Notice

Knowledge and best practice in this field are constantly changing. As new research and experience broaden our knowledge, changes in practice, treatment, and drug therapy may become necessary or appropriate. Readers are advised to check the most current information provided (i) on procedures featured or (ii) by the manufacturer of each product to be administered, to verify the recommended dose or formula, the method and duration of administration, and contraindications. It is the responsibility of the practitioner, relying on his or her own experience and knowledge of the patient, to make diagnoses, to determine dosages and the best treatment for each individual patient, and to take all appropriate safety precautions. To the fullest extent of the law, neither the Publisher nor the Editor assumes any liability for any injury and/or damage to persons or property arising out of or related to any use of the material contained in this book.

Ethics in Transplantation: Allotransplantation and Xenotransplantation

Preface to the First Edition

Renal transplantation is now an accepted treatment of patients in end-stage renal failure. A successful transplant restores not merely life but an acceptable quality of life to such patients. The number of patients in end-stage renal failure in the Western World who might be treated by hemodialysis and transplantation is considerable and comprises some 30-50 new patients/million of population. Unfortunately in most, if not all, countries the supply of kidneys for transplantation is insufficient to meet the demand. Furthermore, hemodialysis facilities are usually inadequate to make up this deficit so that many patients are still dying of renal disease who could be restored to a useful and productive life. Nevertheless, few of us would have imagined even 10 years ago that transplantation of the kidney would have become such a relatively common procedure as is the case today, and indeed well over 30,000 kidney transplantations have been performed throughout the world.

Transplantation of the kidney for the treatment of renal failure has been an attractive concept for many years. As long ago as 1945, three young surgeons at the Peter Bent Brigham Hospital in Boston, Charles Hufnagel, Ernest Landsteiner and David Hume, joined the vessels of a cadaver kidney to the brachial vessels of a young woman who was comatose from acute renal failure due to septicemia. The kidney functioned for several days before it was removed, and the woman regained consciousness. Shortly afterwards, the woman's own kidneys began to function and she made a full recovery. The advent of the artificial kidney at that time meant that this approach to the treatment of acute renal failure was no longer necessary, but attention was soon given to the possibility of transplanting kidneys to patients with end-stage renal failure who were requiring dialysis on the newly developed artificial kidney to stay alive.

Although the first experimental kidney transplants in animals were reported first in Vienna by Dr. Emerich Ulmann in 1902 and then in 1905 by Dr. Alexis Carrel in the United States, the problem of rejection was not mentioned by either author. Later in 1910, Carrel did discuss the possible differences between an autograft and a homograft. The vascular techniques developed by Carrel for the anastomosis of the renal vessels to the recipient vessels are still used today. But in 1923, Dr. Carl Williamson of the Mayo Clinic clearly defined the difference between an autografted and homografted kidney and even published histological pictures of a rejecting kidney. Furthermore, he predicted the future use of tissue matching in renal transplantation.

> It is unfortunate that the lower animals, such as the dog, do not possess a blood grouping like that of man. In the future it may be possible to work out a satisfactory way of determining the reaction of the recipient's blood serum or tissues to those of the donor and the reverse; perhaps in this way we can obtain more light on this as yet relatively dark side of biology.

The recognition that allogeneic tissues would be rejected was further established in later years by Drs. Gibson and Medawar, who treated burn patients with homografts in Glasgow during the Second World War. Indeed, it was the crash of a bomber behind the Medawars' house in Oxford during the early years of the war that first stimulated his interest in transplantation, especially of skin.

In his address at the opening of the new Oxford Transplant Unit in 1977, Sir Peter Medawar recounted this event.

> Early in the war, an R.A.F. Whitley bomber crashed into a house in North Oxford with much serious injury and loss of life. Among the injured was a young man with a third degree burn extending over about 60% of his body. People burned as severely as this never raised a medical problem before: they always died; but the blood transfusion services and the control of infection made possible by the topical use of sulphonamide drugs now made it possible for them to stay alive. Dr. John F. Barnes, a colleague of mine in Professor H. W. Florey's School of Pathology, asked me to see this patient in the hope that being an experimental biologist I might have some ideas for treatment. With more than half his body surface quite raw, this poor young man was a deeply shocking sight; I thought of and tried out a number of ingenious methods, none of which worked, for ekeing out his own skin for grafting, trying to make one piece of skin do the work of ten or more. The obvious solution was to use skin grafts from a relative or voluntary donor, but this was not possible then and it is not possible now.
>
> I believe I saw it as my metier to find out why it was not possible to graft skin from one human being to another, and what could be done about it. I accordingly began research on the subject with the Burns Unit of the Glasgow Royal Infirmary, and subsequently in the Zoology Department in Oxford. If anybody had then told me that one day, in Oxford, kidneys would be transplanted from one human being to another, not as a perilous surgical venture, but as something more in the common run of things, I should have dismissed it as science fiction; yet it is just this that has come about, thanks to the enterprise of Professor Morris and his colleagues.

Nevertheless in 1951, David Hume in Boston embarked on a series of cadaver kidney transplants in which the kidney was placed in the thigh of the recipient. All but one of these kidneys were rejected within a matter of days or weeks, the one exception being a patient in whom the kidney functioned for nearly 6 months and enabled the patient to leave the hospital! This event provided hope for the future as no immunosuppressive therapy had been used in this patient. At this time, the problems of rejection of kidney allografts in the dog were being clearly defined by Dr. Morton Simonsen in Copenhagen and Dr. William Dempster in London, but in 1953, a major boost to transplantation research was provided by the demonstration, by Drs. Rupert Billingham, Lesley Brent and Peter Medawar, that tolerance to an allogeneic skin graft in an adult animal could be produced by injecting the fetus with donor strain tissue, thus confirming experimentally the clonal selection hypothesis of Burnet and Fenner in the recognition of self and non-self. The induction of specific unresponsiveness of a host to a tissue allograft has remained the ultimate goal of transplant immunologists ever since.

Then in 1954, the first kidney transplant between identical twins was carried out successfully at the Peter Bent Brigham

Hospital which led to a number of further successful identical twin transplants in Boston and elsewhere in the world over the next few years.

There still remained the apparently almost insoluble problem of rejection of any kidney other than an identical-twin kidney. The first attempts to suppress the immune response to a kidney allograft employed total body irradiation of the recipient and were carried out by Dr. Merril's group in Boston, two groups in Paris under the direction of Drs. Kuss and Hamburger, respectively, and by Professor Shackman's group in London. Rejection of a graft could be suppressed by irradiation, but the complications of the irradiation were such that this was really an unacceptable approach, although an occasional relatively long-term acceptance of a graft provided encouragement for the future.

Then came the discovery by Drs. Schwartz and Dameshek in 1959 that 6-mercaptopurine could suppress the immune response of rabbits to human serum albumin. Shortly afterwards, they showed that the survival of skin allografts in rabbits was significantly prolonged by the same drug. This event ushered in the present era of renal transplantation, for very quickly Roy Calne in London and Charles Zukoski working with David Hume in Virginia showed that this same drug markedly prolonged the survival of kidney allografts in dogs. And indeed, 6-mercaptopurine was first used in a patient in Boston in 1960. Elion and Hitchings of the Burroughs Wellcome Research Laboratories in New York State then developed azathioprine, which quickly replaced 6-mercaptopurine in clinical practice as it was less toxic. With the addition of steroids, the standard immunosuppressive therapy of today was introduced to the practice of renal transplantation in the early sixties.

Not that this meant the solution of the problems of renal transplantation for this combination of drugs was dangerous and mortality was high in those early years. But there was a significant number of long-term successful transplants, and as experience grew, the results of renal transplantation improved. Another major area of endeavor in renal transplantation at that time was directed at the study of methods of matching donor and recipient for histocompatibility antigens with the aim of lessening the immune response to the graft and so perhaps allowing a decrease in the immunosuppressive drug therapy. Although this aim has only been achieved to any great extent in siblings who are HLA identical, tissue typing has made a significant contribution to renal transplantation, perhaps best illustrated by the recognition in the late sixties that the performance of a transplant in the presence of donor-specific presensitization in the recipient leads to hyperacute or accelerated rejection of the graft in most instances. Nevertheless, the more recent description of the Ia-like system in man (HLA-DR) may have an important impact on tissue typing in renal transplantation. The present decade also has seen an enormous effort directed at immunological monitoring in renal transplantation and at attempts to induce experimental specific immunosuppression. We have solved most of the technical problems of renal transplantation; we have been left with the problem of rejection and the complications arising from the drug therapy given to prevent rejection.

Although the contributions in this book cover all aspects of renal transplantation, certain subjects, as for example immunological monitoring before transplantation, transplantation in children and cancer after renal transplantation, have received considerable emphasis as they do represent developing areas of great interest, and I must take responsibility for this emphasis. For in the seventies we have seen many of the principles and practice of renal transplantation become established and the areas of future investigation become more clearly defined. With an ever-increasing demand for renal transplantation, more and more people in many different disciplines, doctors (surgeons, physicians, pathologists, virologists, immunologists), nurses, scientists and ancillary staff are becoming involved in renal transplantation either in the clinic or in the laboratory. It is to these people I hope this book will be of value.

Oxford, November 1978 **PETER J. MORRIS**

Preface to the Sixth Edition

It is now 7 years since the fifth edition of this book was published, and it is fair to say that since the first edition, published in 1979, each edition has reflected the rapid and continuing advances in renal transplantation. All chapters have been rewritten and updated, many by new contributors. As always, subjects of relevance come and go. In this edition, a separate chapter on transplantation in the highly sensitized recipient and across the ABO blood barrier appears, whereas a chapter on fine needle aspiration cytology of the transplanted kidney as well as a chapter on renal xenotransplantation, which appeared for the first time in the fifth edition, have been discarded. Xenotransplantation remains a major area of research endeavour; however, there is no clinical application in sight at this time, which perhaps seemed more likely at the time of the fifth edition. Overall, the format is much the same as before, with many new contributors and also, above all, a new editor—Stuart Knechtle has joined Peter Morris for the first time in the production of this edition.

We continue to see evidence of the advances in immunosuppression, but there is also a recognition of the increasing morbidity associated with using immunosuppression long term. Furthermore, the long-term results of renal transplantation are not as good as the short- and medium-term results might have led one to anticipate. Thus, there is now a major emphasis on chronic allograft nephropathy, which may be due to a host of injurious events, and the possibility of its prevention or treatment. Considerable attention has been given to calcineurin-sparing and steroid-sparing protocols using the more powerful new immunosuppressive agents in an attempt to achieve this goal, and several approaches are contained within the various chapters on immunosuppressive agents.

This edition, like the fifth edition, illustrates the continuing progress in all aspects of renal transplantation, but disappointingly there is little to describe in the way of induction of tolerance in clinical practice, which is to some extent due to the lack of appropriate biomarkers of tolerance or immunosuppression. We suspect that the next edition will have a whole chapter on biomarkers of immunosuppression, but at the moment their role is more speculative than actual. Patient and graft survival figures continue to improve in the short and medium term, graft survival now being around 90% or even better at 1 year. This is quite remarkable in view of the increasing number of high-risk patients undergoing transplantation, as well as the greater use of marginal donors. Without doubt, this is a tribute not only to the work of the scientists and clinicians who have made this possible but also to the thousands of patients who have participated in this evolution of what has been described as one of the medical miracles of the 20th century.

Sir Peter J. Morris

Chapter 1

Kidney Transplantation: A History

David Hamilton

The modern period of transplantation began in the late 1950s, but two earlier periods of interest in clinical and experimental transplantation were the early 1950s and the first 2 decades of the 20th century. Hamilton[21] provides a bibliography of the history of organ transplantation. Table 1-1 summarizes landmarks in kidney transplantation.

EARLY EXPERIMENTS

Interest in transplantation developed in the early part of the 20th century because experimental and clinical surgical skills were rapidly advancing, and many of the pioneering surgeons took an interest in vascular surgical techniques as part of their broad familiarity with the advance of all aspects of surgery. Payr's demonstration of the first workable, although cumbersome, methods of vascular suturing led to widespread interest in organ transplantation in Europe. Many centers were involved, notably Vienna, Bucharest, and Lyon. The first successful experimental organ transplant was reported by Ullmann in 1902. Emerich Ullmann (1861-1937) (Fig. 1-1) had studied under Edward Albert before obtaining a position at the Vienna Medical School, which was then at its height. Ullmann's article shows that he managed to autotransplant a dog kidney from its normal position to the vessels of the neck, which resulted in some urine flow. The animal was presented to a Vienna medical society on March 1, 1902, and caused considerable comment.[53] At this time, Ullmann was Chief Surgeon to the Spital der Baumhertigen Schwestern, and his experimental work was done in the Vienna Physiology Institute under Hofrath Exner. Exner's son Alfred had already tried such a transplant without success. In the same year, another Vienna physician, Alfred von Decastello, physician assistant at the 2nd Medical Clinic, carried out dog-to-dog kidney transplants at the Institute of Experimental Pathology.[14]

Ullmann and von Decastello had used Payr's method, and later in 1902 Ullmann demonstrated a dog-to-goat kidney transplant that, to his surprise, passed a little urine for a while. Neither Ullmann nor von Decastello continued with this work, although von Decastello was noted for his work on blood groups, and Ullmann published extensively on bowel and biliary surgery.

In Lyon, the department headed by Mathieu Jaboulay (1860-1913) had a major influence (Fig. 1-2). In his research laboratories, his assistants Carrel, Briau, and Villard worked on improved methods of vascular suturing, leading to Carrel's famous article credited with establishing the modern method of suturing.[9] Carrel left to work in the United States, and in the next 10 years he published extensively on organ grafting, successfully carrying out autografts of kidneys in cats and dogs and showing that allografts eventually failed after functioning briefly. He was awarded a Nobel Prize for this work in 1912.

HUMAN KIDNEY TRANSPLANTS

Jaboulay, Carrel's teacher, had carried out the first recorded human kidney transplant in 1906,[27] although Ullmann later claimed an earlier attempt in 1902.[54] Jaboulay was later to be better known for his work on thyroid and urological surgery, but, doubtless encouraged by the success of Carrel and others in his laboratory, he carried out two xenograft kidney transplants using a pig and goat as donors, transplanting the organ to the arm or thigh of patients with chronic renal failure. Each kidney worked for only 1 hour. This choice of an animal donor was acceptable at that time in view of the many claims in the surgical literature for success with xenograft skin, cornea, or bone.

More is known of the second and third attempts at human kidney transplantation. Ernst Unger (1875-1938) (Fig. 1-3) had a thorough training in experimental work and set up his own clinic in 1905 in Berlin, being joined there by distinguished colleagues. He continued with experimental work and by 1909 reported successful transplantation of the kidneys en masse from a fox terrier to a boxer dog. The urine output continued for 14 days, and the animal was presented to two medical societies. By 1910, Unger had performed more than 100 experimental kidney transplants. On December 10, 1909, Unger attempted a transplant using a stillborn child's kidney grafted to a baboon. No urine was produced. The animal died shortly after the operation, but postmortem examination showed that the vascular anastomosis had been successful. This success and the new

knowledge that monkeys and humans were serologically similar led Unger to attempt, later in the same month, a monkey-to-human transplant.[55] The patient was a young girl dying of renal failure, and the kidney from an ape was sutured to the thigh vessels. No urine was produced. Unger's report concluded that there was a biochemical barrier to transplantation, a view mistakenly advocated by the basic science of the day; his main contributions thereafter were in esophageal surgery. (For a biography of Unger, see Winkler.[58])

These early experiments established that kidney transplants were technically possible. Methods of study of renal function were primitive then; without routine measurement of blood urea and without any radiological methods, subtle studies of transplant function were impossible. This impossibility plus the uncertainty of the mechanism of allograft rejection led to a diminished interest in organ transplantation after about 10 years of activity. By the start of World War I, interest in organ transplantation had almost ceased and was not resumed in the European departments of surgery after the war. Carrel had switched his attention to studies of tissue culture. Interest elsewhere also was low; in Britain and the United States, scarce research funds were being applied to fundamental biochemistry and physiology, rather than applied projects of clinical relevance. Transplantation immunology faded away after the bright start in the capable surgical hands of Carrel, Murphy's sound grasp of immunosuppression, and Landsteiner's awareness of the serological detection of human antigens. Carrel, Murphy, and Landsteiner all worked at the Rockefeller Institute in New York.

In 1914 in a remarkable lecture to the International Surgical Society, Carrel did anticipate the future development of transplantation. His colleague, J. B. Murphy, at the Rockefeller Institute, had found that radiation or benzol

Figure 1–1 Emerich Ullmann (1861-1937) in 1902 carried out the first experimental kidney transplants in dogs. (Courtesy of The Vienna University, Institute for the History of Medicine.)

treatment would increase the "take" of tumor grafts in rats, and Carrel realized the potential of these findings:

It is too soon to draw any definite conclusions from these experiments. Nevertheless it is certain that a very important point has been acquired with Dr. Murphy's discovery that the power of the organism to eliminate foreign tissue was due to organs such as the spleen or bone marrow, and that when the action of these organs is less active a foreign tissue can develop rapidly after it has been grafted.

It is not possible to foresee whether or not the present experiments of Dr. Murphy will lead directly to the practical solution of the problem in which we are interested.

The surgical side of the transplantation of organs is now completed, as we are now able to perform transplantations of organs with perfect ease and with excellent results from an anatomical standpoint. But as yet the methods cannot be applied to human surgery, for the reason that homoplastic transplantations are almost always unsuccessful from the standpoint of the functioning of the organs. All our efforts must now be directed toward the biological methods which will prevent the reaction of the organism against foreign tissue and allow the adapting of homoplastic grafts to their hosts.[10]

THE MIDDLE YEARS

Until the revival of interest in transplantation in the 1950s, the 1930s and 1940s were a stagnant period in clinical science. The great European surgical centers had declined; in North America, only at the Mayo Clinic was there a cautious program of experimental transplantation without building on Carrel's work, notably failing to make attempts at

Figure 1–2 Mathieu Jaboulay (1860-1913) and his surgical team at Lyon in 1903. Until his death in a rail accident, Jaboulay made numerous surgical contributions and encouraged Alexis Carrel's work on vascular anastomosis. In 1906, Jaboulay reported the first attempt at human kidney transplantation

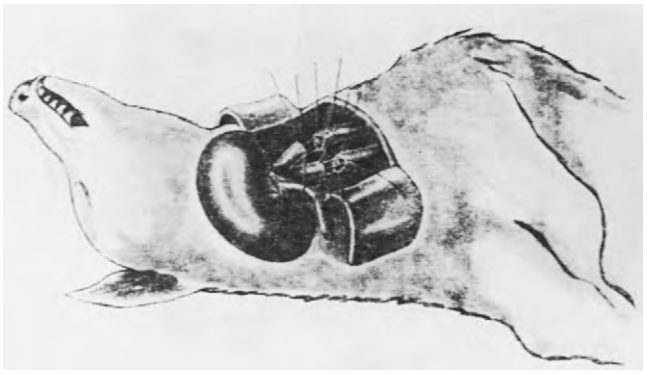

Figure 1–4 Yu Yu Voronoy (1895-1961) had experience with dog allografts before carrying out the first human kidney allograft in 1933 at Kherson in the Ukraine. His experimental animal model is shown here.

immunosuppression. In transplantation circles, such as they were, there was not even the confidence to counter the vivid claims of Voronoff to rejuvenate human patients via monkey gland grafts, and the endless reports of successful human skin grafts were not examined critically.

The main event of this period was an isolated and little known event—the first human kidney allograft. It was performed in the Ukraine by the Soviet surgeon Yu Yu Voronoy.[56] Voronoy was an experienced investigator, and he eventually performed six such transplants up to 1949. Voronoy (1895-1961) trained in surgery at Kiev under Professor V. N. Shamov and obtained experience there with serological methods of blood transfusion, then in their developmental stage. He used these methods to detect complement-fixing antibodies after testis slice transplants, and later he had some success with the same methods applied to kidney grafts (Fig. 1-4). In 1933, Voronoy transplanted a human kidney of blood group B to a patient of blood group O with acute renal failure as a result of mercuric chloride poisoning. The donor kidney was obtained from a patient dying as a result of a head injury and was transplanted to the thigh vessels under local anesthetic; the warm time for the kidney was about 6 hours. There was a major mismatch for blood groups, and despite a modest exchange transfusion, the kidney never worked. The patient died 2 days later; at postmortem, the donor vessels were patent. By 1949, Voronoy reported six such transplants, although no substantial function had occurred in any. (For a biography of Voronoy, see Hamilton and Reid.[22])

POST–WORLD WAR II

The sounder basis of transplantation immunology, which followed Medawar's pioneer studies during World War II, led to a new interest in human transplantation. In 1946, a human allograft kidney transplant to arm vessels under local anesthetic was attempted by Hufnagel, Hume, and Landsteiner at the Peter Bent Brigham Hospital in Boston. The brief period of function of the kidney may have helped the patient's recovery from acute renal failure; it marked the beginning of that hospital's major interest in transplantation and dialysis.[33]

In the early 1950s, the interest in experimental and clinical kidney transplantation increased. With a growing certainty that immunological mechanisms were involved, the destruction of kidney allografts could be reinvestigated. Simonsen, then an intern in Ålborg in Denmark, persuaded his surgical seniors to teach him some vascular surgery; using dog kidney transplants, he reported on the mechanism of kidney rejection.[47] Dempster in London also re-examined this question.[15] Both workers found that the pelvic position of the kidney was preferable to a superficial site, and both concluded that an immunological mechanism was responsible for failure. Dempster found that radiation, but not cortisone, delayed rejection. Both workers considered that a humoral mechanism of rejection was likely.

In the early 1950s, two groups simultaneously started human kidney transplantation. In Paris, with encouragement from the nephrologist Jean Hamburger, the surgeons Küss (five cases),[31] Servelle (one case),[46] and Dubost (one case)[16] reported on kidney allografts without immunosuppression in human patients, placing the graft in the now-familiar pelvic position. The Paris series included a case reported by Hamburger of the first live related kidney transplant, the donor being the mother of a boy whose solitary kidney had been damaged in a fall from a height. The kidney functioned immediately, but was rejected abruptly on the 22nd day.[32] In the United States, the Chicago surgeon Lawler had been the first to attempt such an intra-abdominal kidney allograft in 1950; it was met with the intense public interest and professional skepticism that were to characterize innovative transplantation thereafter.

A series of nine cases, closely studied, was recorded from Boston, using the thigh position of the graft, and for the first time hemodialysis had been used in preparing the patients, employing Merrill's skill with the early Kolff/Brigham machine. David Hume (Fig. 1-5) reported on this Boston experience in 1953. Modest unexpected survival of the kidney was obtained in some of these cases and served to encourage future careful empirical surgical adventures, despite advice from scientists to wait for elegant solutions. Although small doses of adrenocorticotropic hormone or cortisone were used, it was thought that the endogenous immunosuppression of uremia was responsible for these results, rather than the drug regimen. Many of Hume's tentative conclusions from this short series were confirmed later, notably that prior blood transfusion might be beneficial, that blood group matching of graft and donor might be necessary, and that host bilateral nephrectomy was necessary for control of post-transplant blood pressure.[26] The first observation of recurrent disease in a graft was made, and accelerated arteriosclerosis in the graft vessels was noted at postmortem. Other cases were reported from Chicago, Toronto, and Cleveland in the early 1950s, but because no sustained function was achieved, interest in clinical and experimental renal allograft transplantation waned, despite increasing knowledge of basic immunological mechanisms in the laboratory.

Figure 1–5 David M. Hume (1917-1973) pioneered human kidney transplantation at the Peter Bent Brigham Hospital, Boston, and the Medical College of Virginia. He died in an air crash at the age of 55.

The technical lessons learned from the human allograft attempts of the early 1950s allowed confidence in the surgical methods, and in Boston, on December 23, 1954, the first transplant of a kidney from one twin to another with renal failure was performed. From then on, many such transplantations were performed successfully in Boston.[38] Although sometimes seen now merely as a technical triumph, valuable new findings emerged from this series. Some workers had predicted that in the short-term, the activity of the inactive bladder could not be restored, and that in the long-term human kidney grafts would decline in vitality as a result of denervation or ureteric reflux. Other workers were convinced that a single kidney graft could not restore biochemical normality to an adult, and that in any case the existing changes caused by chronic renal failure were irreversible. All of these gloomy predictions were neutralized by the success of the twin kidney transplants, and the greatest triumph came when one such recipient became pregnant and had a normal infant, delivered cautiously by cesarean section, with the anxious transplanters in attendance. Many of the twin recipients are still alive today, although the good results were tempered by failures caused by the prompt return of glomerulonephritis in some transplanted kidneys. This complication was later much reduced by immunosuppression. Other lessons learned were that the hazard of multiple donor renal arteries provided a need for pretransplant angiography of the kidneys in living donors, although it still was not thought necessary to perfuse or cool the donor organ. Lastly, there was the first airing of the legal aspects of organ donation, particularly the problem of consent in young, highly motivated related donors. (For an account of this period, see Murray and colleagues.[40])

IMMUNOSUPPRESSION AND THE MODERN ERA

In 1948, the first patients crippled with rheumatoid arthritis were given the Merck Company's Cortone (cortisone) at the Mayo Clinic, and intense worldwide interest in the pharmacological actions of adrenal cortical hormones followed. Careful studies by Medawar's group in the early 1950s suggested a modest immunosuppressive effect of cortisone, but when Medawar shortly afterward showed profound, specific, and long-lasting graft acceptance via the induction of tolerance, the weak steroid effect was understandably sidelined and thought to be of no clinical interest. Induction of tolerance in adult animals (rather than newborns) was accomplished by lethal irradiation and bone marrow infusion, and with this strong lead from the laboratory, it was natural that the first attempts at human immunosuppression for organ transplants were with preliminary total-body irradiation and allograft bone marrow rescue. These procedures were carried out in Paris, Boston, and elsewhere in the late 1950s.

This regimen was too difficult to control, and graft-versus-host disease was inevitable. It was found unexpectedly that sublethal irradiation alone in human patients was quite

immunosuppressive, however, and this approach was used until 1962, the year of the first general availability of azathioprine (Imuran). In Boston, 12 patients were treated in this way, but with only one long-term survival in a man receiving his transplant from his nonidentical twin.[37] In Paris, similar success was obtained with sibling grafts.[19,29] These isolated kidney survivals after a single dose of radiation gave further hope and showed again that the immunology of humans, dogs, and mice is different. These cases also showed that if a human organ could survive the initial crucial rejection period, it could be protected or adapted to the host in some way, possibly shielded by new endothelium, by enhancement, or, as suggested later, by microchimeric tolerance induced by mobile cells in the graft.

CHEMICAL IMMUNOSUPPRESSION

In 1958, at the New England Medical Center, attempts were made at human bone marrow transplantation for aplastic anemia and leukemia. To enable the marrow grafts to succeed, irradiation of the recipient was used. Results were poor, and mortality was high. Dameshek and Schwartz looked for alternatives to irradiation and reasoned that an anticancer drug, such as 6-mercaptopurine (6-MP) or methotrexate, might be of use for immunosuppression in their patients. (For an account of this period, see Schwartz.[44]) Their important paper in 1959, showing a poor immune response to foreign protein in rabbits treated with 6-MP,[45] was noticed by Roy Calne, then a surgeon in training at the Royal Free Hospital, London, and David Hume, new Chairman of Surgery at the Medical College of Virginia. Calne had been disappointed at the failure of irradiation to prolong kidney allograft survival in dogs and, similar to others looking for an alternative, he found that 6-MP was successful.[5] Zukoski and colleagues[59] in Richmond found the same effect.

In 1960, Calne visited Boston for a period of research with Murray, and Hitchings and Elion of Burroughs Wellcome, then at Tuckahoe, provided him with new derivatives of 6-MP. Of these, BW57-322 (later known as azathioprine [Imuran]) proved to be more successful in dog kidney transplants and less toxic than 6-MP.[7]

In 1960 to 1961, 6-MP was used in many human kidney transplants. In London at the Royal Free Hospital, three cases were managed in this way, but without success, although one patient receiving a live related transplant died of tuberculosis rather than rejection.[23] In Boston, no lasting human kidney function was obtained, but in Paris, Küss and associates[30] reported one prolonged survival of a kidney from a nonrelated donor when 6-MP was used with intermittent prednisone in a recipient who also had received irradiation as the main immunosuppressive agent (Fig. 1-6). This case was the first success for chemical immunosuppression.

This change in approach, giving lifelong, risky medication with toxic drugs, although an obvious development in retrospect, was accepted with reluctance because it meant leaving aside, at least in the short-term, the hopes from the work of the transplantation immunologists for the elegant, specific, one-shot, nontoxic tolerance regimen. Many workers thought that entry into this new paradigm was only a temporary diversion.

In 1961, azathioprine became available for human use; the dosage was difficult to judge at first. The first two Boston cases using the drug did not show prolonged survival of the grafts, but in April 1962 the first extended successes with human kidney allografts were obtained.[39] Shortly afterward, at the bedside rather than in the laboratory, it was discovered that steroids, notably prednisolone, when given with azathioprine had a powerful synergistic effect. The regular use of both together became a standard regimen after reports by Starzl and colleagues[49] and Goodwin and coworkers,[18] and this combined therapy continued to be the routine immunosuppressive method despite many other suggested alternatives, until azathioprine was displaced by cyclosporine much later. Use of the combined immunosuppression and the increasing use of live related donors (rather than occasional twin or free or cadaver kidneys), along with the remarkably good results reported in 1963 from Denver[49] and Richmond,[25] greatly encouraged the practice of transplantation. (For an account of this period, see Starzl.[48])

The patient and her brother-in-law donor (*center right*) are shown with the staff of the unit at the Hôpital Foch. Immunosuppression with irradiation and mercaptopurine was used. (Courtesy of Prof. M. Legrain.)

A TIME OF OPTIMISM

The mid-1960s was a period of great optimism. The rapid improvement in results seemed to indicate that routine success was at hand. Looking to the future, calculations were made that suggested that enough donor organs would be available in the future if all large hospitals cooperated, and such donations did start to come from outside the transplantation pioneer hospitals. Transplantation societies were set up, and specialist journals were started. The improvements in regular dialysis treatment meant an increasing pool of patients in good health suitable for transplantation, and this allowed for better and planned preparation for transplantation. With a return to dialysis being possible, heroic efforts to save a rejected kidney were no longer necessary. Management of patients improved in many aspects, and the expected steroid long-term effects were met and managed (primarily by the demonstration that low-dose steroids were as effective as high-dose steroids). The need for cooling of donor organs was belatedly recognized, many tests of viability were announced, and transport of organs between centers began. Bone disease and exotic infections were encountered and treated, but the kidney units were affected by a hepatitis B epidemic in the

mid-1960s, which affected morale and status. The narrow age limit for transplantation was widened, and in Richmond the first experience with kidney grafts in children was obtained.

Recipients of kidney transplants re-entered the normal business of life and became politicians, professors, pilots, and fathers and mothers of normal children. Other good news in the United States came when the federal government accepted the costs of regular dialysis and transplantation in 1968. There were always unexpected findings, usually reported from the pioneer units with the longest survivors. Cautiously, second kidney transplants were performed at Richmond when a first had failed; these did well, and the matter became routine. Chronic rejection and malignancy first were reported in kidney transplant recipients from Denver. As a result of the optimism, experimental heart transplantation started, the first human livers were grafted, and there was a revival of interest in xenotransplantation. Although the attempts of Reemtsma and coworkers,[42] Hume,[24] and Starzl[48] at transplantation with chimpanzee or baboon kidneys ultimately failed, rejection did not occur immediately, and the cases were studied closely and described.

In the search for better immunosuppression, there was great excitement when laboratory studies by Woodruff and Medawar produced a powerful immunosuppressive antilymphocyte serum, and production of a version suitable for human use started. Initial results were favorable, but the antilymphocyte serum had an unspectacular role thereafter, supplanted from 1975 onward to a large extent by the production of monoclonal antibodies. Hopes for another biological solution to transplantation were raised in 1969 when French and Batchelor[17] found an enhancing serum effect in the new experimental model of rat kidney transplantation made possible by the development of microsurgical methods, but it proved impossible to mimic the effect in humans.

TISSUE TYPING

The greatest hopes resided in the evolution of tissue typing methods, which entered routine use in 1962 (Fig. 1-7).[13,20] The increasing identification of the antigens of the HLA system seemed to promise excellent clinical results in the future from close matching made possible when choosing from a large pool of patients. Sharing of kidneys in Europe started in 1967 at van Rood's suggestion,[43] and in North America, Amos and Terasaki set up similar sharing schemes on both coasts of the United States. Others followed throughout the world, and these organizations not only improved the service but also soon gathered excellent data on kidney transplant survival. The need to transport kidneys within these schemes encouraged construction of perfusion pumps designed to increase the survival of organs and the distance they could be transported.[1] Much work on perfusion fluids was done until the final intracellular type of fluid devised by Collins in 1969 allowed a simple flush and chill to suffice for prolonged storage.[11] Although the hopes for typing were not fully realized, such schemes had other benefits in obtaining kidneys when urgently required for patients with rarer blood groups, for children, or for highly sensitized patients. Such patients had been recognized by the new lymphocytotoxicity testing using a crossmatch between donor cells and recipient serum. First noted by Terasaki and associates[51] and described in more detail by Kissmeyer-Nielsen and colleagues[28] in 1966, such pretransplant testing explained cases of sudden failure and led to a marked diminution in hyperacute rejection.

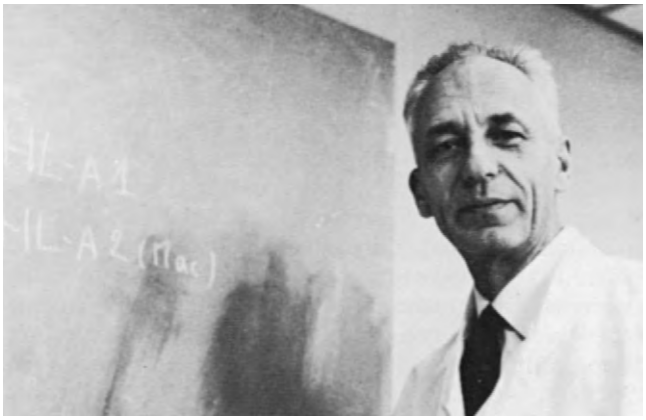

Figure 1–7 Jean Dausset first described an antigen MAC, later known as HL-A2, defined by numerous antisera from multitransfused patients, and which later was shown to be part of the major histocompatibility complex in humans (HLA).

THE 1970s PLATEAU

The 1970s was a period of consolidation, of improvements in data collection such as the valuable European Dialysis and Transplant Association surveys, and increased sophistication in HLA typing methods and organ-sharing schemes. Cadaver organ procurement generally increased as a result of wider involvement of the public and medical profession, although the number of patients waiting for transplantation persistently exceeded the organs available, and donation declined transiently during times of public concern over transplantation issues. Governments took initiatives to increase donations; in Britain, the Kidney Donor Card was introduced in 1971, becoming a multidonor card 10 years later. In hospital practice, methods of resuscitation and intensive care improved, and the concept of brain death was established to prevent prolonged, pointless ventilation, although its immediate application to transplantation provoked controversy. Despite many new claims for successful methods of immunosuppression, such as trials of splenectomy, thymectomy, and thoracic duct drainage, as well as a new look at cyclophosphamide, no agent except antithymocyte globulin became established in routine use.

Although patient survival after kidney transplantation continued to increase, the 1970s did not show the expected increase in cadaver graft survival. Some groups reported decreased survival figures; this paradox was solved partly by the demonstration that blood transfusion during regular dialysis, which had been discouraged because of the risk of sensitization, was beneficial to the outcome of kidney transplantation,[41] an observation made some years earlier by Morris and coworkers.[35]

The 1970s ended with two innovations that revived hopes of reaching the goal of routine, safe, and successful kidney transplantation. Ting and Morris[52] reported the successful clinical application of HLA-DR matching, and Calne and associates[8] revived memories of the excitement of the early days of the use of azathioprine by introducing into clinical

practice the first serious rival to it in 20 years, cyclosporine, which had been discovered to be a powerful immunosuppressive agent by Borel.[3] Cyclosporine replaced the earlier drug regimens and was the dominant agent in use until the 1990s. Transplantation had grown to a sufficiently large clinical service that it was worth the attention of the pharmaceutical companies, and in the 1990s steady production of new agents occurred—tacrolimus, mycophenolate mofetil, rapamycin, FTY720, brequinar, and others. Any drug with promise was marketed aggressively, and sponsored trials became a routine part of clinical life.

The improved results of transplantation meant that the procurement of organs became a more dominant issue. Comparisons of transplantation practice throughout the world showed remarkable differences in attitudes to use of live related donors and cadaver organs, depending on religion and cultural traditions. Kidney transplantation had started as a difficult surgical and scientific challenge confined to a few academic centers in the developed world, but its success had led to the technique becoming a routine service in all parts of the world.[4] In some nations not sharing Western attitudes, the donor shortage meant the appearance of undesirable commercial developments in renal transplantation, such as the purchase of kidneys from living unrelated donors (discussed in more detail in Chapter 39).[34]

WAITING FOR XENOGRAFTS

As the demand for kidney transplants continued to exceed supply, other initiatives appeared and included study of nations and areas with high donation rates (e.g., Spain), the regulated use of properly motivated unrelated individuals, and a return to use of marginal cadaver kidneys, notably from non–heart beating donors. As all attempts to increase donor supply fell short of the ever-rising target, the radical alternative of the use of animal organs was examined afresh. Profound immunosuppression alone was ineffective and, at first, methods of removing natural antibody from recipient plasma were tried to deal with the hyperacute phase of xenograft organ rejection. Although the traditional hopes for xenografting of human patients had assumed that concordant species such as the monkey would be used, a new strategy using genetic engineering methods first used a line of transgenic pigs, a distant species discordant with humans, with a modified endothelium that reduced the complement-mediated immediate reaction.[2]

These new hopes for xenografts raised old fears among the public and legislators, notably regarding disease transmission. Although this had been a familiar problem in human-to-human transplantation and had been met regularly and dealt with, governments required reassurances about xenotransplantation with the added threat of retrovirus transmission. Hopes faded that these early developments would evolve into a sophisticated routine. Instead, the kidney transplanters could only watch, with detached interest, the emergence of stem cell use in cellular transplantation.

CONCLUSION

Kidney transplantation was the first of the organ transplant procedures to develop because of availability of live donors and the crucial backup of dialysis. When radical new ideas are to be tested, pioneers still turn to kidney transplantation. Kidney transplantation is where it all started, with good reason, and it will always be a test bed for major innovation.

In the early 1990s, Murray[36] was awarded the Nobel Prize in Medicine for his pioneer work in renal transplantation and in the development of many new immunosuppressive agents, including drugs and monoclonal antibodies. The future promises to be exciting. Nowhere is the excitement of the past reflected better than in the recollections of 35 of the pioneers of transplantation gathered together by Terasaki.[50]

Chapter 2

Immunology of Graft Rejection

Margaret J. Dallman

Transplantation remains the treatment of choice for patients with renal failure. In most cases, this procedure entails the use of an organ from a genetically disparate individual and inevitably results in a response in the host and in the graft. Some responses occur as a result of the trauma associated with organ harvest, perfusion, and surgery, whereas others involve specific recognition by the immune system of antigenic differences between donor and recipient. The cumulative effect of these events is a destructive response that, if uncontrolled, leads to loss of the transplant, as originally highlighted by workers such as Little and Tyzer.[201] The immunological nature of tissue rejection as originally suggested by Gorer[105] was firmly established more than 50 years ago by Medawar[99,232,233] after the demonstration that the rejection process in humans and rodents displays marked specificity and memory for donor tissue and is accompanied by infiltration with leukocytes.

Our understanding of the immune system has evolved considerably, and we now are able to describe more fully the molecular and cellular events that result in graft rejection. With such knowledge has come an impressive range of new, primarily biological agents, including antibodies and fusion proteins that are targeted to specific aspects of the immune response in an attempt to deliver better and more selective immunosuppression. Many of these agents are currently in clinical use or trial (see Chapters 20 and 21), complementing established agents such as cyclosporine, tacrolimus, and steroids. Despite the wealth of immunosuppressive agents, clinically detectable acute rejection is common, and although this in itself may not result in graft loss, it undoubtedly contributes to slowly deteriorating renal dysfunction, which is accompanied by the histological changes of chronic allograft nephropathy (see Chapters 24 and 25). Current use of immunosuppressive agents, although becoming more sophisticated, remains heavy-handed because suitable predictive criteria and assays that can dictate an individualization of therapy in different patients are still lacking. An ability to tailor therapy remains a major challenge in transplantation and is likely to be achieved only when we can develop a full profile of the evolution of the immune response after transplantation and understand the parameters that control immunity. Developing accurate, early, noninvasive, and predictive biomarkers to trace the emerging immunity and to indicate a response to therapeutic intervention remains a crucial but elusive goal.

This chapter describes the molecular and cellular events of the immune response that are understood. It assumes a basic level of knowledge of the cells and molecules involved in immune responses. The reader is referred to other books for general descriptions of the immune system.[147,160] See Table 2-1 for terminology.

TRAUMA OF TRANSPLANTATION

The response to a transplant occurs in a series of relatively well-defined stages (Fig. 2-1), the first of which involves the severe physical assault that the graft undergoes during harvest from the donor and transplantation into the recipient and includes the hemodynamic and neuroendocrine responses to brainstem death in cadaver donors. Harvesting and preservation involve cooling the kidney to reduce its metabolic rate; perfusion with preservation solution, which is designed to reduce cold-induced cell swelling and prevent loss of potassium from the cell; storage for sometimes long periods, which results in pH changes and the accumulation of toxic products; and the surgical procedures required for transplantation to the recipient. All of these events sensitize the organ to reperfusion injury when the organ is warmed rapidly on revascularization in the recipient. Preservation solutions, alongside approaches that upregulate or provoke overexpression of heme oxygenase 1, aim to reduce these effects on the kidney (see Chapter 9); nevertheless during and shortly after the ischemic and reperfusion periods, a variety of genes become activated, and inflammatory cells begin to infiltrate the graft.

Table 2–1 **Transplant Terminology**	
Autograft (autologous transplant)	Transplantation of an individual's own tissue to another site (e.g., the use of a patient's own skin to cover third-degree burns or a saphenous vein femoropopliteal graft)
Isograft (syngeneic or isogeneic transplant)	Transplantation of tissue between genetically identical members of the same species (e.g., kidney transplant between identical twins or grafts between mice of the same inbred strain)
Allograft (allogeneic transplant)	Transplantation of tissue between genetically nonidentical members of the same species (e.g., cadaver renal transplant or graft between mice of different inbred strains)
Xenograft (xenogeneic transplant)	Transplantation of tissue between members of different species (e.g., baboon kidney into a human)

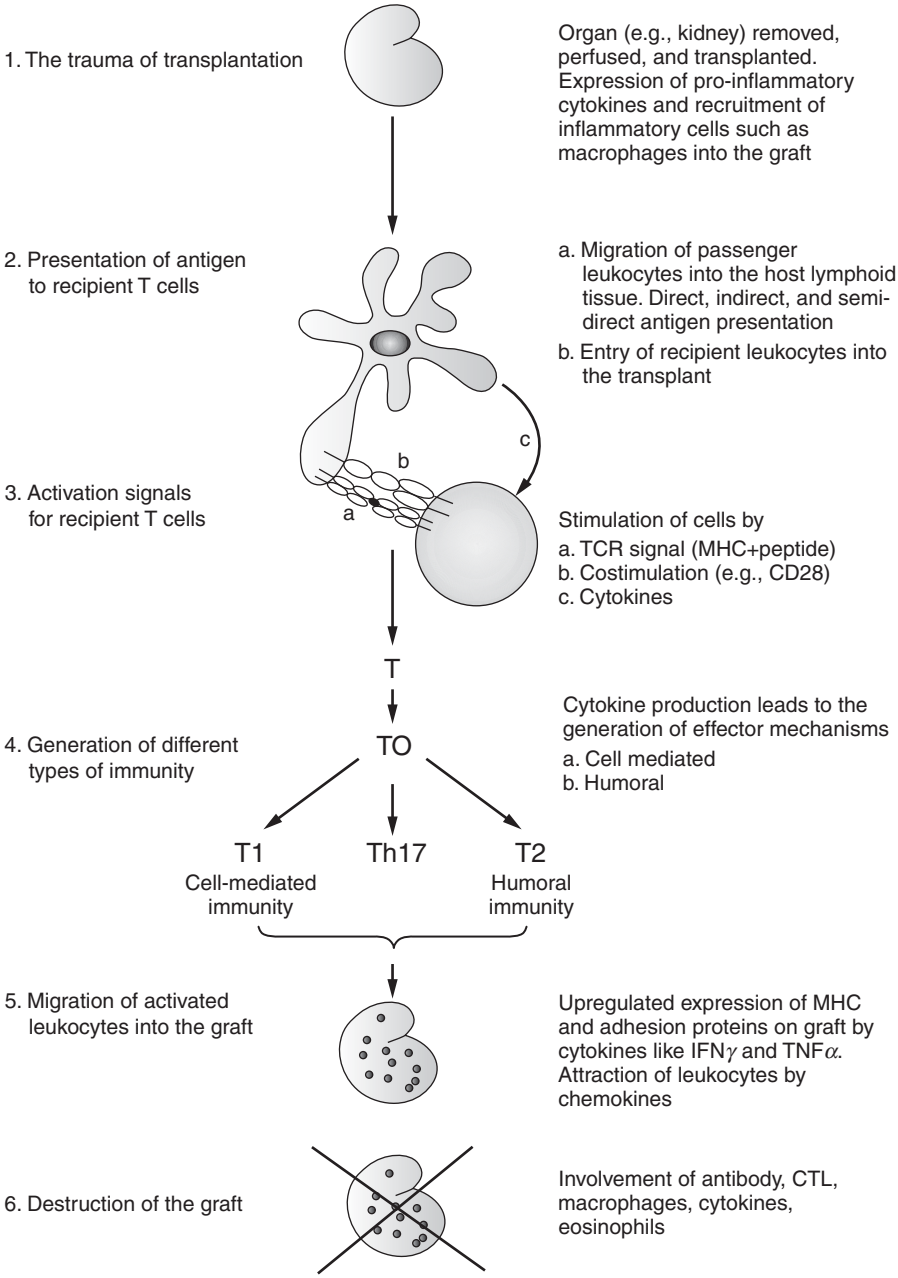

Figure 2–1 The evolution of the immune response after kidney transplantation. CTL, cytotoxic T cell; IFN, interferon; MHC, major histocompatibility complex; TCR, T cell receptor; TNF, tumor necrosis factor.

The importance of these aspects of transplantation is shown by the superior outcome of live donor transplants even in the face of significant major histocompatibility complex (MHC) mismatch,[217] the importance of cold ischemia time in graft outcome,[315] and reportedly higher rates of rejection observed in individuals with delayed graft function.[287] In experimental transplantation between identical individuals, graft histology similar to that seen in chronic allograft nephropathy may be observed after prolonged ischemia.[363]

INNATE IMMUNE RESPONSE

Cells and mediators involved in the early nonadaptive, non–antigen-specific response are components of the innate immune system that provides the body with a first-line defense against damage and invading pathogens. Activation of the endothelium together with the induction of several soluble proteins or cytokines (or transcripts of cytokines), such as interleukin (IL)-6 and IL-1, can be shown at early time points after transplantation, even of syngeneic grafts, in which there is no antigenic difference between donor and recipient and in which an antigen-specific immune response is not generated.[58,358] Probably as a result of this induction, combined with an upregulated expression of adhesion proteins on the vascular endothelium and other cells of the graft,[172] an early infiltrate of inflammatory cells, including macrophages, develops.[231] This early inflammatory response also triggers the migration out of the graft of tissue-resident, bone marrow–derived dendritic cells (DCs).[184,185] These early events in themselves do not result in graft rejection and, as noted, are observed in syngeneic grafts. The severity of the initial injury and the nature of the subsequent inflammatory infiltrate are central, however, in the stimulation of antigen-specific immunity: A maximally damaged organ generates a maximal "danger signal,"[227] which can initiate adaptive or antigen-specific immunity manifested as rejection when antigenic differences between donor and recipient exist.

Receptors of the Innate Immune System

Cells of the innate immune system bear receptors (pattern recognition receptors) that recognize and respond to molecules expressed by pathogens (pathogen-associated molecular patterns), sensing danger. Innate immune cells, such as macrophages and DCs, are activated via their cell surface and internal pattern recognition receptors to a heightened cytocidal state and antigen-presenting capacity. One group of pattern recognition receptors, the Toll-like receptors,[234] have received much attention in recent years, and there is evidence that signaling via Toll-like receptors can be important, at least in experimental transplantation.[103]

Why should such activation via pattern recognition receptors occur after apparently sterile procedures such as transplantation? Although still controversial, it seems that endogenous ligands released after tissue damage also can bind certain pattern recognition receptors, activating cells of the innate immune system.[264] The antigenic differences between donor and recipient can then be efficiently presented to cells of the adaptive immune system, and antigen-specific immunity ensues.

Other Aspects of Innate Immunity

Other cells of the innate immune system contribute not only at the early stages after transplantation (e.g., interferon [IFN]-γ produced by natural killer [NK] cells[241] is a factor in the activation of DCs) but also at the later phases of rejection (e.g., eosinophils can be involved in tissue destruction). We return to this subject later in this chapter for a fuller description of NK cells and eosinophils and their role in the effector phase of rejection.

Complement

The complement system is a humoral component of innate immunity, composed of a well-defined group of soluble proteins, enzymes, and receptors that act in a cascade fashion to mediate their effector functions. Although normally activated in the presence of infections, complement also can be activated by a variety of endogenous signals, including hypoxia and stress.[376,377] Complement activation generates numerous products that are important not only for host defense but also for regulation of inflammatory processes and adaptive immunity.[35] Conventionally thought to be a product of the liver, it is now clear that there are many extrahepatic sites of complement synthesis and that myeloid cell–derived complement component C3 is important in the generation of adaptive immunity.[374,375] In the context of transplantation, production of C3 by the donor organ in experimental and clinical studies is an important factor in the generation of alloimmunity.[23,286] It has been found that DCs themselves are able to produce C3 and that this can regulate the maturation of DCs and their ability to activate T cells. DCs from C3-deficient ($C3^{-/-}$) mice stimulated diminished T cell responses and notably seemed to be particularly good at inducing T cells with a regulatory phenotype that could be responsible for dampening immune responses.[277,391] How exactly C3 production by DCs affects T cell responses is the focus of current interest in this area.[392]

ADAPTIVE IMMUNITY—THE AFFERENT ARM

The antigen-specific or adaptive immune response to a graft occurs in two main stages. In the first, the afferent arm, donor antigens are presented to recipient T lymphocytes, which become activated, proliferate, and differentiate further while sending signals for growth and differentiation to a variety of other cells. In the second stage, or efferent arm, effector leukocytes are recruited into the organ, where they can wreak the havoc that results in tissue destruction.

Antigens That Stimulate Graft Rejection

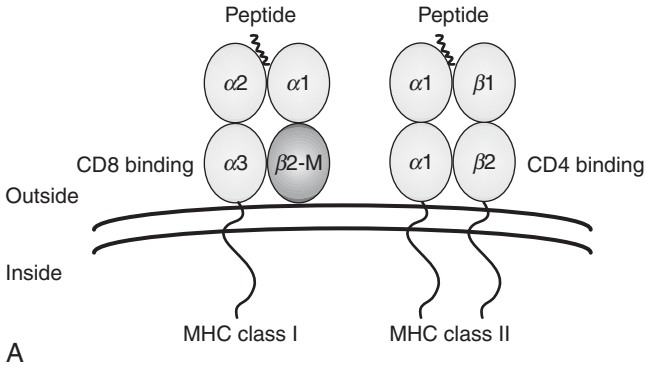
Histocompatibility antigens determine the outcome of tissue allografts between different members of the same species. In all vertebrate species, histocompatibility antigens can be divided into a single MHC and numerous minor histocompatibility (miH) systems. Incompatibility for either MHC or miH antigens between donor and recipient leads to an immune response against the graft, but more vigorous rejection occurs in the face of MHC differences. In a nonsensitized recipient, rejection of MHC-compatible organ grafts may not occur or may be delayed, although there is evidence

that multiple miH differences alone can result in cardiac allograft rejection in mice as rapidly as that seen with transplantation across a full MHC barrier.[280] It is a different matter with bone marrow, however, in which transplants between HLA-identical siblings may be rejected or cause graft-versus-host disease because of a disparity between host and donor in only one or a few minor antigens.[106,107]

Major Histocompatibility Antigens

There is substantial similarity between the MHC in different species with respect to immunogenetics and protein structure. The genes within the MHC are divided into class I, class II, and class III types[31,169]; the human MHC (HLA) is described more fully in Chapter 10. MHC class I proteins (Fig. 2-2) are cell surface glycoproteins composed of two chains—the heavy chain (molecular weight approximately 45 kD), which is highly polymorphic and encoded within the MHC by a class I gene, and a nonvariable light chain, β_2-microglobulin (molecular weight approximately 12 kD), which is encoded at another chromosomal location. In contrast to the heavy chain, β_2-microglobulin is not anchored in the membrane (Fig. 2-2A) so that it may be exchanged for, or stabilized by, β_2-microglobulin from the surrounding fluid. MHC class I proteins are expressed on most nucleated cells, albeit at variable levels, and are generally responsible for activating T cells bearing the CD8 surface protein ($CD8^+$ cells) (see later). MHC class II proteins are encoded entirely within the MHC and are composed of two membrane-anchored glycoproteins (see Fig. 2-2A) of similar molecular weight (alpha chain, molecular weight approximately 35 kD; beta chain, molecular weight approximately 28 kD). These chains primarily stimulate T cells bearing the CD4 surface protein ($CD4^+$ cells). The tissue distribution of MHC class II proteins is far more restricted than that of class I, being expressed constitutively only by B lymphocytes, DCs, and some endothelial cells, the last being particularly the case in humans. During an immune or inflammatory response, however, many other cell types, with a few exceptions, may be induced to express MHC class II proteins.[54,68,86,91,182,225,383]

MHC class I and class II proteins form a similar three-dimensional structure at the cell surface (see Fig. 2-2B and C



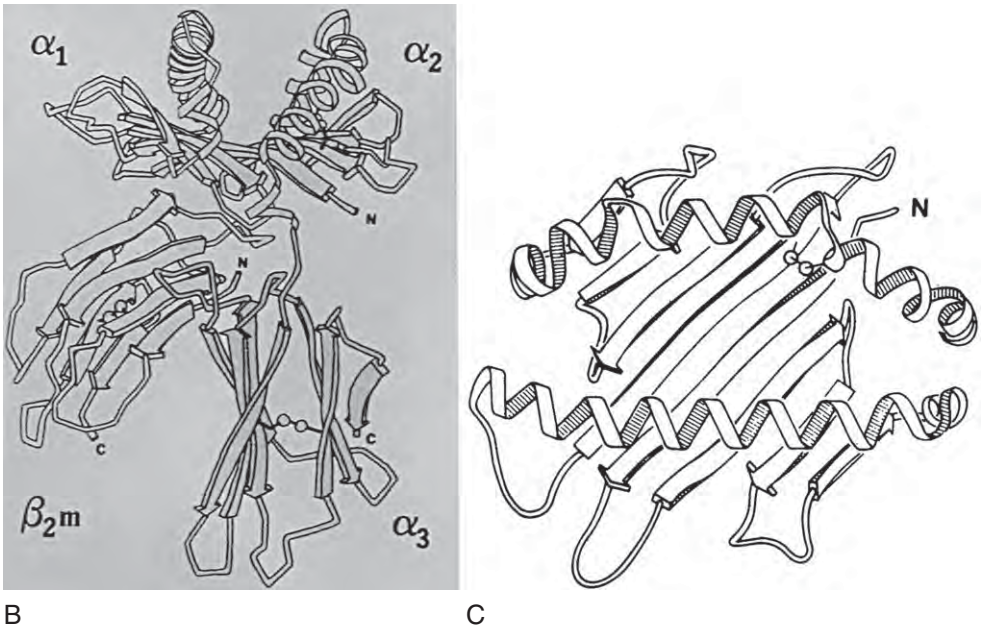


Figure 2–2 Stick diagrams of MHC class I and II and ribbon diagrams of HLA-A2. **A**, Stick diagram showing MHC class I and II as associated with the cell membrane. The MHC class I–associated molecule, β_2-microglobulin (β2-M), is not membrane-inserted. **B** and **C**, The structure of the human MHC complex class I antigen HLA-A2. The peptide groove is clearly visible lying between the two alpha helices. **B**, Side view. **C**, Bird's eye, or the T cell's, view. MHC class II proteins have a similar structure, although the ends of the groove are less closely associated allowing the peptide to extend beyond the constraints of the groove.

for ribbon diagrams of HLA-A2). Within this structure is a groove flanked by two alpha helices, and the amino acids in this groove show the highest degree of polymorphism within a species. During the synthesis and transport of MHC class I and class II proteins to the cell surface, they become associated with small peptides that fit into the groove. The groove of MHC class I has a closed structure, allowing peptides no longer than about 8 to 10 amino acids in size to be accommodated, whereas that of MHC class II has a more open structure permitting the ends of the peptides to flop out of the groove, allowing it to accommodate peptides of at least 13 and often many more amino acids in length.

A major difference between proteins of the two MHC classes is in the origin of these peptides, which are acquired primarily (although not exclusively) from the intracellular environment in the case of class I and extracellular environment in the case of class II (Fig. 2-3). The combination of MHC and peptide is recognized by the antigen receptor (T cell receptor [TCR]) on the T cell. In a pathogen-free immune system, the peptides contained within the MHC proteins originate largely from self-proteins, and many may be derived from the MHC proteins themselves. It is only when a foreign pathogen invades or a graft is in place that the MHC proteins become loaded with foreign peptides. The ability to extract peptides from within MHC proteins[289,308] has shown what types of peptides reside within the MHC groove.[330,349] It is possible to predict from the protein sequence of an antigen which peptides could be recognized in the context of different MHC antigens,[24] and how post-translational modifications of the peptides can affect binding.[79,349] It is possible, with a knowledge of the MHC and peptide sequences, to predict which amino acids in the peptide will be associated with the floor and sides of the groove, and which will be in contact with the TCR.

Several other proteins encoded within the MHC aid the assembly and loading of class I and class II proteins with their peptides (see Fig. 2-3). One type of class II protein, HLA-DM, does not appear on the cell surface, but plays a role in exchanging the class II–associated invariant chain peptide for the antigenic peptide in class II proteins before they emigrate to the cell surface.[297] The LMP (proteosome components) and TAP (transporters associated with antigen processing) genes also lie within the class II region of the MHC and are involved in processing and loading of peptides for MHC class I presentation. Understanding of such antigen processing and presentation pathways has increased[11,51,98,113,196,243-245,296]; this understanding and the structural resolution of MHC (see Fig. 2-2) and TCR proteins[17,18,97] represent some of the most important advances in immunology in the 1990s.[310]

In addition to its value regarding our knowledge of how the immune system works, our insight into the process of antigen processing and presentation has practical value as we begin to explore how peptides may be used in vaccination and tolerance strategies. Although, as mentioned, exogenously derived peptides are generally found presented by MHC class II and endogenously derived peptides by MHC class I proteins, the reverse also can be true owing to a process termed cross-presentation. Originally described for exogenously derived peptides entering the MHC class I pathway,[13] it has been shown that endogenously derived peptides can enter the MHC class II pathway.[355] This increases the diversity and origin of peptides available not only for presentation but also as potential therapeutic candidates.

Data from experiments performed between congenic strains of animals in which only MHC class I or class II antigens differ in donor and recipient show that both are important in graft rejection, although frequently grafts with only MHC class I disparities reject more slowly than grafts with class II only or class I and class II differences.[168,303] Mice with disrupted expression of either β_2-microglobulin (in which surface expression of the whole class I protein is largely prevented, class $I^{-/-}$ mice) or class II genes (class $II^{-/-}$ mice) have been generated and used as recipient (see later) or donor in transplantation experiments. The literature regarding this work is complex. In many studies, a lack of class I or class II antigens alone on donor tissue has little effect on graft survival.[6,74,135,200,221] In other experiments, graft survival may be prolonged or permanent when donor tissue lacks either class I[135,224] or class II only[32,135] or both class I and class II antigens.[32,221,268] It is clear from all of this work that results vary when different types of grafts are used, probably reflecting a greater or lesser involvement of the different T cell subsets ($CD4^+$ and $CD8^+$; see later).[32,135] The interpretation of some of these apparently straightforward experiments is complicated, however, by the suggestion that grafts from class $I^{-/-}$ mice may be reconstituted in their expression of class I by serum β_2-microglobulin in the recipient or may express residual cell surface class I protein in the absence of β_2-microglobulin.[195,200]

One notable feature of MHC protein that makes it different from any other region of the chromosome and the feature that creates serious problems for the transplant clinician is the high degree of variation or polymorphism in the class I and class II cell surface proteins that it encodes within a species. It is likely that this extensive polymorphism has evolved as a product of immune defense mechanisms against infection[169] because of the crucial role of MHC proteins in presentation of pathogen-derived peptides to the immune system, and the fact that, as described earlier, MHC proteins exhibit selectivity in the peptides that they can present. Certain species that have limited polymorphism at class I or class II loci can be devastated by infections that in closely related species with a polymorphic MHC are cleared without difficulty.[263] With two alleles at each MHC locus, most individuals can express six different MHC class I proteins and eight different MHC class II proteins. Combined with the polymorphism at this locus, this means that for transplantation between unrelated individuals, MHC-identical donors and recipients are rare, and even when they are found, miH antigens are almost undoubtedly different. It is only realistically possible clinically to graft tissue that is MHC and miH antigen identical between monozygotic twins; this is why immunosuppression is needed routinely in clinical transplantation.

As described earlier, several genes within the class II and class I regions do not encode classic MHC proteins. In addition to the genes mentioned previously, some of these encode nonclassic MHC proteins that are similar in structure to classic MHC proteins, but that are nonpolymorphic. These may have antigen-presenting capacity for specialized antigens, such as lipids (e.g., mycolic acid and lipoarabinomannan from *Mycobacterium*) or peptides of different sequence but with common characteristics (e.g., with *N*-formylated amino termini).

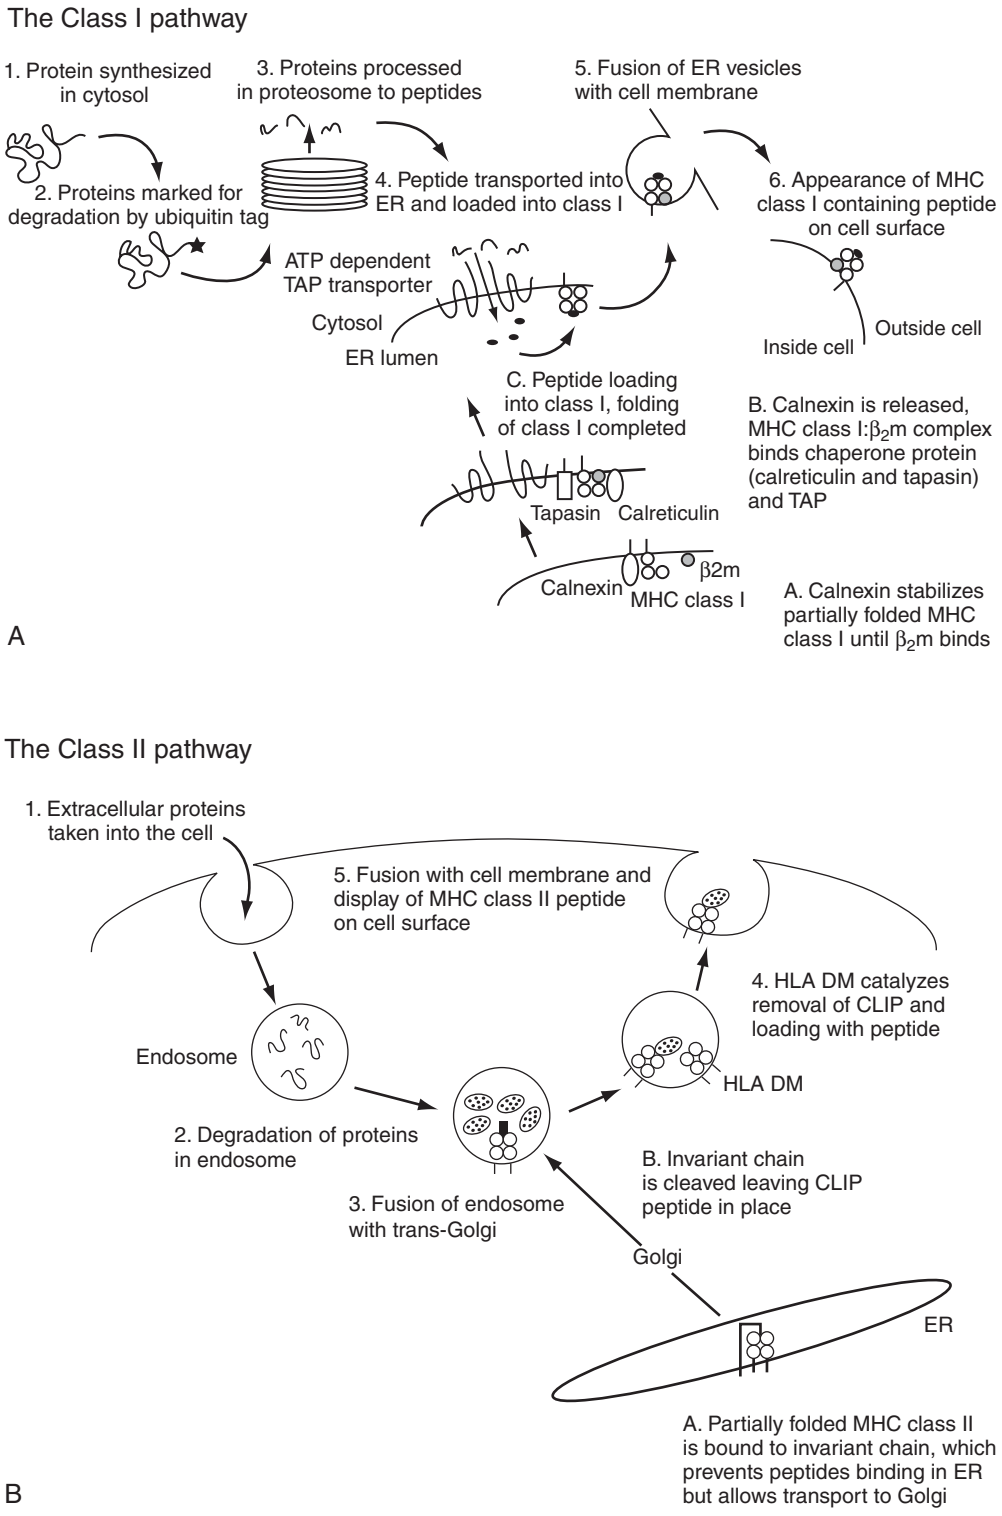

Figure 2–3 Antigen processing and presentation in the MHC class I and class II pathways. **A**, Processing of endogenous antigens occurs primarily by way of the class I pathway. Peptides are produced and loaded into MHC class I proteins as shown in steps 1 through 4. During the synthesis of MHC class I proteins (steps A through C), the alpha chain is stabilized by calnexin before β_2-microglobulin (β_2m) binds. Folding of the MHC class I/β_2-microglobulin remains incomplete, but the complex is released by calnexin to bind with the chaperone proteins, tapasin and calreticulin. Only when the TAP transporter delivers peptide to the MHC class I/β_2-microglobulin can folding of this complex be completed and transport to the cell membrane occur (steps 5 and 6). **B**, Processing of exogenous antigens occurs primarily by way of the class II pathway. Antigens are taken up into intracellular vesicles where acidification aids their degradation into peptide fragments (steps 1 and 2). Vesicles containing peptides fuse with trans-Golgi containing CLIP-MHC class II complexes (step 3). DM aids removal of CLIP and loading of peptide before the class II peptide complex is displayed on the cell surface (steps 4 and 5). MHC class II proteins are synthesized in the endoplasmic reticulum where peptide binding is prevented by invariant chain. Invariant chain is cleaved leaving the CLIP peptide still in place (steps A and B) before fusing with acidified vesicles containing peptide. In B lymphocytes and epithelial cells of the thymus, an atypical class II protein, HLA-DO, is expressed that is a dimer of HLA-DOα and HLA-DOβ. Similar to HLA-DM, it is not expressed at the cell surface and inhibits the action of HLA-DM. Its precise role is unknown. ATP, adenosine triphosphate; CLIP, class II–associated invariant chain peptide; ER, endoplasmic reticulum; MHC, major histocompatibility complex; TAP, transporters associated with antigen processing.

The class III region of the MHC is large and is increasingly well characterized.[31,130,238] Genes in this region encode proteins with a wide diversity of different functions, and although they themselves do not stimulate T cells in the same way as class I and class II proteins, many have important activities in generating and influencing immunity. Tumor necrosis factor (TNF)-α and TNF-β are encoded in the class III region, and a marker of TNF-α polymorphism associated with high TNF production has been found in heart transplant patients.[366]

Minor Histocompatibility Antigens

Although the highest degree of genetic polymorphism within a species lies within the MHC, many other loci encode proteins with a lower degree of variability, and from genetic studies it is clear that such proteins can act as transplantation antigens. They have been termed miH antigens, although their structure and distribution for many years were elusive. Although T cells could recognize and respond to cells from MHC-identical individuals, it was almost impossible to raise antibodies against the antigens involved, making biochemical characterization difficult. The knowledge that T cells recognize small peptides from antigens, together with the resourceful application of molecular techniques, allowed the characterization of the prototypic miH antigen, the male antigen or H-Y.[326,379] From such work, it is clear not only that miH antigens are a composite of peptides from low-polymorphic or nonpolymorphic proteins, presented in the MHC groove, but also that the so-called H-Y antigen is derived from a group of proteins encoded on the Y chromosome.[111,326,327,379] The former finding explains why it has been difficult to raise antibodies to miH antigens because antibodies frequently recognize conformational determinants on proteins, and peptides bound within the MHC groove may not be accessible for recognition by the antibody-producing B lymphocyte.

miH antigens may play a prominent role in graft rejection in a recipient who is given an MHC-compatible graft but in whom preexisting sensitization to miH antigens exists. This situation can be shown in the rat and mouse[81,280] and probably explains the occurrence of rejection episodes (which rarely result in graft loss) in renal transplants performed between HLA-identical siblings. Multiple miH differences have been shown to represent an immunogenic stimulus equivalent to that of the MHC in a nonsensitized recipient of a cardiac allograft in the mouse,[280] but it is difficult to gather similar data in clinical transplantation. Polymorphic tissue-specific antigens also may be common, and such systems have been shown for mouse skin[344] and rat kidney.[127] In the rat, incompatibility for kidney antigens alone is incapable of causing rejection of a renal allograft, even when the recipient has been presensitized. An endothelial-monocyte antigenic system has been shown in humans, and it has been suggested that cells sensitized to these antigens can cause graft damage. More miH antigens are being characterized, and this whole area has been reviewed extensively by other authors.[107,298,334]

Antigen Presentation

Donor Dendritic Cells and Direct Antigen Presentation

Immunization with MHC antigen in the form of a soluble membrane extract or in liposomes may not produce an immune response, whereas integrated cell surface MHC proteins may be highly immunogenic. Presentation of MHC class I antigen on cells that do not express class II antigens (e.g., red blood cells in rodents or platelets) does not produce a good primary immune response, suggesting that MHC class II antigens must be present on the immunizing cells for an optimal immune response to be generated. In some cases, presentation of incompatible class I antigens in the absence of class II antigen not only may fail to evoke a primary immune response but also may initiate a state of active suppression or tolerance (see Chapter 23).

The level of immunogenicity of MHC proteins varies considerably with the cell type on which they are found. Cells with the characteristics of bone marrow–derived leukocytes are found throughout the body in nonlymphoid and in lymphoid tissues.[52,128] As previously alluded to, these cells migrate rapidly out of a tissue after transplantation to the recipient lymphoid organs, where they are able to interact with and stimulate the host immune response.[184,185] Such tissue-resident leukocytes have the characteristics of immature DCs,[292] which on migration mature rapidly into antigen-presenting cells that are particularly potent in their ability to stimulate T lymphocytes.[340-342] Mature DCs express a high level of MHC class I and class II antigens together with a range of costimulatory proteins and cytokines (see later) and as such are able to stimulate $CD4^+$ and $CD8^+$ T lymphocytes. They are uniquely powerful in stimulating naive (previously unactivated) T cells, earning them the title of professional antigen-presenting cells, and it is generally accepted that such cells, derived from the transplant itself, can stimulate strongly adaptive immunity in the recipient (Fig. 2-4A).

This suggestion is perhaps counterintuitive when one considers that the T cell restriction is skewed (by positive selection of T cells in the thymus) toward recognition of peptide in the context of self-MHC proteins. It is clear experimentally, however, that allogeneic MHC/peptide complexes provide a uniquely strong stimulus to the immune system, and a high frequency—1% to 10%—of all T cells respond to allogeneic MHC. The allogeneic MHC contains peptides derived from the donor tissue originating mainly from normal nonpolymorphic proteins[308] or the MHC itself.[101,269] In the context of self-MHC, the former type of peptide would not normally induce an immune response because the body would be tolerant of them. When the MHC is allogeneic (i.e., when a graft is placed into an MHC-disparate recipient), the sum of the MHC plus nonpolymorphic peptide may now be recognized as nonself and stimulate a T cell. The real job of such T cells is not to respond to alloantigen, but to eliminate invading organisms. Their ability to respond to alloantigen is due to an inconvenient cross-reactivity of their receptor for self-MHC plus foreign peptide with allogeneic MHC plus self-peptide. For many T cells that have reactivity with a foreign peptide plus self-MHC, it is possible to show cross-reactivity on one or more alloantigens. Also, different peptides from the same proteins may be displayed by the foreign MHCs and self-MHCs because of the different peptide-binding capacities of each MHC groove. Peptides normally not displayed in self-MHC do not have an opportunity to induce tolerance in the recipient and may induce an immune response when presented on allogeneic MHC proteins. Alloreactive cytotoxic T lymphocytes (CTLs) induced by direct antigen presentation are able

to recognize a wide spectrum of different peptide-MHC aggregates and empty MHC molecules, as elegantly shown by Rotzschke and colleagues.[308] The unusually high number of T cells that react to any given allogeneic MHC exist because many different self-peptides are derived from the graft, and the combination of these with the allogeneic MHC stimulates many different T cell clones in the recipient.[75]

Indirect Antigen Presentation

Elimination from the graft of passenger leukocytes does not abrogate rejection completely, suggesting that there is a second route to sensitization of the recipient that requires antigen presentation by an MHC class II–expressing cell. In humans, the endothelium bears MHC class II antigens constitutively and may provide such a route, but it has also become apparent that foreign, graft-derived antigens (of MHC and non-MHC origin) can be presented to the recipient immune system by its own DCs in the process termed indirect antigen presentation (see Fig. 2-4B). This is the process by which normal antigens are displayed to the host on an antigen-presenting cell. From what we understand about antigen processing and presentation (see Fig. 2-3), it seems likely that most allogeneic MHC peptides are presented in the context of class II MHC antigens because it is this pathway that deals with proteins exogenous to the cell. Cross-presentation (see earlier) does allow for presentation of cytosolic proteins in MHC class II, however. Fangmann and coworkers[83] showed that indirect presentation may have a practical significance in transplantation responses. They showed that peptides derived from rat class I antigens were able to immunize animals via the indirect pathway for accelerated rejection of a subsequent skin graft carrying the class I antigens from which the peptides were derived.

Further information on this issue comes from experiments in which skin grafts from class $II^{-/-}$ mice are transplanted onto normal mice. Antigen-presenting cells from these grafts do not directly stimulate $CD4^+$ cells because of the absence of class II antigen, but graft rejection still occurs and is $CD4^+$ cell dependent. In this case, the $CD4^+$ cells are presumed to have been stimulated by indirect presentation of donor alloantigens on self-MHC.[6,194,195] Further experiments addressing this issue involve antigen-presenting cells from the recipient or host that are disabled by genetic manipulation such that they no longer express costimulatory molecules, which are one of the hallmarks of professional antigen-presenting cells ($B7^{-/-}$ mice)[218] (see also later in this chapter). These workers observed that the absence of B7 on donor cells had no effect on the kinetics of vascularized heart allograft rejection. Absence of such proteins on the cells of the recipient had a dramatic effect, however, and allowed long-term survival of normal, B7-expressing hearts, data that were taken by the authors to suggest that in this mouse model, costimulation provided by recipient antigen-presenting cells is much more important in the initiation of graft rejection than is the costimulation provided by donor antigen-presenting cells. The simplest interpretation is that indirect presentation is playing a more important role than direct presentation in this model, although the possibility that costimulation provided by recipient antigen-presenting cells is important, rather than antigen presentation and costimulation, cannot be discounted completely.

Some workers have long believed that indirect antigen presentation plays the dominant role in acute graft rejection,[7] and there is plentiful evidence of its importance. Indirect antigen presentation also can provide the continuing antigenic stimulus required for chronic graft rejection,[49,331,387] at a time when, because donor DCs are lost quickly from the graft, direct antigen presentation assumes a lesser or absent role.

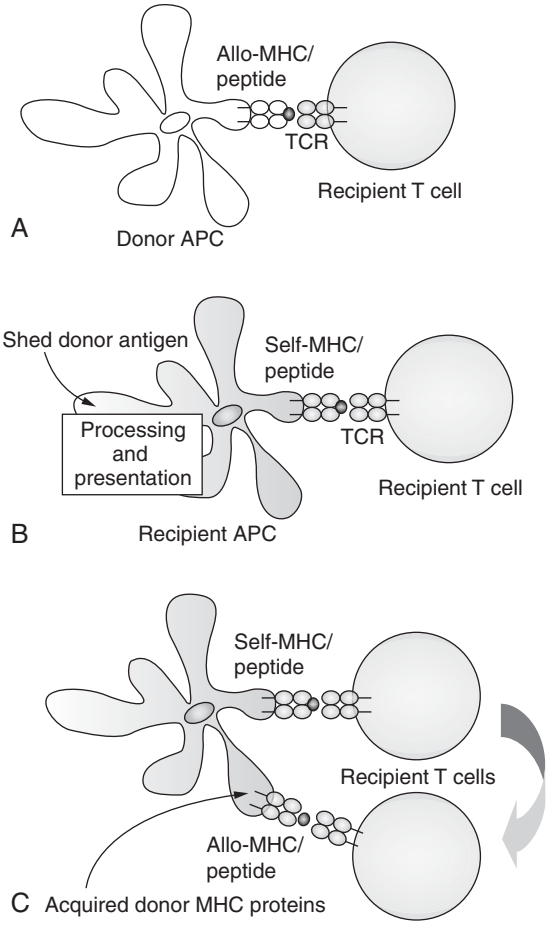

Figure 2–4 **A-C**, Direct, indirect, and semidirect pathways of antigen presentation. Sensitization of the recipient can occur by antigen presentation delivered through passenger leukocytes or dendritic cells of donor origin (direct antigen presentation) (**A**) or recipient origin (indirect or semidirect antigen presentation) (**B** and **C**). APC, antigen-presenting cell; MHC, major histocompatibility complex; TCR, T cell receptor.

Semidirect Antigen Presentation

If host T cells are stimulated by recipient-derived DCs via indirect antigen presentation, the MHC restriction of the effector cell population is to host rather than donor. A problem could arise if a cytotoxic T cell, previously stimulated with self-MHC and allogeneic peptide, comes to lyse its target cell—in the case of graft rejection, the foreign transplanted tissue, which does not express self-MHC molecules. This problem is overcome if the foreign MHC on the target cell appears to be identical to the degraded foreign MHC in association with self insofar as the T cell is concerned, if the effector arm of the immune response does not require MHC restriction (e.g., macrophages, delayed-type hypersensitivity), or if the effector population is primed by the donor-derived MHC. How could the last situation arise if the T cells are primed by recipient-derived DCs? Intact proteins can be

exchanged between cells in cell culture systems, and MHC proteins transferred in this fashion can stimulate alloreactive responses.[10,126,312] Donor MHC acquired by a recipient's DCs could stimulate the T cells such that they could react with the graft itself. The importance of this reaction in stimulation of alloreactive responses in the whole animal has been highlighted in recent work,[137] although its importance in inducing graft rejection has yet to be established.

Activation and Types of Dendritic Cell

So far this chapter has concentrated on the role that DCs (or other antigen-presenting cells) play in activating T lymphocytes. T lymphocyte–DC interactions are reciprocal, however, and it is becoming increasingly clear that T cells control the maturation[333] and functional phenotype[294] of DCs. Ligation of CD40 on DCs by CD154 (CD40 ligand) on the T cell results in the upregulation of the B7 proteins, which may affect the T cell further.

Several types of DC have been described, including bloodborne conventional DCs that are delivered to lymphoid organs (and which have several different cell surface phenotypes), tissue-resident DCs such as Langerhans cells (the skin-resident passenger leukocyte), and plasmacytoid DCs. These DCs are characterized not only by the expression of different cell surface proteins but also by different functional phenotypes.[332,343] Although this chapter has concentrated on the role of DCs in activating the immune response, it is becoming increasingly apparent that some of these DC subsets may be crucial in the induction and maintenance of tolerance.[216] This view is becoming widely held, and the consequences of this for the regulation of transplantation responses is increasingly a focus of attention.[228]

Activation of Recipient T Cells

Location of T Cell Activation

After small bowel transplantation, recipient-derived leukocytes, including T lymphocytes, migrate in large numbers into the mesenteric lymph nodes and Peyer's patches of the graft, generating a marked cytokine response within 24 hours of grafting.[145,159,359,360] This situation may represent normal homing of such cells because the small bowel is so rich in lymphoid tissue. It is likely that these T cells, if not already activated, may become so within the transplant, which is rich in mature DCs.

Naive lymphocytes are thought normally to recirculate from blood into lymphoid tissues without entering peripheral tissues and as such would be unlikely to become activated in a graft. The extent to which naive T cells enter transplants other than small bowel and become activated in situ is therefore less clear—the cells neither express the adhesion proteins and chemokine receptors normally associated with homing to peripheral tissues, nor are the DCs within the graft mature. More recent experiments have reinvigorated the idea, however, that naive cells can recirculate in small numbers through peripheral tissues,[46,47] although the extent to which they can become activated within such peripheral sites is unclear. Indeed, in mice lacking secondary lymphoid tissue, graft rejection can be abrogated or seriously attenuated.[179,180] In certain chronic inflammatory situations, lymphoid neogenesis or ectopic accumulations of lymphoid cells develop within peripheral tissues, however, and can provide an environment in which naive cells can become activated. The possibility that lymphoid neogenesis also occurs and is important in the context of transplantation has been suggested by studies in a mouse cardiac transplant model in which the presence of such accumulations occurred in a high proportion of grafts undergoing chronic rejection.[8]

During acute graft rejection of organs other than small bowel, it would seem that T cells are most likely to become activated in draining or local lymphoid tissue where they can interact in an optimal fashion with donor or host-derived DCs. The contribution of naive T cell recirculation to acute graft rejection is probably minor, although its role in the longer term may become more important. The possibility that naive cells recirculate through peripheral tissues for the purposes of tolerance induction rather than activation[47] is interesting and should be considered in the context of longer term graft function and survival.

Immune Synapse

T lymphocyte activation, central to the immune response to a transplant, is a complex process. Much information has been accumulated in this area, and although the antigen signal delivered to the T cell through the TCR/CD3 complex (Fig. 2-5) is absolutely required for activation, T cells also receive many other signals via cell surface receptors without which they do not become fully able to initiate a productive immune response. It is becoming increasingly clear that the contact between antigen-presenting cells and T lymphocytes (and other cells of the immune system) involves supramolecular organization of receptors and ligands into microdomains, or immune synapses, which exhibit reproducible patterns of the receptor-ligand pairs. For instance, it has been shown that adhesion molecules cluster with TCRs on the lymphocyte.[246] In the T cell–antigen-presenting cell synapse, MHC protein initially accumulates in a ring around adhesion proteins, but on interaction with the TCR moves to a central patch[109]; this clustering of proteins involved in T cell activation seems to be crucial for consolidation or

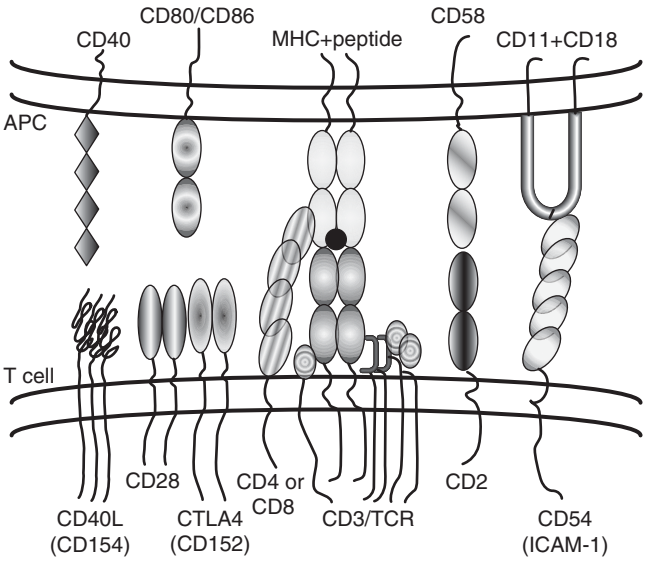

Figure 2–5 Antigen-presenting cell (APC)–T cell protein interactions that are required for T lymphocyte activation. Many cell surface proteins are involved in the interactions of T cells with their APCs. The interactions often may be bidirectional and affect APC and T cell.

maintenance of signaling or both. This is a newly emerging area of immunology, and increased knowledge in this area is likely to help in predicting more accurately the outcome of intercellular interactions.[36]

T Cell Receptor Signals

Without an interaction of the TCR with its cognate antigen, T cells remain in a quiescent or resting state and can recirculate through the lymphoid tissues for many years.[29,108] Most T cells bear a TCR composed of two similar chains, the alpha and beta chains, which are complexed with several more proteins, the gamma, delta, epsilon, and sigma chains of the CD3 complex. The TCR confers specificity of antigen/MHC binding (see Fig. 2-5), whereas the sigma chains of the CD3 complex transduce signals of activation to the T cell. Many intracellular signaling pathways are activated, resulting in de novo expression of a range of genes, including genes encoding cytokines and new cell surface proteins. The signaling pathways are increasingly well characterized and have been described fully elsewhere.[33,257,367,370] They form the target of many immunosuppressive drugs.[22,115,118,249,250]

Second or Costimulatory Signals

The fate of a $CD4^+$ T cell when in receipt of a TCR signal depends critically on whether or not it secures other so-called costimulatory or second signals. Without these second signals, a T cell may become anergic or unresponsive,[148,149,324,325] a state that also may result in an ability to prevent the activation of its neighboring T cells.[34,89,203] The fact that deprivation of second signals can result in an unresponsive or regulatory fate for T cells has attracted enormous interest because it has implications in preventing graft rejection. There are many cell surface proteins on a T cell that potentially contribute to its activation (see Fig. 2-5). CD4 and CD8 proteins act by binding to class II and class I on the antigen-presenting cell. CD4 and CD8 are linked to intracellular proteins, which are involved in transducing further signals to the T cell. A series of additional proteins on the T cell surface, such as CD54, CD2, CD11a/CD18, and CD5, act largely to increase the affinity of interaction between the T cell and its antigen-presenting cell, although they also may transduce further signals to the T cell.

The cell surface protein CD28 was the first to be described as a costimulatory protein. Now known to be a member of a family of similar proteins,[39,112,293] CD28 still attracts attention as a potential target for the regulation of transplantation responses.[188,335] Activation of the downstream signaling via CD28 results from ligation with one of the B7 family of proteins, CD80 or CD86. These proteins are expressed by antigen presenting cells such as DCs and are readily able to engage CD28 during antigen presentation. Signaling through CD28 in the context of TCR ligation results in an increase in glucose metabolism, high levels of cytokine and chemokine expression including the production of very high levels of IL-2, resistance to apoptosis, and long-term expansion of T cells. This powerful driver to activation and proliferation is counterbalanced by the presence on activated T cells of CTLA-4. Similar in structure to CD28, CTLA-4 inhibits the earliest events in T cell activation. CTLA-4 has a higher affinity for CD80 and CD86 than does CD28,[42,323] and its engagement with CD80 induces a lattice structure at the cell surface consisting of alternating CTLA-4 and CD80 homodimers.[42,323] These properties of CTLA-4 may limit the ability of CD80 to interact with and cluster CD28 at the immune synapse, potentially explaining the finding that low levels of CTLA-4 can be effective at inhibiting immune responses.

The requirement of CD28 signals for $CD4^+$ T cells in secondary immune responses or for $CD8^+$ T cells is less clear. The prevailing view for $CD4^+$ cells is that if they have not been stimulated very recently by antigen (e.g., they have developed into memory cells), they will require costimulation for reactivation, but recently activated cells also have been shown to be costimulation dependent.[119,222] Experimentally, it can be shown that in certain situations virus-reactive $CD8^+$ cells require neither costimulation through CD28 nor CD28-dependent help.[176,393] To achieve this, however, they may require prolonged TCR stimulation (e.g., provided by a replicating virus), a situation that infrequently may occur during other immune responses. Even for $CD4^+$ cells, overwhelming stimulation through the TCR may obviate the requirement for CD28-mediated costimulation. This is important in the context of clinical transplantation, where a large proportion of the alloreactive pool has previously been antigen activated as a result of its cross-reactivity with pathogen-derived peptides (see earlier) providing one possible explanation for the finding that targeting this costimulatory pathway is less effective in attenuating transplantation responses in humans than would have been predicted from rodent studies.

Mice with a disrupted *cd28* gene have impaired immune responses, but can reject skin grafts, albeit in a delayed fashion[158]; this is likely due to the plethora of other costimulatory proteins that can substitute the action of CD28.[39,293,329] The severe phenotype of CTLA-$4^{-/-}$ mice, in which animals die from lymphoproliferative disorder within a few weeks of birth, illustrates the crucial role of CTLA-4 in counterbalancing the effects of CD28. Blocking the CD28 pathway in normal animals may have effects on the generation of immune responses and may result in prolonged graft survival or tolerance of grafts.[198,276,365] The most widely used reagent for this purpose has been CTLA-4-Ig, which potentially blocks all CD28 and CTLA-4-B7 interactions. The fact that CTLA-4 seems to provide an essential signal in the resolution of immune responses indicates this is unlikely to be the optimal strategy, however, and reagents that effectively block only CD28-B7 interactions (and perhaps interactions between the other costimulatory receptor ligand pairs) should be sought.

As mentioned earlier, there are several other members of the CD28 family of costimulatory proteins, including ICOS, PD-1, and BTLA,[112] and another T cell costimulatory family of proteins, the TNF/TNFR family, which includes CD27, CD134 (OX40), and CD137 (4-1BB).[380] The ligands of these proteins are more broadly distributed, including on cells not thought to have a role in activating naive T cells. Such receptor-ligand pairs may be important in maintaining immune responses and act to sustain detrimental immunity in the setting of chronic graft rejection. Indeed, blocking ICOS has been found to reduce the pathophysiology of experimental chronic allograft rejection. All of these costimulatory proteins seem to have counterbalancing proteins analogous to CTLA-4, showing the critical nature of delivering controlled immunity.

On activation, T cells express another cell surface protein, CD154 (CD40 ligand, gp39). Interaction of this protein with its counterreceptor, CD40, is crucial for the activation of

B cells, DCs, and monocytes. Larsen and coworkers[186] showed that blocking this interaction could prolong graft survival in a mouse cardiac transplant model. Even more impressive, however, are more data from this group showing that combined blocking of CD28 and CD40 interactions can induce permanent survival of allogeneic skin grafts in mice with no long-term deterioration of graft integrity.[187] Tolerance to the graft antigens could not be shown in these mice despite the excellent survival of the transplant itself. Other groups have now taken up this approach, always with dramatic effects on the regulation of immunity. Kidney graft rejection in monkeys can be prevented completely with antibodies to CD154 CD40 ligand.[163] Similar antibodies have been developed for use in the clinical setting and are in trials. The first antibody of this type to have been used clinically has now been withdrawn, however, because of its side effects.

Initiation of the Immune Response—CD4$^+$ and CD8$^+$ Cells

As described in previous sections, the interaction of the T cell with antigen-presenting cells plays a fundamental role in initiation of the immune response. The consequences of this interaction include proliferation and differentiation of the so-called helper T cells with the concomitant production of growth and differentiation factors (or cytokines) that are required by other cells so that a potent effector response can be mounted. In many cases, these helper T cells bear the CD4 surface protein, but in certain situations CD8$^+$ cells are able to respond in the absence of CD4$^+$ cells and themselves meet all of the requirements of a helper T cell.[209,304,338] That CD4$^+$ cells frequently are required to initiate graft rejection has been shown by many workers in a variety of experimental systems,[55,116,117,205,207] although depending on the mismatch between donor and recipient, CD8$^+$ cells may be additionally required or may act independently of CD4$^+$ cells.[300,301,303,338,356]

Investigation of the effects of CD4$^+$ and CD8$^+$ cells in transplantation responses has included the use of knockout mice that are deprived of these populations through genetic manipulation. Mice lacking class I or class II antigens are severely depleted of CD8$^+$ or CD4$^+$ cells, as are mice in which either the *cd4* or the *cd8* gene has been disrupted.[4,64,65,74,174,181,221,321] The effects on graft rejection of a lack of CD4$^+$ or CD8$^+$ cells produced in this manner have not been predictable and often depend on the nature of the mismatch between donor and recipient. Further, despite an apparent depletion of CD8$^+$ cells in class I$^{-/-}$ mice, CD8$^+$ CTLs can be generated in large numbers after transplantation and may be involved in the rejection process.[4,194,321] The results of such experiments are essentially consistent with previous ideas in this area—CD4$^+$ cells seem normally to initiate graft rejection, but there are experimental models (usually when there is a dominant or sole MHC class I mismatch) in which CD8$^+$ cells also are required for rejection to proceed with normal kinetics or may act independently of the CD4$^+$ cell.

GENERATION OF EFFECTOR IMMUNITY—THE EFFERENT ARM

T1-, T2-, and Th17-Driven Immunity

After stimulation of the immune system, a response develops in which either humoral or cell-mediated immunity may be seen to dominate,[156,271] and it has become clear that cytokines play a determining role in this process (Fig. 2-6).[69,230,251-253] The cells (and the cytokines they produce) that drive a cell-mediated response have been called Th1, and the cells driving humoral immunity have been called Th2. It has been shown that both helper and cytotoxic T cell populations diverge in their cytokine production, and so here we refer here to T1 and T2 populations. More

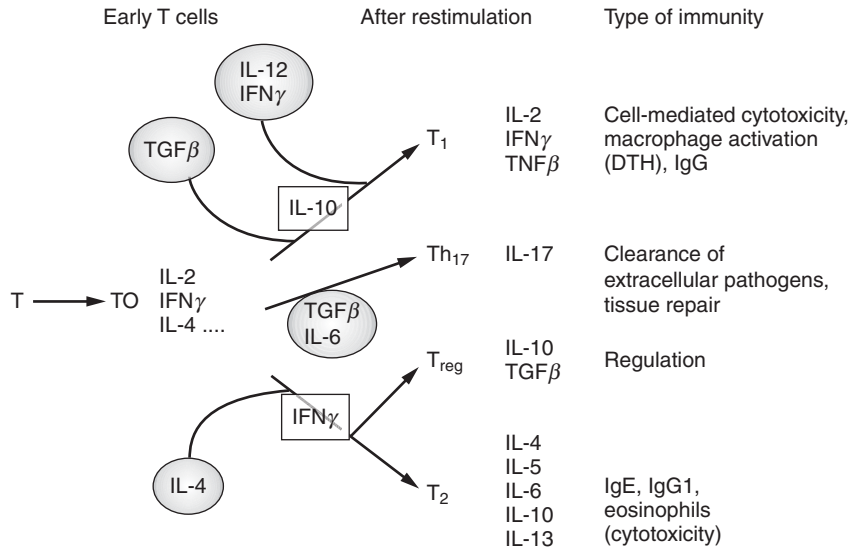

Figure 2–6 T1/T2/Th17 cell differentiation and immunity. Cytokines produced by T cells and that influence their divergence to T1, T2, and Th17 subsets are shown, defining the effector immunity generated. Cytokines that may positively (*in circles*) or negatively (*in squares*) regulate divergence of the T1, T2, and Th17 cells are shown. Cells with a regulatory or suppressive function (Treg) also may be generated de novo during an immune response, likely diverging from the T2 pathway. Such cells differ from naturally occurring Tregs, which have a CD25$^+$ cell surface phenotype, but nevertheless function in a similar fashion to control immunity. DTH, delayed-type hypersensitivity; IL, interleukin; IFN, interferon; TNF, tumor necrosis factor.

recently, a discrete population of T cells has been described, characterized by production of IL-17 in the relative absence of IFN-γ, which also can contribute to the development of cell-mediated immunity and which may be responsible for driving the pathology in autoimmune conditions previously ascribed to an inappropriate Th1 response.[124,125,183,372,373] To date, most work on such cells has focused on the $CD4^+$ population, and whether or not $CD8^+$ cells also make a major contribution to IL-17 production remains to be determined.

