelled all non-volatile weak acids in each compartment as having a single anionic form ( $\text{A}^-$ ) and a single conjugate base form (HA).

By applying the Law of Mass Action:

$$[\text{H}^+][\text{A}^-] = K_{\text{eq}}[\text{HA}] \quad \text{Equation 84.4}$$

4. Conservation of mass. Stewart termed the total concentration of non-volatile weak acids in any compartment ‘ $A_{\text{TOT}}$ ’, where  $A_{\text{TOT}} = [\text{HA}] + [\text{A}^-]$ .  $A_{\text{TOT}}$  is an imposed mass constant. It does not vary with pH. A change in pH merely signals a shift in the balance between HA and  $\text{A}^-$ .

5. Electrical neutrality, linked to Stewart’s concepts of strong ions and strong ion difference. Certain elements such as  $\text{Na}^+$ ,  $\text{K}^+$ ,  $\text{Ca}^{++}$ ,  $\text{Mg}^{++}$  and  $\text{Cl}^-$  exist as completely ionised entities in body fluids. At physiological pH this includes anions with pKa values of 4 or less, for example sulphate, lactate, and  $\beta$ -hydroxybutyrate. Stewart described compounds exhibiting this property as ‘strong ions’. In body fluids there is a surfeit of strong cations, referred to by Stewart as the strong ion difference (SID). In other words,  $\text{SID} = [\text{strong cations}] - [\text{strong anions}]$ . Being a ‘charge’ space, SID is expressed in mEq/l. SID calculated from measured strong ions in normal plasma is 42 mEq/l.

Hence, by the Law of Electrical Neutrality:

$$\text{SID} + [\text{H}^+] - [\text{HCO}_3^-] - [\text{CO}_3^{2-}] - [\text{A}^-] - [\text{OH}^-] = 0 \quad \text{Equation 84.5}$$

6. Gibbs Donnan forces. These alter equilibria across semi-permeable membranes, with electrical gradients balanced against concentration gradients. The plasma compartment (volume 3 l), the erythrocyte compartment (volume 2 l) and the interstitial space (volume 13.5 l) each contains different concentrations of non-diffusible anions, mainly albumin or haemoglobin. Erythrocytes, which harbour most of these trapped negative charges, attract diffusible cations (such as  $\text{Na}^+$ ,  $\text{K}^+$ ) from adjacent compartments while repelling diffusible anions (primarily  $\text{Cl}^-$ ). However, several cations are continually redistributed against the Donnan forces by energy-dependent transmembrane pumps, to prevent cell swelling and haemolysis. Importantly, chloride, the major anion, remains fully susceptible to the Donnan effects.

The trapped anions have weak acid properties. Any pH shift alters their negative charge, driving further ionic redistributions, particularly chloride, between compartments. The net effect is that plasma SID goes up and down with  $P_{\text{aCO}_2}$  (Figure 84.2), the origin of the so-called Hamburger effect. Importantly, ionic shifts are confined within the total extracellular space, so that extracellular SID does not alter with  $P_{\text{CO}_2}$ . This is fortuitous for clinicians, forming the basis of the  $\text{CO}_2$  invariance of standard base excess (see below).

At any equilibrium, Equations 1–5 plus the Donnan equilibria must be satisfied simultaneously. In such a system, pH and  $\text{HCO}_3^-$ , as well as  $\text{CO}_3^{2-}$ ,  $\text{A}^-$  and  $\text{OH}^-$ , cannot be altered directly, only via any of three independent variables imposed on the system but not altered directly by the system. These are SID (total extracellular SID, immune to Gibbs Donnan forces), extracellular  $A_{\text{TOT}}$ , and  $P_{\text{aCO}_2}$ , which is externally regulated by alveolar ventilation. Hence, in arterial blood, pH is defined by  $P_{\text{aCO}_2}$ , extracellular SID and extracellular  $A_{\text{TOT}}$ .

Thus it can be seen that for any individual the  $P_{\text{aCO}_2}$ /pH relationship is a unique acid–base ‘signature’ (Figure 84.1) and ultimately a complex function of extracellular SID and  $A_{\text{TOT}}$ .

**Figure 84.2** Gamblegrams of plasma strong and weak ions (in vitro data from  $\text{CO}_2$  equilibrated normal blood). On the left,  $P_{\text{CO}_2} < 20$  mmHg; on the right, the same blood with  $P_{\text{CO}_2} > 200$  mmHg. The transition from hypocapnia to hypercapnia increases SIDa, with ionic redistribution between red cells and plasma due to altered Gibbs Donnan forces. There are almost identical increases in SIDe ( $[\text{A}^-] + [\text{HCO}_3^-]$ ), also known as ‘buffer base’, although  $[\text{A}^-]$  actually falls. Note that the SIG, which is SIDa minus SIDe, remains close to zero.

### WEAK IONS AND BUFFER BASE

SID is a charge space. Weak ions, which arise from variably dissociating conjugate bases, occupy this space. These include  $\text{H}^+$ ,  $\text{OH}^-$ ,  $\text{HCO}_3^-$ ,  $\text{CO}_3^{2-}$  and  $\text{A}^-$ . Their total net charge must always equal SID. However,  $\text{HCO}_3^-$  and  $\text{A}^-$ , together known as the ‘buffer base’ anions, take up virtually the entire space on their own (Figure 84.2) since the other ions are measured in either micromoles/l or, in the case of protons, nanomoles/l. SID therefore not only dictates the buffer base concentration but is also numerically identical to it. In other words,  $\text{SID} = [\text{HCO}_3^-] + [\text{A}^-]$ . This fact, plus Figge’s linear approximations<sup>2</sup> for calculating  $\text{A}^-$ , allows us to simplify Stewart’s equations in plasma, reducing them to three without sacrificing accuracy.<sup>3</sup>

$$[\text{A}^-] = [\text{Alb}] \times (0.123 \times \text{pH} - 0.631) + [\text{Pi}] \times (0.309 \times \text{pH} - 0.469)$$

$$[\text{HCO}_3^-] = 0.0301' P_{\text{CO}_2}' 10^{(\text{pH}-6.1)}$$

$$\text{SIDE} = [\text{HCO}_3^-] + [\text{A}^-]$$

$[\text{Alb}]$  is albumin concentration expressed in g/l.  $[\text{Pi}]$  is phosphate concentration in mmol/l.  $P_{\text{CO}_2}$  is in mmHg. SIDE is effective SID, also known as ‘buffer base’ (Figure 84.2).