Early on during an immune response, T cells seem to make a wide range of cytokines, a clear divergence of cytokine production at the population level and individual cell level being observed only after continued antigenic stimulation. IFN-γ is the prototypic cytokine of T1 cells, and a predominance of this population results in the appearance of cell-mediated immunity involving the generation of specific CTLs and activated macrophages. T2 cells make cytokines such as IL-4, IL-5, and IL-6, which are crucial for the induction of humoral immunity, for class switching to certain immunoglobulin isotypes, and eosinophilia. Th17 cells are characterized by the production of IL-17 and their involvement in a variety of experimental pathologies.[125]

Much is now understood about how such responses are determined[291] in terms of the molecular and the cellular interactions involved. The local cytokine milieu,[92,94,95,140,141,351,352] involvement of antigen-presenting cells other than DCs,[210,211] and the type of CD28 signal delivered (i.e., through either CD80 or CD86)[90,175,198,290] all have been suggested as important factors. Most recently, it has been suggested that signals delivered through the evolutionary conserved cell surface protein, Notch, can determine the ability of T cells to become T1 or T2 producers; ligation by the delta-like family of ligands, inducing IFN-γ–producing cells; and the jagged ligands inducing IL-4 producers.[2] Other data suggest, however, that ligation by delta induces IL-4–producing cells, inhibiting Th1 cell differentiation.[362,384] Although this area remains confused, it is clear that the Notch signaling pathway, first described for its role in cell fate determination during development across the species, can strongly influence differentiation of mature T cells and other cells of the peripheral immune system.[63]

Interest of the transplantation community has focused on the possibility that although a T1-driven response may inevitably be damaging and result in graft rejection, a T2-driven response may not have this effect and may be associated with the induction of tolerance to a graft.[61,62,259,282,347] Many groups have found that tolerance or reduced donor-directed reactivity is associated with a decrease in the prolonged expression of the T1-associated cytokines IL-2 and IFN-γ.[1,25,26,59,242,353] It has been tempting to speculate that this decrease is accompanied by or even due to the expansion of regulatory T2 cells.[353] There is some evidence that the expression of cytokines such as IL-4, IL-5, and IL-10 is preserved during the development of tolerance.[60,104,320,353] Cells other than T2 lymphocytes can produce such cytokines, however, meaning that their detection does not infer the presence or action of the T2 population. As described in the following sections, an immune response to a transplant is complex; humoral mechanisms and a variety of cellular mechanisms can effect graft destruction, and it is likely that any type of immunity, T1, T2, or Th17 driven, would result in graft rejection. Clones of T lymphocyte that have T2-like properties are as capable of initiating graft rejection as are clones of T1 cells,[371,390] and it has been suggested that T2 cells drive chronic graft rejection.[331] In models of true tolerance, rather than prolonged graft survival, a rapid shutdown of cytokine, rather than preferential T2 cytokine production, may be observed.[150,276]

Several groups have tried to assess the role of key cytokines by performing experiments in which their overexpression or absence is tested. Two groups have shown that tolerance can be induced using reagents that block CD28 signaling in $IL\text{-}4^{-/-}$ mice.[178,260] An important additional finding from these studies was that tolerance was induced more easily in homozygous $IL\text{-}4^{-/-}$ mice than in heterozygous $IL\text{-}4^{+/-}$ mice,[260] the implication being that the presence of IL-4 itself can be damaging to the graft. In other experiments, it was shown, again using knockout mice, that neither IL-2 nor IFN-γ is required for rejection,[171,318,339,347] but that both are required for tolerance induction.[53] Interpretation of these experiments can be complicated by the fact that cytokines often can substitute each others' function, and it is unclear whether or not the phenotype of knockout mice reflects accurately the importance of these cytokines in normal mice. IL-15 can substitute many of the actions of IL-2 and IL-13 for IL-4. In the experiments described earlier, IL-15 transcripts were found in grafts put into the $IL\text{-}2^{-/-}$ mice, and IL-13 transcripts were found in grafts transplanted into IL-4 knockout mice. The fact that $IL\text{-}2^{-/-}$ or $IFN\text{-}\gamma^{-/-}$ mice were unable to become tolerant suggests a nonredundant role for these cytokines in the induction of tolerance, a finding that a few years ago not many people would have predicted. The recent findings that, first, regulatory cells elaborate IFN-γ[386] and, second, a major population of regulatory cells expresses the IL-2 receptor constitutively[313,314] provide a reasonable explanation.

An alternative method of investigation has been used by several groups in experiments in which cytokines have been injected or overexpressed in animal transplant models in an attempt to deviate the immune system toward a T1 or T2 response. Paradoxically, given the aforementioned data, injection of IL-2 or IFN-γ can prevent the induction of tolerance.[25,59] Injection or overexpression of IL-4 cannot induce tolerance,[254] however, and although this treatment may prolong graft survival marginally, it may inhibit tolerance induction.[260]

The conclusion from all of these studies is that an effector immune response driven by either T1 or T2 cells is damaging, although in some cases the response driven by T2 cells may be less detrimental acutely than that driven by T1 cells. T2 cells may be the primary drivers of chronic rejection. The individual actions of certain cytokines still are not fully understood, but it would seem, given the data on IL-2 and IFN-γ, that such cytokines may assume different functions depending on the timing or perhaps location and origin of their production. The involvement of Th17 cells in protective immunity and immune-mediated pathology is an area of intense current investigation. The role of such cells in transplantation merits investigation, particularly because an early study indicated participation of IL-17 in rejection.[3]

Migration of Activated Cells into the Graft

To enter a site of inflammation or immune response, leukocytes must migrate across the vascular endothelium. This migration process is controlled by the elaboration of cell attractants or chemokines and by cell-cell interactions

between the leukocyte and the endothelium.[346,389] Activated and memory cells bear adhesion proteins, chemokine receptors, and addressins, which allow homing to and migration into peripheral tissues.[212,213]

Cell-Cell Interactions

The adhesion of leukocytes to the endothelium is a complex multistep process that involves a series of interactions between the surface of the leukocyte and the endothelial cell or its extracellular matrix.[29,162,346] The proteins involved fall into three groups—the selectins and members of the integrin and immunoglobulin superfamilies. Initial interaction and rolling of leukocytes along the endothelium allows the leukocyte to sample the endothelial environment, while maintaining its ability to detach and travel somewhere else. This step is largely controlled by the selectins, although, for example, α_4 integrins also may play a role at this stage. At this time, the endothelial cells begin to express IL-8 and platelet-activating factor, which induces strong leukocyte adhesion. Under the correct conditions, this interaction leads to signaling to the leukocyte, slowing down and arresting the rolling process. Shedding of L-selectin by leukocytes allows their detachment and extravasation.[229] These latter stages are regulated mainly by the β_2 integrins and adhesion proteins of the immunoglobulin superfamily.

The expression of many adhesion proteins involved in these interactions is upregulated by proinflammatory cytokines. Ischemic damage alone results in increased expression of several cytokines, and of these, IL-1 upregulates the expression of members of the selectin family.[43,283] Other adhesion proteins, such as intercellular adhesion molecule (ICAM)-1 and vascular cell adhesion molecule (VCAM)-1 of the immunoglobulin superfamily and E-selectin (endothelial-specific selectin), are known to be upregulated by the type of cytokines also induced by donor brain death[189] and after the trauma of transplantation. Before an immune response has been generated, the graft becomes attractive to circulating leukocytes, although, as previously mentioned, naive lymphocytes tend not to home into nonlymphoid sites. Antigen-activated lymphocytes have an altered recirculation pattern, however, and migrate into extralymphoid sites.[28,212,281] They may show tissue-selective homing and show preference for sites in which they are most likely to re-encounter their specific antigen.[319] The process seems to be facilitated further by recognition by the T cell of MHC class II/peptide complexes on the vascular endothelium.[223] This process is likely to result in the accumulation of antigen-specific lymphocytes within the site of inflammation, in this case the graft.

One practical aspect with respect to transplantation is that it may be possible to hide or block the expression of the proteins involved in leukocyte extravasation, slowing or preventing the rejection process. Blocking the adhesion proteins by using antibodies or by inhibiting their expression has been attempted in experimental and clinical transplantation settings.[48,57,129,133,139] In general, cocktails of antibodies are more potent than single antibodies,[146,388] although the results vary, and in one case a combination of antibodies to ICAM-1 and lymphocyte function-associated antigen (LFA)-1 was shown to result in accelerated rejection of rat cardiac allografts.[247] Antisense oligonucleotides have been used in an attempt to prevent the expression of ICAM-1 and have been effective in prolonging graft survival in experimental models.[345] Small molecule inhibitors also may effectively interrupt the interactions required for leukocyte adhesion and extravasation.[258,348] The possibility that these types of reagent may simultaneously be effective in blocking ischemia-reperfusion injury and in controlling the rejection process[258,265,348] is an attractive one, which merits further study.

Chemokines

Several chemokines—small soluble proteins, similar to cytokines—have been identified and form two major groups based on their structure: the CXC or alpha chemokines, which primarily attract neutrophils and T cells, and the CC or beta chemokines, which attract T cells, monocytes/macrophages, DCs, NK cells, and some polymorphs.[122,123,237,266,307] The CXC chemokines include IL-8 and IFN-γ–inducible protein, and the CC chemokines include macrophage inflammatory protein (MIP)-1α/β, RANTES, and macrophage chemoattractant protein-1 (MCP-1).

Transplantation studies have suggested that chemokines are important not only in the development of graft infiltrates[73,82,110,122,123] but also in reperfusion injury.[122,199] The indications are that they act not only as attractants for various leukocyte populations but also by augmenting the effector functions of leukocytes within the graft.[170] CCR1$^{-/-}$ mice accept MHC class II mismatched grafts without immunosuppression and MHC class I and class II mismatched grafts with low-dose immunosuppression.[96] Long-term surviving grafts do not appear to show signs of chronic dysfunction. Although CXCL10$^{-/-}$ recipients show normal rejection kinetics of a CXCL10$^{+/+}$ graft, CXCL10$^{-/-}$ grafts placed in normal recipients show prolonged survival.[121] All of these data indicate that blocking chemokine-chemokine receptor interactions could be a useful adjunct to immunosuppressive regimens. One of the most potent agents that interferes with chemokine function, FTY720, acts by sequestration of lymphocytes in the secondary lymphoid tissue,[134] rather than by directly influencing migration of cells into the graft.

DESTRUCTION OF THE GRAFT

The immune system generates many different effector mechanisms depending on the challenge it meets. In certain infections, a single mechanism seems to be essential for the clearance of the organism, and the absence of that mechanism renders the host susceptible to disease. In the clearance of lymphocytic choriomeningitis virus infections in mice, cytotoxic cells are absolutely required, and disabling this arm of immunity by disrupting the perforin gene leads to death of infected animals.[151] As seen in detail subsequently, most of the known effector mechanisms of the immune system are capable of damaging a graft such that the obliteration of any single effector mechanism has little beneficial effect on graft survival. This is most likely the reason that it is so difficult to prevent graft rejection without disabling the central components of the immune system.

Specificity of Rejection

The nature of tissue destruction during rejection reveals a lot about the processes involved; that is, graft destruction can show fine specificity for cells carrying donor alloantigens. The elegant studies of Mintz and Silvers[239,240] showed an

exquisite specificity of donor cell lysis in experiments using allophenic mice as tissue donors. Such allophenic, or tetraparental, mice are bred by fusing the embryos from mice of two different genetic origins. The tissues of the resulting mosaic offspring are composed of patches of cells from each parental type. Mintz and Silvers performed experiments using mice with different coat colors, and when skin from an allophenic donor was grafted to mice of either parental origin, only the cells of nonidentical type were rejected, leaving cells of recipient type intact and capable of hair growth. These studies have been repeated and extended in experiments performed by Rosenberg and Singer[302]; in this work, an initial large inflammatory/immune response was observed, but this resolved, remarkably leaving cells only of the recipient genotype in place. In a different type of experiment, Sutton and colleagues[350] showed that transplantation of an intimate mixture of allogeneic and syngeneic pancreatic islets resulted in destruction only of the allogeneic cells, with no evidence of bystander damage to the syngeneic islets. It is difficult to imagine how an essentially nonspecific effector mechanism, such as that involved in delayed-type hypersensitivity lesions, could mediate graft rejection in the exquisitely specific manner observed in these experiments.

Bystander destruction of tissue may be observed, however, after the activation of specific immune responses to foreign antigens.[309] Snider and Steinmuller[336] have shown that destruction of bystander tissue may occur in the immune response to miH antigens. In their experiments, cytotoxic T cell clones reactive with a variety of minor antigens (e.g., H-Y and Epa-1 antigens) were injected intradermally together with their specific antigen into a syngeneic animal, which did not express that antigen. As a result, ulcerating skin lesions developed that were radiosensitive, suggesting the involvement of a nonspecific, host-derived effector mechanism in the tissue destruction. In the experiments described earlier using donor material from tetraparental animals, if most cells in the graft were allogeneic to the recipient, the overwhelming inflammatory response could lead to destruction of the entire tissue.

From these experiments, we can conclude that antigen-specific and antigen-nonspecific effector mechanisms may be involved in graft destruction. In both types of experiment, the initial damage was mediated in a specific fashion—it was only when this initiated a massive inflammatory response that the nonspecific elements resulted in tissue destruction. The various effector systems that can damage tissue are described subsequently, and their roles in hyperacute, acute, and chronic rejection are discussed.

Antibody

The target antigens for damaging antibodies are the MHC class I and class II molecules, the ABO blood group antigens, other minor alloantigens that may be expressed selectively by the endothelium, and autoantigens including the angiotensin II type I receptor (expressed by vascular smooth muscle cells) and vimentin.[45] Antibody may cause tissue damage through antibody-dependent cellular cytotoxicity, where the antibody acts as a bridge between the target tissue and the effector cell, activating the lytic machinery cell and resulting in tissue damage.[278,279] Alternatively, antibody is able to fix complement, and complement component 4d (C4d), produced during complement activation, is detectable in tissues that are undergoing antibody-mediated rejection, even in the apparent absence of immunoglobulin. Complement fixation also results in the recruitment of macrophages and neutrophils with consequent injury to the endothelium. In addition, antibody binding activates endothelial cells, which can result in remodeling of the arteries and basement membranes. The latter damage is associated with irreversible damage and chronic graft dysfunction.[45] Activation of the endothelium results in an upregulated expression of adhesion molecules, cytokines, and chemokines and proliferation and synthesis of tissue factor (part of the extrinsic clotting system). Complement-independent activation also can occur that results in activation of the innate NFκB pathway and expression of proinflammatory cytokines.

Antibodies to ABO blood group antigens are preformed or natural antibodies. The presence of ABO blood group incompatibility between donor and recipient is generally considered a contraindication to transplantation because it induces hyperacute graft rejection, where the organ fails minutes after revascularization. After the removal of these antibodies, however, it is possible to undertake successful transplantation,[161] and with protocols for reduced intervention in the recipient,[337] this is becoming an increasingly attractive proposition (see also Chapter 22). The subsequent return of antibodies generally is not associated with antibody-mediated rejection, and this resistance of the organ to their action is termed accommodation. Accommodation is a complex process and not fully understood,[70,71,161,316] but it is thought to involve downregulation of antigen density and the development of resistance in endothelial cells to antibody-mediated injury that may involve changes in coagulation and in the expression of antiapoptotic proteins.

Patients who have been exposed to MHC antigens through transplant, blood transfusions, or pregnancy often develop antibodies reactive with those MHC antigens, which also can cause hyperacute rejection.[166,248,272,381] Hyperacute rejection of this nature is now largely a thing of the past since the introduction of pretransplant screening by the crossmatch test for antibodies directed toward donor antigens (see also Chapter 10). The conventional crossmatch test detects not only harmful MHC-directed cytotoxic antibodies but also harmless autoantibodies.[357] In most cases, it is now possible to distinguish autoreactive from alloreactive antibodies, and it has become possible to transplant an increasing number of patients across an apparent positive crossmatch, but in whom the reactivity is due to autoantibodies.[191]

All of this information suggests that we should focus attention on inhibiting the B cell response after transplantation, and newer reagents confirm that this is a valuable approach. Rituximab has been a useful addition to the immunosuppressive arsenal and is thought to act in part by depleting B cells.[317]

Cellular Mechanisms

The involvement of cell-mediated mechanisms usually is invoked in acute or chronic graft rejection, but although hyperacute rejection almost always has been attributed to antibody, in certain situations a rapid rejection may occur when the role of antibody has been excluded. In these situations, a cellular mechanism of rejection has been implicated.[164]

Natural Killer Cells

NK cells do not need prior exposure to antigen to become lytic to target cells (although their activity can be increased by certain cytokines) and as such provide a component of the primary defense mechanism of innate immunity. NK cells may be recovered from the blood or spleen and are able to lyse NK-sensitive targets, which tend to be of tumor origin.[136] Until more recently, the NK cell was not thought to play a central role in solid organ graft rejection, although its importance in bone marrow transplantation was not disputed.[255,256] Several laboratories using different experimental models have found that grafts survive indefinitely in the presence of demonstrable NK effector activity.[5,21,226] The role of NK cells in activation of the afferent arm of immunity via their interaction with DCs and their production of high levels of IFN-γ has prompted a re-evaluation of their role. Compelling data now exist to suggest that, although insufficient to cause graft rejection, NK cells can contribute to the process. In costimulation-deficient ($CD28^{-/-}$) mice, NK cell depletion prolongs allograft survival significantly.[167]

The method of target cell recognition employed by the NK cell is increasingly understood,[20,44,197,204,270,361] and the nature of the immune synapse between effector and target cell is the subject of considerable interest.[66,67] In contrast to T cells, the interaction with MHC on a target cell can result in the delivery of a negative signal to the NK cell through the so-called missing-self hypothesis,[155,202] preventing the activation of its lytic machinery. The absence of self-class I MHC antigens triggers the NK cell to attack its target, a finding that is consistent with the observation that NK cells are important in the rejection of bone marrow cells that express little or no class I antigen.[16] This fact is important to remember in any approach that considers the removal or blocking of donor MHC antigen as a strategy to overcome rejection of allogeneic or xenogeneic graft rejection. More recently, is has been shown that NK cells also can be triggered into cytotoxicity by recognition of selected antigens—the balance between signals of inhibition and activation determining whether NK cells kill or not.[165]

Specific Cytotoxic T Cell

In cell culture systems, MHC-mismatched lymphocytes proliferate and produce cytokines in response to one another in the mixed lymphocyte reaction. The resulting cytokine production allows the differentiation of precursor CTLs into effector cells that lyse target cells bearing the mismatched MHC antigens.[131,138] The fact that a powerful yet antigen-specific response is generated rapidly in mixed lymphocyte reaction has made the CTL a prime suspect as the central effector mechanism of acute graft rejection.

Considerable evidence suggests that CTLs may be involved in graft rejection. First, CTLs may be recovered from allografts that are undergoing rejection, but they are present only at low levels in grafts of animals that have been treated with cyclosporine to prevent rejection.[21,226] Second, cloned populations of CTLs are capable of causing the type of tissue damage associated with rejection.[80,368] Third, most MHC class I antigen-directed CTLs express the CD8 protein, and graft rejection often may be delayed after the depletion of $CD8^+$ cells.[40,207,214,215,356]

Conversely, graft destruction may occur in the absence of demonstrable CTL activity, and the presence of such cells within a graft may not always lead to graft destruction.[5,56] Rats given a donor-specific preoperative blood transfusion may retain a subsequent renal allograft indefinitely, but cells extracted from such grafts show high and persistent donor-specific CTL activity. The simple conclusion from these studies is that CTLs cannot always reject grafts, although the possibility that the action of these CTLs may be blocked in the graft itself, or that the activity of CTLs in cell culture does not accurately reflect their potential in the animal must be considered. These results remain intriguing, however, and provide direct evidence of the presence of cytotoxic effector cells within an organ graft that is not ultimately rejected.

CTLs are able to kill their targets through the elaboration of perforins, granzymes, and granulysin through activation of the Fas death pathway, or through secretion of the cytokine TNF-α. Their involvement in graft rejection has been questioned further by the finding that mice deficient in perforin (perforin knockouts) are able to reject tumor,[378] skin,[328] and organ[322] grafts, even when the grafts are resistant to Fas-mediated and TNF-α–mediated killing.[378] In the experiments of Schulz and colleagues,[322] grafts mismatched only at the MHC class I are rejected more slowly in perforin knockout mice, however, indicating that, in this situation at least, cytotoxic cells are important in rejection.

As alluded to earlier, even if CTLs themselves do not mediate the tissue damage that ultimately results in graft loss, they still may be important in generating the destructive response to the graft. Through the elaboration of high levels of IFN-γ and other cytokines or chemokines, they are able to recruit and activate cells involved in delayed-type hypersensitivity lesions, initiating acute or chronic rejection.

Macrophages and Delayed-Type Hypersensitivity Reactions

T cells initiate a delayed-type hypersensitivity reaction,[206] which involves an essentially nonspecific effector phase (as described by Koch in 1891 in the tuberculin skin reaction[87]), characterized by an infiltrate of lymphocytes and cells of the monocyte/macrophage lineage. Damage occurs in a tissue during a delayed-type hypersensitivity reaction through the elaboration of various noxious substances, including reactive nitrogen and oxygen intermediates and TNF-α. Support for this idea comes from situations in which CTL responses are not detectable (e.g., in irradiated rats reconstituted with $CD4^+$ cells).[208]

The high level of inflammatory mediators and the type of changes within grafts undergoing chronic rejection suggest a role for activated macrophages in this process.[38,132,273,275] Cytokines such as IL-1, TNF-α, transforming growth factor-β, and platelet-derived growth factor lead to smooth muscle proliferation; transforming growth factor-β and platelet-derived growth factor result in an increased synthesis of extracellular matrix proteins. These cytokines are products of activated macrophages and may result in the atherosclerotic and fibrotic changes associated with chronic graft failure.

Cytokines

The primary role of cytokines in an immune response to a graft is to initiate proliferation, differentiation, and homing of leukocytes in the generation of immunity. However, Certain cytokines also may directly damage tissue acutely or chronically. As described earlier, TNF-α, produced by CTLs and macrophages, may damage a graft, and blocking the

effects of TNF with neutralizing antibodies can prolong organ graft survival.[19,142-144] The minimal effects of these antibodies suggest, however, that the TNFs may not contribute centrally to graft rejection, or that when neutralized other effector mechanisms take over. Islets seem to be particularly susceptible to damage mediated by proinflammatory cytokines, such that these may be a more important component in the rejection of islet transplants.[219,220,288,382]

Eosinophils

It has been recognized for years that episodes of acute and chronic kidney allograft rejection are associated with various levels of eosinophilia,[88,173,262] but the significance of this association in terms of its contribution to rejection has not been acknowledged widely. In an experimental model of acute mouse cardiac allograft rejection in which the depletion of $CD8^+$ T lymphocytes results in a dominant T2 response, rejection seems to be mediated by eosinophils.[37] In another model, in which acute rejection of MHC class II disparate mouse skin grafts was studied, IL-5–dependent infiltration with eosinophils was observed. In this model, when Fas/FasL interactions were absent, neutralizing antibodies to IL-5 blocked eosinophilia and rejection, implicating the eosinophil as an effector cell in this system.[193] In another experimental model of skin allograft rejection, the same group showed a role for IL-5 and eosinophilia in chronic rejection, but in this system, not all of the pathology could be attributed to eosinophils.[192] In situations in which classic pathways of graft rejection are absent or are dominated by a T2-type response, the eosinophil seems to be crucial in graft destruction.[102]

Target Cells of Destructive Immunity

Damage to the vascular endothelium, which may express MHC class I and class II and autoantigens, some of which may be specific to the vasculature, is likely to result in rapid cell necrosis and graft loss.[100,157] The predominantly vascular changes that occur during rejection of an organ graft[78,177,284] suggest that this is the case. The development of antibodies reactive with donor endothelium is strongly correlated with early severe rejection.[100] It is likely that parenchymal cells also may be targets for tissue destruction, and in the kidney tubular cells elaborate cytokines and chemokines that attract and activate T cells,[295,385] but damage to the parenchyma is likely to be secondary to the initial attack on endothelium. The increase in expression of MHC class I and class II antigens together with increased adhesion molecule expression after transplantation is likely to increase susceptibility of endothelium and parenchymal cells to destruction. The marked arterial changes seen as a manifestation of acute and chronic rejection also suggest the importance of the endothelium as the main target of the response, and in the case of chronic rejection, the fibrotic changes seen histologically could be due in large part to ischemia resulting from gradual vascular obliteration.

PRIVILEGED SITES

Tissue allografts placed in certain sites may evoke a weak immune response, and the grafts may survive for prolonged periods.[14] The anterior chamber of the eye, the cornea, the brain, and the testis all show immune privilege either in that transplantation of tissue into these sites evokes a reduced immune response, or in that they themselves seem to have low immunogenicity. The classic privileged site experimentally is the cheek pouch of the Syrian hamster, in which a skin allograft survives indefinitely, provided that the host has not been specifically sensitized against donor histocompatibility antigens.[15] The historical view has been that physical and physiological barriers were critically involved in delivering immune privilege. The aforementioned sites have in common to a greater or lesser extent a lack of or abnormal lymphatic drainage, which seems to play such an important role in sensitization of the host against a free graft such as skin. More recently, it has been suggested that a much broader spectrum of sites, including the liver, the mucosal surfaces of the gastrointestinal tract, and the developing fetus, show many of the features of immune privilege.[235] The developing fetus, although antigenically different from the mother, is not usually rejected, commensal bacteria survive within the gut, and transplantation responses to the liver are diminished.

Calne and colleagues[30] first showed that outbred pigs often failed to reject orthotopic liver allografts; kidney allografts transplanted at the same time and that normally are rejected also show prolonged survival. In certain strain combinations in the rat in which an orthotopic liver allograft is not rejected, the liver allograft has been shown to abrogate an existing state of sensitization of the host against donor histocompatibility antigen.[152] Although HLA matching and crossmatching have been shown to be beneficial in liver transplantation,[76,285] usually the urgency with which the graft is required precludes the use of matching, yet these grafts survive well. The reasons for the refractoriness to immune rejection displayed by liver grafts are not fully understood and may be due partly to the size and enormous capacity for regeneration displayed by the liver. The immune response to liver transplants also differs from that to other grafts, however, and spontaneous tolerance can develop in several rat and all mouse strain combinations. An understanding of this phenomenon may help workers design new strategies of tolerance induction.[84,85,153,154]

What the liver and other sites of apparent immune privilege have in common are mechanisms to regulate or suppress immune responses negatively—it is suggested that immune privilege is a very active process involving mechanisms ranging from cytotoxicity directed at immune effector mechanisms delivered by Fas-FasL interactions[12,93,114,190,200,261] to those delivered by regulatory or suppressor cells.[41] The reader who wishes to delve deeper into the area of immune privilege is referred to an entire review volume covering this area.[235a]

CHRONIC ALLOGRAFT NEPHROPATHY

Although chronic rejection has been mentioned at various points in this chapter, most of what has been said refers to the acute processes that occur rapidly after transplantation. (See Chapter 25 for a more complete discussion of chronic allograft nephropathy.) That these may influence the likelihood of more chronic changes seems reasonable, although accumulating evidence in favor of this suggestion has not been easy.[9,354,364] As better immunosuppression reduces the loss of organ allograft to acute rejection, chronic rejection becomes more evident; currently, the greatest loss of kidney grafts is to chronic rather than acute rejection.

Multiple effector mechanisms are thought to contribute to the immunological aspects of chronic graft rejection, but it has become apparent that other factors are involved in

this process, which have nothing to do with the immune response. The development of experimental models of chronic allograft rejection has increased knowledge of the possible causative mechanisms and pointed to therapies that might prevent the development of the obliterative arterial changes of chronic rejection in the future.[132, 274] An inflammatory cellular infiltrate is always seen, comprising macrophages, eosinophils,[192] NK cells,[167,369] and T cells. The T cells comprise $CD4^+$ and $CD8^+$ cells, with usually a predominance of the former.[50,72,77,120]

Because of the predominant vascular nature of chronic rejection, alloantibody has been long thought to play a role in the development of this process, and the demonstration of donor-specific alloantibodies in patients with chronic rejection of cardiac allografts[299] and the deposition of immunoglobulin in graft vessel walls of chronically rejected organs[27,306] would be compatible with that concept. In experimental systems, B cell–deficient mice do not develop arterial lesions.[311] It also is possible, however, to show immunoglobulin and complement deposition in organs that show no evidence of rejection so that the role of antibody remains uncertain.

The graft arteriosclerosis seen in chronic rejection is concentric and affects all graft arteries, and this forms the basis of a working hypothesis for the development of chronic rejection proposed by Hayry and associates.[132] It is suggested that low-grade damage to the graft endothelium, with possible loss of endothelium, allows platelet deposition on the arterial wall, and the production of a variety of growth factors, which cause proliferation of smooth muscle cells in the media of the arterial wall and their subsequent invasion of the intima. This response-to-injury hypothesis first proposed for atherosclerosis[305] has been tested in an experimental model in the rat using an aortic allograft.[236] These grafts undergo an initial acute inflammatory reaction in the adventitia, which subsides and is followed by gradual migration of proliferating muscle cells from the vascular media to the intima and the appearance of intimal fibrosis. When induced, this allograft arteriosclerosis is not reversible by transplanting the aortic allograft into a syngeneic recipient. The development of the chronic arterial lesion is associated with cytokines (IL-1, IL-6, TNF, IFN-γ), growth factors (platelet-derived growth factor, transforming growth factor-β), and lipid mediators of inflammation (eicosanoids and platelet activation factor). The demonstration that a particular somatostatin analogue, lanreotide, which downregulates the production of several growth factors, prevents smooth muscle proliferation and the development of arteriosclerosis in the aortic allograft model suggests that these growth factors may be important effector molecules in the development of the chronic lesion.[132]

The causes of chronic rejection are immunological and nonimmunological,[267] with the immunological causes being important, and the primary target of the immunological response being the endothelium. Nonimmunological causes are attracting increasing attention, but a full discussion of these is outside the scope of this chapter.

CONCLUSION

The immune response to a tissue allograft is complex, not only in the manner by which allogeneic histocompatibility antigen is recognized but also in the response to this recognition, which generally results in graft damage. In the recognition of antigen, the DC, be it of donor or recipient origin, plays a central role, whereas the effector arm is mediated by cells and by antibody. The hierarchy of importance of all the effector mechanisms described is affected by the type and nature of the graft, the incompatibility between donor and recipient, and the type of immunosuppression used. Because all potential effector mechanisms can cause graft damage, adequate immunosuppression usually seems to require disabling the immune system at a central point. The consequence of this requirement is that patients become susceptible to infection, are at increased risk of cancer, and experience the other side effects of long-term immunosuppression. For continued success with organ transplantation, strategies that strive to reduce and tailor immunosuppression are paramount, as are strategies that aim to achieve immunological tolerance.

Chapter 3

Nontransplant Modalities of Kidney Replacement Therapy

Lisa Nanovic • Bryan N. Becker

Dialysis is the most well-established mode of mechanical organ replacement in use today. Dialysis attempts to replace a complex and vital organ that regulates electrolyte and fluid status and endocrine and metabolic function. It is readily acknowledged that dialysis—whether peritoneal dialysis (PD) or hemodialysis (HD)—remains a nonphysiological replacement for normal healthy kidney function. Dialysis may become necessary with acute deterioration of kidney function or in the context of a progressive decline of kidney function. Although clinical and laboratory measurements need to be considered for an appropriate assessment of renal replacement therapy need, the decision to dialyze a patient remains predominantly a clinical judgment in nearly all instances.

There are five absolute indications to begin dialysis (Table 3-1): (1) pulmonary edema resistant to diuretics; (2) hyperkalemia unable to be managed medically; (3) severe uremic symptoms, such as intractable nausea and vomiting, and mental status changes with no other obvious cause; (4) metabolic acidosis not responsive to medical management; and (5) a pericardial effusion in the presence of an elevated blood urea nitrogen (BUN) level. Only one of these five indications needs to be present for initiation of kidney replacement therapy.

Definitive recommendations regarding the optimal timing of initiation of kidney replacement therapy in patients with acute kidney injury (either with baseline normal renal function or baseline chronic kidney disease [CKD]) are unavailable and remain subject to debate and investigation. Historical data that are primarily retrospective strongly supported the prophylactic initiation of dialysis before the onset of advanced uremia. A five-center collaborative effort studying acute kidney injury in 2006 showed lower crude survival rates for patients initiating HD with BUN levels greater than 76 mg/dL.[29] Although these studies support the initiation of treatment by the time the BUN level is 80 mg/dL or greater, data addressing the question of earlier initiation of therapy are limited.

When it has been established that a patient requires dialysis therapy, the next step is to select what form of therapy is appropriate for that clinical situation. The form varies depending on the acute or chronic nature of the kidney dysfunction. Selection also is based on the patient's hemodynamic status. There are two major forms of kidney replacement therapy: HD, using a machine and artificial kidney membrane for diffusion and ultrafiltration, and PD, using the peritoneal membrane for diffusion and ultrafiltration. There are several variations of HD, including hemodiafiltration, continuous venovenous hemofiltration (CVVH), and continuous venovenous hemodialysis (CVVHD). In PD, the two major forms are continuous ambulatory peritoneal dialysis (CAPD) and continuous cyclic peritoneal dialysis (CCPD).

Patients with CKD are now staged based on level of estimated glomerular filtration rate (GFR) (Table 3-2). Kidney replacement therapy should be discussed with patients when they are in stage 4 CKD and should be offered to patients when they have reached stage 5 CKD. The modalities used for kidney replacement therapy for such patients include HD and PD. The goal for access in patients with CKD is for the patients to be educated at stage 4 of CKD in the different forms of renal replacement therapy and to have obtained the appropriate access before initiation of dialysis. In acute kidney injury, it is impossible to plan access and prepare for initiation of dialysis.

GFR is used more in the chronic setting to gauge disease progression by monitoring the trend, whereas in the acute setting, the daily increase in serum creatinine or other markers of kidney dysfunction (e.g., cystatin C) are laboratory signs of kidney failure, regardless of the calculated GFR. Electrolyte measurements and the patient's overall clinical status are more important in the decision to initiate dialysis.

Table 3–1 **Absolute Indications for Dialysis**
Hyperkalemia—unable to be controlled medically
Acidosis—unable to be corrected medically
Pulmonary edema/volume overload—unresponsive to diuretics
Pericardial effusion
Severe uremia—includes intractable nausea, emesis, mental status changes

In acute kidney injury, access and dialysis itself are initially considered for short-term use, and this influences the type of access and form of dialysis. Although more common in pediatric patients, in whom vascular access can be problematic, PD is still used in cases of acute renal failure in adults. This practice has declined with the increasing use of slow, continuous HD. HD remains the predominant form of renal replacement therapy in acute and chronic kidney failure.

HEMODIALYSIS

Process

HD is an extracorporeal therapy. HD uses the mechanism of diffusion of the patient's blood against dialysate through a membrane contained in an artificial kidney. The movement of solutes by diffusion is the result of random molecular motion that can be manipulated by the concentration gradient of the dialysate compared with the patient's plasma, and by the size of the pores of the semipermeable membrane of the dialyzer compared with the molecular weight of the solutes in the plasma.

Approximately 250 to 500 mL of blood is removed from the patient's body via a form of vascular access into tubing that attaches to a dialysis machine. This blood circulates into a dialysis membrane containing artificial semipermeable fibers and then back into tubing connected to the dialyzer through an outflow track. This filtered blood is returned to the patient through the vascular access. The dialysis machine features a pump that delivers the patient's blood to the dialyzer at a constant rate (200 to 500 mL/min). Dialysate is circulated in a single-pass fashion, countercurrent to the blood flow. This allows for solute removal by diffusion, based on concentration gradients of solutes between the blood and dialysate across the semipermeable membrane.

Dialysis membranes are classified according to their composition, biocompatibility, and pore size. The two major types of material used to form dialysis membranes are cellulose and synthetic polymers. The type of material influences membrane biocompatibility and function. Biocompatibility refers to the reactions that occur as a result of blood-membrane interactions. These include activation of complement and coagulation cascades and cell activation, in particular, peripheral blood leukocytes and platelets. Reactions can manifest as thrombosis in the dialyzer and, rarely, as acute anaphylactoid reactions.

Function refers to the ability of the dialyzer to clear the blood of particular proteins or molecules. A typical modern hemodialyzer is composed of several thousand parallel hollow fibers. The walls of these fibers are semipermeable, separating the blood in the fiber lumen from the dialysate outside. The total internal surface area of all the fibers is usually 0.5 to 1.2 m^2, although some dialyzers are even larger, providing greater solute transport. High efficiency in HD refers to a high rate of removal by diffusion of small-sized solutes. The high-efficiency dialyzer contains membranes with larger surface area (1.5 to 2.1 m^2) and achieves a higher rate of removal of solutes with greater blood flows. High flux connotes a high rate of removal by diffusion of "middle molecules" larger than urea; this is achieved with membranes containing larger pore sizes (60 Å compared with low-flux dialyzer pore sizes of 25 Å).

Hemofiltration membranes are always high flux and are usually made of synthetic materials (polysulfone, polyamide, cellulose acetate, polyacrylonitrile). Synthetic membranes are generally more biocompatible.

Dialysate is composed of water containing sodium, potassium, calcium, magnesium, chloride, acetate, dextrose, and bicarbonate. Optimal dialysate flow rates during HD are 800 mL/min, and the average time on HD is approximately 3 to 4 hours. Patients are exposed to 120 L or more of water during each dialysis treatment. All small-molecular-weight substances present in the water have direct access to a patient's circulation as if they had been administered by intravenous injection. For this reason, it is important that the purity of the water used for HD be known and controlled. Significant contaminants in dialysate water with their associated complications include aluminum, associated with bone complications, neurological disease, and anemia; copper, associated with hemolytic anemia; chloramine, associated with hemolytic anemia; and fluoride, associated with cardiovascular, gastrointestinal, and neuromuscular derangements (with intoxication can prove fatal).

Purifying water for HD is a stepwise process, usually conducted in a dedicated central system within a freestanding HD unit. Purification begins with softening to remove most of the calcium and magnesium. Water is then passed through a series of carbon filters to remove organic and inorganic impurities, such as chloramine and chlorine. The water is passed through a semipermeable membrane with pores that prevent passage of small-molecular-weight solutes, such as chloride, sodium, and urea. Reverse osmosis removes more than 90% of the impurities. Deionizers that exchange charged solutes for hydrogen and hydroxyl ions, removing charged solutes from water, can be used as an alternative to reverse osmosis or to refine water already treated with a reverse osmosis system. The bacterial counts should be less than 100 colonies/mL in the water and less than 500 colonies/mL in the final dialysis solution. Despite the efficiency of the dialyzer membrane as an effective barrier to bacteria and endotoxins in dialysate, maintaining the aforementioned colony counts significantly limits any

Table 3–2 **Stages of Chronic Kidney Disease**

potential for transmission of endotoxin or bacterial products across the dialyzer, enhancing patient safety.

Access (see Chapter 5)

Vascular access that allows for a high-flow state is necessary for adequate HD. This access can be achieved through an arteriovenous (AV) fistula, an AV graft (polytetrafluoroethylene or bovine endovascular material), or a venous catheter. Each of these forms of access has risks and benefits, but it is widely accepted that the AV fistula is the best form of vascular access for HD.

The National Kidney Foundation–Kidney Disease Outcomes and Quality Initiatives (NKF K/DOQI) guidelines recommend access placement at stage 4 CKD (estimated GFR 15 to 29 mL/min); this allows adequate time for maturation of a vascular access without need for emergent catheter placement. AV fistulas and grafts have better survival if used at the time of initiation of HD compared with their use in patients initiated on HD with a catheter. Data from the United States Renal Data System (USRDS) indicate that now approximately 40% of prevalent HD patients use AV fistulas.[4] This percentage is significantly greater in many other countries around the world.

After the creation of an AV fistula, a certain period is necessary for maturation of the fistula to occur for the fistula to be functional as a vascular access for HD. In European centers, greater than 80% of medical directors recommend using an AV fistula within 2 months of fistula creation, whereas in Canada and the United States, more than 75% of medical directors wait longer than 2 months.[35] Cannulation of the AV fistula within 14 days of creation is associated with reduced long-term fistula survival.[42]

Synthetic AV grafts and central venous catheters have more problems with flow, morbidity, and increased cost compared with AV fistulas, but there are circumstances where a synthetic graft is required for long-term HD, such as suboptimal arterial or venous anatomy for AV fistula creation. Compared with fistulas, grafts have a reduced primary failure rate, have a shorter time to use and successful cannulation, and potentially require fewer salvage procedures for the primary access. A central venous catheter may be required when immediate access to the circulation is required, or when there is insufficient time for an AV fistula or graft to mature. Many patients with catheters become difficult or impossible to convince to proceed with an AV fistula, as they have become used to a needle-free and painless initiation of HD when using a catheter. The duration of catheter dependence is inversely correlated with the likelihood of proceeding with the creation of an AV fistula or graft.

Vascular access, important for being the patient's lifeline, all too often is the cause of the HD patient's death. Infection is the second leading cause of death in dialysis patients. Death rates from septicemia have been estimated to be 100-fold to 300-fold higher than in the general population. The risk for infection-related death is greater in catheter-dependent patients. In an analysis of data from the HEMO trial, the frequency of hospitalization as a result of access-related infection was greatest among HD patients with catheters.[2,3] Several studies show a gradient of patient mortality risk by access type, with the highest risk observed with central venous catheters, and the lowest risk with AV fistulas. Prophylactic measures, such as use of antimicrobial lock solutions or exit site antibiotic ointments, may reduce the frequency of catheter-related bacteremia.

Maintenance of vascular access is a major challenge for long-term HD. A loss of flow in the fistula or graft can be devastating, with subsequent loss of the access if not addressed in a timely manner. Vascular access complications are one of the main causes associated with an increase in morbidity and mortality in end-stage renal disease (ESRD). For AV fistulas, it is important to assess potential salvage procedures early (within 4 to 6 weeks) after fistula creation. Changes in blood flow or arterial or venous pressures during HD can raise concerns for stenosis or collateral blood flow or both. Stenosis is the major cause of dysfunction in an AV fistula. Ultrasonic investigation of the fistula can determine flow states within the fistula and indicate possible stenotic areas that may benefit from intervention with fistulogram plus angioplasty and possible stenting.[7] Collateral vessels may require surgical revision. Clinically, loss of blood flow within the fistula or graft is associated with a decrease in intensity of an audible bruit along the access. This is likely due to thrombosis and can result from hypotension, a hypercoagulable state, or constriction of the graft. Swift thrombolytic intervention can save the access.

Steal syndrome is an uncommon but serious condition of arterial insufficiency distal to a fistula. The diagnosis is largely based on clinical features of numbness, pain, or a coolness of the extremity distal to the access site. In some cases, angiography may be necessary to ascertain the lesion leading to steal syndrome.[20] The cause is usually high fistula flow, but other causes, such as inflow or anastomotic stenoses, or a combination of these causes, have to be considered. The main treatment options are flow-reducing procedures or distal revascularization with selective ligation. In some cases, fistula ligation is the method of choice.

Fluid Status

Compartments

Approximately 60% of the body is composed of water with two thirds of total body water being intracellular and the rest extracellular. Extracellular fluid (ECF) can be divided further into the plasma, interstitial, and transcellular compartments. Approximately one fifth of ECF is intravascular within plasma (Fig. 3-1). When monitoring patients on HD, the focus is on the ECF, particularly the plasma compartment. In a person with normal kidney function, if the ECF compartment is volume expanded, the kidney excretes the excess sodium and water in the urine, maintaining a normal plasma volume. In ESRD when excretory capacity is diminished, sodium and water retention persists despite expansion of the ECF volume, creating total body sodium and water excess. The dysregulation of fluid volume can lead to pulmonary and peripheral edema. Elevated intravascular volume increases the intravascular pressure, leading to hypertension and cardiac hypertrophy. Regulation of total body fluid status is no small task because the kidney filters 180 L of plasma daily. Inability to regulate total body fluid status is an indication to begin renal replacement therapy.

Ultrafiltration

Ultrafiltration during HD removes water accumulated either by ingestion of fluid or by metabolism of food during the

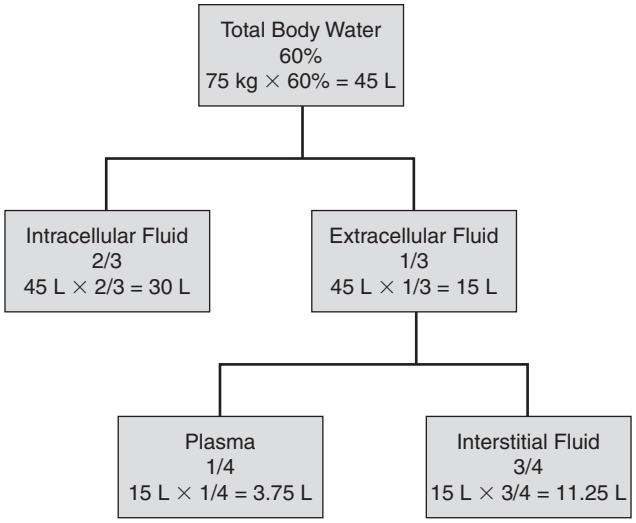

Figure 3–1 Fluid compartments in a 75-kg patient.

interdialytic period. Solutes are removed via diffusion during an HD treatment, and free water can be removed via convective forces during a treatment. Water driven by either a hydrostatic or an osmotic force is pushed through the membrane of the dialyzer. Typically, a patient dialyzed three times a week gains 1 to 4 kg of weight between treatments, most of which is water. This water needs to be removed during a 3- to 4-hour dialysis session. Normally, ultrafiltration is performed at the same rate throughout the dialysis session.

Problems can arise with excessive ultrafiltration on HD. These occur either in the amount of volume removed or with the rapidity of rate of removal; either can result in hypotension, muscle cramping, and mental status changes. Patients may develop nausea and emesis that may be erroneously attributed to uremia.

The amount of fluid that should be removed as ultrafiltrate during HD is clinically determined by assigning a dry weight to each patient. Dry weight is defined as the postdialysis weight at which the blood pressure is lowered into the presumed normal range without the development of intradialytic hypotension, and without clinical signs of pulmonary congestion or peripheral edema. The discontinuous and brief nature of routine dialysis therapy often requires high ultrafiltration rates to reach a patient's "dry weight."

Fluid Assessment

Clinical signs are the primary tool used to assess volume overload in patients. There are other methods to ascertain volume status, however. Biochemical markers of dry weight include plasma levels of atrial natriuretic peptide and cyclic guanosine monophosphate. Plasma levels of atrial natriuretic peptide are elevated in HD patients because of their inability to remove excess intravascular volume. Ultrafiltration of excess fluid during dialysis can reduce plasma atrial natriuretic peptide levels. Fluid overload also has been associated with elevated serum levels of cyclic guanosine monophosphate.

Anatomical measures of dry weight include the diameter of the inferior vena cava. Central venous and right atrial pressures reflect right ventricular function. Right ventricular function is an indicator of volume status. Central venous pressure as measured by the diameter of the inferior vena cava is an indirect measurement of total body fluid. During fluid removal with ultrafiltration during HD, intercompartmental fluid shifts occur. The diameter of the vena cava at the end of HD reflects blood volume, not total body water volume. The bedside correlate to this is ultrasonographic visualization of the internal jugular vein. Notably, a distended internal jugular vein on ultrasound potentially can indicate increased right atrial pressures, but stenosis of the distal vasculature also can imitate this and must remain in the differential diagnosis. The clinical examination is a less expensive and useful tool for estimation of dry weight because all current modalities are not exact indicators of dry weight.

The assessment of dry weight and volume status in patients undergoing HD is extremely important because of the detrimental effects of chronic fluid overload on the heart. HD patients have hypertension, subsequent left ventricular hypertrophy, and cardiomyopathy, all in part resulting from persistent hypervolemia. Sodium and fluid restriction can be used in addition to ultrafiltration to maintain a stable weight and volume status, especially during the intradialytic period (Table 3-3). Aggressive fluid restriction stimulates thirst, and patients with ESRD already have a plasma osmolality set higher than normal, further stimulating thirst. This can complicate patient adherence to dietary advice.

Electrolytes

Sodium

Sodium chloride is the most abundant molecule in the ECF. At steady state, urinary sodium excretion essentially is identical to the dietary intake of sodium. ECF volume increases linearly as the dietary intake of sodium increases.

The volume of the ECF is directly proportional to the content of sodium in the body. An increase in ECF volume increases the plasma volume. Sodium is the ion that allows us to use osmosis for dialysis. Osmosis is the movement of water across a membrane from an area of lower solute concentration to an area of higher concentration of solutes until both solutions on either side of the membrane reach equal concentrations. The osmotic pressure of a solution depends on the number of particles dissolved in a unit volume of solvent. These particles are referred to as osmoles. Osmolality refers to the number of particles (osmoles) in 1 kg of water. Tonicity refers to the solutes that remain in the ECF compartment causing water movement. Solutes such as sodium and glucose increase tonicity because they do not pass freely through cell membranes, causing

Table 3–3 **Nutritional Recommendations for Dialysis Patients**

	Hemodialysis	Peritoneal Dialysis
Sodium	<90 mEq daily	≤150 mEq daily
Potassium	<60 mEq daily	≤90 mEq daily
Phosphorus	800-1000 mg daily	800-1000 mg daily
Calcium	<2 g daily	<2 g daily
Fluid	1-1.5 L daily	≤2 L daily

water movement. The osmolality of plasma is largely a function of sodium concentration. Patients with ESRD have excess nitrogenous waste contributing to an elevated plasma osmolality. Yet, urea, an example of a nitrogenous waste product, is readily diffusible across cell membranes and does not contribute to the tonicity of plasma. This leaves sodium as the major contributor to body tonicity. The kidney is no longer able to excrete a sodium load in ESRD, resulting in sodium retention, ECF hypertonicity, and hypertension.

COMPLICATIONS OF SODIUM BALANCE

Disorders of sodium balance are disorders of ECF volume. Patients with ESRD have expanded ECF volume despite normal sodium intake. Dialysis uses dialysate, a synthetic plasma water component, to remove soluble wastes from the blood by diffusion. The average dialysate sodium concentration is 135 to 145 mmol, close to normal physiological serum levels. Sodium crosses dialysis membranes by diffusion and convection. Sodium removal can be increased by applying higher ultrafiltration volumes and by lowering dialysate sodium concentration.

Plasma volume depletion and hemodynamic instability during HD are a function of the dialysate-to-plasma tonicity gradient because it is the tonicity that determines water movement across cell membranes to influence plasma refilling and intradialysis discomfort. Supraphysiologic dialysate sodium concentrations have been used to reduce volume shifts and to maintain hemodynamic stability. These elevated dialysate sodium concentrations have caused an increase in hypertension, increase in thirst, and increase in intradialytic weight gain.

Sodium intake is the most important determinant of intradialytic weight gain in nondiabetic patients. The biggest difficulty with a sodium-restricted diet is patient adherence. The most recent dietary recommendations are a sodium restriction of 2 to 3 g a day (Table 3-4). In HD patients requiring parenteral nutrition, it may not be necessary to add sodium to the formulation, unless the patient is having significant sodium loss from gastrointestinal fluids.

Potassium

Two percent of a patient's total body potassium content is located in the extracellular compartment. This uneven distribution reflects the large potassium concentration gradient between the intracellular fluid and ECF compartments that determines cell resting membrane potential. A disruption of this ratio can have detrimental consequences on the function of excitable tissues, especially muscle (myocardium in particular) and nerve. The most prominent adverse effects of hyperkalemia include potentially lethal arrhythmias, respiratory depression, and enhanced weakness and fatigue.

In the normal state, 90% to 95% of daily potassium intake is excreted by the kidneys. Although HD is the primary method of potassium removal for ESRD patients, they too rely on gastrointestinal excretion and cellular uptake for potassium homeostasis. ESRD patients eliminate 25% of their daily potassium load via increased colonic secretion.

Persistent hyperkalemia in dialysis patients is due to excessive potassium intake, inadequate potassium elimination, or a combination of the two. Excessive potassium intake is most commonly due to dietary noncompliance. Dietary restriction in HD patients should be less than 60 mEq of potassium daily. Patients requiring parenteral nutrition may require only 10 to 40 mEq/day of potassium in their formulation.

As previously mentioned, ESRD patients depend heavily on gut elimination of potassium. The amount of potassium excreted through the gastrointestinal tract is roughly proportionate to the stool volume. Constipation has been

Table 3–4 **Management of Electrolyte Abnormalities in Dialysis Patients**

Electrolyte Abnormalities in HD and PD Patients	Complications if Untreated	Management
Hypernatremia	Hypertension	HD—decrease ultrafiltration PD—decrease dextrose concentration in dwells Medications—evaluate for sodium-containing medications (i.e., antibiotics, sodium bicarbonate) Nutrition—restrict sodium to <2 g daily
Hyperkalemia	Cardiac arrhythmias; cardiac arrest	HD—decrease K^+ bath PD—patients usually hypokalemic and may need K^+ supplementation Medications—calcium gluconate, insulin (followed by 50% dextrose), bicarbonate, albuterol, Kayexalate Nutrition—restrict K^+ <60 mEq daily; ensure patient *not* consuming K^+-containing salt substitutes
Hypercalcemia	Secondary hyperparathyroidism; calciphylaxis	HD—lower calcium bath PD—lower dialysate calcium Medications—change phosphate binder if calcium containing to non–calcium containing (i.e., sevelamer, lanthanum carbonate); begin calcimimetics (check parathyroid hormone level); stop supplemental vitamin D Nutrition—<2 g daily of calcium (including calcium-containing medications)
Hyperphosphatemia	Pruritus; calciphylaxis	HD—increase HD run time PD—increase dwell time or volume of dwell Medications—phosphate binders Nutrition—decrease dairy intake; ensure patient taking binders *with* meals; restrict to 800-1000 mg daily

HD, hemodialysis; PD, peritoneal dialysis.

reported to occur in 40% of HD patients and can predispose ESRD patients to hyperkalemia.[37] Inadequate dialysis is another common factor leading to hyperkalemia.

The indication for dialysis related to hyperkalemia is different when comparing acute kidney injury versus CKD. Patients with CKD have a diminished ability to excrete a potassium load acutely, creating more severe and prolonged hyperkalemia when challenged. Recognition that mild-to-moderate hyperkalemia is an adaptive response in CKD should lead to tolerance of a steady-state serum potassium concentration of 5 to 5.5 mmol/L in patients with CKD.[16] Many signs of hyperkalemia are more difficult to identify in this patient group. Patients who present with severe hyperkalemia may have a normal electrocardiogram or have changes that are so subtle that physicians have difficulty attributing these changes to increased serum potassium levels.[39] Individuals also may have less overt weakness. Clinical diligence is necessary, however, to monitor these patients and avoid any additional complications. Dialysis is the definitive treatment for significant hyperkalemia (see Table 3-4).

Ingestion of high-potassium foods and medications that potentially can cause hyperkalemia (Table 3-5) needs to be changed with education and alternative prescriptions. By controlling the concentration of potassium in the dialysate, it is possible to decrease elevated serum potassium levels.

Phosphorus

Phosphorus constitutes approximately 1% of an individual's total body weight. Phosphate is unevenly distributed in different compartments of the body. Only a very small amount of phosphate (approximately 1%) is present in the accessible plasma compartment of the ECF. The kidney, gastrointestinal tract, and bone are the major organs involved in phosphorus homeostasis.

Phosphate balance is disturbed in most ESRD patients because absorption from the diet exceeds the elimination through HD treatment. The positive phosphate balance of HD patients leads to a chronic phosphate load. Elevated serum phosphorus levels are associated with an increased mortality rate in patients with CKD. This increased mortality is most likely due to the development and progression of vascular calcification owing to higher serum phosphorus levels in a population already at increased risk of cardiovascular disease.

Secondary hyperparathyroidism also occurs in patients with ESRD as a result of dysregulation of stimuli affecting parathyroid hormone (PTH) (Table 3-6). ESRD with loss of renal mass impairs phosphate excretion and the synthesis of 1,25-dihydroxyvitamin D_3. Hypocalcemia and hyperphosphatemia stimulate PTH release and its synthesis and decrease the intracellular degradation of PTH. Electrolyte imbalances between calcium and phosphorus ensue, and if left untreated result in debilitating bone resorption.

PHOSPHORUS MAINTENANCE

Despite adequate dialysis three times weekly, patients with ample diets remain in a positive phosphate balance. The next steps in treatment of hyperphosphatemia include phosphate binders and more efficient dialysis.

Phosphate-binding medications bind to phosphate in the gastrointestinal tract and prevent its intestinal absorption (see Table 3-4). The most widely used phosphate binders are calcium based. Calcium carbonate and calcium acetate are well-established effective phosphate binders, with calcium acetate having a smaller calcium load per equivalent phosphate-binding dose. Sevelamer hydrochloride (Renagel), lanthanum carbonate (Fosrenol), and magnesium-containing compounds are the only nonaluminum, noncalcium binders currently available. Sevelamer hydrochloride is an effective binder with a favorable side-effect profile. Lanthanum carbonate has a side-effect profile similar to that of calcium carbonate, currently showing no deleterious effects on bone (4-year follow-up) when compared with aluminum-containing binders used in the past. Magnesium binders are limited by the development of overt hypermagnesemia, gastrointestinal side effects, and the need for individualization of dialysate magnesium concentrations. Calcimimetics (cinacalcet) bind to the calcium-sensing, G protein–coupled receptor in the parathyroid gland and allosterically alter sensitivity of the calcium-sensing receptor to calcium in the gland.

Phosphate removal in HD is limited after the initial hour of dialysis clearance because of the rate-limiting step of transfer of phosphate from the intracellular to extracellular space. Only a small percentage of phosphate is distributed in the extracellular space, with most of the total body phosphate concentration located intracellularly. Increased dialysis time or increased frequency of dialysis treatments possibly can remove more phosphate as it is transferred from the intracellular space to the dialyzable, extracellular space. As a result of the kinetics of phosphate metabolism, increasing the frequency of dialysis sessions more effectively removes phosphate than increased time at individual dialysis sessions.

Calcium

Calcium is the most abundant divalent ion in the body. Of total body calcium, 99% is located in the bone, with the remaining 1% found in teeth, soft tissues, plasma, and cells. Approximately 1.2 to 1.3 kg of calcium is present in a 70-kg individual. Calcium homeostasis is maintained by

reabsorption and formation interplay between the intestine, bone, and kidney.

Approximately 1000 mg of calcium is ingested daily. Of that 1000 mg, about 400 mg is absorbed along the intestine, primarily in the duodenum and jejunum, and the remaining 600 mg is excreted in the feces. Intestinal absorption of calcium is accomplished through passive and active mechanisms, the active mechanism via vitamin D_3. Net calcium reabsorption and formation in bone is important in maintenance of plasma calcium concentration. Daily turnover occurs via activity of PTH, active vitamin D_3, and calcitonin. PTH regulates plasma calcium concentration by (1) stimulating bone resorption by activating osteoclasts, which demineralize bone; (2) increasing the synthesis of active vitamin D_3; and (3) increasing calcium reabsorption in the distal tubule of the kidney. Active vitamin D_3 promotes calcium uptake in the intestine. Calcitonin is released in response to elevated calcium concentrations and acts by directly inhibiting the activity of osteoclasts, decreasing serum calcium levels.

Patients with ESRD initiating HD are usually hypocalcemic. This hypocalcemia is due to the inability to reabsorb filtered calcium along with decreased production of 1,25-dihydroxyvitamin D_3 in the nonfunctioning kidney. Dialysate usually contains 1.75 mmol/L of calcium. This degree of calcium in the dialysate stabilizes myocardial function during dialysis and reduces the risk of hypotension in HD patients during treatment.

Treatment for hypocalcemia is with calcium and vitamin D supplementation. Patients with ESRD may already be on calcium-containing phosphate binders. Active vitamin D_3 promotes not only active absorption of calcium in the intestine, but also absorption of phosphorus. This absorption can worsen hyperphosphatemia and cause an increased calcium-phosphorus product.

The calcium-phosphorus product is the number obtained by multiplying the serum calcium by the serum phosphorus value. Current guidelines state that a calcium-phosphorus product greater than 55 mg/dL can increase the risk of soft tissue calcification or calciphylaxis. This can lead to tissue necrosis, periarticular calcification, and vascular calcification including the coronary vasculature along with an increased mortality risk.

Anemia

Normal red blood cell production is primarily regulated by circulating erythropoietin. The kidney produces 90% of circulating erythropoietin, accounting for its pivotal role in erythropoiesis. When erythropoietin binds to its receptors on bone marrow erythroid progenitor cells, their proliferation, differentiation, and development into mature erythrocytes is increased. Nonkidney erythropoietin is produced by the liver by centrilobar hepatocytes. Nonkidney erythropoietin production is rarely able to provide for significant erythropoiesis in an anephric state, however.

The pathogenesis of anemia in kidney failure is multifactorial. Erythropoietin deficiency, shortened erythrocyte survival, the presence of uremic inhibitors of erythropoiesis, hemolysis, bleeding, and iron deficiency all are contributors. Erythrocyte survival is 60 to 90 days in uremic patients versus 120 days in normal individuals and generally does not improve with dialysis therapy. NKF K/DOQI guidelines recommend a hemoglobin level of 11 mg/dL for premenopausal women and a level of 12 mg/dL for men and postmenopausal women. These target levels were selected for the reduced need for blood transfusions and improved quality of life. Anemia may predispose patients to left ventricular dilation and hypertrophy that can predispose to heart failure and mortality.[15] A normal hemoglobin target in ESRD patients may not be optimal, however, because such individuals seem to risk an increased rate of ischemic cardiac events and access complications and cerebrovascular events compared with individuals with slightly lower hemoglobin values. Therapeutic modalities for treatment of anemia in ESRD include recombinant erythropoietin, darbepoetin alfa, iron supplementation when indicated, and packed red blood cell transfusions.

Adequacy

Numerous outcome studies have shown a correlation between the delivered HD dose and patient morbidity and mortality.[18] Clinical signs and symptoms alone are unreliable indicators of HD adequacy. To ensure that ESRD patients treated with long-term HD receive a sufficient amount of dialysis, the delivered dose should be measured and monitored routinely. Adequacy is a method to quantify the optimal amount of HD that should be delivered to a patient in a dialysis session that has been widely based on the removal of urea. Urea is a small, readily dialyzed solute that is the bulk catabolite of dietary protein. It constitutes 90% of waste nitrogen accumulated in body water between HD treatments, it is easily measured in blood, and the fractional clearance of urea in body water correlates with morbidity and mortality.[27]

A dose of dialysis is best described as the fractional clearance of urea as a function of its distribution of volume. Kt/V is the formula used in the urea kinetic model that helps guide the nephrologist for proper dialysis dosing. K is the hemodialyzer clearance (in L/min), t is the duration of the dialysis session (in minutes), and V is the volume of distribution of urea in the body (in liters). Maximum solute clearance has been shown to occur in the first hour of HD, and increasing dialysis time does not equate to improved adequacy.[27] Daily dialysis has shown improved clearance as opposed to increasing time of thrice-weekly dialysis sessions. Current NKF K/DOQI recommendations are for a weekly Kt/V of 1.2 for thrice-weekly dialysis, and a Kt/V of 0.57 for short daily and nocturnal HD.

Cardiovascular Disease

ESRD patients manifest extraordinary risk for cardiovascular disease, including myocardial infarction, atherosclerotic heart disease, and congestive heart failure. In addition, patients with ESRD have a unique excess of sudden death from cardiac arrest[49]; this may be due partly to the tremendous prevalence of left ventricular hypertrophy in this group. Eighty percent of all individuals who reach stage 5 CKD (<15 mL/min) have left ventricular hypertrophy.[14]

Traditional and nontraditional risk factors are present in ESRD patients, and dialysis seems to exacerbate them. ESRD patients are elderly and have a high prevalence of diabetes. Yet, even markers of inflammation are elevated eightfold to tenfold in long-term dialysis patients compared with healthy controls.

Other cardiovascular complications common to dialysis include atrial fibrillation. Significantly, there is a twofold increased risk of death and 50% increased rate of stroke associated with atrial fibrillation in dialysis patients. Increased aortic stiffness also has been shown in ESRD patients.[31] The decreased distensibility of the large elastic arteries is likely due partly to increased collagen deposition, shown in animal models and human studies. Aortic stiffening is characterized by decreased buffering capacity of the ascending aorta to reduce the pulsatile impact of ejected blood from the heart during systole. Increased pulse wave velocity and early wave reflections back to the heart result, increasing systolic load and decreasing diastolic blood pressure and coronary perfusion, ultimately leading to myocardial hypertrophy. Aberrant aortic stiffness has been noted in patients with ESRD independently of age and blood pressure.[43]

Complications

The procedure of HD itself is not without complications. Problems can arise at any part of the HD run. Common complications include hypotension, cramping, febrile episodes, arrhythmias, nausea, and vomiting.

Hypotension during HD is a common complication that occurs in 40% of all dialysis treatments. Hemodynamic instability contributes to the morbidity associated with dialysis.[13] Maintenance of intravascular volume during HD depends on the rapid refilling of the intravascular compartment from surrounding tissue spaces. The process of HD itself, with the removal of 500 mL of blood extracorporeally to the dialysis machine and removal of fluid from ultrafiltration, creates a decrease in the intravascular volume. This decrease results in decreased cardiac filling, which leads to reduced cardiac output and ultimately hypotension. Other factors contributing to hypotension during HD include splanchnic vasodilation, commonly as a result of food ingestion, and overly warm dialysate, which also can lead to vasodilation. Patients unable to vasoconstrict adequately, owing to autonomic dysfunction such as with long-standing diabetes, have an increased risk of developing hypotension during HD. Cardiac patients with poor myocardial contractility and diastolic dysfunction also are at increased risk of developing hypotension with HD. Less common causes include infection, pericardial tamponade, myocardial infarction, cardiac arrhythmias, and air emboli. Each patient's medical history, medications, and current clinical situation should be considered before the HD prescription to prevent hypotension during HD.

In the case of intravascular volume depletion as the source of hypotension, ideally, the rate of fluid removal should be constant throughout the dialysis session. It is important to educate the patient on the importance of fluid restriction to prevent intradialytic weight gain. A goal of less than 1 kg/day prevents excessive ultrafiltration during HD. Shorter treatments with higher rates of ultrafiltration increase the risk of hypotension. If a patient requires more than 3 to 4 L of fluid removal, the dialysis time should be increased to allow for continued controlled fluid removal. Sodium modeling is a process in which the sodium content of the dialysate is higher than the patient's serum sodium (i.e., 152 mEq/L) with controlled decrements in the sodium level to approximate 140 mEq/L to maintain a stable plasma osmolality within the patient during the course of ultrafiltration on dialysis. Studies have shown that blood pressure is well supported during sodium modeling protocols, but excessive thirst is reported in the intradialytic period.[11]

Dialysis solutions are normally kept at 37°C, but temperatures can be decreased to 34°C. These lower dialysate temperatures cause vasoconstriction and have been shown to maintain blood pressures during HD. The shivering and cramping that some patients experience with this method often limit its use.

Blood volume monitors are either an optical or an ultrasonic sensor located on the inflow blood line within the HD circuit. This sensor detects changes in hematocrit during dialysis. The blood volume monitor can indirectly monitor the effects of ultrafiltration during HD on intravascular volume by associating an increase in hematocrit with a reduction in plasma volume. Continuous monitoring of blood volume can be used to predict symptoms resulting from intradialytic hypovolemia.

Splanchnic vasodilation can be prevented by prohibiting eating during dialysis and holding meals until after HD is complete. In patients with refractory cases of hypotension, such as patients with autonomic neuropathy, α-adrenergic agonists such as midodrine should be considered, which can be given 30 minutes before scheduled dialysis time. Patients on antihypertensive medications should have their blood pressure medications held on the day of their dialysis, especially if they frequently develop hypotension with HD. A higher calcium dialysate concentration should be considered in cardiac patients to help with overall myocardial contractility.[48] When an acute hypotensive episode occurs during HD, ultrafiltration should be turned off, the patient should be placed in Trendelenburg position, nasal cannula oxygen should be given, and fluid in the form of 0.9% normal saline should be administered rapidly through the venous HD line.

The exact cause of cramping during HD is unknown but is commonly attributed to aggressive ultrafiltration and taking a patient below his or her "dry weight." During HD, treatment for cramping includes stopping ultrafiltration and, in instances when cramping does not resolve, administering 250- to 500-mL normal saline boluses to restore intravascular volume. Preventive measures, especially in patients with a history of cramping during HD, include prescribing quinine sulfate at least 2 hours before the next dialysis run.

Cardiac arrhythmias during HD are related to changes in blood volume affecting coronary artery perfusion and electrolyte abnormalities. Arrhythmias related to electrolyte abnormalities are due not only to a high serum level of potassium but also to the extreme changes of potassium during the HD run. Slower declines in potassium levels during HD have shown decreased incidences of supraventricular and ventricular arrhythmias. The incidence of cardiac arrhythmias during HD is estimated to be 50%. The most common sustained cardiac arrhythmia during HD is atrial fibrillation. Atrial fibrillation can occur in 20% of HD treatments and is more common in patients with left ventricular diastolic dysfunction, particularly patients with reduced intravascular volume and patients with ongoing sepsis.[5] Multiform ventricular ectopic arrhythmias are usually nonsustained and asymptomatic, resolving with completion of HD. Atrial fibrillation usually corrects spontaneously within a few hours of HD, but requires rate control with amiodarone or other agents in symptomatic patients. Impaired cardiac function, underlying autonomic neuropathy, an elevated calcium-phosphorus product,

and elevated PTH levels all have been shown to increase the incidence of cardiac arrhythmias during HD.

PERITONEAL DIALYSIS

In PD, the patient's own peritoneal membrane is the dialysis membrane. The patient is able to transport solutes and water from blood in the peritoneal capillaries to a dialysis solution in the peritoneal cavity via the peritoneal membrane. Peritoneal membrane transport consists of three simultaneous processes: (1) diffusion down a concentration gradient between the patient's blood and peritoneal dialysate, (2) ultrafiltration resulting from the osmotic gradient between these two fluid compartments, and (3) fluid absorption via lymphatics at a relatively constant rate. Although in ESRD a patient's blood has elevated concentrations of urea, the blood remains hypotonic to peritoneal dialysate. The peritoneal dialysate consists of sodium, chloride, water, and elevated concentrations of glucose to maintain a hypertonic solution relative to the patient's blood.

Process

Although there is an intermittent regimen of PD in which the dialysis is performed periodically or several times a week, the common practice of PD is a continuous regimen in which there is a constant presence of peritoneal dialysate in the peritoneal cavity 24 hours a day, 7 days a week. There are two techniques for a continuous regimen of PD: (1) a continuous flow technique using either two catheters or a double-lumen catheter, which allows for simultaneous and continuous inflow and outflow of dialysate, and (2) an intermittent flow technique in which a single catheter provides discrete inflow, dwell, and outflow phases of dialysate, with the flow of dialysate being completely interrupted during the inflow, dwell, and outflow portion of PD. The two major forms of PD, CAPD and CCPD, combine a continuous regimen with an intermittent technique.

A standard CAPD regimen consists of four 2-L dialysate exchanges daily. This regimen involves an infusion of the dialysate into the peritoneal cavity through the abdominal catheter for approximately 10 to 20 minutes; a dwell period in which the dialysate remains within the peritoneal cavity 3 to 8 hours; and the drainage of dialysate out of the peritoneal cavity through the same catheter, which takes an estimated 10 to 20 minutes. The infusion time and dwell time are dictated by the flow through the catheter along with the patient's anatomy. The overall dwell time is defined by the transport characteristics of the peritoneal membrane. As the name states, the patient is actively dialyzing with a "dwell" in the peritoneum while ambulatory, carrying out daily activities.

CCPD is an automated form of PD that is performed while the patient sleeps. All connections and preparation of equipment take place at bedtime. The dialysate bags are placed on a "cycler," a machine that has programmed infusion, dwell, and drain time. The patient is supine for CCPD, which allows for better surface area interface between the peritoneum and the dialysate. A supine position also allows dwell amounts larger than 2 L because there is less intra-abdominal pressure with the dialysate compared with a person standing upright. Because an entire nighttime of cycling may not be enough for adequate dialysis, an additional daytime dwell of dialysate may be necessary to improve clearance and ultrafiltration. This use of CCPD with an additional exchange during the day is referred to as PD Plus. The last automated exchange is provided by the cycler, with the second exchange during the day usually provided by manual CAPD, commonly called a "pause."

Access (see Chapter 5)

PD catheters are constructed from silicone rubber or polyurethane and have one or two Dacron cuffs. The silicone rubber or polyurethane surface promotes development of squamous epithelium in the subcutaneous tunnel next to the catheter, at the exit site, and within the abdominal wall. The presence of this epithelium increases the resistance to bacterial penetration of the tissue near the skin exit and peritoneal entry sites. The Dacron cuff provokes a local inflammatory response that progresses to form fibrous and granulation tissue within 1 month. This fibrous tissue serves to fix the catheter cuff in position and to prevent bacterial migration from the skin surface or from the peritoneal cavity past the cuff into the subcutaneous tunnel.

An extensive review of more than 17 trials comparing different catheter insertion techniques and catheter types was conducted.[46] This review showed no reduction in the incidence of peritonitis among catheter types or insertion techniques. Trials comparing single- versus double-cuffed catheters show no significant difference in the risk of peritonitis, exit site/tunnel infection, or catheter removal or replacement.[46]

After a PD catheter is placed, PD exchanges should be delayed for 2 to 4 weeks when appropriate. If the PD need is acute, the catheter can be used the day it is placed, but the method of dialysis is altered to prevent possible leakage around the catheter site. If PD is required the day of catheter placement, or before the 2-week waiting period, nephrologists usually prescribe smaller dwells and keep the patient in a supine position to prevent increased intra-abdominal pressure. If leakage occurs around the catheter site, the dialysis must be stopped, and the patient should go on temporary HD until the catheter site has completely healed.

Fluid Status

As with HD, patients with ESRD on PD can develop difficulties with hypervolemia causing hypertension and left ventricular hypertrophy over time. Several studies have shown that fluid status in PD patients is not better maintained compared with HD patients. Studies evaluating ECF volume in PD patients found that patients with significantly reduced residual kidney function had significantly elevated ECF volumes, even when using high-dextrose concentrations in their PD dwells to promote maximal ultrafiltration.[50] Peritoneal membrane characteristics and residual kidney function are important in the maintenance of fluid balance in PD patients.

Most attention has been devoted to peritoneal membrane characteristics as a culprit for excessive fluid status in PD patients. Ultrafiltration in PD is achieved by osmotic forces using dextrose concentrations in the PD fluid. The higher the dextrose concentration, the more free water is filtered from the extracellular compartment. Adequate clearance and ultrafiltration also is directly related to the permeability of the patient's peritoneal membrane. The chronic exposure to these dextrose peritoneal dialysate dwells, although required for fluid removal, can work against the patient.

Long-term exposure to glucose and glucose degradation products may have detrimental effects on the peritoneal membrane, with the gradual loss of ultrafiltration capacity.

Methods to improve fluid balance in PD patients include a sodium-restricted diet, fluid restriction, and the use of diuretics in patients with adequate residual renal function. Alternatives to glucose-containing solutions in PD dialysate, such as icodextrin, also need to be considered to save the peritoneal membrane from the effects of chronic exposure to glucose and to improve ultrafiltration. Improving fluid balance results in improved blood pressure control and cardiac status with reduction in left ventricular hypertrophy.

Electrolytes

Sodium

PD solution typically contains 132 mmol/L sodium. Most patients maintain normal serum sodium on PD. Patients who drink excessive amounts of water can get a dilutional hyponatremia. Conversely, with rapid ultrafiltration, hypernatremia may occur owing to the different convective forces of sodium on the semipermeable peritoneal membrane, resulting in more free water being ultrafiltrated compared with sodium (see Table 3-4). Current dietary restriction for sodium is slightly less stringent than that of HD. Although a 2-g restriction is preferred, 4 g of daily sodium intake is allowed (see Table 3-3).

Potassium

Standard PD solution contains no potassium. As in HD, potassium is removed during PD by diffusion and convection. Usually, only patients who are noncompliant in performing their dialysis exchanges have ongoing problems with hyperkalemia. Cases of hypokalemia are usually seen in patients undergoing continuous ambulatory PD with poor nutritional intake (see Table 3-4). PD patients usually do not require a potassium-restricted diet. In some cases of persistent hypokalemia, potassium supplementation my be required. This is reflected in current dietary recommendations of 3 to 4 g of daily potassium intake (see Table 3-3).

Calcium and Phosphorus

PD patients have the same difficulties with hyperphosphatemia as HD patients. The same treatments apply to both dialysis populations, including dietary recommendations (see Table 3-4). Patients taking calcium-containing phosphate binders may have hypercalcemia. In these particular patients, lower calcium–containing peritoneal dialysate can be used at 1.25 mmol/L in place of the normal 1.75 mmol/L of calcium in the dialysate.

Anemia

There is an increased incidence of iron deficiency, ranging from 40% to 90% of patients on PD. Lower intestine mucosal uptake and rates of iron transfer are present in PD patients. Usually these patients are able to retain only approximately 5% of oral iron therapy they are taking under ideal conditions. As anemia improves during iron therapy, there is a downregulation of iron mucosal uptake mechanisms that may be responsible for the dramatic reduction in iron retention found in these patients. In three separate studies, three fourths of PD patients known to respond inadequately to oral iron supplementation responded to intravenous iron therapy with improvement in hemoglobin, hematocrit, and iron parameters.[1,12] When iron is replete, there seem to be minimal differences in responsiveness to erythropoietic stimulating proteins.

Adequacy

A PD patient's treatment success depends on the functional and morphological integrity of the peritoneal membrane. NKF K/DOQI guidelines for PD adequacy include a weekly peritoneal and renal Kt/V of greater than 1.7 in both CAPD and CCPD. The functional integrity of the peritoneal membrane is investigated with kinetic modeling; this is done every 4 months and assesses the clearance of the peritoneal membrane and the clearance of the residual kidney function. The principal determinants of PD dose are the patient's body mass, residual kidney function, and peritoneal transport rates. Residual kidney function is important in maintaining PD adequacy and assisting in fluid removal. It contributes substantially to the PD adequacy, maintenance of fluid balance and kidney endocrine function, and a reduction in systemic inflammation. Several studies have confirmed the finding that there is a 12% survival advantage for every 5 L/wk/m^2 increase in residual kidney function.[50]

There are numerous techniques for measuring peritoneal transport, the most widely used being the peritoneal equilibration test for examining the morphological integrity of the membrane. This is usually performed 4 weeks after starting PD to define an appropriate dialysis schedule based on membrane properties. Long-term PD may lead to anatomical changes in the peritoneal tissues, including fibrosis, neoangiogenesis, vasculopathy, and peritoneal sclerosis. These anatomical changes cause alterations to the peritoneal membrane, which have an impact on a patient's dialysis and are reflective in changes of a peritoneal equilibration test.[6]

Complications

The most common and most dangerous complication involving PD is infection, specifically infection of the exit site of the peritoneal catheter, the tunnel of the peritoneal catheter, and peritonitis itself. Other important complications unique to PD include leaking around the catheter, bloody peritoneal effluent, abdominal pain *not* related to peritonitis, hyperlipidemia, new-onset or worsening diabetes, and chronic hypoalbuminemia.

Infection

Daily human error with PD technique can enhance infection risk. Peritonitis and exit site and tunnel infections remain the predominant complications of PD, ranging from abdominal pain and poor dialysis to permanent damage of the peritoneal membrane, loss of the catheter, sepsis, and death. Peritonitis remains a leading complication of PD. Although it can occur spontaneously, most cases are due to an initial exit site or catheter infection that eventually seeds the peritoneum.

The most common exit site pathogens are *Staphylococcus aureus* and *Pseudomonas aeruginosa*.[40] Because these organisms also lead to peritonitis, exit site infections must be

treated aggressively. The exit site should be cultured because other bacteria can be involved, and proper diagnosis should direct treatment. Gram-positive organisms are treated with oral penicillinase-resistant penicillin or a first-generation cephalosporin. In slow-to-resolve or severe *S. aureus* exit site infections, rifampin may be added, but it should never be used as monotherapy or where tuberculosis is endemic. *Pseudomonas aeruginosa* exit site infections often require prolonged therapy with two antibiotics. Oral quinolones are recommended as the first choice, with the second drug being intraperitoneally dosed ceftazidime.[40] Two weeks is the minimal treatment time for exit site infections. Any pain or erythema along the tunnel of the PD catheter should raise concerns for a possible tunnel infection. A bedside ultrasound examination along the tract of the tunnel with echogenic findings can lead one to presume likely tunnel infection.

PD patients presenting with cloudy effluent should be presumed to have peritonitis. Peritonitis should always be included in the differential diagnosis of a PD patient with abdominal pain, even if the effluent is clear, because a small percentage of patients with peritonitis present with such symptoms. Although patients with peritonitis often have severe pain, some episodes are associated with mild or even no pain. Peritonitis is confirmed by obtaining effluent cell count, differential, and culture. Although the Gram stain is often negative in the presence of peritonitis, this test should be performed because it may indicate the presence of yeast, allowing for prompt initiation of antifungal therapy and permitting timely arrangement of catheter removal. An effluent white blood cell count of greater than 100/μL, with at least 50% polymorphonuclear neutrophil cells,[40] indicates the presence of inflammation with peritonitis as the most likely cause.

Antibiotic therapy should be initiated as soon as cloudy effluent is seen, without waiting for the confirmatory cell count. Empirical antibiotics must cover gram-positive and gram-negative organisms. Intraperitoneal vancomycin or a cephalosporin (cefazolin) can be used for gram-positive coverage with a third-generation cephalosporin (ceftazidime, cefepime) or aminoglycoside for gram-negative coverage.[40] Aztreonam is an alternative to ceftazidime or cefepime for gram-negative coverage if aminoglycosides are not used and patients have a cephalosporin allergy. Antibiotic therapy should be adjusted when culture results are known. The antibiotics are given through the intraperitoneal route, and there are dosing schedules for once-daily extended dwells with intraperitoneal antibiotics versus antibiotics in each dwell. In intermittent dosing, the antibiotic-containing dialysis solution must be allowed to dwell for at least 6 hours to enable adequate absorption of the antibiotic into the systemic circulation. If there is no growth of the cultured peritoneal fluid by 3 days, a repeat cell count with differential should be obtained. If the repeat cell count indicates that the infection has not resolved, special culture techniques should be used for the isolation of potential unusual causes of peritonitis, including lipid-dependent yeast, *Mycobacterium, Legionella*, slow-growing bacteria, *Campylobacter*, fungi, *Ureaplasma, Mycoplasma*, and enteroviruses.

For gram-positive infections, vancomycin can be given intermittently with the next dosing based on serum trough levels drawn 72 hours after initial dose.[40] Repeat dosing is appropriate when serum vancomycin levels reach 15 μmol/L or less. Coagulase-negative *Staphylococcus* peritonitis, including *S. epidermidis*, is due primarily to touch contamination and is generally a mild form of peritonitis. This peritonitis responds readily to antibiotic therapy, but sometimes can lead to relapsing peritonitis as a result of biofilm involvement. In such circumstances, catheter replacement is advised. Most patients with *S. epidermidis* peritonitis have mild pain and can be managed on an outpatient basis. In programs with a high rate of methicillin resistance, vancomycin can be used as empirical therapy. Streptococcal and enterococcal peritonitis tend to be severe, causing considerable abdominal pain. They are best treated with intraperitoneal ampicillin.[40] Because enterococci are frequently derived from the gastrointestinal tract, intra-abdominal pathology must be considered, but touch contamination as a source is always possible. Peritonitis with enterococci or streptococci also may derive from infection of the exit site and tunnel, which should be carefully inspected.

S. aureus causes severe peritonitis. Although it may be due to touch contamination, it is often due to catheter infection. Catheter-related peritonitis is unlikely to respond to antibiotic therapy without catheter removal. After a rest period from PD (generally a minimum of 2 weeks), PD can be tried again. Polymicrobial peritonitis secondary to multiple gram-positive organisms is not only more common than polymicrobial gram-negative peritonitis but also has a much better prognosis than that due to enteric organisms. The source is most likely contamination or catheter infection.

Short-term use of aminoglycosides seems to be safe, inexpensive, and efficacious for gram-negative coverage. Oral quinolones are an acceptable alternative because they reach adequate bactericidal levels within the peritoneum, even with the cycler. Oral therapy is unsuitable for more severe cases of peritonitis. *P. aeruginosa* peritonitis is generally severe and often associated with catheter infection. If catheter infection is present or has preceded the peritonitis, catheter removal is necessary. Two antibiotics for 2 weeks of therapy should always be used to treat *P. aeruginosa* peritonitis. Single-organism gram-negative peritonitis (*Escherichia coli, Klebsiella, Proteus*) may be due to touch contamination, exit site infection, or transmural migration from constipation or colitis. Outcomes of these infections are worse than outcomes with gram-positive infections and are more often associated with catheter loss and death. If multiple enteric organisms are grown on culture, there is a possibility of intra-abdominal pathology, such as ischemic or perforated bowel, gangrenous cholecystitis, appendicitis, or diverticulitis. A surgical evaluation along with abdominal radiographs or computed tomography scan, or both, to rule out free air and identify intra-abdominal pathology is helpful. The minimal period of therapy for peritonitis is 2 weeks, and although not evidenced based, the common practice is to increase therapy to 3 weeks for more severe infections.[40]

Refractory peritonitis, defined as failure to respond to appropriate antibiotics within 5 days, should be managed by removal of the catheter to protect the peritoneal membrane for further use. Fungal peritonitis is serious, leading to death of the patient in approximately 25% or more of episodes. Some evidence suggests that prompt catheter removal poses less risk of death. Intraperitoneal use of amphotericin causes chemical peritonitis and pain, and intravenous administration leads to poor peritoneal penetration. Therapy with oral antifungals should be continued after catheter removal for an additional 10 days.[40] Mycobacteria are an infrequent cause of

peritonitis but can be difficult to diagnose, and the treatment requires multiple drugs. When culture is being considered, special attention should be paid to culture technique.

Catheter Leak

A catheter leak should be classified according to when the catheter was originally placed. An early leak is one that occurs within 30 days of catheter placement. A late catheter leak is more than 30 days from placement. A simple bedside test to determine if the clear exudate is dialysate is to place a urine dipstick against the fluid; a positive glucose on the urine dipstick is confirmatory. Early leaks usually are related to catheter placement and manifest as external leakage, either at the exit site or at a medial or parasternal surgical wound. Early leaks also can occur if the catheter site has not been given enough time to heal fully after implantation, and dwell size is creating enough intra-abdominal pressure to cause extravasation of PD fluid. Late leaks are most often related to a mechanical or surgical tear in the peritoneal membrane, presenting as internal leakage, which can be found in the pleural cavity, abdominal wall, and external genitalia.

Bloody Effluent

Hemoperitoneum is a benign condition of PD, with no significant long-term effects on patient survival, no predisposition to peritonitis, and no predisposition to ultrafiltration failure. Bloody effluent can occur at any time during a PD treatment, but usually disappears spontaneously. It is not associated with a specific disease, but nonperitoneal causes include retrograde menstruation and renal cyst hemorrhage. Treatment includes three 1.5% dextrose rapid exchanges with no dwell time or infusion of unwarmed dialysate, which induces peritoneal vasoconstriction.

Abdominal Pain Not Related to Peritonitis

Pain with PD with clear dialysate without an elevated cell count still must be evaluated thoroughly to ensure continued, adequate daily dialysis. Inquiring about fill and drain times can help discern if there is a mechanical problem with the catheter; this can be reviewed further with an abdominal film to look at the position of the catheter. An abdominal film also can diagnose other potential complications of PD, including free air and diaphragm perforation. Fibrin also can be a culprit for pain on fill or drain, and adding heparin to the dialysate bags can alleviate this problem. Pain on drain can be due to part of the membrane forming suction to the catheter. This can be remedied by decreasing dwell time or adding a tidal volume, which allows for an excess of dialysate in the abdominal cavity to keep the catheter free floating. Pancreatitis also should be considered, checkings amylase and lipase levels, because the calcium in the dialysate comes in direct contact with the lesser sac of the pancreas.

Hypoalbuminemia

Approximately 0.5 g of protein can be lost per each 1 L of dialysate drained during PD. This can account for 20 g of protein loss a day. Although the protein loss is predominantly albumin, 15% can be IgG. Higher peritoneal transport rates can cause increased albumin loss, and acute inflammation of the peritoneal membrane, as in peritonitis, creates a more permeable membrane and leads to higher protein losses. It is important to evaluate both peritoneal and renal losses of protein in a hypoalbuminemic patient.

Hyperglycemia and Hyperlipidemia

Glucose is a cheap, stable, and standard osmotic agent in peritoneal dialysate. With each CAPD exchange, 80% of dialysate glucose is absorbed across the peritoneal membrane, which can lead to metabolic derangements, in particular hyperglycemia. Peritoneal glucose absorption also may lead to abnormalities in the lipid profile and hyperinsulinemia. Increased glucose absorption also may lead to fatty liver infiltration. Hyperinsulinemia can result in persistently elevated plasma insulin levels, which are an independent risk factor for atherosclerosis. Supplemental insulin may be required for a diabetic patient undergoing PD. Regular insulin can be added to the dialysate, with specific amounts of insulin corresponding to the dextrose concentration within the PD dialysis solution. Serum blood glucose should be monitored closely. Compared with HD patients, PD patients have more difficulties with weight gain; 800 kcal/day can come from the dialysate dextrose alone. The elevated serum glucose levels from the dextrose dwells play a large part, along with the additional or increased need for exogenous insulin administration.

CONTINUOUS RENAL REPLACEMENT THERAPY

The major difference between intermittent and continuous therapies is the speed at which water and wastes are removed. Intermittent HD removes large amounts of water and wastes in a short time (usually over 2 to 4 hours), whereas continuous renal replacement therapy (CRRT) removes water and wastes at a slow and steady rate. Although intermittent dialysis allows patients with chronic renal failure to limit the amount of time that they are connected to a machine, the rapid removal of water and wastes during intermittent treatments may be poorly tolerated by hemodynamically unstable patients. The basic principles of conventional HD with slow, extended dialysis allowing gradual volume removal have resulted in the creation of CRRT.

Although initially developed for fluid management in patients with diuretic-resistant fluid overload, modifications of the original technique have provided a collection of related therapies designed to provide uninterrupted renal support to critically ill patients over a period of days. Hemofiltration, HD, and hemodiafiltration differ primarily in their mechanism of solute movement. In hemofiltration, solute removal occurs predominantly by convection; in HD, it occurs by diffusion; and in hemodiafiltration, it occurs by both convection and diffusion. Although achievable clearances of low-molecular-weight solutes are similar with hemofiltration and HD, the convective therapies provide higher clearances for solutes with molecular weights greater than 500 to 1000 D. It has been postulated that enhanced clearance of inflammatory mediators in this molecular weight range, particularly in patients with acute renal failure associated with sepsis, provides an added benefit to convective therapies. Although modulation of plasma levels of tumor necrosis factor-α and interleukin-6 can be achieved with CVVH, a corresponding clinical benefit has not yet been shown.[17,25]

CVVH is the removal of large amounts of water across the filter membrane for the purpose of clearing wastes. When large volumes of water are washed across the membrane, solutes are dragged along with the water (convection).

Hemofiltration is the removal of water over and above the surplus water removed during ultrafiltration. To prevent hypovolemia, any water removed during hemofiltration must be returned to the blood before it reaches the patient. This is called "replacement" fluid. Hemofiltration rates of 1 L/hr mean that 1 L of fluid is removed from the patient's blood and eliminated in the drainage fluid, and 1 L of replacement fluid is returned to the circuit before it reaches the patient. Hemofiltration rates are set by adjusting replacement rates. Any fluid removed during hemofiltration is given back to maintain a net neutral fluid balance. Replacement fluid must be sterile intravenous fluids with concentrations of electrolytes similar to plasma. Replacement fluids can be returned either before or after filter; this is referred to as predilution or postdilution sets. Predilution means that the replacement solution is returned to the blood before it reaches the filter, diluting the blood in the hollow fibers. Postdilution means that the replacement fluid is returned to the blood after the filter (but before the return side of the access catheter). Predilution dilutes the blood in the filter, reducing clotting. Postdilution concentrates the blood in the filter, enhancing clearance.

CVVHD is the infusion of dialysis fluid into the dialyzer. Solutes that are small enough to fit through the membrane of the dialysis filter move from an area of high concentration to low concentration (diffusion). The dialysate determines the solutes that will be removed. To remove solutes, the concentration in the dialysate should be made lower compared with the blood concentration. To increase solutes, such as electrolytes, in a patient, the concentration of solutes in the dialysate is higher than the blood. CVVHD is the removal of wastes by diffusion only, without the use of hemofiltration (replacement fluid). It can be administered with or without fluid removal from the patient.

Continuous venovenous hemodiafiltration is the use of dialysis and hemofiltration. Therapy includes the use of dialysate and replacement fluids and can be administered with or without fluid removal from the patient.[36]

Process

Although the machines may differ, the basics of the system setup remain relatively the same. For all modalities of CRRT, vascular access is the double-lumen HD catheter. In CVVH, blood is drawn out from the arterial port by a pump and is delivered to a dialyzer through tubing. Before the patient's blood reaches the dialyzer, there is a port for anticoagulation. When the blood reaches the dialyzer, a convective process occurs across a pressure gradient within the dialyzer. Ultrafiltrate is pulled off within the dialyzer through a separate pump, and this effluent is collected in a separate bag. When passed through the dialyzer, the blood is returned to the patient by another pump passing the blood back to the patient in the venous port. Replacement fluid is crucial to the circuit, mixing with the patient's blood either right before or after the dialyzer.

In CVVHD, the circuit is similar, with blood coming from the arterial port of the HD catheter by a pump, with anticoagulation added before the blood enters the dialyzer. Blood traverses the dialyzer by diffusion across a concentration gradient. Dialysate is pumped countercurrent to the blood when in the dialyzer, and ultrafiltrate is collected from the dialyzer through separate tubing into a separate effluent collection bag. When passed through the dialyzer, the patient's blood is returned by a pump through the venous port. Continuous venovenous hemodiafiltration is a combination of CVVH and CVVHD, using replacement fluid and dialysate along the same circuit. The current dialysis dose of replacement fluids in CVVH is 35 mL/kg/hr. Blood flow in CVVH runs between 100 and 300 mL/min. Replacement fluid runs between 1000 and 3000 mL/hr. Dialysate flow runs at 1000 mL/hr. Ultrafiltration varies depending on the clinical situation, ranging from none to 200 mL/hr.

Anticoagulation is needed in CRRT because the clotting cascades are activated when the blood touches the nonendothelial surfaces of the tubing and filter. CRRT can be run without anticoagulation, but filters last much longer if some form of anticoagulation is used. Advantages for longer filter life include reduced time off therapy. The main options for anticoagulation include heparin, citrate, or no anticoagulation. Regional anticoagulation of the filter can be achieved through the use of citrate.

Electrolyte Abnormalities

The convection in CRRT can predispose a patient to hypocalcemia, hypomagnesemia, hypophosphatemia, and metabolic acidosis with loss of bicarbonate. These conditions can be easily circumvented through the additional infusion of calcium and magnesium through a central line and addition of phosphorus and bicarbonate in the replacement fluids. To maintain normal serum electrolyte levels, dialysate fluid contains sodium, chloride, and magnesium levels that are equal to serum concentrations (removal of these electrolytes should occur only if the blood level exceeds normal serum concentrations). In renal failure, potassium is often high at the start of a treatment; we may begin dialysis with a low concentration of potassium in the dialysate. Because potassium is easily removed during dialysis, and continued dialysis is required to ensure removal of other wastes, such as urea and creatinine, potassium concentrations in the dialysate often require upward adjustment as the potassium level in the blood falls. Although in theory, potassium levels should not decrease to less than 4 mmol/L in the serum if the dialysate contains 4 mmol/L, many factors influence serum potassium levels in critical care. Insulin therapy and the use of sympathomimetic drugs promote the movement of potassium from the blood into the cells; this can reduce serum levels. Additionally, potassium loss through the gastrointestinal tract can increase the potential for hypokalemia. Low magnesium levels also suppress the serum potassium levels; magnesium deficits should be replaced as needed. Additionally, high hemofiltration rates can lead to additional potassium clearance. Potassium levels must be monitored closely and adjusted to maintain normal serum concentrations. In renal failure, serum bicarbonate levels are generally low; a source of bicarbonate is added to the dialysate to facilitate diffusion of bicarbonate into the blood.