SID calculated from measured plasma concentrations of strong ions is termed the ‘apparent’ SID, or SIDa (Figure 84.2). Discrepancies between SIDE and SIDa imply the presence of unmeasured ions in plasma (see below).

### ISOLATED CHANGES IN SID AND $A_{\text{TOT}}$

At any given  $P_{\text{aCO}_2}$ , a falling SID or a rising  $A_{\text{TOT}}$  reduce pH, moving the equilibrium towards a metabolic acidosis. Conversely, a rising SID or a falling  $A_{\text{TOT}}$  create a metabolic alkalosis. Many argue that SID and  $A_{\text{TOT}}$  act individually and should therefore be regarded as independent metabolic acid–base variables. By this argument we could have a strong ion acidosis or alkalosis combined with either a hyperalbuminaemic (high  $A_{\text{TOT}}$ ) acidosis or a hypoalbuminaemic (low  $A_{\text{TOT}}$ ) alkalosis.<sup>4</sup> However, SID and  $A_{\text{TOT}}$  do appear to be linked, with the SID set-point adjusting to  $A_{\text{TOT}}$ . In particular, SID seems to fall in hypoalbuminaemia, presumably by renal chloride adjustment.<sup>5,6</sup>

### HOW ACID–BASE DISTURBANCES AFFECT THE $P_{\text{ACO}_2}$ /PH RELATIONSHIP

Acute respiratory disturbances move data points along the prevailing  $P_{\text{aCO}_2}$ /pH curve, to the left in respiratory alkalosis, and to the right in respiratory acidosis (Figure 84.1). In contrast, metabolic disturbances (altered extracellular SID and/or  $A_{\text{TOT}}$ ) shift the entire curve up or down (Figure 84.3). A down-shifted curve means that the pH at any given  $P_{\text{aCO}_2}$  is lower than normal, which – depending on the  $P_{\text{aCO}_2}$  – represents either a primary metabolic acidosis or else metabolic compensation for a respiratory alkalosis. With an up-shifted curve, the pH at any given  $P_{\text{aCO}_2}$  is higher than normal, signifying either a primary metabolic alkalosis or else compensation for a respiratory acidosis.

### TEMPERATURE CORRECTION OF BLOOD GAS DATA – ‘ALPHA-STAT’ VERSUS ‘PH-STAT’ APPROACHES

Blood gas analysers operate at  $37^\circ\text{C}$ . Their software can convert pH and gas tensions to values corresponding to the patient core temperature for interpretation and action. This is the ‘pH-stat’ approach. The alternative is

**Figure 84.3**  $P_{\text{aCO}_2}$ /pH curve shifts and associated SBE values (mEq/l). Alterations in metabolic acid–base status shift the curve down (SBE increasingly negative) or up (SBE increasingly positive).

to act on values as measured at 37°C – the ‘alpha-stat’ approach.

‘Alpha’ is the ratio of protonated imidazole to total imidazole on the histidine moieties in protein molecules. At 37°C, under normal acid–base conditions, the mean intracellular pH is 6.8 (the neutral pH at 37°C). Alpha is then approximately 0.55. Maintaining alpha close to 0.55 preserves enzyme structure and function, and is thus a fundamental goal.

‘Alpha-stat’ logic is best illustrated by considering blood in a blood gas syringe. When placed on ice, the  $P_{CO_2}$  falls as its solubility coefficient increases. Water dissociation is reduced, due to the hypocapnia and to the temperature-induced decrease in  $K'w$ . Consequently, there is a progressive alkalaemia, which on rearming in the blood gas analyser reverts immediately. Throughout these phenomena, alpha stays constant. The reason is that the fall of the imidazole pKa with temperature is about half the fall in  $pK'w$ .

Hence, a simple way to keep alpha at 0.55 in hypothermia is to maintain uncorrected  $P_{aCO_2}$  and pH measurements in their 37°C reference ranges.<sup>7,8</sup> This mimics the hypothermic physiology of ectothermic (cold-blooded) animals. Similar arguments apply in fever, the more common intensive care unit (ICU) scenario. Many intensivists follow the alpha-stat approach, whatever the core temperature.

Those who favour the pH-stat approach argue that it is more consistent with the physiology of hibernating endothermic mammals, and that it allows better maintenance of cerebral perfusion in hypothermia.<sup>9</sup> This approach was used during an influential trial of mild hypothermia following out-of-hospital cardiac arrest.<sup>10</sup>

### RENAL PARTICIPATION IN ACID–BASE

In the absence of renal function, there is a progressive metabolic acidosis. About 60 mEq of strong anions, particularly sulphate, but also hippurate and others, are produced daily as metabolic end-products. These accumulate in renal failure, reducing extracellular SID. So does free water, which brings sodium concentrations closer to chloride, again reducing SID. Hyperphosphataemia contributes by increasing  $A_{TOT}$ , although in acute renal failure this is commonly offset by coexistent hypoalbuminaemia.<sup>11</sup>

Traditionally, renal acid–base homeostasis is described in terms of resorption of filtered bicarbonate primarily in the proximal tubule, and excretion of fixed acids through titration of urinary buffers, particularly phosphate, and through excretion of ammonium, primarily in the distal tubule.<sup>12</sup>

From the physical chemical perspective, the traditional analysis of renal acid–base homeostasis is misleading, since it is based on  $H^+$  or  $HCO_3^-$  ‘balances’.  $H^+$  and  $HCO_3^-$  are dependent variables, responsive exclusively to  $P_{CO_2}$ , SID and  $A_{TOT}$ , and not subject to ‘in versus out’ balance sheets. The physical chemical explanation is simple. The kidneys regulate extracellular SID via urinary

SID, the principal tool being tubular  $NH_4^+$  acting as an adjustable cationic partner for tubular  $Cl^-$  and other urinary strong anions.<sup>13</sup> The kidneys also modify  $A_{TOT}$  via phosphate excretion, which is a totally different concept from that of ‘titratable acidity’.