Complications

Citrate Toxicity

Citrate is used as an anticoagulant during CVVH. Preventing clotting of the system is crucial to maintain adequate clearance and proper electrolyte balance. Citrate has been

shown to increase kidney filter half-life over normal saline.[34] It works as an anticoagulant by binding to calcium, an essential element to coagulation in the intrinsic pathway. Citrate is introduced into the system through the arterial line after the blood has left the patient and before it reaches the dialyzer. When in the dialyzer, it binds to calcium to prevent clotting within the membrane. Its efficacy is measured by comparing the ionized calcium in the blood before the filter (prefilter calcium) with the ionized calcium leaving the filter (postfilter calcium). A decrease in ionized postfilter calcium compared with prefilter calcium shows a trend toward adequate anticoagulation because it represents a binding up of citrate with ionized calcium, preventing the coagulation cascade. Understanding this process helps to interpret laboratory results during CRRT properly, specifically total and ionized serum calcium. Within the first 24 hours of starting citrate, there is an increase in the total calcium. This increase is to be expected because not only is circulating calcium bound to citrate, but also a separate infusion of calcium is infusing into the patient to ensure adequate levels of ionized calcium systemically. Calcium also can be bound by albumin, contributing to the total calcium. Problems arise when citrate levels become critically elevated in patients, causing acid-base and calcium disturbances.

The difference between citrate toxicity and citrate excess denotes not only changes in ionized calcium but also a serological change, which can be corrected and citrate continued (citrate excess) or cannot be corrected unless citrate is discontinued (citrate toxicity). In the instance of citrate toxicity, citrate is unable to be metabolized within the liver or skeletal muscle or both, leading to an acidosis and a decrease in ionized calcium with continued increase in total calcium. This condition is to be differentiated from citrate excess, in which citrate is able to be metabolized but, as citrate level increases, a profound metabolic alkalosis can occur. Although total calcium levels increase, the ionized calcium remains relatively stable. Appreciating these differences allows for appropriate decisions regarding citrate with CRRT. Patients exhibiting clear clinical signs of citrate toxicity need to have their citrate infusion stopped. Patients with citrate excess benefit from continuing CRRT, but with a lower rate of citrate infusion.

Access Issues

Because continuous modalities are considered temporizing measures for renal replacement therapy, the access for these therapies remains dialysis catheters. Even if a patient is a long-term HD patient and has a working fistula or graft, owing to the fact he or she would need to be cannulated for the entire duration of CRRT, the risk of needle infiltration or accidental misplacement can predispose the patient to thrombosis of the fistula or graft or possible exsanguination. A temporary dialysis catheter needs to be placed, along with another central line if CVVH is the chosen modality. These patients then have the same access issues as mentioned in the HD access section.

SUMMARY

Renal replacement therapy has had significant advances since its infancy in the early 1960s, but it remains an imperfect modality. The decision of what form of renal replacement to use must be based on the chronicity of the renal dysfunction and the patient's medical history, combined with the known outcomes of each type of modality. HD and PD differ from each other in their procedure and have risks and benefits unique to their technique.

Outcomes in fluid status, bone metabolism, anemia, cardiovascular disease, diabetes, nutrition, and overall morbidity and mortality have been compared between HD and PD. Patients on PD have improved stable fluid status compared with patients on HD, relative to the patient's residual renal function.[19,38] When residual renal function is lost, hypervolemia can worsen in PD patients, resulting in difficult-to-control hypertension. Related to bone metabolism, secondary hyperparathyroidism with elevated prevalence of bone lesions is more common in HD patients, whereas adynamic bone disease is much more frequent in PD patients.[9,47] Red blood cell survival is higher in PD patients, and PD has been found to be more effective in maintaining erythropoiesis compared with HD.[28,33,41]

Cardiovascular diseases are the main cause of death in dialysis, without a significant difference between the two modalities.[45] Although PD is associated with a higher atherogenic risk, after stratification by diabetic status and adjustment for differences in age, gender, and previous cardiovascular disease, Cox analysis showed no significant difference in the risk of developing cardiovascular disease between PD and HD.[30] Related to morbidity, hospitalizations between HD and PD patients are skewed toward PD, related in part to peritonitis. Findings from the USRDS 2003 Annual Report show that the number of admissions is similar but that the number of hospital days is higher by approximately 15% in PD patients.[10] The easily diffusible dextrose contained in PD dialysis solutions can cause new-onset hyperglycemia and cause worsening blood glucose levels in established diabetics. A large assessment of more than 890 diabetics treated with HD and PD found no difference in survival, although the survival curve indicated worse results in the PD population after 2 years.[32] Several reports have confirmed that nutritional indices are worse in PD patients compared with HD patients.[22,23,26] Nutritional status is influenced by dialysis dose and residual renal function.

There have been conflicting outcome studies regarding comparison of mortality between the two modalities. A comparative analysis of HD and PD survival controlled for the delivered dose of dialysis showed that when the dose of dialysis is the same between modalities, HD and PD have comparable 2-year survival rates, independent of diabetes, age, and history of cardiovascular disease.[24] In contrast to the previous study, a prospective cohort study published in 2005 showed the risk of death to be significantly higher among patients undergoing PD in the second year of follow-up.[21] Other studies have shown that in diabetics and nondiabetics, PD patients with chronic heart failure have a greater risk of death than HD patients.[45] Stratifying for diabetes, a study in 2004 found that diabetics older than 65 years had a similar risk of death in HD and PD, with younger patients, diabetic and nondiabetic, having a significantly lower risk of death on PD.[8]

Neither HD nor PD poses a greater long-term outcome after renal transplantation. Although early post-transplant PD patients have been observed to fare better with transplant function, long-term results of renal transplantation are no different in patients treated with either PD or HD.[44]

When a patient proceeds to dialysis, he or she must make necessary changes to his or her lifestyle to promote the best

outcome on dialysis. These changes include fluid restriction; a renal diet that includes moderation in potassium-containing, sodium-containing, and phosphorus-containing foods balanced with adequate protein intake; close monitoring and treatment of hypertension; and maintenance of dialysis access.

Chapter 4

The Recipient of a Renal Transplant

Jeremy R. Chapman

THE PATIENT WITH CHRONIC KIDNEY DISEASE

Most patients with chronic kidney disease (CKD) in developed countries present to medical services at a stage when there is still time to plan their transition to end-stage renal failure treatment. Only a few take the opportunity to understand their disease, learn about their dialysis and transplant options, and then plan smooth adoption of one or another therapy. Insidious and asymptomatic decline in renal function perhaps accounts for the naive attitude that most people have when it comes to ignoring warnings. The physician's primary aim should be to educate and inform the patient and family, while treating the treatable components and retarding the progression of CKD. More educated and financially stable patients tend to be better prepared for the onset of end-stage kidney disease, whereas at the other extreme, poorly educated, frightened, or noncompliant patients tread a hazardous course to dialysis and often an earlier death.

Individuals who plan their treatment well and receive a living donor transplant preemptively before the requirement for dialysis tend to have the best outcomes.[17,63] Most transplant recipients worldwide do not have this optimal approach and are treated by hemodialysis or peritoneal dialysis for weeks, months, or years before the transplant operation. There are some benefits to pretransplant dialysis, especially if the patient is chronically debilitated by CKD, or if time is needed to enable a family member to understand the benefits of offering a kidney. The experience of dialysis also provides a window on the alternatives to a renal transplant, either strengthening or weakening an individual's resolve for the operation and the long-term consequences of immunosuppression. Each patient comes to make the decision about whether or not to opt for a renal transplant slightly differently, based on his or her precise medical, social, and family circumstances. This chapter presents the issues that the patient, the patient's family, and the community must consider in making the irreversible step of undergoing a renal transplant.

GENERAL CONCEPTS

Fitness for Transplant

The patient has, in principle, a simple question to consider: Will the quality and quantity of life be better after a transplant than on dialysis? For many individuals, the answer is clear and unequivocal—either because the alternative of long-term dialysis treatment is unavailable or unaffordable[41] or because transplantation is the obvious solution because the individual is young and otherwise fit. For some individuals, however, the answer is not clear because of the relative unavailability of organs for transplantation or because the individual has comorbid conditions that would be exacerbated by the operation or the ensuing immunosuppression. There is little information available to help individuals make the decision easily.

Quality of life is the most important issue for most individuals, and yet good studies comparing quality of life on dialysis and after transplantation have not been done. The clinician working in a transplant unit seldom identifies individuals with a lower quality of life after a successful transplant than they had or would have had on dialysis and finds it easy to advocate for transplantation. This simple perspective ignores the patient deaths and graft failures and ignores the individuals who struggle with the consequences

of the iatrogenic immunodeficiency state, with its attendant infections and malignancies. In the absence of information, transplant programs tend to substitute graft survival data for true quality-of-life data and use it as a surrogate, but objective, measure of the success that each individual might expect.[87]

The most secure data on which to base the decision to use dialysis or to receive a transplant are measured comparisons of quantity of life.[70,100] In a country without effective access to dialysis, the decision is obvious for all patients, except those with severe comorbid conditions that would prevent a safe operation. Transplantation is, for many individuals, the only alternative to a slow death from uremia. This statement assumes access to immunosuppressive drugs and lifelong specialist medical follow-up, either of which may be unavailable. The patient's and family's understanding of the commitment that a transplant requires is an important factor. Patient survival rates are substantially affected by compliance with follow-up, and that is substantially altered by the expectations of the patient. Transplantation has been promoted as a cure, when it is actually a complicated treatment requiring regular follow-up by specialists working in sophisticated medical centers and using expensive drugs that have been priced against the costs of a year of dialysis treatment. If the patient and family fail to understand the costs, level of follow-up, and compliance required of them, the published statistics of average survival likely would not apply to them.

Predicting the success rate after transplantation relies on characteristics of the recipient and the donor. Probably the most comprehensive studies comparing transplant recipients with patients remaining on dialysis come from the United States, where it has been possible to track the outcomes of all individuals entered onto the transplant waiting list and compare the individuals who underwent transplantation with those who remained on dialysis.[60,100] These studies show that transplantation carries the greater risk of death for the first 3 months or so, reversing after that time so that the risk of death is equal by 6 to 9 months, and thereafter favoring the transplant recipient (Table 4-1). Similar analyses show that a patient who is transplanted preemptively carries an advantage compared with a patient who has needed time on dialysis, and the longer the period of dialysis, the worse the outcome (Fig. 4-1).[17] These data apply to patients receiving an "average" donor graft, highlighting the fact that recipients of well-matched, young, living donor grafts fare substantially better.[69] The converse also is true: A marginal donor graft from an elderly deceased donor with hypertensive renal damage may not confer much survival advantage.[76] A dilemma exists for each patient on a deceased donor waiting list—whether to accept a worse quality graft early or to wait longer on dialysis for a better graft. Most patients take the first opportunity for a transplant instead of waiting in hope for a better one.

The patient's expectations from a successful transplant are to die in old age with a perfectly functioning kidney. The reality is that patients die much earlier than age-matched and sex-matched individuals without renal disease, and more than half lose their graft before they die.[14,68] From the patient's perspective, graft failure represents transplant failure, but from the community's perspective, premature death with a functioning graft represents wasted years of graft function that could have been applied to someone else.

Appropriateness for Transplant

There are two ways to examine the question of appropriateness for transplant, which can be considered from the view of the recipient or the donor. These views are not the same, and these perspectives may lead to different decisions about the appropriateness of a particular transplant. To illustrate the difference, consider an elderly father or mother in his or her late 60s without any comorbid conditions, deciding whether or not to accept a donation from a 30-year-old son or daughter. The son or daughter may consider it appropriate to offer a kidney to the parent, acknowledging the small but real immediate risks and possible, but unknown, long-term risks. The parent may consider it inappropriate to place his or her offspring at even the slightest risk to provide a benefit to the parent that would amount to only a few years of better quality of life. In the reverse situation, it may be considered appropriate for a 20-year-old recipient to undergo transplantation but not to accept a donor offer from an elderly parent because of the increased risk of donation by an elderly individual and because of the worse outcome predicted from an older kidney. Living donor transplantation provides the opportunity to address the individual circumstances of the donor and the recipient in great detail. It is the responsibility of the transplant unit to provide each individual with an independent medical advisor to ensure that the donor and the recipient can arrive at a considered decision.

In contrast to the living donor situation, the decisions on appropriateness to receive a transplant from a deceased

Table 4–1 **Survival Advantage in the United States during the 1990s Comparing Transplant Recipients with Patients on the Waiting List but Remaining on Dialysis**

Group	Relative Risk 18 Months after Transplant	*P* Value	Projected Years of Life without Transplant	Projected Years of Life with Transplant
All recipients of cadaver transplant	0.32	< .001	10	20
Age 0-19 yr	0.33	.03	26	39
Age 40-59 yr	0.33	< .001	11	22
Age 60-74 yr	0.39	< .001	6	10
Diabetes	0.27	< .001	8	19

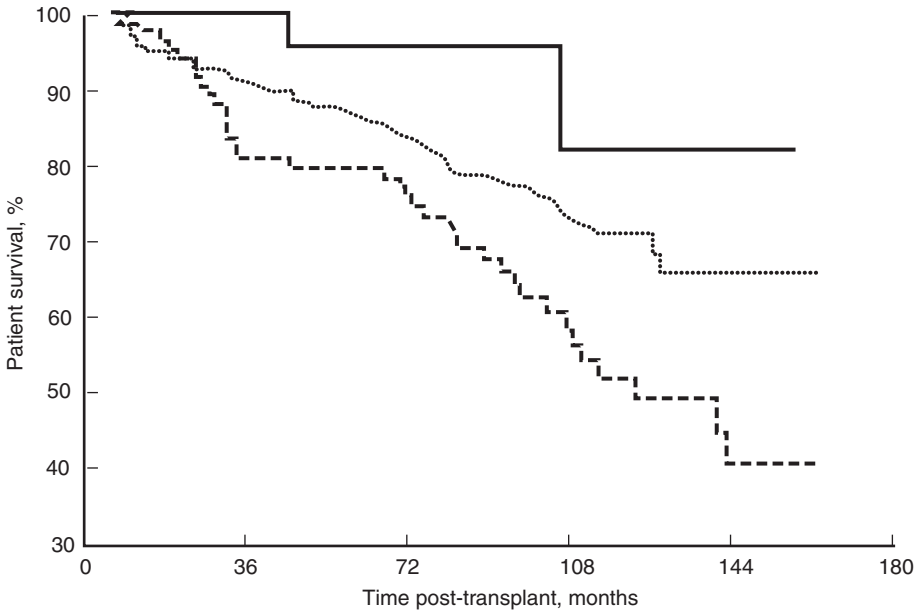

Figure 4–1 The role of preemptive transplantation in improving transplant survival. Kaplan-Meier plots of patient survival. Patients were divided into three groups according to the time they had spent on dialysis (any modality) before transplantation: no dialysis (—); 1 to 2 years (...); 3 or more years (---). Cox regression: P = .0003. (From Aalten J, Christiaans MH, de Fijter H, et al: The influence of obesity on short- and long-term graft and patient survival after renal transplantation. Transpl Int 19:901, 2006.)

donor organ have to be made largely in the absence of specific considerations and in advance of any offer. How many functioning years should the community expect from donation of a deceased donor kidney? For an elderly recipient, the decision to accept a transplant is, as described earlier, a reasonably simple equation comparing the prospects of life on dialysis and after a transplant.

For the individual, a likely benefit of 1 or 2 years of better quality life may be sufficient to sway the decision to accept a transplant. The community, as a whole, is faced with a different equation because of the undersupply of organs for transplantation in almost all countries. Should a kidney be allocated to a patient who has a life expectancy after transplantation of only 1 or 2 years, or should it be allocated only to someone with a life expectancy greater than the survival expectancy of the graft? As the mismatch between recipient and graft life expectancy increases, the community would be wasting functioning graft years and blighting the lives of individuals who could have used the organs better. If a community takes the view that only individuals with the best chance of maximizing the graft potential should be allocated a kidney, they would allocate only to young, unsensitized first-graft recipients without comorbid conditions; everyone else would be banned from receiving a deceased donor organ. All deceased donor allocation systems need to find balance between utility and fairness or equity. The elements of such systems include criteria for acceptance onto transplant waiting lists, including criteria such as age and medical fitness, and algorithms for allocation of particular organs, taking into account issues such as blood group, histocompatibility, crossmatching, waiting times, and donor and recipient ages.[55,66]

Most developed countries have well-organized computer algorithms determined by committees including medical and lay representatives, with audit of compliance. In allocation systems in which such algorithms are not applied, it is hard to see how either fairness or utility can be served and the appropriateness of organ allocation shown. The overall final impact of the multiple selection criteria can be seen in the Australian data (Fig. 4-2) in which the proportion of the dialysis population in each age cohort actually awaiting a deceased donor transplant is shown to diminish dramatically as age increases, whereas children are few in number and frequently transplanted with living donor kidneys.

COUNSELING

What the Patient Needs to Know

The transplant unit has the responsibility to provide each patient with advice based on his or her own medical conditions and education about the options for long-term treatment. The starting point for such education is comprehensive evaluation of the availability and financial cost of dialysis options. The physical and emotional well-being provided by dialysis therapy usually becomes abundantly clear to most patients through meeting other patients already on dialysis, through dialysis education programs, and finally through direct personal experience except in the few patients able to undergo preemptive transplantation.

The transplant unit needs to provide a comprehensive evaluation of each individual's medical risks if he or she were to undergo a renal transplant.[44] Much of the rest of this chapter details the medical assessment; a checklist is provided in Table 4-2. This list includes the issues that affect an individual patient's transplantability and the short-term and long-term factors that influence outcomes. In assessing the patient's suitability for a transplant operation, the physician focuses on the heart and lungs, and the surgeon focuses on the blood vessels and bladder. The surgeon needs to discuss the various complications and risks of the surgical procedure, whereas the physician discusses the drugs and long-term

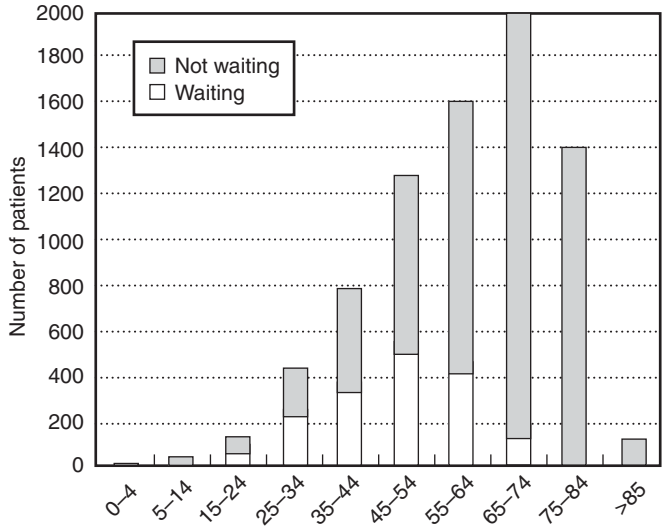

Figure 4–2 The proportion of patients on dialysis in each age group who were actively awaiting a cadaver donor transplant in Australia in 2000. (Data courtesy of ANZDATA.) Available at www.anzdata.org.au.

risks and follow-up protocols. Providing the patient with sufficient knowledge about organ allocation processes, the pros and cons of particular donor kidneys, and the financial costs that the patient will be expected to bear can be easily left out of a traditional medical consultation. Most established transplant programs have additional formal education sessions provided by a range of specialized coordinators, social workers, and pharmacists. The Internet also provides a wide range of good and bad information, which patients are sure to access extensively.[39,40] Guides to the good sources and warning against the bad sources of information also must be a part of the advice provided by the transplant program.

It is normal practice to seek written informed consent just before undergoing any surgical procedure, and all transplant operations are preceded by such a ritual signing of a legalistically phrased document. Somewhere among this scant and hastily signed documentation is the expectation that the individual has accepted the myriad risks of transplantation, ranging from transmission of serious disease from the donor to the side effects of every drug that recipient will be given. Many patients also are presented with an array of research protocols to sign up to, with patient information sheets of many pages of closely typed and densely constructed language designed to protect the researcher more than the patient. This documentation of "consent" often takes place under pressure of time and in the middle of the night, even sometimes via the telephone. It is hard to see how anything provided by the patient in the haste of the anesthetic workup, no matter what it is written on, can be argued to be informed consent. Legal opinions have been given that suggest that no reliance can be placed on a patient's decision taken under the pressure of an immediate pretransplant consent, unless backed by extensive prior education and information. In constructing education programs, it would be wise for the transplant unit to consider the traditional "operation consent form" a legally valueless document.

Table 4–2 **Checklist for Pretransplant Education of the Patient and Family**

1. Medical condition
   - General cardiorespiratory fitness for operation
   - Impact of obesity
   - Vascular system suitability for operation
   - Urological complications
   - Risks of recurrent renal disease
2. Fitness for lifelong immunosuppression
   - Infections
   - Malignancies, especially skin cancers
   - Cardiovascular risk factors
3. Histocompatibility and organ donor source impact on outcomes
4. Waiting times and allocations systems on the deceased organ donor waiting list
5. Availability and donor outcomes of living donor procedures
6. Financial costs and specific risks of the donor and transplant procedures, including disease transmission from the donor
7. Financial and adverse-event costs of prophylactic immunosuppressive and anti-infective drugs
8. Long-term follow-up protocol
9. Short-term and long-term risks of graft failure and death after transplantation
10. Consideration of acceptance of extended criteria donor organs
11. Patient-specific issues
    - Options for pancreas transplantation in diabetics
    - Options for liver-kidney transplantation in primary oxalosis

What the Potential Living Donor Needs to Know (see also Chapter 7)

A potential living donor usually needs to be provided information on the recipient outcomes and the donor operation with its attendant risks to decide on whether or not to proceed.

A donor who expects only a successful outcome of the donation for the recipient has a reasonable chance of being badly disappointed. It is essential that the best estimates of the risks of death and graft failure are clearly laid before the donor.[46,47] It also is important for most donors to understand the dialysis alternatives available to the patient and the deceased donor waiting lists times. In countries with substantial waiting list and long waiting times, living donation offers huge advantages that are not so clearly apparent in countries where waiting times are short. In countries with high deceased donor rates, the advantages of providing a better kidney with better long-term survival may be less obvious.

A living donor must provide fully informed consent to a surgeon with no conflicts of interest through his or her care of the potential recipient (see Chapters 7 and 38).[24] In addition, it is relevant for the donor to understand the blood group and histocompatibility match with the recipient and any concerns that there might be about the crossmatching data (see Chapter 10). A general overview of the risks that the recipient faces would help to ensure that the few procedures that end in disaster are not followed by endless recrimination and litigation. More importantly, a well-prepared donor is better able to face the future after a failed transplant or even death of the recipient.

What the Family Needs to Know

The families of pediatric patients are best regarded as if they were the patient with respect to the information and counseling that they require, although there are special considerations that young age brings to bear on the decision making in renal transplantation (see Chapter 35). The family of an adult patient is in a special situation compared with other areas of medicine because the family members represent a potential source of organ donation and cannot simply be thought of as interested onlookers and supporters for the patient. Transplant units vary in the way in which information is provided about family members' potential to donate a kidney; some units distribute information packs directly to all known family members, whereas others await specific approaches before providing information on living related donation. In countries with low deceased organ donation rates, the increasing attention being placed on living donation creates the atmosphere for routine dissemination of information to family members and friends.[86] Accurate provision of specific relevant information depends on the consent of the recipient to release private medical details. Asking the question, "Is there anyone in the family who would donate you a kidney?" elicits interesting insights into the dynamics of families with members with serious chronic illness. Some patients refuse to consider a discussion of their illness with their families, whereas others are glad that an independent individual is prepared to raise awareness in their family of the seriousness of their illness.

Lack of information is almost always the starting point for a breakdown in trust and communication among patients, their families, and their medical attendants. For this reason, it is important that even the most distant of families are aware of the possibility of a poor outcome from transplantation and the importance of compliance with medication and follow-up to the long-term success of the transplant.

SPECIFIC MEDICAL CONSIDERATIONS

Cardiac

The first consideration of any patient undergoing a 3- or 4-hour operation is the state of the patient's cardiac function. Dialysis patients and especially diabetic dialysis patients have high incidences of symptomatic and asymptomatic ischemic heart disease, and a careful evaluation of the heart is essential.[56] Evidence-based agreement on how to perform that assessment is lacking, so the assessment is highly dependent on local expertise and opinion.

All patients require a careful clinical history and examination, including an electrocardiogram and usually an echocardiogram to assess left ventricular function and a stressed myocardial perfusion study to exclude significant ischemic heart disease. Although CKD itself is the strongest risk factor for coronary artery disease, it also is important to assess obesity, family history, lipid profile, blood pressure, smoking history, and diabetes.[44] Attitudes toward smoking history vary among transplant units from refusal to transplant patients who continue to smoke to more liberal approaches.[18]

Some transplant programs require routine coronary angiography before acceptance onto a waiting list. A rationale exists for such an approach given the high levels of coronary disease uncovered by such a strategy.[27] The only randomized trial of surgical or medical intervention in this situation (diabetics with CKD) was so unequivocal about the value of intervention that the trial was halted, and the nonintervention arm was offered surgery or angioplasty.[60] The weaknesses of this study (it assessed only diabetics, and optimal medical therapy would not have been considered optimal more than 10 years on) and the lack of alternative randomized studies leave the field with uncertainties, but a clear view that diabetic patients need comprehensive cardiac evaluation.

An alternative strategy is to use a noninvasive test, such as a stress dopamine echocardiogram[91] or stress nuclear study,[16] as a screening method for asymptomatic and low-risk patients, reserving coronary angiography for patients with symptoms, significant risk factors, or a positive stress test. This strategy is not foolproof and relies on the negative predictive value of the screening test so that the occasional patient with ischemic heart disease would still be transplanted unknowingly and without the consideration of prior treatment of the cardiac disease.

Proceeding to transplantation in patients with normal left ventricular function and normal coronary vasculature is an easy decision. More complex issues surround deciding who to transplant despite their cardiac disease, which needs to be considered not only on its own merits but also because of the implications that it carries for widespread vascular disease.[44] There is no evidence-based answer to this question, and clinicians must rely on local opinion-based decisions, guided by some general principles, as follows.

Treatable coronary and valvular disease is almost always worth treating before transplantation rather than afterward because of the risks posed by the cardiac disease during the transplant procedure, and because of the risks that cardiac interventional procedures carry in the presence of immunosuppression and a functioning transplant.[59]

It is usually wiser to avoid transplantation if, despite treatment of coronary artery disease or valvular disease, or both, there remains a substantial risk of infarction of a large area of myocardium, or there is substantial left ventricular dysfunction. Cardiac disease is the largest cause of mortality in the dialysis and transplant populations, and there is little evidence that transplantation would beneficially alter the outcome of ischemic heart disease.[29] Less certainty exists with respect to congestive cardiac failure, where poorly dialyzed patients may recover significant function when uremia and chronic fluid overload are corrected by transplantation.[8] In patients with severe and irreversible cardiac dysfunction, the remaining consideration is the option of combined heart and kidney transplantation, available to limited numbers of young and otherwise healthy individuals treated in highly specialized centers.[36]

Vascular

An available artery for anastomosis of the transplant renal artery is absolutely required (see also Chapters 11 and 26). Atheromatous iliac arteries that have been ossified through years of CKD management must be assessed carefully by the surgeon planning to perform the transplant. Absence of intermittent claudication and presence of palpable femoral and pedal pulses may be sufficient to confirm transplantability. There are, however, many potential recipients with a high risk of severe vascular disease, where duplex ultrasound scanning of the femoral and carotid vessels would identify those who may have peripheral or cerebrovascular events either during or after transplantation.[73]

Selection of patients with known preexisting peripheral vascular disease must include a general assessment of their prognosis and specific assessment of the vascular supply needed for the transplant operation. The largest numbers of patients starting dialysis in most developed countries are elderly, obese, type 2 diabetics, and many have severe peripheral vascular disease.[95] Only a few such patients prove to be suitable for transplantation because of the combined effects of obesity and cardiac and vascular disease on their operative mortality and 3- to 5-year survival rates.[3] Two thirds of dialysis patients requiring lower limb amputations are dead within 2 years, implying that this group of patients has such a poor prognosis that they should not be accepted for transplantation.[26]

Symptomatic cerebrovascular disease presents a separate problem in selection for transplantation. A history of transient ischemic attacks should have promoted a search for a cardiac or carotid vascular cause, which if diagnosed and resolved or treated should not contraindicate subsequent transplantation.[21] The complication that warfarin anticoagulation of patients with atrial fibrillation provides the transplant unit usually can be overcome with a rapid anticoagulant reversal protocol and use of heparin in the post-transplant period before reinstituting warfarin anticoagulation. Warfarin therapy is not an absolute contraindication to acceptance for a deceased donor transplant. Completed stroke and severe carotid disease often place the patient in the same category, however, as patients with severe cardiac or peripheral vascular disease with respect to their general prognosis and the futility of transplantation. One group of patients that needs particular attention are those with adult polycystic kidney disease, especially if they have a personal or family history of cerebral aneurysm.[42] Evaluation of such high-risk patients requires cerebrovascular imaging, such as cerebral computed tomography (CT) angiography, to exclude berry aneurysms and specific neurosurgical advice, before considering transplantation.

Respiratory

Assessment of respiratory disease in the potential transplant candidate has two purposes: (1) to identify patients at risk from the anesthetic and (2) to identify patients who would be at risk of life-threatening infection in the long-term as the result of immunosuppression. The former is based around assessment of smoking and chronic obstructive airways disease and is no different from the assessment that must be made before any elective operation.[43] The latter is a more complex decision and remains largely subjective. The diseases of importance are bronchiectasis, tuberculosis, and prior fungal infections, all of which may become uncontrollable under the influence of immunosuppression. Formal evaluation of the degree of respiratory compromise and the frequency and severity of infective exacerbations determines the advisability of transplantation of a patient with bronchiectasis.

Active pulmonary tuberculosis must be identified from routine chest films and treated before consideration of transplantation.[4] Patients at high risk of reactivation of tuberculosis after transplantation include those from areas with high endemic rates.[90] History of exposure, calcified lesions seen on chest films or elsewhere, and a positive skin test to purified protein derivative all provide evidence of past exposure and risk of disease, but a negative purified protein derivative test cannot be relied on to exclude disease in anergic dialysis patients. Bacille Calmette-Guérin vaccination is not safe in transplant recipients[96]; in endemic areas, transplant units tend to advise high-risk patients to take a full treatment course for tuberculosis after transplantation, whereas in developed countries the practice, based on slender evidence,[4] is usually to add a prophylactic course of isoniazid for 6 months.[83]

Hepatic Disease

Hepatitis B

Most dialysis patients with past or current hepatitis B are identified through routine testing of serum for hepatitis B surface antigen (HBsAg) and antibodies to hepatitis B core and surface antigens (see also Chapter 30). Many dialysis programs have a routine hepatitis vaccination policy to improve protection from cross-infection, even though vaccination is much more effective if administered before the need for dialysis.[45] Most patients being assessed for transplantation have been screened for prior exposure to hepatitis B.

Data from transplantation of chronically infected HBsAg-positive patients, predominantly gained in the 1980s and 1990s, show worse outcomes than for HBsAg-negative patients.[30] Knowledge of the status of the liver histology is important in predicting outcomes after renal transplantation, with poor medium-term to long-term results with preexisting chronic active hepatitis and with cirrhosis.[32] It is unclear if the poor outcomes would still be reflected in data from transplantation performed in the past few years, with

use of post-transplant lamivudine therapy.[79] Choice of immunosuppression after transplantation may influence the progression of hepatitis, with concern expressed about steroids, azathioprine, and cyclosporine reactivating hepatitis B in a chronic carrier.[20] Hepatitis B is not a contraindication to renal transplantation, but established cirrhosis raises the option of combined liver-kidney transplantation.

Hepatitis C

Hepatitis C represents a different challenge to transplant programs in different countries, with very high prevalence in some dialysis programs and in patients who were dialyzed and transfused in the 1980s (see also Chapter 30). A high proportion of patients with hepatitis C infection eventually develop significant liver disease.[53] Treatment of patients with hepatitis C infection is made complex, if not impossible, by renal failure and requirement for dialysis because peginterferon alfa-2b and ribavirin are poorly cleared in, and thus not tolerated by, dialysis patients.[23] Hepatitis C genotypes 2 and 3 are more responsive to therapy than genotype 1, and it is warranted to attempt to treat patients before the onset of dialysis, although the genotype may not affect post-transplant outcomes.[74] Assessment of patients for the transplant waiting list should include hepatitis C antibody routinely, and, if that test is positive, hepatitis C RNA testing and assessment of viral load and genotyping. Most units rely on liver histology to assess the severity of hepatitis in potential transplant recipients, with advanced disease providing a contraindication to renal transplantation.[32] Patients without significant liver disease survive better if transplanted than if they remain on dialysis[81] but do not fare as well as patients without hepatitis C. The shortage of donor organs raises the question of whether patients with hepatitis C, especially hepatitis C RNA positive with genotype 1, should accept a kidney from a donor who is positive for hepatitis C antibodies, and which would otherwise be discarded. There is an argument for such a strategy in this limited group of recipients because they already are currently infected with hepatitis C, and the potential additional risk of transmission of further virus is small. There is no suggestion that a patient who has never been infected or who has cleared virus (i.e., is hepatitis C antibody positive, but RNA negative) should risk reinfection from a hepatitis C antibody–positive donor because the infection rates are high.[82]

Other Liver Disease

Potential renal transplant recipients may have other types of significant liver disease, such as alcoholic liver disease, polycystic liver in association with polycystic kidney disease, or cholelithiasis. It is important and simple to assess liver function and appearance of the liver on ultrasound. Fatty infiltration of the liver is the most common finding of such screening protocols and may be associated with diabetes, but is not in itself a contraindication to transplantation. Severe liver disease, no matter what the cause, inhibits acceptance for renal transplantation of most patients. Opinions on the role of prophylactic cholecystectomy in dialysis patients with known gallstones are diverse, but larger studies do not support this approach.[35]

Infectious Disease

See Chapter 29.

Vaccination Strategies

General community protection from infectious disease in most countries results in routine childhood vaccination against measles, mumps, polio, rubella, diphtheria, tetanus, pertussis, *Haemophilus influenzae* b, and varicella zoster; it is hoped that papillomavirus will soon be added to this list. Pneumococcal and hepatitis B vaccination programs are becoming more widespread but are far from universally applied. It is especially important in pediatric practice to ensure that vaccination has not been forgotten among the problems of pediatric renal failure.[28] In adult practice, it also is important to understand each patient's vaccination history and to remedy deficiencies as soon as possible because the responses to vaccines are generally impaired in the dialysis population.[52]

Vaccination of patients after transplantation is dangerous with live vaccines or may fail with killed antigen vaccines because the medication used to prevent allograft rejection is well designed to suppress production of an antibody response to a viral antigen. Mycophenolate mofetil is especially capable of preventing antibody production after vaccination.[92] Live vaccines are contraindicated after transplantation, with the most common error being the use of chickenpox vaccination with attenuated virus leading to life-threatening disseminated virus infection in transplant recipients.

Human Immunodeficiency Virus

Transplantation of patients with human immunodeficiency virus (HIV) was contraindicated until the recent era of antiretroviral therapy. The dire consequences of immunosuppression in a patient who was infected with HIV were discovered during the 1980s in patients infected before transplantation or when the virus was unwittingly transmitted through organ donation.[88] In the past few years, a few centers have developed expertise in managing HIV-positive patients after transplantation and have acceptable results.[80] It is universal practice to test recipients and donors for antibodies to HIV, with the decision to transplant the positive recipient depending on the concomitant availability of highly active antiretroviral therapy and local expertise in the transplant center.

Other Viral Infections

Knowledge of a recipient's status with respect to all herpes viruses has become increasingly relevant with developing understanding of the impact of these viruses after transplantation. Prophylaxis for cytomegalovirus, which also protects recipients for human herpesvirus 6 and human herpesvirus 7, is usually based on knowledge of the donor and recipient cytomegalovirus serological status (see Chapter 29). Transplantation of an Epstein-Barr virus–positive organ into an Epstein-Barr virus–negative recipient carries an increased risk of active Epstein-Barr virus infection after transplantation and of development of post-transplant lymphoproliferative disease. There is some evidence that anticytomegalovirus viral prophylaxis may reduce this risk.[85] All patients should be tested for antibody status with respect to each of the herpes viruses.

Dental Infections

The traditional approach to evaluation of the transplant recipient includes ensuring adequate dental hygiene and

review of dentition before acceptance for transplantation. Gingival hypertrophy is a consequence of higher doses of cyclosporine, especially when combined with nifedipine, and infected dentition may cause problems after transplantation, but it would be an unusual candidate in whom the risk of transplantation outweighed the risk of continued dialysis therapy on the basis of the patient's dentition.

Miscellaneous Infections

Transplant programs must pay heed to the particular infectious risks that are endemic and prevalent in their geographical region to evaluate properly the post-transplant risks for their transplant recipients (see also Chapters 29 and 36). *Trypanosoma cruzi*, the causative organism of Chagas' disease, is prevalent in South and Central America. It may be transmitted by donation and reactivated by immunosuppression, requiring serology and blood polymerase chain reaction surveillance and early treatment.[58]

Syphilis, strongyloidiasis, and toxoplasmosis all have been reported as opportunistic reactivations after transplantation. In most areas of the world, transplant programs require a heightened awareness and lower threshold for suspicion of these diseases, rather than specific strategies for these uncommon problems. Testing for syphilis serology is still practiced by many programs, but is not seen as essential in recipients from most developed countries.

Malignancy

It is well known that there is an increased risk of malignancy after transplantation, which is assumed to be due to an effect of immunosuppression on normal mechanisms for control of neoplastic cells or the impact on viral oncogenesis (see also Chapters 32 and 33). This knowledge has been translated to a reluctance in transplant patients who have had a prior cancer, for fear that immunosuppression would allow recurrence that might otherwise not happen. More recent data have questioned this set of assumptions in two ways. First, the increased risk of some cancers also is seen in CKD patients on dialysis and after transplantation, and a few cancers also are increased in the 5 years preceding the onset of dialysis. Second, the major increase in risk is restricted to many types of cancer, such as skin and lip cancers, renal tract cancers, and cancers for which a viral cause is either established or suspected.[97] The implication for the potential transplant recipient is that cancers that are now understood to occur at the same or a modestly increased rate as in the normal population probably should be considered differently from cancers where the risk is increased substantially.

It has been standard advice not to transplant a patient within 2 to 5 years of diagnosis and definitive treatment of cancer, depending on which cancer is under consideration. It also is advised to consider careful screening for some cancers in patients on the transplant waiting list.[44] Such blanket rules, although easy to apply, do not take into consideration the variability of the biology of the different cancers and especially do not consider the individual risks of recurrence. Table 4-3 provides a list of cancer types that are known to be increased in dialysis and transplant patients and should be viewed with considerable caution in patients being assessed for transplantation. Melanoma is known to respond to T cell immunotherapy and has a substantially increased risk after transplantation. It is known to recur in normal individuals and to metastasize aggressively. Melanoma also has been observed to recur after transplantation with long disease-free intervals before transplantation and must be approached very conservatively. Breast cancer and prostate cancer are not increased in dialysis and transplant patients, but they have substantial metastatic potential. To avoid transplanting a patient who would die as a result of metastatic cancer soon after transplantation, it is prudent to advise a waiting period of at least 2 years, depending to a certain extent on the predicted risk of spread in any given individual.

Common cancers also occur commonly in dialysis and transplant patients. It is important not to shift the clinical emphasis from common cancers to rare cancers, such as Kaposi's sarcoma, just because these rare cancers occur with a greatly increased risk compared with the general population. Common cancers, in the Australian population, each occurring in more than 60 patients in a series of nearly 900 cancers occurring in almost 25,000 dialysis patients, were kidney, bladder, colon, lung, melanoma, breast, and prostate (see Table 4-3). At present, there are no specific guidelines for cancer screening in dialysis and transplant patients, so it would be reasonable to implement guidelines recommended in the general population—such as for cervical, breast, and bowel screening—in patients on the transplant waiting list.

Psychiatric Disease and Drug Dependency

Compliance after transplantation and the patient's responses to the psychological stresses of transplantation should be uppermost in the minds of clinical teams evaluating recipients. Noncompliance with medication and clinical follow-up are among the most distressing and devastating causes of loss of grafts. Prevention of this problem starts with understanding the patient before transplantation and responding to the different risks for noncompliance.[15] Most noncompliant patients do not have a psychiatric disorder, but many with a psychiatric disorder are at risk of poor compliance.

There are two dominant reasons for careful evaluation of the psychiatric state of the potential recipient: the individual's ability to understand and consent to the transplant procedure and the impact of psychiatric disease after transplantation. Formal psychological testing and psychiatric assessment may be required to evaluate an individual's capacity to provide properly informed consent (see also Chapter 38). Alcohol and drug abuse raise many practical, medical, ethical, and moral questions, which also have to be evaluated carefully in each individual. Abstinence from chemical dependency would be regarded as essential for acceptance to the transplant waiting list by most transplant programs, but it is difficult to ensure and monitor in practice.

Bone

Renal bone disease status and the degree of control of the calcium-phosphate product are important indicators of bone disease and vascular risk after transplantation. In children, the additional consideration of growth potential and the impact of uremia on the one hand and corticosteroids on the other are relevant considerations (see Chapter 35). Recent years have seen an explosion in available therapies for renal bone disease, and the exact status of hyperparathyroidism at the time of transplantation is less critical than it was in the past.[78] It is still relevant to optimize control of the features of

renal bone disease, with special attention to attempting to normalize the calcium-phosphate product to minimize osteoporosis and vascular calcification after transplantation.[73]

Gastrointestinal Tract

Perforation of a peptic ulcer has led to many transplant recipient deaths in the era of high corticosteroid use and before the routine introduction of H_2 receptor blockers after transplantation. The incidence of untreated *Helicobacter pylori*/peptic ulcer disease is now quite low, and many units use low-dose or no steroids combined with omeprazole or a similar proton-pump inhibitor to prevent peptic ulceration. Gastroesophageal reflux, malabsorption syndromes, celiac disease, diverticulosis, and cholelithiasis all may present issues for specific consideration in individual patients. It is difficult to justify routine screening for peptic ulcer disease or cholelithiasis, but there are proponents for both strategies.

Diabetes

Recipients with diabetes require special consideration, with different issues in patients with type 1 diabetes and type 2 diabetes. Transplantation rates of diabetic patients have fluctuated widely driven by the observed mortality rates, development and availability of simultaneous pancreas-kidney transplantation, and comorbid conditions experienced by many patients with type 2 diabetes.[13]

Type 1 Diabetes Mellitus

The primary decision for patients with type 1 diabetes is whether or not to seek a simultaneous kidney and pancreas transplant (see also Chapter 34). In countries where this expertise is available, the two options that provide the best patient survival are preemptive living related renal transplantation and simultaneous pancreas-kidney transplantation. Acceptance criteria for simultaneous pancreas-kidney transplantation usually include a stricter age cutoff than for kidney transplants and routine invasive cardiac investigation, ensuring that it is a realistic therapy for approximately half of the potential type 1 recipients with end-stage renal failure.[13] Selection of patients for simultaneous pancreas-kidney transplants is focused more on vascular and cardiac operative risks but is otherwise similar to selection for kidney transplantation. The procedure is more demanding on the surgeon and the patient; it takes longer; and it involves the additional risk of pancreas exocrine drainage into either the bladder or, more commonly, the bowel. Postoperative recovery takes longer because of the ileus induced by the bowel surgery, and immunosuppression is on the whole more intense than for a simple kidney transplant. Against these issues, the patient must set the benefits of good glucose control without exogenous insulin administration, reduced long-term complications of diabetes, and improved survival.[37] Detailed consideration of simultaneous pancreas-kidney transplantation is beyond the scope of this chapter, but it is a good solution for a proportion of patients with type 1 diabetes. The evolving role of islet transplantation is still such that consideration of islet transplantation before, after, or with a simultaneous kidney transplantation is subject to formal clinical trial conditions in only a few centers globally.

Type 2 Diabetes Mellitus

Transplantation of most patients with end-stage renal failure secondary to type 2 diabetes represents a challenge to surgical and medical expertise because the epidemic of type 2 diabetes that is sweeping the developed and developing world involves predominantly obese older patients with significant comorbid vascular disease. The disease is treacherous because the neuropathy that so often accompanies the nephropathy leads to underestimation of the severity of symptoms, especially ischemic heart disease, and to exacerbation of the clinical impact of comorbid peripheral vascular disease. Only a small proportion of type 2 diabetics are suitable for transplantation because of the impact of age, obesity, and these comorbid conditions. Routine evaluation of the diabetic potential transplant recipient usually exposes the issues that affect postoperative mortality and the medium-term to long-term success of renal transplantation; however, many units have specific policies in place for evaluation of potentially asymptomatic cardiac and vascular disease in these patients.

Renal Disease

The underlying renal diseases of patients on dialysis and patients accepted for transplant waiting lists are similar because few diseases prevent successful renal transplantation. The physical size of the kidneys in patients with adult polycystic kidney disease may prevent the operation. The threat of oxalate deposition in primary oxalosis and the presence of anti–glomerular basement membrane antibodies in Goodpasture's syndrome are sufficient to ensure immediate graft failure, but there are few other renal diagnoses that provide absolute contraindications to transplantation. The causes of renal failure in patients beginning dialysis and patients receiving a renal transplant are listed in Table 4-4. These data show the skewed distribution of proportions of each type of disease in the transplant population, especially noting the underrepresentation of type 2 diabetes.

Recurrent Renal Disease

See also Chapters 24 and 25.

GLOMERULONEPHRITIS

Recurrence of glomerulonephritis in the renal transplant is an issue that requires routine discussion with patients who

have a diagnosis of focal and segmental glomerular sclerosis, IgA nephropathy, and, to a lesser extent, other immune-mediated glomerular diseases. It is important to distinguish between the risk of recurrence and the risk of graft failure owing to recurrence, and although the risk is real, it is seldom sufficient to contraindicate transplantation. An analysis of the ANZDATA database showed, however, that recurrent disease is a significant cause of late graft loss, causing twice as many losses over a 10-year period as acute rejection, but half as many as episodes of chronic allograft nephropathy or death with a functioning graft.[9] There have been many attempts over the years to summarize the risks for different diseases,[9,44,49,64,84] and a further attempt is shown in Table 4-5, in which the risks of disease recurrence and graft failure are presented from general literature review.

FOCAL SEGMENTAL GLOMERULOSCLEROSIS

Recurrence of primary focal segmental glomerulosclerosis is a difficult issue that must be addressed by transplant units. Risk factors for recurrence include young age of the recipient, duration of native disease from onset to development of end-stage renal failure, mesangial proliferative pathology, and the possibility that the risk is higher in related donor grafts.[67,93] There is a very high risk of recurrence in a second graft after loss of the first graft from focal segmental glomerulosclerosis, questioning the wisdom of retransplantation under those circumstances. The disease behaves as if there is a circulating plasma factor that causes the disease—from data identifying a putative factor and from partial response to intervention using plasma exchange.[34,62,93]

IgA NEPHROPATHY

IgA glomerulonephritis is a common disease in most countries, accounting for a relatively high proportion of end-stage renal failure. Recurrence rates are high, especially if sought using specific identification of IgA deposits in the glomeruli.[6] IgA nephropathy is one of the most common recurrent diseases, but it is generally slow to cause renal impairment and graft loss.[67] It is more common after living related donor grafts, but recurrence does not seem to have an impact on early and medium-term graft survival and should not restrain use of living donors.[10] Assessment of the family donor needs to include consideration of the possibility that IgA nephropathy may be a familial disease, however, and may affect the potential donor.

HENOCH-SCHÖNLEIN PURPURA

Henoch-Schönlein purpura is a predominantly pediatric disease with a high recurrence rate and graft loss in 10% or more.[64,71] It is uncertain whether there is increased risk in living related donor grafts, and it is common practice not to transplant during active clinical disease.

MEMBRANOUS NEPHROPATHY

Membranous glomerulonephritis may occur as either primary or recurrent disease after transplantation. It causes progressive renal impairment. Because it is untreatable, membranous glomerulonephritis leads to a significant chance of graft loss when recurrence is identified.[19,67]

MESANGIOCAPILLARY GLOMERULONEPHRITIS

Type I, type II, and type III mesangiocapillary glomerulonephritides are uncommon diseases with quite high recurrence rates after transplantation.[2,50] Type II mesangiocapillary glomerulonephritis has the highest risk of graft failure.

ANTI–GLOMERULAR BASEMENT MEMBRANE DISEASE

There is little recent experience of recurrence of Goodpasture's syndrome after transplantation because of the early and

Table 4–5 **Risks of Recurrence of Renal Disease after Transplantation and Risks of Graft Loss as a Result of Recurrence, Derived from Literature Review**

Disease	Risk of Recurrence (%)	10-Yr Risk of Graft Loss from Recurrence (%)

Mixed essential cryoglobulinemia	50	40
Scleroderma	20	5-10

*The risk of de novo anti–glomerular basement membrane antibody–mediated Goodpasture's syndrome.

ANCA, antineutrophil cytoplasmic antibody.

convincing reports of recurrence in the presence of circulating antibody and advice to await clearance before transplantation.[12,99] It is standard clinical practice to ensure a negative anti–glomerular basement membrane antibody test before transplantation. Patients with Alport's syndrome have abnormal basement membrane antigens and may produce an immune response to the normal basement membrane of a transplanted kidney, resulting in the unusual appearance of allogeneic Goodpasture's syndrome in a small percentage of patients.[33,77]

RECURRENT VASCULITIS

Antineutrophil cytoplasmic antibodies have been discounted as a possible cause of recurrent crescentic glomerulonephritis in a pooled series of 127 patients in which recurrence was 17%, but in which there was no association with presence of antineutrophil cytoplasmic antibodies. Recurrence has been treated with cyclophosphamide, and some authors support the use of co-trimoxazole as a prophylactic agent.[75]

HEREDITARY DISEASE

Primary oxalosis has a high recurrence rate after transplantation and is now usually successfully treated by combined kidney-liver transplantation, correcting the metabolic abnormality simultaneously. The condition has been mimicked by self-administration of long-term high-dose vitamin C in a dialysis-dependent patient, leading to widespread secondary deposition of oxalate throughout the body giving the appearance of pseudogout.

Fabry's disease and cystinosis are inherited enzyme deficiencies that cause renal disease through accumulated glycosphingolipid and cystine. The former leads to recurrent disease in the transplant, but the latter only to extrarenal deposition of cystine. Both are, to a certain extent, treatable, and recurrent disease should be preventable with recombinant α-galactosidase A enzyme replacement and oral analogues of cysteamine.[54,61]

Tuberous sclerosis, although it does not lead to recurrent disease, warrants special consideration because of the high lifetime risk of developing renal cell carcinoma in the native kidneys. The risk of tumor can be managed by bilateral nephrectomy or through regular screening by CT.

Urogenital Tract Abnormalities

Bladder

Recognition of a patient with bladder dysfunction is important and sometimes obvious and sometimes subtle. Patients with the triad syndrome or other congenital obstructive uropathy, spina bifida, and diabetes have an easily recognizable risk of poor bladder function. This risk usually can be recognized on careful history taking and can be investigated appropriately with urodynamic studies. More subtle problems that may be encountered include asymptomatic prostatic enlargement in an anuric dialysis-dependent patient and the very small capacity bladder encountered in patients who have been anuric for many years (see Chapters 11 and 12). There is less tendency to provide patients with alternative bladder conduits now than there was 10 years ago because of the morbidity of the surgical procedures required and the long-term risks of carcinoma if a bladder reconstruction has been achieved using bowel. Self-catheterization has become an easier and safer option than major abdominal surgery for most patients with bladder dysfunction.

Reflux Nephropathy

Recurrent urinary tract infection and reflux nephropathy seldom lead to life-threatening septicemia before transplantation, but when the experience of an individual indicates otherwise, bilateral nephrectomy can be justified if antibiotic prophylaxis fails to ameliorate the risk. Recurrent urinary sepsis is much more common after transplantation despite prophylactic measures and may threaten the graft and the patient. Bilateral native nephrectomy becomes the lesser risk in a few patients after transplantation.

Polycystic Kidney Disease

The size of polycystic kidneys must be evaluated before transplant surgery, preferably by the surgeon who will be implanting the new kidney into the space that may be occupied by the native kidneys. CT can provide an excellent view of the anatomical challenge that will face the surgeon when the patient is horizontal on the operating table, but it underplays the space available for the transplant when the patient stands up. Unilateral nephrectomy may be needed between the onset of dialysis therapy and a renal transplant, precluding preemptive transplantation.

Coagulation Disorders

Hemorrhage during the transplant and coagulation of the graft or other vital vascular conduit after the operation require careful prediction and management (see also Chapter 26). Coagulation disorders and the risk of thrombosis are much more predictable today through screening tests (Table 4-6). Use of heparin starting soon after transplantation in patients identified as having a possible thrombotic tendency seems to reduce the risk of thrombosis.[51]

The risk of hemorrhage usually is easily identified from the medical history and from a careful review of the medication list. Iatrogenic hemorrhage is much more common than inherited disorders such as hemophilia, especially with the widespread use of anticoagulation for atrial fibrillation and after vascular stenting. Each transplant unit requires a protocol for the rapid reversal of anticoagulation,

Table 4–6 Screening for Risk of Thrombosis and Coagulation Disorders

Coagulation
Medical history of thromboses
Coagulation tests—prothrombin time, activated partial thromboplastin time, factor V Leiden, protein C, protein S, antithrombin III deficiency
Antiphospholipid antibodies
Complete blood count
Hemostasis
Medication history (warfarin, aspirin, clopidogrel, dipyridamole)
Medical history of bleeding
Medical history of liver disease
Coagulation tests—skin bleeding time, activated partial thromboplastin time, congenital factor deficiencies

usually involving small doses of vitamin K with fresh frozen plasma replacement.

Obesity

Increasing body mass index is associated with increased risks of death and complications of surgery and with new-onset post-transplant diabetes mellitus.[1] The depth of abdominal fat not only causes an increased complexity during the surgery but also leads to an increased risk of wound infection and poor wound healing. The cutoff body mass index values for acceptance and for the risks of post-transplant complications vary with the surgeon, the ethnic background of the patient, and the guidelines of the transplant program. A body mass index of 28 might not be seen as a problem in a white population but might represent significant obesity in an Asian population. There is little disagreement that obesity increases the risks of transplantation—quantified to be an 8% to 9% increased risk of death and graft loss by 5 years.[1] The problem that the physician and the patient face is the task of reducing weight before transplantation. In patients treated by peritoneal dialysis, it is especially hard to change the body habitus derived from the high carbohydrate intake from peritoneal dialysis fluids, such that a switch to hemodialysis may be the only option.

Psychosocial Factors

Smoking presents serious cardiovascular and pulmonary risks before, during, and after transplant surgery and is heavily discouraged by all programs.[7] The unanswered question remains whether or not it is appropriate to transplant patients who continue to smoke. There are many who would argue that it is inappropriate for the community to provide access to the scarce resource represented by a donated kidney if the patient continues self-harming behavior by smoking.

Recreational drug abuse is often a more covert, but equally important risk, factor for success after transplantation.[89] It is important to wean patients from drug dependency, testing compliance and assessing the possibility of recent hepatitis or HIV infection before activating them on the transplant waiting list. Psychiatric evaluation and treatment are often an essential component of preparation for transplantation in drug dependency but may be rejected or unsuccessful. Families may be harsh critics of such individuals and not offer living kidney donation, leaving transplant programs with the decision of whether or not it is appropriate to provide access to scarce community resources. Documented abstinence for 6 months and determination of likely compliance after transplantation provide a nonjudgmental approach to resolving this dilemma but are in themselves complex assessments.

Alcohol dependency leads to challenges similar to those presented by other recreational chemicals. Alcoholism may be well hidden and necessitates an enquiring and suspicious clinical evaluation to detect reliably. When detected, the impact of alcohol on the liver needs to be evaluated, as does the psychological state of the patient. Compliance and reliability for follow-up after transplantation are important factors that influence patient and graft outcomes.

Mental illness requires formal evaluation and treatment, with the additional facet of determination of the ability of the patient to understand and consent to renal transplantation. In a small cluster of patients, renal failure results from chronic lithium toxicity used in the treatment of bipolar depression. Additionally, patients with a variety of psychiatric diseases are not immune from developing renal failure. There is no substitute for an independent psychiatric evaluation of fitness to consent and ensure optimal preoperative and postoperative psychiatric treatment.

Sensitization and Transfusion Status

Blood transfusion was a measurable factor in the success of a transplant during the 1970s and early 1980s. Graft survival was enhanced by 10% when using azathioprine and prednisolone immunosuppression, and it was routine practice to ensure pretransplant transfusion.[94] Transfusion was always a double-edged sword because it is also associated with the development of antibodies to HLA antigens, which limit the available donors because of positive crossmatches.

The other powerful influences on sensitization to HLA antigens are pregnancy and previous transplantation.[98] There is still debate about the relative roles of inherited and noninherited maternal and paternal haplotypes in regulation of the immune response after transplantation,[11] but that debate has had little or no practical impact on clinical decision making. Good knowledge of the antibody status and the patient's HLA type provides a prognostic guide to the likely availability of deceased and living donors and to the likely immune responses after transplantation. See Chapter 10, which discusses this issue in depth.

Previous Transplantation

One or more previous renal transplants provide visible and invisible barriers to the next transplant, both of which need to be considered carefully. There is need to focus on the physical aspects of retransplantation and the immunology.

Retransplantation is less successful than the first transplant procedure, especially if the first graft is lost within 3 months because of acute rejection.[57] Careful assessment of immunological reactivity and selection of the second donor has removed this disincentive in patients who lost their first graft chronically. Although the proportion of patients losing their first graft acutely has decreased dramatically in the past 10 years, the total number of individuals with chronic graft loss is increasing, presenting a significant challenge to the fair allocation of deceased donor kidneys.[22] The decision to accept retransplantation is one that the patient is in a better position to make because he or she has been educated in the hard school of reality. The clinician's decision to offer transplantation is sometimes harder. Should a patient who has lost the first graft because of noncompliance with medication be offered the chance to destroy another priceless donation the same way? Would the older, wiser, and now experienced individual be a model of compliance the second time around? Assessment of the medical suitability for transplantation needs to be just as rigorous the second time as it was the first time, noting especially that infective, malignant, and cardiovascular diseases all are more common in the transplanted patient than the dialysis patient.

Opinion and practices vary with respect to the management of a failed graft.[5,25] Transplant nephrectomy is

a reasonably low-risk procedure that removes an ongoing source of foreign antigenic stimulation and allows for discontinuation of immunosuppression without risk of incurring a rejection response. Nephrectomy is always done in cases of early acute graft failure from whatever cause, but it may not be required in many chronically failed grafts. A proportion of long-term failed grafts still undergoes a significant rejection process when immunosuppressants are reduced and stopped, leading to swelling and tenderness of the kidney and general symptoms of malaise and lethargy. The unanswered question is whether or not there is good reason to remove the grafts that are quiescent despite removal of immunosuppression, other than to make a second transplant physically possible at the same site. Some data suggest that antibody development is enhanced if a nonimmunosuppressed graft is left in situ, whereas other data identify the graft as a sink for antibody binding, which, when removed, exposes the circulating antibody.[48] Other opinions note that if the patient has developed antibodies to the graft antigens, those HLA antigens need to be avoided anyway, whether or not the graft is still in situ.[31]

PREPARATION FOR TRANSPLANTATION

Joining and Remaining on Deceased Donor Waiting List

Most of this chapter has defined the issues of importance for assessment, selection, and preparation of candidates for the transplant waiting lists. Table 4-7 lists issues that should be considered in every patient. Acceptance should lead to histocompatibility testing and entry on the transplant waiting list. The care with which the initial evaluation is usually performed is not often replicated in repeated reassessment in the subsequent years. Depending on the waiting list allocation strategy, it may be many years before a kidney is allocated, with the local record being 33 years and 4 months on the waiting list before transplantation. Re-evaluation of the physical fitness of patients on the transplant waiting list is an essential component of safe transplantation, but one of the more difficult to achieve. Annual reconsideration of suitability for the transplant waiting list is a reasonable precaution against calling unsuitable patients in for operation with the attendant delays and disappointments.

Compliance with the needs of the transplant waiting list and, in particular, providing a current blood sample for crossmatching may sort out willing and motivated patients from noncompliant patients. Most programs maintain serum screening protocols to identify patients who are sensitized to predict the chances of receiving a transplant and to better evaluate donor T and B cell crossmatch results obtained after working hours (see Chapter 10).

Maintaining a current record of clinical events and relevant serology for infectious disease (especially HIV, hepatitis B, and hepatitis C) should be the province of the dialysis unit responsible for the patient's treatment. Ensuring that all these data are available to the transplant program in the middle of the night is challenging and likely to fail without a good information system. In the final analysis, there is little alternative but to ensure that the individuals who are managing the patient on a daily basis are always contacted when a kidney offer is made.

Table 4–7 Screening Tests That Should Be Routinely Considered before a Live Donor Transplant or Acceptance onto a Transplant Waiting List

General history and physical examination
Diagnosis of cause of renal disease, with specific tests as required
Virus exposure
HIV antibody—HIV 1 and HIV 2
Hepatitis B—HBsAg, HBcAb, HBsAb
Hepatitis C—HCVAb (HCV RNA if HCVAb positive)
Cytomegalovirus—CMV IgG
Herpesvirus—herpes simplex IgG, herpes varicella zoster IgG, HHV 6 and HHV 7 IgG
Epstein-Barr virus—EBV IgG
Other infectious disease
In endemic areas
Purified protein derivative skin testing
Trypanosoma cruzi serology
Coccidioides serology
Strongyloides serology
West Nile virus serology
HTLV I and II serology
HHV 8 serology
Toxoplasma screening
Syphilis screening
Chest x-ray with follow-up tests as required if abnormal
Other disease
Electrocardiogram
Echocardiogram/stress cardiac test—with follow-up tests as required if abnormal
Abdominal ultrasound (kidneys, gallbladder, liver, spleen)
Vascular duplex ultrasound (femoral/carotid)

CMV, cytomegalovirus; EBV, Epstein-Barr virus; HBcAb, hepatitis B core antibody; HBsAb, hepatitis B surface antibody; HBsAg, hepatitis B surface antigen; HCV, hepatitis C virus; HCVAb, hepatitis C virus antibody; HHV, human herpesvirus; HIV, human immunodeficiency virus; HTLV, human T leukocyte virus.

Undergoing Elective Living Donor Transplantation

The assessment of the recipient of a living donor graft is, in contrast to the deceased donor recipient, a more orderly and planned affair (see Chapter 7). Despite this fact, the focus is often more on the suitability of the donor and less on the recipient. Ensuring that the donor and recipient are assessed by different nephrologists and different surgeons brings suitable attention back to the recipient. Provided that there is good communication between the two teams, it is possible to manage the interface between donor and recipient issues smoothly and effectively. It is just as important for the donor to understand the risks of a poor outcome in the recipient as it is for the recipient to understand them. A donor unaware of the possibility of recurrent disease in a patient with focal segmental glomerulosclerosis would reasonably ask why he or she was not informed before the donation. The risk of death at operation for a particular recipient may be acceptable to the recipient, but not to the donor, who may be unprepared for the possibility that the transplant procedure could lead directly to the death of the recipient. The opposite situation also may occur. A donor may undertake risky behavior, such as intravenous drug abuse or unprotected high-risk intercourse, which the recipient may know more about than either the donor's medical team or the recipient's

medical team. Understanding the level and nature of the risk is paramount for the recipient. Table 4-7 lists issues that should be attended to before living donor transplants.

Undergoing Deceased Donor Transplantation

A transplant team receives the news that a kidney is available for a particular patient only a few hours before the operation must be performed. The allocation often takes place in the middle of the night, and the news is passed through a transplant coordinator and junior medical officer. The patient and family are not in contact with the individuals who have assessed them and who care for their dialysis. The questions and uncertainties that they harbor are carried away in a rush of investigations, including a chest radiograph, an electrocardiogram, routine blood tests, bowel preparation, shower, anesthetic evaluation, immunosuppressive medication, and perhaps preoperative hemodialysis. The pressure to reduce cold ischemia time for the kidney and to meet the deadlines and timetables of operating suites tends to overshadow the needs for discussion and informed consent. This situation emphasizes the need for full education and information during the workup for acceptance onto the transplant waiting list.

Chapter 5

Access for Renal Replacement Therapy

Nicholas R. Brook • Michael L. Nicholson

The steadily increasing acceptance rate for renal replacement therapy[42,96] and prolonged patient survival on dialysis[149] mean that provision and maintenance of reliable access for peritoneal and hemodialysis, suitable for long-term use, presents a considerable challenge. The workload involved traditionally has been the responsibility of the transplant surgeon, but in more recent years vascular surgeons and interventional radiologists have become more interested in vascular access surgery.

Patients requiring vascular access are becoming progressively more elderly and often have numerous comorbidities and atheromatous or calcified vessels. There has been a concomitant increase in the number of patients with inadequate forearm veins, removing the simplest option of creating an arteriovenous fistula (AVF) at the wrist. This situation has required the judicious use of long-term central venous catheters; upper arm fistulas, including the brachiobasilic operation; and prosthetic grafts in the arms and the legs. Simultaneously, there have been improvements in fistula surveillance to diagnose failing AVFs and grafts and an increasing role for interventional radiology.

VASCULAR ACCESS CATHETERS

Temporary Vascular Access

Approximately 40% of patients with end-stage renal failure present acutely and require some form of temporary vascular access. Table 5-1 lists the indications for venous catheter insertion. The vessel of choice is the internal jugular vein. The subclavian approach gained popularity in the 1960s and early 1970s, providing convenient positioning and allowing patient ambulation, in contrast to the femoral approach of nontunneled catheters. Subclavian vein cannulation is associated with an incidence of 42% to 50% stenosis, however, as detected by venography (Fig. 5-1).[77,124,137] The risk of stenosis is greater when the procedure is difficult or is complicated by hematoma formation. The point at which the subclavian vein runs between the first rib and the clavicle is the most common site of injury, and stenosis is more common on the left and when multiple catheterizations have been performed.

Schwab and colleagues[124] evaluated 47 patients with fistula dysfunction using upper arm venography. Subclavian vein stenosis was documented in 12 patients, all of whom had undergone previous subclavian vein catheterization. This study highlights two further important points. First, subclavian stenosis may be clinically asymptomatic until an AVF is fashioned in the ipsilateral arm. Second, central venous stenosis accounts for 40% of venous stenoses associated with AVFs. It is vital that long-term access options are preserved at all costs when providing acute vascular access for hemodialysis. For this reason, subclavian vein catheterization is now avoided except as a last resort.

Adoption of the internal jugular site, along with the use of soft Silastic catheters and short catheterization periods, has been effective in reducing the venous complications of temporary hemodialysis access.[23,25] The disadvantage of jugular catheters is that they remain visible when clothed, and some patients find this unacceptable. The preferred site for insertion is the right internal jugular vein because this provides the most direct route to the superior vena cava (SVC) and right atrium and is associated with greater patency rates and fewer complications than other sites,[29] including the left internal jugular vein.[79] Catheters introduced through the left internal jugular vein have a tendency to abut the caval wall and are not as successful as catheters placed on the right.

The internal jugular vein is approached easily through a transverse incision centered over the lower part of the sternocleidomastoid muscle. The tip of the catheter should be placed at the junction of the SVC and the right atrium.

Table 5–1 Indications for Tunneled Hemodialysis Catheters

Maturation of autogenous AVF
Maturation of CAPD
Patients waiting for living related transplantation
Dialysis bridge after failed previous vascular access/CAPD to allow planning and imaging for long-term access
Permanent access—all other sites exhausted, severe cardiac dysfunction, vascular arterial disease

AVF, arteriovenous fistula; CAPD, continuous ambulatory peritoneal dialysis.

When the catheter tip is placed in the right atrium itself, there is the danger of a thrombus developing around the tip. Because internal jugular "permcaths" can function for many months or years, their insertion allows for a period of careful investigation and planning for long-term definitive vascular access. In selected subgroups, in which all other routes have been exhausted, tunneled catheters can be placed in the external iliac vein, the femoral vein,[146] or the inferior vena cava via a transhepatic[109] or translumbar approach.[82]

Types of Tunneled Catheters

Modern cuffed, tunneled hemodialysis catheters, made of silicone or polyurethane, have many advantages over noncuffed, nontunneled catheters. Silicone is thermoset, and the catheter is soft and flexible at room temperature, whereas polyurethane is thermoplastic and softens at body temperature. Either way, endothelial damage and thrombogenicity are reduced.[77] Incorporation of the cuff into surrounding tissue and the formation of a subcutaneous tunnel provide physical barriers to infection.[137] Other features of catheter design, such as larger lumens and the separation of inlet and outlet ports, maximize flow and reduce recirculation. Designs vary among different types of catheters; common catheters in use are dual-lumen catheters (Permacath, Quinton Instrument Co, Bothell, Wash; Vascath, Bard, Salt Lake City, Utah), although twin single-lumen catheters also are used (Tesio, Medcomp, Harleysville, Penn). A prospective, randomized study of these three types of hemodialysis catheter in 64 patients compared mean blood flow, reliability (defined as the percentage of treatments performed at a median blood flow of ≥350 mL/min), and recirculation.[9] The mean blood flows were 384 mL/min (Permacath), 396 mL/min (Tesio), and 320.4 mL/min (Vascath). Permacath and Tesio catheters had significantly higher blood flows and reliability than Vascath catheters ($P < .005$), whereas recirculation rates were comparable (3.7% to 4%). Although there were clear differences among these catheters, all three catheters proved inferior to the control AVF group, necessitating longer dialysis times.

Despite modifications in catheter design, thrombosis and catheter-related sepsis remain the major complications limiting long-term use.[51,52,114,124] Catheter-related bacteremia rates for nontunneled, noncuffed hemodialysis catheters range from 0.16 to 0.86 per 100 days,[4] whereas the rates for tunneled, cuffed catheters range from 0.016 to 0.29 per 100 days.[92,112] Andrivet and coworkers[6] showed a reduction in catheter-related sepsis with cuffed, tunneled catheters in immunocompromised patients, although this failed to reach statistical significance, whereas Timsit and associates[137] showed a significant reduction in catheter-related sepsis in patients who received a tunneled internal jugular catheter after admission to the intensive care unit ($P < .02$).

Catheter Insertion Techniques

Tunneled catheters traditionally have been inserted by surgeons in the operating room, using a cutdown method. Interventional radiologists and nephrologists are increasingly inserting them, however, by percutaneous Seldinger techniques in the radiology department or treatment rooms. Results from percutaneous techniques are encouraging and seem comparable to surgical insertion.[138] The use of ultrasound to guide percutaneous cannulation significantly increases first-time successful cannulation rates.[87]

Whichever technique is used, the catheter should be placed under fluoroscopic control[41] with its tip in the SVC. Deitel and McIntyre[33] reported a malposition rate of 29% in the absence of radiological guidance. Some authors report improved patency with the tip in the atrium.[128] Atrial placement also minimizes recirculation[71] and catheter migration associated with changes in posture. Atrial perforation and catheter-induced arrhythmias have been reported, but are less likely to occur with softer silicone tunneled catheters. Overall, the risk of thrombosis outweighs the benefits of atrial placement, however. Table 5-2 lists complications of insertion.

Figure 5–1 Venogram shows central venous stenosis at the junction of the right subclavian and right brachiocephalic veins.

Venous Catheters for Long-Term Use

Some patients who require hemodialysis do not have any suitable arm or leg vessels, and in this situation a long-term central venous catheter is placed. The main problem with long-term central venous catheters is thrombosis. This situation may respond to thrombolysis using streptokinase or recombinant tissue plasminogen activator, but the catheter also may need to be replaced. This procedure usually can be done over a guidewire placed through the nonfunctioning catheter. Long-term anticoagulation with warfarin should be considered in patients who are maintained purely on a central venous catheter.

Complications of Hemodialysis Catheters

Catheter Dysfunction

Catheter dysfunction is defined as failure to attain and maintain an extracorporeal blood flow sufficient to perform hemodialysis, without significantly lengthening the dialysis treatment. Adequate extracorporeal flow is estimated to be 200 to 300 mL/min (Table 5-3). Inadequate flow accounts for 17% to 33% of catheter removals.[109,126] Early catheter dysfunction in the postoperative period is due to technical errors in catheter placement. Common problems include kinking of the catheter in the subcutaneous tunnel and malpositioning. Later dysfunction is due to catheter thrombosis, fibrin sheath formation, or central vein thrombosis.[48,93] Other causes of catheter dysfunction are catheter migration or vascular underfilling.[67]

The reported incidence of catheter lumen thrombosis is 46% and accounts for most catheter dysfunction.[71,138] Intracatheter instillation of a fibrinolytic agent such as urokinase (5000 IU/mL) is the primary management of catheter dysfunction. In 70% to 90% of cases, 1 to 2 mL fills the internal lumen of the catheter and results in successful restoration of function.[53,138] If this treatment fails, higher doses of 40,000 IU/mL for 6 hours may be attempted.[57] Shrivastava and associates[127] salvaged 21 catheters in 24 patients using mechanical clearance with a guidewire in whom urokinase instillation had previously failed. If the fibrinolysis infusion fails and catheter migration or patient dehydration has been excluded, the presence of mural thrombus in the SVC or the presence of a fibrin sheath should be suspected. Injection of contrast material through the catheter ports under fluoroscopic screening (a "permacathogram") may show features that suggest a fibrin sheath (a persistent filling defect at the catheter tip or reflux of the contrast material retrogradely along the sheath).[32]

Table 5–3 **Definitions of Catheter Function**

Patency	Length of time that catheter provides adequate extracorporeal flow for effective hemodialysis (in practice >300 mL/min)
Primary patency	Cumulative catheter patency until first therapeutic intervention required to maintain patency
Secondary patency	Cumulative patency from catheter placement to failure regardless of number of therapeutic interventions required to maintain patency

Fibrin sheaths account for 13% to 57% of catheter dysfunction,[133] but are a ubiquitous response to indwelling catheters because they are present in 100% of patients with central catheters at postmortem.[63]

Treatment of fibrin sheaths is by prolonged infusion of fibrinolytic agents (6 hours), mechanical stripping by means of a snare inserted via the femoral vein, or exchange of a catheter over a guidewire.[53,57,122] There is no clear indication which of these therapies is superior. Fibrin stripping is reportedly successful at restoring function in 92% to 98% of cases with acceptable primary patency (28% at 6 months).[53] Other published short-term results of this procedure are poor, however, with catheter dysfunction returning in most patients by the fifth dialysis session after initial stripping.[53,59] Alternatively, catheter exchange over a guidewire or guidewire-assisted manipulation of the catheter tip can be attempted.

Angle and coworkers[7] reviewed their experience of 340 dysfunctioning tunneled hemodialysis catheters referred to a single institution's interventional radiology department. Failure rates were higher after catheter exchange or catheter tip manipulation compared with fibrin stripping or infusion of thrombolytic agent.

Central Vein Thrombosis

Mural thrombus in the SVC can be detected on transesophageal echocardiogram in 30% of patients with central catheters and is often asymptomatic, although it can manifest with arm and facial edema. Magnetic resonance or conventional venography can identify central vein thrombosis. Treatment with infusion of a fibrinolytic agent produces good results, but angioplasty and stenting may be required for organized thrombus.[29] More recently, attention has focused on the prevention of thrombotic complications from these catheters. Trials of anticoagulant therapy in patients with end-stage renal failure are awaited, and low catheter thrombosis rates have been reported in patients on low-dose aspirin and warfarin therapy.[114] In a randomized controlled trial of low-dose warfarin (1 mg/day) in cancer patients with central catheters for chemotherapy, subtherapeutic anticoagulation reduced thrombotic complications from 38% to 10%.[14]

Infection

Catheter infection is responsible for the failure of 6% to 28% of catheters[4,114,124] and represents a major cause of catheter-associated morbidity and mortality. The causative organism is usually a coagulase-negative *Staphylococcus*, although *Staphylococcus aureus*, gram-negative bacilli, and *Pseudomonas* also are common.[77] Infection occurs most commonly by migration of (skin) organisms along the external surface of the catheter from the exit-site wound or via the lumen of the catheter.[41] The organisms are embedded in a biofilm layer that confers protection from antibiotic therapy, and there is a link between the number of organisms retrieved by culture from a catheter surface and the risk of systemic sepsis. Infection occurs when the organisms on the catheter exceed a certain quantitative threshold.[109] Reported rates of exit-site infections and catheter-related systemic sepsis range from 6 to 45 and 2 to 18 per 100 patient days, respectively.[4,73,77,114,124]

In most cases (90%),[4,114] exit-site infections respond to oral antibiotics without necessitating catheter removal.

Topical antibiotics should be used for minor infections; parenteral antibiotics are indicated if there is a discharge from the tunnel or exit site, and there are no signs of systemic sepsis or positive blood cultures. If the infection fails to resolve using these measures, the catheter should be removed, and a new one should be inserted through a different track. Systemic sepsis or bacteremia is associated with a much higher rate of catheter removal, with conservative measures successful in treating the infection in only 20% to 25%.[4,114] Catheter-associated sepsis has considerable morbidity, with the potential for severe complications such as osteomyelitis, septic arthritis, septic discitis, endocarditis, and death. Rapid catheter removal is recommended in unstable patients with bacteremia, or in stable patients remaining symptomatic 36 hours after achieving bactericidal serum levels of antibiotic. The National Kidney Foundation–Kidney Disease Outcomes and Quality Initiatives recommended that parenteral antibiotics be continued for 3 weeks in such cases,[64] although the evidence to support this recommendation is sparse. Preventive strategies aimed at reducing the rates of catheter infection include the handling of dialysis catheters only by specially trained staff, the use of dry gauze dressings at the exit site, and (possibly) the use of antibiotic-coated catheters. Although antibiotic-coated catheters reduce the incidence of line sepsis in intensive care unit patients,[109] the antibiotic tends to be washed off with time and may not be beneficial in catheters used for intermediate-term or long-term dialysis. Other recommendations, such as the routine application of topical antibiotic to the exit site, are unproved and may encourage colonization with fungi or multiresistant organisms.

FISTULAS AND SYNTHETIC GRAFTS

Autogenous vein AVFs are the vascular access of choice in patients requiring long-term hemodialysis because they are associated with good long-term patency and low complication rates.[17,39] These advantages are offset by high primary failure rates (11% to 30%)[73,116] and the time taken for maturation (at least 6 weeks for radiocephalic fistulas).[94] Arteriovenous grafts (synthetic materials) display low rates of primary failure[123] and can be used 2 weeks after formation for hemodialysis. They are associated with inferior patency and higher complication rates, however, leading to increased overall morbidity and escalating hospital costs in the long term.[58]

Historical Development of Vascular Access Surgery

In 1960, Quinton, Dillard, and Scribner described the external arteriovenous shunt (Fig. 5-2) and opened the era of repeated hemodialysis for end-stage renal disease. The technique had many disadvantages, however. External shunts were inconvenient for the patient, were prone to infection and thrombosis, and often required many revision procedures. The introduction of the Brescia-Cimino internal radiocephalic AVF in 1966 was the next major advance and solved many of the problems associated with external shunts. This operation has been so successful that it remains the first-choice procedure for dialysis vascular access. The number of patients with inadequate forearm veins or previously failed radiocephalic AVFs increased, and the 1970s saw the introduction of various elbow AVFs. Prosthetic graft fistulas for dialysis followed; these have been favored more in the United States than in Great Britain, Europe, and Australasia.

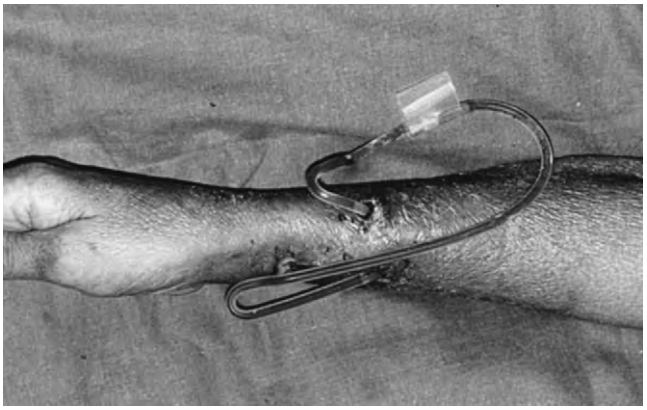

Figure 5–2 Scribner shunt.

Planning Vascular Access

Patients with end-stage renal failure are living longer and may need to be maintained on dialysis for decades. Careful planning is a key feature of vascular access surgery, and this includes protecting the venous system of chronic renal failure patients. The veins of the forearm and antecubital fossa must not be used for phlebotomy or for intravenous catheterization. These procedures should be confined, as far as possible, to the veins on the dorsum of the hand. Most medical and nursing staff members working in renal units understand this issue, but staff members working outside the renal unit may be less well informed. The importance of preserving the arm veins should be emphasized to all dialysis patients so that they are in a position to take some responsibility for their own veins. The central veins are equally important, and every effort must be made to avoid direct catheterization of the subclavian vein. Temporary vascular access catheters placed through this route may be complicated by subclavian stenosis, which can preclude subsequent ipsilateral access operations.

A few general rules relate to the planning of vascular access. Arm vessels should be used in preference to the legs, and the nondominant arm should be used first. The latter rule is especially important in patients who needle their own fistula for home hemodialysis. Distal sites should be used first because this allows the greatest possible length of vascular conduit and preserves proximal sites for the future. When possible, the AVFs should be created preemptively. This approach requires careful judgment and the use of a reciprocal creatinine plot to estimate when individual patients will reach end-stage disease.

The Brescia-Cimino radiocephalic fistula is the first choice for long-term hemodialysis access. If a radiocephalic AVF fails in the longer term, it usually is because of the development of intimal hyperplasia at or near the anastomosis. In some cases, the patient still has usable forearm veins that can be anastomosed to the radial artery at a more proximal site. In patients with unsuitable forearm veins or failed wrist fistulas in both arms, the next step should be

formation of a brachiocephalic fistula. If this is impossible, a brachiobasilic AVF using superficially transposed vein should be considered. Prosthetic AVF grafts are most commonly created using expanded polytetrafluoroethylene (PTFE), but should not be used until all the native arm veins, including both basilic veins, have been used or deemed to be unsuitable. Patients with failed secondary and tertiary access procedures may be suitable for long-term management using tunneled, cuffed central venous catheters.

Many patients who need vascular access surgery develop central venous stenoses or occlusions, including lesions in the SVC. These patients present some of the most challenging vascular access problems. Interventional radiology is an important adjunct to management because some central venous lesions can be treated successfully by percutaneous transluminal angioplasty with or without stenting. Only when all potential upper limb procedures fail should the legs be considered for vascular access using a prosthetic graft AVF.

Requirements of Arteriovenous Fistulas for Hemodialysis

The veins of the arm can be catheterized easily and repeatedly, but their blood flow is too low to support hemodialysis. The creation of an AVF produces an arterialized venous channel, which yields the combined advantages of large diameter and high blood flow. The ideal AVF has the following features:

1. A blood flow of at least 300 mL/min
2. A large diameter, which facilitates venipuncture
3. Sufficient length to allow two dialysis needles to be inserted
4. Creation by a simple and quick operation, preferably under local anesthesia
5. A good long-term patency rate

A small anastomosis between the radial artery and cephalic vein leads to arterialization of much of the venous system of the arm, and this has profound hemodynamic consequences. Immediately after creation of a radiocephalic AVF, the radial artery blood flow increases tenfold to 200 to 400 mL/min. The flow rate increases further over the next 2 to 4 weeks, after which it plateaus. The underlying mechanism is a loss of the downstream resistance in the arterioles and capillary bed. To achieve these dramatic flows, the artery and the vein must dilate. Although failure of maturation of a radiocephalic AVF may be due to an inadequate vein, it also can be due to an atheromatous or frankly calcified artery that is unable to dilate. The vessels of diabetic patients often fall into this category.

Preoperative Assessment

The three requirements for a successful AVF in the arm are the following:

1. A good arterial inflow
2. A suitable superficial vein
3. Patent axillary and subclavian veins

The first two of these requirements usually are assessed clinically, but the third requires radiological investigation. The radial and ulnar arteries can be palpated at the wrist to assess the pulse volume and to identify overt atheromatous disease, such as calcification. Allen's test usually is described as a method of establishing the patency of the palmar arches, but it also can provide a subjective assessment of the arterial inflow to the hand and define dominance of the radial or ulnar artery. The veins of the forearm can be assessed by simple inspection and palpation after placing a tourniquet around the upper arm. The cephalic vein is most often used for AVF creation, and for success it needs to be patent from the wrist to the antecubital fossa and have a diameter of at least 3 mm.[116] The patency of the vein can be established easily by lightly percussing it at the wrist and feeling for a transmitted wave at the elbow. A good-caliber cephalic vein at the wrist may divide quickly into many small branches in the forearm, and this relatively common anatomical variation may preclude successful AVF formation.

Assessment of the patency of the major venous drainage of the upper limb is particularly important. The only overt clinical signs of stenosis or occlusion in the axillary and subclavian venous system are prominent collateral veins around the shoulder and chest and associated arm swelling. Most venous stenoses and some occlusions are clinically silent, and the venous drainage of the arm can be assessed properly only by performing a duplex ultrasound scan or a contrast venogram. Logistical and financial constraints usually dictate that these investigations are performed selectively, but it is wise to perform some form of imaging in any patient who has previously had an ipsilateral temporary subclavian vascular catheter.

Anesthesia

Patients with end-stage renal failure commonly have comorbid conditions, such as cardiovascular disease and diabetes, and may be a poor risk for general anesthesia. Many vascular access procedures can be performed using a local anesthetic. For simple operations such as wrist fistulas, local infiltration of 1% lidocaine usually suffices. The addition of epinephrine is helpful in reducing the oozing that commonly occurs in renal patients as a result of qualitative platelet dysfunction. Regional anesthesia can be achieved by local anesthetic blocks, and these techniques are ideal for more extensive operations, such as elbow AVFs and forearm prosthetic loop grafts. These methods also block the sympathetic nervous system, which has the advantage of inhibiting vasospasm. An alternative for more extensive operations is to use simple local anesthetic infiltration and to ask the anesthesiologist to supplement this with boluses of a short-acting sedative, such as propofol.

Surgical Technique

Vascular access surgery requires adhering to the basic principles of vascular anastomosis. The vessels are anastomosed using a fine, continuous, nonabsorbable, monofilament suture with eversion of the edges to ensure a smooth transition between the two intimal surfaces. There must be no tension between the anastomosed vessels, and the sutures must pick up all layers of the arterial wall to avoid the creation of a subintimal flap. Because suture placement is so crucial, optical magnification using surgical telescopes is an advantage, and good-quality microvascular instruments should be available.

Autogenous Arteriovenous Fistulas

Wrist Arteriovenous Fistulas

The radiocephalic AVF is the first-choice procedure in vascular access surgery. This operation is straightforward and can be performed under local anesthesia as an outpatient procedure. It has a low complication rate and excellent long-term patency rates. The original operation described by Brescia and colleagues in 1966 was a side-to-side, radial artery–to–cephalic vein AVF formed close to the wrist joint (Figs. 5-3 and 5-4). The main variant, a side of artery–to–end of vein fistula, is preferred by many surgeons because there is a lower incidence of venous hypertension in the hand (Fig. 5-5). Radiocephalic AVFs have a primary patency rate of approximately 80% at 2 years.[39,116]

A radiocephalic fistula can be fashioned in the anatomical snuffbox. This is a greater technical challenge because the vessels are of smaller diameter, but the advantage of this site is that it maximizes the length of cephalic vein available for venipuncture. If the cephalic vein or radial artery at the wrist is found to be unsuitable or thrombosed, an AVF can be fashioned by anastomosing the basilic vein to the ulnar artery. The awkward medial position of the basilic vein can make venipuncture difficult, and this operation should not be performed after a failed radiocephalic fistula because there is a theoretical risk of ischemia to the hand.

The surgical technique for formation of radiocephalic fistulas follows. The radial artery and cephalic vein are exposed at the wrist using an S-shaped, longitudinal or transverse incision depending on how close together the vessels are and the surgeon's preference. Hemostasis is achieved using diathermy, which should be in bipolar mode if the patient is awake. The lateral skin flap is elevated to expose the cephalic vein, which is mobilized over a distance of approximately 3 cm, preserving the sensory dorsal branch of the radial nerve. The radial artery is sought just lateral to the flexor carpi radialis tendon and exposed by dividing the transverse fibers of the deep fascia of the forearm over the pulse. Only 2 cm of artery needs to be mobilized by ligating and dividing any small branches. The cephalic vein and radial artery may be anastomosed in a side-to-side or an end-to-side arrangement. We prefer the end-to-side arrangement in which the spatulated end of the divided cephalic vein is anastomosed to the side of the radial artery using a continuous monofilament 7-0 vascular suture.

Figure 5–4 An established Brescia-Cimino radiocephalic arteriovenous fistula.

Figure 5–3 Operative photograph of a completed side-to-side radiocephalic arteriovenous fistula.

Figure 5–5 Venous hypertension in the thumb secondary to a side-to-side radiocephalic arteriovenous fistula.

After controlling the artery with Silastic vessel slings or miniature vascular clamps, a short arteriotomy is made. The length of the arteriotomy depends on the diameter of the cephalic vein and radial artery, but usually is in the region of 5 mm. Systemic anticoagulation with heparin is unnecessary and unwise in renal patients, but the proximal and distal radial artery can be filled locally with heparinized saline solution. For a side-to-side anastomosis, the vessels are mobilized sufficiently to allow them to be held together over a distance of 2 cm, and the cephalic vein is not divided. Both vessels are opened by equal-length longitudinal incisions, and the side-to-side anastomosis is completed using a fine monofilament suture.

At clamp release, the flow should be high enough to produce an obvious thrill in the cephalic vein. The causes of an absent thrill include systemic hypotension, adventitial bands that kink the venous runoff, and technical errors in constructing the anastomosis. It also is possible that the radial artery or the cephalic vein, or both, are too small to support a high flow. If there is any doubt, the anterior wall suture line should be taken down to look for an intimal flap or other technical error.

Elbow Fistulas

Many patients referred for vascular access have either inadequate forearm veins or a previously failed wrist fistula. The principal choice for secondary vascular access in this situation is between an upper arm AVF using autogenous vessels or a prosthetic graft AVF. Autogenous elbow fistulas have proved to be more popular in European countries than in the United States, where prosthetic grafts have tended to be favored for secondary access.

Brachiocephalic Arteriovenous Fistulas

Brachiocephalic AVFs probably are the best option when it is impossible to form a wrist fistula in either arm. The direct brachiocephalic AVF was first described by Cascardo and colleagues in 1970.[26] The operation is straightforward to perform and can be done under local anesthesia. The side of artery–to–end of vein configuration is preferred. A side-to-side anastomosis may be possible if the cephalic vein and brachial artery are close enough but, as with radiocephalic fistulas, this arrangement may give rise to venous hypertension in the hand. The main disadvantage of brachiocephalic fistulas is that they produce a relatively short length of arterialized vein. The procedure may be unsuitable for the arms of obese patients.

Several technical variations of the brachiocephalic fistula are possible, depending on the venous anatomy in the antecubital fossa. When present, the median cubital vein may be anastomosed directly to the brachial artery, and this technique has the advantage of arterializing the cephalic and the basilic venous systems. Alternatively, the deep perforating branch of the median cubital vein can be anastomosed to the brachial artery. The long-term results of brachiocephalic AVFs are good, with secondary cumulative patency rates approximately 80% at 3 years[13] and 70% at 4 years.[38] Elbow fistulas can have high flow rates, and hemodynamic complications, such as steal syndrome and high-output cardiac failure, occur more commonly in these fistulas than in wrist fistulas. To avoid these complications, the length of the brachial arteriotomy should be limited to a maximum of 75% of the diameter of the artery.

Brachiobasilic Arteriovenous Fistulas with Vein Transposition

Only a short section of the basilic vein at the elbow is superficial, and most of the vein is protected under the deep fascia. The subfascial position of the basilic vein means that it is protected from venipuncture, and this usually ensures that it is of good quality and diameter. If the basilic vein is left in this anatomical position and anastomosed to the brachial artery, only a short length of vein is available for venipuncture. A much longer conduit can be created by dissecting the basilic vein from its bed and transposing it into a more convenient subcutaneous position down the middle of the upper arm. The operation is best performed under general anesthesia because of the extensive incision required. This incision runs along the median aspect of the arm from the antecubital fossa to the axilla, but staged incisions with short skin bridges also can be used. The medial cutaneous nerve of the forearm usually is closely applied to the basilic vein and needs to be preserved carefully during dissection. The vein is transposed into its new position using a subcutaneous tunneling device and anastomosed end of vein to side of brachial artery (Figs. 5-6 and 5-7).

The operation may be performed as a tertiary procedure after failed wrist and brachiocephalic fistulas, but it also is particularly useful as a primary procedure in small children. The formation of the brachiobasilic AVF does not compromise the arm for future prosthetic grafting. This operation probably has been underused.

The 1- and 2-year functional patency rates are approximately 50% to 80%.[20,38,95] The disadvantage of the brachiobasilic fistula lies in the extensive incision required. Postoperative analgesia can be improved by administering boluses of a long-acting local anesthetic such as bupivacaine via an epidural catheter placed directly into the axillary sheath at the time of surgery.[21]

Graft Arteriovenous Fistulas

In Europe and Australasia, graft AVFs are reserved for patients with previous multiple access failures. In contrast, many centers in the United States favor prosthetic grafts as primary or secondary access procedures. Graft AVFs can be

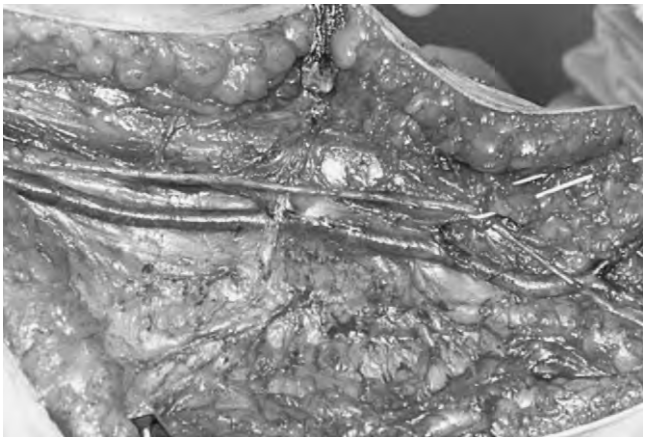

Figure 5–6 Operative photograph of the extensive incision required to dissect the left basilic vein free from its subfascial bed. The medial cutaneous nerve of the forearm runs parallel to the basilic vein.

Figure 5–7 Operative photograph shows the use of a Kelly-Wick tunneling device to create the transposition tunnel of a left brachiobasilic arteriovenous fistula.

constructed under local or regional anesthesia with a short inpatient stay. The graft material is tunneled subcutaneously between a suitable artery and vein and anastomosed to these using an end-to-side technique. The choice of graft material is between biological materials, such as autogenous long saphenous vein, and prosthetic materials, of which expanded PTFE is preferred.

The use of autogenous saphenous vein is attractive in principle, but has been limited by the variable quality of this vein. This variable quality has been reflected by the poor patency rates of 20% to 66% at 2 years.[75,90] The extensive dissection of the long saphenous vein can be performed only under general anesthesia, and the procedure is not cost-effective because the patient needs to be hospitalized for several days owing to the leg incision. In view of these disadvantages, the long saphenous vein is used rarely in vascular access surgery. Other biological materials, including human umbilical vein and bovine carotid artery, have not been found to be successful. Although these materials handle well, they are associated with high incidences of infection, rupture, and false aneurysm formation, and overall patency rates are poor.[47,70] More recently, a bovine ureteric graft, which is chemically treated to remove the urothelium and leave what is essentially a collagen tube, has been introduced into clinical practice (Cryolife, Hampshire, United Kingdom). Early results from the Oxford group show encouraging patency rates and an acceptable complication profile,[44] but longer term follow-up is required to define the role of this new graft.