### ACID–BASE ASSESSMENT – THE TWO ‘SCHOOLS’

By convention, acid–base disorders are divided into respiratory ( $P_{aCO_2}$ ) and metabolic (non- $P_{aCO_2}$ ).  $P_{aCO_2}$  is the undisputed index of respiratory acid–base status. Two ‘schools’, Boston and Copenhagen, separated by a large ocean,<sup>14</sup> have formed around the identification and quantification of metabolic acid–base disturbances. Both succeed as navigation systems, if used correctly.

Stewart’s concepts neither invalidate nor supplant the traditional approaches,<sup>15–17</sup> but rather help us to understand their physiological basis, evaluate their relative merits, and extend their utility.<sup>18</sup> SID by itself is not a reliable measure of metabolic acid–base status, for three reasons:

- Plasma SID, the only SID measurable by clinicians, is subject to Donnan effects, which means it varies with  $P_{aCO_2}$  (the only SID that does not is total extracellular SID).
- In any compartment, SIDa and at times SIDe can be quite inaccurate reflections of the true SID. For example, unmeasured strong anions give SIDa positive bias, and unmeasured weak anions such as infused gelatin give SIDe negative bias.
- SID on its own is only half the story, since metabolic acid–base status is a function of the interplay between SID and  $A_{TOT}$ . In a healthy individual a plasma SID of 42 mEq/l may be normal, but in the presence of hypoalbuminemia (reduced  $A_{TOT}$ ) it represents a metabolic alkalosis. Hence there is little point in attempting to track SID clinically.

For a pure metabolic index to succeed, it must integrate the effects of extracellular SID and  $A_{TOT}$ , irrespective of the  $P_{aCO_2}$ . The best of these (in the author’s opinion) is standard base excess, the flagship of the Copenhagen school. However, Boston school devotees can navigate quite successfully using empiric plasma bicarbonate-based ‘rules of thumb’.

### BASE EXCESS AND STANDARD BASE EXCESS

In 1960, Siggaard-Andersen introduced ‘base excess’ (BE).<sup>19</sup> BE was defined as zero when  $pH = 7.4$ ,  $P_{CO_2} = 40$  mmHg (both at 37°C). If  $pH \neq 7.4$  or  $P_{CO_2} \neq 40$  mmHg, BE was defined as the concentration of titratable hydrogen ion required to return the pH to 7.4 while maintaining  $P_{CO_2}$  at 40 mmHg.

In the lead-up, Astrup, Siggaard-Andersen, Engel and others had equilibrated the blood of Danish volunteers with known  $CO_2$  tensions at varying haemoglobin concentrations, after first adding known amounts of acid or base. The data were then used to create an ‘alignment nomogram’ which allowed the determination of BE from

simultaneous measurements of pH,  $P_{\text{CO}_2}$  and haemoglobin concentration.

Seventeen years later, Siggaard-Andersen published the Van Slyke equation for calculating BE.<sup>20</sup> It was derived from known physical chemical relationships, and was claimed to match the empiric nomogram. The Van Slyke equation computes  $(\Delta[\text{HCO}_3^-] + \Delta[\text{A}^-])$  – in other words, the deviation from normal of the buffer base concentration in whole blood. From the Stewart perspective, buffer base and SID are interchangeable terms. Hence Stewart would describe BE as the abnormality in whole blood SID at the prevailing  $A_{\text{TOT}}$ .

It became clear that BE loses its  $\text{CO}_2$  invariance *in vivo*, where Gibbs Donnan forces drive ions between intravascular and interstitial compartments. As a result, a primary change in  $P_{\text{aCO}_2}$  shifts BE in the opposite direction. The solution was to calculate BE at a haemoglobin concentration of approximately 50 g/l, replicating the mean extracellular haemoglobin concentration and thus more closely modelling the extracellular environment.<sup>21</sup> This is standard base excess (SBE).

As a metabolic acid–base index, SBE is close to ideal, being both quantitative and demonstrably independent of  $P_{\text{aCO}_2}$ .<sup>22</sup> A useful formula is:

$$\text{SBE} = 0.93 \times ([\text{HCO}_3^-] + 14.84 \times (\text{pH} - 7.4) - 24.4)$$

with SBE and  $[\text{HCO}_3^-]$  values in mEq/l. This formula can be further refined to allow for changes in plasma  $A_{\text{TOT}}$  due to variations in albumin and phosphate.<sup>23</sup> However, because haemoglobin is the predominant weak acid, the end result is very similar.

A typical SBE reference range (in mEq/l) is  $-3.0$  to  $+3.0$ . If  $\text{SBE} < -3.0$  mEq/l, there is a down-shifted  $P_{\text{aCO}_2}/\text{pH}$  curve. This could represent either a primary metabolic acidosis or else compensation for a primary respiratory alkalosis, depending on the  $P_{\text{aCO}_2}$  and the pH (see below). SBE quantifies the increase in extracellular SID (in mEq/l) needed to shift the curve back to the normal position without changing  $A_{\text{TOT}}$  (Figure 84.3). In terms of the original BE definition, this is roughly the required dose of sodium bicarbonate in mmol per litre of extracellular fluid. Similarly, if  $\text{SBE} > 3.0$  mEq/l, there is an up-shifted curve, either a metabolic alkalosis or compensation for a respiratory acidosis. The SBE is the decrease in extracellular SID needed to shift the curve back to the normal position at the prevailing  $A_{\text{TOT}}$ . Conceptually, it approximates the dose of HCl required per litre of extracellular fluid. SBE is thus ‘extracellular SID excess’ or ‘SIDex’.<sup>24</sup>

#### THE BICARBONATE-BASED APPROACH TO METABOLIC ACID–BASE – THE BOSTON ‘RULES OF THUMB’

Boston ‘school’ devotees calculate the plasma  $[\text{HCO}_3^-]$  from the measured pH and  $P_{\text{aCO}_2}$ , and match this value with the  $[\text{HCO}_3^-]$  deemed appropriate for the measured  $P_{\text{aCO}_2}$ , using empiric ‘rules of thumb’ derived from clinical and experimental data (Table 84.1).<sup>25</sup> An offset denotes a metabolic acid–base disturbance.