Expanded PTFE is the most popular prosthetic graft material in access surgery. It is easy to handle, of predictably high quality, and available in a wide range of sizes. The expected 2-year graft patency rate using expanded PTFE is approximately 60%. The disadvantages of expanded PTFE are its expense and higher complication rates than those seen with autogenous AVF. A further disadvantage of PTFE is the need to wait 6 weeks before venipuncture because the PTFE wall is not self-sealing, and perigraft fibrosis must develop before the graft can be punctured safely. Of particular concern is the overall infection rate of 11% to 35%[115] compared with 2% to 3% for autogenous fistulas.[89] Thrombosis and intimal hyperplasia at the venous anastomosis are more common with prosthetic graft materials than autogenous vessels. Newer graft materials, such as stretch PTFE, have improved compliance and elastic recoil, and these properties may reduce the incidence of intimal hyperplasia and permit earlier venipuncture. It remains to be seen whether or not such innovations will translate into better long-term graft patency rates.

Many variations of prosthetic interposition grafts have been used, including loop, straight, or J-shaped configurations. Forearm graft AVFs can take their arterial inflow from the brachial or radial artery, and any of the antecubital fossa veins can be used for the outflow. The most popular configuration is a loop graft between the brachial artery and the basilic vein. This configuration is favored by many surgeons because its full length facilitates the rotation of needle sites, reducing the risk of thrombosis, infection, and false aneurysm formation. In the absence of suitable veins in the antecubital fossa, a graft AVF can be placed between the brachial artery and the axillary vein. These vessels can be exposed through two short incisions, and the operation can be performed under local anesthesia. This technique seems to be an effective tertiary or quaternary vascular access procedure with 1-year primary and secondary patency rates of approximately 70% and 90%, respectively. A brachiojugular graft fistula may be performed in patients with exhausted arm and axillary veins.[111] Interposition loop grafts can be placed in the leg with anastomosis to the common femoral artery and vein in the groin. In this site, there is a particular susceptibility to infection, especially in diabetic patients. An alternative method that avoids the groin involves exposure of the superficial femoral artery and femoral vein in the midthigh where they run in the adductor canal. This is a clean area and allows a graft to be positioned in a loop configuration in the lower thigh.

Fistula Maturation and Venipuncture

The venous outflow of an autogenous fistula becomes arterialized over several weeks, developing a degree of dilation and thickening of the vessel wall. The time when a new AVF can first be punctured varies and requires some judgment. Hematoma and early thrombosis are potential complications if a fistula is punctured before it has matured sufficiently. A conservative approach is to leave all fistulas for 6 weeks, but in patients with good-quality veins, a new AVF can be punctured successfully after only 2 weeks. The development of a fistula may be aided by exercising the arm, possibly with a tourniquet in place; the rationale is that increased arm blood flow improves fistula maturation, but there are no studies of the effectiveness of such a policy.

In the longer term, persistent venipuncture in exactly the same spot can weaken the vessel wall and may lead to false aneurysm formation. In the same way, the skin over a prosthetic graft may be eroded, leaving the graft exposed and infected. Rotation of the venipuncture site is advisable in autogenous and prosthetic AVFs. This advice often is ignored, and there may be considerable pressure from the patient to use the same venipuncture sites repeatedly because the skin here becomes numb with time, and venipuncture becomes more comfortable.

Complications of Arteriovenous Fistulas and Graft Formation

Hemorrhage

If hemorrhage occurs in the first 24 hours postoperatively, it is usually due to a technical error with the anastomosis or a slipped ligature. Generalized oozing resulting in hematoma formation is more common and is related to the functional platelet disorder associated with uremia.[117] The synthetic vasopressin analogue, desmopressin acetate (DDAVP), can be used as a specific prophylactic measure in uremic patients who have additional risk factors for bleeding and in whom extensive surgery is planned. DDAVP releases stored factor VIII from the endothelium into the circulation and restores the bleeding time to normal by promoting platelet adhesion and aggregation.[88] The desired effect on the bleeding time is short-acting with a return to the pretreatment value after 8 hours.

Late hemorrhage from an AVF can occur after venipuncture or as a complication of aneurysm formation and infection. In the emergency situation, this hemorrhage can be controlled by firm pressure over the bleeding point, but surgical exploration is usually required.

Thrombosis

Thrombosis may occur in the first 24 hours postoperatively. Although thrombosis may result from preoperative overdialysis leading to dehydration or intraoperative hypotension, a technical error should be suspected. Immediate re-exploration is indicated because it may be possible to salvage the situation by thrombectomy using a Fogarty catheter and subsequent refashioning of the anastomosis.

Thrombosis is the most common cause of AVF failure in the long term. In this situation, thrombosis is usually due to an underlying stenosis that develops gradually. The type of access and the site of thrombosis are important determinants of outcome. If a radiocephalic or brachiocephalic AVF thromboses in a localized manner at or close to the anastomosis, the runoff usually remains patent because it has many natural tributaries that maintain some venous flow. This situation can be remedied by refashioning the arteriovenous anastomosis at a more proximal site. In contrast, when a brachiobasilic AVF thromboses, it is usual for the whole vein to clot by propagation of thrombus. This clotting is a direct result of the fact that all the tributaries of the venous outflow will have been ligated during the creation of this type of AVF. The only hope of salvage in this situation is to perform an immediate thrombectomy before the clot organizes. AVFs also can thrombose at venipuncture sites as a result of poor technique leading to hematoma formation or undue postcatheterization compression to control bleeding.

Interventional radiological techniques are being used increasingly in the treatment of thrombosed vascular access conduits. Pulse-spray catheters, which originally were designed for thrombolysis in patients with peripheral vascular disease, can be used with equal success in patients with thrombosed vascular access.[16] The catheter is introduced into the clotted segment, and the thrombus is dissolved by intralesional spray infusion of agents such as streptokinase, urokinase, or recombinant tissue plasminogen activator. Percutaneous access thrombectomy also has been performed using balloon catheters.[12,139] After successful thrombolysis or thrombectomy, any underlying stenotic lesion can be identified by angiography, then treated by percutaneous transluminal angioplasty with or without endoluminal stenting. The immediate success rate of this type of procedure may be 90%.[105,142] Restenosis is frequent, however, and may require repeated angioplasty.

Surgical thrombectomy is the alternative treatment, and many new technologies have been introduced. The standard surgical thrombectomy technique uses a conventional Fogarty balloon catheter. Although this technique is effective in removing soft new thrombus, it is less successful when older, adherent clot is present. Two other catheters, the adherent clot catheter and the graft thrombectomy catheter, are more effective in removing densely adherent thrombotic material. Angioscopy, which allows direct visualization of luminal surfaces and the identification of retained thrombus, also may prove helpful in treating the thrombosed vascular access conduit.

Infection

Although vascular access procedures are essentially clean operations, patients with end-stage renal failure are more susceptible to infection for many reasons. Uremia is associated with a reduction in the chemotactic, phagocytic, and bactericidal actions of neutrophils and defects in T cell–mediated and B cell–mediated immune responses.[56] Patients with renal disease have a 70% incidence of nasal, throat, and skin colonization by *S. aureus* compared with 15% of the general population.[151] Prophylactic antibiotics are essential when prosthetic materials such as expanded PTFE are being used to create a graft AVF. Staphylococci found in renal patients have a high resistance to flucloxacillin, and the best choice of antibiotic is vancomycin.

Wound infection after a vascular access procedure must be treated seriously because there is a risk of massive secondary hemorrhage. The patient must be hospitalized until the situation has resolved completely. Relatively minor infections manifesting with erythema and swelling can be managed by elevation and intravenous antibiotic therapy. If frank pus is present, the wound should be explored under general anesthesia, drained of all pus, and thoroughly irrigated with saline or antibiotic solution. If the vascular anastomosis is directly infected, the risk of serious secondary hemorrhage is high, and the safest course of action is to ligate the fistula. Early infection associated with prosthetic graft material presents a particularly serious management problem. Superficial cellulitis can be treated by high-dose intravenous antibiotics, but for purulent infections, the prosthetic graft must be removed.

Aneurysm Formation

False and true aneurysms (Fig. 5-8) may occur in vascular access conduits. False aneurysms occur most commonly at venipuncture sites that have been overused. The incidence is 10% for PTFE grafts compared with 2% for autogenous AVFs.[152] Treatment is by resection and restoration of the AVF by direct end-to-end anastomosis or by the placement of a short PTFE bridge graft. True aneurysmal dilation of autogenous arterialized veins is common. In many cases, no action is required, but if the overlying skin becomes thin, and evidence of progressive expansion exists, corrective surgery is indicated. Localized aneurysms can be resected and continuity restored by

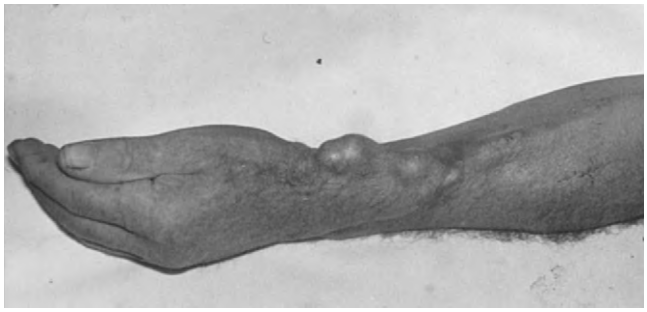

Figure 5–8 True aneurysm of a left radiocephalic arteriovenous fistula.

direct end-to-end anastomosis. Alternatively, if the whole length of an arterialized segment of vein becomes aneurysmal, the AVF may have to be ligated.

Vascular Steal Syndromes

A vascular steal is diagnosed when there is hypoperfusion of the limb (usually the arm) distal to the arteriovenous anastomosis. This hypoperfusion occurs most commonly after procedures involving the brachial artery and in patients with generalized arteriosclerosis and diabetes. The patient complains of a cold, weakened hand, and there may be pain and paresthesias. The incidence of this complication can be reduced by careful attention to detail during the formation of AVFs. Total fistula flow and steal can be limited by reducing the anastomotic length to 75% or less of the proximal arterial diameter; in most patients, this translates into an arteriotomy length of approximately 5 mm. Steal syndromes also can be caused by preexisting arterial lesions and must be investigated by an angiographic study from the aortic arch to the digital vessels. This study may show a distal stenosis that may be amenable to treatment by percutaneous transluminal angioplasty.

Mild steal syndromes can be expected to improve spontaneously over weeks, but in more severe cases further surgery is required to limit the fistula flow. This limitation of flow can be achieved by a crescent-shaped plication suture placed in the vein or graft just beyond the anastomosis.[118] An elegant, albeit more complicated, alternative is to ligate the artery distal to the AVF anastomosis, then to perform a saphenous vein bypass from the proximal artery to a point beyond the ligature.[121] If these interventions are unsuccessful, and in cases in which there are clinical signs of severe hand ischemia, the fistula should be ligated.

Arteriovenous Fistula Surveillance

The aim of fistula surveillance is to detect stenotic lesions before frank thrombosis occurs and to allow treatment of the failing fistula rather than the failed fistula.[125] Methods of surveillance include regular clinical examination, monitoring of venous pressures during dialysis, and measurement of urea recirculation.[125] The failing fistula is characterized by increasing venous pressures and poor flow, sometimes accompanied by a decrease in the palpable thrill or audible bruit. Color flow Doppler examination is another alternative for the detection of intimal hyperplasia; flow rates of less than 500 mL/min should arouse suspicion of venous or graft stenosis.[132] Venous stenoses that are detected by surveillance can be confirmed by contrast fistulography and treated by procedures such as percutaneous angioplasty,[11] endoluminal stent placement,[11] or surgical revision.[40] The establishment of fistula surveillance programs has been shown to reduce the incidence of vascular access thrombosis significantly and to improve long-term patency rates.[98,125]

PERITONEAL DIALYSIS

In the United Kingdom, approximately half of dialysis patients use peritoneal dialysis (PD),[44] compared with 9% in the United States.[148] Most patients favor continuous ambulatory PD. The less common type is continuous cyclic PD. The concept behind PD is straightforward. The peritoneum, with a total surface area 2 m^2, is composed of endothelium, interstitium, and mesothelium, and can act as an efficient semipermeable membrane.[35] Infusing a hypertonic dialysate fluid into the peritoneal cavity allows ultrafiltration of solutes and electrolytes.

Peritoneal Dialysis Delivery Systems and Catheters

PD is a closed loop system comprising dialysate fluid, a delivery system, and an indwelling peritoneal catheter (Fig. 5-9). Fluid is infused under gravity from a reservoir of dialysate. Luer-Lok or rotating safe lock devices have been devised to connect the

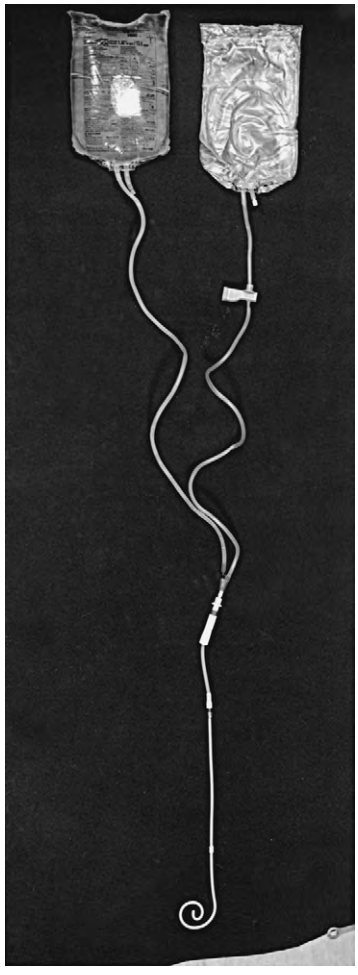

Figure 5–9 Peritoneal dialysis delivery system and catheter. A Y delivery system. The dialysate reservoir (left bag) and collecting bag (right bag) with a titanium connector to the curled, single-cuffed Tenckhoff catheter.

dialysate with the delivery system for ease of connection and sterility. The Italian Y delivery systems[19] are the most common. The single branch of the Y is connected to the indwelling peritoneal catheter via an inert titanium connector, and the upper two branches are connected to the dialysis reservoir and an empty bag. This configuration allows complete drainage of any contaminating dialysate fluid before infusion of sterile, fresh fluid through the indwelling delivery catheter. Several randomized controlled trials have shown the superiority of various Y systems in reducing the incidence of infective complications over conventional PD systems.[28,86]

Catheter Selection

PD catheters should be soft, flexible, atraumatic, radiopaque, and relatively inert. Several different types of catheter are available (Fig. 5-10), but the Tenckhoff catheter is the most popular.[136] The original Silastic Tenckhoff design was a straight, 5-mm external diameter tube, with two Dacron cuffs[136] and a perforated intraperitoneal segment. Many variations of the Tenckhoff device exist, including catheters with single Dacron cuffs and curled intraperitoneal ends. Curled catheters exhibit lower rates of catheter migration than the straight variety.[85]

Catheter Insertion

Not all patients are suitable for PD. Severe peritoneal adhesions, inflammatory bowel disease, and previous sclerosing peritonitis are absolute contraindications. Obesity, advanced age, abdominal hernias, stomas, and chronic obstructive pulmonary disease are relative contraindications. Severe colonic diverticular disease may increase the translocation of gut organisms, and there is a strong association between diverticular disease and gram-negative PD peritonitis. Although PD can be performed in patients with abdominal wall stomas, there is a predisposition to infection. Abdominal wall hernias (Fig. 5-11) may enlarge in patients receiving continuous ambulatory PD and should be repaired if possible at or around the time of catheter insertion. Table 5-4 lists the relative and absolute contraindications to PD catheter insertion.

A variety of techniques for catheter insertion have been described, including open surgical (direct vision), percutaneous (blind), peritoneoscopic, and laparoscopic. Open and closed techniques can be performed with local or general anesthesia, the choice of which may be dictated by comorbidity and fitness for anesthetic.

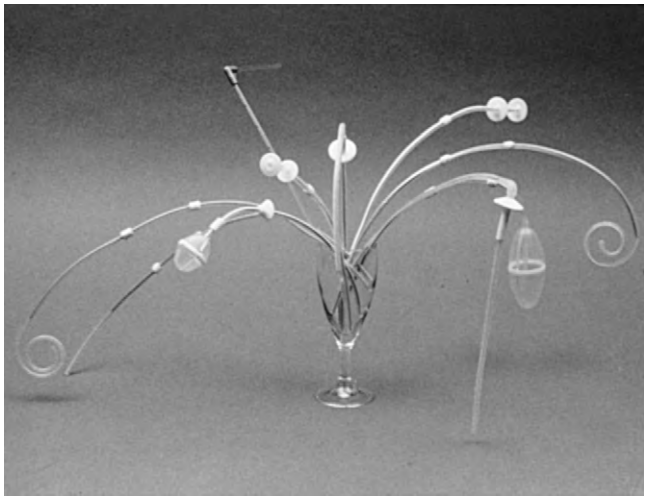

Figure 5–10 Peritoneal dialysis catheters.

Figure 5–11 Reducible umbilical hernia protruding because of increased intra-abdominal pressure from the infusion of peritoneal dialysis fluid.

In the open technique, the catheter is introduced through a small vertical infraumbilical incision placed in the midline or laterally, with the preperitoneal cuff positioned in the rectus abdominis muscle. Before positioning, the catheter should be flushed and immersed in sterile saline because wet cuffs stimulate more rapid ingrowth compared with dry, air-containing cuffs. A small incision is made in the peritoneum, and the tube is inserted using blunt forceps, or a metal stylet placed through the catheter lumen. The tube tip must be placed in the rectovesical pouch in men and the rectovaginal pouch in women (Fig. 5-12). The peritoneum is closed with an absorbable suture around the cuff to create a watertight seal, and the linea alba or rectus sheath is closed using a continuous nonabsorbable suture. The extraperitoneal segment of the catheter is tunneled subcutaneously and brought out at a conveniently placed lateral exit site. At the end of the procedure, the catheter should be flushed to ensure free inward and outward flow of dialysate fluid.

The percutaneous technique of PD tube insertion requires a dilator introduced over a guidewire to develop a track into the peritoneal cavity.[103] This track allows the introduction of a sheath through which the PD tube is inserted. This technique can be performed at the bedside and has equivalent outcomes to open surgical tube insertion.[46,103] In the peritoneoscopic technique, the PD tube also is introduced through a single infraumbilical stab incision, but a 2.2-mm telescope is introduced first to inspect the peritoneal cavity.[2,46] The laparoscopic method of insertion is a similar approach that requires a 10-mm trocar for insertion of the camera and usually two further 5-mm ports for the instruments used to manipulate the PD tube into the pelvis.[5,18]

Complications Associated with Peritoneal Dialysis Catheters

Bleeding

Bloody fluid is a common finding, occurring in 30% of patients for the first few catheter exchanges after insertion.

Table 5–4 **Contraindications to Peritoneal Dialysis**

Absolute Contraindications	Relative Contraindications
Encapsulating peritoneal sclerosis	Severe obesity
Inflammatory bowel disease	Severe peritoneal adhesions
Large irreparable abdominal wall hernias	Large hernias of anterior abdominal wall
	Abdominal wall stomas
	Chronic obstructive pulmonary disease
	Psychosocial factors likely to result in poor compliance
	Physical disability
	Learning disability

The bleeding most often arises from small vessels on the surface of the peritoneum at the point of catheter entry and usually stops within 24 hours.

Pain

The first attempts at dialysate infusion can produce discomfort. This pain is more common with straight Tenckhoff catheters when infusion pressure is greatest. With coiled catheters, pain is less likely because dialysate flows through the side perforations. The pain is most often temporary and resolves within a few weeks. Slower infusion rates and incomplete drainage alleviate these short-term symptoms.[141]

Cuff Extrusion

The most important factor for cuff extrusion is the depth at which the subcutaneous cuff is implanted; at least 2 cm below the skin is required. Tension on the extraperitoneal portion of the catheter, such as during bag exchange, can bring a poorly implanted subcutaneous cuff to the surface. Reimplantation is required.

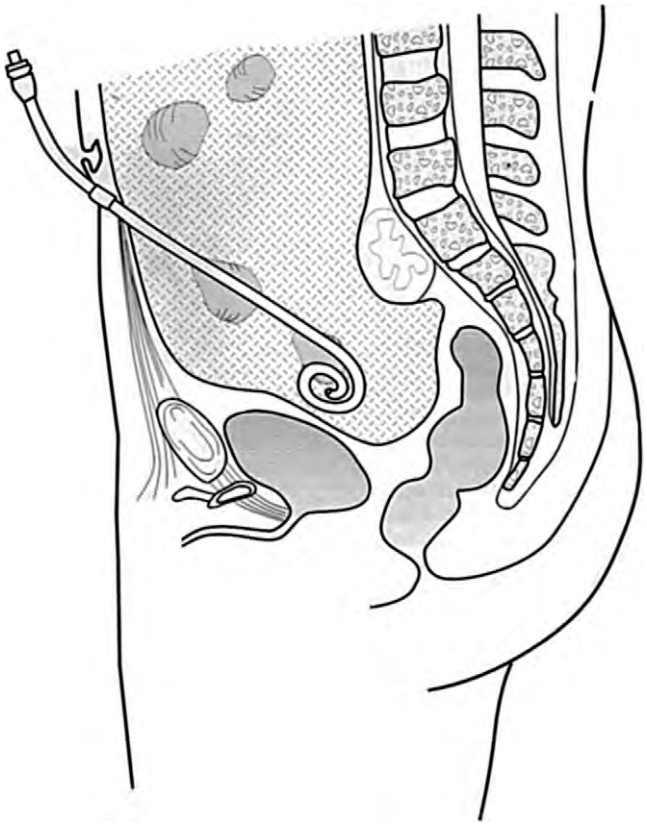

Figure 5–12 Correct anatomical positioning of the peritoneal dialysis catheter in the pelvis.

Catheter Obstruction

Catheter obstruction is usually due to outflow obstruction (Table 5-5). Obstruction may be extrinsic or related to catheter positioning. Clotted blood may collect in the distal portion of the catheter shortly after surgery; this can be treated effectively with a per-catheter infusion of heparin, urokinase, or streptokinase.

Extrinsic compression resulting in obstruction can be caused by bladder distention or an impacted sigmoid colon.[131] Although these causes should be ruled out, they are uncommon causes of obstruction compared with omental wrapping (Fig. 5-13). Intra-abdominal adhesions also can obstruct outflow. In vulnerable patients, this potential problem can be avoided by laparoscopy and adhesiolysis before catheter insertion. Techniques for repositioning or catheter replacement are discussed subsequently.

Catheter Tip Migration

Twardowski[140] stated that the incidence of catheter migration is 20%, but that only 20% of migrated catheters obstruct. Some obstructions resolve spontaneously, but most require intervention to allow repositioning.[78] Treatment of tip migration includes stiff wire manipulation,[68,69] fluoroscopically guided repositioning,[36,66] or (as a last resort) surgical repositioning. Manipulation with a Fogarty catheter inserted into the PD tube has been shown to be successful in repositioning a migrated catheter in 70% of cases.[45]

Pericatheter Leak

Any variable that predisposes to poor wound healing (e.g., steroids, obesity, malnutrition) may culminate in pericatheter leakage. Choice of surgical technique may determine leak rates; leaks are said to be more common with midline catheter insertion compared with lateral insertion through the rectus muscle,[37] but this is not our experience. Pericatheter leakage allows fluid extravasation around the catheter or accumulation in the lower abdominal wall. Leakage rates of 7% to 24% have been described.[49]

Some investigators suggest leak localization with computed tomography combined with peritoneal contrast enhancement[141] or magnetic resonance peritoneography.[8,113] When an early postoperative leak develops, dialysate exchange should be stopped for 2 to 4 weeks, necessitating a

Table 5–5 **Causes of Catheter Obstruction**

Cause	Treatment
Extrinsic	
Omental wrap	Catheter repositioning
Impacted sigmoid colon	Enemas
Urinary retention	Urethral catheter
Adhesions	Adhesiolysis
Luminal	
Blood clot/fibrin	Catheter flush; heparin in dialysate fluid; urokinase/streptokinase
Omentum	Flush or omentectomy
Bowel	Catheter repositioning
Catheter Position	
Malposition or kinking	Reposition by open/laparoscopic surgery or radiologically

temporary vascular catheter for hemodialysis. Late-onset leaks usually require catheter replacement. Pericatheter leaks associated with herniation should be treated by catheter removal and hernia repair. Only after allowing for adequate healing (e.g., 2 to 3 months) should further catheter insertion be attempted.

Hernias

The increased intra-abdominal pressures after infusion of dialysis fluid can enlarge preexisting hernias, so it is best to repair them before catheter insertion, although repair can be performed at the time of, or after, insertion if necessary.

The reported prevalence of de novo abdominal hernias in PD patients is 2.5% to 25%.[99,101,147] One study showed 32% of all hernias occur at the site of catheter insertion, 18% occur in the inguinal region, 27% are epigastric or umbilical, and 23% occur at the site of previous incisions.[101] Herniation into the thoracic cavity also has been reported.[65] The pressure of dialysate fluid can produce recanalization of a patent processus vaginalis, which manifests as scrotal or labial edema, shortly after full dialysate exchange regimens are begun.[72] Surgical ligation is necessary, with a postoperative regimen of low-volume, high-frequency dialysate exchanges until healing has occurred[1] or temporary conversion to hemodialysis.[99]

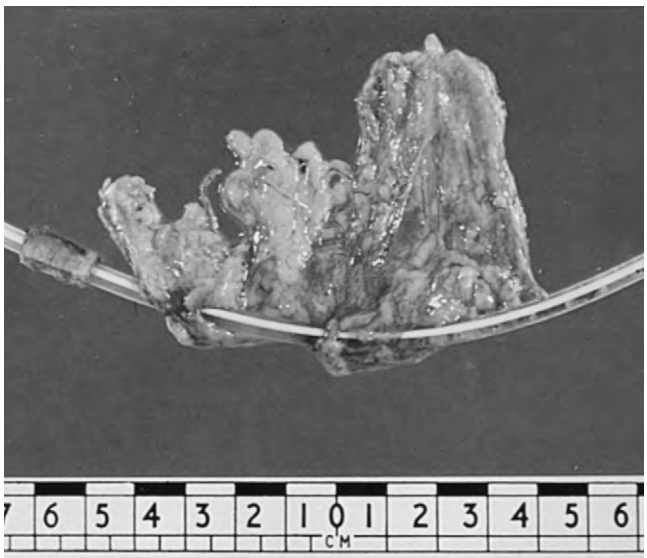

Figure 5–13 Catheter obstruction caused by omental wrapping.

The repair of hernias that develop while a patient is being treated with dialysis is controversial. Ideally, the repair should avoid a breach of the peritoneal membrane. Use of polypropylene prosthetic mesh in incisional hernia repair, attached to the deep fascia of the abdominal aponeurosis without opening the peritoneum, allows immediate use of continuous ambulatory PD.[55]

Some surgeons withhold PD for many weeks after inguinal herniorrhaphy,[106] fearing fluid leak or hernia recurrence. PD can safely be resumed immediately, however, with a modified (high-frequency, low-volume) exchange regimen[91] in the postoperative period.

Exit-Site and Tunnel Infections

As lone entities, exit-site and tunnel infections pose little risk, but the possibility of developing PD peritonitis demands careful attention to these infections; PD peritonitis occurs in approximately 12% of cases of exit-site or tunnel infections.[34,108] A positive culture at the exit site does not indicate an exit-site infection; it merely represents colonization and is not an indication for treatment. Vychytil and colleagues[145] suggested, however, that diabetic or immunosuppressed patients should be treated for a single positive culture indicating exit-site colonization by (or nasal carriage of) *S. aureus*. In all other patients, treatment should be instigated only if there are two or more positive cultures. Rates of exit-site infections range from 0.05 to 1.02 episodes per patient per year.[85,108,143] Table 5-6 lists common microorganisms that cause exit-site infections. *S. aureus* is the most common microorganism, and nasal carriage results in a fourfold increased risk of exit-site infection.[84]

Table 5-7 summarizes suggested management strategies for exit-site problems and infections. Erythema alone with no discharge should be treated with topical chlorhexidine, mupirocin, or hydrogen peroxide. In these circumstances, ultrasonographic examination of the subcutaneous catheter tract can be useful to exclude tunnel infection because this cannot always be ascertained clinically.[61] Purulent exit-site

Table 5–6 Microorganisms Causing Exit-Site Infections

infections should be swabbed for culture and Gram stained, in addition to culture of the peritoneal dialysate. Generally, for gram-positive microorganisms, a cephalosporin or flucloxacillin is indicated while awaiting the results of culture sensitivities. Alternatively, intravenous or per-catheter vancomycin can be used with careful monitoring of levels. If there is no improvement after 1 week, rifampicin should be added, and if infection persists, the tunnel should be explored and the cuff shaved, avoiding interruption of dialysis. Alternatively, the catheter can be removed,[50] although some authors advocate partial reimplantation of the catheter, with removal of the infected portion and connection of the remaining section to a new, divided catheter.[30]

For gram-negative organisms, per-catheter gentamicin or oral ciprofloxacin or both can be used. Persistent gram-negative infections may require catheter removal because infection is usually due to a deep tunnel infection, with a risk of peritonitis. In the absence of peritonitis, simultaneous catheter insertion can be considered with a contralateral exit site. The usual duration of treatment with oral antibiotics should be a maximum of 14 days, to avoid fungal infection.[83,84] When they do occur, fungal infections require catheter removal and systemic antifungal treatment, such as fluconazole.[50] It is unlikely that a *Pseudomonas* exit-site infection would be eradicated by antimicrobial therapy; early catheter removal is required.

Peritoneal Dialysis Peritonitis

Peritonitis is the most significant complication of PD and is the second most common cause of mortality in patients undergoing PD.[27,110] Incidence ranges from 0.5 to 1.4 episodes per patient per year,[10] with about 60% of patients developing PD peritonitis in the first year.[134] At least a quarter culminate in catheter failure. The most common portal of entry for infection is the exit and tunnel site. The first indications of peritonitis are generalized abdominal pain and tenderness in the presence of a cloudy effluent containing greater than 100×10^6/L white blood cells. Cell counts of 50 to 100×10^6/L may result in a cloudy effluent,[74] and for this reason the polymorphonuclear neutrophil cell percentage may be a more useful indicator of infection (>85% polymorphonuclear neutrophil cells is suggestive).[43]

The causative organisms in PD peritonitis generally differ from the organisms causing "surgical" peritonitis. In the latter case, infections are usually polymicrobial consisting of anaerobic and aerobic bacteria. In contrast, a single microorganism, usually a skin-colonizing, gram-positive bacterium, is the common cause of PD peritonitis; *S. aureus, Staphylococcus epidermidis,* and *Streptococcus* species account for 60% to 80% of cases. The categories of microorganisms commonly cultured in the effluent are listed in Table 5-6. Coagulase-negative staphylococci constitute 30% to 40%, and streptococci constitute 10% to 15%. Yeasts, such as *Candida*, are the most common cause of fungal peritonitis, entering the peritoneal cavity via the catheter or commonly from the vagina.[120]

Dialysate samples for microbiological examination should be taken from the first cloudy bag, providing culture with antibiotic sensitivities. Cultures can be negative, however, in half of patients, even when there are signs of PD peritonitis.[144] In a nonsurgical, PD peritonitic patient, clinical signs are usually mild. Along with abdominal pain, signs include pyrexia (35% to 65%), nausea and vomiting (30%), and diarrhea (10%)[144]; bowel sounds are often present. Other investigations include abdominal and chest radiographs to check for the catheter position and air under the diaphragm, although a pneumoperitoneum is not attributable to gastrointestinal perforation in patients with PD.[24]

There have been reports of nonbacterial, nonspecific eosinophilic peritonitis in PD patients.[129] Prognosis is usually excellent with resolution within days,[52] although it can lead to encapsulating sclerosing peritonitis in recurrent cases.[97]

Early surgical assessment and regular review are necessary for distinguishing PD peritonitis from a surgical cause. Antibiotics and peritoneal flushes form the mainstay of treatment. In mild cases, patients do not require hospital admission, unless they are systemically unwell. Because dialysate

From Gokal R, Ash SR, Helfrich GB, et al: Peritoneal catheters and exit-site practices: toward optimum peritoneal access. Perit Dial Int 13:29-39, 1993.

cultures are not available in the first instance, antibiotic coverage should be broad spectrum. Blood cultures are rarely of value in mild cases.[144] Management of so-called sterile peritonitis, in which no microorganisms are cultured, is controversial. Sterile peritonitis may represent inadequate sampling, or may be a result of indiscriminate use of antibiotics.

Where antimicrobial therapy is required, we administer intraperitoneal gentamicin (10 mg/2-L bag q.d.s.) and vancomycin (50 mg/2-L bag q.d.s.) for 10 days. In cases of recurrent peritonitis, it is prudent to use a urokinase flush on days 5 and 7 of antibiotic cover[107] because the focus of infection may have been walled off by protective fibrin deposits. Intraperitoneal *Pseudomonas* infection is difficult to treat.[31] Patients should receive gentamicin, 15 mg added to each 2-L dialysis bag, in combination with oral ciprofloxacin, 750 mg, twice daily; however, as with exit-site infections, the catheter almost always needs to be removed.

Mycobacterium infection is a particular problem in at-risk cohorts, but all patients with end-stage renal failure are generally at risk because of impaired cell-mediated immunity. Diagnosis can be difficult, but should be suspected in the presence of persistently elevated mononuclear cell counts combined with negative cultures. Acid-fast bacilli smears of the dialysate fluid may be negative in 90% of cases, but formal cultures are likely to be positive in most cases.[80]

Treatment consists of long-term antituberculous drugs; a suggested regimen is isoniazid, rifampicin, pyrazinamide, and ofloxacin for 9 to 15 months.[81] Catheter removal is usually undertaken,[80] although it is not considered necessary for cure. Mortality attributable to tubercular peritonitis is approximately 15%, and much of this may be due to treatment delay.[135]

Fungal infection complicating PD requires a different approach because some antifungal treatments, such as amphotericin and ketoconazole, cannot be administered directly into the peritoneal cavity. *Candida* has a tendency to adhere to the catheter making eradication difficult. Recommended treatment is flucytosine, 1 g orally, and intraperitoneal fluconazole, 150 mg daily. If there is no improvement within 48 to 72 hours, the catheter should be removed, and antifungal treatment should be continued. Fungal peritonitis has a mortality of 15%.[27]

Encapsulating Peritoneal Sclerosis

Encapsulating peritoneal sclerosis is a rare, but potentially life-threatening complication of PD. Reported prevalence rates are three to four cases per 1000 PD patient-years.[60,150] Reported mortality rates are 43% to 75%.[3,100,119] Patients present with abdominal pain, a decline in net ultrafiltration, ascites, bloody effluent, or bowel obstruction. Malnutrition and death are common with encapsulating peritoneal sclerosis.

Recurrent episodes of peritonitis result in loss of the mesothelial layer of the peritoneal cavity causing extensive fibrinogenesis, hyalinization, loculated ascites, and eventual encapsulation of the peritoneal cavity. Radiological contrast studies show delayed transit or intestinal obstruction.[22] Abdominal ultrasonography may show loculated ascites containing echogenic fibrin strands. Calcification also may be present, and the bowel wall is thickened[62] with tethering of the small bowel.[130] Computed tomography shows these features in greater detail.[76]

Renal Transplant Issues with Peritoneal Dialysis

When a PD patient receives a successful renal transplant, the PD catheter can be removed, but the timing of removal requires careful judgment. In most cases, transplant recipients have the catheter removed during the first 2 to 3 months post-transplant. Earlier removal is an alternative when good early allograft function is expected, such as after a live donor transplant. In contrast, the PD catheter must be protected in patients who need to continue dialysis in the post-transplant period because of delayed graft function. Every effort must be made not to breach the peritoneum at the time of transplant because this may lead to a PD leak and the need for temporary hemodialysis. There also is a theoretical risk of serious peritransplant infection if PD fluid leaks into the transplant bed.

Active PD peritonitis is an absolute contraindication to transplantation, but it may be safe to proceed with the operation if the patient has had several days of treatment with intraperitoneal antibiotics, and the bags are clear. Previous studies have highlighted the risks of infection after renal transplantation. The incidence of peritonitis can be 35%,[102] but it is not usually life-threatening. Management strategies should include antibiotics and peritoneal lavage, and in resistant cases there should be a low threshold for catheter removal and conversion to hemodialysis. Patients receiving PD at the time of transplantation have significantly higher general infection rates compared with patients receiving hemodialysis.[104] This risk seems to be reduced when patients convert to hemodialysis just before transplantation.[104]

Studies comparing differences in graft survival rates between patients receiving PD or hemodialysis are contradictory. Some report no difference,[51] whereas others have found improved graft survival in hemodialysis patients.[54] It also has been suggested that rejection rates are 50% higher in PD patients.[51] A more recent study involving more than 9000 renal transplant recipients showed no difference between PD or hemodialysis in terms of acute rejection rates.[15]

Chapter 6

Brain Death and Donor Management

Kenneth E. Wood

The most immediate and practical solution to the current organ donor crisis is the maximal use and optimal management of the existing potential organ donor pool. This approach provides the greatest opportunity to enhance the conversion of potential donors to actual donors and similarly maximize the yield and quality of the organs procured from each donor. Organ donor management is fundamentally a standardized process that occurs in the following sequence: (1) surveillance to identify patients with severe neurological injury likely to progress to brain death or eventuate in withdrawal of support, establishing candidacy for donation after cardiac death; (2) declaration of brain death using standardized methodology and a standard protocol for withdrawal and declaration in the cases of donation after cardiac death; (3) a uniform request for consent; and (4) optimal medical management of the potential donor.

With the more recently recognized immunological continuum between the donor and the recipient, optimal medical management mandates continued intensity of support from declaration to procurement. This continued support requires a focus shift away from cerebral-protective strategies to maintaining and optimizing organs for transplantation against the background of the physiology of brain death. Given the possibility of procuring multiple organs per donor for multiple recipients, medical management of the potential donor is analogous to providing critical care to multiple patients simultaneously. This management period is crucial for several reasons, as follows:

1. It ensures donor somatic survival so that procurement can be undertaken.
2. Hemodynamic stabilization and mitigation of repetitive ischemia-reperfusion injury maintain the organs to be procured in optimal condition.
3. With the increasing recognition of an immunological continuum between the donor and the recipient, optimal management of the donor can have an impact on the short-term and long-term graft function and the quality of life of the recipient.

Similar to the care of any critically ill patient, a collaborative multidisciplinary approach that integrates the skill sets of critical care physicians, nurses, respiratory therapists, and the organ procurement coordinator is essential. This chapter provides an overview of the potential organ donor management process in the intensive care unit. Emphasis is placed on the physiology and declaration of brain death and medical management, focusing on the cardiopulmonary system given its crucial role in optimizing all organ systems.

BRAIN DEATH: HISTORICAL PERSPECTIVE AND STANDARD

The contemporary approach to the understanding and the declaration of brain death originates from the report of 23 cases of a new type of coma called "le coma dépasse" in 1959 by Mollaret and Goulon.[47] This comprehensive clinical and electroencephalographic description of irreversible coma effectively defined brain death and the consequent physiological abnormalities. The widespread availability of mechanical ventilation in conjunction with the developing field of transplantation intersected in 1967, when Christian Barnard transplanted the heart of a brain-dead, mechanically ventilated patient into a cardiomyopathy patient. This operation precipitated enormous controversy related to the neurological criteria for death and galvanized the movement to codify brain death criteria[48] and define death by either cardiac or neurological criteria.

In 1968, an ad hoc committee at the Harvard Medical School, consisting of representatives of the Law School; Graduate School; Divinity School; School of Public Health; and physicians from Anesthesiology, Neurology, and Neurosurgery sought to "define irreversible coma as a new criterion for death." After excluding hypothermia and central nervous system depressants, and using a whole brain definition,

the committee proposed that brain death required unreceptivity and unresponsivity, no movements or breathing for at least 1 hour with total absence of respiratory effort when disconnected from mechanical ventilation for 3 minutes, no brainstem reflexes, and a flat electroencephalogram (EEG) for a minimum of 10 minutes.[1] They suggested all tests be repeated and document no change at least 24 hours later. Subsequent commentary from the committee in 1969 suggested that the EEG was not essential to the diagnosis but could provide valuable supporting data.[4] In 1971, the Minnesota Criteria further established the time periods for apnea and observation and, for the first time, attempted to define irreversible damage to the brainstem[46] as the "point of no return" that needed to be established "beyond reasonable doubt." The United Kingdom first established brain death criteria in 1976[10] and subsequently defined brain death as brainstem death.[9]

Cardiac and neurological death in the United States was equated in 1981 when the report of the Medical Consultants on the Diagnosis of Death to the President's Commission for the Study of Ethical Problems in Medicine and Biomedical and Behavioral Research produced "Guidelines for the Determination of Death."[68] Death was defined by either irreversible cessation of circulatory and respiratory functions or irreversible cessation of all functions of the entire brain, including the brainstem. Brain death required the following: (1) cessation defined by deep coma with cerebral unreceptivity and unresponsivity and absence of brainstem functions, including an apnea test with failure to respond to a partial pressure of arterial carbon dioxide ($PaCO_2$) of 60 mm Hg, and (2) irreversibility defined by coma whose cause is established and sufficient to account for the loss of brain functions, exclusion of the possibility of recovery of any brain function, and persistence of the cessation of all brain functions for an appropriate period of observation or trial of therapy, or both.

The committee recommended a 6-hour period of observation documented by clinical examination and a confirmatory EEG; a 12-hour period in the absence of a confirmatory study; and a 24-hour period for anoxic brain injury, in which the extent of the damage is more difficult to ascertain. Confirmation of clinical findings by electroencephalography was deemed desirable when objective documentation was needed to substantiate the clinical findings. Similarly, the committee addressed the issue of drug and metabolic intoxication and recommended that death not be declared until the intoxicant is metabolized or intracranial circulation is tested and found to have ceased. In the case of hypothermia, the committee believed there were insufficient data to know whether tests of absent or diminished circulation are confirmatory.

Although advisory, the President's Commission guidelines effectively established the criteria used for the declaration of brain death. The American Academy of Neurology developed practice parameters reflecting an evidenced-based literature approach in 1993. These parameters comprehensively reviewed clinical testing of brainstem function, observations compatible with the diagnosis of brain death and confirmatory testing. For practical purposes, these practice parameters have become the standard approach throughout the United States.[91]

Although brain death has been accepted in most countries throughout the world, there is substantial variability in the criteria used; the requirement for confirmatory tests, interval between examinations, and number of physicians or nonphysicians required are the main areas of inconsistency. Readers should consult their local statutes to ensure a clear understanding of and compliance with the legal requirements in their state, jurisdiction, or country. Insofar as the elements related to the clinical examination are the most consistent, these are reviewed, and various available confirmatory options are discussed. A full description of brainstem death and its diagnosis is available in the last edition of this book.[56a]

CLINICAL EXAMINATION

Prerequisites, Confounding Conditions, and Exclusions

A clinical diagnosis of brain death requires that certain prerequisites have been met, reversible or confounding conditions have been excluded, and the cause of coma has been established before undertaking a comprehensive examination. Figure 6-1 illustrates a generalized approach to the process. The cause of coma should be obvious and evident. The diagnosis of brain death in patients with coma of undetermined etiology is problematic. Contemporary practice mandates that some form of neuroimaging, usually computed tomography (CT), be undertaken and be consistent with a neurological catastrophe. Most brain-dead patients have CT evidence of herniation, cerebral edema, or large hemispheric lesions. CT findings consistent with brain death should not eliminate the assessment of confounding conditions. A normal CT scan, which occasionally can be seen after cardiac arrest or meningitis, should raise doubt regarding the diagnosis of brain death.

Table 6-1 lists key conditions and their characteristics that must be excluded in the evaluation of brain death. A diagnosis of brain death cannot be made reliably when the core temperature is 32°C or less. A core temperature of 28°C to 32°C is associated with decreased levels of consciousness and pupillary dilation, and a core temperature less than 28°C reportedly aborts brainstem reflexes.[13] This lack of brainstem reflexes effectively precludes assessment of the key portion of the examination needed to establish the diagnosis of brain death. In this circumstance, hypothermia should be aggressively managed, and examination for brain death should proceed only when the core temperature is greater than 32°C and preferably normal between 36°C and 37.5°C. The use of confirmatory studies to establish the diagnosis of brain death in hypothermic patients is controversial and should be avoided.

Coma of undefined etiology necessitates consideration of poisoning or drug intoxication. Barbiturates or tricyclics can mimic brain death by producing coma and abolishing brainstem reflexes. Preserved pupillary reactivity is present in many drug intoxications and is especially helpful in differentiating this condition from brain death. Barbiturate intoxication may abolish pupillary reactivity, however, and mydriasis may be present after intoxication with tricyclic antidepressants, antihistamines, stimulants, and sympathomimetics. The presence of trace drug metabolites can complicate the diagnosis of brain death significantly. In this circumstance, the following approach has been advocated:

1. Administer specific antidotes, such as naloxone or flumazenil.
2. Proceed with a brain death evaluation when screening tests reveal drug levels that are less than therapeutic levels, or the alcohol level is less than the legal driving level.

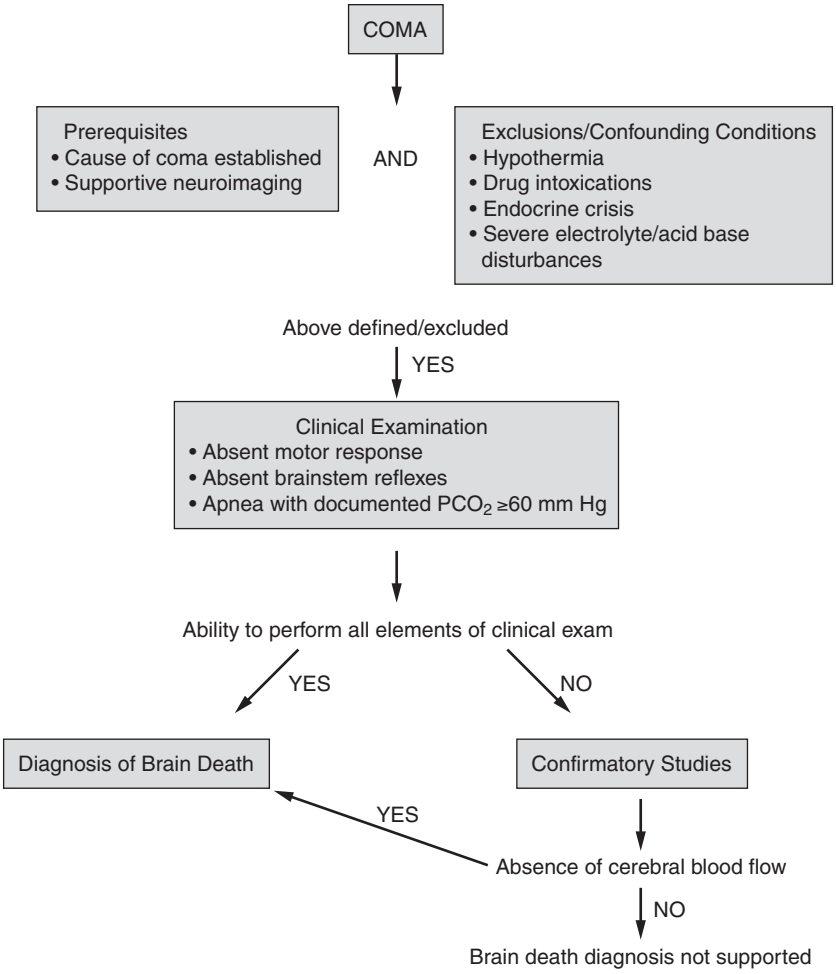

Figure 6–1 General approach to the diagnosis of brain death.

Table 6–1 **Confounding Conditions and Exclusions in the Diagnosis of Brain Death**

Hypothermia
Diagnosis of brain death requires core temperature >32°C
Absence of brainstem reflexes when core temperature <28°C
Drug Intoxications
Barbiturates
Tricyclics
Alcohols
Narcotics
Benzodiazepines
Antipsychotics
Antiepileptics
Antihistamines
Acute Metabolic Endocrine Derangements
Electrolyte, acid-base derangements
Uremia
Hepatic coma
Hypoglycemia
Hypothyroid
Neurological Diseases
Persistent vegetative state
Locked-in syndrome
Akinetic mutism

3. Observe the patient for at least four times the elimination half-life when the drug cannot be quantified.
4. Observe the patient for 48 hours, assessing brainstem function and motor responses in circumstances where suspicion for drug intoxication is high but unknown.

Continued absence of responsiveness and brainstem function necessitates a confirmatory study in this circumstance.[92]

The therapeutic use of barbiturate coma in patients with severe brain injury and intractable intracranial pressure (ICP) elevation can mimic brain death and make the diagnosis of brain death challenging. One approach would be to proceed with a confirmatory study to document the absence of cerebral blood flow and declare brain death. In a study of 36 patients who met clinical and electroencephalograhic criteria for the diagnosis of brain death except for the presence of significant serum levels of barbiturates, demonstration of absent cerebral blood flow with transcranial Doppler and ^{99m}Tc-HMPAO flow scans decreased the period between presumptive and definitive diagnosis of brain death. In the group waiting for the metabolic clearance of the drug, the interval between presumptive and definitive diagnosis of brain death was 34 hours compared with 17 hours for ^{99m}Tc-HMPAO scan and 5 hours for transcranial Doppler; this represented a decrease of 49% and 85%, respectively.[40] Alternatively, it has been suggested that the clinical diagnosis

of brain death is a sacrosanct principle, and that replacement of a comprehensive neurological examination by a technical study in patients to be evaluated for brain death should be considered unacceptable.[93]

Metabolic abnormalities defined in Table 6-1 should be corrected before establishing the diagnosis of brain death. Frequently, brain-dead patients exhibit hypernatremia consequent to diabetes insipidus or hyperglycemia. Levels greater than 160 mEq/L should be corrected before assessment for brain death. Occasionally, patients in a persistent vegetative state or a locked-in syndrome may be mistaken for brain dead. The latter may be attributable to an initial neurological event or reflective of Guillain-Barré syndrome, persistent neuromuscular blockade, or end-stage amyotrophic lateral sclerosis. A thorough and comprehensive neurological examination should exclude these processes.

Coma

Patients in coma reflective of brain death completely lack responsiveness assessed by examination of eye and motor responses to painful stimuli, such as pressure on the nailbed or supraorbital nerve. Occasionally, motor responses of spinal origin can occur spontaneously during apnea testing or hypotension. These responses are brief and episodic and frequently do not persist with repetitive testing. Neuromuscular blockade can produce sustained neuromuscular weakness. Bedside testing using a peripheral nerve stimulator with a train-of-four stimulus should result in four thumb twitches to ensure residual paralytic agents are not contributing to unresponsiveness in patients previously receiving these agents.

Absence of Brainstem Reflexes

Pupils

Pupillary response to bright light evaluates cranial nerves II and III and should be absent in both eyes. Most pupils in brain death are nonreactive and midposition. Round, oval, irregular, or dilated pupils are compatible with brain death, however, provided that they are *not* reactive. Although many drugs can affect pupil size, the response to light should be preserved. Neuromuscular blockade should not affect pupillary reactivity; atropine in conventional doses likewise should not affect reactivity.

Ocular Movements

Any ocular movements, including nystagmus, should be absent in response to head turning or caloric testing, which evaluates cranial nerves III, VI, and VIII. The oculocephalic reflex, or doll's eye reflex, which consists of vigorous rotation of the head from midposition to 90 degrees, should be undertaken only after cervical spine stability is ensured. In non–brain-dead patients, the eyes deviate to the opposite side of the turning, which is termed the presence of doll's eyes. In brain-dead patients, the eyes do not move and retain their orientation, which is termed the absence of doll's eyes. Caloric testing is complementary to the preceding and necessary when the assessment of the oculocephalic reflex cannot be assessed by head turning because of cervical spine injury. Caloric testing is undertaken after inspection visualizes the tympanic membrane and with the head at 30 degrees. Approximately 50 mL of ice water is injected through a small suction catheter directly into the ear canal. In non–brain-dead patients, there is slow deviation to the cold caloric stimulus. In brain-dead patients, there should be no response. One minute of observation and 5 minutes between right and left stimulations are required. Aminoglycosides, sedatives, tricyclic antidepressants, anticholinergics, and antiepileptic medications can minimize or abort the caloric response.

Facial Sensation and Facial Motor Response

The corneal reflex and response to pressure on the supraorbital nerve evaluates cranial nerves V and VII and should be absent in brain-dead patients. A blink response to corneal stimulation with a throat swab represents brainstem function and is inconsistent with brain death. Pressure on the supraorbital nerve or any painful stimulus should not provoke grimacing in brain-dead patients.

Pharyngeal and Tracheal Reflexes

Stimulation of the posterior pharynx with a tongue blade (gag reflex) and bronchial suctioning evaluates cranial nerves IX and X and should produce no response, such as gagging or coughing, in brain-dead patients.

Apnea Testing

After prerequisites have been fulfilled, confounding conditions have been excluded, and absent responses to the preceding brainstem stimulation have been documented, it is appropriate to proceed with apnea testing. Before initiating the apnea test, it is often prudent to assess whether the patient is breathing above the set ventilator rate because this indicates respiratory activity and brainstem function and obviates the need to assess brainstem function or perform an apnea test. Loss of brainstem function precipitates a loss of control of breathing and resultant apnea. The chemoreceptors of the respiratory center in the brainstem are evaluated when maximally stimulated by the elevated Pa_{CO_2} that occurs with apnea. Failure to respond to accepted thresholds of Pa_{CO_2} signifies loss of brainstem function and is consistent with brain death. Before performing an apnea test, it is recommended that the following be addressed[91]:

1. Core temperature should be 36.5°C or greater because lower temperatures may decrease metabolism and carbon dioxide production and shift the oxyhemoglobin dissociation curve to the right, impairing oxygen release.
2. Systolic blood pressure should be 90 mm Hg or greater because lower levels preclude the clinical diagnosis of brain death.
3. Preoxygenation with 100% oxygen for 10 minutes should be applied because the development of desaturation mandates cessation of the test.
4. Eucapnia with a Pa_{CO_2} of 40 mm Hg should be present before the test.

After the preceding have been addressed, the patient is disconnected from the ventilator, with apneic oxygenation provided by a catheter placed at the carina delivering 100% fraction of inspired oxygen (F_{IO_2}) at 6 L/min, and the patient is carefully observed for respiratory activity. Any spontaneous respiratory activity, which usually occurs at the beginning of the test, necessitates reconnection to the ventilator and implies preserved brainstem function. The increase

in $PaCO_2$ is biphasic, with the greatest increase in the first minute and overall $PaCO_2$ increases of 3 to 6 mm Hg per minute.[15] The acknowledged $PaCO_2$ threshold of 60 mm Hg for maximal brainstem respiratory stimulation should be achieved after 8 minutes in apneic patients. Provided that the patient maintains hemodynamic stability and reasonable oxygen saturations, an arterial blood gas measurement should be obtained first, followed immediately by reconnection of the patient to the ventilator at the previous setting. $PaCO_2$ of 60 mm Hg or greater, representing failure of the brainstem to respond to maximal stimulation, is consistent with brain death. $PaCO_2$ of less than 60 mm Hg in the absence of observed respiratory efforts probably signifies reduced carbon dioxide production, necessitating a repeat test of 10 minutes' duration.

The presence of hemodynamic instability, desaturation, or cardiac arrhythmias mandates immediate cessation of an apnea test. In this circumstance, an arterial blood gas measurement should be drawn at the first sign of instability, and the patient should be reconnected immediately to the ventilator. Similar to the preceding, $PaCO_2$ of 60 mm Hg or greater is consistent with brain death, whereas lower levels are indeterminate. In the latter circumstance, the apnea test may be repeated after stabilization. Inability to achieve stability necessitates a confirmatory study. An option to an absolute threshold value of $PaCO_2$ of 60 mm Hg is a 20 mm Hg increase in $PaCO_2$ above the patient's baseline $PaCO_2$. Insofar as it is frequently difficult to define a patient's baseline $PaCO_2$, proceeding directly to a confirmatory test should be strongly considered in patients with suspected baseline $PaCO_2$ elevations.

Provided that appropriate precautions are undertaken, the apnea test generally can be performed safely. In a large series reporting a 25% incidence of complications consisting of hypotension or arrhythmias, or both, 48% of patients began the apnea test with unfavorable conditions; 39% of these patients, compared with 15% of the 52% with favorable preconditions, developed complications. In descending order of frequency, failure to preoxygenate, failure to correct electrolyte and acid-base abnormalities and preexisting cardiac arrhythmias, inotropic drug use, and hypotension were predisposing characteristics of patients developing complications. Preoxygenation was identified as the crucial factor to prevent complications. Cardiac arrest occurred in one patient.[28]

Confirmatory Studies

Unless required by law, a confirmatory study is not mandatory, but it is needed for patients in whom specific components of clinical testing cannot be reliably evaluated. Table 6-2 shows generally available confirmatory studies. All studies except the EEG are predicated on the principle that the absence of cerebral blood flow is consistent with the diagnosis of brain death. As the name implies, these are confirmatory studies and should be undertaken only as required or needed in conjunction with a comprehensive neurological examination and not used in place of a neurological examination unless absolutely necessary.

The diagnosis of brain death should require not only a precise neurological examination but also precise documentation of the findings. More recent retrospective reviews of brain death declarations revealed incomplete documentation.

Table 6–2 **Confirmatory Studies**

Cerebral Angiography
Contrast agent injected under high pressure into anterior and posterior circulations
Absence of cerebral filling at carotid and vertebral entrance into skull
Potential for contrast-induced nephrotoxicity
Rarely performed
Cerebral Scintigraphy (Technetium ^{99m}Tc-HMPAO)
Can be performed at bedside in brief time
Good correlation with conventional angiography
Isotope Angiography
Albumin labeled with technetium 99m
Can be performed at bedside
Delayed filling of sagittal and transverse sinuses
Posterior cerebral circulation not visualized
Transcranial Doppler Ultrasound
Middle cerebral artery through temporal bone above zygomatic arch and vertebral or basilar arteries through suboccipital transcranial windows bilaterally
Lack of transcranial Doppler signals should not be interpreted as confirmatory because 10% of patients may not have temporal windows
May not be diagnostic with intratentorial lesions
Electroencephalogram
No electrical activity for 30 minutes
Complex technical requirements

In this series, the clinical tests most likely to be documented were tests of pupillary (86%) and gag (78%) reflexes. Motor responses were commented on in only 66%, and corneal reflexes were tested in only 57% of cases.[88] In this era in which failure to document presumes failure to perform, it is crucial to ensure that appropriately performed tests are documented. Figure 6-2 is a representative example of a tool that can be implemented to standardize the documentation of brain death.

Donation after Cardiac Death

A prospective donor's death is determined by neurological criteria in the case of donation after brain death or by cardiopulmonary criteria in the case of donation after cardiac death. Both require demonstration of cessation and irreversibility. In the case of donation after cardiac death, cessation of function is defined by a clinical examination documenting absence of responsiveness, heart sounds, pulse, and respiratory efforts. In contrast to the routine pronouncement of general hospital patients using only the preceding criteria, the donation process necessitates confirmation of the physical findings by electrocardiography and an arterial catheter tracing to ensure the patient is dead.[5,61] Equating pulseless electrical activity with asystole because neither results in blood flow is controversial, and individual practitioners should review their hospital donation after cardiac death policy for guidance. Donation after cardiac death irreversibility is defined by cessation for an appropriate period of observation, and death occurs when circulatory and respiratory functions do not resume spontaneously. The Institute of Medicine recommended a 5-minute interval from asystole to the declaration of

DOCUMENTATION OF BRAIN DEATH

death in donation after cardiac death cases.[61] The Society of Critical Care Medicine recommended that at least 2 minutes of observation is required, and more than 5 minutes is not recommended.[16]

PHYSIOLOGY OF BRAIN DEATH

The impact of brain death on the donor graft function was first appreciated in the early 1980s when it was recognized that hearts retrieved from healthy anesthetized baboons functioned immediately on transplantation, yet hearts retrieved from brain-dead donors frequently manifest delayed function. Given the similar retrieval and storage techniques, the differences in post-transplantation function seemed to be attributable to the brain death process.[11] Contemporarily, this is best exemplified in kidney transplantation because non–HLA-matched living donor kidney transplants almost uniformly do better than HLA-matched deceased donor transplants. These observations suggest that the brain death process is not static, and the transplanted graft is not biologically inert.[84]

An immunological continuum between the donor and the recipient has been proposed to explain the influence of brain death on donor organ quality and outcome after transplantation.[24,67] In this model, brain death and other associated ischemia-reperfusion events that can occur with the trauma preceding brain death, procurement, cold storage, and transplantation can induce nonimmunological injuries that are important risk factors for short-term and long-term graft function. This model proposes that brain death induces an intense inflammatory response, and that the graft is inflamed and primed to initiate and amplify recipient responsiveness. Initial and long-term results of deceased donor organ transplantation have been reported to correlate with donor demographics and the cause of the brain injury.[7] Consequently, an implicit understanding of the physiology of brain death not only is crucial to maintaining donor somatic survival and optimizing organ function but also provides a framework to develop strategies that would attenuate this brain death–induced inflammatory response, which potentially may have an impact on early and late graft rejection.

In contrast to animal models of brain death in which the process is well choreographed in a controlled setting, an implicit understanding of human brain death is challenging for multiple reasons, as follows[62]:

1. The time of actual brain death may be different from the certification time, and significant pathophysiological changes may occur during this time.
2. The pathophysiological changes depend on the rapidity of the progression of the brain injury resulting in herniation.
3. Treatment of brain dead donors may result in pathophysiological changes independent of the brain death.
4. No human model will ever be available.

Consequently, an understanding of brain death physiology and its implications must be inferred from animal models and observations in human case series.

Figure 6-3 depicts the distribution and pathophysiological correlation of the rostral-caudal progression of cerebral-spinal ischemia termed coning that eventuates in herniation and brain death. Figure 6-4 shows a magnetic resonance image obtained at brain death compared with a normal magnetic resonance image. Initial cerebral ischemia results in vagal activation and bradycardia decreasing cardiac output and blood pressure. Caudal progression of ischemia to the level of the pons produces superimposed sympathetic stimulation resulting in Cushing's reflex of bradycardia and systemic hypertension. Ischemia at the medullary level begins to inactivate the brainstem, eliminating vagal stimulation and leaving only unopposed sympathetic stimulation.

Termed the autonomic surge and characterized by a hyperdynamic state with tachycardia and frequently extreme hypertension, this condition represents an attempt to maintain a cerebral perfusion pressure gradient against an elevated ICP. The magnitude of the autonomic surge seems to be related to the rapidity of increase in ICP. In animal models, an explosive increase in ICP is associated with profound levels of catecholamines and systemic hypertension, whereas a slow, gradual increase as can be seen after cardiac arrest may not provoke such an exaggerated response. Coincident ischemia at the hypothalamic and pituitary levels produces thermoregulatory dysfunction and the basis for endocrine abnormalities. Herniation produces spinal cord ischemia resulting in sympathetic deactivation characterized by a decreased heart rate, low cardiac output, and vasodilation.[82] Somatic death inevitably occurs within hours to days in the absence of aggressive hemodynamic and hormonal support. Prolonged somatic survival for a mean duration of 23 days has been reported in circumstances where brain death was not acknowledged, and hemodynamic and hormonal support was instituted.[95] Histopathological examination of patients after clinical declaration of brain death reveals necrosis and liquefaction of brain tissue.[6]

The devastating physiological instability and metabolic derangements that may precede the actual herniation process[55] and the above-described brain death process often conspire to produce profound levels of donor instability. The autonomic surge to maintain cerebral perfusion pressure engenders dramatic increases in myocardial work, producing physiological, histological, and electrocardiographic evidence of left ventricular dysfunction.[49] Catecholamines increase cytosol calcium, activating cellular enzymatic pathways, and disrupting adenosine triphosphate (ATP) generation, which compromises myocardial energy production. Activation of xanthine oxidase generates free radicals, impairing organ function further.[50] Autonomic surge–induced vasoconstriction may jeopardize peripheral organ blood flow, and postherniation sympathetic deinnervation with attendant vasodilation may follow. This hemodynamic sequence creates the potential for ischemia-reperfusion injury and the associated inflammatory response. Against this background, there is speculation that hypothalamic-pituitary destruction produces an endocrinopathy of brain death that is

dominated by thyroid and cortisol depletion. The absence of these hormones is proposed to mediate cellular dysfunction and metabolic abnormalities and contribute further to hemodynamic instability.

Ischemia-reperfusion injury may occur as a consequence of the precipitating traumatic event and resuscitation, the brain death process, the removal of the organ, cold storage, and transplantation. Ischemia-reperfusion represents a complex series of molecular and cellular events that produce substantial organ injury. In the case of brain death, autonomic surge–induced vasoconstrictive ischemia is followed by vasodilation and reperfusion with oxygen-rich blood. The latter produces highly reactive oxygen radicals that can directly exert their cytotoxic effects or initiate a cascade of additional molecules with detrimental effects. Damage consequent to oxygen radicals is widespread and characterized by inhibition of ion transmembrane transport, ATP store depletion, disturbances in arachidonic acid metabolism, peroxidation of membrane lipids, and desaturation of proteins, compromising cellular function. Activation of the vascular endothelium and circulating leukocytes along with triggering of the adhesion molecule and cytokine cascade similarly contribute to cellular damage. Endothelial cell swelling compromises vascular space, and the production of chemotactic factors for leukocytes can obstruct the microcirculation further. Release of various lymphocyte-derived and macrophage-derived cytokines may increase the immunogenicity of the donor organs. Tilney and coworkers[84] proposed that ischemia-reperfusion events produce an early insult that precipitates a series of inflammatory events that include the expression of major histocompatibility antigens. This increased immunogenicity of the graft is proposed to amplify the continuum between antigen-independent and antigen-dependent events, which may explain the apparent associations between delayed graft function, acute rejection, and compromised long-term renal graft function.

Brain death–induced hypothalamic-pituitary axis disruption may contribute to donor instability and graft dysfunction. Appreciable disparity exists, however, regarding the functional status of the hypothalamic-pituitary axis between animal and human studies. Low levels of circulating thyroid hormone are proposed to compromise cellular mitochondrial function and impair the use of metabolic substrate, resulting in diminished ATP production.[11,52,53] The transition from aerobic to anaerobic metabolism has correlated with organ dysfunction and hemodynamic instability. Dramatic improvement in cardiovascular stability, abolition of anaerobic metabolism, normalization of acid-base status and electrocardiograms, and improved organ suitability for transplantation have been reported with the use of exogenous thyroid hormone supplementation.[52,53] Several studies in humans have failed, however, to establish the presence of endocrine dysfunction[29,31,65]; correlate hemodynamic instability, inotropic requirements, or lactate levels with hormonal levels[31,65]; or show improvement with supplementation of exogenous hormones.[26,69] Despite the apparent benefits of hormonal supplementation seen in a large retrospective analysis,[72] the standard use of this treatment is controversial. Prospective randomized trials are needed to establish efficacy and practice guidelines.

MEDICAL MANAGEMENT OF A POTENTIAL ORGAN DONOR

General

The causative events precipitating brain death in conjunction with the physiology of brain death often conspire to produce an unstable donor. In addition to the systemic effects of polytrauma, isolated brain injury before brain death is reported to affect the cardiac and neuroendocrine systems. Subarachnoid hemorrhage is associated with

electrocardiographic changes, troponin release, and reduced left ventricular ejection fraction. An apex-sparing pattern of left ventricular dysfunction and diastolic dysfunction are reported to contribute to pulmonary edema in subarachnoid hemorrhage independent of brain death.[3,36,98] Similarly, neuroendocrine dysfunction after traumatic brain injury has been described and is attributed to direct injury to the hypothalamic-pituitary axis, effects of catecholamines and cytokines, or systemic infection and inflammation. The estimated incidence of hormonal reduction is adrenal, 15%; thyroid, 5% to 15%; and vasopressin, 3% to 37%.[64,77] The preceding events and their physiological correlates produce a period between brain death and procurement that is characterized by instability that is directly proportional to the interval between declaration and procurement.[55] It has been estimated that 10% to 20% of potential donors progress from brain death to somatic death during this time.[41] This period after brain death requires a continued intensity of support; however, the focus is shifted away from cerebral protective strategies to approaches designed to optimize the donor organs for transplantation. In effect, this support should be viewed as providing simultaneous critical care to the organs of the multiple recipients. This support facilitates donor somatic survival so that procurement can be undertaken, maintains the organs to be procured in their best condition, and potentially can affect the recipient's quality of life. Standardized guidelines and algorithms focusing on hemodynamic stabilization have proved beneficial in this setting.[34,39,89]

Benefits of these approaches have included recovery of organs initially deemed unsuitable, salvage of unstable donors, and increasing the number of organs procured and transplanted with good outcomes. A trial employing a standardized donor management protocol increased the number of organs procured by 10.3% per 100 donors and the organs transplanted by 11.3% per 100 donors compared with conventional management.[71] The greatest benefit was noted in pancreas, heart, and lung transplantation. All organs benefit from optimal hemodynamic management, which is best illustrated by the increased percentage of kidneys procured with better renal recipient graft function when the heart and the kidneys are jointly procured compared with procurement of the kidneys alone.[71] A review of variables during the care of donors that can influence the outcomes of kidney transplantation concluded that increasing urine output to more than 100 mL/hr at least during the hour before procurement and returning the serum creatinine to admission baseline are the two factors that can be altered during donor management.[63] Insofar as these reflect optimal hemodynamic management, the rest of this chapter is focused on cardiovascular and hemodynamic management.

Echocardiographic and Stability Assessment

Figure 6-5 shows an algorithmic approach to achieving donor hemodynamic stability. While continuing full intensive support, all potential donors should undergo transthoracic echocardiography (TTE) to identify structural abnormalities that might exclude procurement and to define the left ventricular ejection fraction. TTE was first recognized as a potential screening tool for cardiac donors in 1988, when in the absence of TTE, 29% of donor hearts would have been excluded on clinical criteria such as chest trauma, sustained hypotension, prolonged catecholamine use, or cardiac arrest. TTE identified hearts that could be procured and successfully transplanted despite clinical factors previously thought to preclude their use.[25]

Currently, echocardiographic evidence of left ventricular dysfunction is responsible for 28% of hearts that are not transplanted and is the most significant predictor of nonuse with an odds ratio of 1.48 per 5% decrease in ejection fraction.[97] Consequently, it has been suggested that efforts to improve yield should focus on the prevention or reversal of left ventricular dysfunction.[97] Abnormalities of left ventricular function are common with brain injury and brain death.[3,86,96,98] In a study of brain-dead patients, echocardiographic evidence of systolic dysfunction was present in 42%, which was not predicted by electrocardiogram or clinical history. Apical left ventricular function was frequently preserved despite regional abnormalities. This apical sparing is proposed to represent the relative absence of sympathetic nerve terminals and diminished norepinephrine content in this area minimizing damage during the catecholamine surge associated with brain death. There was no reported histopathological correlation with the areas of echocardiographic abnormality postmortem.[14]

Hemodynamic Support

In potential donors in whom the recommended cardiovascular thresholds are not achieved or in whom the ejection fraction is less than 45%, consideration should be given to placement of a pulmonary artery catheter (PAC). Although the use of the PAC is controversial in general,[80] several studies have used the PAC to improve the management of potential organ donors, which resulted in increased rates of recovery and optimized organ function.[34,60,89] As shown in Figure 6-5, the PAC can be used to assess left and right heart filling pressures, define cardiac hydraulic pump function, guide vasoactive medications, and adjudicate the fluid balance between competing organ systems.

Hemodynamic instability is common in 80% of donors and may be sustained in 20% of donors despite vasoactive support.[90] Hypotension is more common in volume-depleted donors treated with vasopressors and donors with diabetes insipidus not receiving antidiuretic hormone.[17] Ongoing hypotension jeopardizes organ function and creates more potential for ischemia-reperfusion injury, donor cardiac arrest, and donor loss.[62] An expeditious approach to diagnosis and treatment of hypotension is imperative. Figure 6-6 presents a three-compartmental model of the circulation that can be used to define the physiological abnormality in any hemodynamically unstable patient. This model conceptualizes the circulatory system as having three compartments: volume in a venous capacitance reservoir, two hydraulic pumps linked in series, and a vascular impedance bed into which the common pump empties. All three compartments usually are affected in potential organ donors.

Volume Resuscitation

In the period immediately after brain death, most donors tend to be intravascularly fluid depleted, which is multifactorial in origin. Although inadequate volume resuscitation from the original trauma or third spacing secondary to the inflammatory response potentially contributes, management of elevated ICP by intentional hypovolemia is

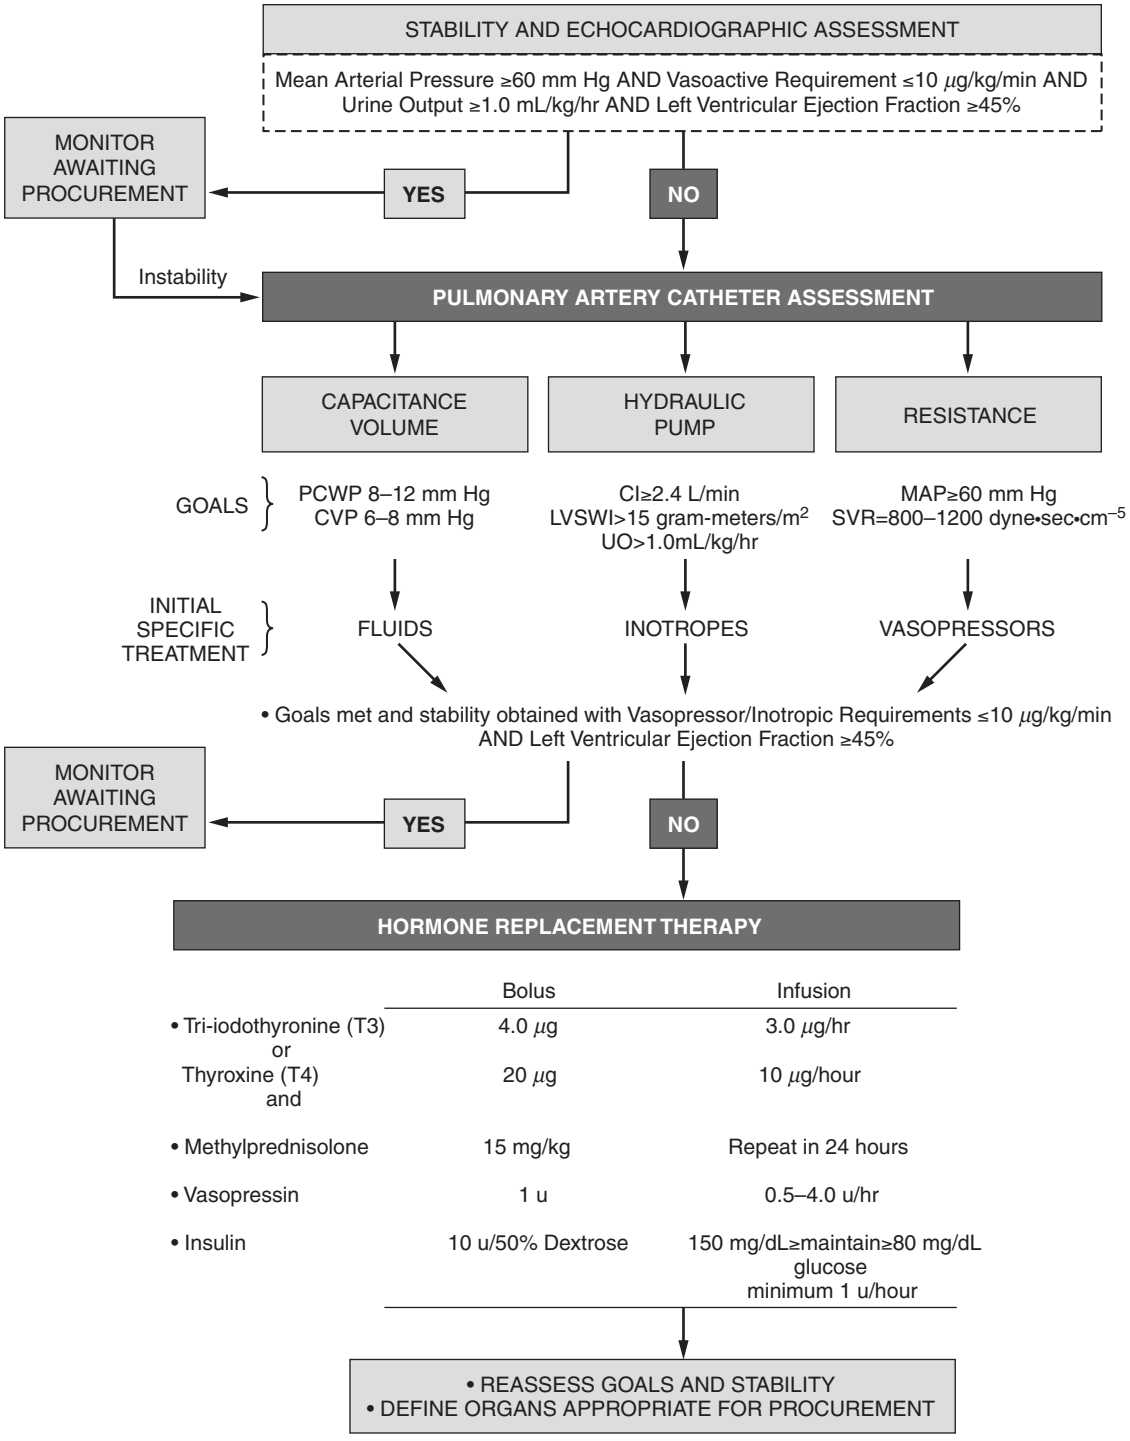

Figure 6–5 Algorithmic approach to achieving donor hemodynamic stability. CI, cardiac index; CVP, central venous pressure; LVSWI, left ventricular stroke work index; MAP, mean arterial pressure; PCWP, pulmonary capillary wedge pressure; SVR, systemic vascular resistance; UO, urine output.

usually responsible. Mannitol, diuretics, and fluid restriction to minimize ICP and preserve cerebral perfusion pressure gradients in conjunction with diabetes insipidus, hyperglycemia-induced osmotic diuresis, and hypothermic cold diuresis tend to deplete the intravascular volume. This depletion is compounded by the loss of vasomotor tone after brain death, resulting in venous and arterial dilation. Initial volume resuscitation should use a balanced salt solution (Ringer's lactate or normal saline) to achieve adequate intravascular volume and packed red blood cells to achieve a hematocrit of 30% to ensure adequate oxygen delivery. Subsequent fluid management strategies need to consider the following:

1. Diabetes insipidus predisposes to hypernatremia. Continued use of normal saline with inadequate control of diabetes insipidus can produce levels of hypernatremia that are associated with impaired liver function in the recipient.[85]

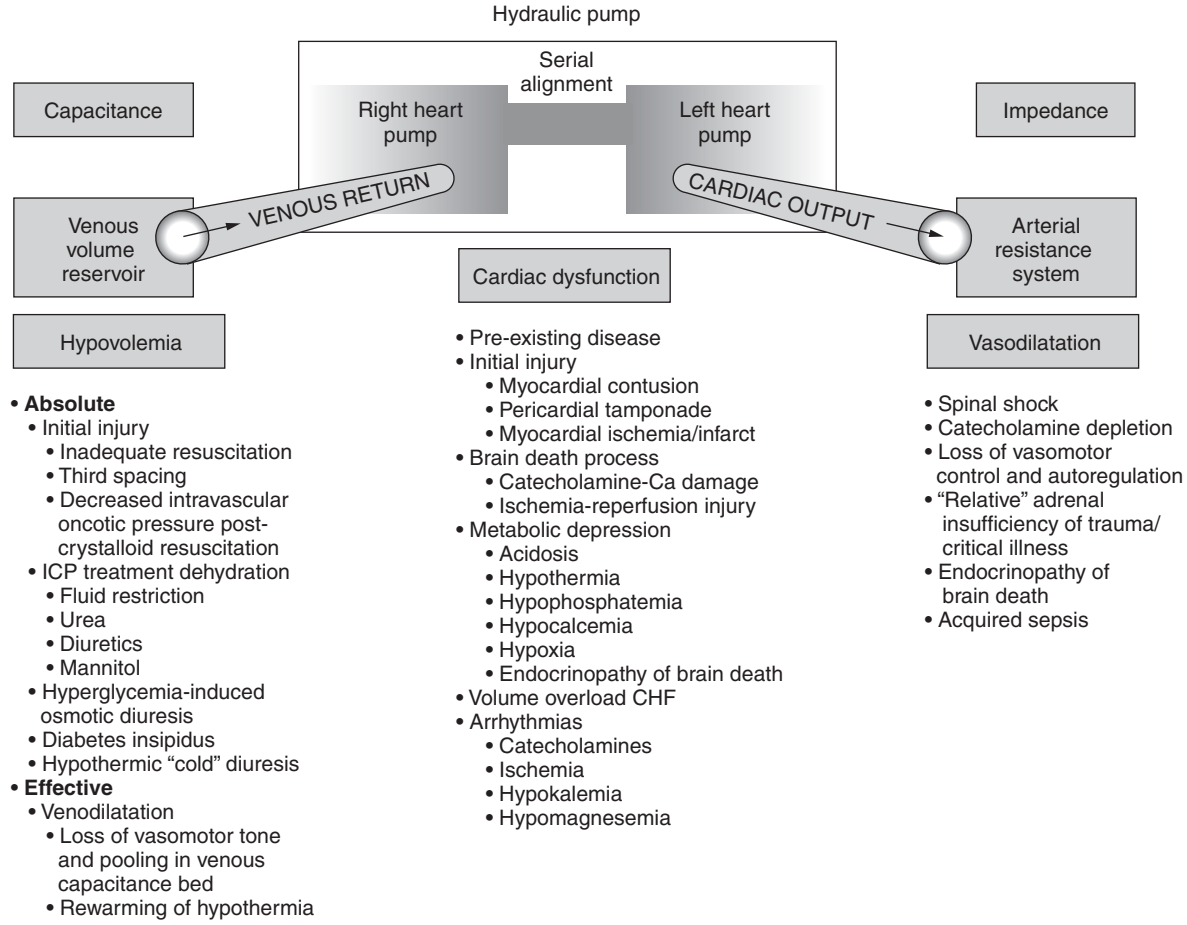

Figure 6–6 Three-compartmental model of the circulation that can be used to define the physiological abnormality in any hemodynamically unstable patient. CHF, congestive heart failure; ICP, intracranial pressure. (Courtesy of Kenneth E. Wood, DO.)

2. Overzealous volume resuscitation with a significantly positive fluid balance is associated with progressive pulmonary dysfunction and loss of donor lungs.[70] An increase in hydrostatic pressure coupled with brain death–induced pulmonary capillary permeability changes is thought to precipitate pulmonary edema.[2]
3. Infusion of substantial amounts of dextrose solution (5% dextrose in water) to treat diabetes insipidus–induced hypernatremia can precipitate hyperglycemia with its attendant problems of worsening osmotic diuresis, electrolyte abnormalities, and the newly recognized inflammatory consequences of blood glucose elevations.[12]

Consequently, fluid management requires vigilant monitoring and ongoing adjustments, with the goals of ensuring adequate intravascular volume for organ perfusion, a serum sodium level of 145 mmol/L or less, and a blood glucose level less than 110 mg/dL. The last goal may require an insulin infusion, which may have the additional benefits of immunomodulation.[12] The appropriate choice of a crystalloid or colloid for donor fluid management is controversial; colloid would seem to be advantageous in an intravascularly depleted, extravascularly edematous patient and was used in a successful management strategy that enhanced lung recovery dramatically.[20] Hydroxyethyl starch has been reported to precipitate injury to renal tubular epithelial cells, possibly impairing early renal graft function, and probably should be avoided.[8] All fluids should be warmed to minimize the risk of hypothermia.

Antagonistic strategies for fluid replacement frequently complicate donor management, pitting lung procurement teams against abdominal organ procurement teams. The former advocate a minimally positive fluid balance because increased lung volume jeopardizes the critical oxygenation ratio (Pa_{O_2}/F_{IO_2}), can worsen the chest radiograph, and is associated with reduced rates of lung procurement.[70] The latter promote aggressive volume repletion to facilitate maintenance of kidney function and urine output, which has been shown to improve renal function in the recipient.[63] Adjudicating these competing interests is necessary for continued optimal management. When the lungs are unsuitable (i.e., massive aspiration, gunshot, significant contusion—all with significantly impaired gas exchange), a more liberal fluid strategy is appropriate, provided that oxygenation is preserved. In the setting of ideal or marginal lungs, invasive monitoring, preferably with a PAC, would be recommended. Brain death–induced left ventricular abnormalities may distort the left ventricular pressure-volume relationship, and the pulmonary capillary wedge pressure may be higher than the central venous pressure. In a controlled trial of donors with a central venous pressure of 6 mm Hg or less, a targeted

central venous pressure end point of 8 to 10 mm Hg was associated with worsening oxygenation—hence the goals in Figure 6-5.[57] Ongoing fluid requirements may be best guided by a PAC with measurements of flow to maintain urine output and pulmonary capillary wedge pressure to minimize lung edema.

Vasoactive Support

The use of vasoactive support is frequently necessary when hemodynamic instability or echocardiographic abnormalities persist despite adequate volume resuscitation. As shown in Figure 6-6, the differential diagnosis of hypotension is complex. Firm recommendations regarding vasoactive support are controversial and compromised by the absence of randomized controlled trials. Many recommendations are derived from retrospective cases series, which may have been compromised by insufficient focus on assessment of the adequacy of volume resuscitation; this is illustrated by studies suggesting adverse[44,76,87,90,94] and beneficial[17,27,43,79] effects of vasopressors. With more recent studies showing either a limited effect or no association between vasopressor requirements of the donor and recipient outcomes,[17,35,78] however, there is evolving consensus that high vasoactive requirements do not preclude successful donation.

After brain death, cardiac dysfunction and vasodilation are usually coincident processes. Ideally, the physiological lesions should be localized, and specific therapy should be initiated: dobutamine or β adrenergics for primary cardiac dysfunction and targeting of α-adrenergic receptors to treat vasodilation. Most donors can be managed successfully with judicious volume resuscitation and low-dose vasoactive agents (5 to 10 μg/kg/min),[39] with management goals depicted in Figure 6-5. Traditionally, dopamine has been the first-line vasoactive agent because it possesses inotropic and vasoconstrictive properties. More recently, vasopressin has been advocated as the vasopressor of choice along with serial lactate levels to monitor perfusion.[81] The specific timing or best combination of vasopressors is unknown at present. Schnuelle and associates[78] reported that combinations of vasoactive agents (dopamine, dobutamine, norepinephrine) were associated with few rejection episodes and a better 4-year survival for renal transplantation. This benefit was attributed to the immunomodulating effects of catecholamines, which have been shown to inhibit the upregulation of adhesion molecules and may diminish brain death–associated inflammation.[78,83] The beneficial effects of catecholamine seen with kidneys did not benefit heart or liver recipients, leaving the best vasopressor or combination uncertain at this time.

Hormonal Replacement

Traditionally, hormonal replacement therapy was reserved for donors with persistent hemodynamic instability despite volume resuscitation/vasoactive support and echocardiographic evidence of a continued low ejection fraction. A large retrospective analysis of brain-dead donors found significant benefits, however, in all donors receiving a methylprednisolone bolus, infusions of vasopressin, and either triiodothyronine or thyroxine. In the 701 donors receiving hormonal resuscitation, the number of organs procured (4.2 organs per donor age 40 years and 3.1 organs per donor age >40 years) was significantly greater than in 10,292 donors who did not receive hormonal resuscitation (3.8 organs per donor age 40 years and 2.5 organs per donor age > 40 years). Hormonal replacement therapy resulted in a 22.5% increase in the number of organs from hormonally resuscitated donors with the following significant increases in the probabilities of an organ being transplanted from a donor: kidney 7.3%, heart 4.7%, liver 4.9%, lung 2.8%, and pancreas 6%. Extrapolation of these results to the donor population at large would translate to an annual increase of 2053 transplantable organs.[72] Insofar as this was not a randomized, controlled trial, it is important to recognize that the hormonally resuscitated group was younger, had fewer deaths related to cerebrovascular accidents, had less diabetes and hypertension, and had a lower creatinine level. Based on such retrospective analyses and other reports,[73] the use of hormonal replacement has been advocated for use in all donors, not just donors with hemodynamic instability.

In early studies, exogenous hormonal supplementation led to dramatic reversals of cardiac dysfunction and acid-base disturbances and were thought to mediate the transition from anaerobic back to aerobic metabolism.[53] More recent studies have been unable to document abnormal hormone levels, however, and speculate that the previous interpretations are more consistent with the inflammatory response of critical illness and brain death.[38] Although the levels of evidence varied, a review of thyroid hormone administration in donor care concluded that no studies supported the routine administration of thyroid hormone for all donors.[66] Of the 10 studies reviewed, 4 supported the use of thyroid hormones,[51,53,56,75] whereas 4 did not offer support.[26,32,58,69] The data related to hormonal resuscitation seem controversial, and individual transplant organizations need to develop an individualized approach to using hormone replacement as routine, as rescue therapy, or only in selected indications.

Disturbances of cardiac rhythm are frequent in brain-dead donors and predominantly occur during the catecholamine surge with brain herniation, consequent to the initiation of vasoactive support or as the terminal event in the 48- to 72-hour period after brain death has occurred. These cardiac dysrhythmias, which are thought to follow the catecholamine surge–induced conduction system necrosis, are frequently resistant to antiarrhythmic therapy. Similarly, acid-base and electrolyte abnormalities are thought to contribute and predispose to the development of these dysrhythmias. After correcting the various electrolyte or acid-base abnormalities, standard antiarrhythmic therapy for ventricular rhythm disturbances (lidocaine or amiodarone) or supraventricular dysrhythmias (amiodarone) should be considered similar to any other rhythm management in a critically ill patient. With brainstem vagus nerve disruption, the bradyarrhythmias that are frequently seen do not respond to atropine, and isoproterenol or epinephrine is needed. Realizing that a small percentage of organ donors sustain cardiac arrest during maintenance, it is crucial to institute full advanced cardiac life support because it has been shown that the recovery of cardiac function of the potential donor can result in successful transplantation.[17]

Respiratory Management

Similar to the previously defined cardiac management approach, an understanding of the pathophysiology of

donor lung injury is useful in facilitating a more optimal management strategy. The pathophysiology of donor lung injury is complicated by multiple factors. Frequently, there is an unknown history of occupational lung injury, infectious disease, or tobacco use. The causative brain death event is commonly associated with aspiration, pulmonary contusion, and the effects of resuscitation for shock patients. Mechanical ventilation is associated with multiple pulmonary problems, including the newly recognized barotrauma/volutrauma, oxygen toxicity, and the development of nosocomial pneumonia.

These events are superimposed on the brain death–induced neurogenic pulmonary edema related to the sympathetic surge that occurs with herniation. Intense catecholamine constriction increases systemic vascular resistance and decreases cardiac output, with a resultant increase in left atrial pressures. Coincidentally, the sympathetic surge increases venous tone, facilitating venous return and increasing pulmonary artery pressures, resulting in a substantial degree of circulating blood volume in the pulmonary capillary bed. The combination of augmented venous return and an increased left atrial pressure precipitates a transient massive increase in hydrostatic pressure with structural damage to the capillary endothelium.[54] Sympathetic alterations of the pulmonary capillary permeability also are thought to contribute to neurogenic pulmonary edema.[2]

More recently, it has been recognized that brain death results in an intense inflammatory response in the lung secondary to elevated levels of circulating cytokines. Tumor necrosis factor-α and interleukin-1 are thought to activate endothelial cells to express adhesion molecules and mediate the production of interleukin-8. This neutrophil activator subsequently binds to endothelial cells and facilitates the migration of inflammatory cells and mediators into the interstitium and alveolar spaces, releasing reactive oxygen species and proteolytic enzymes. The extent to which this intense inflammatory response is present in the donor lung and correlates with recipient outcome is best exemplified by reports defining the inflammatory response of brain death via open lung biopsy and bronchoalveolar lavage. In a report of patients with nontraumatic causes of brain death, Fisher and colleagues[18] showed that there was a dramatic increase in the neutrophil concentration and interleukin-8 signal in biopsy specimens and lavage. This increase strongly suggested that there was an acute systemic inflammatory response to brain death that resulted in the release of proinflammatory mediators from the brain causing injury to the lung before transplant. The same authors performed a subsequent study correlating the extent of inflammation in the donor with recipient outcome.[19] The degree of neutrophil infiltration and interleukin-8 expression in the donor correlated with a degree of impairment in graft oxygenation, the development of severe early graft dysfunction, and early recipient mortality. This study emphasizes further that there is a preexisting subclinical inflammatory response in the lung after brain injury in addition to the multiple other phenomena that can affect pulmonary function.[19]

The respiratory management of the brain-dead donor can be dichotomized into two patient groups: patients with severe lung injury that would preclude lung use and patients with either ideal or marginal lungs. The ventilator management of the former patients is similar to the ventilator management generically used in the intensive care unit for either diffuse or focal lung injury. The goals are to maintain adequate tissue levels of oxygenation and to ensure that mean airway pressures do not impair venous return, which can jeopardize cardiac output and flow to the various organs. Recognizing that the lungs will not be used in transplantation, a higher mean airway pressure or tidal volume may be accepted to facilitate better oxygenation. In the latter circumstance of an ideal or marginal lung, there is significant potential for deterioration in the ideal lung, and the capacity exists to manage a marginal lung that can be used for transplantation.

Table 6-3 outlines a generic approach to the respiratory management of potential organ donors. The goals of respiratory management should be to ensure continued stability and suitability of the ideal lung and to apply intensive care respiratory management to facilitate the use of marginal lungs. It has been reported that implementing a standardized approach to the management of respiratory function in a potential donor has resulted in the procurement and successful transplantation of lungs that were initially deemed unsuitable. Current challenges include developing indices to quantify and qualify the degree of lung injury, identify reversible causes of lung dysfunction, and define interventions to modify the unacceptable lungs successfully. This approach to maximizing lung transplantation is best exemplified in the report by Gabbay and colleagues[22] of applying intense donor pulmonary management to marginal lung donors, which resulted in significant improvement and successful transplantation with outcomes indistinguishable from ideal lungs. The management approach consisted of mechanical ventilation with positive end-expiratory pressure recruitment maneuvers, chest physical therapy, attention to fluid balance, antibiotic administration, and bronchoscopy.[22]

The traditional approach to mechanical ventilation for potential lung donors has been a high tidal volume (10 to 15 mL/kg) and the initial use of positive end-expiratory pressure. The combination of improved oxygenation and

Table 6–3 Respiratory Management

Goals of Mechanical Ventilation
Fraction of inspired oxygen 0.40
Partial pressure of arterial oxygen >100 mm Hg or oxygen saturation >95%
Partial pressure of arterial carbon dioxide 35-40 mm Hg
Arterial pH 7.35-7.45
Tidal volume 8-10 mL/kg of predicted body weight
Positive end-expiratory pressure 5 cm H_2O
Static airway pressure <35 cm H_2O
Bronchoscopy
Evaluate anatomy
Assess for foreign body and assist in removal
Define and locate aspirated material, secretions, or apparent infection
Clearance of Secretions
Pulmonary hygiene
Prevent atelectasis with use of suction, percussion, postural drainage, and lung expansion techniques
Fluid Management
Central venous pressure 6-8 mm Hg
Pulmonary capillary wedge pressure 8-12 mm Hg
Anti-infective Therapy
Use of antibiotic agents based on Gram strain of aspirated secretions

improved lung appearance on chest radiography probably reflects hyperinflation. The recognition that lung injury and inflammation may occur as a result of the use of mechanical ventilation consequent to volutrauma and shear injury to the lung has defined a strategy for alveolar recruitment that seeks to minimize ventilator-associated lung injury. Positive end-expiratory pressure should be applied judiciously, and end-expiratory plateau pressures should be limited to less than 30 to 35 cm H_2O. The high minute ventilation and accompanying low carbon dioxide frequently used to treat elevated ICP can be normalized further, preventing volutrauma to the potential donor lung. Oxygen toxicity should be minimized by using the lowest level of F_{IO_2} to achieve arterial saturations of 90% or greater. Bronchoscopy should be performed in all potential organ donors who are candidates for lung transplantation to inspect the anatomy, remove foreign bodies, and assist in the assessment of donors with abnormal gas exchange and unilateral lung disease. In this circumstance, bronchoscopy and chest radiography can facilitate the evaluation to allow for use of the contralateral lung.