The Boston method is largely qualitative, since by focusing on plasma bicarbonate alone it ignores the  $\text{A}^-$  component of the buffer base (SIDE) concentration (Figure 84.2). The Boston rules of thumb can only tell us whether the  $P_{\text{aCO}_2}/\text{pH}$  curve is shifted up or down. Unlike SBE, they cannot tell us how much.

**Table 84.1** Compensation – mechanisms and rules

Disorder	Compensation	Simple rules	Boston rules
Uncompensated respiratory acidosis and alkalosis	Nil	SBE $-3.0$ to $+3.0$	Respiratory acidosis: $\text{HCO}_3^- = 24 + 0.1 \times (P_{\text{aCO}_2} - 40)$ Respiratory alkalosis: $\text{HCO}_3^- = 24 + 0.2 \times (P_{\text{aCO}_2} - 40)$
Compensated respiratory acidosis and alkalosis	Respiratory acidosis: extracellular SID increased by decreasing urinary SID Respiratory alkalosis: extracellular SID decreased by increasing urinary SID	pH is normal or $\text{SBE} = 0.4 \times (P_{\text{aCO}_2} - 40)$	Respiratory acidosis: $\text{HCO}_3^- = 24 + 0.35 \times (P_{\text{aCO}_2} - 40)$ Respiratory alkalosis: $\text{HCO}_3^- = 24 + 0.5 \times (P_{\text{aCO}_2} - 40)$
Metabolic acidosis	Hyperventilation reduces $P_{\text{aCO}_2}$	$P_{\text{aCO}_2} = \text{last 2 digits of pH}$ or $P_{\text{aCO}_2} = 40 + \text{SBE}$ ( $P_{\text{aCO}_2}$ rarely $< 10$ mmHg)	$P_{\text{aCO}_2} = 1.5 \times (\text{HCO}_3^- + 8)$
Metabolic alkalosis	Hypoventilation increases $P_{\text{aCO}_2}$	$P_{\text{aCO}_2} = \text{last 2 digits of pH}$ or $P_{\text{aCO}_2} = 40 + \text{SBE}$ ( $P_{\text{aCO}_2}$ rarely $> 60$ mmHg)	$P_{\text{aCO}_2} = 0.6 \times (\text{HCO}_3^- - 24)$

SBE, standard base excess; SID, strong ion difference.

## ACID–BASE DISORDERS – CLASSIFICATION

### PRIMARY ACID–BASE DISORDERS

Primary acid–base disorders dictate the direction of the pH disturbance. They are designated by the suffix ‘osis’, and can be either respiratory ( $P_{aCO_2}$ ) or metabolic. Hence we can have a respiratory or metabolic acidosis or alkalosis. The final pH abnormality (if any) is designated by the suffix ‘aemia’. In acidaemia, plasma pH is  $< 7.35$ ; in alkalaemia, plasma pH is  $> 7.45$ . The pH in opposing primary acid–base disturbances can be normal.

### COMPENSATION AND ITS EFFECT ON pH

Compensation is a counterresponse to a primary acid–base disorder. It reduces the severity of the pH disturbance. When the primary disturbance is respiratory ( $P_{aCO_2}$ ), the compensation is metabolic (renal alteration of SID); if the primary disturbance is metabolic (abnormal SID relative to the prevailing  $A_{TOT}$ ), the compensation is respiratory ( $P_{aCO_2}$ ).

#### Metabolic compensation

In respiratory acid–base disturbances, the kidneys adjust extracellular SID by regulating urinary SID, primarily via urinary chloride. In prolonged hypocapnia, there is a compensatory fall in extracellular SID, achieved by increasing urinary SID. In sustained hypercapnia, the kidneys decrease urinary SID and thereby increase extracellular SID. Renal compensation for chronic respiratory acid–base disturbances takes time, but is ultimately very effective. Over the  $P_{aCO_2}$  range 25–80 mmHg, which encompasses most chronic respiratory disturbances, full compensation will normalise the arterial pH.<sup>22,26,27</sup> However, this can take up to 5 days.

#### Respiratory compensation

By contrast, respiratory compensation for metabolic disturbances is much faster, but less effective. A normal pH is *never* regained. Metabolic acid–base disturbances activate feedback loops linked to alveolar ventilation, forcing  $P_{aCO_2}$  in the direction that reduces the pH perturbation. The loops are driven by CSF and plasma pH acting on the central and peripheral chemoreceptors respectively. In severe metabolic acidosis, minute ventilation often increases more than eightfold, the resultant hypocapnia blunting the acidaemia. In contrast, metabolic alkalosis suppresses minute ventilation, the hypercapnia reducing the pH rise.

In both cases the full response evolves over 12–24 hours, at first driven entirely by the peripheral chemoreceptors. The central chemoreceptors dampen the initial response, since SID equilibration between plasma and CSF is gradual, whereas  $P_{CO_2}$  equilibration is immediate.

A normal pH combined with an abnormal  $P_{aCO_2}$  can mean one of two things. Either there are two primary opposing acid–base disorders, one respiratory and one metabolic, or else there is a fully compensated respiratory

acid–base disturbance. A ‘normal’  $P_{aCO_2}$  combined with an abnormal pH always represents two primary acid–base disturbances (see Table 84.1).

## ACID–BASE ‘SCANNING TOOLS’

### ELECTRICAL GAPS (TABLE 84.2)<sup>28</sup>

Accumulating strong anions reduce SID, causing metabolic acidosis. Other than chloride and now increasingly L-lactate, strong anions are not routinely measured. However, they can be especially injurious, creating a need for rapid detection and early intervention. Critical care practitioners use electrical ‘gaps’ as early warning systems.