Atelectasis and pulmonary edema consequent to aggressive fluid resuscitation are probably the two most correctable causes of hypoxia that preclude the use of lungs for transplantation. Strategies targeted at ventilator management focused on lung expansion, early bronchoscopy, frequent suctioning and pulmonary toilet, and judicious volume resuscitation have been reported to increase the rate of lung procurement.[20,22] Adjudication of the competing fluid requirements may require the placement of a PAC as previously defined. Pulmonary capillary wedge pressure of 8 to 10 mm Hg with a central venous pressure of 6 to 8 mm Hg should minimize the accumulation of extravascular lung water. In patients who are edematous with high filling pressures, diuretics may be necessary. Large doses of corticosteroids (methylprednisolone, 15 mg/kg), which are part of the hormonal resuscitation protocol, have been shown to stabilize lung function and facilitate the procurement of lungs that were previously defined as unsuitable.[21] In addition to diuretics, albuterol has been shown in animal studies to facilitate the clearance of pulmonary edema and should be considered in patients with pulmonary edema.[74] Similar to the echocardiographic evaluation of cardiac donors, no procurement decision should be made based on the initial lung evaluation, and suitability should be defined only after therapeutic attempts to optimize the pulmonary status have been exhausted.

Renal Management

Kidneys are extremely susceptible to injury in the potential organ donor for multiple reasons. The initial trauma and hypovolemia with hypotension are associated with a significant incidence of acute kidney injury that has been estimated to occur in 31% of severe trauma cases.[45] Other associations with trauma include elevated intra-abdominal pressure related to an abdominal compartment syndrome impairing renal blood flow, acute crush injuries with rhabdomyolysis, and the use of contrast agents for vascular imaging in trauma patients. Although a more recent study suggested no long-term difference in the recipients of donors who received contrast agents, this study did not address the risk of increased delayed graft function.[30] Brain death and the associated catecholamine surge and inflammatory response can contribute to the renal dysfunction in the potential organ donor.

The variables during the care of adult donors that can influence the outcomes of renal transplantation have been reviewed by Powner.[63] Factors that were most amenable to intensive care unit management included increasing urine output to greater than 100 mL/hr at least during the hour before explantation and returning the creatinine level to match the original serum concentration when the patient was admitted. Although there seems to be benefit in maintaining a urine output of at least 100 mL/hr, there does not seem to be any benefit of an extremely high urine output (>300 mL/hr).[42] Similarly, it has been reported that an improving serum creatinine level of less than 2 mg/dL seems to exert a favorable effect on renal graft function in recipients.[42] Other studies have shown that a serum creatinine level that exceeded 1.5 mg/dL just before explantation shortened the time to graft failure.[59] Elevated serum creatinine in donors was associated with worse renal function 2 or 3 years after transplantation.[37] Ensuring the adequacy of intravascular volume and maintaining appropriate perfusion pressures and flow to the kidneys are the most important donor management factors that govern the success of renal transplantation, and these can be influenced by intensive care unit management.

Supportive Care

Potential organ donors warrant the same level of aggressive intensive care management that is provided to other patients in a critical care unit. This care involves frequent and ongoing assessments of hemodynamic status, respiratory function, and metabolic parameters. Diabetes insipidus is common in potential organ donors secondary to the absence of vasopressin after pituitary destruction during the herniation process. Complications of diabetes insipidus include intravascular volume depletion, hyperosmolality, and electrolyte abnormalities. Diabetes insipidus frequently needs to be differentiated from mannitol-induced, diuretic-induced, or hyperglycemia-induced osmotic diuresis. Table 6-4

Table 6–4 **Evaluation of Polyuria in a Potential Organ Donor**

	Diabetes Insipidus	Mannitol	Hyperglycemia
Serum sodium	≥150 mEq/L	≥150 mEq/L	≥150 mEq/L
Serum osmolarity	≥300 mOsm	≥300 mOsm	≥300 mOsm
Serum osmolar gap	Normal	>10-15 mOsm	>10-15 mOsm
Urine output	≥300 mL/hr	≥200 mL/hr	≥200 mL/hr
Urine sodium	<10 mEq/L	50-70 mEq/L	50-70 mEq/L
Urine osmolarity	<200 mOsm/L	≥300 mOsm/L	≥300 mOsm/L
Urine specific gravity	≤1.010	≥1.020	≥1.020
Urine glucose	Absent	Absent	Present

presents an overview of the differential diagnosis and associated laboratory values of polyuric patients. In most instances, it is appropriate to match the urine output milliliter for milliliter with 5% dextrose in water and monitor the blood glucose closely. When the urine output exceeds 250 mL/hr, it is necessary to give either arginine vasopressin or desmopressin acetate (DDAVP). The former has an antidiuretic effect in addition to vasoconstrictive properties, whereas the latter is purely an antidiuretic. Although DDAVP may be given subcutaneously, intramuscularly, or intranasally, the intravenous route is recommended for a potential organ donor. Judicious monitoring of urine output, serum sodium, and hemodynamic parameters is necessary when using DDAVP. Frequently, the use of 5% dextrose in water for the treatment of hypernatremia, catecholamines, glucose-containing solutions, and corticosteroids produces hyperglycemia in a potential donor. Hyperglycemia has increasingly been recognized as a contributor to inflammation and an impaired immune response. It is similarly likely that these mechanisms are applicable to a potential organ donor. Blood glucose should be controlled with an insulin infusion when necessary.

The combination of brain injury with the release of thromboplastin, ongoing hemorrhage, transfusions, hypothermia, acidosis, and the dilution of coagulation factors frequently conspires to produce coagulopathy in a potential organ donor. Similar to the approach used in other critically ill patients, packed red blood cells and fresh frozen plasma should be administed to achieve a hematocrit of approximately 30% and control of coagulation parameters. Goals should include an international normalized ratio less than 2 and platelet count greater than 80,000/mm^3. Thermoregulation is frequently impaired in potential organ donors. The combination of hypothalamic-pituitary destruction and peripheral paralysis impairs the ability to shiver or vasoconstrict. Impaired thermoregulation is compounded by the use of unwarmed fluids and blood products. Hypothermia can exaggerate the previously described coagulopathy and predispose to cardiac rhythm disturbances and cardiac dysfunction. The donor should have a core temperature of at least 35°C with active and passive rewarming as necessary.

SUMMARY

A standardized approach to declaration of death and management of potential organ donors ensures that the greatest number of organs can be recovered in the best possible condition to provide optimal outcome for recipients. The management of a potential organ donor influences the medical management of seven solid-organ recipients and requires the same level of vigilance and attentiveness provided to other critically ill patients.

Chapter 7

Medical Evaluation of the Living Donor

Dicken S. C. Ko • Francis L. Delmonico

It has been more than half a century since the first successful renal transplant was performed with the donation of a kidney from one identical twin to another who had end-stage renal disease.[56-58] The presence in most normal individuals of two kidneys—each with a physiological reserve capable of providing four to five times the minimal required function—has led to the acceptance of renal transplantation using living related or unrelated volunteers as organ sources.[22,86] The success of live kidney donor transplantation has been so overwhelming that in 2000 to 2004 in the United States, the number of live donor kidney transplants surpassed that of cadaver donors.[63] In many parts of the world where cadaver donor kidney transplants are still limited, live donor kidneys are the most common source of organs for transplantation.[47] The advantages of live donor kidney transplantation include earlier transplantation and excellent long-term survival.

Despite reduced morbidity and mortality of the donation procedure, it is important to discern patients who are not candidates for donation because it might have an impact on their immediate and future health.[2,7,54,60,61,83] Although predicting future health is imprecise at best, clinical experience suggests that there are reasons why it is not medically advisable to donate an organ. However, singular abnormalities, such as well-controlled hypertension or obesity, are no longer considered absolute contraindications to organ donation today.[1,17] Live kidney donors present unique ethical, legal, and social implications[82,91,92] that must be addressed carefully to protect the health and rights of the donor.

JUSTIFICATION FOR LIVE KIDNEY DONATION

Among the many reasons that may be cited for the continued use of living related donors, the most important has been the more favorable results that can be achieved with a physiologically perfect kidney that also is biologically matched. The morbidity and mortality after cadaver donor transplantation were so great until the early 1980s that many dialysis patients were hesitant to consider transplantation unless a related donor was available.[36] With the introduction of calcineurin inhibitors, monoclonal and polyclonal antibody immunosuppression, and other new immunosuppressive drugs into clinical regimens, the historical gap in graft survival between living related and cadaver donor renal transplantation narrowed considerably. This change led some groups to conclude that living related donor renal transplantation might no longer be justified.[84] Living related donor grafts still have a 10% to 12% better survival rate at 1 year and a significantly higher probability of function thereafter.[13] Almost all transplant units continue to recommend live donor renal transplant if suitable individuals volunteer.[18,23]

Because the improved results using familial donors were believed to be directly related to the degree of histocompatibility between donor and recipient, living unrelated donors were historically not thought to provide any biological advantage over cadaver donors. The experience of using living unrelated kidneys in transplantation has shown, however, that such organs have a graft survival profile that approaches that of related donors and is even better than that of parental donors.[37,85] Between 1988 and 1996, the number of living unrelated donor transplants in the United States increased from 4.1% to 14.2% of living donors.[29] Later Organ Procurement and Transplantation Network (OPTN)/United Network for Organ Sharing (UNOS) reports further confirm a trend to use living unrelated donors, which account for 22.6% of the living donor pool.[40]

Even with the current widespread application of calcineurin inhibitors and monoclonal and polyclonal antibody immunosuppression, there is a persisting biological advantage of living donor kidneys (living related donor or living unrelated donor) over cadaver donor allografts. Although short-term graft survival after transplantation from both donor sources is excellent, the 5-year success rate of greater than 80% attained using living donor kidneys exceeds any reported cadaver donor results by 10% to 15%.

Another justification for using living donors is that the timing of the operation can be planned, limiting waiting time on dialysis. This aspect is relevant for socioeconomic reasons. Because successful transplantation allows more

complete patient rehabilitation,[27,28,53] this approach proves to be approximately one third as expensive as long-term dialysis.[43] Of greater importance is the ability to perform the transplant when the recipient is in optimal medical condition. This ability is particularly pertinent for diabetic patients, whose condition may deteriorate rapidly on dialysis. Finally, there is the risk that the patient may develop antibody to HLA antigens (see Chapter 10) during prolonged dialysis, especially if intermittent blood transfusions are required. As a result of such allosensitization, a negative crossmatch donor kidney becomes increasingly difficult and sometimes impossible to find even with today's emergence of desensitization protocols.

The final reason for the continued expansion of living donor transplantation is the insufficient supply of cadaver donor organs required to fulfill the needs of renal failure patients awaiting transplantation.[16] Because the results of kidney transplantation have improved dramatically, increasing numbers of patients are being placed on waiting lists. The supply of kidneys has increased minimally, however.[69] Figure 7-1 shows a flow chart outlining the projected need for donor organs, assuming no net yearly increase in numbers of patients on dialysis. For each 1 million population, approximately 75 to 80 renal transplants would have to be performed annually to keep pace with the more than 100 new patients diagnosed with end-stage renal disease and previous transplant recipients whose allografts eventually fail. Even in areas with outstanding cadaver donor retrieval rates or with less stringent criteria for donor selection, the number of potential recipients greatly exceeds the supply of donor kidneys. A steadily growing population of patients is being maintained on dialysis in most areas of the world.

Despite these compelling reasons for using living donors, the procedure could not be justified if unacceptable morbidity or mortality were to be incurred by the donor. Generally, a specific medical treatment is selected on the basis of a balance in favor of its beneficial effects versus the potential adverse effects. The concept of removal of an organ for transplantation is unique among major surgical procedures in that it exposes the healthy donor to the risks of surgery solely for the benefit of another individual. This concept has been evaluated carefully not only by the medical profession but also by the courts and by life insurance carriers. Some courts have ruled in favor of donation, even by a minor, on the grounds that the donor not only would benefit psychologically and spiritually from the act of charity but also might be psychologically harmed if prevented from donating, at little risk, when the life of a close relative is at stake (see Chapter 39).

With the extension of minimally invasive techniques to living kidney donation, the potential adverse impact of the operation has become less significant. The major advantages to the donor are decreased morbidity of the surgery and quicker return to normal daily activities, including earlier return to work. The worldwide results for laparoscopically removed kidneys are now comparable to the results achieved after transplantation of organs procured through the classic open incision.[10,11,21,39,78,90]

INITIAL DONATION PROCESS

The decision to donate a kidney for the benefit of another individual is one that is arrived at voluntarily by the donor, without coercion and without financial remuneration. The process begins with education when the patients and their family and friends learn about the health care risks of end-stage renal failure. The clearest and most consistent message that patients and family members receive is that the best form of long-term therapy for end-stage renal disease is kidney transplantation. The sources of donor organs are discussed in detail, with particular attention given to the different classifications within live and cadaver donors.

The obligation of the transplant health professional to the potential live donor, independent of the recipient's health condition, is to ensure that the donor fully and undeniably understands the immediate and long-term risks and benefits of organ donation. Because of the unique nature of live donor kidney transplantation, in which there is defined health benefit for the recipient, and the donor bears only the burden of being subjected to a medically unwarranted surgery

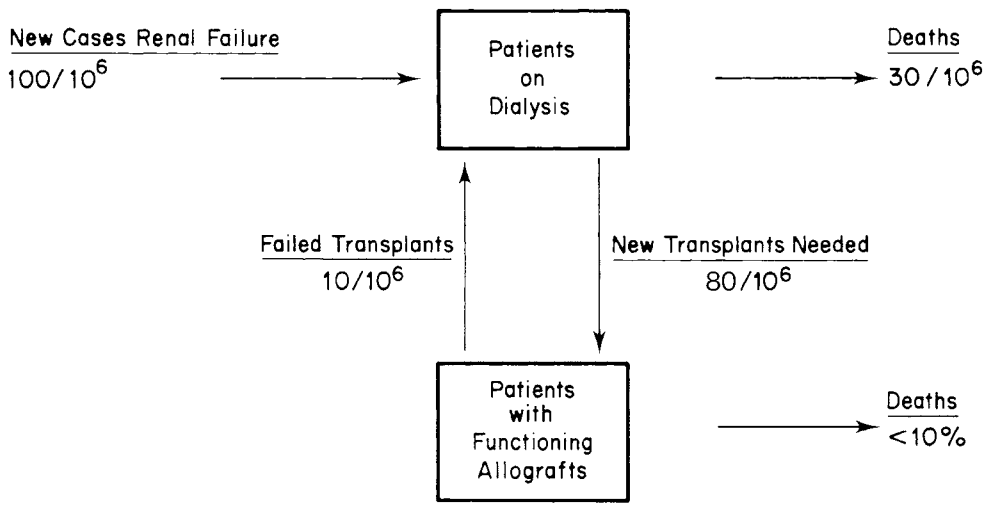

Figure 7–1 Flow chart depicts the annual renal transplant rate required to maintain a stable dialysis population. An estimated total of 75 to 80 transplants per 1 million population is projected if previous failed allografts and new cases of renal failure are included.

without immediate or long-term health improvements, it is important to address "conflict of interest" in management of the recipient and the donor by one team.

From the outset, the donor evaluation must be done by an independent health care team that can provide unbiased medical decision making and advice. Some centers have internists and surgeons evaluate these donors independently and arrive at a decision as to whether they are fit for the donation process, whereas other centers have devised parallel processes in which such evaluations and discussions about donation and transplantation are presented by a team to the family and friends. Approaches to the potential live donor usually include a comprehensive medical team that consists of primary care physicians, nephrologists, psychiatrists, transplant surgeons, coordinators, social workers, and financial coordinators. Only by this process of education and informed consent can a donor truly determine whether to proceed or not with donation. In return, this process allows medical professionals ample opportunities to arrive at a judgment of whether the donor is suitable to donate even if the donor already has committed to doing so.

As more allocation protocols develop to help end-stage renal disease patients obtain organ transplants, we face even more complexities that make the education and evaluation challenging. If a donor-recipient pair is blood group incompatible, the individuals might go on a separate regional list, where they might have opportunities to exchange donors and recipients with other incompatible pairs. The concept of increasing live donor transplantation in this manner benefits both pairs. Since the emergence of this concept in the early 2000s, some regions of the United States and other countries participate in paired-exchange programs that administrate the matching of ABO-incompatible pairs.

Immunological sensitization of a recipient toward potential donors and the process of desensitization also have created more challenges for a potential live donor renal transplant. Many centers have adopted new immunosuppressive strategies, such as plasmapheresis of recipients, to permit long-term allograft survival. However, the cost of more extensive immunosuppressive therapy, coupled with an increased incidence of antibody-mediated allograft rejection, and a more complicated postoperative course have made some donor-recipient pairs reconsider their options and risks during the evaluation process.

The results of ABO-incompatible renal transplants in Japan have been encouraging and prompted some centers to adopt such programs as an alternative for the recipient to have access to kidney transplantation. Such highly specialized programs, which subject the donor kidney to a higher risk of immunological loss and the recipient to more intense immunosuppressive therapy, must be considered carefully. These risks must be disclosed not only to recipients but also to donors in the evaluation process so that they, too, have an opportunity to evaluate the risk of their donated kidney being rejected.

RISKS TO THE DONOR

Because of the unusually careful follow-up of thousands of renal donors, in addition to the extensive information available from other unilaterally nephrectomized cases,[61] the long-term risks of living kidney donation can be assessed precisely.[44] Table 7-1 lists the most common complications observed. Survival studies indicate that the 5-year life expectancy of a unilaterally nephrectomized 35-year-old male donor is 99.1% compared with a 99.3% normal 5-year life expectancy; this has been compared with the risk incurred in driving a car 16 miles every working day. The quality of life after kidney donation has been reported in 979 patients who had donated a kidney for transplantation.[44] Most of the responders had an excellent quality of life.[59,60] Multivariate analysis of individuals who did not respond favorably identified the following two factors for a negative psychosocial outcome: relatives other than first degree and recipients who died within 1 year of transplantation. In an updated survey of major life insurance companies, it was found that 100% now accept applications from kidney donors after nephrectomy, assuming the remaining renal function is normal.[44,80,81] Of these companies, 94% do not consider the otherwise healthy donor to be at increased risk for shortened survival or medical problems; only 2% indicated they would raise the premium for such an individual.

Despite studies of extensive renal ablation in rats, which have shown that glomerular hyperfiltration in the remaining kidney tissue can produce progressive sclerosis and deterioration in renal function,[9] such data correlation in humans has not been found. Concerns had been raised that healthy human donors might develop hypertension and renal dysfunction years after unilateral nephrectomy. However, 20-year follow-up studies of hundreds of living donors have

Table 7–1 Complications of Living Donors

*Similar to general population.[50]

been unable to identify any convincing evidence of long-term functional abnormalities associated with unilateral nephrectomy.[2,3,6,60,61]

A 2002 survey of 234 UNOS-listed kidney transplant programs, to which 171 responded, sought to determine current living donor mortality after donor nephrectomies (open nephrectomy, hand-assisted laparoscopic nephrectomy, and non–hand-assisted laparoscopic nephrectomy). It was discovered that between January 1, 1999 and July 1, 2001, these centers performed 10,828 living donor nephrectomies: 52.3% open nephrectomy, 20.7% hand-assisted laparoscopic nephrectomy, and 27% non–hand-assisted laparoscopic nephrectomy. Two donors (0.02%) died as a result of surgical complications, and one was in a persistent vegetative state (all after laparoscopic nephrectomy).[54] The current estimated mortality of donor nephrectomy is 1 in 3000 donors. The potential donor must understand that the risk of mortality is *not* zero as they weigh their decision to undergo the surgery.

What is the likelihood of renal disease occurring in a donor after kidney donation? One of the most comprehensive reviews of this was the OPTN database in the United States to determine the number of renal waitlist candidates who previously had been living donors.[24] The living renal donors in the OPTN database were cross-referenced against the renal waitlist. Fifty-six previous living donors were identified as having been subsequently listed for cadaver donor kidney transplantation (43 have received transplants, 36 currently have functioning grafts, 1 died after transplantation, and 2 candidates died while waiting). The numbers reported underestimate the actual number of living donors with compromised renal function or actual renal failure because they include only patients listed for a kidney transplant. Patients who are not candidates because of concomitant illness or a variety of other factors are omitted by this analysis. To determine risk factors for postdonation renal failure, long-term living donor follow-up data are needed.

Despite these risk considerations, living donors continue to represent a significant proportion of the total donor pool. The percentage of transplanted kidneys obtained from this source varies, accounting for nearly all renal transplants in areas where cadaver donor transplantation is unavailable, but for less than 5% in other areas. In the United States, approximately 50% of transplanted kidneys are currently obtained from living donors,[63] and in 2005 the number of living donor kidneys transplanted in the United States exceeded the number of cadaver donor kidney transplants for the first time.

PSYCHOLOGICAL ASPECTS OF DONOR SELECTION

The current trend of increased worldwide use of live donor kidneys for transplantation points out the special nature of this form of medical care. First, we must do no harm according to the Hippocratic Oath. However, Hippocrates also alluded to the fact that the art (of medicine) is long, and judgment is difficult. In the setting of live organ donation, an evaluation of the psychological and ethical aspects is a crucial part of the comprehensive medical review of the donor.[20]

Throughout the evaluation, at least some unavoidable family pressure to donate must exist despite the physician's attempts to ensure that the final decision is voluntary, reasoned, and based on full awareness of relevant information. Scrutiny of the decision process of familial donors has revealed that most donors make an immediate decision when first contacted, and this decision precedes the acquisition of further scientific data required for truly *informed consent*. Long-term follow-up of familial donors indicates that they continue to believe they made a correct and an informed decision and would do it again if the opportunity were available.[79] These observations do not diminish the responsibilities of the renal transplant team to supply all relevant medical facts to the potential donor, but the nature of this decision process is complex.

SELECTION OF A POTENTIAL LIVING DONOR

In April 2004, an international consortium of more than 100 leading kidney transplant physicians and surgeons from 40 countries met in Amsterdam to discuss the standard of care for live donors. In conjunction with the World Health Organization, this forum proposed a set of standard recommendations that the World Health Organization could assist to implement worldwide (Table 7-2). A position paper was published in *Transplantation* in 2005 that describes the standards for patients who are potential altruistic kidney donors. Although these recommendations are derived from the best evidence-based medicine available today, they are still only a set of guidelines, not mandatory regulations.[17,26]

Table 7-3 lists considerations for routine evaluation of the potential living kidney donor. Table 7-4 lists screening questions for nondirected altruistic donation. The basic evaluations are the standard history and physical examination and hematological and biochemical profiles. Potential donors remaining after the initial screening process are evaluated meticulously and repeatedly to confirm excellent general health and bilateral renal function. Typical evaluations performed[17,26,45,46] are listed in Table 7-3. Many of the studies are directed toward detection of unsuspected extrarenal pathology. This medical evaluation may reveal significant but treatable problems of which the donor was unaware.

This intensive medical evaluation may exclude the volunteer as a donor, but also is designed to lead to an uncomplicated operative procedure and postnephrectomy recovery period for selected donors. The final studies are concerned with the quality of renal function and the clarification of any anatomical abnormalities in either kidney. It must be determined that the nondonated kidney is normal. This determination is especially relevant when the renal failure in the potential donor's relative has resulted from causes that may be hereditary (e.g., diabetes, polycystic disease, or hypertension).

Family History of Inheritable Diseases

In the case of diabetes, further evaluation, including glucose or cortisone-glucose tolerance tests, may be undertaken to identify any subclinical evidence of diabetes. Because of the hereditary nature of polycystic renal disease, cadaver donors often are needed for these patients. If a familial donor is considered, selection may be limited to relatives older than age 30 years, in whom latent polycystic disease can be ruled out by ultrasonography or computed tomography (CT). Genetic

Table 7–2 **Amsterdam Forum Guidelines: Donor Evaluation**

Before donation, the live kidney donor must receive a complete medical and psychosocial evaluation, receive appropriate informed consent, and be capable of understanding the information presented in that process to make a voluntary decision.
All donors should have standard tests performed to ensure donor safety.

Hypertension

Patients with BP >140/90 mm Hg by ABPM are generally not acceptable as donors.
BP should preferably be measured by ABPM, particularly among older donors (>50 years old) and donors with high office BP readings.
Some patients with easily controlled hypertension who meet other defined criteria (e.g., >50 years of age, GFR >80 mL/min, and urinary albumin excretion <30 mg/day) may represent a low-risk group for development of kidney disease after donation and may be acceptable as kidney donors.
Donors with hypertension should be regularly followed by a physician.

Obesity

Patients with body mass index >35 kg/m^2 should be discouraged from donating, especially when other comorbid conditions are present.
Obese patients should be encouraged to lose weight before kidney donation and should be advised not to donate if they have other associated comorbid conditions.
Obese patients should be informed of acute and long-term risks, especially when other comorbid conditions are present.
Healthy lifestyle education should be available to all living donors.

Dyslipidemia

Dyslipidemia should be included along with other risk factors in donor risk assessment, but dyslipidemia alone does not exclude kidney donation.

Acceptable Donor Renal Function

All potential kidney donors should have GFR estimated.
Creatinine-based methods may be used to estimate the GFR; however, creatinine clearance (as calculated from 24-hour urine collections) may underestimate or overestimate GFR in patients with normal or near-normal renal function.
Calculated GFR values (MDRD [Modification of Diet in Renal Disease study] and Cockcroft-Gault) are not standardized in this population and may overestimate GFR.
GFR <80 mL/min or 2 SD below normal (based on age, gender, and body surface area corrected to 1.73/m^2) generally precludes donation.

Urinalysis for Protein

A 24-hour urine protein >300 mg is a contraindication to donation.
Microalbuminuria determination may be a more reliable marker of renal disease, but its value as an international standard of evaluation for kidney donors has not been determined.

Urinalysis for Blood

Patients with persistent microscopic hematuria should not be considered for kidney donation unless urine cytology and a complete urologic workup are performed.
If urological malignancy and stone disease are excluded, a kidney biopsy may be indicated to rule out glomerular pathology such as IgA nephropathy.

Diabetes

Individuals with a history of diabetes or fasting blood glucose ≥126 mg/dL (≥7 mmol/L) on at least two occasions (or 2-hour glucose with oral glucose tolerance test ≥200 mg/dL (≥11.1 mmol/L) should not donate.

Stone Disease

An asymptomatic potential donor with history of a single stone may be suitable for kidney donation if
- No hypercalcuria, hyperuricemia, or metabolic acidosis
- No cystinuria or hyperoxaluria
- No urinary tract infection
- Multiple stones or nephrocalcinosis are not evident on CT

An asymptomatic potential donor with a current single stone may be suitable if
- The donor meets the criteria shown previously for single stone formers and current stone <1.5 cm, or potentially removable during the transplant

Stone formers who should not donate are those with
- Nephrocalcinosis on x-ray or bilateral stone disease
- Stone types with high recurrence rates and are difficult to prevent (see text)

Malignancy

Prior history of the following malignancies usually excludes live kidney donation
- Melanoma, testicular cancer, renal cell carcinoma, choriocarcinoma, hematological malignancy, bronchial cancer, breast cancer, and monoclonal gammopathy

Prior history of malignancy may be acceptable for donation only if
- Prior treatment of the malignancy does not decrease renal reserve or place the donor at increased risk for end-stage renal disease
- Prior treatment of malignancy does not increase the operative risk of nephrectomy

A prior history of malignancy usually excludes live kidney donation, but may be acceptable if
- Specific cancer is curable, and potential transmission of cancer can reasonably be excluded

Urinary Tract Infections

Donor urine should be sterile before donation; asymptomatic bacteriuria should be treated before donation.
Pyuria or hematuria at the proposed time of donation is a contraindication to donation.
Unexplained hematuria or pyuria necessitates evaluation for adenovirus, tuberculosis, and cancer; urinary tuberculosis and cancer are contraindications to donation.

Table continued on following page

Table 7–2 **Amsterdam Forum Guidelines: Donor Evaluation—cont'd**

Live Unrelated Donors

Current available data suggest no restriction of live kidney donation based on the absence of an HLA match.
An unrelated donor transplant is equally successful to the outcome achieved by a genetically related family member, such as a parent, child, or sibling, who is not HLA identical to the recipient.

Determination of Cardiovascular Risk

Clinical predictors of an increased perioperative cardiovascular risk (for noncardiac surgery) by the American College of Cardiology/American Heart Association standards fall into three categories: major, intermediate, minor

- All major predictors—unstable coronary syndromes, decompensated heart failure, significant arrhythmias, and severe valvular disease—are contraindications to live kidney donation
- Most intermediate predictors—mild angina, previous myocardial infarction, compensated or prior heart failure, and diabetes mellitus—are contraindications to donation
- Minor predictors—older age, abnormal ECG, rhythm other than sinus, low cardiac functional capacity, history of stroke, and uncontrolled hypertension—warrant individual consideration

Assessment of Pulmonary Issues

Careful history and physical examination are the most important parts of assessing risk.
Routine preoperative pulmonary function testing is not warranted for potential live kidney donors, unless there is an associated risk factor, such as chronic lung disease.
Increased risk of postoperative pulmonary complication is associated with FEV_1 <70% or FVC <70% of predicted, or a ratio of FEV_1/FVC <65%.

Smoking Cessation and Alcohol Abstinence

Smoking cessation at least 4 wk before donation is advised based on recommendations for patients undergoing elective surgical procedures.
Alcohol should be avoided for a minimum of 4 wk to decrease the known risk of postoperative morbidity.
Cessation of alcohol abuse defined by DSM-III (*Diagnostic and Statistical Manual of Mental Disorders, Third Edition*): 60 g of alcohol/day sustained over >6 months

ABPM, ambulatory blood pressure monitoring; BP, blood pressure; CT, computed tomography; ECG, electrocardiogram; FEV_1, forced expiratory volume in 1 second; FVC, forced vital capacity; GFR, glomerular filtration rate; HLA, human leukocyte antigen.

tests for the *PKD1* gene and various mutations are available to determine the existence of such genetic predisposition for the development of autosomal dominant polycystic kidney disease.

Hypertension

In the last 25 years, several studies have identified an increased incidence of hypertension in first-degree relatives of patients with renal failure. Potential donors from this pool should be screened carefully for hypertension.[41] The exact risks to this group have not been accurately quantified.[38] Patients with a resting blood pressure greater than 140/90 mm Hg generally are unacceptable as kidney donors.[64,87]

Potentially acceptable individuals for live kidney donation may have a history of mild hypertension that is easily controlled, but their glomerular filtration rate (GFR) should be greater than 80 mL/min and their urinary albumin levels less than 30 mg/day. Older patients (>50 years old) also can be acceptable if these criteria are met. Patients with mild hypertension who elected and are accepted for kidney donation should have close medical follow-up to ensure that their health status remains excellent. Despite these relaxations in acceptability of an individual who has mild hypertension for live kidney donation, the fact remains that the long-term risks are still not entirely delineated.

Obesity

Society faces increasing health-related problems stemming from cultural excesses and increasingly sedentary lifestyles. Obesity is defined as a body mass index greater than 30 kg/m^2; morbid obesity is defined as a body mass index greater than 35 kg/m^2. Obesity is associated with or causally related to comorbidities such as hypertension, cardiovascular diseases, hyperlipidemia, diabetes, and nonalcoholic fatty liver disease. Analogous to hypertension, the long-term risks of obesity and kidney donation are not well understood. In the short-term, the renal function after donation is similar to function in individuals who are not obese.[70] Although we always encourage weight loss and exercise programs for patients, the effectiveness and sustainability of such initiatives are often suboptimal. The fact that we encourage a patient to lose weight before kidney donation does not translate to a long-term adherence to their dietary and exercise regimen. The changes that occur for an individual to lose weight before consideration for kidney donation have to reflect changes in their established lifestyle.

Nephrolithiasis

The incidence in the general population of nephrolithiasis is affected by multifaceted extrinsic and intrinsic factors because the disease varies according to geography, age, anatomical site, climate, water intake, diet, occupation, and genetics.[42,51,65,72-74] In 2005, long-term studies at the Mayo Clinic in Rochester, Minnesota, updated their initial 1979 study to evaluate the longitudinal epidemiology of stone disease in the general population.[51] The age-adjusted incidence of new-onset symptomatic stone disease for men was 105 (± 16.8) per 100,000 per year. For women, the corresponding rate was 68.4 (± 12.3) per 100,000 per year. A prospective

Table 7–3 Routine Screening for Potential Living Kidney Donors

Urinalysis
Dipstick for protein, blood, and glucose
Microscopy, culture, and sensitivity
Measurement of protein excretion rate
Assessment of renal function
Estimation/measurement of glomerular filtration rate
Blood tests
Hematological profile
Complete blood count
Hemoglobinopathy (where indicated)
Coagulation screen (PT and APTT)
G6PD deficiency (where indicated)
Biochemical profile
Creatinine, urea, and electrolytes
Liver tests
Urate
Fasting plasma glucose
Bone profile
Glucose tolerance test (if fasting plasma glucose >6-7 mmol/L)
Blood lipids
Thyroid function tests (if indicated)
Pregnancy test (if indicated)
Prostate-specific antigen (if indicated)
Virology and infection screen
Hepatitis B and C
Toxoplasma
Syphilis
HIV and HTLV 1/2
Malaria (where indicated)
Cytomegalovirus
Trypanosoma cruzi (where indicated)
Epstein-Barr virus
Schistosomiasis (where indicated)
HHV8 and HSV (where indicated)
Strongyloides (where indicated)
Typhoid (where indicated)
Brucellosis (where indicated)
Cardiorespiratory system
Chest x-ray
Electrocardiogram
Stress test
Echocardiography (where indicated)
Assessment of renal anatomy*

*Appropriate imaging investigations should allow confirmation of the presence of two kidneys of normal size and enable abnormalities of the collecting system and calcification or stone disease in the renal tract to be detected. They also must delineate the anatomy of the renal vasculature.

APTT, activated partial thromboplastin time; G6PD, glucose-6-phosphate dehydrogenase; HIV, human immunodeficiency virus; HTLV, human T-lymphotropic virus; HHV, human herpesvirus; HSV, herpes simplex virus; PT, prothrombin time.

Table 7–4 Initial Screening Interview for Nondirected Donation

Medical/Personal History
How old are you?
Are you healthy and physically fit?
Do you have a history of cancer, heart disease, diabetes, kidney disease, or high blood pressure?
Do you take medications?
Have you undergone any previous operations?
Is there a history of kidney disease in your family?
Do you receive disability benefits for any reason?*
Do you live alone; are you married?
Where do you live?†
Knowledge about Nondirected Donation
How did you learn or hear about organ donation?
Do you understand that donating a kidney is not like donating blood?
Are you aware that the risks of donating a kidney include the possibility of dying?
Do you understand that there are risks to the recipient (i.e., that the kidney may be rejected)?
Do you understand that you cannot be paid money for being a donor?
Are you aware that several months may be necessary to determine your suitability as a donor by required clinical and psychological testing?
Do you understand that you cannot select your recipient, and that he or she will be from the list of patients who are already waiting?
Donor-Related Questions
Why do you wish to donate a kidney?
Have you told a member of your family that you wish to be a kidney donor?
Have you and your family considered the burdens associated with donation that could include out-of-pocket expenses for travel, physician appointments, and time out of work?
Is there a specific time frame to have your donor surgery performed?
Would somebody be available to assist you at home during your recovery from surgery?

*This does not rule out a donor a priori; the donor should be asked to elaborate.

†This affects costs and convenience associated with donation.

cohort study in southern Italy of more than 500 men who had no stones at study onset and were followed for 8 years found an overall 10.3% incidence of stone disease.[12] One can extrapolate correctly that the absence of nephrolithiasis at the time of donor evaluation does not imply the patient would not have symptomatic stone disease in the future.

When assessing the risks of kidney donation in the setting of a history of nephrolithiasis, the risks and risk factors for stone formation in that individual have to be delineated. Individuals who have more than one stone or who have metabolically active stone formation are not candidates for kidney donation. Candidates who have a genetic predisposition to stone disease, such as cystinuria or hyperoxaluria, also are unsuitable. Any metabolic abnormalities of hypercalciuria, hyperuricemia, and recurrent urinary tract infections pose higher risks for recurrent stone formation.[17] The true incidence of the risks and complications of recurring stone disease after live kidney donation is unknown and is likely to remain unknown because historically donors have been chosen who are otherwise healthy, non–stone formers.

As a general guideline, stone formers who should be declined as potential donors are individuals who have bilaterality of stone disease or have nephrocalcinosis on radiographic evaluation. In addition, patients contemplating live kidney donation who have stone types with etiological factors that predispose to recurrence should be ruled out. Although the guidelines have indicated that patients who have stone recurrence while on therapy should not be potential donors, some would argue that the need for metabolic therapy in stone disease already suggests either intrinsic or extrinsic factors to promote stone formation; these patients should not donate a kidney.[17]

Malignancy

The risk of malignancy increases with age. It is imperative especially that older donors be screened to exclude malignancy.[66-68] We have detected early breast, lung, and renal cell carcinomas in asymptomatic potential donors. All of these patients are alive without evidence of disease after appropriate treatment for the cancer.

Generally, potential donors with malignancies such as melanoma, renal cell carcinoma, transitional cell carcinomas, hepatocellular carcinomas, hematological malignancies, and lung cancers are precluded from kidney donation. If an individual has been treated for a low-grade curable tumor and has sustained disease-free survival constituting a cure, he or she can be evaluated to be a kidney donor.[17] The risks of transmission are not zero, however, and the discussion of risks and benefits must occur with the potential donor and recipient.

Infectious Disease

The transmissibility of disease is highly scrutinized because many forms of infectious disease may be benign in a nonimmunocompromised host. In a transplant recipient undergoing an immunosuppressive regimen, these disease entities might be detrimental, however, and sometimes can be fatal.

Human immunodeficiency virus (HIV) detected in an individual by antibodies should be confirmed by a neutralization test and a Western blot analysis. If such confirmations are obtained, the donor is ruled out for live kidney donation.[32,33] Hepatitis B virus (HBV) and hepatitis C virus (HCV) are of greater concern because the prevalence of both diseases is enormous worldwide. The transmissibility of hepatitis virus is well documented.[34,48] Individuals who are being evaluated undergo enzyme-linked immunosorbent assays to detect the presence of HBV and HCV antibodies. If the enzyme-linked immunosorbent assays are negative, the individuals are deemed suitable serologically for kidney donation. If these serological tests are positive, confirmatory RNA or DNA polymerase chain reaction quantitative assays for HCV and HBV can ascertain further the presence or absence of the virus. If the kidney recipient is positive for HCV, potential introduction of different genotypes of HCV can offset benefits that the new allograft might confer.[48] With HBV immunization over the past 2 decades, there are many recipients who have developed HBV surface antibodies potentially to protect the host against the virus. Organs from a donor who is either HBV surface antibody positive or HBV core antibody positive can be used successfully in an immunized recipient with remote risk of subsequent infection.[55]

Many other serological screens are commonly performed as part of the donor evaluation, including cytomegalovirus (CMV) screening. Because CMV is so common in the general population, with greater than 85% of the census population likely to have been exposed to CMV, prior infection of the donor is not of consequence most of the time. Nevertheless, the basis of such testing is to determine how best to use prophylactic antiviral agents in the recipients to prevent new infection after the exposure. Serological CMV-positive donors are not precluded from donation to a CMV-negative recipient. The agents for viral prophylaxis might be more intensive during the initial transplant and might extend for a long time to prevent acute infection with CMV in the recipient (see Chapter 29).[31,88,89]

There are regions throughout the world in which there are endemic infectious diseases that have geographical preponderances. Tuberculosis and strongyloidiasis in Asia, Chagas' disease in Central and South America, and schistosomiasis and malaria in Africa are examples of infectious diseases that have risks of transmission at the time of transplantation. It is important for potential donors to be screened for these disease entities in countries where they are endemic. In addition, travelers who have spent considerable time in those regions and are being considered as donors should have screening to exclude the presence of occult exposure.

Reports of rare infections that have had deleterious outcomes in the recipients have been published.[30,49] These publications heighten awareness that immunocompromised hosts respond differently and unpredictably to infectious agents. In a competent host, virus and other agents of disease might not be as virulent, but under heavy immunosuppression, especially with induction therapies, they can cause significant host insult. The fact that these opportunistic infections are rare can delay the diagnosis and treatment. Even if diagnosis is readily achieved, the lack of specific therapies can result in host morbidity and mortality.

ABO Grouping

Incompatibility of ABO between donor and recipient typically has resulted in irreversible rejection so that selection of major blood group compatibility usually is practiced. More recent reports have changed this paradigm, however, as the availability of intensive immunosuppression may have overcome some of these obstacles (see Chapter 22). Even without current ABO-incompatible protocols, historically, some groups have reported successful results after transplantation of blood group A_2 kidneys into group O recipients.[62] Approximately 20% of blood group A individuals are subtyped as A_2. The highly successful transplantation of A_2 kidneys into group O recipients has been explained by the low expression of A determinants in A_2 kidneys compared with A_1 kidneys. A_1 kidneys have been transplanted successfully into O recipients after elimination of ABO isoagglutinins by plasmapheresis and occasional splenectomy of the recipient. (See Chapter 22 for further discussion.)

HLA Typing

If several medically suitable relatives are available, the decision for donation can be made on the basis of histocompatibility testing—an HLA-identical sibling being the ideal choice (see Chapter 10). Not long ago, the decision to proceed with transplantation from a genetically unrelated living donor had been a difficult one to make because it was presumed that living unrelated donor allografts would have survival comparable to that of cadaver donor organs. It was initially proposed that living unrelated donor kidneys should be chosen only in exceptional cases.[8] As noted earlier, however, it is now clear that living unrelated donor kidneys provide significant physiological and consequently long-term survival advantages and are being accepted with increasing frequency. Nevertheless, results with HLA-mismatched living donors are generally superior to even well-matched cadaver donors, suggesting that the quality of the kidney and short preservation time outweigh the benefit of matching. Most centers continue to require that a stable emotional relationship

between donor and recipient exist and that donation for monetary compensation not be allowed.[14,15] In practice, living unrelated donor transplantation occurs most frequently in husband and wife pairs; some spouses have expressed the belief that they have "a right to donate."[82]

Age

Selection also may be determined on the basis of age (avoiding elderly volunteers or minors if possible) or on less objective factors, such as the special social obligations of a particular family member. In different countries, there are special legal constraints for donation by minors. If the only suitable donor has not attained the age of majority, it is necessary in the United States to present the medical facts to a court of law so that the necessity and advisability of donation by a minor can be scrutinized.

An analysis of the UNOS database has indicated that kidneys from live minors were transplanted more frequently to adult than to pediatric recipients. Only 12% of all recipients were identical twins. The report also concluded that the use of a minor donor provided no better long-term outcome than that expected from an adult donor. The resulting recommendation is that live organ donation from a minor should be considered only when there is no other living donor available, and all other opportunities for transplantation have been exhausted.[19] The longer the life expectancy after altruistic kidney donation, the more variables influence outcomes that simply are impossible to predict. Donation from minors is rightfully discouraged.

Normal Renal Function

Although there are many modalities to attempt to quantify renal function, the multifactorial nature of the tests may either overestimate or underestimate the true physiological function of the kidneys.[4] Individuals who are being evaluated for kidney donation should have "normal" renal function as determined by GFR. The GFR can be age dependent, however; it decreases as individuals age.[25,35,52]

Commonly, GFR is estimated by creatinine-based methods calculated from 24-hour urine collections.[75,76] Calculated methodologies, such as MDRD (Modification of Diet in Renal Disease study) and Cockcroft-Gault, are not standardized in normal individuals and can overestimate the GFR. Although isotopic estimation of GFR can be carried out to delineate the renal function further when GFR estimations are borderline, many centers do not do these routinely because of the additional costs and complexities associated with the study.[77]

The current guidelines define unacceptable renal function for donation as GFR less than 80 mL/min or 2 SD below normal when taking into consideration age, gender, and body surface area corrections.[5,45,46] Recipients of a kidney outside of these guidelines have a higher relative risk of graft loss.

Radiological Evaluation of a Living Donor

The optimal study for evaluation of kidney donors has become a subject of debate as newer, more sensitive multiplanar simulation technologies have become available using CT and magnetic resonance imaging (MRI). The ability to visualize data obtained with CT or MRI in a three-dimensional laboratory, carefully reconstructing the images isolating arteries, veins, or parenchymal structures, has immensely assisted surgical planning, particularly with laparoscopic donor nephrectomies (Fig. 7-2).

We retrospectively assessed the sensitivity and specificity of three-dimensional 16-section CT in the evaluation of vessels, pelvicaliceal system, and ureters in living renal donors, with surgical findings as the reference standard. Forty-six renal donors (18 men, 28 women; mean age 42 years) were examined with 16-section CT. Two blinded reviewers independently studied renal vascular and urographic anatomy of each donor CT scan by first using three-dimensional images alone, then transverse images alone, and finally transverse and three-dimensional data set. For three-dimensional images, transverse images, and transverse in conjunction with three-dimensional data sets, the respective sensitivity and specificity of CT in evaluation of accessory arteries and venous anomalies approached 98% for both compared with findings at surgery. We concluded that for focused assessment of renal vascular and urographic anatomy, review of three-dimensional data set alone provides high sensitivity and specificity with regard to findings seen at surgery.[71]

Despite the increasing availability of these noninvasive modalities and their lower risk potential for kidney donor patients, there are centers where these modalities are unavailable, and the traditional aortogram and selective renal angiography might be appropriate. In addition, the aortogram may be the only study that leads to the decision against accepting a particular donor, for example, when unilateral fibromuscular dysplasia is shown. CT or MRI with three-dimensional reconstruction has not been able to identify the more subtle forms of this lesion reliably. Alternatively, some groups traditionally have recommended digital subtraction angiography, which can be accomplished through peripheral venipuncture, avoiding some of the costs and morbidity of the aortogram. Although it is technically reasonable to transplant a kidney with multiple arteries, a kidney with a single artery is preferable. When either kidney is shown to be satisfactory, the left is usually chosen because the longer renal vein contributes to the technical ease of the nephrectomy and subsequent transplant.

SUMMARY

The success of organ transplantation and the shortage of suitable cadaver donor organs worldwide have shifted the paradigm of reluctance to use living donors for transplantation to widespread general acceptance. Of particular concern in this development are the expansion of acceptable criteria for donation and the interplay of physician-patient relationships that rightfully must be addressed before organ donation. Numerous worldwide consensus conferences in recent years have addressed these concerns. These sessions have resulted in proposed guidelines that are generally accepted by practicing communities.

These guidelines and consensus statements can help clinicians understand the nature of how best to proceed with evaluating a potential kidney donor. There are still significant uncertainties, however, regarding the use of donors with isolated medical abnormalities. As we develop a greater understanding and a better ability to predict outcomes, guidelines may be adjusted to reflect those observations and changes.

LIVING DONOR

Donor Nephrectomy

The technical details of donor nephrectomy vary among different centers—some favor an anterior transperitoneal approach, whereas others favor the loin approach. Many centers have embarked on laparoscopic living donor nephrectomy as the standard for anatomically suitable living related donors and living unrelated donors (see Chapter 8B). If an open approach is to be used, the procedure described herein and in Figure 8-1 is our preferred technique. We emphasize the principles of (1) adequate exposure; (2) careful handling of the tissues, especially during periarterial dissection to limit vascular spasm; (3) preservation of adequate perihilar and periureteral fat to ensure adequate vascularity to limit the possibility of subsequent ureteral necrosis; and (4) maintenance of active diuresis, which makes prompt post-transplantation function more likely.

After induction of general endotracheal anesthesia, the donor is placed in the lateral position with the table flexed to extend the presenting flank (Fig. 8-1A). The incision is made anterior to and extending to or, if necessary, over the 11th or 12th rib. The latissimus dorsi muscle posteriorly and the external oblique muscle anteriorly are divided. This step exposes the periosteum and permits the subperiosteal removal of the rib (Fig. 8-1B) if necessary for adequate exposure. In nonobese patients, removal of the rib generally is not required, which results in less postoperative discomfort. The internal oblique and transverse abdominis muscles are divided with the underlying transversalis fascia to enter the retroperitoneal space. Care is taken to avoid entering the pleural or peritoneal cavities (Fig. 8-1C). The paranephric fat and Gerota's fascia, lying in the central part of the wound, are entered. The presenting surface of the kidney is dissected free of the underlying perinephric fat. No dissection is done in the renal hilus to protect the blood supply to the ureter. The renal vein is dissected to its junction with the vena cava, the adrenal and gonadal tributaries being ligated and divided (Fig. 8-1D). The renal artery is skeletonized at its origin from the aorta after lifting the kidney from its bed and rotating it anteriorly (Fig. 8-1E). The ureter is freed, with its investing vessels and fat, down to or below the pelvic brim, then transected. The kidney is now mobilized except for its vascular connections. A brisk diuresis should be evident from the cut ureter, mannitol and furosemide plus adequate crystalloid solutions having been infused during dissection of the kidney.

If the transperitoneal approach is used (which has been the practice, e.g., in Oxford), a transverse incision is made beneath the costal margin on the side of the kidney to be removed. On the left side, the spleen, pancreas, and splenic flexure of the colon are mobilized and retracted to the right to expose the kidney, renal vessels, aorta, and ureter. On the right side, the duodenum and hepatic flexure of the colon are mobilized and reflected to the left to expose the kidney, inferior vena cava, renal vessels, and ureter. Dissection then proceeds much as outlined previously.

When urinary output from the skeletonized kidney is ensured, the renal artery and vein are clamped and divided, leaving a sufficient cuff of the retained donor vessel to allow secure repair. Although some surgeons prefer to anticoagulate the donor systemically before clamping the vessels, most omit this step and simply perfuse the excised kidney with a chilled, heparinized electrolyte solution. Increasing the osmolarity of the perfusate with mannitol is believed by some surgeons to protect the kidney further from ischemic damage. The use of more complex and more expensive preservation solutions (see Chapter 9) is not required for living donor kidneys, which typically are reimplanted with only a brief cold ischemic interval. The wound is closed without drains, and the patient is returned to the recovery room, where a chest radiograph is obtained to exclude the possibility of pneumothorax.

Postoperative Care and Complications

Available evidence indicates that patients undergoing clean contaminated procedures, such as unilateral nephrectomy, can benefit from prophylactic antibiotics.[19] We routinely administer a first-generation cephalosporin for 24 hours, beginning 1 hour before surgery. Nasogastric tubes usually are not required. Bladder catheters, if present, usually are removed in the immediate postoperative period. Graded resumption of oral alimentation is necessary because

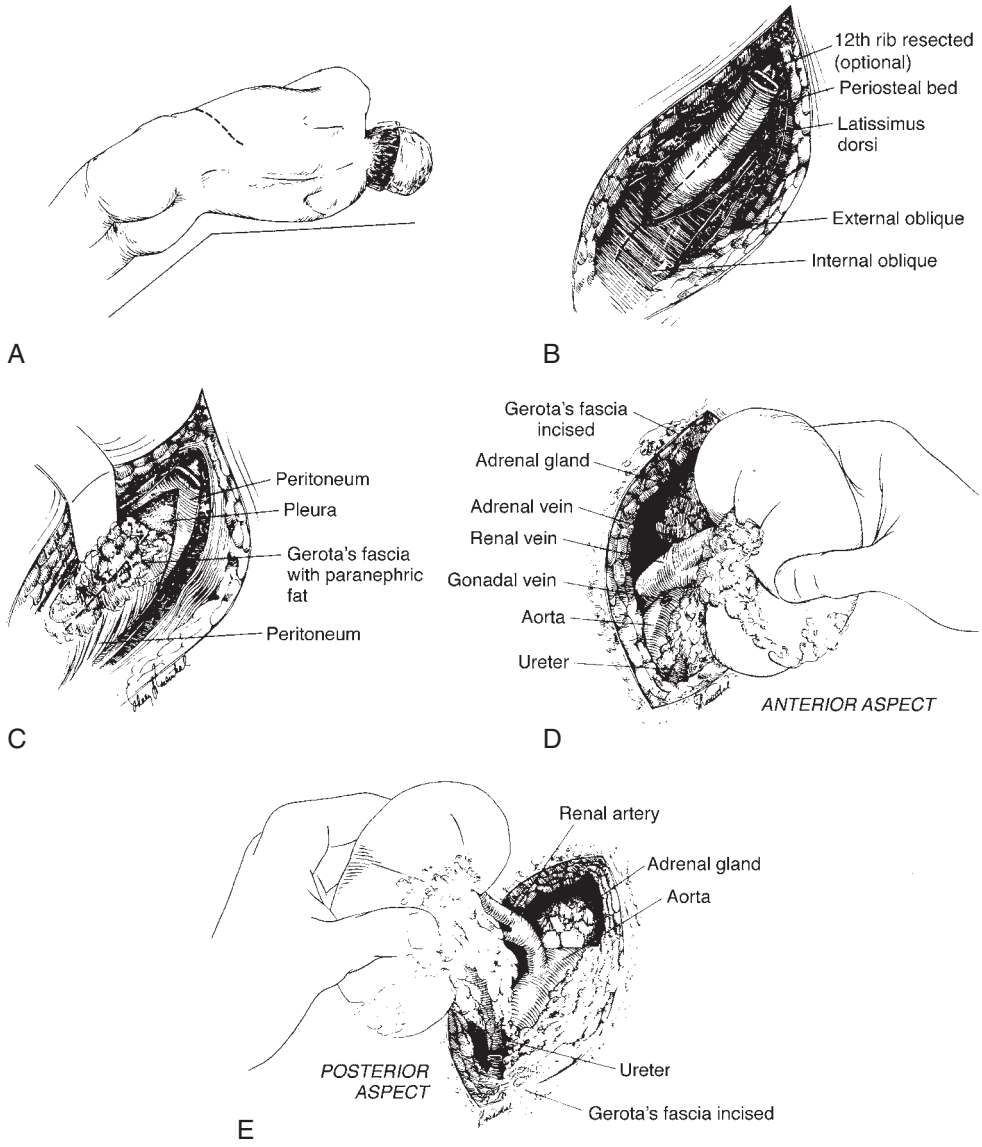

Figure 8–1 Living donor nephrectomy. **A-C**, In this patient, the kidney is approached through the bed of the 12th rib. Care is taken to avoid entering the pleural or peritoneal cavities. **D**, The renal vein is dissected to the vena cava, ligating and dividing the gonadal and adrenal branches. **E**, The renal artery is approached by lifting the kidney anteriorly. Gentle dissection continues down to the aorta. The ureter is divided at or below the pelvic brim, carefully preserving the periureteral vascular supply.

these patients may exhibit a more prolonged ileus than might be anticipated after retroperitoneal surgery. This ileus may be the result of the extensive periaortic dissection and consequent autonomic nerve disruption. Nevertheless, most of these patients are ready for discharge from the hospital in 3 to 4 days and for return to employment by 3 to 4 weeks if unusually strenuous physical labor is not involved. Urine culture, renal function tests, and a complete blood count are obtained and reassessed before discharge. The patient has follow-up evaluations at increasing intervals.

The perioperative mortality rate for kidney donors is estimated to be 0.03%.[9] At least 20 deaths have been reported after living donor allograft donation over 40 years.[8] Other complications of the renal donor procedure are generally minimal and easily remedied.[3,6,7,18] The current overall complication rate is approximately 2%.[2] Table 8-1 lists commonly observed problems and their approximate incidence, compiled from published reports and from our own experience with more than 1000 patients.

Occasionally, a complication occurs during the preoperative evaluation, most likely related to the aortogram, which is now being used less frequently. Such complications include localized hematoma formation, femoral artery thrombosis or false aneurysm formation at the arterial puncture site or, more rarely, reaction to the radiographic dye, such as an allergic response or acute tubular necrosis. Most complications occur in the perioperative period, with atelectasis, urinary retention or infection, wound problems, and prolonged bowel dysfunction accounting for most complications. These conditions typically are resolved by the time the patient is discharged from the hospital. One of the most dangerous complications is thrombophlebitis with possible life-threatening pulmonary embolus. In a worldwide experience estimated to be greater than 100,000 donor operations, the most frequent cause of the approximately 20 known deaths was pulmonary embolus. Single fatal cases of hepatitis, myocardial infarction, and depression leading to alcoholism and death in an automobile accident have been reported.

Table 8–1 **Complications in Living Donors**

Procedure Complications	Incidence (>2000 Cases) (%)
Aortogram	
Prolonged discomfort	<1

*Similar to general population.

Longer term morbidity should be minimal. Endogenous creatinine clearance rates rapidly approach 70% to 80% of the preoperative level, and reports of late renal failure have been extremely rare. An important factor is the exclusion during the selection process of pathology or potential pathology in the donors. As part of a continuing study at Massachusetts General Hospital of the long-term impact of kidney transplantation on patients and family members, 70 adults who had donated a kidney to a close relative between 1963 and 1975 have been studied for the perceptions of the effect of that donation on their lives. No long-term medical problems related to the nephrectomy were identified. As mentioned earlier, in describing how they had come to donate a kidney, more than 50% reportedly made their decision to donate instantaneously and believed that as a result of donation their relationship with the recipient had been strengthened. Approximately one third of the donors reported a positive change in their outlook on life, often citing increased appreciation of their own health. In cases in which the allograft failed, many donors reported initially a sense of anger and frustration. Ultimately, however, they claimed a sense of worthwhile accomplishment and belief that they would pursue the same course again. Representing a wide variety of occupations, the donors agreed almost universally that their earning capacity and ability to carry out their occupational responsibilities were not adversely affected by the donation. The immediate and long-term morbidity of nephrectomy is sufficiently low to make the risk acceptable for fully informed, genetically or emotionally related donors for patients with chronic renal disease.

Open versus Laparoscopic Nephrectomy

Reasons for recommending open rather than laparoscopic donor nephrectomy include (1) lack of surgical expertise with laparoscopic nephrectomy, (2) lack of resources for laparoscopic nephrectomy, (3) previous abdominal surgery in the donor in which the laparoscopic technique is unlikely to be feasible, and (4) need for greater donor vessel length in cases in which the blood vessel anatomy is marginally acceptable. Multiple studies comparing open versus laparoscopic donor nephrectomy have been reported. Studies also have compared minimal open incision and laparoscopic, hand-assisted versus straight laparoscopic, and hand-assisted versus open techniques. The open method was the standard method before the development of laparoscopic nephrectomy and is safe and always the default procedure when other techniques are not feasible.[14] Quality-of-life studies suggest that patients' return to work is slower, narcotic use is higher, but patient satisfaction is equivalent with laparoscopic nephrectomy.[1,10,11,16] In a Swiss study, open nephrectomy was accepted with equal satisfaction as the laparoscopic method and did not deter donation.[5]

DECEASED DONOR

The most commonly practiced procurement technology today continues to be retrieval of viable organs for transplantation from brain-dead patients who are maintained in stable physiological balance by artificial support. This approach gives rise to the term heart-beating cadaver donor. These donors are brought to the operating room where organ procurement is undertaken under semielective conditions while using the usual sterile precautions of any aseptic surgical procedure. The donor may require large volumes of intravenous fluids to restore blood volume, which typically has been severely depleted by premortem attempts to decrease brain swelling and achieve neurological resuscitation. Diuretics, mannitol, and vasopressors are administered as needed to promote diuresis during the nephrectomy procedure. Some groups systemically heparinize the donor and administer vasoactive agents, such as phenoxybenzamine or phentolamine, to combat vasospasm in the kidneys. Other donor pretreatment modalities, such as possible immunomodulating measures, are seldom used, and are not discussed here.

In situations in which the criteria for brain death have been fulfilled, but the concept of heart-beating donation has not been accepted, or in which there is irreversible brain injury, but not fulfilling the criteria of brain death, respiratory support is discontinued in the operating room (termed donation after cardiac death [DCD]). After cardiac function ceases, the donor is declared dead, and the surgical procedure is expeditiously undertaken.[12] The kidneys must be removed and chilled more rapidly than in the heart-beating donation procedure to minimize ischemic damage to the retrieved organs. The goal is to limit the warm ischemic period, whenever possible, to less than 30 minutes.

In an effort to increase further the number of kidneys available for transplantation, interest also has been revived in the possible procurement of organs from donors who are

dead on arrival or who die after unsuccessful cardiorespiratory resuscitation (uncontrolled non–heart-beating donation). Several studies have confirmed that significant numbers of patients die in emergency departments or intensive care units without brain death being declared.[4] Presumably, suitable allografts could be salvaged from such potential donors if reliable methods could be identified to control the ischemic damage that occurs shortly after death. Current approaches include combined in situ kidney flushing and core body cooling by femoral artery and peritoneal catheters placed at the bedside immediately after cardiac arrest.[12,15] The non–heart-beating donor can be transported to the operating room for bilateral nephrectomy.

Removal of Kidneys Alone

If only the kidneys are to be removed, bilateral nephrectomy is accomplished through a long midline incision. The objective is to take both kidneys with the full length of the renal artery and vein, preferably on aortic and vena caval cuffs. This approach limits the possibility of injuring accessory vessels, which are present in 12% to 15% of normal kidneys. The technique we prefer entails en bloc removal of both kidneys with an intact segment of aorta and inferior vena cava to allow early in situ cooling of the kidneys. This approach reduces the time required for the nephrectomies because the fine dissection necessary for identification and isolation of the artery and vein can be performed after the kidneys are removed. With this technique, the risk of damaging accessory vessels is essentially eliminated. Continuous perfusion of the kidneys, if this preservation technique is used, usually can be provided via the aorta, avoiding direct renal artery cannulation and the possibility of intimal injury. Multiple arteries can be left on a cuff of aorta, giving the transplant surgeon the option of using a single Carrel patch anastomosis for a simpler reimplantation procedure.

On entering the donor's abdomen, rapid exploration excludes the presence of unsuspected sepsis, neoplasia, or other important pathology. The small bowel and mesentery are retracted to the right, and the posterior parietal peritoneum is incised over the great vessels and through the ligament of Treitz. The peritoneal incision is extended around the ascending colon so that the bowel can be retracted upward and to the left (Fig. 8-2A). The duodenum and pancreas are retracted superiorly. The proximal aorta is freed to above the celiac axis, dividing and ligating the superior mesenteric artery (Fig. 8-2B).

Tapes or large silk sutures are passed around the distal aorta and vena cava just above the iliac bifurcations. Because only the kidneys are being removed, the proximal aorta also

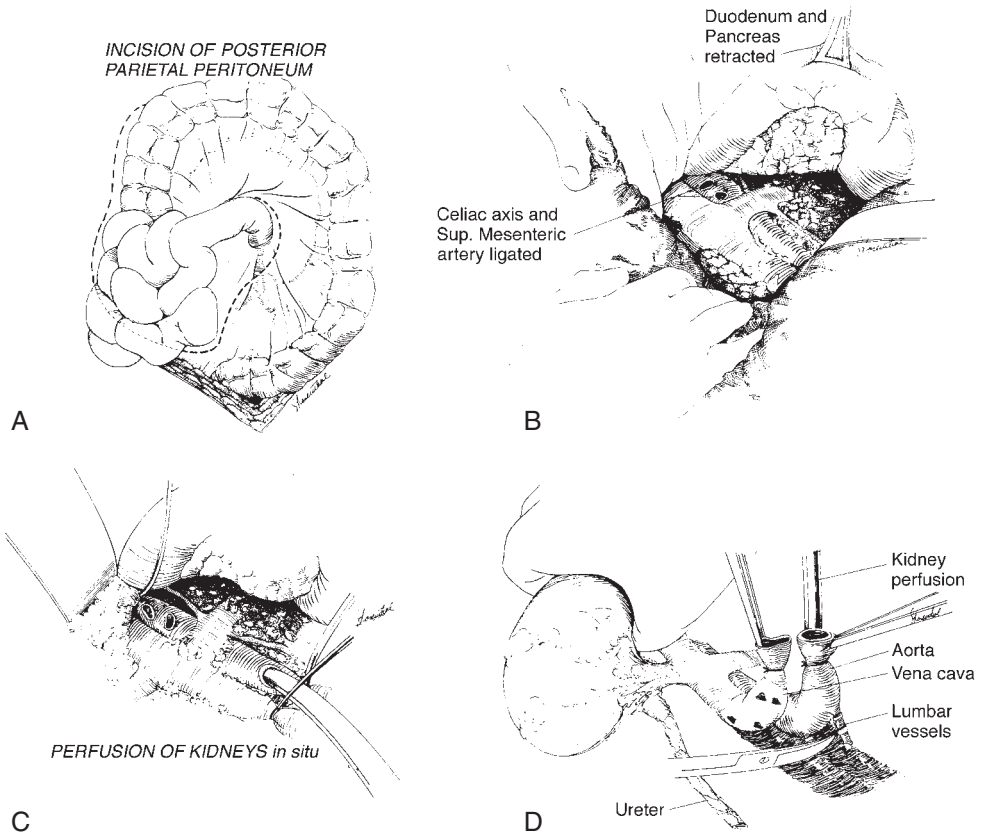

Figure 8–2 Cadaver donor nephrectomy without other organ retrieval. **A**, After widely opening and exploring the peritoneal cavity, the small bowel is retracted to expose the posterior parietal peritoneum, which is incised. This allows retraction of the bowel superiorly and to the left. **B**, The duodenum and pancreas are retracted superiorly to obtain exposure of the proximal aorta and vena cava. The superior mesenteric and celiac trunks are ligated and divided several centimeters above the level of the left renal vein crossing the aorta. **C**, After ligation of the proximal and distal aorta and the distal vena cava, perfusion of the kidneys is begun through the intravenous tubing that has been introduced into the distal aorta. **D**, Isolation of the kidneys and ureters has been completed (left kidney not shown). The distal aorta and vena cava are transected, and the lumbar vessels posteriorly are clamped and divided, allowing removal of the entire block of tissue while cold perfusion continues.

is encircled, enabling isolation of the renal circulation. After achieving proximal aortic, distal aortic, and distal caval occlusion, preservation of the kidneys in situ is begun by perfusion with chilled University of Wisconsin solution, Euro-Collins solution, or Ringer's lactated solution containing mannitol (18 g/L) and heparin (20,000 U/L) infused through sterile intravenous tubing that has been placed directly into the aorta. The perfusate is allowed to return to the donor circulation via the proximal vena cava (Fig. 8-2C). The kidneys are generally cool and pale after rapid infusion of 500 to 600 mL of perfusate, but the perfusion is continued at a slower rate throughout the remainder of the procedure.

The final mobilization of the kidneys is undertaken within the plane of Gerota's fascia in a more leisurely manner. Care is taken to free and section the ureters as far down toward the bladder as possible and to avoid dissection within the renal hilus. The distal aorta and vena cava are divided, and the entire block is lifted anteriorly to expose the lumbar vessels posteriorly (Fig. 8-2D). When the proximal aorta and vena cava have been divided, the block consisting of both kidneys and ureters, aorta, and inferior vena cava can be lifted out of the abdomen and placed immediately into a basin of cooled perfusion solution. A more complete dissection and assessment of the anatomy of the renal vessels can be undertaken. Before closure of the abdominal incision, specimens of donor lymph nodes and spleen are removed for subsequent histocompatibility and other immunological studies.

Removal of Kidneys with Other Organs

The more typical situation involves multiple organ procurement from the same donor. Acceptable donors for heart, liver, or pancreas transplantation are younger (generally <70 years old) and hemodynamically more stable than some donors from whom kidneys alone can be retrieved. Kidneys suitable for transplantation can be salvaged from a donor after cardiac function has ceased, whereas multiple organ procurement is seldom accomplished from a non–heart-beating donor cadaver.

The successful undertaking of multiple organ recovery requires careful coordination among three surgical teams to ensure that there is no compromise in viability of any transplantable organ. It is crucial to have anesthesia support to monitor and maintain cardiovascular integrity of the donor during the extensive dissection, which may take 1 to 3 hours. Although the details differ, depending on the combination of organs to be removed, certain common principles prevail, including wide exposure, dissection of each organ to its vascular connection while the heart is still beating, placement of catheters for in situ cooling, and removal of organs while perfusion continues, usually in the order of heart, lungs, liver, kidneys, and pancreas.[17]

The organs are exposed through a midline incision extending from the suprasternal notch to the pubis (Fig. 8-3A). If the heart is to be retrieved, it is usually partially mobilized as the first maneuver so that it can be removed quickly at any later stage should vascular instability occur during the dissection of the other organs. The preparatory steps for cardiectomy require opening of the pericardium, mobilization of the superior vena cava, and separation of the aorta from the pulmonary artery. Dissection is undertaken to mobilize the liver or pancreas, or both. If the pancreas is not to be used, the splenic and superior mesenteric arteries may be ligated or divided, or both (Fig. 8-3B). The common bile duct is transected, and the gallbladder is incised and flushed with cold saline to prevent biliary autolysis. The portal vein is dissected to the confluence of the splenic and superior mesenteric veins where a catheter can be placed into the splenic vein for subsequent rapid portal perfusion (see Fig. 8-3B). Alternatively, the inferior mesenteric vein is used for the placement of the portal vein catheter. Isolation of the liver is completed by mobilizing the vena cava posteriorly.

If the pancreas is to be transplanted, the spleen is mobilized, the short gastric vessels are divided, and the spleen and pancreas are retracted to the right (Fig. 8-3C). The body and tail of the pancreas are carefully dissected free. Although now used infrequently, this mobilization can terminate at the junction of the splenic and superior mesenteric veins, where the pancreas can be transected for segmental transplantation. More commonly, the entire pancreas and a segment of duodenum can be mobilized for pancreaticoduodenal transplantation.

The kidneys and major abdominal vessels are exposed next by retracting the ascending colon and small bowel to the left and lifting the mobilized duodenum anteriorly (Fig. 8-3D). The kidneys are elevated from the retroperitoneum, and the distal aorta and vena cava are completely freed. The donor is given heparin and mannitol, after which a perfusion catheter is placed in the aorta, and a venous drainage catheter is placed in the vena cava (Fig. 8-3E).

Initial organ cooling usually is begun via the previously placed portal vein catheter (see Fig. 8-3B). When the donor core temperature decreases to about 30°C, or if hemodynamic instability occurs, the aorta is cross-clamped at the diaphragm, and the aortic flush is begun for rapid cooling of the abdominal organs. Precise coordination among the retrieval teams is required at this critical stage. Cardioplegic infusion into the ascending aorta is begun, and cardiectomy and pneumonectomy are performed first. The liver is removed next. Finally, the remaining mobilization of the kidneys is undertaken. Care is taken to free and section the ureters as far down toward the bladder as possible and to avoid dissection within the renal hilus. The distal aorta and vena cava are divided, and the entire block is lifted anteriorly to expose the lumbar vessels posteriorly. These vessels are divided after being doubly clamped with vascular clips (Fig. 8-3F). When these vessels are controlled, the block consisting of both kidneys and ureters, aorta, and inferior vena cava can be lifted out of the abdomen and placed immediately into a basin of cooled perfusion solution. A more complete dissection and assessment of the detailed anatomy of the renal vessels can then be undertaken.

In donors from whom whole pancreaticoduodenal procurement is included, we advise removing this organ block after the kidneys have been taken from the field to avoid possible contamination from the transected duodenum. Although it was previously believed that total removal of the pancreas is anatomically incompatible with simultaneous retrieval of the liver, most groups currently procure both organs from the same donor routinely and use vascular grafts for pancreatic rearterialization in the recipients.[20] Before closure of the abdominal incision, specimens of donor lymph nodes and spleen are removed for subsequent

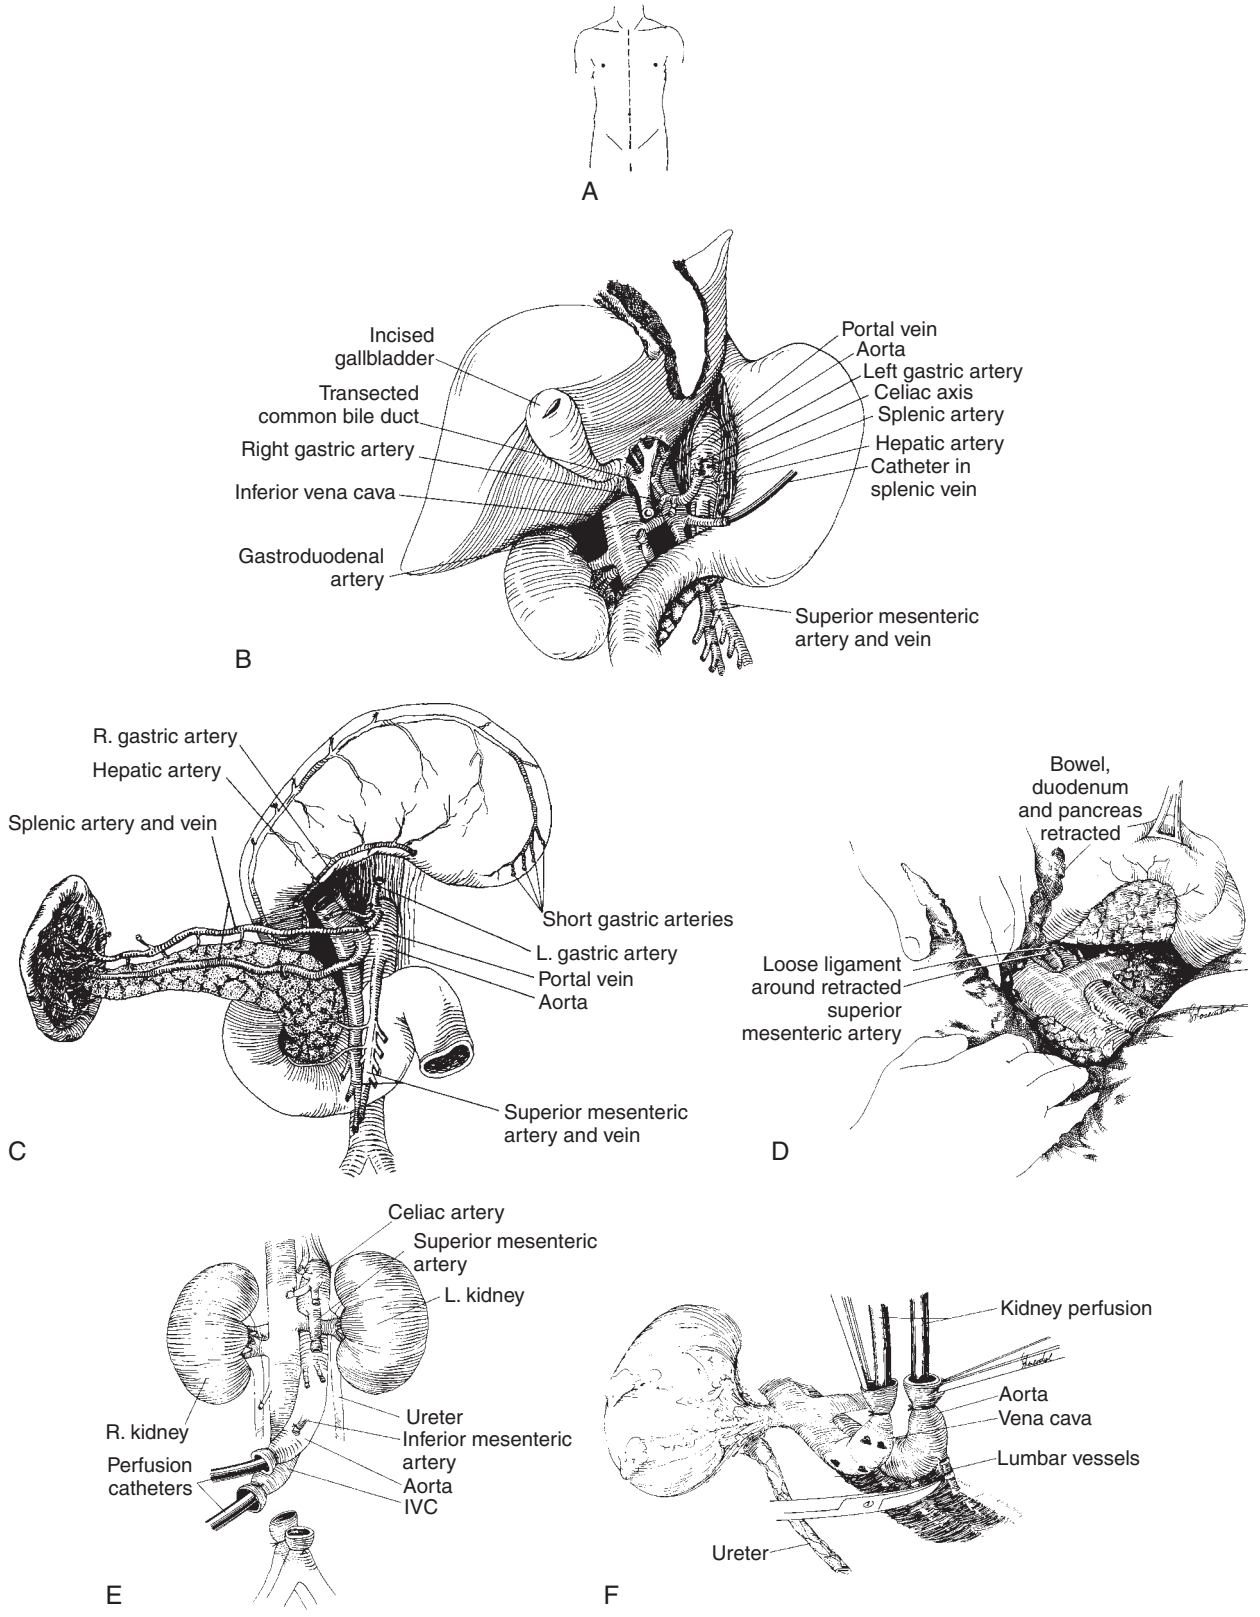

Figure 8–3 Cadaver donor multiple organ retrieval. **A**, The chest and abdominal cavities are entered through a long midline incision. After general evaluation of the organs to be procured and initial mobilization of the heart, the liver dissection is completed. **B**, The splenic vein is catheterized for portal perfusion. The gastroduodenal and splenic arteries are divided if the pancreas is not to be used. **C**, For pancreas retrieval, dissection is begun from the left, retracting the spleen and pancreas to the right, carefully preserving the splenic artery and vein. For simplicity, the superior mesenteric vessels are depicted as separate from the pancreas, but they remain closely adherent to the posterior pancreas. **D**, Returning to the right side, the duodenum and pancreas are retracted exposing the superior mesenteric artery. **E**, Mobilization of the kidneys and ureters from the retroperitoneum is completed, and the distal vena cava and aorta are catheterized. For illustrative purposes, the bowel, which remains attached via the mesenteric vessels, is not shown in this figure. **F**, After cooling and removal of the heart and liver, the kidneys are removed by lifting the entire tissue block (left kidney not shown) anteriorly, while clamping and dividing the lumbar vessels posteriorly. IVC, inferior vena cava.

histocompatibility and other immunological studies. Most groups have concluded that the immediate and long-term functional results observed in transplanted kidneys obtained from multiple organ donors are comparable to those obtained from procedures involving donor nephrectomy alone.[13]

Chapter 8B
Laparoscopic Live Donor Nephrectomy

Christopher E. Simpkins • Robert A. Montgomery

RATIONALE

Despite numerous attempts to promote increased organ donation after death, the disparity between graft supply and demand has continued to broaden. As a result, waiting times for kidney transplantation have increased significantly in recent years. Although live donor renal transplantation has offered numerous recipient outcome advantages compared with deceased donor transplantation, significant disincentives to live donation, including the magnitude of the donor nephrectomy operation, limited the expansion of this source of organs for transplantation. The morbidity and long convalescent period associated with a flank incision represented significant barriers to some individuals interested in donation. Before the development of the laparoscopic technique, a survey of a cohort of patients uncovered common fears about participation in the donor process, which included lost wages owing to prolonged convalescence, job security, inability to tend to other responsibilities such as child care, fear of postoperative pain, and unease about the cosmetic results of the operation.[17,45] Laparoscopic live donor nephrectomy was developed with the intent to limit these deterrents to live kidney donation by reducing the impact of the operation on the donor's life.

The procedure's history dates back to the early 1990s. Clayman and colleagues[7] performed the first successful laparoscopic nephrectomy for renal disease in 1991 and showed that minimally invasive techniques resulted in less pain, shorter hospitalization, and a reduced duration of convalescence compared with the open flank approach. Within 3 years, a laparoscopic renal procurement technique was developed in a large animal model.[12] This was followed by the first human live donor laparoscopic nephrectomy, which was performed by a Johns Hopkins team led by Ratner and Kavoussi in 1995.[43] The donor was discharged from the hospital on the first postoperative day and returned to full activity 2 weeks after the procedure. The recipient had immediate graft function. We later showed that the application of

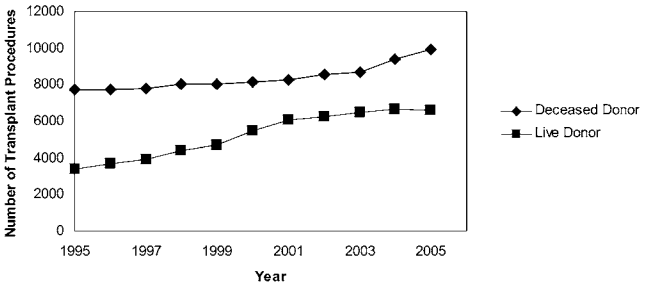

Figure 8–4 Donor nephrectomy procedures in the United States by donor type, 1995–2005. Data from UNOS/OPTN as of January 5, 2007. Following the development of the laparoscopic donor procedure, there has been a substantial increase in the number of renal transplant procedures that have taken place in the United States through an expansion in donation that has largely been attributable to the increase in kidneys from live donors.

minimally invasive techniques resulted in less pain, decreased duration of hospitalization, and a shorter convalescent period compared with the open flank approach.[46,47,52]

Since the development of the laparoscopic donor procedure, there has been a nearly 50% increase in the number of renal transplant procedures that have been performed in the United States through an expansion in donation that has largely been attributable to the increase in kidneys from live donors (Fig. 8-4). Laparoscopic procurement of donor kidneys has become widely adopted and is now becoming the standard technique for live donor procurement in most countries. At our institution, the annual number of live donor renal transplant procedures has increased more than threefold since the introduction of laparoscopic live donor nephrectomy. In a study conducted soon after the routine introduction of the laparoscopic technique at our institution, approximately 20% of donors reported that they would not have donated an organ if the laparoscopic procedure had not been available. Two thirds of donors state that the availability of the laparoscopic operation had a major influence on their decision to donate.[45] The application of minimally invasive techniques to the donor nephrectomy procedure undoubtedly raised consciousness about the gratuitous nature of the flank incision and rib resection and was probably responsible for the transition to the minilaparotomy approach for groups that were disinclined to the laparoscopic approach.

An additional unexpected phenomenon associated with the greater ease of donation resulting from the laparoscopic procedure has been the presentation of numerous individuals with an interest in donation without an intended recipient, so-called nondirected live donation. More than 300 such procedures have been performed in the United States since the 1990s. The availability of a safe operation that uses minimally invasive techniques also may have enabled the advent of innovative protocols to provide transplant solutions to high-risk patients with incompatible live donors, including preconditioning for ABO incompatibility and a positive crossmatch, and kidney paired donation.[35,36,38]

PREOPERATIVE EVALUATION

All live kidney donors receive thorough preoperative surgical, nephrological, and psychological evaluations in accordance with the clinical practice guidelines established by the American Society for Transplantation and the Consensus Statement on the Live Organ Donor.[1,19] As with the open procurement procedure, preoperative consideration of anatomy and functional status of the donor kidneys is crucial. The use of preoperative imaging permits investigation of size, function, and anatomy of the potential donor kidneys to facilitate planning of the safest approach to procurement. We find it useful to obtain three-dimensional spiral computed tomography (CT) scans with intravenous contrast administration.[59] In addition to providing definition of the arterial anatomy, three-dimensional spiral CT provides excellent depictions of the venous anatomy. It provides superb definition of the renal parenchyma and a urography phase for evaluation of outflow. We use this technique in lieu of conventional angiography.[20] Magnetic resonance angiography is an alternative that has been used successfully for preoperative imaging at other centers.

Careful preoperative consideration must be given to the side of the nephrectomy procedure. An important consideration during the planning of this operation is the technical challenge associated with the recipient procedure after laparoscopic procurement of a right donor kidney. Use of the endoscopic GIA stapling device to divide the anatomically shorter right renal vein generally results in the loss of approximately 1 to 1.5 cm of length.[42] This may result in a short renal vein that increases the complexity of the recipient operation and has been associated with an increased risk of venous thrombosis in early series.[32] Because it is no longer acceptable practice to use a non–tissue affixing ligation technique, short right renal vessels are unavoidable. Our practice has been preferentially to use the left kidney, unless it is clearly more advantageous for the donor to retain this kidney because of functional or anatomical considerations. Multiple left renal arteries or anomalous left renal venous vasculature (e.g., circumaortic or retroaortic renal veins) have not been contraindications to the use of the left kidney in our experience.[32]

The contraindications to laparoscopic donor nephrectomy are the same as those established for open nephrectomy. Because the laparoscopic donor operation is performed through a transperitoneal approach, previous abdominal surgery may increase the complexity of the procedure but is rarely a reason for open conversion.[62]

The laparoscopic donor nephrectomy is a technically challenging operation and generally requires more operative time than the open technique. Early in our series, we were unable to identify any preoperative demographic, radiological, or anatomical parameters that accurately predicted operative difficulty.[49] The difficulty with any given procedure seems to be related to mobility of the mesentery, the quality of the retroperitoneal tissue, and laparoscopic working space, none of which can be quantified by noninvasive imaging before surgery. The hand-assisted approach provides tactile feedback to the operator and may be more attractive to surgeons who have limited advanced laparoscopic training. It also has been shown in several series to reduce operative time.[58,70-72]

INTRAOPERATIVE MANAGEMENT

The anesthetic management of patients who undergo a laparoscopic donor nephrectomy is of paramount importance, and good communication between the anesthesiologist and surgeon is essential to a good outcome for the donor

and the recipient. To obtain sufficient laparoscopic working space, the patient must be kept completely relaxed, and nitrous oxide anesthesia should be avoided. In our experience, patient-controlled analgesia should be limited to the night of surgery, and patients should be converted to oral analgesics when clear liquids are introduced on the first postoperative day. Prolonged use of intravenous patient-controlled analgesia can lead to ileus, oral intolerance, and constipation. The greatest postoperative pain manifests on the first evening, and this may be related to peritoneal stretching associated with the pneumoperitoneum. Some additional analgesic benefit leading to postoperative narcotic minimization may be obtained by injecting extraction and trocar sites with 0.25% bupivacaine. Some groups have been successful in limiting hospital stay to 1 day through the use of propofol-based anesthesia supplemented with desflurane to limit postoperative nausea.[26]

The effect of the pneumoperitoneum on renal blood flow dynamics dramatically changes the intraoperative fluid management from that which is used in the open donor operation. Experimental data suggest that the effects of this relative hypoperfusion can be ameliorated by fluid loading.[30] It is not unusual for laparoscopic donors to receive 6 to 8 L of crystalloid during the procedure. We monitor the adequacy of intravascular volume expansion by the turgor of the renal vein. A collapsed renal vein signals the need for more liberal use of intravenous fluids. A brisk diuresis is stimulated throughout the procedure by two 12.5-g bolus administrations of mannitol. Just before removing the kidney, the donor may be given 20 to 40 mg of intravenous furosemide and 3000 U of heparin. When the kidney has been removed, 25 mg of protamine may be given to reverse the anticoagulative effects of heparin.

LAPAROSCOPIC DONOR NEPHRECTOMY OPERATIVE PROCEDURE

The patient is placed in a modified lateral decubitus position with the hips rotated back and the arms extended above the head (Fig. 8-5). The table is flexed to expand the area between the costal margin and the pelvic brim. A 12-mm Hg pneumoperitoneum is established through a Veress needle inserted either above the umbilicus or into the left iliac fossa along the lateral rectus border. A Veress needle placed in the infraumbilical fold may track along the urachus and lead to extraperitoneal insufflation. Right subcostal Veress or Hassan trocar placement may be preferable for patients with previous abdominal surgery to avoid bowel injury. There is a risk of inadvertent liver injury from the right subcostal Veress needle placement, and this should be reserved for surgeons who have experience with this technique. The initial operative trocar placement consists of two 12-mm ports and one 5-mm port that are placed (1) in the midline just above the umbilicus, (2) at the level of the umbilicus or slightly below along the lateral border of the rectus sheath, and (3) in the midline two to three fingerbreadths below the xiphoid process. In patients who have not undergone previous surgery, the first port is placed using an optical access device.[65] The videoendoscope is placed in the umbilical port. The epigastric and lateral ports are the operative ports.

For left-sided procedures, the descending and sigmoid colon are taken down by dividing the lateral attachments with DeBakey graspers and curved scissors (Fig. 8-6). The colon is reflected medially, which exposes Gerota's fascia (Fig. 8-7). Care must be taken not to buttonhole the mesocolon. Much of the dissection can be accomplished bluntly by sweeping the tissue medially and developing a natural plane between the mesocolon and Gerota's fascia.

At this point in the operation, we often make a 4- to 5-cm Pfannenstiel incision just above the pubis and carry it down to the level of the fascia. A 12-mm trocar is placed at the midline in the center of the Pfannenstiel incision to pierce the fascia and peritoneum. The trocar is removed and replaced by an EndoCatch (U.S. Surgical Corporation, Norwalk, Conn) device, which is used during the remainder of the operation to provide medial retraction of the colon.

For right-sided procedures, the cecum is mobilized and reflected medially. The liver is lifted away from the upper pole of the kidney using a laparoscopic retractor placed through a fourth flank port. The right-sided nephrectomy is technically challenging and has unique problems that are discussed later.

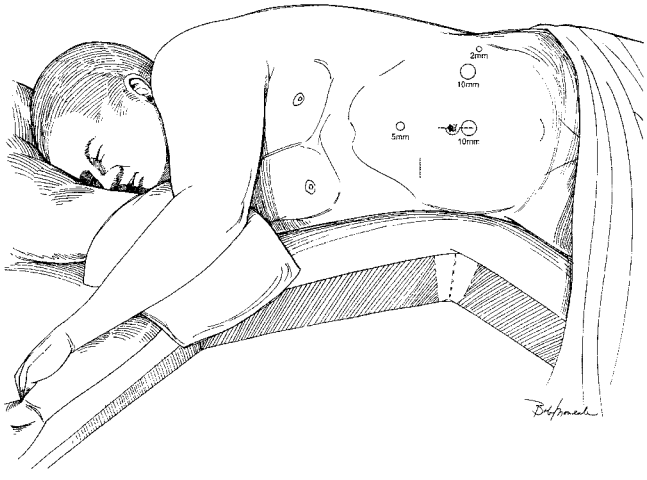

Figure 8–5 The patient is placed in a lateral decubitus position, and three laparoscopic ports are introduced.

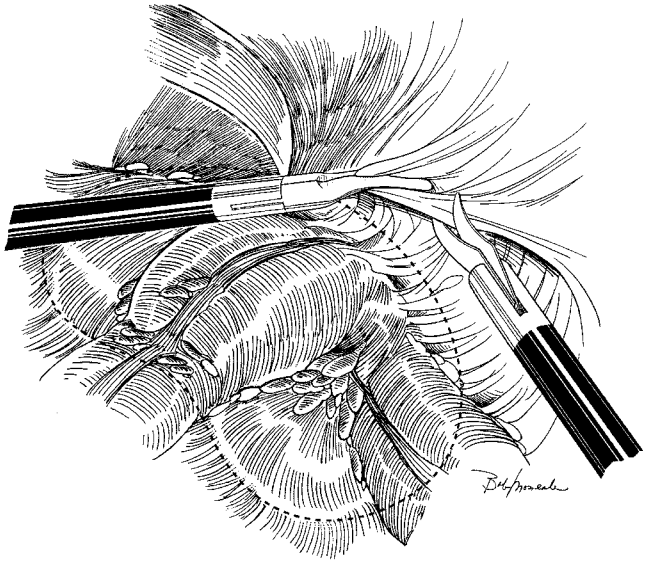

Figure 8–6 The lateral attachments to the colon are taken down.

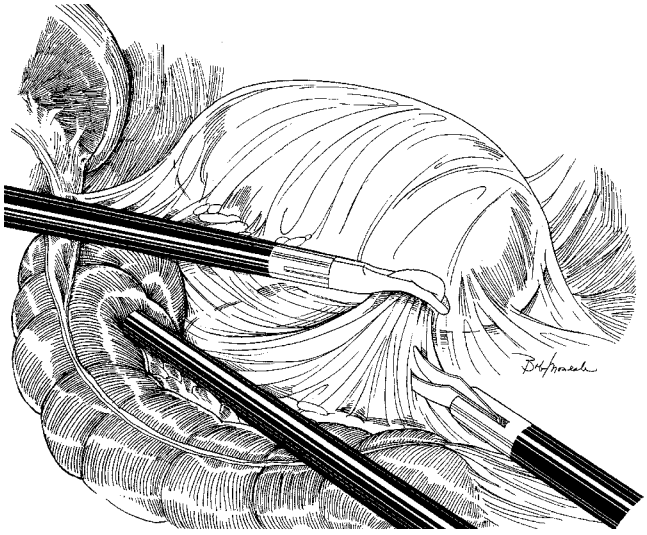

Figure 8–7 Gerota's fascia is separated from the mesocolon.

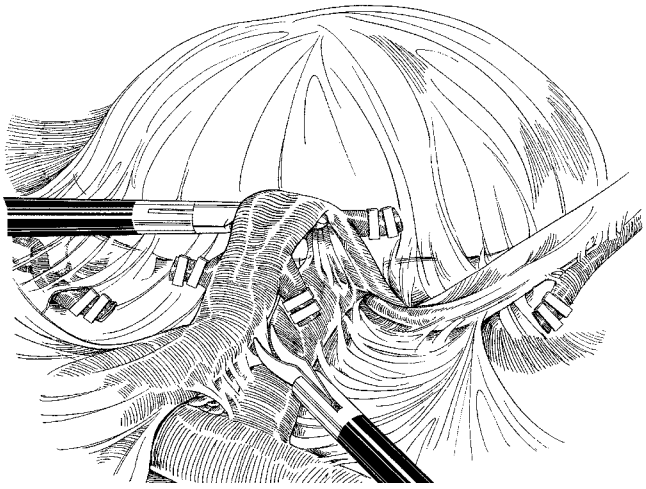

Figure 8–9 Posterior to the vein lies the renal artery, which is freed back to the level of the aorta.

At this point, the renal vein is exposed by tracing the gonadal vein in a cephalad direction or bluntly sweeping the perinephric tissue several centimeters medial to the renal hilum (Fig. 8-8). The renal vein is cleared completely of investing tissue, and the gonadal, lumbar, and adrenal branches are clipped and cut. The renal artery lies posterior to the vein and can be exposed by elevating the lower pole of the kidney with the DeBakey grasper. Dissection should be conducted medial to the gonadal vein to avoid devascularization of the ureter in the hilar region. The artery is separated from the surrounding nervous plexus and isolated to the level of the aorta. The plane of dissection is carried along the cephalad border of the vein between the adrenal gland and the upper pole of the kidney. Vascularized tissue in this region is divided between clips, and the upper pole is shelled out of the envelope of Gerota's fascia. The posterior attachments are lysed by elevating the upper pole and teasing the adherent tissue away.

The DeBakey grasper is inserted medial and posterior to the bundle of tissue that contains the ureter (Fig. 8-8). The gonadal vein, ureter, and mesoureter are separated from the psoas muscle and dissected free from a point below the lower pole of the kidney to the pelvic inlet. At the juncture where the ureter descends into the pelvis, the individual structures of the bundle are isolated, clipped, and cut. Mobilizing the ureter and gonadal vein deep into the pelvis to increase ureter length has been associated with lateral scrotal paresthesias in our experience and should be avoided.[21] The lateral attachments of the mesoureter are cauterized and cut in a caudad-to-cephalad direction. The plane of dissection is carried along the lateral surface of the kidney, completely mobilizing the kidney except for the renal pedicle.

The camera is moved to the lateral port, and a vascular endoscopic GIA stapler is used to divide the renal artery followed by the vein (Fig. 8-9). Before dividing the pedicle, mannitol, furosemide, and heparin are administered. The recipient procedure is facilitated by attempting to optimize the length of each of these vessels on the procured graft. The Endocatch bag that has been placed as a retractor is deployed. The kidney is placed in the bag and is removed by incising the fascia and peritoneum longitudinally through the Pfannenstiel incision.[44]

The fascia is closed with absorbable sutures. The 12-mm port sites are closed with figure-of-eight absorbable sutures

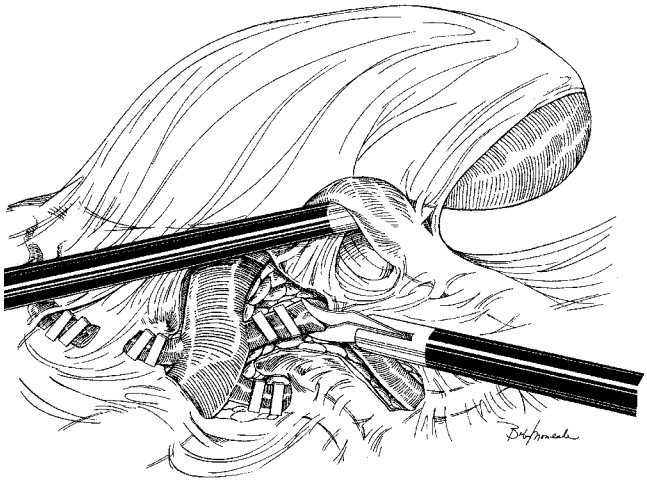

Figure 8–8 The renal vein is exposed, and the adrenal gonadal and lumbar branches are divided.

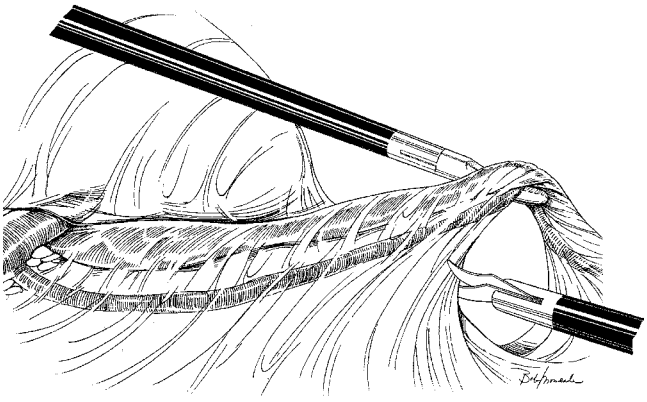

Figure 8–10 The mesoureter is isolated from the lower pole to the pelvic inlet, where it is divided.

aided by the Carter-Thomas instrument. After re-establishment of pneumoperitoneum, the abdomen is inspected for bleeding. The empty Endocatch tube can be reinserted through a gap left in the Pfannenstiel incision to retract the colon while the retroperitoneum is being inspected.

VARIATIONS IN TECHNIQUE FOR RIGHT LAPAROSCOPIC DONOR NEPHRECTOMY

Variations on the left-sided technique are recommended to preserve maximal renal vein length in cases in which it is necessary to procure a kidney from the right side. Port placement is a mirror image of that used for the left-sided procedure, although an additional flank port may be required to insert a fan blade for hepatic retraction. Alternatively, a locking grasper can be used to grab tissue on the right side wall to retract the liver superiorly.

Numerous modifications can be made to achieve maximal length of the renal vessels. The first involves division of the renal vessels in a plane parallel to the inferior vena cava by introducing the endoscopic GIA device into the right lower quadrant port, rather than the infraumbilical port. This modification permits the surgeon to achieve alignment parallel to the inferior vena cava to transect the renal vein in a nonangled plane at its origin.

A second adjunct technique involves making a 5- to 6-cm transverse incision in the right upper quadrant at a point overlying the confluence of the right renal vein and the inferior vena cava. This incision facilitates open placement of a side-biting vascular clamp across the inferior vena cava at the level of the renal vein after the laparoscopic dissection of the kidney is complete.[44] The incision is used for open division of the renal vessels maintaining a generous length of renal vein. The kidney is delivered through this right upper quadrant incision. The vena cava is oversewn on top of the clamp under direct vision.

A third modification is to introduce a hand port at the level of the 11th rib near the junction of the lateral edge of the rectus sheath and the oblique muscles. This modification allows the kidney to be lifted on its pedicle under stretch to divide the vein directly with the endoscopic GIA device, or for a laparoscopic side-biting clamp to be placed through a suprapubic port to divide the renal vein flush with the vena cava and close the vascular defect. If the renal vein is found to be too short after removal of the kidney, back-table reconstruction of the vein can be performed using a panel graft of recipient saphenous vein, but this is rarely necessary.[32]

HAND-ASSISTED LAPAROSCOPIC TECHNIQUE

Initially described in 1998 by Wolf and colleagues,[72] the hand-assisted laparoscopic donor nephrectomy procedure incorporates a hand port, typically placed through a 7- to 8-cm periumbilical midline incision, to provide access to the kidney for manipulation and manual removal through the hand-port site. The hand-assisted variation of the laparoscopic nephrectomy was developed to give surgeons greater tactile feedback and to facilitate the definition of the tissue planes to allow transplant centers that lack advanced laparoscopic expertise to perform the operation safely. Perhaps the most significant advantage is the technical ease with which removal of the kidney occurs by simple inversion of the sleeve, obviating the need to manipulate the kidney into the Endocatch bag and reducing warm ischemic time. To date, however, there has not been a definitive demonstration that the relatively small reduction in warm ischemic time associated with hand port–assisted removal of the kidney improves postoperative outcomes for the recipient compared with the completely laparoscopic approach.[5,54,60] Donor outcomes using the hand-assisted technique compare favorably with the open procedure, and early recipient graft function is comparable to that seen with the purely laparoscopic procurement technique.[3,71]

We prefer the completely laparoscopic technique because the requirement of a slightly larger incision placed more cephalad in the midline and the additional 12-mm port in the subcostal region may eliminate some of the advantages associated with the laparoscopic technique in terms of reduced postoperative pain. The Pfannenstiel incision has proved to be favorable in terms of low morbidity and good cosmesis.

Patient positioning and preparation is essentially unchanged with the hand-assisted technique. The pneumosleeve flange is placed below or at the level of the umbilicus, centered on an incision large enough to permit the smooth insertion of the surgeon's hand. Three 12-mm ports are placed in the following positions: (1) lateral to the midpoint between the umbilicus and the anterior superior iliac spine, (2) four to five fingerbreadths below the xiphoid process in the midline, and (3) along the lateral rectus border in the subcostal region. The operating surgeon's left hand is placed in the pneumosleeve, and the camera is inserted through the supraumbilical port. The surgeon's hand replaces the DeBakey instrument, but otherwise the processes and order of the subsequent stages of the procedure are unchanged.

The camera is moved to the subcostal port when the vascular pedicle is divided. At this point, the surgeon usually switches to the right hand for retraction. The endovascular stapler is introduced through the supraumbilical port.

DONOR SAFETY

The encounter with a live organ donor represents a unique interaction in health care. With no expectations for personal gain in health, these individuals are subjected to an invasive and potentially harmful surgical procedure. To justify the participation in a nontherapeutic procedure, the potential risks associated with the operation must be minimized. The safety of donors is of paramount importance.

Numerous published reports that investigated the issue of donor safety after the laparoscopic donor nephrectomy procedure have emerged. Systematic reviews of the literature comparing the laparoscopic and open donor nephrectomy techniques suggest that the laparoscopic procedure has a complication rate that is similar to the open procedure.[13,34,66] These reviews identified overall donor complication rates that ranged between 0% and 30% for the laparoscopic approach, and 0% and 38% for the open approach in studies that were published between 1997 and 2003. Donor complication rates have been comparable in retrospective analyses that were published by select centers in the early era of the procedure[9,10,17,29,39,46] and in analyses that have been published as the procedure has become more widely accepted

and practiced through the present,* although case definitions differ widely across studies.

Matas and colleagues[33] conducted a national survey of U.S. transplant centers to compare early donor complications between laparoscopic approaches, including hand-assisted and purely laparoscopic approaches, and open techniques.[33] The study included 5660 open donor, 2239 hand-assisted donor, and 2929 purely laparoscopic procedures in contemporaneous patients who underwent operation between 1999 and 2001. Complications that did not require reoperation were observed in 0.3%, 1%, and 0.8% of the open, hand-assisted, and purely laparoscopic groups. Reoperation was performed in 0.4%, 1%, and 0.9% of the respective groups. Although both of these comparisons differed in a statistically significant fashion ($P = .02$ and $P = .001$), the differences in rates are small and remain low relative to other complex surgical procedures. The authors identified two donor deaths (one from pulmonary embolus and one from an unreported cause in the hand-assisted group; donor mortality rate 0.02%) and one patient in a persistent vegetative state following complications caused by intraoperative hemorrhage (purely laparoscopic group). No deaths were observed for patients who underwent donation by the open technique.

A series of prospective, randomized clinical trials of open versus laparoscopic donor nephrectomy have been completed, which included secondary donor safety end points.[23,40,55] Kok and colleagues[23] compared a mini-incision open donor nephrectomy approach ($n = 50$) with the purely laparoscopic technique ($n = 50$) and found similar rates of intraoperative and postoperative donor complications between the two groups. Intraoperative complications occurred in 12% of donors who underwent laparoscopic procurement and consisted of bleeding, colonic injury, bladder injury, and splenic injury. All intraoperative complications that occurred in the open nephrectomy group were hemorrhagic in nature ($P = .23$). Both groups were followed for 1 year postoperatively, and similar rates of postoperative complications were observed. In each group, 6% of the donors encountered postoperative complications which consisted of wound infection at the kidney extraction site and blood transfusion requirement in the laparoscopic group, and urinary tract infection, pulmonary infiltrate, and infected retroperitoneal hematoma in the open group ($P > .05$).

Simforoosh and colleagues[55] conducted a prospective, randomized clinical trial of open donor nephrectomy ($n = 100$) and purely laparoscopic donor nephrectomy ($n = 100$). Although no statistical analysis was performed to compare complications between the two groups, different patterns of complications became apparent at the conclusion of their study. Intraoperative complications occurred in 4% of laparoscopic donors and 18% of open donors. In the laparoscopic group, these included splenic laceration, bowel serosal injury, and cardiac arrhythmia. All complications consisted of pneumothoraces in the group that underwent open procurement. Postoperative complications occurred in 17% of patients in the laparoscopic group and 9% of patients in the open group. The most frequently encountered postoperative complications among patients in the laparoscopic group were ileus, hemorrhage, and scrotal swelling. For patients in the open donor nephrectomy group, the most frequent postoperative complications included ileus and urinary tract infection.

Oyen and coworkers[40] found a greater proportion of postoperative complications necessitating reoperation among patients who underwent laparoscopic donation compared with patients who underwent open donation in a prospective, randomized clinical trial that included 122 donors.[40] Although no reoperations were encountered in the open donor nephrectomy group, five patients (8%) required reoperation after laparoscopic procurement. These reoperations were the result of port site bleeding, retained sponge, jejunal perforations, and postoperative hernias.

Donor safety is an extremely important issue in live donor renal transplantation. Clinicians have achieved a greatly improved understanding of the morbidity associated with procurement of kidneys from live donors. Although these rates vary widely depending on the study design and case definitions that are used, most studies show that the laparoscopic technique for renal allograft procurement is a safe approach and comparable to the traditionally used open donor nephrectomy method. In contrast, understanding of long-term morbidity associated with donor nephrectomy is limited, and few countries perform long-term surveillance of this population of patients. Longer term studies are warranted to better delineate morbidity associated with laparoscopic live donation.

ADVANTAGES OF THE LAPAROSCOPIC APPROACH FOR THE DONOR

The laparoscopic donor nephrectomy procedure was initially developed in response to data collected from prospective donors about perceived disincentives to live donation.[17] Common fears among potential kidney donors include financial concerns owing to lost wages, loss of job security, inability to tend to other responsibilities such as child care, fear of postoperative pain, and unease about the cosmetic results of the operation. Many of these potential deterrents to otherwise willing donors have been addressed by the laparoscopic procedure. We conducted a retrospective comparison of functional recuperative parameters between donors who underwent contemporaneous open ($n = 37$) and laparoscopic ($n = 25$) nephrectomy procedures early in our series (1995 and 1996).[45-47] We found that length of hospital stay, time to return to normal activities, and time to return to work all favored the laparoscopic technique. Mean duration of hospitalization was reduced by 2.5 days (2.9 ± 1 day versus 5.5 ± 1.2 days; $P < .001$). The time necessary to return to normal activities was reduced by more than 2.5 weeks (1.8 ± 1.5 weeks versus 4.5 ± 0.5 weeks; $P < .001$). Donors who underwent laparoscopic nephrectomy were able to return to work on average 3 weeks earlier than donors who underwent open procurement (3.2 ± 2.1 weeks versus 6.2 ± 3.2 weeks; $P < .001$). Numerous studies have since corroborated these findings.†

A principal factor associated with improved functional outcomes after surgery is the reduction in pain associated with the laparoscopic approach. We showed that parenteral narcotic requirements were significantly reduced for patients who underwent laparoscopic compared with open donor nephrectomy.[46] Patients who underwent an open

†References 10, 14, 16, 25, 28, 29, 39, 50, 53, 61, 67, 68, 70, 71.

flank incision required a mean of 124 ± 88 mg morphine sulfate equivalents compared with 34 ± 34 mg morphine sulfate equivalents in patients who underwent laparoscopic procurement (73% reduction). Flowers and associates[10] showed that the duration of parenteral narcotic requirements was reduced by more than 24 hours for patients who underwent laparoscopic compared with open donor nephrectomy, and this finding has been observed in several subsequent investigations.[28,39,68]

Kok and colleagues[23] administered the SF-36 and MFI-20 (Multidimensional Fatigue Inventory-20) questionnaires to randomized clinical trial patients who were being compared across open nephrectomy, mini-incision nephrectomy, and purely laparoscopic nephrectomy to determine patient-reported assessments of health-related quality of life after surgery. Patients who underwent laparoscopic procurement were found to have improved quality-of-life scores for the domains of physical function, general health, vitality, social functioning, emotional well-being, and mental health compared with the donors who underwent open nephrectomy. The laparoscopic group reported significantly reduced physical fatigue as measured by the MFI-20 questionnaire.

RECIPIENT OUTCOMES

Live donor renal allotransplantation provides the recipient with a graft that promptly functions postoperatively and is associated with more durable graft function compared with grafts from deceased donors. Laparoscopic procurement techniques have not been detrimental to these excellent outcomes expected from the live donor graft. From a technical standpoint, adequate lengths of renal artery, renal vein, and ureter can be achieved using a purely laparoscopic approach. In an analysis of our series of more than 500 purely laparoscopic cases, left-sided renal artery, vein, and ureter lengths were found to be 3.1 ± 0.8 cm, 4 ± 1.1 cm, and 11.4 ± 2.3 cm, respectively.[56] The lengths of right-sided structures were comparable with the exception of the right renal vein, which was approximately 1 cm shorter on average (right renal artery, 3.4 ± 1.3 cm; right renal vein, 2.7 ± 1.2 cm; right ureter, 11.6 ± 2.3 cm). Early in our series, the short length of the renal vein was likely associated with two cases of venous thrombosis.[32] Other groups have identified a similar association early in their series.[4] We have since attempted to use the left kidney, unless there is a compelling reason for the donor to retain this kidney. If the right vein is short after the kidney is completely mobilized, we make a transverse rectus-splitting incision and apply a Satinsky clamp to the inferior vena cava, which generally allows for an additional 1 to 1.5 cm of renal vein length. The vena cava is oversewn through the extraction incision. Alternatively, we perform a hand-assisted technique and are able to garner increased venous length through better lateral retraction of the kidney.

Grafts procured by the laparoscopic approach function promptly after surgery. Despite slightly longer warm ischemia times compared with the open (and hand-assisted) approaches, there has been no compelling evidence to suggest that the rate of delayed graft function is increased in recipients of laparoscopically procured kidneys. Delayed graft function occurs in approximately 5% to 10% of recipients. The rate of recovery of renal function, as measured by a decline in the serum creatinine level, has been shown to be comparable for grafts procured using laparoscopic and open techniques.[37,48] Two prospective randomized clinical trials failed to show a difference in renal allograft function at early and later time points.[23,55] These two studies compared renal function within a range of time that extended between 1 day and 1 year after the transplant procedure. Mean renal function at 1 year was excellent in open and laparoscopic groups across both trials (Kok and colleagues:[23] open donor nephrectomy, 114 μmol/L versus laparoscopic donor nephrectomy, 107 μmol/L; Simforoosh and colleagues:[55] open donor nephrectomy, 1.3 mg/dL versus laparoscopic donor nephrectomy, 1.3 mg/dL).

Laparoscopically procured kidneys have durable function that is comparable to grafts that are procured using an open approach. We analyzed more than 28,000 primary live donor renal allograft recipients who were reported to the Organ Procurement and Transplantation Network (OPTN)/United Network for Organ Sharing (UNOS) registry between 2000 and 2005 to compare graft and patient survival by procurement technique. Kaplan-Meier estimates of overall graft survival are shown in Figure 8-11. Graft outcome through 5 years after transplantation has been virtually identical between these two procurement approaches in the United States (P = .59). One-year graft survival estimates in the open and laparoscopic groups were 94.5% and 95.1%. Five-year allograft survival figures were 79.6% and 78.8%.

Estimates of patient survival are shown in Figure 8-12. Comparable mortality rates have been observed between these groups over the last 5 years in the United States (P = .61). One-year estimates of patient survival in the open and laparoscopic groups were 97.6% and 97.8%. Estimates at 5 years after transplantation were 89.2% and 89.1%.

The laparoscopic approach to live donor renal allograft procurement has removed many of the most common disincentives to live kidney donation and promoted an expansion of many live donor programs. The procedure can be undertaken safely, and the graft can be transplanted using standard techniques without modifying expectations of excellent short-term and long-term outcomes for the recipient.

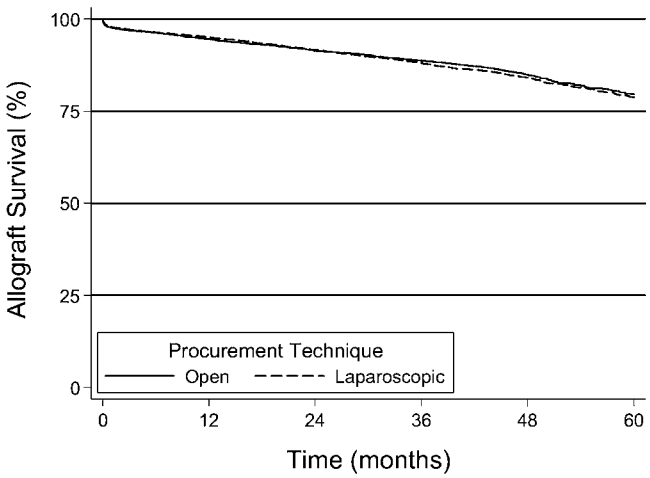

Figure 8–11 Kaplan-Meier estimates of graft survival following transplantation in recipients of primary live donor renal allografts, by procurement type. There was no difference in graft survival between the procurement technique groups (p=0.59).

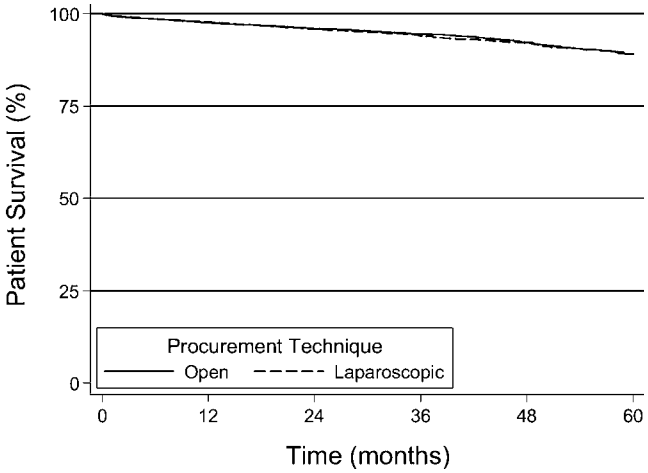

Figure 8–12 Kaplan-Meier estimates of patient survival following transplantation in recipients of primary live donor renal allografts, by procurement type. There was no difference in mortality between the procurement type groups (p=0.61).

Chapter 9
Renal Preservation

Henri G. D. Leuvenink • Rutger J. Ploeg

Effective and successful kidney transplantation depends on a sequence of events. These events can be described as the "transplantation cascade" depicted in Figure 9-1. During this cascade, renal quality is jeopardized by biological and technical moments of danger. Because of the unique character of transplantation when a functioning kidney is retrieved from a human body, transferred to another human body, and connected to the vasculature and blood supply of the recipient, the kidney is exposed to a series of extremely nonphysiological insults.

At the time of retrieval of the organ from the donor, blood supply is interrupted, which results in ischemia. To ensure function after transplantation, this period of ischemia needs to be as short as possible because warm ischemic damage is extremely detrimental to the kidney. During the warm ischemic period, the kidney is devoid of blood, oxygen, and nutrients, while metabolism continues at full strength. Reducing metabolic activity is crucial to prevent organ damage beyond repair. An easy and convenient way is to cool the kidney. Most commonly used nowadays is the static cold storage technique, which includes an initial flush and washout of the kidney with subsequent storage in a preservation solution at 0°C to 4°C. The use of cold storage preservation provides time for tissue typing and crossmatching, allocation and transportation of the organ to the recipient center, and preparation of the recipient.

The implantation phase is another critical period. Apart from technical surgical issues, a second period of warm or semiwarm ischemia occurs. During this phase, vascular anastomoses need to be prepared before blood flow can be reconstituted. Intuitively, one may think that the most dangerous period for the graft should have passed after restoration of blood flow into the transplanted kidney. The supply of warm well-oxygenated blood should lead to an increase of metabolism resulting in a proper functioning graft. The reperfusion phase is not devoid of side effects, however. During the reperfusion phase, the preexisting damage occurring in the donor kidney as a result of brain death, cold preservation, and warm ischemia at the time of implantation becomes apparent, reflecting the viability of the donor kidney. The reintroduction of oxygen leads to enhanced formation of free radical oxygen species. Misbalances in intracellular and extracellular ion concentrations and edema need to be counteracted quickly to limit further damage. Preservation solutions are designed to counteract cold ischemia–induced changes in the graft. This chapter reviews the current use of preservation solutions and methods and discusses many innovations.

CURRENT USE OF PRESERVATION SOLUTIONS

Renal transplantation has become a standard therapy for end-stage renal failure. Owing to standardized techniques, better immunosuppression, and more experience of how to cope with post-transplant complications, the outcome of renal transplantation has improved. As a result, indications for transplantation have broadened—resulting in long recipient waitlists. Despite many major efforts to increase the donor pool of deceased heart-beating, brain-dead (DBD) donors, the addition of living donor programs, and the exploration of deceased cardiac death (DCD) donors, the persisting donor shortage remains a key problem in renal transplantation.

Regardless of the donor source, all kidneys to be transplanted need to be preserved during the time between retrieval and implantation. At present, static cold storage is the preferred organ preservation method, which includes a rapid vascular flush and washout with removal of blood, rapid cooling of the organ, and equilibration between the cold storage solution and tissue.[106,170]

With high patient survival and improved graft survival rates, despite the sometimes relatively long periods of preservation, renal transplantation seems to be a safe and reproducible therapy. This statement may imply that there is no room for improvement, but several authors have

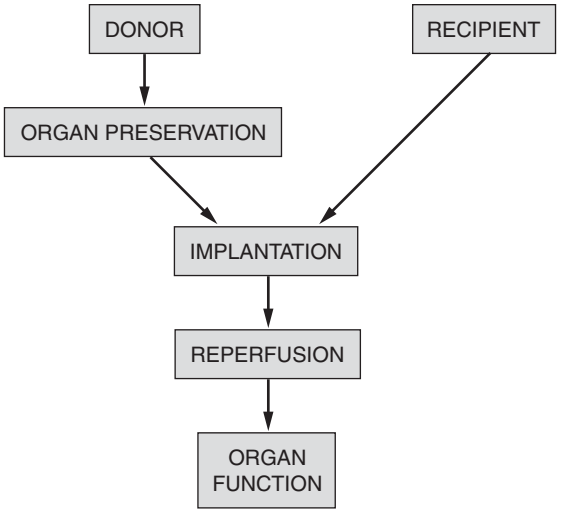

Figure 9–1 The transplantation cascade.

documented that the duration of preservation is one of the factors influencing outcome, especially with cold ischemia times greater than 24 hours.

The qualifications and criteria for kidney donation have changed. In the 1980s, the average deceased donor was a healthy young individual who was involved in an accident leading to cerebral trauma and brain death, whereas nowadays most brain-dead donors are middle-aged individuals who died as a result of a cerebral hemorrhage. Between 1988 and 2005, the United Network of Organ Sharing (UNOS) reported a 170% increase in deceased donors older than 50 years of age (Fig. 9-2A).[46,60]

The increased proportion of older donors is not accompanied by a similar number of renal transplants (Fig. 9-2B). The percentage of nontransplantable kidneys in the United States is increasing with age. In addition to the lower percentage of kidneys transplanted from older donors, graft survival is lower with older donor kidneys.[160] Also, marginal and DCD organs become damaged from additional warm ischemic injury. After kidney transplantation, these kidneys have higher primary graft nonfunction and delayed graft function (DGF), with rates of 4% to 9% and 22% to

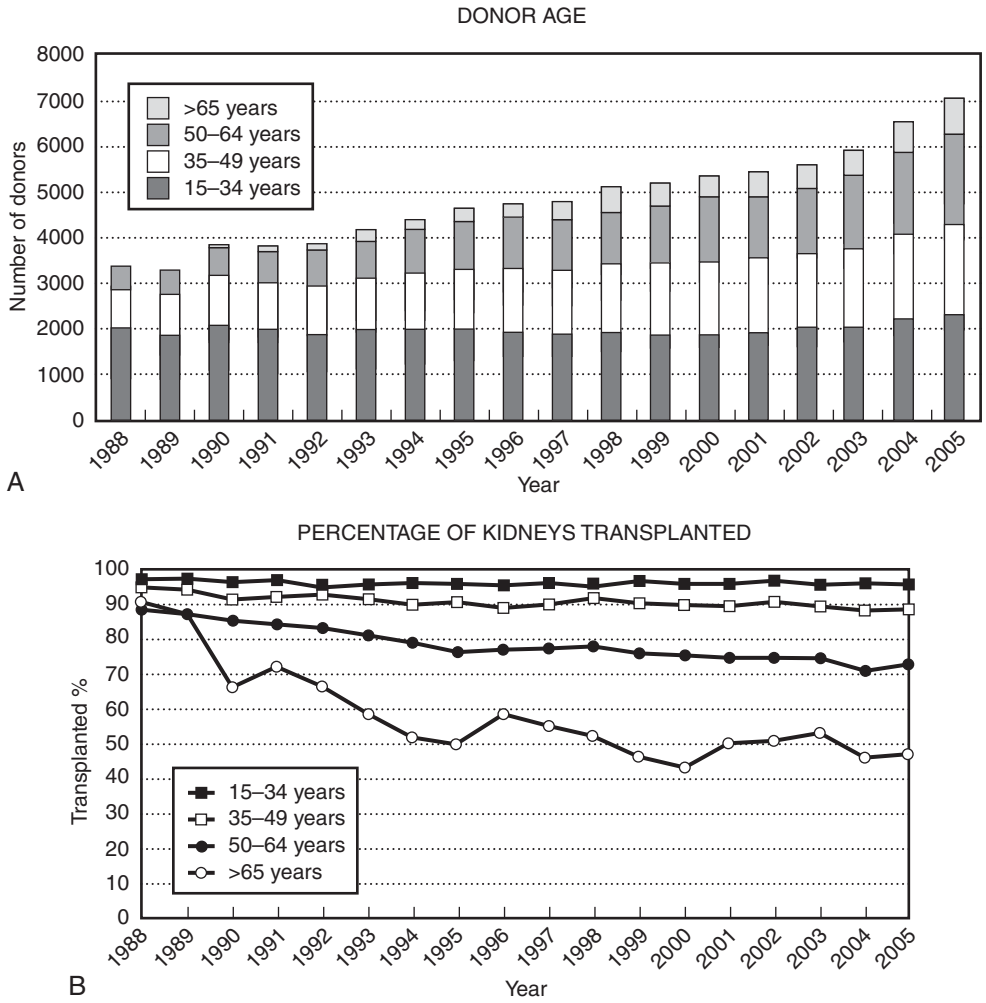

Figure 9–2 **A**, Donor age of retrieved kidneys. **B**, Influence of age on percentage of renal transplants. (Data from Organ Procurement and Transplantation Network.)

84% compared with 1% to 2% and 7% to 25%, respectively, with heart-beating donors.[7,112,136]

Maintaining organ viability during preservation has become an important prerequisite for successful outcome after transplantation. Currently, most centers use static cold storage to preserve organs. This preservation method was developed, however, in an era with younger and better quality donor organs.[20] Despite the aforementioned considerations, preservation of DBD kidneys for less than 24 hours generally results in adequate function and graft survival, whereas preservation times and methods seem to be more critical in the outcome of DCD kidneys, which are associated with inferior graft survival.

As illustrated in Figure 9-3A, in the UNOS region, most kidneys derived from deceased donors have been preserved in University of Wisconsin solution. In recent years, the use of histidine-tryptophan-ketoglutarate (HTK) solution has increased probably partly as a result of the inclusion of DCD donors. In Europe, HTK and University of Wisconsin solutions are both used in DBD donors. Also in the Eurotransplant region, the use of HTK solution is increasing because almost all DCD donor organs are flushed with and stored in HTK solution owing to the lower cost at high volumes (Fig. 9-3B).

PRINCIPLES OF COLD STORAGE PRESERVATION

Removal of the kidney from the circulatory system leads to disruption of the blood supply. The absence of oxygen delivery to the cells rapidly leads to major metabolic problems. Suppression of metabolism is essential to prolong the time of ischemia the kidney can sustain. Reducing the core temperature of the kidney to less than 4°C results in a reduction of metabolism to 5% to 8% in most cells and diminishes enzyme activity.[151] In 1963, Calne and colleagues[43] showed that simple cooling of kidneys in ice water preserved function of kidneys for 12 hours—the temperature effect. With a preservation solution, however, cold ischemia times can be significantly prolonged, and preservation quality can be improved—the solution effect.[109] Despite the beneficial concept of hypothermia, it causes several unwanted side effects in the preserved organ, such as cell swelling, acidosis, and production of radical oxygen species on reperfusion (Fig. 9-4).

Cell Swelling

Histological alterations in cellular structures observed during preservation are cell swelling and formation of protruding pockets.[90] The mechanism underlying these

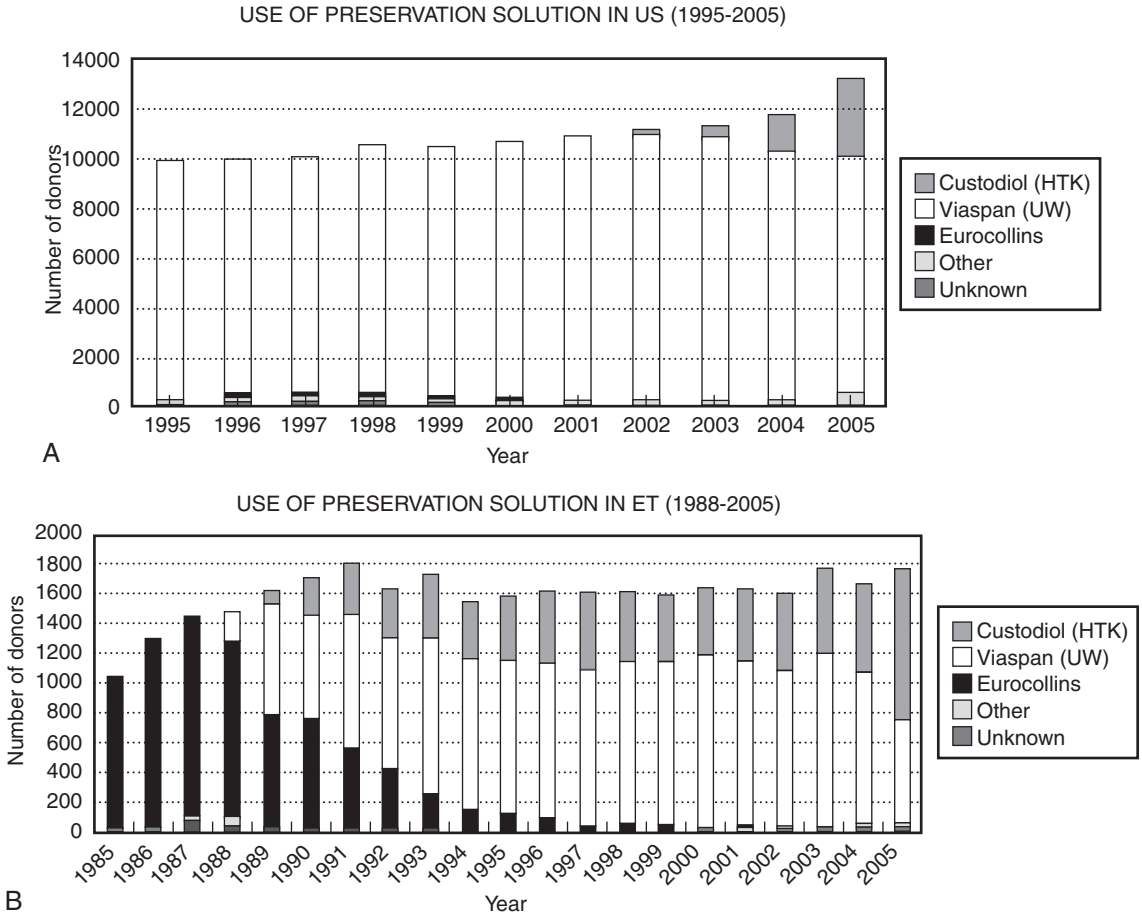

Figure 9–3 **A**, Current use of preservation solutions in the United States in cadaver donors. **B**, Use of cold storage preservation solution in the Eurotransplant (ET) region in cadaver donors. (**A,** Data from Organ Procurement and Transplantation Network; **B,** data from Eurotransplant International Foundation.)

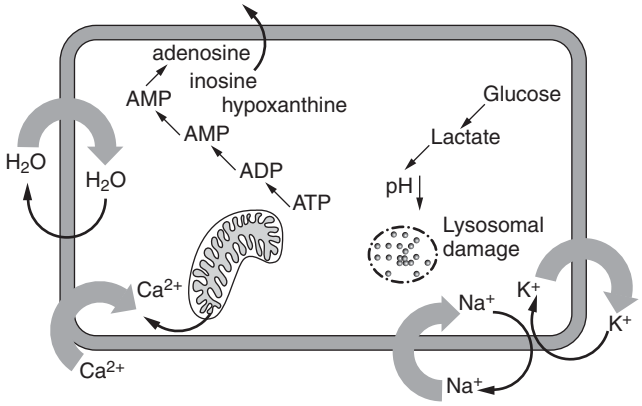

Figure 9–4 Negative effects of cold ischemia are breakdown of adenosine triphosphate (ATP), acidosis, release of lysosomal enzymes, increased Na^+ and Ca^{2+} entrance in the cell, and subsequent cell swelling. ADP, adenosine diphosphate; AMP, adenosine monophosphate.

structural changes is due to impaired activity of Na^+,K^+-ATPase. As a result, sodium is no longer excreted and passively enters the cell attracted by the negative charge of cytoplasmic proteins; this creates a hyperosmolar intracellular environment and subsequently an influx of water. To re-establish the disturbed Donnan's equilibrium of the membrane and to prevent cell swelling, impermeants and colloids are added to preservation solutions. Effective impermeants are saccharides and nonsaccharide anions. Molecular size and effectiveness of saccharides are positively related to prevention of cell swelling, with larger saccharides being most effective.[74,156,175]

Energy and Acidosis

Owing to the nature of aerobic metabolism, the absence of oxygen results in a rapid decrease in intracellular adenosine triphosphate (ATP) levels. Even at a dramatically reduced metabolic rate, at 0°C to 4°C, cellular ATP content is rapidly depleted. Within 4 hours, nearly 95% of ATP has disappeared with a shift to adenosine monophosphate as the predominant nucleotide. During cold storage, anaerobic metabolism of 1 mol of glucose yields only 2 mol of ATP versus a maximum of 38 mol in aerobic glycolysis. Two lactic acid molecules are formed leading to acidosis.[72,106]

The contribution of acidosis to ischemic injury is pH dependent. Severe acidosis activates phospholipases and proteases causing lysosomal damage and eventually cell death.[32] Mild acidosis (pH 6.9 to 7.0) has been suggested to have a protective effect, however, by inhibiting phosphofructokinase as the rate-limiting step in glycolysis.[32,82] Adequate control of pH is an important function of preservation solutions.

Reactive Oxygen Species

Reactive oxygen species (ROS) are generated by several processes in ischemic and postischemic reperfused organs.[110] An extensively studied generator of ROS is xanthine oxidase, which simultaneously produces hydrogen peroxide (H_2O_2) and the superoxide anion (O_2^-).[102,141] The subsequent reduction of H_2O_2, catalyzed by iron, leads to hydroxyl radical formation (OH). ROS reacts rapidly with other molecules, which results in severe damage to lipids, nucleic acids, and proteins during reperfusion.[42,99]

In addition to xanthine oxidase, which, in contrast to rodents, in human renal transplantation may be of minor importance because it is not abundant in humans,[150] several other sources of ROS are important, especially during the reperfusion phase. Infiltration of leukocytes into the graft after reperfusion results in production of mainly superoxides (the respiratory burst). Mitochondrial malfunctioning resulting from partial reduction of the respiratory chain is an important contributor to ROS formation after reperfusion. The formation of ROS has long been considered to contribute to cellular injury during the reperfusion phase, but not during cold preservation.[42,99] During cold ischemia, cellular metabolism and enzymatic activity are very low. Some reports suggest, however, that oxygen radicals are formed during reperfusion and during cold preservation.[137,138] Because free radical–mediated injury during preservation is strongly correlated with immediate and long-term kidney function,[99] preservation solutions should aim to counteract ROS-mediated injury.

Calcium

During normal circumstances, a large difference in free calcium concentration exists between the intracellular and extracellular space fluid. This difference is maintained by active transport of Ca^{2+} by several ATP-demanding processes, including Ca^{2+}-ATPase and Na^+-Ca^{2+} exchanger.[24] During cold preservation, cellular ATP concentrations are low leading to increased intracellular Ca^{2+}. Accumulation of Ca^{2+} in the cold leads to activation of calcium-dependent processes, such as calpain activation and protein kinase C signaling. Calpain activation leads to loss of cell structure by breakdown of the cytoskeleton spectrin.[71] During cold storage, calpain activity has been shown to be increased in cold stored hepatocytes and increased further during rewarming.[94]

Enzymes

Intracellular proteases are involved in the breakdown of proteins during preservation most likely because of the absence of oxygen. Also, matrix metalloproteinases may be activated during cold preservation leading to detachment of endothelial cells from the underlying matrix. This phenomenon has been predominantly studied in the liver, but also occurs in renal preservation.[161,162] To reduce this detrimental effect by blocking matrix metalloproteinases (especially matrix metalloproteinases 2 and 9), the addition of the often disputed colloid hydroxyethyl starch (HES) in University of Wisconsin solution has been shown to play an important role.[162] Another relevant family of enzymes activated during cold preservation are apoptosis-related caspases.[62]

COMPOSITION OF CLINICALLY USED SOLUTIONS

With the introduction of the first static cold storage solution by Collins in 1969,[53] prolonged preservation of kidneys became clinically feasible. The original Collins solution

Table 9–1 **Composition of Major Cold Storage Preservation Solutions**

was modified by the Eurotransplant Foundation in 1976, eliminating magnesium.[9] EuroCollins solution was a simple and cheap, intracellular-like preservation solution (Table 9-1). Phosphate was used for pH buffering, and glucose served as the osmotic agent. Since the introduction of the University of Wisconsin Cold Storage Solution (UW-CSS), most centers have been using this solution (see Fig. 9-3A). A randomized clinical trial comparing EuroCollins with UW-CSS showed that DGF was significantly lower in the UW-CSS group (23% versus 33%). Also, 1-year graft survival was found to be significantly higher in the UW-CSS group.[127] As a result of this study, EuroCollins was no longer the preferred solution for kidney preservation in Europe (see Fig. 9-3B).

University of Wisconsin Solution

Continuous and systematic research by Belzer and Southard in the 1980s led to the development of the University of Wisconsin solution and its clinical introduction in 1987. Metabolic inert substrates such as lactobionate and raffinose served as osmotic agents (see Table 9-1). HES was used as a colloid. Scavengers (glutathione, allopurinol) and an ATP precursor (adenosine) were added to the solution. To date, UW-CSS is considered the "gold standard" preservation solution for kidney, liver, pancreas, and small bowel.[31,45,58,63,67,91,127]

Histidine-Tryptophan-Ketoglutarate Solution

HTK solution was initially introduced as a cardioplegic solution in open heart surgery by Bretschneider in the 1970s.[39] The solution consists of a very potent buffer, histidine, combined with two amino acids (see Table 9-1). Tryptophan serves as membrane stabilizer and antioxidant, whereas ketoglutarate acts as substrate for anaerobic metabolism during preservation. HTK solution has a low viscosity, and to achieve complete tissue equilibration according to Bretschneider, high volumes (approximately 15 L) have to be rinsed through the organs at low flow rates. A multicenter randomized prospective trial comparing UW-CSS versus HTK solution in kidney preservation showed equal results in terms of the incidence of DGF (33% versus 33%).[58] For prolonged cold storage times with HTK solution (>24 hours), few data are available. One single-center study reported a significantly higher incidence of DGF of 50% for HTK solution–preserved kidneys versus 24% for UW-CSS–preserved kidneys when cold ischemia time was greater than 24 hours.[135] The opposite was reported in a more recent study, with a DGF rate of 16% after HTK solution preservation versus 56% after UW-CSS preservation.[1] Direct comparison of these conflicting findings is impossible because of a different definition of DGF in both studies.

Colloids and Impermeants

Glucose is a monosaccharide and was used in early cold storage solutions (e.g., EuroCollins). Because glucose is able to pass the cell membrane, it is a source for ATP and lactate in an anaerobic environment, reducing its impermeant effectiveness.[115] Mannitol is a slightly larger monosaccharide, but is not metabolizable and does not pass the cell membrane easily. It is added for its beneficial effect as a radical oxygen scavenger to HTK solution. The largest and most effective saccharide is raffinose, which is used in UW-CSS.

Nonsaccharide impermeants, such as gluconate, citrate, and lactobionate, limit cell swelling by electrochemical forces. Effectiveness of these anions is determined by molecular size and charge. UW-CSS and Celsior solution, which is a newer solution based on the University of Wisconsin concept, contain lactobionate.

Colloids are macromolecules that do not pass the cellular membrane. Colloids originally were added to hypothermic machine preservation solutions to prevent tissue edema owing to hydrostatic pressure. Belzer and Southard used diafiltrated HES in UW-CSS because they originally aimed at developing one solution suitable for cold storage and hypothermic machine perfusion (HMP). The feasibility of HES as a colloid in UW-CSS has been extensively debated. HES prevents interstitial edema and has a beneficial effect on matrix metalloproteinases, but it increases viscosity.[127,170] Analyzing the effect of HES on red blood cells, several authors have shown an increased red blood cell aggregability when large-molecular-weight HES is present.[113,170] This effect could partially explain the slower washout of blood and initially patchy reperfusion of organs when UW-CSS is used.[76]

The HES controversy initiated a search for other colloids (e.g., dextran and polyethylene glycol [PEG]).[22,26,44] In this respect, UW-PEG–preserved livers have shown lower transaminase levels, higher bile flow, and higher urea

synthesis after transplantation.[114] Several experimental and clinical studies have now confirmed the efficacy of PEG not only for liver, but also for kidney, pancreas, small bowel, and heart preservation.[21,88,179,183]

In contrast to UW-CSS, HTK and EuroCollins solutions do not contain a colloid. In a prospective study with short cold ischemia times, both solutions showed equal efficacy compared with UW-CSS for preserving kidney and liver grafts.[124] With prolongation of preservation times, the presence of a colloid does seem to be important to maintain organ viability.[152]

Electrolyte Composition

During the pioneering years of organ preservation, a high potassium-to-low sodium ratio of the solution (intracellular type) was assumed necessary to prevent cell swelling. It was hypothesized that because of the inactivity of Na^+,K^+-ATPase during hypothermia, an intracellular sodium-to-potassium ratio in the extracellular fluid compartment would prevent sodium and chloride from entering the cell.[13] Balancing extracellular sodium ions and intracellular protein anions creates the Donnan equilibrium, which prevents edema formation.[74] Intracellular-type solutions such as UW-CSS were long considered to be pivotal for preservation of cell viability.[13,54] More recent work has suggested, however, equal or better results of extracellular-type solutions with a low potassium-to-high sodium ratio.[23,79,149,157,163,177] As a result of the lower potassium content, washout of blood during organ procurement is facilitated because no potassium-induced vasospasm occurs.[107,149] In liver preservation, it has been suggested that HTK solution could be advantageous owing to its low potassium concentration. The need to flush the organ before reperfusion would be limited. Although patient numbers were relatively small and cold ischemia times short (<10 hours), two studies using HTK solution in liver preservation concluded equality of HTK solution and UW-CSS for short-term preservation.[63,128]

Reactive Oxygen Species Scavengers

In UW-CSS, the compounds allopurinol and reduced glutathione (GSH) were included to prevent formation of ROS. Allopurinol inhibits xanthine oxidase, which improves kidney preservation, whereas liver or pancreas preservation is almost unaffected.[30]

GSH is a tripeptide that has free radical trapping properties. This important antioxidant is oxidized to glutathione disulfide together with converting peroxides. Experimental studies have shown the importance of GSH in an isolated perfused rabbit liver model. In the absence of GSH, more lactate dehydrogenase was released into the perfusate.[89] Subsequent studies have shown that GSH is especially important in long-term liver preservation.[33]

In HTK solution, tryptophan protects the organs against ROS-mediated damage. Tryptophan acts as an antioxidant through its oxidative metabolites in the kynurenine pathway, such as 5-hydroxytryptophan.[50,66] In a cultured rat hepatocyte experiment, the amount of thiobarbituric acid reactive substances as a marker for ROS-mediated injury was measured. After 24 hours of preservation, thiobarbituric acid reactive substances were significantly higher in HTK solution–preserved hepatocytes compared with UW-CSS–preserved hepatocytes, suggesting superior antioxidant capacity of UW-CSS owing to the combination of GSH and allopurinol.[133]

PRESERVATION BY HYPOTHERMIC MACHINE PERFUSION

In the late 1960s, HMP, developed by Belzer, was used by many centers in the United States to preserve kidneys because it was considered the best and only way to transport organs from the donor to the recipient center.[81] Belzer and coworkers were able to preserve canine kidneys for 72 hours using the HMP technique[18] and introduced the HMP technique clinically 1 year later.[19] With the introduction of an "effective" cold storage preservation solution such as EuroCollins, the number of kidneys preserved by machine decreased. In the United States today, about 10% of kidneys are preserved by machine preservation (Fig. 9-5). In more recent years, a small increase can be observed, presumably as it has become generally accepted that kidneys from DCD donors are better preserved using machine perfusion preservation.

Although modern HMP systems are smaller, lighter, and more sophisticated than the original machine used by Belzer (Fig. 9-6), the principles of HMP have not changed. Machine perfusion generates a controlled continuous or pulsatile recirculating flow of the preservation solution at 0°C to 4°C. This continuous flow allows complete perfusion of the organ promoting a complete washout of blood and subsequent tissue equilibration with preservation solution. Until now, technologies used in preservation machines had remained almost identical for decades, using roller pumps simulating a pulse wave at a low pressure setting. A new machine perfusion system was developed employing centrifugal

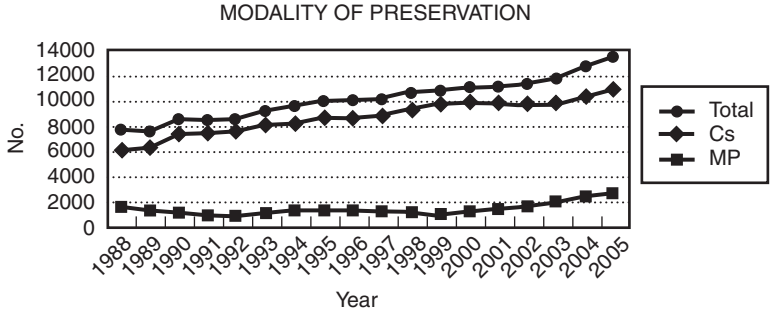

Figure 9–5 Number of kidneys preserved by cold storage (Cs) or machine perfusion (MP). (Data from Organ Procurement and Transplantation Network.)

Figure 9–6 Professor F. O. Belzer with the first "transportable" machine perfusion system.

pumps that allow higher pressures under hypothermic and normothermic conditions using acellular solutions and blood.[172] This machine was shown to result in better porcine kidney preservation compared with cold storage.[105]

Beneficial effects claimed on behalf of machine perfusion are a low incidence of DGF, the possibility of online viability assessment, the ability to provide metabolic support during perfusion, and the potential to add pharmacological agents to the perfusate. In kidney preservation, in animal experiments and in historical controlled clinical studies, HMP has been shown to provide better early graft function compared with static cold storage.[48,51] In addition, when kidneys derived from extended, marginal, or non–heart-beating (NHB) donors were analyzed, HMP was found to be beneficial.[16,19,119,129,145] In most studies, no randomization was used, and patient numbers were not large enough to allow extrapolation of the results. Wight and colleagues[180] reported an excellent meta-analysis based on aggregated results of current literature concerning HMP versus static cold storage, showing a 20% reduction in DGF. DGF is the compilation of accumulated risk factors and depends on the presence or absence of independent donor, preservation, and recipient characteristics.[127] Possibly, some of the detrimental effects caused by these risk factors, which make a kidney susceptible to injury and result in DGF, can be reduced with HMP. The occurrence of DGF after transplantation requires continuation of dialysis and is associated with an increased incidence of acute rejection and inferior long-term outcome.[123,125]

Although individual studies suggest potential benefits of HMP, such as less DGF, less acute rejection, and better short-term and long-term function at reduced cost, no comparative study of these modalities has been performed under strict conditions.[153] For this reason, a European multicenter prospective randomized clinical trial was started in The Netherlands, Belgium, and Germany[126] comparing for the first time a U.S. Food and Drug Administration–approved transportable perfusion machine with cold storage. The results of the trial suggest that there is a beneficial effect of HMP over cold storage both in terms of fewer cases of DGF and graft failure in the first 6 months after transplantation.[184,185]

Overall, experimental and clinical data imply that HMP improves renal preservation. Because modern, portable, and stand-alone HMP systems for kidney preservation are now available, allowing user-friendly transportation within international organ sharing systems, a broader clinical application of HMP should be considered to reduce the impressively high DGF rate of 60% to 85% in NHB donor kidneys.[41,134,182]

RENAL PRESERVATION STARTS IN THE DONOR

In the early days of organ transplantation, all cadaver donor grafts were retrieved from victims of cardiac death.[84,111,174] When legal definitions for brain death (Harvard Criteria) became available in the late 1960s,[8] most centers established transplant programs based on organ retrieval from heart-beating, brain-dead donors, avoiding the warm ischemic damage that NHB donor organs by definition have sustained.[98]

In recent decades, indications for transplantation have been extended, although not accompanied by a substantial increase in donors. In an effort to enlarge the donor pool, living donation has made a valuable contribution to kidney transplantation programs.[57,142] Such programs could never yield sufficient new donor organs to bridge the global gap between supply and demand. Many centers are now actively re-establishing the practice of DCD or NHB donation,[93] although actual numbers are still small in many countries.

In the United States, a gradual increase in living donors has been observed such that almost 50% of all kidney transplants in 2005 were from living donors (Fig. 9-7). In Europe, the growth of living donor programs has been more modest than in the United States, but is continuously increasing.

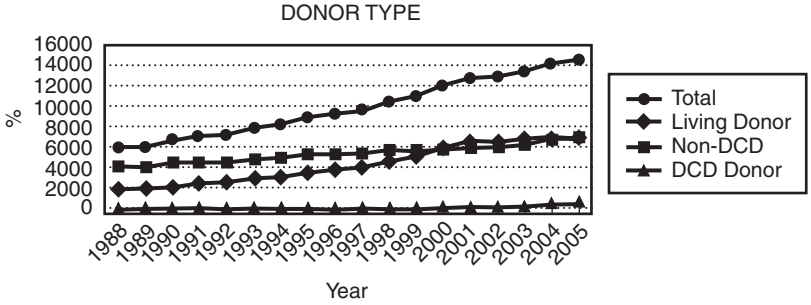

Figure 9–7 Gradual increase in (living) donor number in the United States. DCD, deceased cardiac death donor. (Data from Organ Procurement and Transplantation Network.)

A striking phenomenon is that now, more than 3 decades after the definition of brain death, DCD or NHB donation is being revisited. To date, in The Netherlands, DCD donation contributes 40% of all transplanted cadaver donor kidneys. Transplant outcome achieved with kidneys from living donors is far superior compared with grafts obtained from cadaver donors.[160] The persistent donor organ shortage has led, however, to a gradual shift toward accepting suboptimal donors. The use of older and more marginal donors is now routine, and the number of NHB donors has increased significantly. As mentioned earlier, in the 1980s, the typical donor was younger than age 30, was fairly healthy, and had died of traumatic cerebral injury. Today, the average donor is older than 50, and the main cause of death is intracranial hemorrhage. The improvements that have occurred in immunosuppressive treatment of the recipient, organ preservation, reduction of cold ischemia time, and better allocation of donor organs based on matching have been masked to some extent by the use of lower quality donors. In the past, much effort was directed toward post-transplant immunosuppression and better treatment of complications. Now, risk factors and conditions before organ retrieval in the donor also need to be recognized for their impact on donor organ viability.

Brain-Dead Donors and Preservation

To date, most cadaver donor organs are still retrieved from cerebrally injured brain-dead or cardiac death donors. The condition of the patient before retrieval and preservation, together with the efficacy of preservation, determines the viability of the organ at the time of transplantation. Brain death induces pathophysiological changes in the donor kidney that have a negative impact on the outcome after transplantation. Ischemia of the brain results in nonfunction of the central nervous system and is associated with pertinent hemodynamic instability, hormonal changes, and diminished perfusion. This abnormal physiological state induces proinflammatory changes in the potential donor organs that negatively affect function and cause an increased chance of acute rejection.

Before 1997, the concept of donation after brain death did not exist in Japan. Patients who would be considered brain dead and eligible for organ donation in the United States or Europe were kept in a coma in Japan until cardiac arrest occurred. This presented Nagareda and coworkers[116] with the unique opportunity to investigate the time course of the effects of brain death on the kidney for 48 days. Their study revealed that the mean urinary sodium output increased during the first 14 days, mean urine osmolarity was above normal on the first day but decreased gradually, and urine volume during the first 14 days was high as a consequence of the cerebral injury–related diabetes insipidus. On histological examination, degenerative changes of renal structures were found, including vacuolization, atrophy, and necrosis of renal proximal and distal tubules. Advancing glomerulitis and progressing periglomerulitis expressed inflammatory changes. Fibrosis and proliferation of the arterial intima and glomerular endothelium reflected the structural changes in the kidney.

In experimental conditions in rats, renal function is already adversely affected during 4 hours of brain death followed by inferior results after reperfusion in an isolated perfused kidney model. In the isolated perfused kidney, urine volume and glomerular filtration rate were significantly higher than in controls.[166] Potassium excretion was increased in these kidneys, possibly explained by the depletion of ATP in these kidneys, which can trigger the opening of ATP-sensitive potassium channels. An impaired sodium/potassium homeostasis also was observed after brain death in a renal slice model.[178] Organs also can become more prone to ischemia-reperfusion injury; livers derived from brain-dead rats are more susceptible to hypothermic preservation–induced injury. This susceptibility was shown by a decreased survival after 20 hours of cold storage when compared with living donor livers stored for the same time.[167]

Renal tubular damage as a consequence of brain death can be observed in urine as well. Brush-border enzymes, such as alkaline phosphatase and alanine amino peptidase, and the lysosomal enzyme *N*-acetyl-beta-D-glucosaminidase[166] are released into the urine. Kidney injury molecule 1 is a more recently discovered brush-border enzyme that is considered a marker of tubular damage (e.g., in ischemia-reperfusion injury).[59,85,173] As a result of brain death, kidney injury molecule 1 was massively upregulated. It can be detected on the luminal side of the renal cortical tubule and is shed into the urine,[148] which may simplify viability assessment of potential donor organs.

Immunological Activation

In ischemia-reperfusion injury, a clear-cut correlation was found between endothelial injury and acute rejection. This association between the innate immune response and subsequent alloreactivity could be explained by Matzinger's danger hypothesis.[108] An increased immunogenicity also is observed in the brain-dead donor organ. Endothelial activation is present with the upregulation of adhesion molecules (E-selectin, P-selectin, intercellular adhesion molecule-1, vascular cell adhesion molecule-1) that promote the rolling, adhesion, diapedesis, and subsequent leukocyte migration into the interstitium of the kidney.[95,103,158,168,169] Multiple cytokines and chemokines play a role in the immunological response to cerebral injury. Upregulation of interleukin-1, interleukin-2, interleukin-6, tumor necrosis factor-α, transforming growth factor-β, interferon-γ, vascular endothelial growth factor, macrophage inflammatory protein-1α, macrophage inflammatory protein-1β, monocyte chemotactic protein-1, and osteopontin has been reported.[103,104,146,147,158] The expression of the major histocompatibility complex class II is increased as well.[158] Amplification of cytokines, chemokines, and adhesion molecules causes a chemotactic gradient that promotes the influx of leukocytes to the kidney. T cells, macrophages, and polymorphonuclear neutrophil leukocytes all are found in higher quantities in donor kidneys during brain death.[121,158,168,169]

After reperfusion, a large difference in neutrophil infiltration and P-selectin expression can be observed between living and cadaver grafts. Koo and associates[95] showed that 53% of cadaver renal allografts had increased neutrophil infiltration versus 0% of living related grafts. P-selectin expression was increased in 44% of cadaver grafts and 9% of living related grafts.

In a syngeneic animal model of renal transplantation, Kusaka and colleagues[103] investigated short-term inflammatory changes to the kidneys. Leukocyte infiltration reaches its

peak at 24 hours after transplantation in this syngeneic transplant model and corresponds with the levels of E-selectin and P-selectin. After this period, the extent of immunological activation gradually decreases, but histological changes to the kidney still can be observed. Allotransplant experiments have shown that after experimental brain death, recipients of brain-dead donor kidneys had a greatly increased acute rejection rate.[130] When kidney allografts are treated with cyclosporine to prevent acute rejection, long-term renal function is adversely affected by brain death compared with syngeneic transplants. The state of brain death also can enhance the development of chronic renal transplant dysfunction.[131]

Protection and Repair

Not only detrimental or degenerative changes occur during cerebral injury and preservation; protective or recuperative mechanisms are induced as well. There is increased expression of the cytoprotective genes heme oxygenase-1 (HO-1), heat-shock protein 70, and manganese superoxide dismutase.[121,146,147] Kunzendorf and coworkers[101] showed that a prolonged duration of brain death positively influences long-term graft survival. The mechanism behind this observation could be the delayed induction of protection or initiation of repair. In another study, increased HO-1 expression at organ retrieval was correlated with outcome after renal transplantation in the living donor setting.[121] Expression of HO-1 was not related to graft survival in deceased donor kidneys. Donor HO-1 gene polymorphisms have been associated with transplantation outcome.[12] In a liver transplant study, livers with an initial low HO-1 expression before transplantation, but a high HO-1 expression after reperfusion, had superior outcome compared with livers with high HO-1 expression at organ harvest.[70] These observations indicate that the ability to induce HO-1 is important, and not the high expression of HO-1 per se. Two different mechanisms should be considered here: Although the increase in expression of HO-1 in living donors may initiate protection against the potential injuries to the kidney during transplantation and thereafter, in deceased donors, HO-1 may be a reflection of the level of stress to the kidney owing to brain death. These compromising changes in the donor suggest that there is a need to develop treatment regimens for application during the state of brain death and before retrieval and initiation of preservation.

The use of pharmacological interventions to provide optimal conditions for the donor organ and prevent the decline of renal function is expected to become an important part of the entire donation and transplantation process. Reducing hemodynamic instability is crucial to maintain normal perfusion of organs. The use of catecholamines for this purpose would benefit renal transplant outcome. Caution is needed, however, because interventions that can be beneficial to one organ may be detrimental to another; this was shown by Schnuelle and associates[144] in their analysis of catecholamine use in the donor. Although renal transplant survival was increased, liver transplant outcome was not improved, and cardiac results seemed to be adversely influenced by catecholamine administration in the donor.[143] A randomized prospective clinical trial is currently under way to assess the effects of donor pretreatment with dopamine.

The use of immunomodulators such as corticosteroids or recombinant soluble P-selectin glycoprotein ligand immunoglobulin has shown some promising results in experimental models.[68] Counteracting inflammatory changes in the deceased donor kidney improved function and survival after transplantation.[69] Steroid treatment is effective in modulating the immune response in human organ donors.[100] The use of carbamoylated erythropoietin was shown to decrease breath death–induced inflammation effectively[52] and protect against ischemia-reperfusion injury.[86] Because all organs exhibit inflammatory changes as a result of brain death, immunomodulating treatment has a high probability of being beneficial for all transplanted organs.

The induction of protective mechanisms, such as HO-1 upregulation, is an important development in donor pretreatment. Initiation of protective pathways can diminish brain death–related damage and ischemia-reperfusion injury. The products created during heme degradation by HO-1 are involved in cytoprotective processes. In addition, immunomodulating effects of HO-1 could be useful in the improvement of deceased donor transplantation. Another option is the addition of gaseous substances to the breathing air of brain-dead donors. Carbon monoxide has shown a beneficial effect in modulating ischemia-reperfusion injury,[2] and inhalation of low-dose carbon monoxide after experimental renal transplantation prevents the development of chronic allograft nephropathy.[117]

To date, many challenging opportunities do exist to counteract the deleterious effects of brain death in combination with preservation of the donor kidney. A better characterization and understanding of the mechanisms of injury and repair that play a role during massive cerebral injury, followed by ischemia-reperfusion and its effect on potential donor organs, would lead to novel treatment options. As a result, the outcome after cadaver donor organ transplantation may improve and approach that of living donors.

Deceased Cardiac Death Donation

The use of DCD donors (in Europe often referred as NHB donors) to enlarge the donor pool is a logical step because the potential pool of these donors is many times larger than the amount of available DBD donors.[97,98] In the late 1980s and early 1990s, a few hospitals had already reintroduced DCD protocols. The group from Maastricht, led by Kootstra, was one of the pioneering centers.[80] In 1995, at the First International Workshop on NHB Donors in Maastricht, consensus was reached about donor management protocols, and four different categories of NHB donors were defined (Table 9-2).[96]

The practice of DCD donation has increasingly become part of transplant programs throughout the world. Within Eurotransplant, 6% of all kidney donors in 2005 were DCD donors. Of these donors, 91% came from The Netherlands.

Table 9–2 **Maastricht Classification of Non–Heart-Beating Donors**

Category	Description	Procurement
I	Dead on arrival	Uncontrolled
II	Unsuccessful resuscitation	Uncontrolled
III	Awaiting cardiac arrest	Controlled
IV	Cardiac arrest while brain dead	Uncontrolled

In The Netherlands, 47% of all donors were DCD donors in 2005, mostly Maastricht category III.[10] In Spain, although nationwide only 4% of the donor pool consists of DCD donors, the Hospital Clinico in Madrid developed a well-established NHB program, with approximately 25% of all cadaver donors being DCD (percentages adopted from the website for the Spanish National Transplant Organization, www.ont.msc.es). In the United Kingdom, 11% of all cadaver kidney grafts came from NHB donors in 2005.[11] Worldwide, several centers in the United States and Japan have started extensive DCD programs.[49,77,122,159]

At present, more than 10 years after the Maastricht workshop, many centers have published results of their DCD programs. NHB grafts have a significantly inferior function in the short term, with reported DGF rates of 48% to 94% compared with 19% to 46% for organs retrieved from DBD donors. For primary graft nonfunction, these rates are 4% to 14% and 1% to 8%.* Medium-term and long-term graft survival and acute rejection rates do not differ between these two types of donors.[40,41,47]

Retrieval and preservation of DCD kidneys may involve different approaches compared with living and DBD kidneys. As in DCD donation, blood circulation is no longer present owing to the cardiac arrest, and an important cornerstone of DCD donor management is the reduction of warm ischemia. The major difference between warm and cold ischemia is the rate at which injury develops in the donor kidney. Detrimental effects of ischemia are much more pronounced as long as organ cooling has not yet been initiated. Because metabolism is decreased by approximately 50% for every 10°C of organ cooling, only when hypothermia has slowed down tissue metabolism does accumulation of ischemic injury decrease.[29] Rapid institution of cooling is essential. This cooling can be accomplished in several ways, ranging from an emergency laparotomy with direct aortic cannulation to total body cooling by an extracorporeal pumping device. The Maastricht group and others have advocated the use of a double-balloon, triple-lumen catheter for rapid onset of cooling.[80] Although especially useful for uncontrolled (categories I, II, and IV) NHB kidney-only donors, NHB multiorgan donation is impossible with this technique because only the kidneys are cooled.

Reliable and objective data on the technical effectiveness of cooling by this approach are lacking, as are data for all other cooling techniques. Few groups have measured whether the desired temperature of 0°C to 4°C is ever reached in the time that elapses between the beginning of cooling and organ procurement.[140] Also, the time span needed to reach adequate cooling via various techniques is largely unknown. Future research directed at characterizing and improving cooling dynamics during donor management may be relevant for marginal organs. For this reason, a team from Groningen is currently developing an extracorporeal perfusion system that can be used for in situ cooling of abdominal organs, including the kidneys.

Before cooling is instituted, other actions also can be taken to minimize the amount of injury that donor organs sustain. Management of uncontrolled NHB category I kidney donors by rapid (<15 minutes) emergency service response and continuation of resuscitation after declaration of cardiac death may be useful.[4,5,139] Short-term graft function is similar to kidneys derived from controlled NHB donors (DGF 68%, primary graft nonfunction 6%). Promising results also have been obtained by artificial normothermic recirculation after cardiac arrest of NHB categories II and IV kidney donors, before consent is obtained and cooling is begun.[164,165] A completely different improvement in NHB donor management may emerge someday from donor pretreatment.

In the clinical transplantation setting, cold ischemia time is considerably longer than warm ischemia time, and for every additional 6 hours of cold ischemia time, the likelihood of DGF increases by approximately 25%.[56,145] In NHB donation, warm ischemia and cold ischemia have additive detrimental effects. This is shown by animal studies, in which prolonged cold ischemia after a warm ischemia insult rendered donor kidneys less suitable for transplantation.[37,61] These studies also illustrate that HMP cannot prevent the cold ischemic deterioration of a graft that has sustained a prolonged period of warm ischemia.

To resolve this dilemma, several groups have suggested switching to normothermic (or near-normothermic) machine perfusion as the preferred method for NHB kidney preservation. Normothermic machine perfusion does support metabolism at an almost-normal rate, and by adding oxygen to the perfusate, it prevents further ischemic damage to the graft. In contrast to HMP or cold storage, it can address essential physiological needs of the organ. Several studies have shown that normothermic machine perfusion is superior to HMP or cold storage preservation of severely warm ischemia–damaged NHB donor kidneys.[34-38,154] Apart from this, normothermic machine perfusion may offer a more reliable method for ex vivo pretransplant functional assessment of a kidney graft, based on urine production, perfusion dynamics, and biochemical injury markers in the perfusate.[155]

OUTLOOK

An increasing awareness that ischemia-reperfusion injury does determine a significant part of the outcome after transplantation has stimulated the research of preservation damage and the development of new preservation solutions and methods. A relatively new machine preservation solution developed at the University of Amsterdam is Polysol. Its composition is based on the fact that metabolism is still present at 4°C. Polysol is a classic preservation solution enriched with amino acids, vitamins, and antioxidants.[25,28] Many components in Polysol have not been evaluated separately yet, however. In experimental liver preservation studies, superiority over University of Wisconsin machine perfusion solution (UW-MPS) was seen in isolated perfused models of NHB and steatotic livers. Compared with UW-MPS, Polysol improved functional parameters (e.g., oxygen consumption, ammonia clearance, urea production, and damage markers).[25,27] Transplant data in experimental and clinical preservation are required to determine the efficacy of Polysol. Based on its "metabolic support" design, beneficial effects of Polysol can be expected, especially in damaged organs.

Another new and now clinically available preservation solution is IGL-1, developed by the Lyon group. IGL-1 builds on the heritage of UW-CSS and Celsior.[22,65] It combines the extracellular composition of Celsior with the colloidal support of UW-CSS using PEG instead of HES. In a porcine kidney autotransplantation model with IGL-1, PEG was found

*References 3, 4, 6, 17, 40, 49, 55, 77, 83, 92, 93, 112, 118, 120, 122, 136, 139, 159, 181, 182.

to limit influx of macrophages by approximately 50%.[78] Polymers, such as PEG, spontaneously bind to cell and tissue surfaces and sterically stabilize the underlying surface from interactions with other components. The main advantage of this "immunocamouflage" is that it directly modifies inherent immunogenicity of donor tissue.[64,87] PEG does not exert any aggregating effects on red blood cells, and in combination with the extracellular composition of IGL-1, this should improve the washout of blood.[15,113,170]

Rat and porcine transplantation studies of liver and kidney have shown encouraging results in terms of organ function after transplantation following preservation with IGL-1.[21,23,132] The first preliminary clinical results in renal transplantation with IGL-1 showed a reduction in DGF compared with kidneys preserved with UW-CSS (5.7% versus 13.8%). Also, less apoptosis was seen using terminal deoxynucleotidyl transferase biotin-dUTP nick end labeling (TUNEL) techniques when kidneys were preserved in IGL-1 compared with UW-CSS.[14] Until now, patient numbers have been too small to draw clinical conclusions, however, and a randomized controlled multicenter study is needed to confirm the encouraging initial results. Given its extracellular composition and the beneficial effects of PEG, IGL-1 should be considered as a potential promising successor to UW-CSS.

Despite the fact that static cold storage preservation methods have facilitated many transplant programs throughout the world, it seems that the increasing challenge to maintain viability in marginal or extended criteria donor organs has now touched the limits of cold storage preservation. Even with beneficial additives and enriched compositions, static cold storage, at best, slows down ischemic damage. To improve organ viability further, a more dynamic preservation method is needed to better fulfill metabolic demands of damaged organs. Many groups are switching gears and are revisiting the possibilities of HMP or investigating the possibilities of normothermic (or near-normothermic) perfusion of donor organs.[73,75,171]

Chapter 10

Histocompatibility in Renal Transplantation

Susan V. Fuggle • Craig J. Taylor

HISTORICAL BACKGROUND

In the 1960s, the study of histocompatibility was stimulated as the early pioneers of clinical kidney transplantation realized that immunological mechanisms were responsible for allograft destruction. In 1961, the introduction of chemical immunosuppression using first 6-mercaptopurine followed soon after by azathioprine and corticosteroids enabled short-term and medium-term success. Forty percent to 50% of cadaver grafts were lost, however, as a result of immediate or early graft failure owing to irreversible rejection in the first year, and thereafter there was an insidious decline in graft function. These early experiences severely limited the success of human allotransplantation and led to the study of compatibility of transplanted tissue, which over the following 40 years gave rise to the specialty of histocompatibility and immunogenetics.

The antigens of the ABO blood group system were the first human histocompatibility antigens identified. The vascular endothelium of the donor organ forms an interface with the recipient blood, and expression of ABO blood group antigens on capillary endothelium serves as a target for circulating natural antibodies to blood group A and B glycoproteins. ABO incompatibility leads to complement activation, thrombosis, and hemorrhage (collectively termed hyperacute rejection [HAR]). With only rare exception, ABO blood group–mismatched transplants fail as a result of immediate humoral hyperacute or acute vascular rejection; the requirement for donor and recipient ABO blood group compatibility was quickly established (see also Chapter 22).[95]

The first human leukocyte antigens (HLAs) were discovered in 1958 and subsequent years by Jean Dausset, Rose Payne, and Jon van Rood.[112] During the next few years, many more HLAs were characterized using antibodies in sera obtained from multiparous women and from patients after multiple blood transfusions. Such antibodies also were shown in patients after allograft rejection,[67] and antibodies present in recipient sera before renal transplantation that reacted against donor lymphocytes, either by leukoagglutination or by cytotoxicity, were associated with HAR.[48,124] HLAs were quickly recognized as the human equivalent of the major histocompatibility complex (MHC), previously identified in inbred rodents, the products of which control the recognition of self and foreign antigens.[38] The dual requirements for blood group compatibility and a negative pretransplant donor lymphocyte crossmatch have virtually eliminated HAR; most modern-day transplant surgeons have not encountered (or should not encounter) a case.

Evidence for the major role of HLAs as the dominant transplantation antigens of the human MHC arose from transplants performed using genetically related donors. Despite limited knowledge of HLA polymorphism and definition of only a few HLA class I and class II specificities, it was possible to assign familial HLA haplotypes whereby the genes encoding an individual's HLA type are inherited en bloc. Graft survival was shown to correlate with the number of HLA haplotypes shared between donor and recipient, with 90% graft survival between HLA-identical siblings compared with 70% or 60% when sharing one or no HLA haplotypes.[74] The impact of HLA compatibility on cadaver donor kidney transplantation is more controversial, however, because many factors may confound any clinical benefit in terms of graft outcome. These factors include the limited number of HLA specificities identified, the logistics of matching for such a diverse polymorphic antigenic system, the increased ischemia time that may be associated with the matching process, and a diminishing effect of HLA matching in the presence of more potent immunosuppressive regimens that can override rejection. After the definition of the class II HLAs, however, there was a much more clear-cut association between matching and graft outcome.[116,117]

Despite a complete allelic HLA match, 10% of kidney transplants performed using an HLA-identical sibling donor failed, and 40% of HLA-identical bone marrow transplant recipients still have acute graft-versus-host disease. The occurrence of immunological rejection on the background of HLA identity is likely to result from differences caused by polymorphic proteins at minor histocompatibility complex loci encoded outside the HLA region.[39] Several minor histocompatibility complex antigens have been identified as immunogenic targets in graft-versus-host disease after bone marrow transplantation, including the male antigen H-Y (encoded on the short arm of the Y chromosome), although there is no convincing evidence for a role in solid organ transplantation.

HLA SYSTEM

The HLA system encoded on the short arm of chromosome 6 is the most intensively studied region of the human genome. The region spans more than 4 Mb and contains greater than 250 expressed genes, making it the most gene-dense region characterized to date.[45] Of relevance to transplant clinicians and immunologists is that about 28% of these genes encode proteins that have immune-related functions. Originally discovered in the late 1950s as the equivalent of the human MHC, HLA incompatibility was identified as the principal stimulator of graft rejection. At that time, nothing was known, however, about the natural evolution and role of HLA.

HLA is now recognized to have a central role in immune recognition for the defense against foreign pathogens and neoplasia, mediating T cell signaling through the presentation of self and foreign antigens in the form of short protein fragments (peptides) recognized by self-HLA restricted T lymphocytes (see Chapter 2). Recognition of nonself peptides in the context of self-HLA (i.e., altered self) is the function of the T cell antigen receptor and elicits a powerful immune response. The extensive polymorphism of HLA has evolved to enable efficient binding of peptides from the vast array of potentially pathogenic organisms that invade and colonize human bodies. The evolutionary pressures to develop and maintain diversity vary with time and geographical area. As a consequence, HLA has adapted differently according to geographical region and ethnic group, and HLA phenotypes differ across populations throughout the world.

HLA Genes and Their Products

The HLA system is a complex multigene family consisting of more than ten loci. HLA types are codominantly inherited on a maternal and paternal haplotype and transmitted as a single mendelian trait (Fig. 10-1); an individual can express two alleles at each locus. The genes encoding HLA and their corresponding glycoprotein products are divided into two classes according to their biochemical and functional properties: HLA class I and HLA class II. Between these genes are the so-called class III genes that encode some immune-related proteins, such as complement factors (C2, C4A, C4B, properdin factor B), tumor necrosis factor, lymphotoxin α and β, and heat-shock proteins. The steroid 21-hydroxylase is encoded by the gene *CYP21B*, which is in close proximity to HLA-DR.[9]

HLA Class I

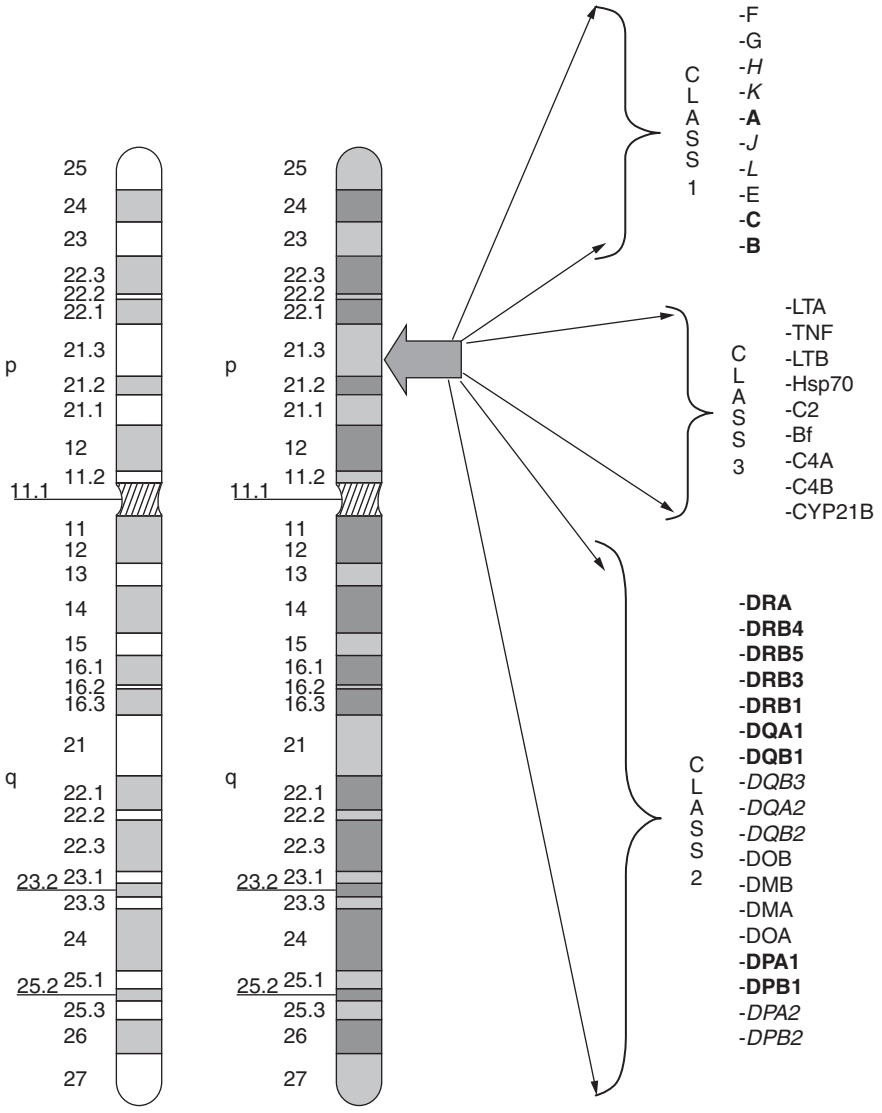
HLA class I genes span 2 Mb at the telomeric end of the 6p21.3 region of chromosome 6. This region encodes the classic transplantation antigens (HLA-A, HLA-B, and HLA-C) that are expressed on virtually all nucleated cells.[17] Genes of the HLA class I loci encode the 44-kD heavy chains that associate with intracellular peptides present within the cytoplasm (Fig. 10-2). The tertiary structure is stabilized on the cell surface by noncovalent association with β_2-microglobulin, a nonpolymorphic 12-kD protein encoded on chromosome 15. The heavy chain consists of three extracellular immunoglobulin-like domains (α_1, α_2, and α_3), a hydrophobic transmembrane region, and a cytoplasmic tail. The two extracellular domains distal to the cell membrane (α_1 and α_2) are highly polymorphic and fold to form a peptide-binding cleft consisting of eight strands forming an antiparallel beta-pleated sheet, overlaid by two alpha helices (Fig. 10-3). The cleft accommodates peptides 8 to 10 amino acids long that are mostly derived from "endogenous" proteins present within the cell cytoplasm. The major areas of amino acid polymorphism line the sides and base of the cleft and govern the peptide-binding repertoire of the HLA molecule. In contrast, the α_3 domain (proximal to the cell membrane) is highly conserved and acts as a ligand for CD8 expressed on T lymphocytes.[88] This interaction confers HLA class I restriction on $CD8^+$ T lymphocytes, which have a predominantly cytotoxic function and form the basis for cellular immunity to intracellular pathogens such as viruses.

There are other class I loci, and knowledge about their expression and function is only beginning to emerge (Table 10-1). HLA-H, HLA-J, HLA-K, and HLA-L are pseudogenes and HLA-N, HLA-P, HLA-S, HLA-T, HLA-U, HLA-V, HLA-W, HLA-X, HLA-Y, and HLA-Z are gene fragments that are not transcribed or translated. HLA-G is expressed on placental trophoblast cells, implicating a possible involvement in fetal-maternal development. HLA-E, HLA-F, and HLA-G have limited polymorphism (9, 20, and 23 alleles) and are known to act as ligands for natural killer cell inhibitory receptors (e.g., CD94). These loci may prove to be important in certain experimental xenograft models and in bone marrow transplantation (where natural killer cells are involved in the rejection process), but they have not been shown to be relevant in clinical solid organ transplantation. There is, however, an emerging role for these molecules in innate immunity to persistent viruses such as cytomegalovirus, and they may prove to have an important role in post-transplant viral defense.

HLA Class II

The HLA class II region consists of three main loci, HLA-DR, HLA-DQ, and HLA-DP. The glycoprotein products are heterodimers with noncovalently associated alpha and beta chains of molecular weight 33 kD and 28 kD. Both chains have two extracellular immunoglobulin-like domains—a transmembrane region and a cytoplasmic tail (see Fig. 10-2). The distal membrane domains α_1 and β_1 form a peptide-binding cleft similar to, but less rigid than, that of HLA class I, accommodating peptides 10 to 20 amino acids long that are derived predominantly from ingested (endocytosed or phagocytosed) extracellular (exogenous) proteins. The β1 domains of HLA-DR, HLA-DQ, and HLA-DP are highly polymorphic and govern the peptide-binding repertoire.

Figure 10–1 Genomic organization of the HLA region on chromosome 6. HLA antigens are codominantly inherited en bloc as a haplotype from maternal and paternal chromosomes. Italic type indicates pseudogenes. Normal type indicates "nonclassic" HLA genes with no known role in clinical solid organ transplantation. Bold type indicates genes encoding HLA products with clinical relevance to solid organ transplantation.



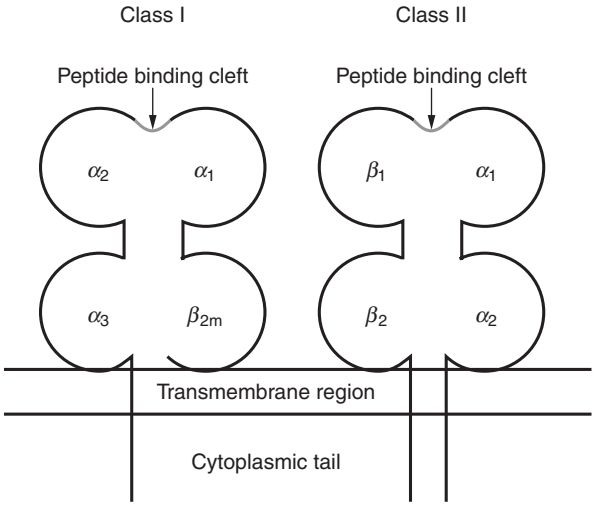


Figure 10–2 Schematic representation of the domain structure of HLA class I and class II.

They are constitutively expressed on cells with immune function, such as B lymphocytes, activated T lymphocytes, and antigen-presenting cells (monocytes, macrophages, and cells of dendritic lineage). HLA class II expression can be induced on most cell types during inflammatory responses (including allograft rejection) by cytokines such as interferon-γ and tumor necrosis factor-α.[18,28,29] The β_2 domain associates with CD4 on T lymphocytes with predominately helper/inducer function and confers HLA class II restriction (Fig. 10-4) and forms the basis of cellular and humoral immunity to circulating pathogens such as bacteria.

HLA Polymorphism and Nomenclature

Early investigations into HLA polymorphism used relatively crude alloantisera that were able to distinguish only a few antigens. There was international collaboration between HLA serologists to identify specificities defined by common sets of reagents, and a nomenclature system to denote these polymorphisms was devised in a series of International Histocompatibility Workshops. Nearly half a century later, these simple techniques have been complemented by molecular methods capable of resolving HLA variants at the DNA

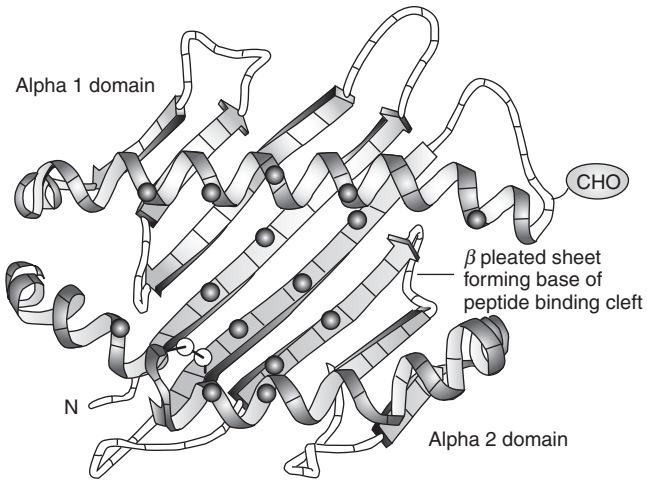

Figure 10–3 Ribbon diagram of the peptide-binding cleft of HLA class I. The peptide-binding cleft is formed by two alpha helix protein chains (alpha 1 and alpha 2) that overlay a beta-pleated sheet. The *boxes* indicate amino acid positions that form the protein structure, and as an example of the HLA polymorphism, the *dots* denote the amino acid residues that differ between two HLA-A specificities (HLA-A1 and HLA-A2) that line the base and sides of the peptide-binding cleft (and govern the peptide-binding repertoire for antigen presentation) and those that face the outer surface toward the T cell receptor (governing the self-restricted or alloreactive T cell specificity).

sequence level and identifying single amino acid polymorphisms that are indistinguishable by serology. For example, there are currently 19 HLA-DR specificities defined by serological methods compared with more than 450 sequence variants (alleles) detected using DNA-based typing methods. The number of newly defined alleles identified is still increasing rapidly and has now surpassed even the highest expectations of the early pioneers.

Concomitant with the ever-increasing complexity of the HLA region, a nomenclature system has been developed to assign accurately HLA loci and their alleles.[89] This nomenclature system encompasses the methodology (serology, biochemistry, and DNA sequencing) and level to which the HLA genes and their products have been resolved. The nomenclature is complex and, to individuals outside the field, can be confusing.

Resolution of HLA Typing Methods

Serologically based HLA typing uses alloantisera and monoclonal antibodies that bind to tertiary epitopes of the cell surface HLA glycoproteins. There is a high degree of sequence homology between HLA specificities, and identical amino acid sequence motifs are often shared between groups of antigens.[2,57] These related structures give rise to cross-reactivity because many HLA-specific antibodies bind epitopes that are shared between HLA specificities. Serologically detectable HLA epitopes that are common between different specificities are called public or supertypic determinants and form cross-reactive groups (CREGs), whereas epitopes that are unique to an antigen are termed private determinants. In some cases, antigens that were originally defined as single specificities could be subdivided into two or more specificities called splits. For example, some alloantisera were able to discriminate the broad HLA-A9 specificity into two subgroups, A23 and A24. These specificities are annotated as HLA-A23(9) and HLA-A24(9), where the A23 and A24 denote the split specificity and the number in parentheses (9) denotes the broad specificity.

The degree of HLA compatibility between transplant donors and recipients can be considered at many different levels of resolution, depending on the HLA typing method (Table 10-2); this can range from single amino acid differences detected by high-resolution, DNA sequence–based

Table 10–1 HLA Genes and Their Products

Name	Molecular Characteristics
HLA-A	Class I alpha chain
HLA-B	Class I alpha chain
HLA-C	Class I alpha chain
HLA-E	Associated with class I 6.2-kb Hind III fragment
HLA-F	Associated with class I 5.4-kb Hind III fragment
HLA-G	Associated with class I 6-kb Hind III fragment
HLA-H	Class I pseudogene
HLA-J	Class I pseudogene
HLA-K	Class I pseudogene
HLA-L	Class I pseudogene
HLA-N	Class I gene fragment
HLA-P	Class I gene fragment
HLA-S	Class I gene fragment
HLA-T	Class I gene fragment
HLA-U	Class I gene fragment
HLA-V	Class I gene fragment
HLA-W	Class I gene fragment
HLA-X	Class I gene fragment
HLA-Y	Class I gene fragment
HLA-Z	Class I gene fragment (located in HLA class II region)
HLA-DRA	DR alpha chain
HLA-DRB1	DR beta 1-chain determining specificities DR1 to DR18
HLA-DRB2	Pseudogene with DR beta-like sequences
HLA-DRB3	DR beta 3-chain determining DR52 found on DR17, DR18, DR11, DR12, DR13, and DR14 haplotypes
HLA-DRB4	DR beta 4-chain determining DR53 found on DR4, DR7, and DR9 haplotypes
HLA-DRB5	DR beta 5-chain determining DR51 found on DR15 and DR16 haplotypes
HLA-DRB6	DRB pseudogene found on DR1, DR2, and DR10 haplotypes
HLA-DRB7	DRB pseudogene found on DR4, DR7, and DR9 haplotypes
HLA-DRB8	DRB pseudogene found on DR4, DR7, and DR9 haplotypes
HLA-DRB9	DRB pseudogene, probably found on all haplotypes
HLA-DQA1	DQ alpha chain
HLA-DQB1	DQ beta chain determining specificities DQ1 to DQ9
HLA-DQA2	DQ alpha chain–related sequence, not known to be expressed
HLA-DQB2	DQ beta chain–related sequence, not known to be expressed
HLA-DQB3	DQ beta chain–related sequence, not known to be expressed
HLA-DOA	DO alpha chain
HLA-DOB	DO beta chain
HLA-DMA	DM alpha chain
HLA-DMB	DM beta chain
HLA-DPA1	DP alpha chain
HLA-DPB1	DP beta chain
HLA-DPA2	DP alpha chain–related pseudogene
HLA-DPB2	DP beta chain–related pseudogene
HLA-DPA3	DP alpha chain–related pseudogene

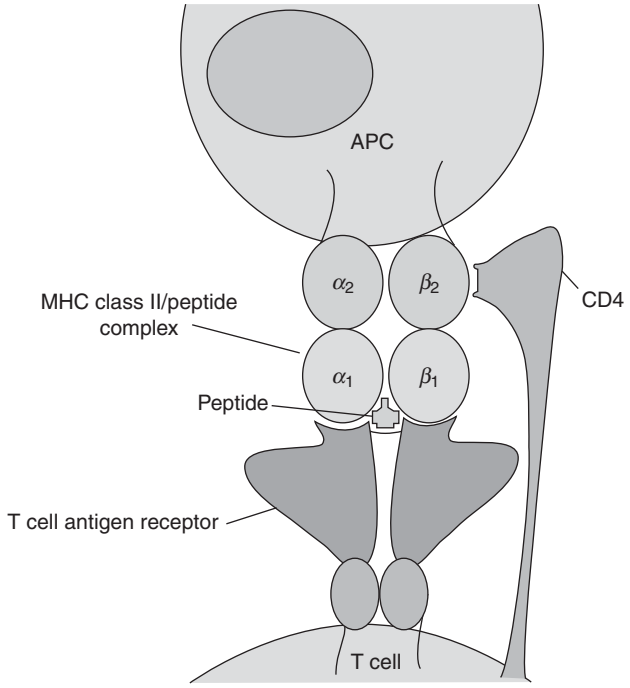

Figure 10–4 Cartoon diagram depicting the presentation of peptide by an HLA class II molecule on an antigen-presenting cell (APC) to the antigen receptor on $CD4^+$ T helper cells. (Redrawn from Taylor CJ, Metcalfe S: The Immunobiology of Organ Transplantation. In Klinck JR, Lindop MJ [eds]: Anesthesia and Intensive Care for Organ Transplantation. London, Chapman & Hall, 1998.) (See color plate.)

methods (allele matching) to broad and split specificity matching or matching for the small number of common CREGs. The influence of all levels of donor and recipient HLA compatibility has been considered in cadaver donor renal transplantation.[106] Although strongly implicated for negating graft-versus-host disease after unrelated bone marrow transplantation, a role for high-resolution allele matching in renal transplantation has not been firmly established. However, matching for serologically defined amino acids, specificities, and CREGs all have been reported to benefit transplant outcome.[49,101,120,126] Generally, the more discerning the matching criteria, the greater the correlation with graft outcome.

World Health Organization Nomenclature for HLA

Many HLA genes have been characterized and cloned and have been given official designations using the following principles. The genes are prefixed by the letters HLA followed by the loci or region (e.g., HLA-A, HLA-B, or HLA-D). The HLA-D region has several subregions denoted HLA-DR, HLA-DQ, HLA-DP, HLA-DO, and HLA-DM (see Fig. 10-1). These are followed by the letters A or B to define the gene encoding the alpha and beta chain gene product of that subregion, respectively (e.g., HLA-DRB genes code for the DR beta-chain protein product). Where there is more than one A or B gene within a subregion, a corresponding number is given (e.g., HLA-DRB1) (see Fig. 10-1 and Table 10-1).

Each allele has a unique 4-digit number prefixed by an asterisk (*) where DNA sequence–based information is available. The first 2 digits identify the broad specificity based on homology between allele "families." These digits usually correlate with the serological specificity, for instance HLA-B*27 correlates with the serological specificity HLA-B27. For most serologically defined antigens, there is further polymorphism, however, detectable at the DNA and amino acid sequence level. Where sequence information is available, the third and fourth digits denote the precise allele. For example, there are 35 subtypes (allele variants) of HLA-B27 involving amino acid substitutions at 23 positions. These are represented as HLA-B*2701, HLA-B*2702, and so forth. In cases where a DNA base change does not alter the amino acid sequence (termed silent substitution or synonymous variants), fifth and sixth digits are applied to differentiate the noncoding base change (e.g., HLA-DQB1*050301 and HLA-DQB1*050302).

Some alleles or genes contain a sequence defect that prevents normal antigen expression at the cell surface. Nonexpressed alleles (null alleles) are indicated using the suffix "N" (e.g., HLA-DRB4*010301N), whereas alleles with low expression or soluble (secreted) alleles carry the suffix "L" or "S." Further mutations have been detected outside the coding region, and additional digits have been added to indicate these intronic polymorphisms (e.g., HLA-DRB4*01030102N, HLA-A*24020102L, HLA-B*44020102S).

The HLA-DR and HLA-DP alpha chains are less polymorphic (DRA is diallelic), and the HLA-DRB1 or HLA-DPB1 allele (which code for the main polymorphic amino

Table 10–2 **Resolution of HLA Typing Methods and Their Application to Renal Transplantation**

HLA Typing Resolution	Method
HLA allele matching	High-resolution DNA sequence-based typing*
Split HLA specificity matching	Serology and low-resolution (generic) DNA typing†
Broad HLA specificity matching	Serology and low-resolution (generic) DNA typing
HLA-B, HLA-DR matching	Serology and low-resolution (generic) DNA typing
Epitope matching	Serologically defined cross-reactive groups
	Serologically defined motifs/determinants
	Single amino acid residues
	Linear peptides and conformational epitopes
	Supertypic antigen matching
	Triplet amino acid mismatches (HLA Matchmaker)

*High-resolution DNA typing can be translated into low-resolution serological equivalents (allele families).

†Low-resolution HLA typing by polymerase chain reaction uses DNA primers designed to identify polymorphisms at a level comparable to serology.

Adapted from Taylor CJ, Dyer PA: Maximising the benefits of HLA matching for renal transplantation: alleles, specificities, CREGs, epitopes or residues? Transplantation 68:1093-1094, 1999.

acid determinants present on the beta chain) is usually annotated alone. In contrast, both the HLA-DQ alpha and beta chains are polymorphic. To describe one of these alleles precisely, definition of both the A and the B alleles may be required (e.g., HLA-DQA1*0101 and HLA-DQB1*0501). Although the alpha and beta chain protein products of the A and B gene pairs associate preferentially, there is also the possibility of the formation of novel hybrid molecules (e.g., HLA-DRA and HLA-DQB1*0402). A complete list of recognized HLA genes and their expressed products can be found at www.bmdw.org (Bone Marrow Donors Worldwide; HLA information).