**Table 84.2** Factors affecting the anion gap (AG), the albumin-corrected anion gap (AGc) and the strong ion gap (SIG)

Factor	AG	AGc	SIG
[Pi] ↑	Increased	Increased	No effect
[Pi] ↓	Decreased	Decreased	No effect
pH ↑	Increased	Increased	No effect
pH ↓	Decreased	Decreased	No effect
[Ca <sup>++</sup> ] and [Mg <sup>++</sup> ] ↑	Decreased	Decreased	No effect
[Ca <sup>++</sup> ] and [Mg <sup>++</sup> ] ↓	Increased	Increased	No effect
[Alb] ↑	Increased	No effect	No effect
[Alb] ↓	Decreased	No effect	No effect
L-Lactate	Increased	Increased	No effect
Unmeasured strong anions (e.g. D-lactate, ketoacids, salicylate)	Increased	Increased	Increased
Unmeasured weak anions (polygelinate, myeloma IgA bands)	Increased	Increased	Increased
Unmeasured strong cations (lithium)	Decreased	Decreased	Decreased
Unmeasured weak cations (THAMH <sup>+</sup> , myeloma IgG bands)	Decreased	Decreased	Decreased
Chloride overestimation (bromism, hyperlipidemia, high bicarbonate)	Decreased	Decreased	Decreased
Sodium underestimation (hypernatraemia)	Decreased	Decreased	Decreased

**Anion gap (AG)**

The plasma AG is calculated (in mEq/l) as  $[\text{Na}^+] + [\text{K}^+] - [\text{Cl}^-] - [\text{HCO}_3^-]$ , although  $[\text{K}^+]$  is omitted in many laboratories. A typical reference range is 7–17 mEq/l. The AG quantifies [unmeasured anions] – [unmeasured cations], both strong and weak. The AG is increased by unmeasured anions, and reduced by unmeasured cations. In health, most of the AG consists of  $\text{A}^-$ , the negative charge on albumin and phosphate. The AG is altered by  $\text{A}_{\text{TOT}}$  fluctuations, which affect  $\text{A}^-$  directly, and by severe pH disturbances, which act via the  $\text{A}^-$  component (Table 84.2). When used for its primary purpose, which is scanning for unmeasured strong anions, AG sensitivity and specificity are low.

**Albumin-corrected anion gap (AGc)<sup>4</sup>**

The AGc was devised to correct for variations in plasma [albumin]. It is calculated as  $\text{AG} + 0.25 \times (40 - [\text{albumin}])$ , assuming a normal plasma [albumin] of 40 g/l. By attributing a fixed negative charge to albumin, and making no adjustment for pH, error remains. This is minor, except in severe alkalaemia.

**Strong ion gap (SIG)**

The SIG concept was proposed by Jones in 1990,<sup>29</sup> and progressed by others.<sup>2,30</sup> It is calculated as  $\text{SIDa} - \text{SIDE}$ , where  $\text{SIDa} = [\text{Na}^+] + [\text{K}^+] + [\text{Ca}^{++}] + [\text{Mg}^{++}] - [\text{Cl}^-] - [\text{L-lactate}]$ , and  $\text{SIDE} = [\text{A}^-] + [\text{HCO}_3^-]$ . The unmeasured ions creating the ‘gap’ can be either strong or weak, but the term ‘strong ion gap’ has persisted.

In the absence of measurement error, the SIG should be zero unless there are unmeasured ions, the list of which is smaller than with AG and AGc (Table 84.2).<sup>28</sup> SIG is under evaluation as a scanning tool. Its signal is subject to the summated variability of multiple analytes. In many centres, the normal SIG is 4 mEq/l or more, the positive bias presumably due to locally adopted measurement technologies and variations in analytic reference standards. A refinement, ‘net unmeasured ions’ (NUI), has been successfully incorporated into an acid–base diagnostic module and linked to a laboratory information system.<sup>31</sup>

**THE OSMOLAL GAP**

The osmolal gap scans for unmeasured osmotically active molecules. It is calculated as measured osmolality –  $(1.86 \times ([\text{Na}^+] + [\text{K}^+] + [\text{urea}] + [\text{glucose}]))$ . The normal osmolal gap is < 10 mosm/kg. If there is an unexplained high AGc, a simultaneously raised osmolal gap suggests poisoning by methanol or ethylene glycol. However, a number of other molecules elevate the osmolal gap. These include other alcohols, mannitol and glycine, acetone and glycerol in ketoacidosis, and unknown solutes in lactic acidosis and renal failure.

**PRACTICAL CONSIDERATIONS****THE DIAGNOSTIC SEQUENCE**

At the outset, the clinician examining a set of blood gases should ignore derived variables such as bicarbonate or

standard base excess. Most (frequently all) of the important information can be gleaned from the measured variables,  $P_{\text{aCO}_2}$  and pH.

**PRIMARY SURVEY**

1. Take a history and perform a clinical examination.
2. Scan for primary disorders by matching the  $P_{\text{aCO}_2}$  and pH combination with one of nine possible scenarios (Table 84.3).

**SECONDARY SURVEY**

1. Apply ‘rules of thumb’ (Table 84.1) where applicable. This step assesses compensation for any primary acid–base disturbances.
2. Note absent or inappropriate respiratory compensation in primary metabolic acid–base disorders, and identify this as a separate acid–base disturbance. For example, in diabetic ketoacidosis, if the arterial pH = 7.20 and the  $P_{\text{aCO}_2} = 20$  mmHg, the patient has a metabolic acidosis with normal respiratory compensation (Table 84.1). If, however, the pH = 7.20 with a  $P_{\text{aCO}_2} = 32$  mmHg, the metabolic acidosis has an accompanying respiratory acidosis (despite the hypocapnia). This is a greater cause for concern, signalling imminent respiratory decompensation. Conversely, if at this pH,  $P_{\text{aCO}_2} = 12$  mmHg, there is an accompanying respiratory alkalosis.
3. Calculate the AG or preferably the AGc. If either is elevated, unmeasured anions are likely. If low or negative, suspect laboratory error, but consider lithium intoxication, IgG myeloma and others (Table 84.2).

**Table 84.3** Acid–base status – primary survey

pH	$P_{\text{aCO}_2}$ (mmHg)	Primary process(es)
7.35–7.45	35–45	None
7.35–7.45	> 45	1. Chronic respiratory acidosis or 2. Respiratory acidosis, metabolic alkalosis
7.35–7.45	< 35	1. Chronic respiratory alkalosis 2. Respiratory alkalosis, metabolic acidosis
< 7.35	< 35	Metabolic acidosis
< 7.35	> 45	Respiratory acidosis
< 7.35	35–45	Respiratory acidosis, metabolic acidosis
> 7.45	> 45	Metabolic alkalosis
> 7.45	< 35	Respiratory alkalosis
> 7.45	35–45	Respiratory alkalosis, metabolic alkalosis

- Compare any AGc elevation with the SBE or  $[\text{HCO}_3^-]$ . An elevated AGc should be accompanied by a similar reduction in SBE or  $[\text{HCO}_3^-]$ . If not, there are dual disorders. For example, if AGc = 20 mEq/l and SBE = -15 mEq/l, the metabolic acidosis is due to a combination of an unmeasured anion and a narrowed difference between chloride and sodium (a combined normal and raised anion gap metabolic acidosis). If AGc = 20 mEq/l and the SBE = 0 mEq/l, there is a combined metabolic alkalosis and anion gap metabolic acidosis.
- If there is no obvious cause for an elevated AGc, perform specific assays (e.g. L-lactate,  $\beta$ -hydroxybutyrate, D-lactate, salicylate). A concurrently raised osmolal gap suggests methanol or ethylene glycol toxicity. Urinary organic anions may reveal pyroglutamate.<sup>32</sup>

## CLINICAL ACID–BASE DISORDERS

### METABOLIC ACIDOSIS

In metabolic acidosis, the extracellular SID is low relative to  $A_{\text{TOT}}$ . This can represent a narrowing of the difference between  $[\text{Na}^+]$  and  $[\text{Cl}^-]$  (normal AGc, Table 84.4), or an accumulation of other anions (elevated AGc, Table 84.4). Although a normal AGc acidosis is often hyperchloraemic, the absolute  $[\text{Cl}^-]$  is not important, just its value relative to  $[\text{Na}^+]$ .

### Clinical features

Clinical features are those of acidaemia itself (Table 84.5), combined with specific toxicities of individual anions. These include blindness and cerebral

**Table 84.5** Adverse effects of metabolic acidosis

Reduced myocardial contractility, tachy- and bradycardias, systemic arteriolar dilatation, vasoconstriction, centralization of blood volume
Pulmonary vasoconstriction, hyperventilation, respiratory muscle failure
Reduced splanchnic and renal blood flow
Increased metabolic rate, catabolism, reduced ATP synthesis, reduced 2,3-DPG synthesis
Confusion, drowsiness
Increased inducible nitric oxide synthase (iNOS) expression, proinflammatory cytokine release
Hyperglycaemia, hyperkalaemia
Cell membrane pump dysfunction
Bone loss, muscle wasting

oedema (formate),<sup>33</sup> crystalluria, renal failure and hypocalcaemia (oxalate),<sup>34</sup> and tinnitus, hyperventilation and fever due to uncoupling of oxidative phosphorylation (salicylate).<sup>35</sup>

The adverse effects of acidaemia (Table 84.5) are more prominent at pH < 7.2. Acidaemia also has potential benefits. For example, the Bohr effect increases tissue oxygen availability, although this is rapidly counteracted by reduced 2,3-diphosphoglycerate concentrations. Lowering pH is protective in a number of experimental hypoxic stress models.<sup>36,37</sup> During mild acidaemia therefore, the net result of harm versus benefit can be debated.

### Infusion-related acidosis<sup>38,39</sup>

Large volumes of intravenous saline cause a normal AGc metabolic acidosis. The SBE rarely falls below -10 mEq/l. With appropriate respiratory compensation, the pH will frequently remain above 7.3. An unresolved question is whether this is severe enough to cause harm.

Infusion-related acidosis is driven by the 'effective' SID of the crystalloid. Rapid infusion alters plasma SID towards the effective crystalloid SID, but also causes a metabolic alkalosis by diluting  $A_{\text{TOT}}$ . The SID of saline is zero (equal concentrations of the strong cation  $\text{Na}^+$  and the strong anion  $\text{Cl}^-$ ). At such a low SID, rapid infusion reduces extracellular SID precipitously, outstripping the metabolic alkalosis of  $A_{\text{TOT}}$  dilution.

To balance saline, some  $\text{Cl}^-$  must be replaced with  $\text{HCO}_3^-$ , or else with strong anions which undergo metabolic 'disappearance', such as lactate, gluconate or acetate. Enough chloride must be replaced to balance the fall in extracellular SID against the  $A_{\text{TOT}}$  dilution effect. Experimentally this value is 24 mEq/l.<sup>38</sup>

### Renal tubular acidosis (RTA)

In RTA, urinary SID is inappropriately high in the setting of a low extracellular SID. The disturbance is in renal tubular  $\text{Cl}^-$  handling, either from reduced ammonium production proximally (Type 4) or distally (Type 1), or

**Table 84.4** Causes of metabolic acidosis

Normal AGc	Raised AGc
Saline infusions	L-Lactate acidosis
Organic anion excretion	Ketoacidosis
Ketoacidosis	$\beta$ -Hydroxybutyrate, acetoacetate
Glue sniffing	Renal failure
(hippurate, benzoate)	Sulphate, hippurate, urate,
Loss high SID enteric fluid	other organic anions
Small intestinal,	Phosphate accumulation
pancreatic, biliary	increases $A_{\text{TOT}}$
Urinary/enteric diversions	Ethylene glycol poisoning
High urinary SID	Glycolate, oxalate
Renal tubular acidosis	Methanol poisoning
High urinary SID	Formate
Post hypocapnia	Pyroglutamic acidosis
High urinary SID	Pyroglutamate
TPN and $\text{NH}_4\text{Cl}$	Toluene (glue sniffing)
administration	Hippurate, benzoate
	Short bowel syndrome
	D-lactate

AGc, albumin-corrected anion gap; SID, strong ion difference; TPN, total parenteral nutrition.