Extended HLA Haplotypes

The HLA region displays strong linkage disequilibrium whereby certain HLA alleles are inherited together as a conserved HLA haplotype. Extended HLA haplotypes involving HLA-A, HLA-B, HLA-C, HLA-DR, and HLA-DQ commonly exist within and between ethnic groups. The probability of locating an HLA-matched unrelated donor is greatly improved because common HLA haplotypes are frequently found within a population (e.g., HLA-A*0101, HLA-B*0801, HLA-C*0701, HLA-DRB1*0301, HLA-DRB3*0101, HLA-DQA1*0501, HLA-DQB1*0201).[108] These extended haplotypes also involve the class III region with the previous example being linked to the tumor necrosis factor-α promoter polymorphism (TNFA2) associated with increased production of this proinflammatory cytokine. Linkage within the HLA class I region has been extended a further 4 Mb telomeric to HLA-A, to the class I–like gene *Hfe*. A point mutation that substitutes cystine or tyrosine at position 282 of the Hfe protein is the major cause of hereditary hemochromatosis and explains the weaker association of this disease observed with HLA-A3 more than 20 years ago. There is only relatively weak linkage centromeric to HLA-DQ because of a recombination "hot spot" between HLA-DQ and HLA-DP.

HLA on the Web

Information concerning the HLA system is rapidly expanding, and articles are always out of date by the time they go to print. Numerous Internet websites with useful links are regularly updated, however. The following websites provide contemporary articles and information concerning HLA genes, nomenclature, polymorphism, DNA, and amino acid sequences for lay and professional readers:

www.bmdw.org
www.ashi-hla.org/index.htm
www.bshi.org.uk
www.efiweb.org

www.sanger.ac.uk

HLA MATCHING

It was first noted 40 years ago that HLA matching between donor and recipient was associated with better transplant and patient survival.[62,79,110] Matching for the class I HLA-A and HLA-B antigens influenced survival, but matching for the class II HLA-DR antigens had the most powerful effect.[116,117] Over the years, there has been an overall improvement in transplant survival and a decrease in the survival advantage conferred by HLA matching.[11,62] The improvement can be attributed to numerous factors, but one of the most powerful is advancement in the potency of immunosuppression. This was clearly demonstrated in a local comparison of transplant survival in patients receiving azathioprine and prednisolone; cyclosporine and prednisolone; and cyclosporine, azathioprine, and prednisolone triple therapy: 1-year transplant survival rates were 65%, 69%, and 81% respectively.[104] In this analysis, HLA-DR compatibility still had a marked effect on the post-transplant clinical course, with an increased incidence of rejection in HLA-DR–mismatched grafts, the socioeconomic effects of which were increased use of immunosuppressive drugs, longer hospital stays, and higher 3-month creatinine levels.[105]

A beneficial effect of HLA matching still can be shown in analyses of large datasets and national and international databases,[11,52,75] but as already discussed, the genes of the HLA region are highly polymorphic, and HLA typing can be performed at many different levels of resolution. In solid organ transplantation, the effects of HLA matching reported are generally based on matching at the HLA-A, HLA-B, and HLA-DR loci, but the definition of a match may vary according to whether matching is considered only at the level of "broad" specificities, or whether the associated "splits" also are considered. For example, a donor and recipient who type as HLA-A2, HLA-A24(9) and HLA-A2, HLA-A23(9), where HLA-A23 and HLA-A24 are both splits of HLA-A9, may be considered to have no HLA-A mismatches at the broad antigen level, but as having one mismatch at the split antigen level. Reports have suggested an additional benefit of matching at the split antigen level.[75] The effects of matching other HLA loci have been analyzed. Matching for HLA-DQ has been variously reported as having either a beneficial effect[121] or no effect on transplant outcome.[7,27] Registry analysis has shown that HLA-DPB matching has an effect on the transplant survival of regrafts, but not of first transplants[70]; a report has shown this effect to result from matching for certain immunogenic HLA-DPB epitopes.[51]

Analyses of the effects of matching at the level of the CREGs have been performed, but the conclusions regarding the benefit on outcome are conflicting.[60,93,96,98,126] This conflict may be partly because of the complexity in the serological cross-reactions, whereby the antigens can be grouped in slightly different ways, and the grouping used differs between analyses. Furthermore in these analyses, a proportion of the CREG-matched transplants also are matched for HLA-A, HLA-B, and HLA-DR in a conventional sense, and this may explain an observed benefit of matching CREGs.[52,106]

In analyzing the effect of HLA on transplant outcome, it is important that other factors known to have a strong influence on outcome are taken into account. In a rigorous multivariate analysis of factors influencing the outcome of primary deceased donor transplants in a cohort of transplants performed in the United Kingdom from 1986 to 1993, the year of transplant, donor and recipient age, waiting time to transplant, diabetes in the recipient, donor cause of death, exchange of kidneys, cold ischemia time, and HLA mismatching were found to influence transplant survival (death with function treated as failure). The best transplant survival was achieved in transplants that had no mismatches at HLA-A, HLA-B, and HLA-DR (000 mismatch grade). Other well-matched transplants, termed *favorably matched* transplants,

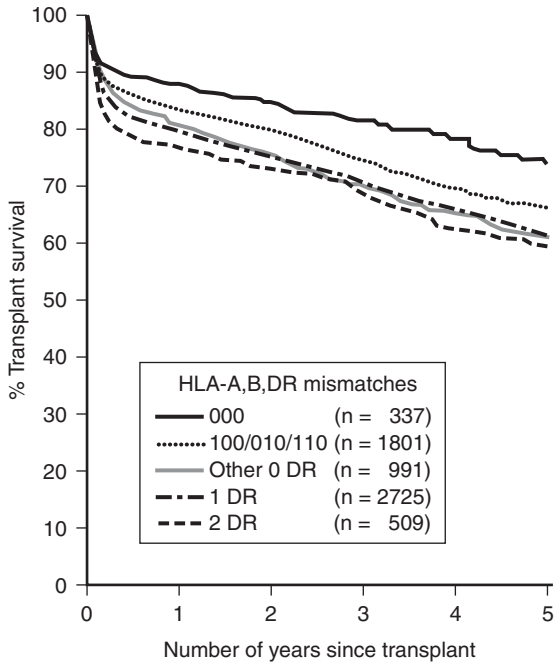

Figure 10–5 Survival of first cadaver renal allografts by HLA match grade. The curves differ significantly ($P = .0001$). (From Morris PJ, Johnson RJ, Fuggle SV, et al: Analysis of factors that affect outcome of primary cadaveric renal transplantation in the UK. Lancet 354:1147, 1999.)

with a maximum of one HLA-A and one HLA-B antigen mismatched in the absence of mismatches at HLA-DR (110, 100, and 010 mismatch grades) had a significantly improved survival over transplants of all other match grades (Fig. 10-5).[68] An analysis of factors influencing the long-term outcome of these transplants revealed that for patients with transplants functioning after 6 years, only older donor age and diabetes had a significant detrimental influence on survival.

The influence of HLA mismatch on outcome of first deceased donor transplant has been investigated in a more recent cohort of patients in the United Kingdom, transplanted between 1995 and 2001. As a result of the allocation policy, the more recent transplants were significantly better matched than the previously analyzed cohort (1986 to 1993), where 46% transplants were 0 DR mismatched, and 10% had 2 DR mismatches compared with 60% 0 DR mismatched and only 3% 2 DR mismatches in the 1995 to 2001 cohort. In a multivariate analysis, there was no longer an effect of HLA-A mismatching, but the levels of HLA-B and HLA-DR mismatching were statistically significant: level 1, 000 mismatches; level 2, 0 DR and 0/1 B mismatches (relative risk 1.06, 95% confidence interval 0.87-1.30); level 3, 0 DR and 2 B or 1 DR and 0/1 B mismatches (relative risk 1.22, 95% confidence interval 0.99-1.49); level 4, 1 DR and 2 B or 2 DR mismatches (relative risk 1.41, 95% confidence interval 1.11-1.80).

In many countries, HLA matching is one of the factors considered in the allocation of kidneys. There has been considerable discussion about HLA matching and the allocation of organs, and this has been the subject of numerous reviews and articles.[23,31,44,56,69,100,119] One disadvantage of allocation based on HLA matching is that patients with rare HLA types are difficult to transplant. The allocation scheme in the United Kingdom has been revised recently, and although HLA matching is still an important feature, the scheme contains factors to increase access to transplantation for patients with rare HLA types. One feature is to decrease the number of specificities used for matching by defaulting HLA-A, HLA-B, and HLA-DR specificities with a frequency of less than 2% in the donor population to a more frequent counterpart, based on serological and sequence similarity. For example, on the United Kingdom transplant waiting list, 0.2% of patients are HLA-A36, a specificity found in 0.05% of United Kingdom donors. By mapping HLA-A36 to its closest common counterpart HLA-A1, HLA-36 typed patients have access to HLA-A1 donors, which constitute 18% of the donor pool. The simulations of transplant activity suggest that this strategy will increase the transplant rate for the most difficult-to-match patients by 11% and for ethnic minority patients by 14%. The strategy was incorporated into the allocation scheme implemented in April 2006, and the early results suggest the strategy is effective in achieving transplants for these patients.

SENSITIZATION

Routes of Sensitization

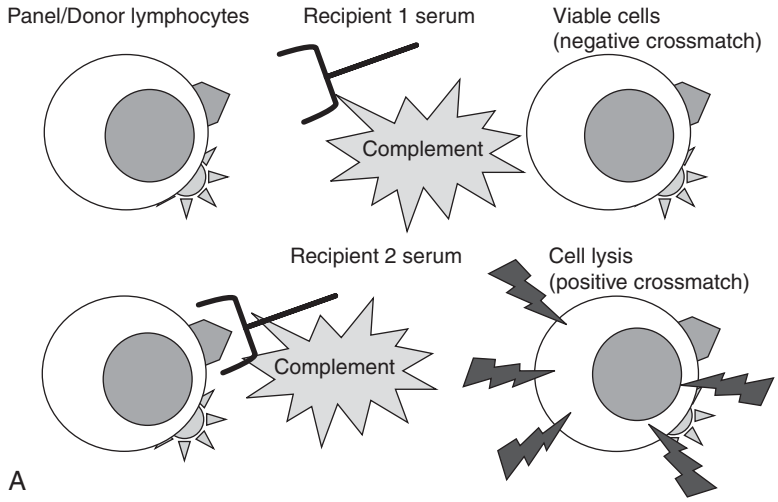
An individual can become sensitized to HLA alloantigens as a result of blood transfusion, pregnancy, or previous organ transplantation. Transplantation of poorly HLA-matched kidneys can result in allosensitization to the mismatched HLA antigens. In the United Kingdom, an audit of the national transplant waiting list showed that 20% of patients waiting for a first transplant were sensitized, but 77% of patients waiting for a second transplant were sensitized.[32] Approximately 20% of pregnant women produce HLA-specific antibodies to paternally derived fetal HLA antigens. The use of erythropoietin for the treatment of patients with anemia has decreased the use of blood transfusion in renal patients with a consequent decrease in the number of patients becoming sensitized by this route. It would be expected that the use of leukocyte-depleted blood would prevent allosensitization, but there is evidence to suggest that this is not the case.[123] Furthermore, HLA-specific antibodies may be detected in patients who have not been exposed to these classic routes of sensitization. These idiopathic HLA antibodies may result from cross-reactivity with infectious agents and are usually IgM.

Antibody Detection and Specificity Definition

In recent years, there have been significant advances in the technology for the detection and definition of HLA antibodies, and these can be used to define precisely the specificity of HLA antibodies in serum samples and to elucidate a patient's sensitization profile. The available technologies are briefly described next.

Complement-Dependent Cytotoxicity

Complement-dependent cytotoxicity (CDC) was the first technique routinely used for HLA antibody detection and for the crossmatch test (Fig. 10-6). In this assay, lymphocyte target cells are used to detect complement-fixing IgG and IgM antibodies present in patient's serum samples after the addition of rabbit complement. IgM antibodies can be



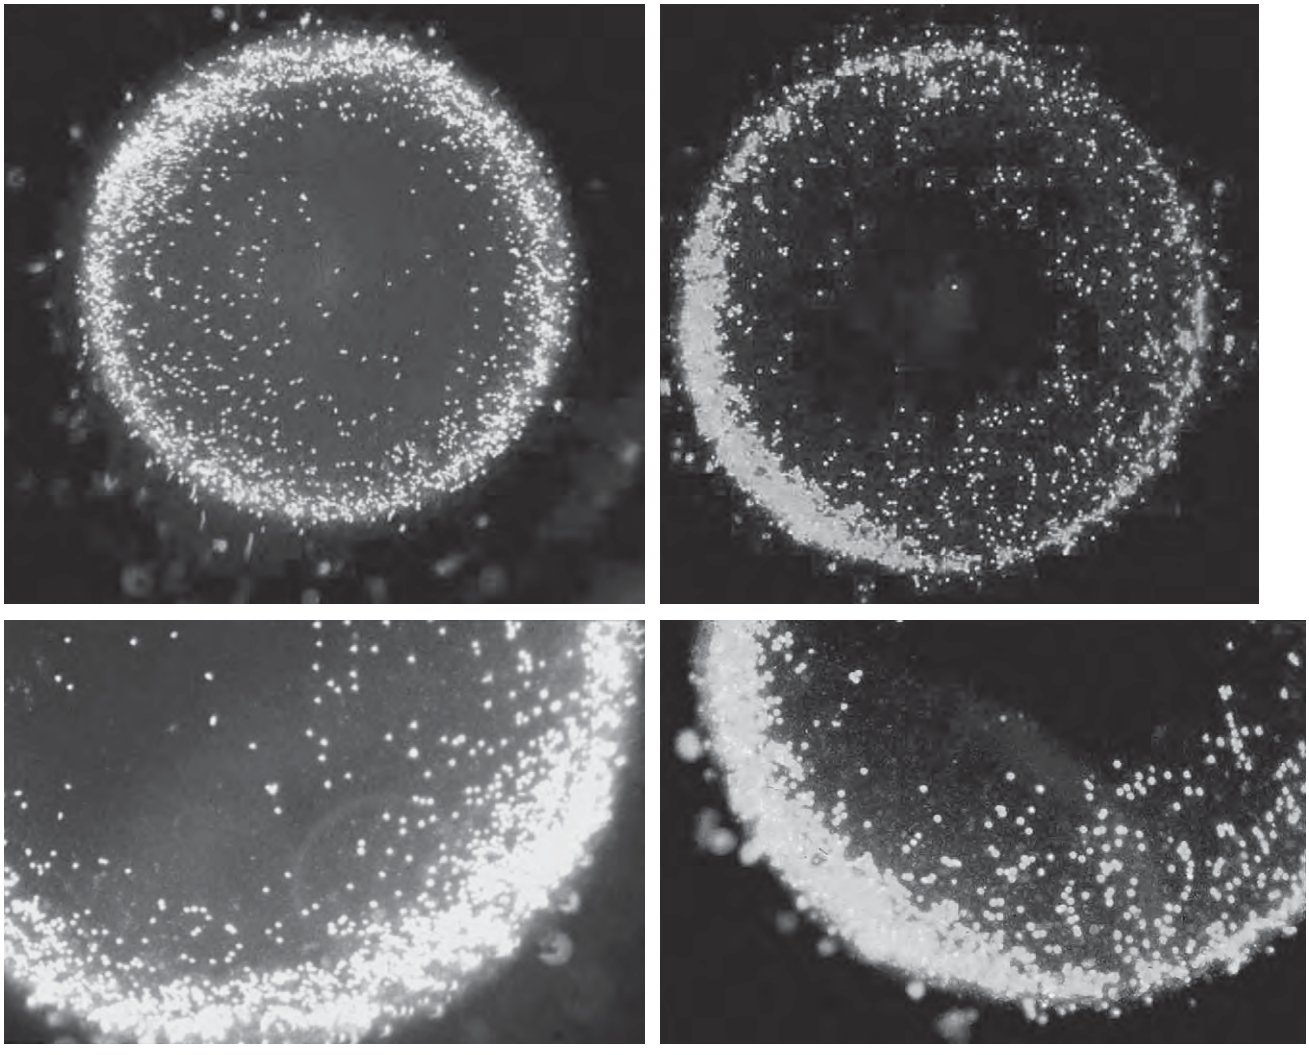


Figure 10–6 **A,** Lymphocytotoxic crossmatch test. Panel or donor lymphocytes are incubated with recipient serum in the wells of a microtiter (Terasaki) tray, followed by the addition of rabbit complement. After a second incubation period, vital stains (e.g., acridine orange and ethidium bromide) are added, and the wells are viewed using fluorescent (ultraviolet) microscopy to determine cell viability. **B**, Lymphocytotoxic (complement-dependent cytotoxicity) crossmatch results. *Left*, Viable lymphocytes take up acridine orange and appear a yellowish orange color (negative crossmatch). *Right*, Lysed cells (have pores in the lymphocyte cell membrane caused by antibody binding and complement activation) take up ethidium bromide and appear a brown color (positive crossmatch). (See color plate.)

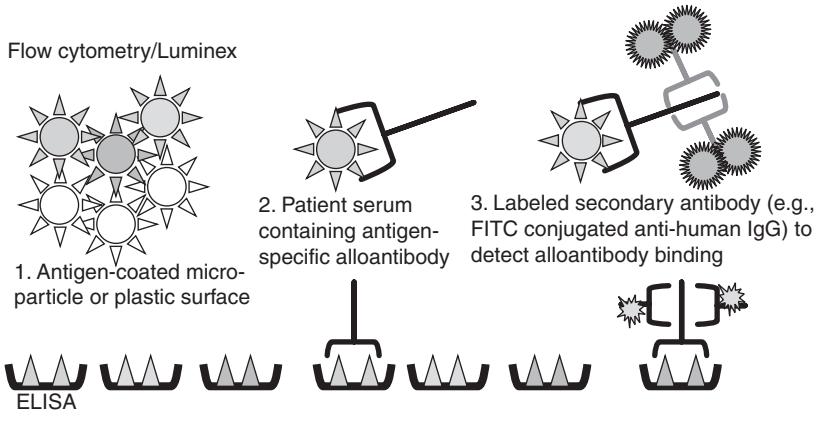
differentiated from IgG antibodies by the use of dithiothreitol (DTT). DTT reduces the disulfide bonds in the IgM pentamer and consequently renders negative a reaction due to IgM. Serum samples are tested against panels of cells that can be "random" or alternatively can be "selected" to represent the spectrum of HLA types in the population. The technique can be used for specificity definition, but the results are often expressed as the percentage of the panel to which the sample has reacted (% panel reactive antibody [%PRA]). This term has limited value, and its use is now strongly discouraged because the figure entirely depends on the composition of the panel used for testing. If a patient has a monospecific antibody to a specificity that is common in a population, and a random panel is used, the %PRA is high, but if the panel has been carefully selected to cover rare and common specificities, the %PRA value for the same antibody may be low. Values for %PRA cannot be compared between panels or laboratories.

There are other limitations of the CDC technique. Only complement-fixing antibodies are detected, and the sensitivity of the technique depends on the viability of the target cells and the particular batch of rabbit complement used. Both HLA and non-HLA antibodies are detected. Although the use of DTT can differentiate IgM from IgG antibodies, this does not indicate the specificity of the antibody. Reactivity resulting from an IgM HLA-specific antibody would be indistinguishable from reactivity of an IgM autoreactive antibody. Autoantibodies are frequently weak or nonreactive with lymphocytes from patients with chronic lymphocytic leukemia, however, and including these cells in a panel can be useful in elucidating a patient's antibody profile.[118] Alternatively, serum samples can be preabsorbed with autologous cells to remove autoreactive antibodies, before screening for alloreactivity.

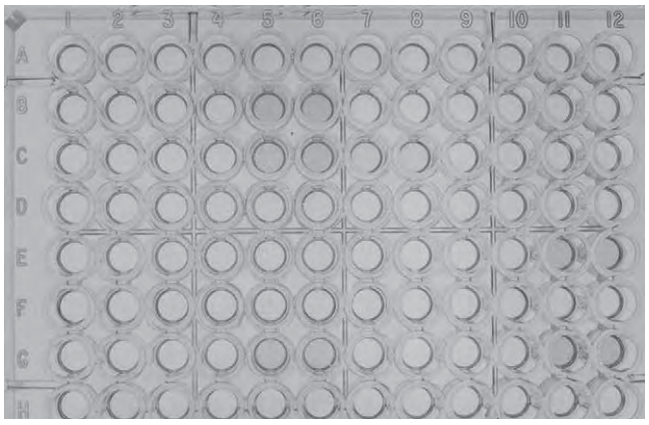
There have been a number of approaches used to increase the sensitivity of the CDC test, including increasing the incubation times, the wash (Amos) technique, and augmentation with antihuman globulin. In the Amos technique, unbound serum is washed from the cell suspension before the addition of rabbit complement, removing the anticomplement factors in the serum. In the antihuman globulin augmentation CDC test, anti–kappa light chain is added to the washed cells before the addition of complement. The techniques that include wash steps preferentially detect IgG antibodies because the lower affinity IgM antibodies become detached during the washing process.

Enzyme-Linked Immunosorbent Assays

The targets in an enzyme-linked immunosorbent assay (ELISA) are soluble HLA antigens coated onto plastic, and this is termed a *solid-phase assay* (Fig. 10-7). These commercially available kits have immediate advantages over CDC in that the test does not rely on viable cells, and only HLA antibodies are detected. The overall sensitivity of ELISA is greater than CDC. Two different types of ELISA are routinely used—assays to detect the presence or absence of HLA antibodies that can be used as a prescreen of a patient's



A



B

Figure 10–7 **A,** Schematic representation of antibody screening using solid-phase binding assays (enzyme-linked immunosorbent assay [ELISA] and flow cytometry/Luminex). *1*, Purified HLA proteins (either pooled HLA specificities or single antigen specificities) coated onto a solid phase (microtiter tray [ELISA] or microparticles [flow cytometry/Luminex]) are incubated with patient serum. *2*, HLA-specific antibodies bind to the antigen-coated solid phase, and nonspecific antibodies are washed off. *3*, IgG HLA-specific antibodies bound to the antigen-coated solid phase are detected using a conjugated (e.g., alkaline phosphatase [ELISA] or fluorescein isothiocyanate [FITC] [flow cytometry/Luminex]) anti–human IgG secondary antibody and detected by colorimetric analyses (ELISA, e.g., using p-nitrophenyl phosphate) or fluorescent signal (flow cytometry/Luminex after excitation by a laser). **B**, Example of HLA-specific antibody screening by ELISA. The plastic surface of each well in the microtiter tray is coated with pooled HLA specificities. Patient serum containing IgG HLA-specific antibodies is determined and quantified by colorimetric analyses (brown denotes a positive result). (**B**, See color plate.)

serum sample and assays that are designed for antibody specification. The assays have been shown to be reliable for the detection of IgG antibodies, but less so for the detection of IgM, probably because of the washing steps required and the lower affinity of IgM antibodies.

Flow Cytometry

The original use of flow cytometry in antibody screening was as a test to determine the presence or absence of antibody. Pools of HLA-typed target cells from chronic lymphocytic leukemia patients,[43] lymphoblastoid cell lines,[42,54] or peripheral blood lymphocytes,[92] constructed to cover the most frequent HLA specificities and cross-reactive groups, have been used. Flow cytometry is more sensitive than CDC and primarily detects IgG antibodies; this offers the advantage that IgM autoreactive antibodies are not detected. Although less frequent, however, IgG autoreactive antibodies will be detected by this method.

There have been advances in commercial products for antibody detection and specification with the development of antigen-coated microparticles (see Fig. 10-7). Kits of microparticles allow the detection of HLA-A, HLA-B, HLA-Cw, HLA-DR, HLA-DQ, and HLA-DP antibodies, and exquisitely specific microspheres coated with a single antigen can be purchased to elucidate highly complex antibody profiles.[78] These assays are more sensitive than CDC; they primarily detect IgG, but also can be modified to detect IgM.[47] A further development is an assay that uses multiplexed microparticles and allows the simultaneous detection and specification of multiple antibodies in a serum sample.[33] Many laboratories are rapidly gaining experience with this technology, although the precise relationship between antibodies identified using such sensitive techniques compared with conventional methods and their clinical relevance has not been fully evaluated.

Antibody Screening Strategies

The aim of an antibody screening strategy is to determine whether the patient has developed HLA alloantibodies and, if so, the antibody class and specificity of the antibodies. All laboratories supporting renal transplantation have an antibody screening strategy, but may use different approaches and technologies to achieve the goal. One common strategy, because many patients are unsensitized, is to screen samples first with a sensitive method to detect the presence of HLA antibody and then to perform further testing and analysis to determine the specificity of the antibodies in samples that are positive. To perform effective antibody screening, samples should be obtained regularly from patients on the waiting list, on at least a 3-monthly basis. Information about the nature and timing of potential sensitizing events is important in a patient's sensitization profile. If sensitization occurs, additional samples are required (e.g., 14 and 28 days after a transfusion with blood products).[6]

Patient Sensitization Profile and Definition of Unacceptable Specificities

The cumulative information obtained from an antibody screening program, together with knowledge of the potential sensitizing events, enables the laboratory to develop a sensitization profile for patients on the transplant waiting list. The sensitization profile is based on the complete sensitization history for the patient and includes the timing of appearance or disappearance of antibody reactivity, the specificity and antibody class of HLA antibodies, and the presence or absence of autoreactive antibodies.

The characterization of HLA antibody specificities for a patient enables the definition of unacceptable HLA mismatches in a donor. HLA mismatches from a previous transplant and mismatched paternal specificities in multiparous women also may be considered unacceptable specificities. In countries and regions where there is exchange of kidneys, these unacceptable specificities are registered with the Organ Exchange Organisation and facilitate efficient allocation of organs and prevent unnecessary shipping of organs to patients where the crossmatch would be positive. All of the information obtained through regular antibody screening of patients awaiting transplantation is crucial in interpreting the results of a crossmatch test and in assessing the immunological risk of transplantation for a patient.

DONOR CROSSMATCH

Kidney transplantation in patients with donor-specific sensitization has a significant detrimental impact on graft survival, with most transplants undergoing hyperacute or acute humoral rejection. Recipient antibodies against donor histocompatibility antigens bind to the vascular endothelium of the transplanted organ, which disrupts the intercellular junctions and causes release of cell surface heparin sulfate and loss of the antithrombotic state, leading to rapid uncontrollable activation of the thrombotic and complement cascades. The resultant intravascular coagulation and interstitial hemorrhage can lead to graft destruction within minutes or hours after revascularization.

Hyperacute allograft rejection was first reported in the 1960s and was associated with recipient antibodies that agglutinate donor leukocytes, whereas recipients with no detectable antibodies had a good prognosis. The donor leukocyte agglutination assay was soon replaced by the more robust CDC assay, in which recipient serum is incubated with donor lymphocytes in the presence of complement followed by the addition of vital dyes to visualize cell lysis (see Fig. 10-6B). Using these techniques, in 1965, Terasaki and colleagues[110] reported a case of immediate failure of a kidney transplanted from a brother to a sister who had lymphocytotoxic donor-reactive antibodies. A year later, Kissmeyer-Nielsen and colleagues[48] reported a series of 21 consecutive kidney allografts, with 2 cases of immediate failure (which they termed HAR) in multiply-transfused and multigravid recipients who had high-titer (1:512) donor leukocyte agglutinating antibodies. This report was soon followed by seminal papers from Terasaki and colleagues[111] and Williams and colleagues[124] with larger series of transplants (218 and 132 transplants, respectively), each with seven cases of HAR, all having circulating pretransplant donor reactive cytotoxic antibodies. Patel and Terasaki[77] concluded that "the ethics of transplanting kidneys without prior knowledge of the crossmatch test, or across a known positive crossmatch result can reasonably be expected to be questioned in the face of this evidence." This statement established a mandate to perform a prospective pretransplant crossmatch, and the dogma arose that a positive crossmatch was an absolute contraindication to transplantation.

Crossmatch Techniques and Their Clinical Relevance

Complement-Dependent Lymphocytotoxic Crossmatch

The donor lymphocytotoxic crossmatch using the CDC techniques was established in the 1960s and has remained a cornerstone for determining donor and recipient compatibility. The standard National Institutes of Health crossmatch technique involves the incubation of donor lymphocytes isolated from peripheral blood, lymph node, or spleen with recipient sera in the wells of a microtiter (Terasaki) tray, followed by the addition of rabbit serum as an exogenous source of complement (see Fig. 10-6A). Recipient cytotoxic antibodies (predominantly IgM, IgG3, and IgG1) that bind donor cells cause activation of the classic complement pathway resulting in cell lysis, the extent of which can be quantified by the addition of vital stains and determination of viability by microscopy (see Fig. 10-6B). A high percentage of cell death above background levels is interpreted as a "positive crossmatch" with the potential to damage a transplanted kidney. Ensuring a negative pretransplant lymphocytotoxic crossmatch using this basic technique has virtually eliminated HAR, but in its simplest form the CDC crossmatch carries several major drawbacks and has been subject to many modifications.

During the 1970s, it emerged that not all lymphocytotoxic antibodies that cause a positive crossmatch are specific for donor histocompatibility antigens, and that some antibodies display autoreactivity, causing in vitro lysis of the patient's own cells in the CDC assay. In 1976, Stastny and Austin[97] reported a successful transplant using an HLA-identical sibling donor with a positive autologous and donor lymphocyte crossmatch. Larger studies confirmed that a positive crossmatch caused by non-HLA (autoreactive) lymphocytotoxic antibodies could be safely ignored,[16,83,115] with transplant survival rates being equivalent to, or even higher than, transplants with a negative crossmatch.[19] Taylor and colleagues[103] characterized these autoantibodies as polyreactive IgM, capable of low-affinity binding to multiple antigens owing to weak electrostatic interactions.[103] Depending on antibody titer or affinity or both, the antigens may display in vitro cytotoxicity to autologous and third-party (panel) B lymphocytes alone, or T and B lymphocytes, and are often negative or only weakly reactive with B lymphocytes from patients with chronic lymphocytic leukemia.

The good sensitivity but poor specificity of the CDC assay in preventing HAR prompted numerous technical modifications. These included the Amos wash technique, which removed nondamaging low-affinity IgM antibodies and anticomplement immune complexes and was effective at improving the assay specificity. It was noted, however, that sensitized patients and patients receiving a regraft had a higher incidence of primary graft nonfunction or delayed graft function and poorer graft survival, despite a negative donor lymphocytotoxic crossmatch. This poor outcome was assumed to be caused by low antibody levels below the threshold of detection of the standard National Institutes of Health CDC assay, or by noncomplement fixing antibodies (e.g., IgG2 and IgG4) that are not detected by CDC. Two further modifications were introduced to address this: extended postcomplement incubation times (increased from 1 hour to 2 hours), and the addition of antihuman globulin to enhance the detection of low-level IgG bound to donor cells. Although inconclusive, these modifications were perceived as beneficial, particularly in sensitized patients and second grafts, and were widely adopted in Europe and North America.

B Cell Crossmatch

Further advances came with the discovery by Ting and Morris in 1978[116] of the strong effect of HLA-DR matching on graft outcome that prompted investigators to consider the clinical relevance of HLA-DR–specific antibodies in rejection. Numerous studies were undertaken using separated donor B lymphocytes (that express HLA class I and class II) as targets in the crossmatch test. The results of the analyses were contradictory and ranged from showing no effect, enhanced graft survival, and poor graft survival. These findings now can be explained by the heterogeneous antibodies that cause a positive B cell crossmatch. Most studies did not differentiate between nondamaging (autoreactive) and potentially harmful (HLA specific) B lymphocyte–reactive antibodies. The clinical interpretation of a B cell crossmatch result is impossible without definition of the specificity of the antibody; d'Apice and Tait[20] showed that most positive donor B cell crossmatches are not caused by HLA-DR–specific antibodies. In the studies where antibody specificity was defined, it was clear that most positive B cell crossmatches are caused by non–HLA-specific, usually B cell–autoreactive, antibodies that are not harmful to a transplant. A minority of positive B cell crossmatches are caused by HLA class II–specific antibodies that can be deleterious to transplant outcome, but are unlikely to cause HAR. The presence of unusually high-titer HLA-DR–specific antibodies can cause HAR, however, and such antibodies are more common in patients with previous graft rejection.[1,4,65,91]

Further indirect evidence of the importance of HLA class II–specific sensitization and the B cell crossmatch is indicated by the poor survival of HLA-DR–mismatched regrafts, most of which were performed with no knowledge of the patient's HLA class II sensitization status or the pretransplant donor B cell crossmatch result. In contrast, in single-center and larger multicenter reports in which detection of HLA class II–specific sensitization and performing a pretransplant donor B cell crossmatch is routine, regraft survival is equivalent to that of primary grafts.[104]

Crossmatch Serum Sample Selection (Timing)

An essential feature of the immune system is immunological memory and its ability to produce a rapid and vigorous secondary response on re-exposure to antigens to which an individual is already primed. To avert the risk of rejection caused by an anamnestic memory response, crossmatch regimens include serum samples obtained throughout a recipient's time on the transplant waiting list, selected to represent peak periods of sensitization. The introduction of calcineurin-based immunosuppression in 1982 prompted Cardella and colleagues[10] to question the relevance of "historical" allosensitization in patients in whom antibody levels had declined over time. They reported a series of 15 transplants in which the donor crossmatch was positive using noncurrent (historical) serum samples, but negative using serum obtained at the time of transplantation (so-called peak positive current negative), with graft survival rates (60% at 1 year) equivalent to their negative

crossmatch transplants. Similar outcomes were confirmed by other groups, and many concluded that memory B cell responses were short-lived and could be adequately controlled by immunosuppression. A significant proportion of transplants still underwent irreversible acute rejection, however, and past donor reactive sensitization was particularly associated with poor regraft survival.

Immunoglobulin Class and Specificity

The aforementioned findings of acceptable primary graft survival, but poor regraft survival associated with an historical positive crossmatch prompted further modification of the CDC crossmatch assay to identify the immunoglobulin class and specificity of antibodies causing a positive crossmatch. Patient crossmatch serum was preincubated with a reducing agent (2-mercaptoethanol and DTT) to distinguish IgM and IgG antibodies in the donor CDC crossmatch assay.[3,12] In addition, Taylor and colleagues[102] defined the antibody specificity (HLA-A, HLA-B, HLA-C, HLA-DR, and HLA-DQ) using a cytotoxicity inhibition assay to distinguish accurately between HLA class I–specific, HLA class II–specific, and non-HLA–specific antibodies causing a positive donor T cell or B cell (or both) crossmatch. The studies found acceptable primary and second graft survival associated with historical IgM HLA-specific sensitization, but poor graft survival with historical IgG HLA-specific antibodies. These results indicated that past allosensitization events that resulted only in a transient primary response and IgM alloantibody production could be readily controlled by conventional cyclosporine-based immunosuppression, whereas secondary responses (denoted as IgG positive) that commonly occur after pregnancy and previous transplant rejection indicate immunological priming accompanied by T cell and B cell memory that is poorly controlled by immunosuppression. A number of studies provided corroborative evidence that historical DTT-resistant (IgG), CDC-positive crossmatches were immunologically high risk, whereas IgM alloantibodies could be safely ignored and the use of DTT has been widely adopted in the donor crossmatch assay.[109]

Flow Cytometry Crossmatch Test

Although the CDC crossmatch was effective at averting HAR, a number of transplants still had primary nonfunction or delayed graft function, and this was particularly prevalent in sensitized patients and regrafts. This indicates that early graft dysfunction in sensitized recipients may be caused by low levels of antibody, below the sensitivity threshold of the conventional CDC crossmatch. Garovoy and colleagues[34] addressed this question using a flow cytometry crossmatch test (Fig. 10-8) capable of detecting weak IgG antibodies that were undetectable by CDC. In this retrospective study, there was a higher incidence of delayed graft function and graft failure

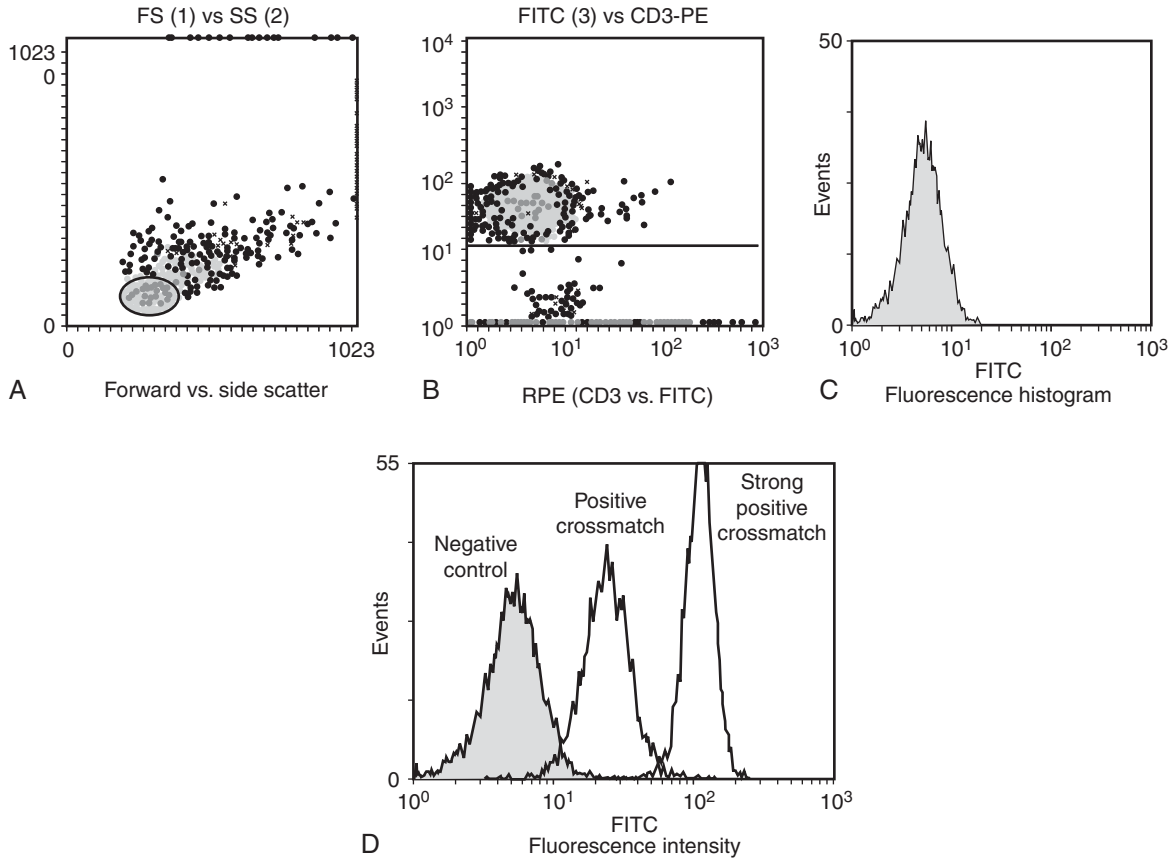


Figure 10–8 Flow cytometry crossmatch test. **A**, Cells pass through a laser beam, and "forward and side light scatter" (FS and SS) is detected by photomultiplier tubes. An "electronic gate" is used to select cells of morphological interest (in this case, lymphocytes). **B**, T lymphocytes are identified using a recombinant phycoerythrin (RPE)–labeled CD3-specific antibody, and HLA-specific IgG bound to cells is identified with fluorescein isothiocyanate (FITC)–labeled antihuman IgG. **C**, Light emission is detected and displayed as a "fluorescence histogram." **D**, Increased FITC fluorescence (a shift to the right on the fluorescence histogram) is a measure of HLA-specific IgG bound to T lymphocytes above that of the negative control indicating a positive crossmatch. (See color plate.)

in the presence of a pretransplant flow cytometry–positive (but CDC-negative) donor crossmatch, indicating a pathogenic role for weak, sublytic, HLA-specific antibodies. Other studies quickly corroborated this finding, but a significant proportion of patients had an uneventful clinical course, despite a positive flow cytometry crossmatch. These data showed a high sensitivity, but lower specificity of a positive flow cytometry crossmatch in predicting early graft dysfunction caused by antibody-mediated rejection. Many centers were concerned that false-positive crossmatches would unnecessarily deny patients the opportunity of a transplant and were deterred from adopting the technique in routine clinical practice.[53] Nevertheless, the predictive value of a positive result was high in sensitized patients and second grafts, which carry an increased immunological risk of rejection, and the increased assay sensitivity is widely used in such scenarios.[14,46]

Crossmatch Policies and Clinical Interpretation

The purpose of a pretransplant donor crossmatch is to detect donor-specific sensitization that is predictive of hyperacute, acute, and chronic rejection (cellular and humoral) and to ensure appropriate therapeutic strategies are in place that are effective at controlling the ensuing rejection response. The crossmatch strategy must define the immunological risk by distinguishing antibodies that would be harmful, and the type of rejection response that is likely to occur. Because of the intricate relationship between this strategy and the clinical program, crossmatch strategies vary between centers, depending on laboratory and clinical facilities and expertise.

Crossmatch Veto: Which Antibodies Are Harmful?

It is important to distinguish damaging from nondamaging antibodies, and in this context the crossmatch can be viewed as a risk assessment for antibody-mediated rejection (Table 10-3). Donor-specific antibodies that are predictive of HAR (e.g., CDC-positive or strong positive flow cytometry crossmatch detecting IgG HLA class I–specific and HLA class II–specific antibodies present at the time of transplantation) in most cases constitute an absolute veto to transplantation, unless preemptive antibody removal (desensitization) and post-transplant immunological monitoring programs are instituted (see Chapter 22). Weaker IgG HLA-specific antibodies that are detectable only using flow cytometry crossmatch assays (i.e., CDC-negative) are associated with delayed graft function and acute humoral rejection and should be considered a contraindication to transplantation.[32] There is accumulating evidence that hitherto undefined HLA-DP–specific antibodies are commonly found in patients with graft rejection, and this suggests that it is necessary to avoid retransplantation in patients with donor-reactive HLA-DP antibodies.[80]

The prognostic relevance of historical IgG HLA class I–specific and class II–specific positive crossmatches that are negative at the time of transplantation has not been rigorously addressed using the diverse armory of modern immunosuppressive options. In this scenario, although HAR would not occur, early acute humoral or accelerated cellular rejection (or both) that is refractory to treatment with conventional calcineurin-based immunosuppressive agents is likely.[12,102,109] It has been suggested that historical IgG alloantibodies act as a marker for T cell priming and the presence of antigen-specific memory helper and cytotoxic T lymphocytes.[73,84] Such cells display cyclosporine resistance, and their rapid reactivation on repeat exposure to alloantigen elicits a powerful rejection response. Transplantation in patients with past IgG donor HLA–specific sensitization should be approached with caution and requires an augmented immunosuppressive therapy designed to control secondary (memory) T cell or B cell (or both) responses.

There is no doubt that IgM non–HLA-specific lymphocytotoxic antibodies that cause a positive donor B cell or T and B cell crossmatch are benign and have no harmful effect on transplant survival. In addition, good graft survival is reported with historical IgM donor HLA–specific positive crossmatches, which also can be safely ignored.[87,102] Many centers believe this also is true for current IgM donor HLA–specific antibodies despite their potential to bind vascular alloantigens and activate complement. High-titer IgM antibodies are thought to cause HAR in ABO blood group–incompatible transplants and in discordant xenotransplantation, and IgM alloantibodies may exhibit potential to

Table 10–3 **Risk Assessment for Antibody-Mediated Rejection**

*Contraindicated unless the donor-specific antibody can be removed with desensitization protocols.

†High risk of antibody-mediated rejection in the first month post-transplant requiring additional treatment or antibody removal; post-transplant antibody monitoring essential; augmented immunosuppression may be indicated.

‡Augmented immunosuppression may be indicated; post-transplant antibody monitoring advisable.

§Because of the variable sensitivity of the cytotoxic crossmatch, a negative result does not indicate a low risk, particularly for sensitized patients or in the absence of comprehensive antibody specificity data for the patient.

From Fuggle SV, Martin S: Toward performing transplantation in highly sensitised patients. Transplantation 78:186, 2004.

cause HAR. Most IgM HLA-specific antibodies have low affinity, however, and appear only transiently after blood transfusion, whereas persistent high-titer IgM HLA-specific antibodies with potential to cause HAR are rare.

Pretransplant Donor Crossmatch Testing

Prolonged cold ischemia time is a significant and controllable factor that has a detrimental effect on cadaver donor kidney transplant outcome. There is a progressive detrimental effect of cold ischemia time on transplant outcome with 90% survival at 1 year for organs transplanted within 20 hours compared with 83% for organs transplanted at more than 30 hours (relative risk 1.9) (data from United Kingdom Transplant). It is essential that cadaver donor organ allocation and crossmatch policies are designed to ensure a safe decision making process and minimize delays in transplantation associated with the allocation process. Recent technical advances have facilitated HLA typing and donor crossmatch strategies that can identify suitable recipients before completion of the organ retrieval operation and remove delays caused by histocompatibility testing.

Many histocompatibility laboratories receive donor peripheral blood obtained early in the donation process, before beginning the retrieval operation. This early receipt enables prospective donor HLA typing using a combination of molecular and serological techniques and completion of local and national allocation algorithms to identify potential recipients before organ donation. In addition, modern cell separation techniques using immunomagnetic particles enable the recipient crossmatch to be performed using donor peripheral blood. In selected cases (e.g., nonsensitized patients with low immunological risk), archived sera collected within the last 3 months can be used in the crossmatch test, which can be completed before patient admission. In cases in which a patient's antibody profile has been completely characterized, and comprehensive data concerning allosensitization events are available, a negative donor crossmatch can be predicted with absolute certainty. It such cases, it is possible to omit a pretransplant crossmatch.[107] With the adoption of these and similar crossmatch policies, there is no histocompatibility-associated cold ischemia time.

STRATEGIES FOR TRANSPLANTING SENSITIZED AND HIGHLY SENSITIZED PATIENTS

Patients with HLA antibodies reactive with a high proportion of a donor pool are difficult to transplant, and special strategies are required to find suitable kidneys for these patients. Highly sensitized patients have been defined as patients with a %PRA value of 85% or more, but a more meaningful definition may be patients who would have a positive crossmatch with greater than 85% of available donors.

To find a crossmatch-negative kidney, highly sensitized patients need access to a large donor pool. Numerous approaches have been adopted for transplanting highly sensitized patients. Eurotransplant introduced an Acceptable Mismatch Program for highly sensitized patients. In this program, extensive antibody screening was performed to identify "windows" in the patient's immune repertoire. The HLA antigens of cells unreactive with the patient's serum were the "windows" or specificities to which the patient had not made antibodies. The Acceptable Mismatch Program includes minimal mismatching criteria of full HLA-DR compatibility or matching for one HLA-B specificity and one HLA-DR specificity. Of patients entered in the program, 43% are transplanted within 6 months, and 58% are transplanted within 21 months.[13] When this system was first introduced, the antibody screening was performed on carefully selected cells that had only one mismatched antigen with the highly sensitized patient. This approach was extremely labor intensive and would be possible only in a laboratory that had access to very large panels of HLA-typed cells. The advent of solid-phase assays with single antigen preparations, or cell lines expressing single HLA antigens,[128] greatly expedites this type of approach.

A computer algorithm HLA Matchmaker developed by Duquesnoy may assist in defining acceptable mismatches.[24,25] In the algorithm, an HLA specificity is represented as a string of amino acid triplets, and it is possible to compare HLA specificities and identify mismatched triplets. The theory is that if there are no triplets mismatched, the specificity would not be recognized, and an immune response would not be generated. Clearly, HLA antigens are not linear sequences; nor are the amino acids in a protein in triplets; nevertheless, the algorithm has been shown to assist in the process of specifying a patient's sensitization profile.[37]

In the United Kingdom, the approach has been different. In the national kidney allocation scheme implemented in 1998, highly sensitized patients were prioritized for well-matched transplants with no HLA-A, HLA-B, or HLA-DR mismatches between the donor and recipient (000 HLA-A, HLA-B, or HLA-DR mismatch grade).[30] Sensitization data also were collected nationally and used for allocation purposes. The data collected were designed to capture an expert view of the patient's sensitization status, based on the patient's history, antibody screening data, and the policy of the local transplant unit. Rather than reporting sensitization as a %PRA value, the key data registered were unacceptable specificities and HLA reactivity in a patient's serum that could not be accounted for from the unacceptable specificities defined. This was termed *residual reaction frequency*, and in highly sensitized patients if this figure was zero (i.e., the antibody profile has been completely specified), the highly sensitized patients also were eligible for favorably matched transplants. These were transplants where there was a maximum of one HLA-A and one HLA-B mismatch in the absence of mismatches at HLA-DR (denoted 100, 010, 110 HLA-A, HLA-B, HLA-DR mismatches). This policy resulted in a threefold increase in the number of highly sensitized patients transplanted, 62% of these transplants having a 000 mismatch grade.[32]

The basis for national kidney allocation has changed more recently in the United Kingdom, but the 2006 allocation scheme has retained the priority given to highly sensitized patients for 000 mismatched transplants and access to other, less well-matched kidneys for highly sensitized patients where the antibody profile is completely specified. One of the benefits of defining antibody profile is to make it possible to estimate a patient's chance of receiving a transplant and make informed decisions about the best therapeutic option for a patient. In the United Kingdom, a "matchability score" is calculated for all patients on the transplant waiting list, by comparing a patient's HLA type, unacceptable specificities, and blood group against a file of

10,000 United Kingdom donors.[31] Patients with a high matchability score are likely to be easy to transplant with a well-matched transplant. This is particularly informative in planning transplantation for children, who are given high priority for national kidneys. Patients with a low matchability score are less likely to receive an offer of a deceased donor kidney through the national scheme, and alternative approaches to transplantation may be explored.

Antibody Removal

There has been a resurgence of interest in using antibody removal techniques to reduce donor-specific HLA antibody before transplantation (see Chapter 22).[35] Two main approaches are being used with successful outcomes: high-dose intravenous immunoglobulin[36,122] used for transplantation with living or deceased donors, and plasmapheresis combined with low-dose cytomegalovirus hyperimmune globulin[66,90,94,127] used for transplantation with living donors.

In considering patients for antibody removal, it is important for the HLA specificity and titer of the antibodies to be determined before beginning antibody removal; this may help determine whether this approach is appropriate for a particular patient. During antibody removal, it is important to monitor antibody levels to determine the effectiveness of the treatment regimen. The plasmapheresis and hyperimmune globulin regimen can be monitored using a solid-phase assay, but the high-dose intravenous immunoglobulin regimen requires the use of a sensitive cytotoxicity assay because the intravenous immunoglobulin interferes with the solid-phase assays. Most centers advocate that a final crossmatch against the potential donor is performed, regardless of the methods used for monitoring. After transplantation, antibody rebound usually occurs, and monitoring antibody levels provides valuable information to indicate whether additional antibody removal is required. Experience in performing transplants after desensitization is mounting, but because of the complexity in the management before and after transplantation, it may be that in the longer term, patients are referred to specialist centers for transplantation after antibody removal.

Paired Exchange

Paired exchange, or living donor exchange, is another possible option for patients who have a potential living donor, but for reasons of HLA or ABO antibody incompatibility the transplant cannot proceed.[85,86] In such schemes, donors and recipients are paired, and crossover transplants are undertaken. Simple systems pair recipients and their respective donors, but it is possible that multiple exchanges can be undertaken. There is a well-established living donor exchange scheme in South Korea,[76] and other regional and national schemes have been reported from the United States.[22,59] In Europe, the encouraging results of the first year of the Dutch national living donor kidney exchange program have been reported,[21] and in the United Kingdom paired exchange became possible in September 2006 because of a change in legislation, and the first exchanges are planned for early in 2007.

Combined Transplants

One further approach for transplanting highly sensitized patients is to perform a combined liver-kidney transplant in the presence of a positive crossmatch. The rationale for this procedure is that the liver, or soluble antigen derived from the liver, is capable of absorbing the donor-specific antibody and protects the kidney from HAR. This in vivo absorption has been successfully performed with no reported HAR or accelerated acute rejection episodes, but as yet only a few patients have been treated.[40,72]

POST-TRANSPLANT MONITORING

There is an expanding literature on the development of HLA antibodies after renal transplantation and consideration of the role these antibodies may play in transplant failure.[8,113] The proportion of recipients developing antibodies has been reported to range between 12% and 60%.[61] This figure not only is influenced by the sensitivity of the assay system, but also by clinical factors, such as the nature and degree of mismatching between the donor and the recipient and the immunosuppressive regimens.

The appearance of donor-specific antibodies has been shown to be associated with a poorer outcome and with the occurrence of acute and chronic rejection. In recent reports in which serial post-transplant serum samples were analyzed, donor-specific HLA antibodies were strongly predictive of allograft failure being detected before chronic rejection or transplant failure.[55,125] A large international prospective trial that included more than 4500 patients from 36 units also concluded that HLA antibody production predicts transplant failure.[114]

Mismatched HLA antigens are important stimuli for an alloimmune response, but antibodies to nonclassic polymorphic MHC antigens also may contribute. The MHC-related chain A and B antigens (MICA and MICB) are expressed on epithelia in response to cellular stress and on endothelium in vitro. In the kidney, MICA and MICB expression has been reported on tubular epithelia.[41,81] Antibodies to MICA were first reported in the sera of transplant recipients,[99,131] but because the antigens are not expressed on lymphocytes,[129,130] MICA and MICB antibodies would remain undetected in standard antibody screening and crossmatch tests. Reports in which MICA has been included as one of the targets studied have shown the presence of MICA antibodies in transplanted patients, and a higher incidence of antibodies was found in patients whose transplants failed.[63,64]

The histological detection of immunoglobulins bound to the transplant endothelium is difficult because antibody is rapidly removed from the endothelium. After activation of the classic complement pathway, however, one of the components, C4d, remains covalently bound to the endothelial surface, acting as an imprint of antibody binding. Following the original observation by Feucht and colleagues[26] that C4d deposition on the endothelium of renal peritubular capillaries was a marker of acute humoral rejection, this has become an accepted diagnostic tool. There is strong evidence that circulating donor-reactive antibodies are associated with C4d deposition in the transplant,[5,15,58,71] and that this is highly specific for antibody-mediated rejection.[50] The Banff 97 classification of renal allograft rejection has been modified such that the definition of acute humoral rejection includes C4d deposition, histological evidence of graft injury, and donor-reactive antibodies.[82]

Currently, HLA matching, definition of sensitization, and donor crossmatch are making an important contribution to

successful renal transplant programs. It is an exciting time as many of the traditional boundaries are being challenged to enable transplantation of patients who previously would have been unlikely to be transplanted.

Chapter 11

Surgical Techniques of Renal Transplantation

John M. Barry • Peter J. Morris

Renal transplantation is a major surgical procedure that includes a vascular component and a urological component. Although in the past it was common for a general or vascular surgeon to do the vascular component of the implantation and a urologist to do the urological component of the operation, today the entire procedure generally is performed by a transplant surgeon, regardless of his or her background training as a general surgeon, vascular surgeon, or urologist. The recipient, who is uremic and usually being maintained on hemodialysis or peritoneal dialysis, often is a poor-risk patient with comorbid disease (e.g., diabetes, cardiovascular disease, obesity). If poorly dialyzed, the recipient has a significant degree of platelet dysfunction with a resultant tendency to bleed. The need for meticulous techniques cannot be stressed enough, bearing in mind that the operation could be the only opportunity that the patient may have to obtain a successful kidney transplant, which can change the quality of life dramatically.

PREPARATION OF RECIPIENT

The general preparation and selection of recipients for transplantation is discussed in Chapter 4. On admission for transplantation, a careful history and physical examination is required to ensure that there is no immediate contraindication to major surgery, and particular attention should be paid to the patient's fluid and electrolyte status. The patient may require dialysis before going to surgery because of fluid overload or a high potassium level. Although dialysis may delay surgery by several hours, this should not influence the decision to dialyze the patient before surgery, bearing in mind that if the patient is to receive a cadaver donor kidney, there is a significant chance of delayed graft function.

Immunosuppression, whatever the protocol, is often begun before the patient goes to surgery. Although there is no hard evidence that preoperative immunosuppression is necessary, the rationale is that a loading dose of a calcineurin inhibitor ensures a better blood level in the first 12 hours because most patients are unable to take oral medication in the first 24 hours after surgery.

The use of preventive antibiotics is advised because although the operation is a clean one, the patient is uremic and will be immunosuppressed, which puts the patient at high risk for wound infection. There is always a possibility of contamination of a cadaver donor kidney, and the combination of a vascular procedure with a urological procedure increases the risk of infection in the vicinity of the vascular anastomosis. An infection of the vascular anastomosis with subsequent secondary hemorrhage is a catastrophic complication, resulting in loss of the kidney, compromise of distal circulation, and a threat to life. The case for preventive antibiotics is a strong one. In the Oxford Unit, cefuroxime, 1.5 g intravenously, is given with the induction of anesthesia.

After the induction of anesthesia, a central catheter is inserted into the internal jugular vein or into the subclavian vein. Insertion of the catheter is facilitated by the use of duplex ultrasound. Although a central line is not essential intraoperatively, it facilitates management because many patients who have been on long-term hemodialysis are dehydrated and require significant amounts of fluid to maintain a central venous pressure of 7 to 10 cm H_2O. Other aspects of the induction of anesthesia and monitoring during the operative procedure are discussed in Chapter 13.

A balloon catheter is inserted into the bladder with full aseptic technique (see later) on the operating table. The skin

should be prepared carefully in the operating room, first with thorough removal of hair with clips followed by preparation of the skin of the abdominal wall with an antimicrobial agent, such as povidone-iodine or chlorhexidine gluconate. It is wise to prepare the entire abdomen from nipples to midthighs, especially in a recipient with vascular disease, because the original incision may need to be extended or abandoned and the opposite iliac fossa opened.

SITE

Although traditionally the right iliac fossa was used for implantation of the kidney since the early descriptions,[30,38,49,50,66] today it is more usual to place the left kidney in the right iliac fossa and the right kidney in the left iliac fossa, other things being equal. This approach places the pelvis and ureter anteriorly, which to some extent facilitates the urological tract reconstruction, particularly if a subsequent urological complication requires surgical intervention. If a continuous ambulatory peritoneal dialysis catheter or stoma were emerging from one side of the abdomen, the contralateral side would usually be chosen. In the presence of polycystic kidneys, one would choose the side of the smaller polycystic kidney, assuming that there was room for the transplanted kidney below it. Often, one polycystic kidney has to be removed to make room for a transplanted kidney, and this preferably is done as a separate operative procedure before transplantation because a large polycystic kidney is removed more easily as a transperitoneal procedure, and one or more of the cysts may harbor bacteria. It can be done at the time of the transplant procedure, however, through the same extended retroperitoneal approach or through a midline incision with extraperitoneal placement of the kidney transplant. In the case of nephrectomy for polycystic kidney disease, a fluoroquinolone antibiotic is often used instead of a cephalosporin because of better antibiotic penetration into renal cysts with the former.[19] In children, in whom the vascular anastomoses of the renal vessels may be to the aorta and vena cava because of the size of the kidney, the right side is preferred because the kidney is placed behind the cecum and ascending colon. Simultaneous pancreas and kidney transplantations usually are accomplished by a vertical midline transperitoneal approach, and torsion of the renal pedicle with kidney transplant thrombosis has been reported.[70] This torsion can be prevented by nephropexy or retroperitoneal placement of the kidney graft. The iliac fossa can be developed by inserting an index finger into the prevesical space just lateral to the midline.

INCISION

An oblique Rutherford Morison[40] or curvilinear incision is made in the right or left lower quadrant of the abdomen beginning almost in the midline and curving upward parallel to the inguinal ligament and approximately 2 cm above it and ending just above the anterior superior iliac spine of the iliac crest. In a child or small adult, this incision can be carried up to the costal margin to increase exposure (Fig. 11-1).[42] The external oblique muscle and fascia are divided in the line of the incision and split to the lateral extent of the wound.

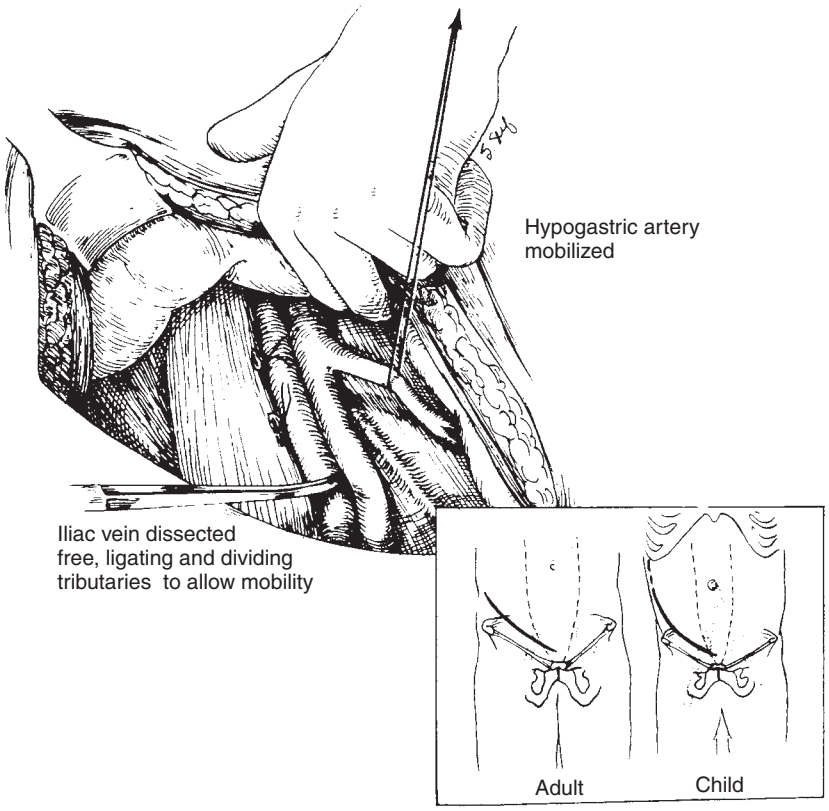

Figure 11–1 Iliac vessels dissected free. *Inset*, Incision for adult; incision for child. (From Lee HM: Surgical techniques in renal transplantation. In Morris PJ [ed]: Kidney Transplantation. London, Academic Press/Grune & Stratton, 1979, p 146.)

This incision is carried medially onto the rectus sheath to permit retraction or division of part of the rectus muscle for later exposure of the bladder. To expose the peritoneum, either the internal oblique and transverse muscles are divided with cautery in the line of the incision, or the confluence of the oblique muscles and the rectus sheath is divided medially lateral to the rectus muscle as a pararectus incision, which avoids division of the internal oblique and transversus muscles. The inferior epigastric vessels are ligated and divided, but if there are multiple renal arteries, the inferior epigastric vessels should be preserved in the first instance in case the inferior epigastric artery is required for anastomosis to a lower polar renal artery or if a chevron incision with division of the superior epigastric vessels had been used to remove an ipsilateral kidney, gallbladder, or spleen. Although division of the spermatic cord was advocated in early descriptions of the procedure and was common practice for many years, it should not be done and rarely is required for adequate exposure. The spermatic cord is not cut, but freed laterally, which allows it to be retracted medially.[29] The round ligament can be divided.

PREPARATION OF OPERATIVE BED

After exposure of the transversalis fascia and peritoneum, the transversalis fascia is divided, and the peritoneum is reflected upward and medially to expose the psoas muscle and the iliac vessels. At this stage, a self-retaining retractor is inserted. We find the Bookwalter retractor system satisfactory because it provides excellent exposure and allows the assistant to have both hands free to assist with the anastomoses. Depending on whether the internal iliac artery is to be anastomosed to the renal artery of the transplant kidney or whether the renal artery with a cuff of aorta is to be anastomosed to the external iliac artery, dissection proceeds in the first instance to expose the external, common, and internal iliac arteries. The lymphatics that course along and over the vessels must be ligated with a nonabsorbable suture such as silk and divided, rather than cauterized, to prevent the later occurrence of a lymphocele (see Chapter 26). The surgeon must be careful not to mistake the genitofemoral nerve for a lymph vessel. It lies on the medial edge of the psoas muscle, and a branch may cross the distal external iliac artery. If the internal iliac artery is to be used, it is important to mobilize a length of the common and external iliac arteries so that the internal iliac artery can be rotated laterally without kinking at its origin and so that the vascular clamps can be applied to the common and external iliac arteries when the internal iliac artery is short. Care is taken to inspect the origin of the internal iliac artery, if this is to be used, for any evidence of atheroma and, similarly, any atheromatous disease in the common or external iliac artery should be noted. If there are two or more renal arteries not on a cuff of aorta, the dissection of the internal iliac artery is extended distally to expose the initial branches of the internal iliac artery, some of which may be suitable for anastomosis to individual renal arteries.

Having completed the exposure of the appropriate iliac arteries, dissection of the external iliac vein is begun. If a left kidney with a long renal vein is available, dissection of the external iliac vein alone generally allows a satisfactory anastomosis without tension. If a right kidney, which has a short renal vein, is to be used, or a left kidney, in which a short renal vein has been provided, is to be used, or if the recipient is obese, the internal iliac vein and usually one or two gluteal veins can be ligated with silk and divided.[29,64] This technique allows the common and external iliac veins to be brought well up into the wound, particularly if the internal iliac artery is divided, and this facilitates the performance of a tension-free anastomosis. The peritoneum is reflected further up laterally to prepare the final pocket for the kidney in the parapsoas gutter. Temporary placement of the cold kidney graft into the wound assists in the selection of the recipient artery and vein for revascularization.

When the kidney has been prepared and is ready for implantation, the vessels are now ready for clamping. Heparin is commonly administered in a modest dose of 30 IU/kg.

Vascular clamps are applied to the external iliac artery proximally and distally if an end-to-side anastomosis is to be performed, and if the internal iliac artery is to be used, a vascular clamp is applied to the internal iliac artery at its origin or to the common and external iliac arteries. The vein is clamped proximally and distally with vascular clamps or isolated between tourniquets, or a Satinsky side clamp is used. After division of the internal iliac artery distally, the lumen is flushed out with heparinized saline. Similarly, if the external iliac artery or common iliac artery is to be used, an appropriate-sized arteriotomy is made, usually enlarged with a vascular punch, and the lumen is flushed out again with heparinized saline. The venotomy similarly is flushed out with heparinized saline, and if a valve is present at the site of the venotomy, it should be removed carefully. Before making the arteriotomy or venotomy, the surgeon should mentally visualize the kidney in situ in its parapsoas gutter and the course that the renal artery and vein would take to ensure the optimal site for the anastomoses.

PREPARATION OF KIDNEY

A varying degree of dissection of the kidney is required when it is received in ice. In the case of a cadaver kidney, in which the kidneys usually have been removed as part of an en bloc procedure, considerable dissection needs to be performed, and this should be done carefully and with a good light on a back table with the kidney in a bowl of ice slush. The dissection of the cadaver kidney usually is done in advance of the transplant procedure in case some anomaly is present that would preclude going ahead with the transplant. In the dissection, great care must be taken in protecting the blood supply to the ureter, and the so-called golden triangle should not be broached (see Chapter 27).

A kidney from a living donor generally has a single renal artery, but there may be additional arteries. In this case, reconstruction usually is done on the back table, and either the arteries are joined together at their orifices to form a common trunk (Fig. 11-2),[42] or a smaller artery is anastomosed end-to-side to a larger renal artery. It is imperative that a lower polar artery be revascularized because this almost certainly gives rise to the ureteric blood supply. It also is possible to use the epigastric artery to revascularize a lower polar artery, but in general it is preferable to anastomose a lower polar artery to the major renal artery, either end-to-side or as a common trunk. It also is possible to use a portion of saphenous vein as a graft bridge. A small upper polar artery, if thought to be too small to anastomose safely to the major

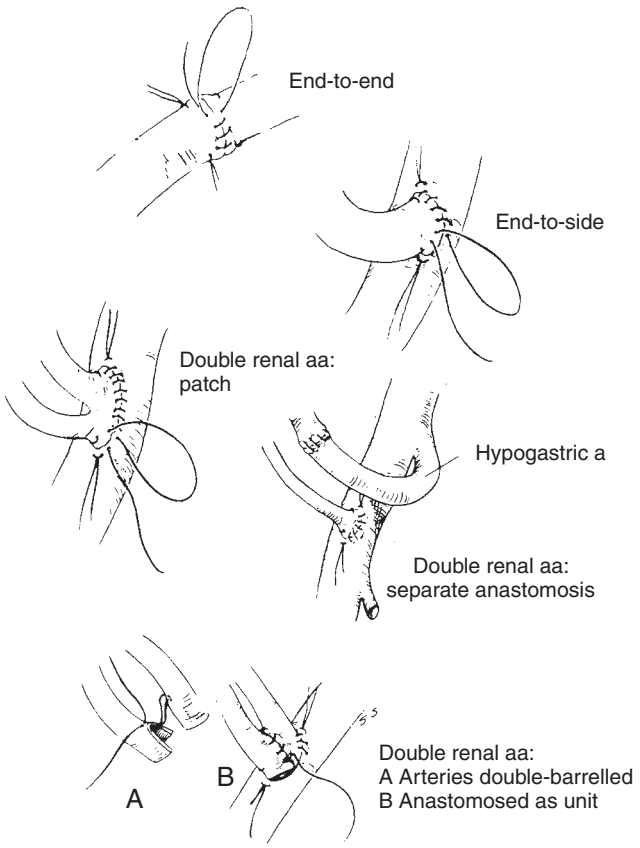

Figure 11–2 Variations of renal artery anastomoses. (From Lee HM: Surgical techniques in renal transplantation. In Morris PJ [ed]: Kidney Transplantation. London, Academic Press/Grune & Stratton, 1979, p 150.)

renal artery, may be ligated, provided that it supplies less than one eighth of the kidney (which should be evident on perfusion of the kidney after removal).

A cadaver kidney usually has a renal artery or arteries arising from an aortic patch, and this patch should be trimmed to an appropriate size and used for anastomosis to the external iliac artery. If two renal arteries are widely separated on the aortic patch, the patch may be divided to allow separate implantation into the external iliac artery, or one may be implanted end-to-side and the other to a branch of the internal iliac artery.

If there is more than one renal vein, smaller veins can be ligated, assuming that there is one large renal vein. If two renal veins are of equal size and are not arising from a Carrel patch, there is some risk of subsequent venous infarction if one vein is ligated, and it is preferable to join the veins to form a common trunk for the subsequent anastomosis. A short right renal vein can be extended with donor inferior vena cava or external iliac vein, or with a recipient renal vein if a native nephrectomy had been done as a preliminary procedure under the same anesthetic.

When the kidney finally is prepared and ready for implantation, a technique that we use in Oxford ensures that the kidney remains cool during the time of the anastomoses. A surgical glove (size 8) is used, with the fingers knotted and the ends cut off. The glove is packed partially with crushed ice, and the kidney is inserted, with care being taken always to have the upper pole of the kidney at the finger end of the glove ("fingers up"). More crushed ice is inserted into the glove, and the glove is tied at its wrist end. A 1.5-cm hole is made over the vessels, which can be brought through this opening in turn. This technique not only keeps the kidney cool during the anastomosis,[57] but also facilitates handling the kidney because an artery clamp can be placed on the glove itself to allow the kidney to be held in position during the procedure. When the anastomoses are completed, the glove is removed, and the kidney is reperfused.

REVASCULARIZATION

The question of whether the arterial anastomosis or the venous anastomosis should be done first depends on the final position of the kidney and the ease with which the second anastomosis may or may not be done. In general, if the renal artery is to be anastomosed to the internal iliac artery, the arterial anastomosis should be done first because this enables the renal vein to be positioned appropriately. If the renal artery is to be anastomosed end-to-side—usually with a cuff of aorta—to the external iliac artery, it is preferable to do the venous anastomosis first, then the end-to-side arterial anastomosis can be positioned correctly.

Arterial Anastomosis

The internal iliac artery is anastomosed end-to-end to the renal artery with 5-0 or 6-0 monofilament vascular suture using a three-point anastomosis technique, as described by Carrel in 1902,[16] or a two-point anastomosis (Fig. 11-3).[42] If there is a disparity between the renal artery and the internal iliac artery, the renal artery being considerably smaller in diameter, the renal artery should be spatulated along one side to broaden the anastomosis. If one side of the renal artery is spatulated, care should be taken to place the spatulation of the renal artery appropriately, taking into consideration the final curve of the internal iliac artery and the renal artery so that one or the other would not be kinked when the kidney is placed in its final position (Fig. 11-4).[42] If both arteries are small, at least one third of the anastomosis should be performed with interrupted sutures to allow for expansion. In a child or a small adult with small arteries, the whole anastomosis should be performed with interrupted sutures unless the recipient arteriotomy is greater than 5 mm in diameter.

An end-to-side anastomosis of the renal artery to the external iliac artery usually is performed using an appropriately trimmed cuff of aorta attached to the renal artery. An arteriotomy appropriately placed is performed in the external iliac artery, then the anastomosis is done with a continuous 5-0 or 6-0 monofilament vascular suture (see Fig. 11-2).[42]

Venous Anastomosis

The renal vein is anastomosed end-to-side, usually to the external iliac vein using a continuous 5-0 monofilament vascular suture, with the initial sutures placed at either end of the venotomy (Fig. 11-5).[42] An important aspect of this technique is the placement of an anchor suture at the midpoint of the lateral wall, which allows the external iliac vein and the renal vein on the lateral side of the anastomosis to be drawn clear of the medial wall of the anastomosis. This technique avoids any possibility of the back wall being caught up

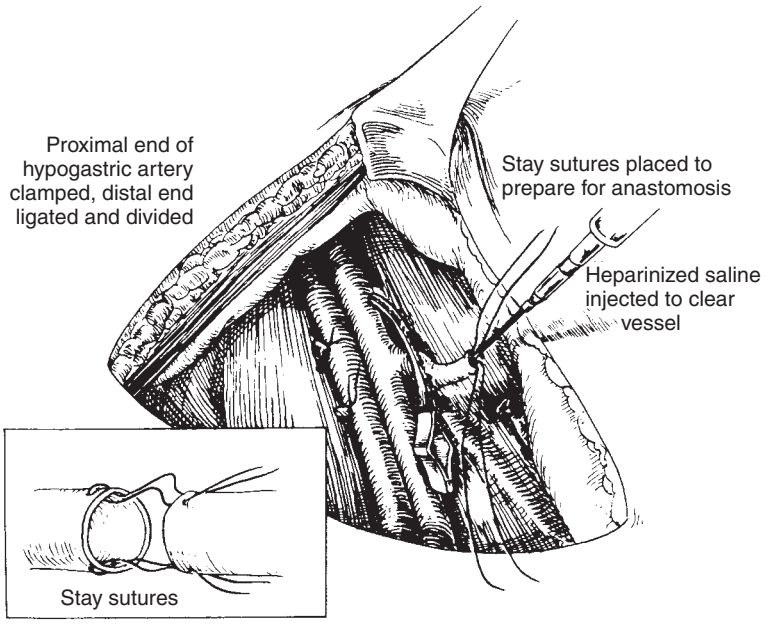

Figure 11–3 Hypogastric artery ligated and divided, the lumen flushed with heparinized saline. (From Lee HM: Surgical techniques of renal transplantation. In Morris PJ [ed]: Kidney Transplantation. London, Academic Press/Grune & Stratton, 1979, p 148.)

in the suture while the medial wall is being sutured. The renal vein may be anastomosed to the external iliac vein lateral or medial to the external iliac artery. This anastomosis depends on the length of the renal vein lateral to the artery, but if the external and common iliac vein has been mobilized as described earlier, usually even with a short vein the venous anastomosis can be performed medial to the artery. Wherever the anastomosis is positioned, it is important to ensure that the renal vein is under no tension, and care should be taken that the vein is not twisted before starting the anastomosis. When a small child receives an adult kidney, it is sometimes necessary to shorten the renal vein to prevent kinking, especially when the vein is anastomosed to the inferior vena cava.

RECONSTRUCTION OF THE URINARY TRACT

After renal revascularization, the kidney is placed in what is to be its final position, and re-establishment of urinary tract continuity begins. Transplantation of the left kidney into the right iliac fossa and the right kidney into the left iliac fossa reverses the normal anterior-to-posterior relationship of the vein, artery, and collecting system and positions the renal pelvis and ureter of the kidney transplant so that they are the most medial and superficial of the hilar structures.[49] This positioning simplifies primary and secondary urinary tract reconstruction, especially if pyeloureterostomy, ureteroureterostomy, or pyelovesicostomy is to be done. The factors that determine the type of urinary tract reconstruction are the length and condition of the donor ureter, the condition of the recipient's bladder or bladder substitute, the condition of the recipient's ureter, and the familiarity of the surgeon with the technique.

Suture material is an individual choice. Although urinary tract reconstruction with nonabsorbable sutures has been described,[31,48] it leaves the recipient with the risk of stone formation if the suture material is chronically exposed to urine. Currently available synthetic absorbable sutures have characteristics suitable for the immunocompromised kidney transplant recipient who has the potential for delayed wound healing.[58] In vivo strength retention is poorest with natural fibers (plain gut and chromic gut), better with synthetic braided materials (polyglycolic acid and polyglactin), and best with synthetic monofilament materials (polyglyconate and polydioxanone). Monofilament suture has less tissue drag than braided suture, but knot security is better with braided suture. We have found polydioxanone to be satisfactory and use 3-0 for bladder closure and 4-0 or 5-0 for ureteric or renal pelvic anastomoses.

Ureteroneocystostomy

Ureteroneocystostomy is the usual form of urinary tract reconstruction. Its advantages are (1) it can be performed regardless of the quality or presence of the recipient ureter, (2) it is several centimeters away from the vascular anastomoses, (3) the native ureter remains available for the treatment of ureteric complications, and (4) native nephrectomy is unnecessary. The goal is to create a 2- to 3-cm submucosal tunnel with muscle backing of the ureter so that when the bladder contracts, there is a valve mechanism to prevent reflux of urine up the ureter.[43,53,55,68]

The genitals are prepared with an antiseptic solution, and a lubricated balloon retention catheter is passed into the urinary bladder or bladder substitute. The catheter is connected to a sterile Y-tube system (Fig. 11-6).[37] This system has a bag filled with an antibiotic solution on one line and a collection bag on the other. With this system, the bladder can be filled, irrigated, drained, and refilled during the procedure. It is especially helpful when the bladder is difficult to identify because of pelvic scar tissue, recipient obesity, or reduced capacity. After initially accommodating a small volume, the defunctionalized bladder often accepts more fluid 1 or 2 hours into the transplantation procedure.[4]

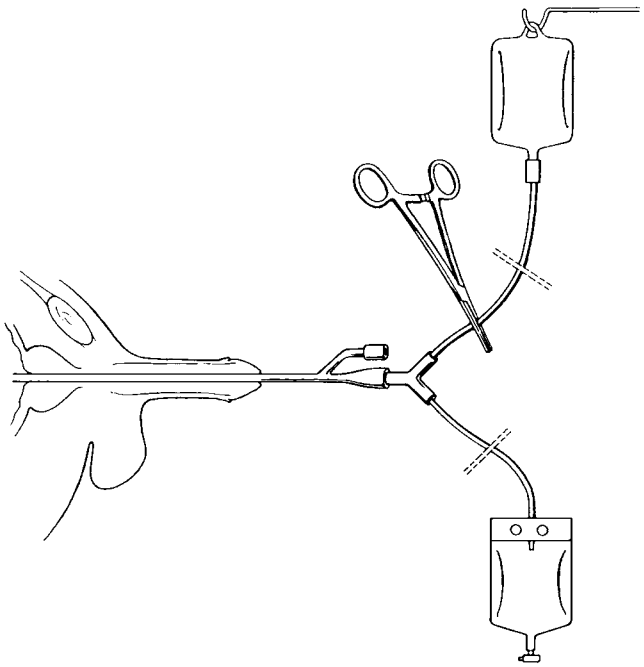

Figure 11–6 Y-tube system for rinsing, filling, and draining bladder or bladder substitute. (From Kostra JW: Kidney transplantation. In Kremer B, Broelsch CE, Henne-Bruns D [eds]: Atlas of Liver, Pancreas, and Kidney Transplantation. Stuttgart, Georg Thieme Verlag, 1994, p 128.)

Transvesical Ureteroneocystostomy

The technique for transvesical ureteroneocystostomy is similar to that described by Merrill and colleagues[49] in the first successful kidney transplant from a twin (Fig. 11-7).[42] The dome of the bladder is cleared off, and stay sutures or Allis clamps are placed on either side of a proposed vertical midline incision. The urinary bladder is drained, and an incision is made through all layers of the anterior bladder wall. A padded retractor is placed into the dome of the bladder to expose the trigone. A point clear of the native ureter is selected, and a transverse incision is made in the mucosa. A submucosal tunnel is created with a right-angle clamp or Thorek scissors for about 2 cm. The clamp or scissors is punched through the bladder, and the muscular opening is enlarged to accept the kidney transplant ureter. The ureter is drawn under the spermatic cord or round ligament and into the bladder, where it is transected at a length that prevents tension or redundancy. The cut end of the ureter is incised for 3 to 5 mm and approximated to the bladder mucosa with fine absorbable sutures. The inferior suture includes the bladder muscularis to fix the ureter distally and to prevent its movement in the submucosal tunnel. The padded retractor is removed, and the cystotomy is closed with a single layer of 3-0 absorbable suture, although some surgeons use a two-layer or three-layer closure. The bladder can be refilled to check for leakage, and points of leakage can be repaired with one or two interrupted sutures. Some surgeons use two bladder mucosal incisions about 2 cm apart[65]; when this technique is used, the proximal bladder mucosal incision is closed with a fine absorbable suture.

Extravesical Ureteroneocystostomy

Compared with the transvesical procedures, the extravesical techniques are faster, a separate cystotomy is not required,

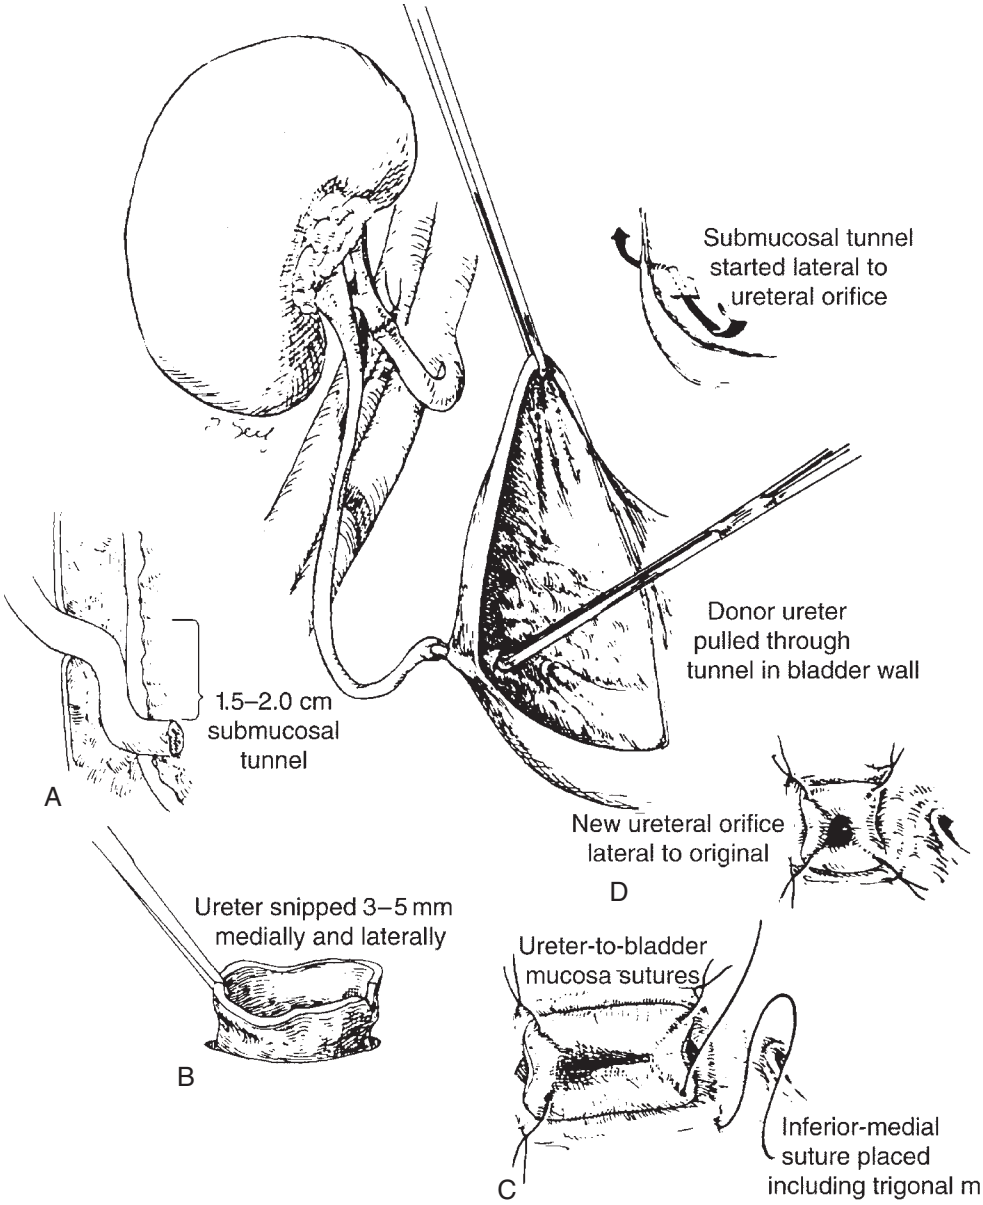

Figure 11–7 **A-D**, Transvesical ureteroneocystostomy. (From Lee DM: Surgical techniques of renal transplantation. In Morris PJ [ed]: Kidney Transplantation. London, Academic Press/Grune & Stratton, 1979, p 153.)

and less ureteric length is necessary (Fig. 11-8). These factors should reduce operating time, bladder spasms, and hematuria, and improve the probability of adequate distal ureteric blood supply. Extravesical techniques are based on the procedure described by Lich and associates.[43] Extravesical ureteroneocystostomy was adapted for renal transplantation by Woodruff in 1962,[72] and it is well illustrated by Konnak and colleagues (see Fig. 11-8).[36] A subsequent modification was the addition of a stitch to anchor the toe of the spatulated ureter to the bladder to prevent proximal slippage of the ureter in the submucosal tunnel with loss of the antireflux valve and disruption of the ureteric anastomosis.[9,14]

The bladder is distended with an antibiotic solution through the urethral catheter. The lateral surface of the bladder is cleared of fat and the peritoneal reflection, a padded retractor is placed medially, another is placed inferolaterally, and a third retractor is placed cephalomedially to hold the peritoneum and its contents out of the way. It is important to place the ureter under the spermatic cord or round ligament to prevent post-transplant ureteric obstruction. A T-shaped or longitudinal oblique incision is made for approximately 3 cm until the bladder mucosa bulges into the incision. The bladder is partially drained, and the mucosa is dissected away from the muscularis to make a submucosal tunnel for the ureter. The bladder mucosa is grasped with atraumatic forceps, the urinary bladder is drained, and an incision is made in the mucosa. The ureter is laid in the trough, spatulated, and anastomosed to the bladder mucosa with running or interrupted fine absorbable sutures. A horizontal or vertical mattress suture is placed in the toe of the ureter and passed submucosally through the seromuscular layer of the bladder

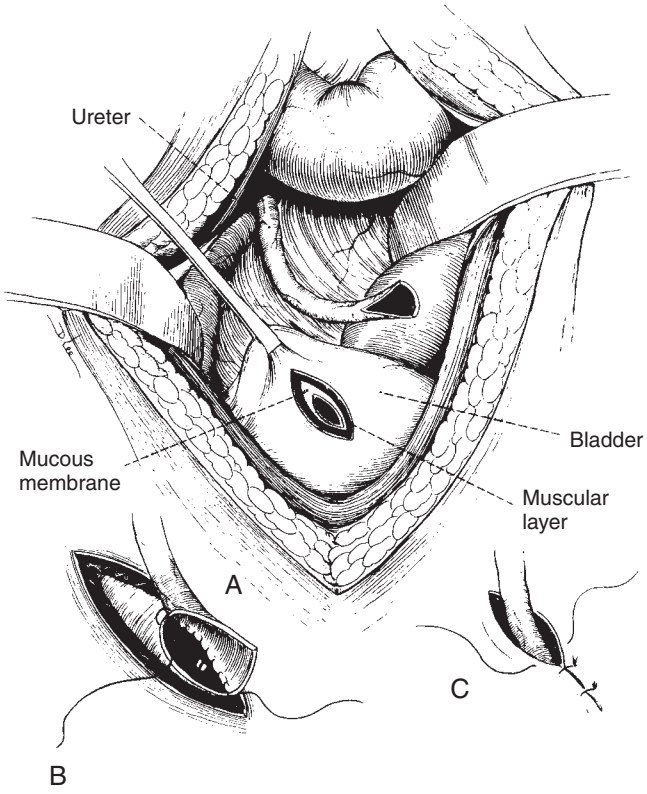

Figure 11–8 **A-C**, Extravesical ureteroneocystostomy. (From Konnak JW, Herwig KR, Turcotte JG: External ureteroneocystostomy in renal transplantation. J Urol 108:380, 1972.)

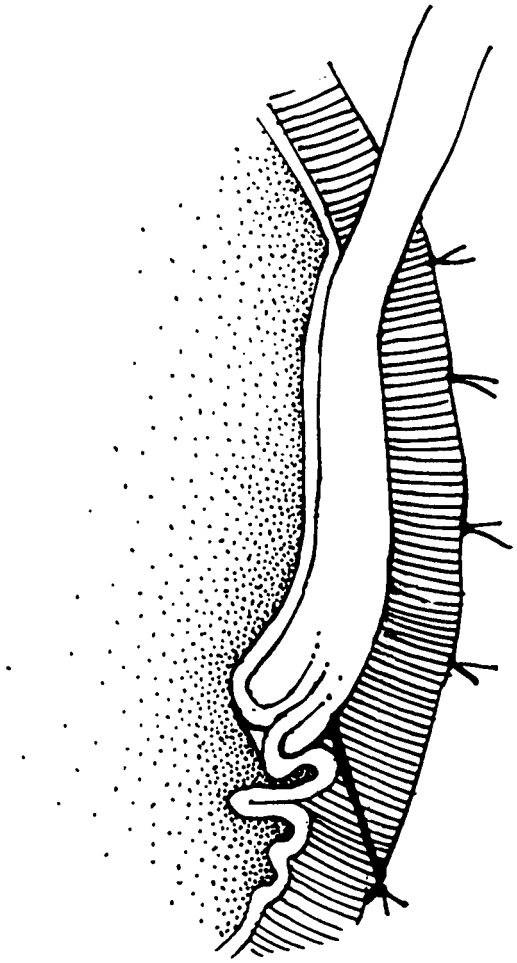

Figure 11–9 One or two mattress sutures to anchor toe of transplant ureter to full-thickness bladder. This prevents ureteric slippage in the submucosal tunnel. (From Hinman F Jr: Ureteral reconstruction and excision. In Hinman F Jr [ed]: Atlas of Urologic Surgery, 2nd ed. Philadelphia, WB Saunders, 1998, p 799.)

and tied about 5 mm distal to the cystotomy (Fig. 11-9). The seromuscular layer is closed over the ureter with interrupted sutures so that the proximal one or two sutures can be removed if the ureteric lumen has been compromised by the closure.

The one-stitch[63] and two-stitch[46] extravesical ureteroneocystostomies are modifications of the Lich procedure in which one or two mattress sutures are placed full thickness through the spatulated ureter and the bladder without an attempt at mucosa-to-mucosa approximation (Fig. 11-10).[46] If the ureter lies too loosely in the partial cystotomy, the seromuscular layer is closed over the ureter with interrupted stitches.

The parallel-incision extravesical ureteroneocystostomy commonly is used in the Oregon program (Fig. 11-11).[3,23] The setup is the same as for a modified Lich procedure. Parallel incisions are made in the lateral bladder about 2 cm apart until the bladder mucosa bulges into both incisions. The bladder is drained partially, and a submucosal tunnel is created between the two incisions. The ureter is drawn through the tunnel, transected, spatulated, and anastomosed to the bladder mucosa with interrupted fine absorbable sutures. Sometimes extra stitches are placed between the quadrant sutures to prevent urinary leakage. A vertical or horizontal mattress suture is used to anchor the toe of the ureter to the urinary bladder. This suture is tied about 5 mm distal to the cystotomy. Finally, the distal cystotomy is closed with a running fine absorbable suture. The parallel-incision extravesical ureteroneocystostomy has been slightly modified by Caparros and associates[15] by application of the one-stitch principle with no suture approximation of the ureteric and bladder mucosa, and by Knechtle,[34] who described a longitudinal distal bladder incision.

Double Ureters

Double ureters can be managed simply by leaving them in their common sheath, trimming them to appropriate length, spatulating them, and either anastomosing the medial edges together with a running fine absorbable suture (Fig. 11-12)[17,56] or joining them, one on top of the other, with a single stitch from the toe of the upper one to the heel of the lower one (Fig. 11-13).[5] The conjoined ureters can be treated as a single ureter by any of the previously described ureteroneocystostomy techniques. The submucosal tunnel needs to be made a bit wider. Others have used a separate ureteroneocystostomy for each of the ureters.[69] These same techniques can be used for the en bloc transplantation of pediatric kidneys or the transplantation of two adult kidneys, stacked one on top of the other,[47] into one recipient. Fjeldborg and Kim[22] described a pyeloureteric anastomosis in which both renal pelves are joined after dividing the ureters at their ureteropelvic junctions and suturing the posterior walls together,

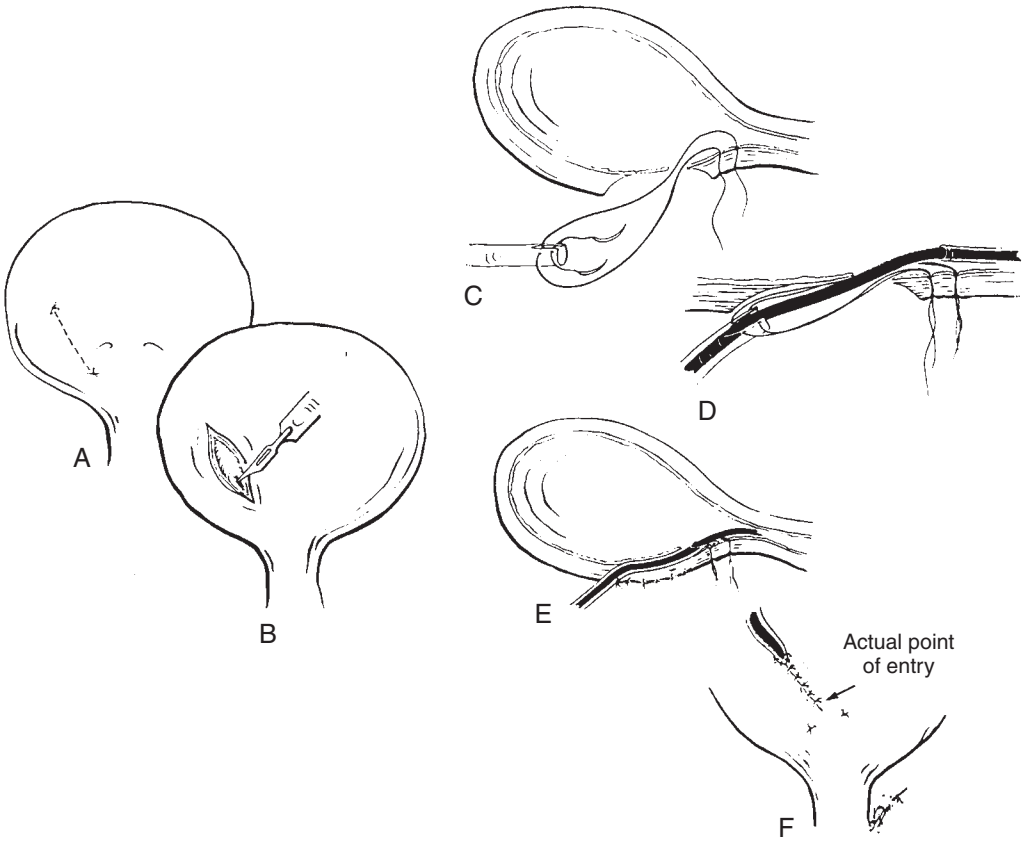

Figure 11–10 **A-F**, Extravesical ureteroneocystostomy without mucosa-to-mucosa anastomosis. This also is done without a stent. (From MacKinnon KJ, Oliver JA, Morehouse DB, et al: Cadaver kidney transplantation: emphasis on urologic aspects. J Urol 99:46, 1968.)

leaving the anterior halves for anastomosis with the recipient ureter (Fig. 11-14).