Table 84.6 Types of renal tubular acidosis

	Type 1	Type 2	Type 4
Mechanism	Impaired distal $\text{NH}_4^+$ secretion	Increased proximal chloride resorption	Hyperkalaemic suppression of proximal tubular $\text{NH}_4^+$ production
Some causes	Idiopathic, hypercalciuric, amphotericin B, lithium carbonate, rheumatoid arthritis, Sjögren's disease, systemic lupus erythematosus, cirrhosis, renal transplant rejection, obstructive uropathy, primary hyperparathyroidism, hyperglobulinaemia	<i>With other proximal tubular defects = Fanconi syndrome:</i> Genetic, light chain nephropathy, acetazolamide, heavy metals, aminoglycosides, valproate, chemotherapy, renal transplantation, amyloidosis, paroxysmal nocturnal haemoglobinuria	<i>Reduced aldosterone secretion or sensitivity:</i> Hyporeninaemia, adrenal insufficiency, ACE inhibitors, NSAIDs, cyclosporin, heparin, amiloride, spironolactone, triamterene, pentamidine, diabetes, obstructive uropathy, interstitial nephropathies, renal transplant rejection, analgesic nephropathy
SBE	Can be $< -15$ mEq/l	$-6$ to $-15$ mEq/l	A $-6$ to $-8$ mEq/l
Plasma $[\text{K}^+]$	Usually low	Low	High
Urine pH post furosemide	$> 5.5$	$< 5.5$ (Bicarbonaturia with $\text{NaHCO}_3^-$ infusion)	Usually $< 5.5$
Urinary AG	Positive	Negative	Positive
Urinary $\text{NH}_4^+$	Reduced	Normal or high	Usually reduced

AG, anion gap; SBE, standard base excess.

increased proximal tubular chloride resorption (Type 2). Causes are legion (Table 84.6).

Apart from treating underlying causes and preventing hypercalciuria, management in Types 1 and 2 RTA is based on administering sodium bicarbonate or citrate to correct extracellular SID, and preventing and treating hypokalaemia using potassium citrate (not chloride). In Type 4 RTA, inciting agents are ceased where relevant, and adrenal insufficiency treated with mineralocorticoid replacement. Alkali supplements and furosemide are occasionally necessary.<sup>12</sup>

### Lactic acidosis

This is discussed in Chapter 15.

### Management of metabolic acidosis

Management is directed at the underlying cause. When instituting mechanical ventilation, a sudden reduction in minute volume can be lethal. For example, a patient with an arterial pH of 6.9 and  $P_{\text{aCO}_2}$  of 10 mmHg is hyperventilating maximally. If the  $P_{\text{aCO}_2}$  is allowed to return to 'normal' (40 mmHg) on instituting mechanical ventilation, the arterial pH will immediately fall to 6.7. If the  $P_{\text{aCO}_2}$  is inadvertently allowed to rise to 60 mmHg, the pH will be 6.6.

### Administration of buffers – sodium bicarbonate, 'carbicarb' and sodium lactate

In lactic acidosis and organic acidoses in general, it is difficult to justify the administration of buffers (see Chapter 15).<sup>40</sup> However, infusing  $\text{NaHCO}_3$  to correct a severe normal

AGc acidosis may be appropriate. Other conditions where  $\text{NaHCO}_3$  administration is often indicated include severe hyperkalaemia, methanol and ethylene glycol poisoning, and tricyclic and salicylate overdose. A  $\text{NaHCO}_3$  dose of 1 mmol/kg increases SBE approximately 3 mEq/l.

When administering  $\text{NaHCO}_3$ , the aim is to increase SID. The active agent is therefore sodium, not bicarbonate. The only reason NaOH is not used is its alkalinity (pH 14). However, two problems arise from the high  $\text{CO}_2$  content ( $\text{CO}_{2\text{TOT}}$ ) of  $\text{NaHCO}_3$  (approximately 1028 mmol/l in a 1 M solution): one is the need for  $\text{CO}_2$  impermeable storage; the other is the potential to create paradoxical intracellular respiratory acidosis, which can be demonstrated in vitro by adding  $\text{NaHCO}_3$  to cultured cells.<sup>41</sup>

One approach is to reduce  $\text{CO}_{2\text{TOT}}$ , the trade-off being a rise in pH. In carbicarb ( $\text{CO}_{2\text{TOT}} = 750$  mmol/l,  $P_{\text{CO}_2} = 2$  mmHg, pH = 9.8), half the monovalent bicarbonate becomes divalent carbonate. Its use is still under evaluation. In Europe, sodium lactate (0.167 M, pH 6.9) is an alternative. The role of lactate is not to generate bicarbonate, but to undergo metabolic 'disappearance', leaving sodium to increase the SID.

Adding a weak base ( $\text{B}_{\text{TOT}}$ ) will also shift the  $P_{\text{aCO}_2}$ /pH curve upward. THAM (tris-hydroxymethyl aminomethane, or tris buffer) is a weak base with a pKa of 7.7 at 37 °C. THAM- $\text{H}^+$  allows buffer base and thus SBE to increase without changing extracellular SID or  $A_{\text{TOT}}$ . THAM is  $\text{CO}_2$  consuming, with good cell penetration, and causes an immediate intracellular metabolic and respiratory alkalosis.

Presumably in CSF this phenomenon is behind its propensity to cause sudden apnoea. THAM accumulates in renal failure. Other problems include hyperosmolality, coagulation and potassium disturbances, and hypoglycaemia. The use of THAM requires further evaluation.

Finally, it should be recognised that to cause an appreciable increase in  $P_{aCO_2}$ ,  $NaHCO_3$  has to be administered very rapidly (e.g. over 5 minutes).<sup>42</sup> Even then the rise is transient, and usually less than 10 mmHg. With slow administration, over 30–60 minutes,  $NaHCO_3$  should have minimal effects on  $CO_2$  production and intravascular  $P_{CO_2}$ . The exception is when pulmonary perfusion is massively reduced, such as in cardiac arrest.

Other potential adverse effects of buffer administration include a sudden increase in haemoglobin–oxygen affinity, the production of a hyperosmolar state, reduced  $[Ca^{++}]$  and  $[Mg^{++}]$ , and rebound alkalosis on resolution of an organic acidosis.

### METABOLIC ALKALOSIS

In metabolic alkalosis, extracellular SID is high relative to  $A_{TOT}$ . Metabolic alkalosis has been described as the most common acid–base disturbance. With modern definitions it is more often seen as part of a ‘mixed’ disorder.

#### Causes (Table 84.7)

Metabolic alkalosis can be precipitated by:

- low urinary SID
- loss of low SID enteric fluid
- gain of high SID fluid

#### Clinical features

A high plasma pH (> 7.55) has a number of adverse effects (Table 84.8). Mortality in critical illness escalates as the pH rises above 7.55, although how much is causation versus association is unclear.

#### Treatment

The first step is to remove the cause. Measures can then be instituted to accelerate the reduction in extracellular SID. They include:

- Correcting effective volume depletion (reduced skin turgor, postural hypotension, high urea:creatinine ratio, urinary  $[Cl^-] < 20$  mmol/l). Albumin preparations simultaneously increase  $A_{TOT}$  and reduce SID, and are thus likely to be more effective than saline.<sup>43</sup>
- Administering KCl to correct potassium depletion. The vital component here is the chloride. Simplistically, potassium (strong cation) enters the depleted intracellular compartment in excess of chloride (strong anion), increasing extracellular SID. This explanation ignores associated Gibbs Donnan phenomena.

Table 84.7 Metabolic alkalosis – causes

Low urinary SID	Enteric losses of low SID fluid	Gain of high SID fluid
Loop or thiazide diuretics	Pyloric stenosis, vomiting,	$NaHCO_3$ administration
Post hypercapnia	nasogastric suction	Sodium citrate (plasma exchange,
Corticosteroids	Villous adenoma	> 8 units stored blood)
Cushing's syndrome	Laxative abuse	Renal replacement fluids with high SID (> 35 mEq/l)
Primary mineralocorticoid excess		Milk-alkali syndrome
Carbenoxolone		
Glycyrrhethinic acid (liquorice)		
Hypercalcaemia		
Milk-alkali syndrome		
Magnesium deficiency		
Bartter's and Gitelman's syndromes		

SID, strong ion difference.

Table 84.8 Severe metabolic alkalosis – multisystem effects

Central nervous system
Vasospasm
Seizures
Confusion, drowsiness
Neuromuscular
Weakness, tetany, muscle cramps
Cardiovascular
Arrhythmias – supraventricular and ventricular
Decreased contractility
Respiratory
Decreased alveolar ventilation
Atelectasis, hypoxaemia
Metabolic
Hyperlactaemia
Low $[Pi]$ , $[Ca^{++}]$ , $[Mg^{++}]$ and $[K^+]$
Haemoglobin–oxygen affinity
Initially increased (until counteracted by increased 2,3-DPG)

- Acetazolamide therapy to increase urinary SID (requires adequate renal function).
- Administration of HCl, which has a negative SID.<sup>44,45</sup> Minute ventilation, hypercapnia and oxygenation generally (but not invariably) improve. For full correction the calculated HCl requirement (in mmol) is  $0.3 \times SBE \times Wt$  (kg). HCl can be infused over 24 hours

as a 0.2 M solution in dextrose through a central venous catheter. Regular checks of SBE (every 4 hours) are advisable. HCl can also be given indirectly, as  $\text{NH}_4\text{Cl}$ , or arginine or lysine hydrochloride. All require hepatic deamination.

- Renal replacement therapy.

Metabolic alkalosis in the setting of effective volume depletion has been termed 'saline responsive', in the sense that saline overcomes the alkalinising renal hypovolaemic response (low urinary SID). In fact, all metabolic alkaloses will respond if sufficient saline can be administered safely (see Infusion-related acidosis).

As with metabolic acidosis, care is required when instituting mechanical ventilation. Unless minute volume settings are reduced, it is possible to precipitate extreme alkalaemia.

### RESPIRATORY ACIDOSIS

#### Causes (Table 84.9)

The risk is increased when  $\text{CO}_2$  production is high and when ventilation is inefficient (large alveolar or apparatus dead space, respiratory muscle disadvantage due to hyperinflation).

### Clinical features

These include the effects of acidaemia (Table 84.5). However, acute hypercapnia has important central nervous effects, including confusion, drowsiness, asterix, fitting and raised intracranial pressure. Hypercapnia also activates the sympathetic-adrenal and renin-angiotensin systems, reducing renal blood flow, glomerular filtration rate and urine output.

### Treatment

Management is directed at the underlying cause. Mechanical ventilation, either non-invasive or invasive, may be required.

### RESPIRATORY ALKALOSIS

#### Causes

Respiratory alkalosis arises in a number of clinical scenarios (Table 84.10).

### Clinical features

With the exception of the complications of hypoventilation, all the multisystem effects of alkalaemia apply.

### Treatment

Management should be directed towards the underlying cause.

Table 84.9 Some causes of respiratory acidosis

Mechanism/ affected site	Acute	Chronic
Respiratory centre suppression	Sedative and narcotic drugs, CNS injury, CNS infection, brainstem vasculitis or infarction	Obesity hypoventilation syndrome
Airway obstruction	Inhalational injury, Ludwig's angina, laryngeal trauma	Obstructive sleep apnoea, vocal cord paresis, subglottic and tracheal stenosis
Mechanical ventilation	Permissive hypercapnia	
Neural/ neuromuscular	Spinal cord injury, Guillain-Barré syndrome, myasthenia gravis, muscle relaxants, envenomation, acute poliomyelitis, critical illness weakness syndromes	Phrenic nerve damage, paraneoplastic syndromes, post-polio syndrome
Muscle	Myopathy, low $[\text{K}^+]$ , high $[\text{Mg}^+]$ , low $[\text{Pi}]$ , diaphragmatic injury, shock	Muscular dystrophies, motor neurone disease
Decreased chest wall compliance	Abdominal distension, burns, pneumothorax, large pleural effusions	Obesity, kyphoscoliosis, ankylosing spondylitis
Loss of chest wall integrity/geometry	Flail segment	Thoracoplasty
Increased small airways resistance	Asthma, bronchiolitis	Chronic obstructive pulmonary disease
Decreased lung compliance	Acute lung injury, pneumonia, pulmonary oedema, vasculitis, haemorrhage	Pulmonary fibrosis

Table 84.10 Conditions predisposing to respiratory alkalosis

Acute	Chronic
Hypoxaemia	Pregnancy
Hepatic failure	High altitude
Sepsis	Chronic lung disease
Asthma	Neurotrauma
Pulmonary embolism	Chronic liver dysfunction
Pneumonia, acute lung injury	
CNS disorders – stroke, infection, trauma	
Drugs – salicylates, selective serotonin reuptake inhibitors	
Opiate and benzodiazepine withdrawal	
Mechanical hyperventilation – intentional or inadvertent	
Pain, anxiety, psychosis