Augmented Bladder

It is important to know the blood supply of an augmentation patch so as not to interfere with it during the renal transplant procedure. With the possible exception of stomach, development of a submucosal tunnel for ureteroneocystostomy is usually easier in the bladder itself. Ureteric stents are usually used.

Pyelopyelostomy

Pyelopyelostomy has been used for orthotopic renal transplantation, usually in the left flank.[24] The native kidney is removed, and the kidney transplant is revascularized with the native renal artery or the splenic artery and the native renal vein. The proximal ureter and renal pelvis of the kidney transplant are opened medially, and the native renal pelvis is anastomosed to the kidney transplant renal pelvis with a running fine absorbable suture. After completion of one wall, a double-pigtail ureteric stent is passed with or over a wire through the native ureter into the bladder, and the wire is withdrawn to allow the bladder curl to form. Its position in the bladder is confirmed by reflux of bladder irrigant up the stent. The proximal coil is placed in the renal pelvis of the kidney transplant, and the remaining half of the suture line is completed. Compared with ureteroneocystostomy, an advantage of urinary tract reconstruction with the native renal pelvis or ureter is the ease with which subsequent retrograde pyelography, stent placement, or ureteroscopy can be accomplished through the normally positioned ureteric orifice.

Pyeloureterostomy and Ureteroureterostomy

Pyeloureterostomy and ureteroureterostomy usually are done when the transplant ureter's blood supply seems to be compromised, when the urinary bladder is difficult to identify because of pelvic scar, when the bladder does not distend enough for a ureteroneocystostomy, or when the surgeon prefers one of them to ureteroneocystostomy.[25,39,41] The techniques for ureteropyelostomy and ureteroureterostomy are similar (Fig. 11-15). The posterior, or back wall, anastomosis of the kidney transplant pelvis or ureter to the side or to the spatulated end of the native ureter is completed; a double-pigtail ureteral stent is placed, and the anterior suture line is completed. The proximal native ureter is managed by (1) leaving the native kidney in situ and using the side of the native ureter for the anastomosis, (2) ipsilateral nephrectomy and proximal ureterectomy, or (3) ligation of the proximal ureter with the obstructed native kidney left in situ. Although Schiff and Lytton[59] and Lord and colleagues[45] have described the safety of native ureteral ligation with kidney transplant urinary tract reconstruction, we prefer to leave the native ureter in continuity with its kidney and to anastomose the pelvis or ureter of the renal transplant to the

side of the native ureter. This technique ensures a good blood supply to the native ureter and removes an obstructed, hydronephrotic kidney from the differential diagnosis of a post-transplant problem.

Pyelovesicostomy

Pyelovesicostomy has been described by Bennett,[8] Herwig and Konnak,[28] and Firlit[21] for urinary tract reconstruction when the native ureter and the renal transplant ureter are unsuitable or become so (Fig. 11-16).[21] The bladder must reach the renal pelvis without tension; a bladder extension with a psoas hitch or Boari flap may be necessary.

Ureteroenterostomy

Ureteroenterostomy into an intestinal conduit or an intestinal pouch has been successful.[26,32] It is performed by slight distention of the conduit or pouch with antibiotic-containing irrigant and then using one of the extravesical ureteroneocystostomy techniques. Successful anastomosis of the transplant ureter to the afferent limb of a Koch pouch has been described.[27] If it is difficult to identify the intestinal conduit or pouch because of surrounding intestines, the addition of methylene blue to the irrigant stains the conduit or pouch and makes it easy to find.[71] This topic is discussed more completely in Chapter 12.

Ureteric Stents

We use ureteric stents when there is concern about urinary leakage or temporary obstruction because of edema, periureteral bleeding, or a thickened bladder; when pyelopyelostomy, pyeloureterostomy, or ureteroureterostomy has been performed; or when the ureter has been anastomosed to an intestinal conduit or pouch. The length of the stent is determined by the estimated distance between the renal pelvis of the kidney graft and the bladder or its substitute. A double-pigtail 5F × 12 cm stent is the most common type and size used when the transplanted kidney is located in the iliac fossa. A prophylactic ureteric stent for all kidney transplant ureteroneocystostomies was shown by Pleass and colleagues[54] in a randomized prospective trial to reduce the incidence of urological complications.

Management of Catheter and Stent

The urinary bladder or reservoir catheter usually is removed on postoperative day 5 after a urine specimen is tested at the bedside for nitrites and sent for bacterial culture and after

a single dose of a broad-spectrum antibiotic has been administered. If the urine is shown to be infected, an antibiotic is chosen based on sensitivity results and is prescribed for 10 to 14 days. If a stent had been placed and attached to the indwelling bladder or reservoir catheter, the stent comes out as the catheter is withdrawn. If not, the stent is removed in the outpatient clinic 6 to 12 weeks later.

CLOSURE

Many units obtain a biopsy specimen of the kidney routinely before closure of the wound. This biopsy can be used to provide baseline histology and can provide evidence of ischemic reperfusion injury or early antibody-mediated damage (see Chapters 24 and 25). Methods of closing the wound vary, but, in general, closure with loop nylon in two layers—internal oblique and transverse muscles followed by external oblique—is common practice, with subcuticular nylon or polyglactin closure of the skin.

The question of drainage is controversial because of the risk of providing a portal for entry of microorganisms. If drainage is required, it should be a closed system of suction drainage, and drains should be removed at the earliest opportunity. The exit site of the drain is cleaned daily with an antimicrobial solution and dressed until the drain is removed.

In the past, a capsulotomy of the transplanted kidney before closure was advocated[29,62] by carefully splitting the renal capsule at its convex surface from pole to pole, but not stripping it. This technique was proposed to prevent ischemic injury when the kidney swells as a result of edema; there is no evidence that this is the case, and this practice has now been abandoned.

PEDIATRIC RECIPIENT

For older children, the transplant procedure is the same as for adults if their weight is more than 20 kg.[7,20,52] The renal vessels are anastomosed end-to-side to the iliac vessels or aorta and vena cava.[10,13]

In smaller children (weight <20 kg), the right extraperitoneal space can be developed by extending the incision to the right costal margin,[51] or a transperitoneal approach can be used.[67] In the case of the latter, the abdomen is opened through the midline incision from the xyphoid to the pubis, and the posterior peritoneum is incised lateral to the ascending colon, which is reflected medially. The terminal portion of the vena cava is dissected over 3 to 4 cm, ligating and dividing two to three lumbar veins posteriorly. The terminal aorta also is dissected free at its junction with the right common iliac artery. A partial occluding clamp is used to isolate the vena cava and aorta, and the renal vein is anastomosed to the vena cava first in an end-to-side technique with sutures of 5-0 monofilament vascular suture (Fig. 11-17).[42] The renal artery is anastomosed to the common iliac or terminal aorta in an end-to-side fashion using 5-0 or 6-0 monofilament vascular suture. The renal artery is usually brought in front of the vena cava, but sometimes behind the vena cava. Another approach is to dissect the inferior vena cava, proximal common iliac veins, common iliac arteries, inferior mesenteric artery, and aorta and to control the venous system with tourniquets and the arterial system with a combination of vessel loops and vascular clamps. Use of a 5- or 6-mm aortic punch prevents coaptation of the recipient aorta and renal artery occlusion if significant hypotension occurs. Careful observation of the recipient hemodynamic response on clamping and declamping the vena cava and aorta is required.

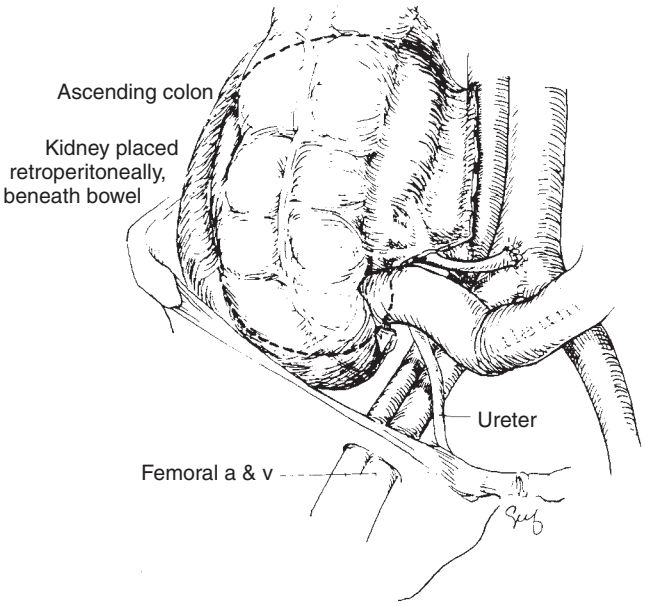

Figure 11–17 Renal transplant in small children (<20 kg). (From Lee HM: Surgical techniques of renal transplantation. In Morris PJ [ed]: Kidney Transplantation. London, Academic Press/Grune & Stratton, 1979, p 159.)

The ascending colon is placed back over the anterior surface of the kidney. No fixation is necessary. The ureter is brought down retroperitoneally crossing the common iliac artery at its midpoint and is implanted into the bladder as a ureteroneocystostomy.

Calne[11] expressed concern about the development of stenosis of the vascular anastomosis in growing children as a result of the use of continuous sutures. He advised performing at least half of the anastomosis with interrupted sutures in children. This advice may apply when one performs end-to-side anastomosis of the renal artery or the renal vein, but Starzl and colleagues[67] stated that after end-to-side anastomosis, there is little likelihood of the development of relative stenosis as a result of growth of the child.

PEDIATRIC DONOR

When a child's kidney is used as a donor kidney for an adult or child recipient, the surgical technique is essentially the same as has been described. Because of the small size of the renal vessels, however, use of aortic and vena caval patches generally is necessary. Interrupted sutures are used by some surgeons for at least half the circumference of the anastomosis. When pediatric kidneys are very small, double kidneys are transplanted en bloc into adults and bigger children.[1,18,33,44,60]

For en bloc transplantation, both kidneys are removed with a segment of aorta and vena cava. The cranial ends of the aorta and vena cava are oversewn. The caudal ends of the aorta and vena cava are anastomosed end-to-side to the iliac vessels. The superior poles of the kidneys are sutured to the sides of the aorta to prevent the torsion or kinking of renal vascular pedicles. Ureters are implanted to the bladder

separately using the extravesical approach or are joined together to form a common funnel, as described earlier. Another technique is to remove segments of the recipient's external iliac artery and vein and anastomose the tubular aorta and inferior vena cava into the defects. A third technique is to incise longitudinally the posterior aorta and inferior vena cava and anastomose these vascular patches to the iliac vessels. A fourth useful technique is to remove a segment of aorta and vena cava below the renal vessels and to reanastomose these segments to the aorta and vena cava above the renal vessels. This technique allows the kidneys to be placed quite low over the iliac vessels and provides a short distance for the ureters to traverse to the bladder.

TRANSPLANT NEPHRECTOMY

Removal of a graft that has undergone chronic rejection and has been in place for many months or years can be extremely difficult and should be performed by an experienced transplant surgeon. The usual approach for the transplant nephrectomy is through the original transplant incision. An abdominal incision may be preferred in small children, particularly if the transplantation was performed intra-abdominally. One also may use the abdominal approach to control the iliac artery system in case of a mycotic aneurysm or a perinephric abscess, in which a potential exists for blowout of vessels.

In the early postoperative period, removal of the transplant in toto is simple with easy identification of the renal pedicle structures. The long-standing transplanted kidney should be removed subcapsularly to lessen the technical difficulty and the bleeding. After deepening the incision sharply to the false capsule, which is incised, the kidney is freed subcapsularly with blunt dissection all around the kidney. The capsule around the hilum has to be incised to get outside it again so as to isolate the pedicle. The pedicle is mass clamped with a Satinsky clamp and divided to remove the kidney. Many surgeons use monofilament vascular suture to oversew the vessels as well as for the ligature. One also may dissect the artery and the vein at this time and ligate them separately, but this is difficult, especially if end-to-side anastomoses have been used. Sometimes the segmental renal arteries and venous branches are ligated and divided as they appear during dissection within the renal hilar scar. Meticulous hemostasis should be obtained with the use of electrocautery. The wound is irrigated with a liberal amount of topical antibiotic solution. It is wise to use prophylactic antibiotics. The technique of deep wound closure depends on the quality of the tissues and the experience of the surgeon, and it can range from interrupted wound closure with buried, absorbable retention sutures to a single-layer closure with synthetic monofilament sutures.

If the wound is grossly contaminated or infected, it should be left open with packing, with secondary closure in mind. Insertion of drains should be avoided because it may increase the incidence of infection, and if drains are considered necessary, a closed system of drainage should be used for a short time.[2,6,35,61]

Chapter 12

Transplantation and the Abnormal Bladder

Julie Franc-Guimond • Ricardo González

The ability of the bladder to store urine at low pressure and to empty completely at intervals is essential to preserve the integrity of the kidneys and to achieve continence. Although an abnormal lower urinary tract is not a contraindication to renal transplantation, bladder dysfunction needs to be addressed before renal transplantation.

Children with end-stage renal disease at risk for bladder dysfunction include patients with known congenital urological anomalies, such as posterior urethral valves, prune-belly syndrome, neurogenic bladder dysfunction, bladder exstrophy, Hinman syndrome, and Ochoa syndrome, and patients with vesicoureteral reflux who have recurrent urinary tract infections.[59,91,106] Familiarity with the evaluation and the management of patients with an abnormal lower urinary tract is important because more recent series report that such patients represent 20% to 30% of renal transplant recipients depending on the given transplant population.[2,35] A large proportion of children with the diagnosis of neurogenic bladder required renal transplantation in some series. In some of the above-mentioned conditions, particularly neurogenic bladder, renal failure is preventable with good management and patient education.

The management of the child with an abnormal lower urinary tract who is awaiting renal transplantation presents a unique series of challenges. When renal failure results from underlying urological anomalies (e.g., posterior urethral valves, prune-belly syndrome, neurogenic bladder), it can be assumed that the abnormal bladder that contributed to the destruction of the native kidneys might adversely influence the outcome of the transplant. Many reports have shown that bladder dysfunction can negatively affect graft function if left untreated. Reinberg and colleagues[93] first pointed this out in 1988. Correction of structural anomalies and optimization of storage and emptying functions of the bladder are often recommended before transplantation. We also support the concept of doing all anticipated reconstructive procedures on the lower urinary tract, including procedures needed to achieve continence, before transplantation.

Urinary diversion has been shown to be safe in renal transplantation.[57,70] With the development of innovative reconstructive techniques, and with the acceptance of clean intermittent catheterization, a permanent incontinent diversion is rarely required today. Instead, patients who require bladder reconstruction can benefit from an augmentation cystoplasty, which is a more attractive alternative. Refunctionalization of the urinary reservoir can be accomplished in patients with a previously defunctionalized bladder in anticipation of renal transplantation.

Although favorable long-term results have been reported, bladder augmentation with gastrointestinal segments carries a significant lifelong complication risk.[109] Despite possible complications, bladder reconstruction has major relevance in the pediatric renal transplant population with small noncompliant bladders. It remains unproven, however, that the benefits of bladder augmentation in cases of posterior urethral valves and renal failure outweigh the risks of reconstruction.

Kelly and coworkers[57] first reported renal transplantation into an ileal conduit in 1966. Marshall and colleagues[70] introduced the concept of combining augmentation cystoplasty with renal transplantation in 1982. Since then, the compatibility of bladder reconstruction and renal transplantation in all age groups has been documented often, but most authors report small series, and controlled studies are lacking. Nonetheless, most publications confirm that patients with dysfunctional bladders treated with an augmentation cystoplasty or a continent diversion may be successfully transplanted, despite the increased morbidity.[47,48,84]

CAUSES OF ABNORMAL BLADDERS

Pediatric end-stage renal disease and its management are unique owing to the high incidence of underlying urological disease—hence the high incidence of patients with possible dysfunctional bladders. Bladders that seem to have normal function initially may become abnormal over time, such as seen in cases of valve bladders. Classically, pediatric patients identified with abnormal bladders carry the following diagnoses: posterior urethral valves, prune-belly syndrome, urethral hypoplasia/atresia and neurogenic bladder, vesicoureteral reflux with renal dysplasia, bladder exstrophy, and cloacal anomalies. Most renal transplant recipients identified as having a dysfunctional bladder are diagnosed and treated before adulthood.

ASSESSMENT OF BLADDER FUNCTION

All patients with known or suspected genitourinary abnormalities require evaluation. Patients without lower urinary tract abnormalities need specific therapy only rarely.[43,107] Other authors have reported, however, that some patients with end-stage renal disease not related to urological problems have abnormal lower urinary tracts when evaluated before renal transplantation. The abnormality is often secondary to prolonged anuria or polyuria, depending on the initial disease.[37] Also, certain urological diseases occasionally may not be obvious or may not have contributed to the progression to end-stage renal disease, such as occult urinary tract neoplasms or urolithiasis, but still need attention. A complete evaluation of the urinary tract before renal transplantation is necessary to limit unforeseen problems occurring after transplantation. If this assessment is consistently adhered to, only in very rare situations does a potential recipient have to be denied the opportunity of receiving an allograft based on preexisting urological diseases. A Spanish group evaluated patients based on the following indications: (1) lower urinary tract symptoms, (2) defunctionalized bladder, and (3) complex urological history (e.g., reflux, neurogenic bladder, urethral valves). The investigators found that 45% of the patients showed abnormal urodynamic studies.[33]

The evaluation starts with a complete history, including voided volumes and frequency, incontinent episodes, and presence of nocturia or nocturnal enuresis. In anuric patients, the history before the onset of anuria is very valuable. In most cases of lower urinary tract anomalies, a voiding cystourethrogram is valuable to outline the bladder contour, evaluate urethral anatomy, and determine the presence of reflux to the native ureters. Noninvasive urodynamics including the pattern of the uroflow examination, the maximal and average flow rate, and the residual urine measured by bladder scanning are invaluable. In most patients without symptoms, a normal uroflow examination and the absence of residual urine are sufficient to rule out significant bladder dysfunction.

Invasive urodynamic studies, including cystomanometry with or without simultaneous intrarectal pressure measurements and electromyography of the pelvic floor, are needed when the bladder capacity and compliance are questionable. The simultaneous performance of a voiding cystourethrogram and cystomanometry (videourodynamics) is most useful in these cases.

The pretransplant urological evaluation aims to diagnose, treat, and optimize any preexisting urological disease.[19,56,91] Cystoscopy is indicated in cases in which the urinary flow is abnormal, residual urine volumes are elevated, or the urethra is difficult to catheterize.

After the evaluation is completed, decisions need to be made regarding the adequacy of the lower urinary tract. Criteria for a usable bladder relate to bladder capacity, bladder compliance, the bladder's ability to empty completely, and urinary continence. The presence of vesicoureteral reflux also should be taken into consideration.

Bladder capacity varies with age. Known formulas exist to determine if the bladder capacity for age is satisfactory for a given patient. With the capacity of the newborn bladder at about 30 to 60 mL, and bladder capacity increasing by about 30 mL/yr each year almost until puberty, bladder capacity in childhood may be reasonably well estimated by a simple formula (capacity in ounces = age in years + 2),[63] although numerous other formulas have been proposed.[13,52,53,55] Although most calculations use the patient's age assuming that the body habitus is within normal limits, this is often not the case in patients with spina bifida and end-stage renal disease. A formula based on weight, such as 7 mL/kg, should be used for that population.

Bladder compliance is defined as the change in bladder pressure for a given change in volume. It is calculated by dividing the volume change (ΔV) by the change in detrusor pressure (ΔP_{det})—compliance = $\Delta V/\Delta P_{det}$—and is expressed in mL/cm H_2O. Decreased bladder compliance implies a poorly distensible bladder in which the pressure/volume curve is steep, and the pressure rise is rapid for low-volume increases. The lowest full resting pressure is preferable regardless of the maximal bladder capacity. In the presence of reduced compliance, medical management can be attempted first, but if the problem remains despite of the use of anticholinergics, bladder augmentation needs to be performed.

The question of what pressure is dangerous for the upper tracts has no straightforward answer. McGuire and associates[75] stated that sustained detrusor pressures greater than 40 cm H_2O put the upper tracts at risk. Also, the bladder capacity and compliance should always be looked at together, and the overall medical and surgical approaches should address both to obtain an optimal storage phase. The optimal bladder capacity is difficult to evaluate or predict in polyuric patients. A polyuric child with end-stage renal disease may have a bladder capacity that, although normal for age or weight, may be inadequate to handle an extremely large diuresis, yet it is often difficult to predict what capacity would be adequate after transplantation. This is a common dilemma in children with posterior urethral valves.[68]

Normal bladder emptying implies complete emptying without dyssynergia or the use of Credé's maneuvers. When the emptying phase is inadequate, the bladder is emptied periodically by means of catheterization either urethrally or through a continent catheterizable channel using the surgical principles described by Mitrofanoff[79] and Monti and colleagues[81] positioned preferably in the umbilicus or at the level of the lower quadrants (Figs. 12-1 to 12-3). Finally, incontinence can sometimes be treated medically with anticholinergics if the problem is related to uninhibited bladder contractions. Incontinence caused by decreased bladder outlet pressure always requires surgical attention,

A B

Figure 12–1 **A**, Catheterization through an umbilical stoma in a patient who had a continent catheterizable channel accomplished using the Mitrofanoff principle. **B**, Larger view of an umbilical stoma in another patient. (See color plate.)

however, using various types of bladder neck procedures (urethral sling, Young-Dees-Leadbetter bladder neck procedure, artificial urinary sphincter implantation, or injection of bulking agents in the bladder outlet) (Figs. 12-4 and 12-5). Artificial urinary sphincter implantation is compatible with renal transplantation.[84]

A functional bladder may need to be re-evaluated over time if the waiting time for renal transplantation is prolonged or if new lower urinary tract symptoms occur. It also is known that bladder dysfunction in children and adolescents occurs after transplantation, even when the bladder was normal before renal transplantation, warranting careful follow-up.[50,115]

MEDICAL MANAGEMENT OF AN ABNORMAL BLADDER

Small and poorly compliant bladders can be managed initially with anticholinergics often combined with clean intermittent self-catheterization. The response to anticholinergic agents should be evaluated not only by the clinical symptoms but also urodynamically. Clean intermittent self-catheterization also is essential to treat hypocontractile bladders with incomplete emptying. The compatibility of clean intermittent self-catheterization with immunosuppression and renal transplantation is well established.[40] Some patients ultimately may require bladder augmentation or urinary diversion before transplantation if urodynamic parameters do not improve or worsen over time.[105]

SURGICAL MANAGEMENT OF AN ABNORMAL BLADDER

Urinary Diversion

Decreased bladder capacity and compliance not responsive to anticholinergic agents should be treated surgically by means of bladder augmentation. The compatibility of intestinal diversions with renal transplantation has been reported often, but the numbers of patients included in controlled studies are often small. Since the 1980s, bladder augmentation and continent reservoir have gained popularity over urinary diversion because they are more socially suitable options for most patients. Nonetheless, patients can be considered for transplantation with an incontinent urinary diversion, such as an ileal conduit. These patients should be appropriately assessed before transplantation occurs. Investigation of such patients particularly should include

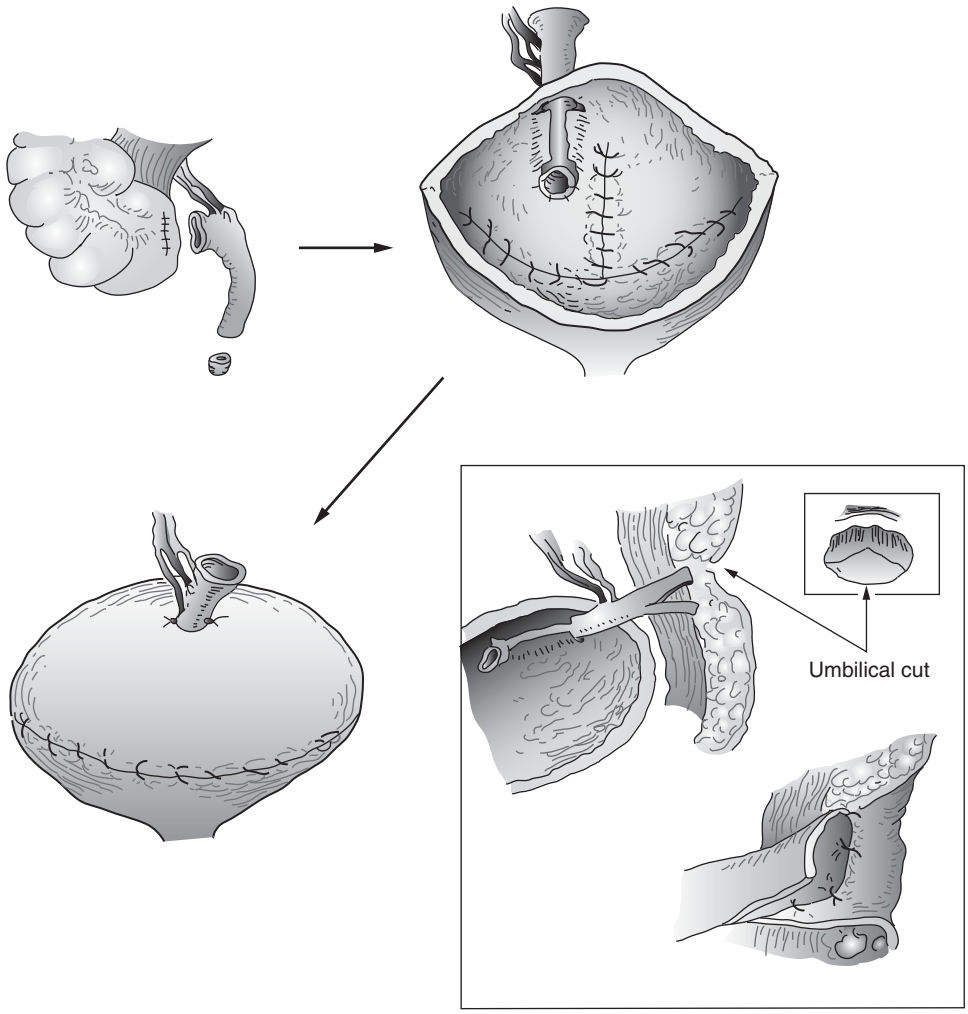

Figure 12–2 Illustration showing the creation of an appendicovesicostomy using the Mitrofanoff principle.

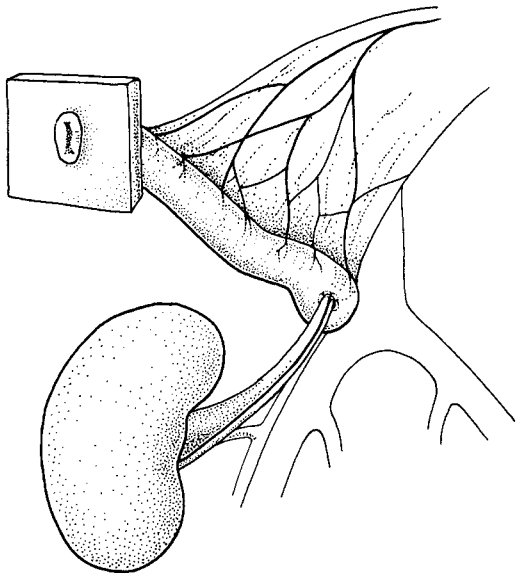

Figure 12–3 Illustration showing the creation of a continent catheterizable channel with a bowel segment using Monti's principle.

a contrast study of the conduit to evaluate its course and length before transplantation. Also, the possibility of urinary undiversion before transplantation should be considered in selected cases. Careful assessment of the native defunctionalized bladder before kidney transplantation may reveal a usable lower urinary tract in many patients. Most of these bladders need some kind of rehabilitation, however. An assessment of the continence mechanism also is mandatory.

Bladder Reconstruction

Augmentation cystoplasty performed using various bowel segments is now used routinely for treatment of reduced bladder compliance and capacity, but the use of intestinal tissue to increase the size of the bladder is not a modern idea. In 1888, Tizzoni and Foggi[114] reported an animal model of bladder augmentation by connecting a loop of ileum to the bladder neck. During the late 19th and early 20th centuries, there were various attempts at lower urinary tract substitution, usually involving some form of rectal pouch.[65,73,96,102] In the preantibiotic era, results in humans were poor, tempering enthusiasm for such surgical techniques. During the 1950s, interest in cystoplasties was renewed, with Couvelaire[25] and Gil-Vernet[41] reporting good results using

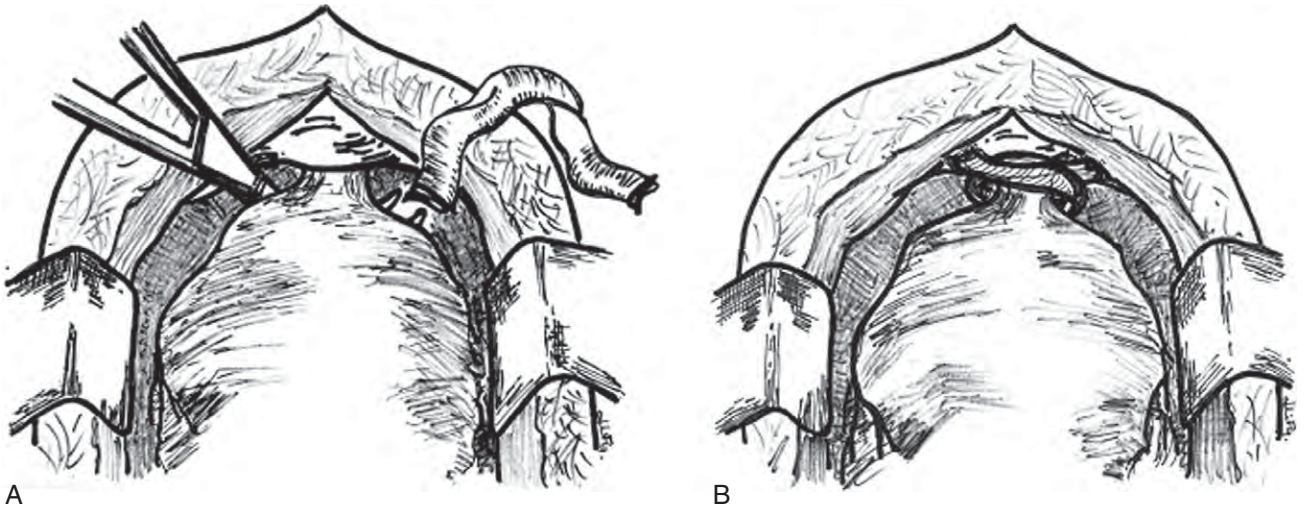

Figure 12–4 Illustration showing how the installation of a sling can be done in pediatric patients. The sling (allograft fascial sling or autologous) is transferred around the bladder neck and crossed anteriorly. The ends are secured with permanent sutures and anchored suprapubically to Cooper's ligaments.

large and small bowel segments. During subsequent years, use of these procedures increased rapidly as their technical aspects were better defined. The use of clean intermittent catheterization also broadened considerably the applicability of these surgical techniques because appropriate urinary drainage is needed for patients with neurogenic bladder and others unable to empty spontaneously.[66]

The principal indication for bladder augmentation is a small-capacity, poorly compliant bladder that precludes storage of urine for a reasonable amount of time at a "safe" pressure, allowing continence and avoiding damage to the upper tracts (Fig. 12-6).[89] Incontinence also may be a problem, and it should be addressed simultaneously.

Augmentation cystoplasty has been used in a diverse group of patients, including patients with neurogenic bladder (especially due to myelomeningocele), exstrophy, posterior urethral valves, bilateral ectopic ureters, inflammatory disorders (including tuberculosis and interstitial cystitis), and

miscellaneous causes. Although the ideal material for bladder augmentation has not been developed, we do know its ideal properties. It should be easily available as a viable graft, easily shaped, compliant, easily accessible for periodic endoscopic examination, impermeable, and exempt of mucus production. Although bowel does not meet all of these criteria, most notably the latter two, in many ways it has served well for many years. Sigmoidocystoplasty and ileocystoplasty have become standard techniques (Fig. 12-7).

Because of the relatively high morbidity of intestinal cystoplasty, there is renewed interest in alternative techniques, such as seromuscular augmentation, various alloplastic or biodegradable scaffolds, and in vitro culture with subsequent grafting of autologous urothelium. These alternative procedures all have been reported to avoid inclusion of intestinal mucosa in the urinary tract while creating a compliant bladder of adequate capacity. Although encouraging results have been reported in animals and humans, each technique is associated with its own limitations and disadvantages. Nonetheless, we prefer to use the seromuscular colocystoplasty lined with urothelium rather than conventional surgical techniques when feasible and appropriate for a given patient (Fig. 12-8).[54]

CONSIDERATIONS IN MANAGEMENT OF AN ABNORMAL BLADDER

Reflux

High-grade vesicoureteral reflux that is left untreated after transplantation is accompanied by a higher risk of urinary tract infections even if it was not a problem before transplantation.[15] Surgical options for treatment—ureteral reimplantation or nephrectomy—have been associated with a reduced risk of infection after transplantation.[15,34] Endoscopic injections also have been used to treat children with vesicoureteral reflux awaiting renal transplantation.[5,44,58]

Timing

More challenging for pediatric urologists is the question of when to augment the bladder in children with posterior urethral valves. Bladder dysfunction and urinary incontinence in children with a history of posterior urethral valves is more common in the presence of renal insufficiency. One of the factors that contribute to a relative decreased storage capacity and incontinence in such cases is polyuria from renal tubular dysfunction. The bladder that seems inadequate before

(**B**-**E**, See color plate.)

the renal transplant may behave normally when the polyuria resolves. A bladder that has inadequate capacity and compliance for a given urine output may contribute to or accelerate the progression of renal failure.[68]

The timing and type of bladder augmentation relative to the transplantation warrants comment. Most authors have performed the augmentation before the transplantation. This seems to be a safe approach but presents a management problem when the patient is anuric and expecting a cadaver donor organ. Cycling the augmented bladder by clean intermittent self-catheterization is necessary while waiting for a kidney to become available. The small number of cases in which the bladder was augmented after transplantation attests to the feasibility of such an approach when needed. Nevertheless, it is generally recommended that if a conduit or a bladder augmentation is needed, it should be done several weeks before transplantation, although ureterocystoplasty may be performed simultaneously.[86]

Segment to Use

As mentioned earlier, sigmoidocystoplasty, ileocystoplasty, and variants such as the seromuscular colocystoplasty lined with urothelium[54] have become standard techniques for reconstructive procedures, and this is also true for the transplant population. Nonetheless, alternatives exist. Bellinger[12] described, in 1993, the technique of ureterocystoplasty using a detubularized segment of dilated ureter to augment the bladder. Soon after this initial publication, other reports of ureterocystoplasty were published.[22,51,92,117] These series show that in many ways ureterocystoplasty may be a good technique for bladder augmentation. It produces a compliant reservoir lined with urothelium, avoiding metabolic complications, mucus production, and the cancer risk of a heterotopic epithelium. Ureteral tissue should be used to augment the bladder when possible.[49,64,110] This approach is not frequently practical, however, because it is applicable only in a highly select group of patients with unilateral megaureter and poorly functioning kidney, and it may not provide sufficient functional capacity. The most common candidate is a boy with posterior urethral valves with a noncompliant bladder. These children are often polyuric, however, and, in our experience, the increase in capacity obtained with the ureter is often insufficient for the high urine output.

Gastrocystoplasty, another option, was initially thought to be a great idea, but as the popularity of gastrocystoplasty increased, so did awareness of the potential complications, such as severe metabolic derangements and the so-called hematuria-dysuria syndrome (bladder/urethral pain, hematuria in the absence of infection, skin excoriation), which has been seen in 36% of patients after gastric augmentation.[85] Another concern is having gastric tissue in the bladder of an anuric patient because of the risk of peptic perforation. We were the first to describe this complication,[94] and others made similar observations.[38,68,110] The widespread use of gastrocystoplasty seems to be fading given the serious potential complications; patients with preexisting gastrocystoplasty must be followed carefully for possible hypochloremic alkalosis and treated effectively with suppression of acid production, especially in the oliguric phase of disease.

Management of Anuric Patients

The management of a patient with a bladder augmentation or reservoir before transplantation is problematic, particularly if the patient is anuric or oliguric. This issue is magnified in the patient on a cadaver donor waiting list because the bladder or neobladder must be kept sterile so as not to miss possible opportunities to use a well-matched organ. We usually recommend daily bladder irrigations and instillation of an antibiotic solution. Instillation of aminoglycosides, which is usually safe, may lead to complications in patients with end-stage renal disease.[29]

Prophylactic Antibiotics

Other vexing problems are maintaining bladder sterility until the transplant is performed and preventing urinary tract infections after renal transplantation. Suboptimal bladder function in transplant recipients is linked to an increased risk of urinary tract infections, which could affect graft outcome.[26] This is particularly true for patients with small, noncompliant bladders.[56] Most authors recommend identification and normalization of bladder dysfunction before renal transplantation.[19,38,64,67]

Clean Intermittent Catheterization

Most patients with an augmented bladder and all patients with a continent diversion empty by clean intermittent catheterization. Although clean intermittent catheterization results in virtually universal bacteriuria, the safety of clean intermittent self-catheterization in renal transplantation has withstood the test of time,[6,40] and renal recipients performing clean intermittent self-catheterization can expect outcomes comparable to outcomes of children with normal bladder function.[21,28,38,49,67]

Complications of Reconstructive Lower Urinary Tract Procedures

The many metabolic and surgical complications observed with intestinal cystoplasties have been well published in the medical literature. One of the first reports of metabolic disturbances associated with intestinal urinary diversion appeared in 1931.[17] Since this initial publication, a wide variety of metabolic disturbances associated with use of intestine in the urinary tract have been reported. The main problem is a functional mismatch. Bowel mucosa and urothelium have different absorptive properties, the latter being impermeable to most electrolytes and ammonia under normal conditions. The severity of the disturbance is affected by the segment of bowel used, the amount of time spent in contact with urine, and the concentration, composition, and pH of the urine.[60-62,87] Other metabolic anomalies have been observed in addition to the hyperchloremic acidosis typical of ileal and colonic augmentation, including growth retardation,[82] malignancy,[8,36,74] interrupted bile acid recirculation,[7] and impaired clearance of drugs.[16] Urolithiasis formation in the augmented bladder or urinary reservoir is another complication of intestinal bladder substitution and augmentation that is seen in 30% of patients after augmentation cystoplasty, but it also can be seen in patients on clean intermittent self-catheterization

without augmentation.[9] The predominant stone composition is triple phosphate, usually identified in the reconstructed lower urinary tract.[14] The predisposition for stone formation in these patients may be due to infection, mucus retention, or the presence of foreign bodies.[88] Surgical complications of intestinal cystoplasty also are well known—perhaps the most devastating is spontaneous perforation of the bowel segment.[4,11,24,32,42,100,103,108]

Surgical Complications of Renal Transplantation into Reconstructed Abnormal Bladders

Our experience and the reviewed literature suggest that transplantation can be performed safely in patients with reconstructed bladders and urinary diversions with acceptable graft survival and function. Some authors reported an increased incidence of urological complications, such as urinary leak, ureteral stenosis, symptomatic urinary tract infections, metabolic acidosis, and calculi. There are few controlled studies that permit meaningful comparisons between results of transplantation in native versus reconstructed bladders. Comparison among reported series is difficult because some fail to define the source of the graft, which is one of the best-known determinants of graft survival. Some series combine patients with bladder augmentation with patients with diversions; this is problematic because it is well recognized that nonrefluxing ureteroenterostomies, in contrast to ureteroneocystostomies, carry a risk of stenosis of greater than 10%.[112] Nevertheless, one retrospective controlled study that included mostly adult patients with urinary diversion failed to show any differences with control patients with normal bladders.[116]

There is little question that in patients who must have bladder augmentation to attain continence or prolong life of the native kidneys, such as patients with neurogenic bladder or after cystectomy, renal transplantation can be accomplished with satisfactory results. The "catastrophic results" reported by one author[3] in a few cases are not the rule in the published literature or our experience.

Results of Pediatric Series

Most authors agree that although more complicated, it is feasible to proceed with renal transplantation in patients who are known to have an abnormal bladder with good results. Nahas and colleagues[83] reported on 24 patients (mean age 27.6 years), 21 of whom had the enterocystoplasty performed before transplantation. Seventeen transplants were from living donors. This is the largest series from a single center. In their series, the graft survival at a mean of 5 years was 78%, and the mean serum creatinine level was 141 μmol/L. Four patients died with functioning grafts. One patient died of bladder cancer 25 years after the augmentation, which was done because of tuberculosis of the bladder. The surgical complications mentioned included ureteral stenosis in two patients and a lymphocele in another. Urinary tract infections occurred at least once in 56% of patients, and 32% required hospitalization.

The largest pediatric series reported is by Hatch and coworkers,[49] which consists of a retrospective review of children operated on in 16 North American centers over 28 years. The series includes patients with bladder augmentation ($n = 17$) and patients with urinary diversion ($n = 13$). Of the transplants, 45% were from living related donors. A surgical complication rate of 19% was reported. Surgical complications consisted of renal artery stenosis ($n = 1$), urinary leak and fistula ($n = 2$), bladder calculus ($n = 1$), and wound dehiscence ($n = 1$), or were related to the cutaneous stoma ($n = 2$). Five patients developed metabolic acidosis (four augmented). The incidence of postoperative urinary tract infections was not reported. Graft survival by donor type was not reported. The mean serum creatinine level for all patients was 133 μmol/L at 5 years and 221 μmol/L at 9 years. The graft survival was not significantly different for augmentation and diversion groups (78% versus 46%), but the trend suggests better results in the augmented group. More recently, Martin and associates[71] and DeFoor and coworkers[27] published great results using enterocystoplasties.

Another multi-institutional review from 15 centers in France[99] included 20 patients with bladder augmentation, 8 with continent diversion, and 23 with incontinent diversion who received deceased donor renal transplants. The graft survival was 76% at 5 years, and there were no statistical differences between patients with augmentation or diversion. Data on renal function were not reported. Thirteen of 51 patients required repeat operations, including three for ureteral complications, three for lithiasis, and one for adenocarcinoma of the pouch. The incidence of urinary tract infections was 18%.

Another report from France[38] included 14 children (10 posterior urethral valves), all with bladder augmentation (10 performed before transplantation). The graft survival was 84% and 73% at 5 years and 10 years, respectively. The serum creatinine level was less than 124 μmol/L in 9 of 14 patients after a mean follow-up of 80 months. Complications included symptomatic urinary tract infections in four patients, metabolic acidosis in two, lithiasis in two, and hematuria-dysuria syndrome in the only patient who underwent augmentation with stomach.

Koo and associates[64] reported on 18 children (mean age 8.4 years); 4 had an enterocystoplasty, 2 had a ureterocystoplasty, and 7 had a diversion (5 continent, 2 incontinent). The remaining five patients were transplanted into their native bladders. Eight had a history of posterior urethral valves. Fifteen patients received kidneys from living related donors. Graft survival at a median follow-up of 4.4 years was 81%, and the mean serum creatinine level was 124 μmol/L. Complications included ureteral stenosis in two patients, incontinence in one, lithiasis in two, and stomal stenosis in one. Allograft thrombosis occurred in two patients. Metabolic acidosis was observed in 12 patients, and urinary tract infections were seen in 10.

Power and colleagues[90] published results of 17 cadaver donor renal transplantations in 16 patients with spina bifida (mean age 20 years). Eight patients had enterocystoplasty, five had ileal conduits, and three had native bladders that emptied by clean intermittent self-catheterization. Graft survival was 65% at 53 months, and the mean creatinine level was 113 μmol/L. There were two deaths after failed transplantation.

A report of nine children (seven augmentations, two continent diversions) from three centers included patients with posterior urethral valves ($n = 3$), urogenital sinus anomalies ($n = 2$), and miscellaneous conditions ($n = 4$).[110] Five augmentations were accomplished with stomach.

Two patients had artificial urinary sphincters. Graft survival (initial transplantation) was 56% at 29 months. At last follow-up, eight of nine patients were dialysis-free, and the mean creatinine level was 106 μmol/L. Complications occurred in five patients, including small bowel obstruction ($n = 1$), hematuria-dysuria syndrome ($n = 1$), stomal stenosis ($n = 1$), and ureteral obstruction ($n = 2$).

Nguyen and colleagues[84] reported 17 patients with a mean age of 20 years who underwent 20 transplantations (14 living related donors). This was a retrospective controlled study, which included 7 patients with previously defunctionalized bladders, and 10 with either augmentation or diversion. There were no statistical differences in graft survival (70%) and patient survival (88%) among augmented/diverted bladders, previously defunctionalized bladders, and control patients. Mean serum creatinine level was 80 μmol/L for the previously defunctionalized bladders at 5 years and 106 μmol/L in the diversion/augmentation group at more than 5 years. There were no surgical complications in the previously defunctionalized bladders. In contrast, in patients with bowel incorporated into the urinary tract, there were four ureteral complications, one wound dehiscence, and one lithiasis. One patient developed metabolic acidosis, and four had urinary tract infections. Three other series looked at graft survival among augmented/diverted cases; although they reported better results in the diverted groups, the differences are not significant.[76,77,98]

A report on 13 patients transplanted into small bladders that had been defunctionalized for 3 to 20 years but not augmented (3 posterior urethral valves) indicated a graft survival of 62% at 4 years.[69] There were no surgical complications. Another seven patients considered to have unusable bladders underwent transplantation into an existing urinary conduit. Their graft survival was 57% at 4 years. Patient survival was comparable.

In contrast, Alfrey and coworkers[3] reported kidney transplantation in eight patients with an enterocystoplasty as bladder augmentation. In five patients, the augmentation was taken down before the transplant, and in three the kidney was transplanted into the augmentation. Of those three patients, all had severe urinary tract infections. One died, one lost the graft, and another was being considered for an incontinent diversion. In contrast, the patients whose augmentation was taken down fared well, and the authors concluded that augmented bladders represent a significant risk in kidney transplantation.

Rigamonti and colleagues[98] published a distinctive study that looked at long-term results. From September 1987 to January 2005, 255 patients (161 males and 94 females) with a median age of 14 years (range 7 months to 39 years old) received 271 kidney transplants. The cause of end-stage renal disease was lower urinary tract disease in 83 cases. Among them, 23 had undergone bladder augmentation ($n = 16$) or incontinent urinary diversion ($n = 7$). Cumulative graft survival rates of all cases transplanted was 69.4% after 15 years; in the two investigated groups, augmented group and diverted group, graft survival was 80.7% (augmented group) and 55.5% (diverted group) (P value not significant). The Italian authors concluded that bladder augmentation or urinary diversion is an appropriate management strategy when the native bladder is unsuitable and yields similar results to those obtained in the general population with normal lower urinary tracts.

Additional publications warrant comment. In a retrospective controlled study from Sweden[116] involving four institutions during a 15-year period, the outcomes of transplantation in patients with continent and incontinent diversion were compared with patients with normal bladders. The only difference among the groups was the surgical time, which was longer in the diverted group. Graft survival (70% versus 74%) and patient survival at greater than 5 years were similar. Likewise, there was no statistical difference in the 5-year serum creatinine level, but the data presented suggest a tendency toward a higher serum creatinine in the continent diversion group. Another controlled study published in 1994 by Griffin and coworkers[45] stated that graft survival and patient survival were comparable, with graft survival being 70% at 5 years for both groups and patient survival being 82% and 90%.

Riedmiller and associates[97] reported 12 patients (7 children) with renal transplantation (all cadaver donors) into continent diversion (4 with posterior urethral valves). Technical difficulties led to the need for reoperations in 6 of 12 patients, including 1 child requiring a second transplantation. At 32 months of follow-up, the mean creatinine level was 115 μmol/L, and 11 of 12 initial grafts were functioning. Bacteriuria was present in all cases, but no episodes of pyelonephritis were recorded. All of the aforementioned studies are summarized in Table 12-1.

Posterior Urethral Valves

Renal transplantation in patients with posterior urethral valves is unique. It is well known that many of these children have bladder dysfunction with poor compliance,[20] and the proportion may be higher in children who have renal failure. Although many uncontrolled studies suggest that renal transplantation into the valve bladder is associated with good results,[23,101] close examination of every controlled study reported to date indicates that patients with renal transplantation into nonreconstructed valve bladders exhibit higher creatinine levels at the end of 5 years compared with controls. This higher creatinine level has been observed in virtually all studies reported and has been attributed to bladder dysfunction.[2,18,46,93] In 1997, Salomon and colleagues[104] reported worse results of transplantation in children with posterior urethral valves and symptomatic bladder dysfunction than with children without such symptoms. The graft survival may be normal or marginally decreased in these cases.[30,101] It has been tempting to pursue an aggressive approach to the valve bladder in hopes of improving the life span of the native kidneys and improving the results of renal transplantation. Others[10] have shown, however, that patients with posterior urethral valves managed by a limited intervention approach had better outcomes than patients who underwent extensive urological procedures. Nonetheless, transplantation into a nonreconstructed valve bladder and into an augmented bladder can yield acceptable graft survival rates.[28] Lacking controlled studies of patients with posterior urethral valves to define the possible advantages and risks of lower urinary tract reconstruction, no recommendations can be made based on the available evidence as to the indications of bladder augmentation in this condition.

In addition, one study indicates that the rate of post-transplantation urinary tract infections is greater in patients with a history of posterior urethral valves, regardless of the

presence of reflux.[80] This information is important, not to discourage renal transplantation in young patients with a history of posterior urethral valves but rather to pay particular attention to bladder care in these cases. It would seem rational to do everything feasible to optimize bladder function before transplantation by improving emptying, decreasing storage pressures, and providing adequate capacity. When evaluating these bladders, it must be remembered that what is considered adequate bladder capacity and compliance varies with the obligatory diuresis of a given patient. Inadequate capacity in a polyuric child with end-stage renal disease may become acceptable after the transplant when the urine output normalizes. Measures such as clean intermittent self-catheterization and anticholinergics should be used if indicated.[3]

Prune-Belly Syndrome

The first renal transplant in a patient with prune-belly syndrome was reported in 1976 by Shenasky and Whelchel[111] followed by other single case reports.[31,78] In 1998, Fontaine and colleagues[38] reported on a controlled study done retrospectively, indicating that the results of renal transplantation with regard to graft survival and function in cases of prune-belly syndrome were comparable to those of controls. These results confirm previously reported results by Reinberg and coworkers in 1989,[95] which is not surprising because bladder storage pressures are low in most cases of this syndrome. Later, an Italian group published their experience with a series of five boys and reported good results as well, but they stressed the need to address the lack of abdominal wall musculature by performing abdominal wall reconstruction in selected patients.[39] A unique complication specific to renal transplantation performed in patients with prune-belly syndrome is torsion of the graft, attributed to the laxity of the abdominal wall or improper fixation of the kidney.[1,72]

FOLLOW-UP

Abnormal bladders must be assessed urodynamically before and after transplantation. Adequacy of urinary storage and drainage must be reassessed after renal transplantation even in patients known to have a normal lower urinary tract before the transplantation because they also may exhibit abnormal bladder function. A Swedish study published in 2005 showed that abnormal bladder capacity was found in 26%, abnormal urinary flow in 50%, and residual urine in 32% of the patients, and there was no significant difference in bladder or renal function in children with urinary tract malformations and those with normal urinary tracts.[50] Prophylactic antibiotics are now given for the first 6 months, and urinary tract infections must be treated promptly. With these measures, good results, similar to those in patients without urological problems, can be obtained.

CONCLUSION

End-stage renal disease caused by congenital genitourinary anomalies is common, especially in pediatric patients. Integrity of the lower urinary tract is mandatory, and proper investigation should be done in a given population. Graft implantation into the native bladder is always preferred. Surgical correction may be required, however, if the bladder is unsuitable. Planning ahead is crucial, and a multidisciplinary approach is advocated if possible. Bladder reconstruction and procedures to correct incontinence should be done before transplantation when clinically indicated.

Bladder reconstruction, although not exempt from complications, is an acceptable method for patients with abnormal lower urinary tracts who are candidates for renal transplantation. The use of bladder reconstruction before transplantation in children with posterior urethral valves is different, however. The appropriate management of the valve bladder in patients requiring renal transplantation is still in question because results tend to vary between studies. In such cases, the complications associated with the reconstructed bladder should always be balanced against the possible risks of performing renal transplantation into an abnormal bladder. Finally, even if the reported series of renal transplantation into abnormal bladders are small, and there are few controlled studies, the graft and patient survival rates in most series seem to be comparable to the rates for transplants into nonreconstructed bladders.

Chapter 13

Anesthesia for Patients Undergoing Renal Transplantation

John W. Sear • Oliver J. Dyar

Patients with end-stage renal failure may receive replacement therapy by dialysis or by renal transplantation from a living related donor or a cadaver donor. Many factors that contribute to end-stage renal disease—generalized atherosclerosis, uncontrolled hypertension, and diabetes mellitus, among others—also increase the perioperative cardiovascular risk associated with anesthesia and surgery. Chronic renal failure increases the risks of ischemic heart disease and poor anesthetic outcome.

In 1996, in one of the first reports of the anesthetic problems associated with renal transplantation, Strunin[187] reported a 56% mortality rate within 3 months of surgery. More recent data show a considerable improvement. Solomonson and coworkers[183] observed a 30-day mortality rate of 2.8% in patients undergoing formation of an arteriovenous fistula, whereas Humar and coworkers[96] reported a 6.1% overall perioperative cardiac complication rate among 2694 renal transplant recipients, and Gill and Pereira[74] reported a 4.6% first-year all-cause mortality rate in 23,546 adult first-transplant patients, with greater than 25% of these being secondary to cardiac causes. The main predictors of adverse outcome are a past history of pretransplant cardiac disease or myocardial infarction within the previous 6 months and age older than 40 years.

A patient with end-stage renal disease scheduled for renal transplantation presents the anesthesiologist with many clinical problems. Successful outcome depends on a clear understanding of the clinical issues of renal failure; the influence of renal failure on the pharmacokinetics, metabolism, and pharmacodynamics of anesthetic drugs; the correct management of the intercurrent problems that caused the renal failure; and the choice of an appropriate anesthetic technique for renal transplantation.

CLINICAL PROBLEMS RELEVANT TO ANESTHESIA FOR RENAL TRANSPLANTATION

Cardiovascular Disease

The two main cardiovascular effects of chronic renal failure are arterial hypertension and atherosclerosis and hyperlipidemia leading to ischemic heart disease. Hypertension and ischemic heart disease are common complications in patients presenting for renal transplantation. The incidence of preoperative hypertension is about 80% in patients undergoing renal transplantation.[192] Hypertension of chronic renal

failure often is a consequence of volume expansion secondary to salt and water retention.[19] It usually can be controlled with dialysis and appropriate antihypertensive therapy. In patients in whom the hypertension cannot be controlled by dialysis alone, it has been suggested that an abnormal relationship exists among plasma renin activity, intravascular fluid volume, and blood pressure. There also may be an inappropriate level of sympathetic activity.[36] Patients needing treatment in addition to dialysis are often refractory to single agents and require large doses of combinations of antihypertensive drugs (e.g., β-adrenoceptor blocking drugs, calcium channel blockers, vasodilators, and angiotensin-converting enzyme inhibitors), which all may combine to produce significant drug interactions with volatile and intravenous anesthetic agents.[172,176]

In a post-transplant patient in whom there is correction of the uremia and fluid imbalance, persistence of hypertension may be due to acute or chronic rejection of the allograft, the presence of native diseased kidneys, or transplant artery stenosis. Cyclosporine therapy also may produce hypertension; this often is accompanied by renal dysfunction. It seems to be a direct vasoconstrictor response and an action of cyclosporine on intracellular calcium homeostasis. Cyclosporine reduces renal tubular sensitivity to aldosterone. Other contributory factors include the presence of cyclosporine-induced hypomagnesemia and the renal production of thromboxane A_2.

Despite seemingly adequate therapy, 50% to 70% of patients receiving a renal transplant experience marked swings in blood pressure during surgery (± 30% shifts from the awake preinduction value) and show exaggerated vascular responses to induction of anesthesia, laryngoscopy, and intubation and extubation. Induction of anesthesia is best achieved by combining a hypnotic agent supplemented with an opioid (remifentanil, fentanyl, alfentanil, or sufentanil). Patients receiving antihypertensive or antianginal treatment (especially patients receiving β-adrenoceptor blocking drugs, angiotensin-converting enzyme inhibitors, and calcium channel blockers) should receive their "regular" therapy as part of their premedication. In patients not receiving therapy and presenting for surgery with elevated blood pressure, Stone and colleagues[185] showed the efficacy of preoperative oral β-adrenoceptor blockade as an adjunct to premedication in reducing the hemodynamic lability in response to surgical stress and its associated incidence of myocardial ischemia (Fig. 13-1).

Patients with renal failure, especially patients on dialysis, are prone to develop accelerated atherosclerosis. Left ventricular function may be compromised further by uremic cardiomyopathy and pericarditis.

Anemia

Anemia has been a major problem in the anesthetic management of patients with renal failure. Hemoglobin concentrations in patients receiving hemodialysis before transplantation often were 6 to 8 g/100 mL with hematocrit values of 20% to 25%, although this is now uncommon with the more liberal use of erythropoietin in anemic patients with renal failure, at least in the Western world. The normal picture is that of a normochromic, normocytic anemia of complex origin that usually is due to impaired erythropoiesis secondary to decreased erythropoietin synthesis and release.

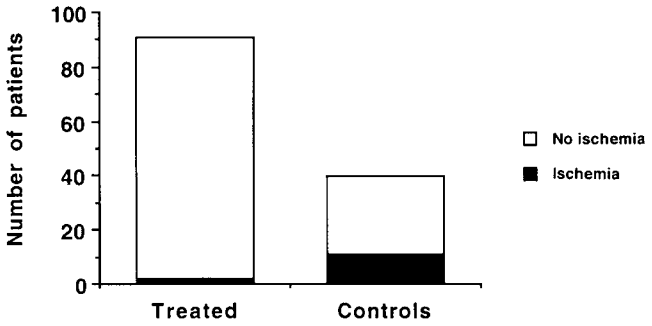

Figure 13–1 Reduction in the incidence of myocardial ischemia during surgery after pretreatment of untreated or poorly treated hypertensive patients with oral β-adrenoceptor antagonists. (From Stone JG, Foex P, Sear JW, et al: Myocardial ischemia in untreated hypertensive patients: effect of a single small oral dose of a beta-adrenergic blocking agent. Anesthesiology 68:495, 1988.)

Other factors include a decreased red blood cell life span, increased hemolysis and bleeding, repeated blood loss during hemodialysis, aluminum toxicity, uremia-induced bone marrow suppression, and iron, folate, and vitamins B_6 and B_{12} deficiencies.[64]

In the absence of a correction of the anemia, there are compensatory mechanisms for the reduction in oxygen-carrying capacity. At a hemoglobin concentration of 6 to 8 g/100 mL, the oxygen-carrying capacity of the blood is about 50% normal (i.e., about 10 mL oxygen per 100 mL blood). The normal tissue arteriovenous oxygen difference is 5 mL oxygen per 100 mL blood, although the heart extracts two to three times this amount. Various compensatory mechanisms exist to overcome the decrease in oxygen-carrying capacity, including an increase in cardiac output and an increase in the red blood cell 2,3-diphosphoglycerate. The latter causes a shift of the oxygen dissociation curve to the right, improving tissue oxygenation. The shift seems to be greater in uremic patients who are well managed by hemodialysis compared with patients in renal failure who are poorly managed or are not on dialysis. This difference may reflect the influence of acidosis on the oxyhemoglobin dissociation curve. Severe anemia also affects the blood-gas partition coefficient for the volatile anesthetic agents, with an increase in the rate of onset and recovery from anesthesia.

Respiratory System

Between dialysis sessions, pulmonary congestion and edema often are seen with a resultant hypoxemia and hypocapnia. The use of peritoneal dialysis can aggravate the problem because the intraperitoneal fluid causes diaphragmatic splinting with basal pulmonary atelectasis and shunting. Uremic lung is a radiological entity characterized by perihilar pulmonary venous congestion secondary to fluid retention. Uremia can cause pleuritis. Immunosuppressed transplant patients are more susceptible to pulmonary infections, with preexisting disease often exacerbated by airway instrumentation and general anesthesia.

Acid-Base Status and Electrolyte Imbalance

Patients with renal failure have an impaired ability to excrete water, electrolytes, and free acids. The presence of a metabolic

acidosis with its associated electrolyte disturbances (hyponatremia, hyperchloremia, and hyperkalemia) may cause problems with respect to the adequacy of reversal of residual neuromuscular blockade at the end of anesthesia.

With the introduction of routine dialysis in most patients before transplantation, preoperative electrolyte disturbances have largely disappeared. Of more importance is the blood potassium concentration. At serum concentrations greater than 7 mmol/L, abnormal electrocardiogram (ECG) changes are common, with the possibility of developing ventricular tachycardia and ventricular fibrillation. A high potassium level before anesthesia is potentially dangerous and must be avoided. Evidence exists, however, that uremic patients can tolerate mild-to-moderate degrees of hyperkalemia (see later). It is probably safe to administer anesthesia in the presence of higher than normal potassium concentrations, unless there are ECG changes associated with hyperkalemia (high-peaked T waves, decreased amplitude of the R wave, widened QRS complexes, and progressive diminution of P wave amplitude).

Methods available for the preoperative correction of hyperkalemia include glucose-insulin therapy and administration of bicarbonate (these are acute temporary methods rather than being corrective), or continuous hemofiltration or hemodialysis leading to increased potassium elimination. Situations that may increase further the plasma potassium concentration (including infusions of stored blood and hypoventilation causing respiratory acidosis) are best avoided.

Coagulation

Some patients show persistent heparinization after hemodialysis before transplantation.[82] A few uremic patients, normally patients who are inadequately dialyzed or undergo transplantation before requiring dialysis, exhibit a separate hemorrhagic diathesis.

Several abnormalities of the coagulation factors have been described (platelet dysfunction, decreased levels of platelet factor III resulting in poor adhesiveness, and thrombocytopenia). Laboratory investigations show no alteration in prothrombin or partial thromboplastin time, but the bleeding time is prolonged. The decrease in platelet factor III occurs because of accumulation of toxic endogenous waste products, including guanininosuccinate, phenol, and phenolic acid. These products are removed by adequate dialysis with a return to normal platelet function.

Other methods of treatment of uremic coagulopathy include platelet transfusion, cryoprecipitate, and infusions (0.3 μg/kg) over 15 minutes of desmopressin acetate. Desmopressin acetate acts to increase the activity of coagulation factors VIII and XII, von Willebrand's factor, and high-molecular-weight kininogen.[130,131]

Despite these theoretical problems, the blood loss during transplantation normally is less than 500 mL. If blood loss occurs, it may be rapid, and all replacement fluid should be administered through large venous catheters.

Central Nervous System

The central nervous system features of uremia are initially malaise and reduced mental ability. Other manifestations include myoclonus, seizures, coma, and death. Patients complain of pruritus, which tends to be severe at night and at rest and is relieved by movement. Peripheral neuropathies also may occur, especially in the lower limbs, and may involve the autonomic nervous system, leading to postural hypotension. Dialysis is associated with neurological sequelae, such as the dysequilibrium syndrome. This sequela arises from sudden changes in extracellular volume and electrolyte composition and cerebral edema. The dysequilibrium syndrome is characterized by dehydration, weakness, nausea and vomiting, hypotension, and occasionally convulsions and coma. Treatment should be symptomatic and aggressive.

Endocrine System

Diabetic nephropathy is a common cause of end-stage renal disease and may be accompanied by accelerated atherosclerosis. Severe coronary artery disease may be a significant presenting feature of the triad of diabetes, hypertension, and hyperlipidemia (the so-called syndrome X).[204] Diabetes may lead to an autonomic neuropathy that can cause gastroparesis and hemodynamic instability. Long-term problems in diabetic patients include stiffening of the temporomandibular joints and difficulty with laryngoscopy and intubation (see later).

Uremic osteodystrophy encompasses many separate skeletal problems, including osteomalacia, osteosclerosis, and osteitis fibrosa cystica—the last-mentioned developing as a result of secondary hyperparathyroidism. As renal function decreases, phosphate excretion declines, resulting in hyperphosphatemia. Failure to convert 1-hydroxyvitamin D to 1,25-dihydroxyvitamin D leads to a reduced absorption of calcium, which results in hyperparathyroidism. The sequela is bone demineralization, making patients susceptible to spontaneous fracturing of long bones and vertebrae.

Gastrointestinal Tract

Common gastrointestinal symptoms in uremic patients are anorexia, nausea and vomiting, gastrointestinal hemorrhage, and diarrhea. Most of these problems are attenuated by the introduction of dialysis before transplantation. Renal failure patients have delayed gastric emptying in addition to an increase in acidity and gastric volume.[186] Patients benefit from administration of a histamine H_2-receptor antagonist as part of premedication. A rare, but important, complication of end-stage renal disease is ascites (accompanied by hypoalbuminemia), which may lead to splinting of the diaphragm and basal pulmonary atelectasis with resultant hypoxemia.[75]

Immune System

Uremia impairs normal immune mechanisms, and these mechanisms may be obtunded further by administration of glucocorticoids and immunosuppressant drugs for treatment of the underlying renal pathology (e.g., systemic lupus, scleroderma, nephrotic syndrome). As a result, sepsis remains a major cause of morbidity and mortality. Particular attention should be paid to strict aseptic technique when inserting a urinary catheter, inserting invasive monitoring devices, or administering peripheral infusions.

Preoperative Assessment

Preoperative assessment should lead to optimization of any persistent serious cardiorespiratory complications, such as congestive heart failure, ECG abnormalities resulting from

myocardial ischemia, and autonomic dysfunction in patients with diabetes mellitus. With increasing numbers of elderly and diabetic patients being accepted for renal transplantation, careful assessment of cardiorespiratory function is needed before placement on the transplant list. This assessment should include referral, when appropriate, for an anesthetic consultant opinion and clear indication in the case notes of special problems relating to the individual patient at the time of surgery. Patients maintained on hemodialysis usually undergo a dialysis session at some point during the 24- to 36-hour period before transplantation. Predialysis and postdialysis weight and electrolyte status should be recorded.

A common complication of dialysis in the preoperative transplant recipient is hypotension, which is predominantly due to ultrafiltration-induced hypovolemia. However, it also may be due to the reduction in plasma osmolality, to reflex sympathetic inhibition, or to the autonomic neuropathy associated with diabetes mellitus or systemic sepsis, and to electrolyte abnormalities (especially hypokalemia, hyperkalemia, and hypocalcemia). Treatment is administered by infusing normal saline and reducing the rate of ultrafiltration if it occurs during preoperative dialysis.

Protection of Veins, Shunts, and Fistulas

Functional shunts or fistulas should be protected carefully during surgery, with the sphygmomanometer cuff placed on the other arm. Venous lines should be restricted when possible to peripheral veins, preferably on the dorsum of the dominant hand, with the preservation of all forearm and antecubital fossa veins.

Nonanesthetic Drugs Given during Renal Transplantation

The policy relating to immunosuppressive therapy varies among units, but the anesthesiologist may be required to institute the appropriate therapy (e.g., glucocorticoids, azathioprine, cyclosporine, antilymphocytic globulin, OKT3, tacrolimus, sirolimus, and alemtuzumab [Campath]) during the perioperative period.

INFLUENCE OF RENAL DISEASE ON PHARMACOKINETICS AND PHARMACODYNAMICS OF DRUGS USED DURING ANESTHESIA

Many important changes occur in the uptake, disposition, metabolism, and excretion of drugs given to patients with chronic renal failure, as follows:

1. Altered absorption: Because of gastric stasis, there are delays in the uptake of orally administered drugs.
2. Altered apparent volumes of distribution: Because of increased extracellular and intracellular fluid volumes, apparent volumes of drug distribution of water-soluble compounds are increased.
3. Altered plasma protein binding and free drug fraction: Plasma concentration of albumin (binding site for acidic drugs) is usually decreased in uremia, whereas concentration of α_1-acid glycoprotein (binding of basic drugs) is increased.
4. Altered drug and xenobiotic metabolism: This is a variable effect that can include reduced renal breakdown of insulin and glucagon, increased hepatic clearance (owing to increased free fraction) of drugs such as phenytoin and nifedipine, and decreased hepatic clearance of erythromycin, propranolol, and verapamil.
5. Altered drug elimination: This effect occurs as a result of the decreased glomerular clearance of filtered drugs (e.g., aminoglycosides, β-lactams, vancomycin, digoxin) and of active metabolites (e.g., morphine-6- glucuronide and normeperidine), and competition for the carriers involved in the excretion of acidic drugs.

Premedicant Drugs

Anticholinergic Drugs

Atropine and glycopyrronium are eliminated by the kidney (20% to 50% of the total dose).[107] Because these agents are usually administered only as single doses, however, accumulation with toxic side effects is unlikely.

Antacids and Prokinetic Drugs

The handling of H_2-histamine receptor antagonists, such as cimetidine and ranitidine, is largely unaltered by end-stage renal disease. Similarly, the disposition of proton-pump inhibitors (omeprazole, lansoprazole, and rabeprazole) is not changed in renal failure.

Metoclopramide is eliminated via the kidney unchanged (<20%) and as the *N*-4-sulfate (≤50%) and *N*-glucuronide. The kinetics of metoclopramide are complex because the elimination half-life is dose dependent after intravenous and oral administration. When given to patients with end-stage renal disease, there is a significant reduction in clearance (16.7 L/hr compared with 52.5 L/hr) and prolongation of the terminal half-life (13.9 hours compared with 2.8 hours).[10] This is not the result of reduced renal clearance, but rather impaired metabolism and alteration in the amount of drug-glucuronide conjugates undergoing enterohepatic recirculation. In a study in patients maintained on hemodialysis, Lehmann and colleagues[120] found altered kinetics of metoclopramide and reported significant side effects (especially drowsiness, restlessness, and diarrhea) after single doses of 10 mg. Hemodialysis does not affect metoclopramide elimination from the body, and clearance of the drug after dialysis is unaltered.[206]

Benzodiazepines

The kinetics and dynamics of the benzodiazepines are altered in patients with acute or chronic renal failure.

DIAZEPAM

Although Andreasen[3] found no correlation between the serum albumin concentration and protein binding of diazepam in patients in acute renal failure, Kangas and associates[103] showed a decrease in the plasma protein binding of diazepam in patients with chronic renal failure. In a further investigation of the disposition of diazepam in patients with chronic renal failure, Ochs and coworkers[147] found an increase in the apparent volume of distribution and increased systemic clearance, both secondary to an increase in the free unbound drug fraction (from 1.4% to 7.9%). There was no difference, however, in free drug clearance in

the uremic and healthy patients, although there was a smaller volume of distribution in the renal failure group.

MIDAZOLAM

The kinetics of the short-acting, water-soluble benzodiazepine, midazolam, are of greater interest to the anesthesiologist. Total drug clearance and apparent volumes of distribution were significantly greater in patients with chronic renal failure than in healthy controls.[196] These changes are secondary to an increased free drug fraction (6.5% compared with 3.9%). There were no differences in unbound drug kinetics, and the elimination half-life was similar in the two groups (4.6 to 4.9 hours). In patients with impaired renal function, there was no correlation between onset time of midazolam sedation and the free drug fraction; this may have been due to inherent alterations in drug sensitivity in the uremic patient. Because the increased free fraction of unbound drug is rapidly distributed to the richly vascularized tissues, it is probably advisable to give intravenous midazolam slowly, titrating dose to effect. In this way, the anesthesiologist can minimize any effects of relative overdosage of free drug to the heart and brain.

OTHER BENZODIAZEPINES

Odar-Cederlof and colleagues[148] investigated the disposition of oxazepam in patients with renal failure. After an oral dose of 0.2 mg/kg, there was significant prolongation of the terminal half-life (range 5.9 to 25 hours in healthy subjects, and 24 to 91 hours in uremic patients), decreased plasma protein binding in renal failure, and an increased fecal excretion of the drug. Initial data analysis suggests unaltered systemic drug clearance; if correction is made for the decreased absorption of the oral drug in uremia, there is reduced clearance of oxazepam in renal failure. Altered clearance of oxazepam was not confirmed in a subsequent study by Murray and associates.[144]

Single-dose studies with lorazepam indicated no alterations in the terminal half-life in renal failure[194]; however, the same authors described impaired drug elimination after long-term administration to two patients with uremia.[195] Although temazepam is widely used as a premedicant, there are few data on its kinetics or dynamics in patients with end-stage renal disease. A single oral dose study in dialysis patients by Kroboth and colleagues[119] indicates that lower maximal plasma drug concentrations are achieved together with an increased free drug fraction compared with healthy subjects.

Induction Agents

The most widely used hypnotic agent for induction of anesthesia in patients undergoing renal transplant surgery is probably propofol, although some anesthesiologists may favor etomidate or a barbiturate. There also are reports of ketamine's use as part of a total intravenous technique.

Propofol

Kinetic studies after induction and maintenance with propofol (diisopropyl phenol) show no major alteration in terminal half-life or clearance in patients with renal failure,[56,99,109] although Ickx and colleagues[99] reported a greater apparent volume of distribution of propofol in patients with end-stage renal disease. There is no significant effect of end-stage renal disease on the plasma protein binding of propofol (Table 13-1).[43]

In a comparison of propofol induction doses in healthy patients and patients with end-stage renal disease, Goyal and associates[79] found a greater dose requirement for attaining hypnosis and a bispectral index monitor level of 50 in patients with renal failure. They attributed these effects to the increased cardiac output accompanying the anemia seen in renal failure.

Morcos and Payne[142] and Kirvela and coworkers[109] reported the cardiovascular effects of an induction dose of propofol (2 to 2.5 mg/kg) preceded by fentanyl (3 to 5 μg/kg) in adequately volume-loaded end-stage renal failure patients and compared the data with data from healthy subjects. This induction sequence caused significant vasodilation in all patients, with 24% to 30% decreases in systolic blood pressure and 22% to 32% decreases in diastolic pressure in the healthy subjects, and similar changes of 19% to 39% and 14% to 39% in the renal disease patients. In the study by Kirvela and coworkers,[109] the maintenance of adequate antihypertensive therapy in the uremic patients up to the time of surgery may have contributed to the cardiovascular stability. Infusions of propofol also have been used for maintenance of anesthesia for renal transplantation.[50,112]

Note: Mean values are given except where indicated.

Etomidate

The dynamic properties of the carboxylated imidazole in patients with impaired cardiovascular function may be useful. The well-documented side effects of etomidate on the adrenal gland (to suppress steroidogenesis) are short-lived and would be of little relevance in transplant patients concurrently receiving a glucocorticoid for immunosuppression. There are no formal studies of the disposition of etomidate in patients with renal failure; several authors have reported a significant decrease in the plasma protein binding of etomidate in patients with uremia.[25,138]

Barbiturates

Although there is evidence for an increased sensitivity of patients in chronic renal failure to barbiturate drugs, thiopental is still used by some anesthesiologists for induction of anesthesia in patients undergoing transplantation. When given as an induction dose comparable to that used in healthy patients, thiopental induces prolonged unconsciousness. Dundee and Richards[60] showed that the duration of effect was related to the blood urea concentration. Various causes have been proposed, including increased blood-brain barrier permeability, increased free plasma barbiturate concentrations in uremic patients, qualitative plasma albumin abnormalities leading to decreased drug binding, and abnormal cerebral uptake and metabolism of the barbiturate.

Burch and Stanski[20] and Christensen and associates[33] formally investigated the disposition of thiopental in patients with chronic renal failure. Burch and Stanski[20] found an unaltered total drug elimination half-life, but an increased free drug fraction. There were no differences compared with healthy patients in unbound drug apparent volumes of distribution and systemic clearance. The increased free drug fraction results in higher brain concentrations of thiopental. If there is assumed to be no alteration in brain or cardiovascular sensitivity to thiopental in the patient with chronic renal failure, the rate of administration rather than the drug dose should be decreased during induction of anesthesia.[20]

This hypothesis is supported by the studies of Christensen and colleagues,[32,33] who have found no differences in the dose of thiopental (milligrams per kilogram) required to induce anesthesia successfully in healthy patients and in patients with renal failure; there also were no differences in arterial and venous drug concentrations at the point of hypnosis. This finding also suggests that there is no alteration in brain sensitivity to the thiobarbiturate. The kinetics of pentobarbital (an active metabolite of thiopental) are unaltered in patients with end-stage renal disease.[158]

Ketamine

Ketamine is probably best avoided for induction of anesthesia for transplantation because it causes increases in heart rate and blood pressure, which may be deleterious in a patient with preexisting hypertension or coronary arterial disease. In end-stage renal disease, elimination of the metabolites of ketamine (especially the active norketamine and the glucuronide conjugates) is reduced.[118]

There are reports of ketamine being used successfully as part of a total intravenous anesthetic technique for renal transplantation, in combination with fentanyl-droperidol, fentanyl-propofol, or remifentanil-propofol. There are, however, no dynamic or outcome data available against which to judge these techniques in renal transplantation.

Opioid Drugs

Renal failure has significant effects on the disposition, metabolism, and excretion of many opioid drugs. Most are biotransformed into inactive or less active compounds, which are excreted in the urine or bile (e.g., pethidine [meperidine], alfentanil, fentanyl, sufentanil, and morphine). Of particular interest to the anesthesiologist has been the introduction of the esterase-metabolized drug remifentanil, where the disposition and dynamics are not significantly altered by chronic renal impairment.

Morphine

Morphine is still the most widely used drug for the provision of perioperative and postoperative analgesia, but inappropriate dosing can result in important effects. There are many reports in the literature of prolonged or exaggerated clinical effects when morphine was given to patients with chronic renal failure. What is the basis of these observations? Olsen and colleagues[149] compared the plasma protein binding of morphine in healthy patients and in patients with renal failure and found an increased free drug fraction (from 65% to 70% to 75%) in the presence of uremia.

Morphine is metabolized primarily in the liver, where it undergoes glucuronidation to the 3-glucuronide (M3G) (the main metabolite, ≤50%) and the 6-glucuronide (M6G) (about 10%). Other metabolites in humans include *N*-demethylation to normorphine. Although M6G is a more potent analgesic than the parent drug, M3G has been shown in animal models to antagonize the dynamic properties of morphine and M6G.[182] Any change in the concentrations of these metabolites (or the parent drug) could have considerable dynamic sequelae. When the influence of end-stage renal disease on morphine disposition and metabolism has been examined in awake[1,169,205] and anesthetized patients,[31,175] most studies show renal failure to have little effect on morphine clearance, but to result in the accumulation of the various metabolites—M3G, M6G, and normorphine (Fig. 13-2 and Table 13-2). In patients undergoing transplantation who received 10 mg of morphine intravenously as a supplement to nitrous oxide–oxygen anesthesia, we found the elimination half-lives of the derived glucuronides M3G and M6G ranged from 300 to 920 minutes (M3G) and 220 to 900 minutes (M6G).[175] These estimates are prolonged compared with values of 100 to 200 minutes in healthy anesthetized patients. Loetsch and colleagues[127] determined the half-lives of M3G and M6G in healthy volunteers to be of the order of 2.8 to 3.2 hours (M3G) and 1.7 to 2.7 hours (M6G), whereas Hanna and coworkers[84] reported the half-lives of M6G when given by intravenous administration to patients with renal failure to be similar to the values reported in our study.

The longer half-lives of M3G and M6G (41 to 141 hours and 89 to 136 hours) reported by Osborne and colleagues[152,153] and Sawe and Odar-Cederlof[169] in patients with impaired renal function could be clinically important in the prolonged effect of the parent drug. These higher concentrations of M6G may account for the profound analgesia and sedation seen in the uremic patient who has received large doses of morphine or papaveretum.[153]

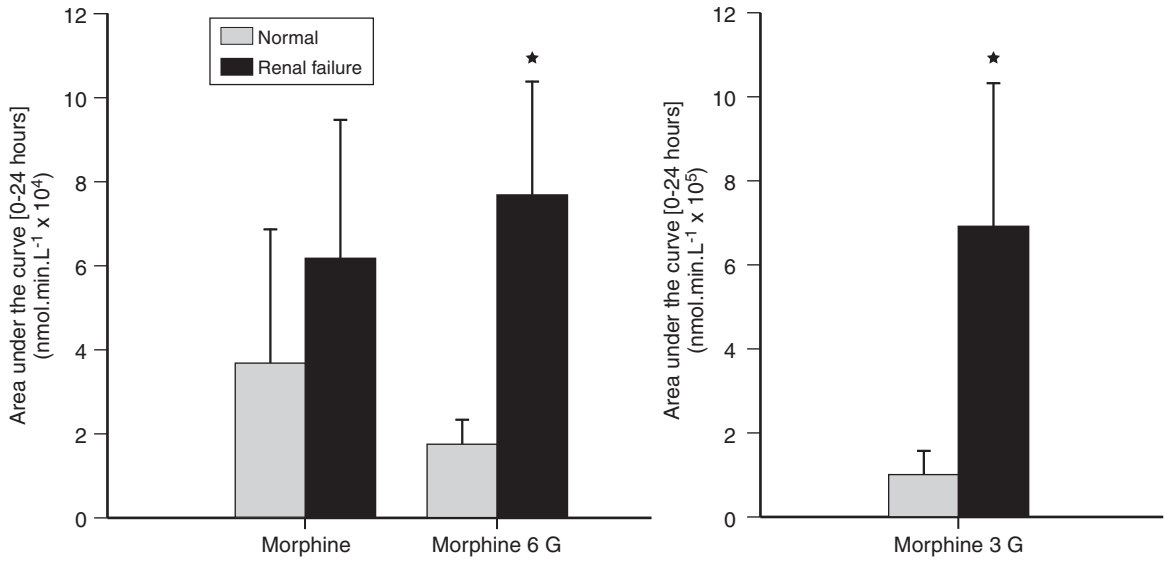

Figure 13–2 Areas under the concentration versus time curve for morphine and its two metabolites, morphine-6-glucuronide and morphine-3-glucuronide in 5 anesthetized healthy subjects with normal renal function (*gray columns*) and in 11 patients with renal failure receiving kidney grafts (*solid columns*) (*$P < .05$). (Adapted from Sear JW, Hand CW, Moore RA, et al: Studies on morphine disposition: influence of renal failure on the kinetics of morphine and its metabolites. Br J Anaesth 62:28, 1989.)

Although we would expect chronic renal impairment to result in larger areas under the concentration-time curve (AUCs) for M3G and M6G, our data[175] and those of Mazoit and coworkers[133] and Sloan and colleagues[181] also show greater AUCs for the parent drug morphine. These data suggest that the kidney itself may play a role in morphine disposition and metabolite elimination. The studies of Mazoit and Sloan suggest that approximately 30% to 35% morphine elimination may be by nonurinary excretion, nonhepatic degradation (i.e., potentially by renal parenchymal metabolism). Our data[175] and the data of Osborne and associates[152] offer another explanation: the increased plasma morphine concentrations (and larger AUCs) could have occurred by hydrolysis of one or another of the accumulating glucuronides (probably M3G) back to the parent compound. This would tend to reduce the AUC M3G-to-M6G ratio. In Osborne's study,[152] there was a mean value of about 5 in the healthy patients, and 3.9 and 4.5 in the groups of patients with end-stage renal disease. In our patients, similar ratios were found in the healthy anesthetized patients and in the patients undergoing renal transplantation (8 and 9).[175] Although we found no difference in the AUC M3G-to-M6G ratio between the healthy patients and patients with end-stage renal disease undergoing transplantation, this model for

studying drug disposition has limitations because the pharmacokinetics of morphine may be influenced by the onset of graft function.

Hasselstrom and Sawe[87] showed that renal clearance of morphine and M6G exceeds creatinine clearance, suggesting there may be an active secretion process in the kidney. The relationship between creatinine clearance and the renal clearances of morphine, M3G, and M6G also has been studied by Milne and colleagues[139] in intensive care unit patients with variable degrees of renal impairment. For all three compounds, there was a linear relationship between free drug clearance and creatinine clearance. The unbound clearance of morphine exceeded that of creatinine, whereas the clearances of M3G and M6G were similar. The ratios of the plasma concentrations of M3G to morphine and M6G to morphine ranged from 4 to 170, and 0.79 to 51. Similar values have been reported by Petersen and colleagues[154] in terminal cancer patients with impaired renal function receiving subcutaneous morphine. The mean plasma concentration ratio of M3G to M6G was 5 (similar to the ratios of AUCs seen in the study of Osborne and associates[152]). The unbound fractions for morphine, M3G, and M6G were 74%, 85%, and 89%, respectively; the first figure was significantly greater than that determined by Olsen and colleagues.[149]

Can we relate these kinetic changes to the preoperative renal status of the transplant recipient? Sawe and Odar-Cederlof[169] showed a significant correlation between the M3G half-life and the plasma urea concentration. Although we did not find a significant correlation between the AUCs of M3G and M6G and the immediate postoperative 24-hour creatinine clearance in the patients undergoing transplantation, there was an association between the creatinine clearance and the elimination half-life of the two glucuronide metabolites ($r = .87$ and $r = .63$; $P < .01$ and $P < .05$). There was no relationship between creatinine clearance and morphine clearance.

MORPHINE BY INFUSION OR AS PATIENT-CONTROLLED ANALGESIA

When infusions of morphine are administered to patients with impaired renal function, there is accumulation of M6G to give the clinical picture of a persistently narcotized patient.[88,153,179] The importance of M6G also can be seen in the case reported by Covington and colleagues,[44] in which severe respiratory depression was observed in a patient with end-stage renal disease receiving morphine patient-controlled analgesia (PCA) for postcholecystectomy pain; the blood morphine concentration was within the therapeutic range, but the M6G level was significantly elevated. Similar data have been described by Carr and associates,[26] in which the PCA dose requirements after cadaver renal transplantation ranged from 3 to 4.7 mg/hr compared with 4.6 to 23.6 mg/hr in patients with normal renal function undergoing lower abdominal surgery. As might be expected, the former group showed considerably greater AUCs for M6G.

D'Honneur and colleagues[58] have studied the transfer of morphine and its metabolites across the blood-brain barrier. Fourteen patients (six with end-stage renal disease) received a single oral dose of morphine before the onset of continuous spinal anesthesia for peripheral vascular or orthopaedic surgery. Plasma concentrations of morphine, M3G, and M6G were greater in the renal failure patients, but only the glucuronide concentrations (not the parent drug) were greater in the cerebrospinal fluid of the renal patients. This study did not address the key issue, however, of whether the higher cerebrospinal fluid concentrations of M6G were associated with greater respiratory depression, or sedation, or prolonged analgesia.

There is no question regarding the analgesic and central nervous system depressive effects of M6G, but its effect on respiration is more uncertain. A reduction in M6G binding at the μ_2 receptor may be one reason why the effect of this metabolite on respiration varies. Although M6G crosses the blood-brain barrier slowly, once in the central nervous system, its effects can be dramatic and prolonged.[4] M6G may exist in two forms—an extended hydrophilic molecule and a folded, more lipophilic compound, which remains in the fatty tissues of the brain. The latter configuration may explain why after discontinuation of morphine dosing or dialysis, the central nervous system effects of the drug persist for long periods, as the M6G only slowly re-equilibrates back across the blood-brain barrier into the systemic circulation.

INFLUENCE OF RENAL FAILURE ON OTHER MORPHINOIDS

Similar alterations in the disposition and dynamics of codeine, dihydrocodeine, and propoxyphene (with active metabolite accumulation) have been observed in patients with renal failure.[7,72,80] These drugs are best avoided for postoperative pain relief. Whether these altered kinetics of morphine and its congeners are the sole explanation for their prolonged dynamic effects is uncertain. Uremia is itself associated with central nervous system depression; the increased sensitivity to central nervous system depressant drugs also may be due to increased receptor responsiveness or increased meningeal or cerebral permeability.

Fentanyl, Alfentanil, and Sufentanil

Because of the exaggerated dynamic effects of morphine and its metabolite M6G, many anesthesiologists prefer to provide intraoperative analgesia with drugs of the phenylpiperidine type. Only a small fraction of each of the three main drugs (fentanyl, alfentanil, and sufentanil) is excreted by the kidney unchanged, and their metabolites are inactive.

The disposition of fentanyl was first studied in awake patients with end-stage renal failure by Corall and coworkers,[42] who showed an increased clearance. Other studies confirm these findings, with all showing wide interindividual variability in kinetic parameters and no differences in the disposition of fentanyl in renal transplant patients compared with comparable patients undergoing lower abdominal surgery.[61,116,174] Although Koehntop and Rodman[116] found an inverse relationship between the degree of azotemia and fentanyl clearance, Bower[14] and Sear and Hand[174] showed no alteration in fentanyl binding in patients with uremia, and no relationship between preoperative creatinine or urea and the disposition parameters of fentanyl.

Similarly, chronic renal failure has no effect on drug binding to plasma proteins or disposition of sufentanil.[51,70,171] There are case reports of prolonged narcosis after administration of sufentanil to patients with chronic renal failure. These cases are probably due to alterations in the dynamics of the opioid in the uremic patient.[70,203] Studies examining the disposition of alfentanil in anesthetized patients with chronic renal failure showed an increased free drug fraction, together with greater total drug clearance

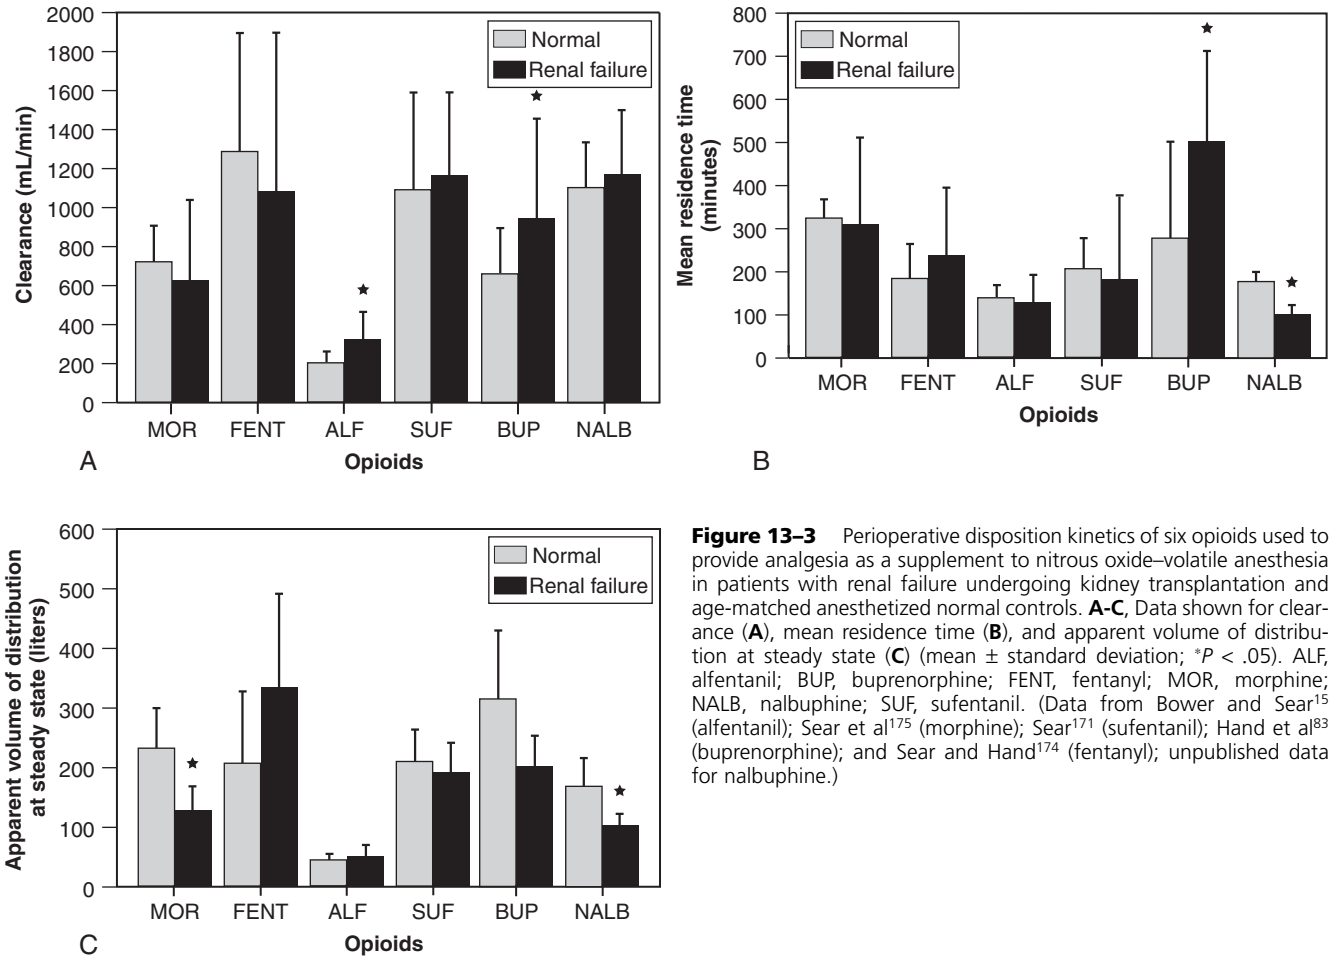

Figure 13–3 Perioperative disposition kinetics of six opioids used to provide analgesia as a supplement to nitrous oxide–volatile anesthesia in patients with renal failure undergoing kidney transplantation and age-matched anesthetized normal controls. **A-C**, Data shown for clearance (**A**), mean residence time (**B**), and apparent volume of distribution at steady state (**C**) (mean ± standard deviation; $^{*}P < .05$). ALF, alfentanil; BUP, buprenorphine; FENT, fentanyl; MOR, morphine; NALB, nalbuphine; SUF, sufentanil. (Data from Bower and Sear[15] (alfentanil); Sear et al[175] (morphine); Sear[171] (sufentanil); Hand et al[83] (buprenorphine); and Sear and Hand[174] (fentanyl); unpublished data for nalbuphine.)

rates and volumes of distribution. There were no differences, however, in the free drug apparent volume of distribution or clearance.[15,30]

Figure 13-3 summarizes data from our own studies examining the perioperative disposition of morphine, the three phenylpiperidine drugs, and buprenorphine and nalbuphine when given to provide analgesia during surgery for renal transplantation in patients receiving a balanced anesthetic technique with controlled ventilation to normocapnia. The main kinetic changes are the increased total drug clearances of alfentanil and buprenorphine and the longer mean residence time for buprenorphine.

Remifentanil

Although remifentanil also is a piperidine derivative, its elimination does not depend on either hepatic metabolism or renal elimination, but rather plasma and tissue nonspecific esterase hydrolysis. In healthy individuals, remifentanil clearance is high (25 to 45 mL/kg/min), and its major metabolite (GI 90291) has only minimal analgesic activity.

The kinetics of remifentanil are unaltered in awake patients with end-stage renal disease.[95] Because of its short half-life (4 to 9 minutes), the drug is best given by continuous infusion; it also has a short context-sensitive half-time (3 minutes) after prolonged periods of infusion—implying that there would be a rapid offset of its analgesic and respiratory depressant effects at the end of a surgical procedure. The dynamics of remifentanil were unaffected in renal failure patients.

In anesthetized patients with renal failure undergoing fistula surgery, Dahaba and associates[49] found no alteration of the distribution half-life of remifentanil, but significantly smaller estimates for clearance and a longer elimination half-life. There were higher blood concentrations in the renal patients. Hoke and colleagues[95] also showed that the main metabolite had a longer terminal half-life and reduced clearance in patients with renal failure. The main differences between Dahaba's study and the earlier publication of Hoke and colleagues[95] relate to the influence of anesthesia in the study of Dahaba and associates[49] and the preoperative hemodialysis of Dahaba's patients compared with awake subjects and predialysis hypervolemic patients in the Hoke study. In a separate study in which remifentanil was infused to intensive care unit patients with renal impairment, Breen

and colleagues[17] found no prolongation of the dynamic effects of the opioid, even after a 72-hour continuous infusion, when the patients with renal failure were compared with other intensive care unit patients who had normal renal function.

Pethidine (Meperidine)

There are few kinetic data on the disposition of pethidine in patients with renal failure. The drug is mainly metabolized in the liver, with only 1% to 5% excreted unchanged in the urine. Chan and coworkers[28] showed that the systemic clearance of pethidine depends on renal function, with accompanying reduced excretion of the metabolite norpethidine. Burgess and colleagues[21] assessed the dynamics of pethidine in patients with end-stage renal disease. They found that the renal failure group had a reduced ventilatory response to carbon dioxide, but subcutaneous administration of 1 mg/kg of pethidine did not exaggerate the effect. Whether this observation is transferable from the laboratory to the ward scenario remains untested.

As with morphine, Szeto and colleagues[189] found that when repeated doses of pethidine are given to patients in chronic renal failure, the *N*-demethylated metabolite, norpethidine, accumulates. This compound is about half as potent as an analgesic, but has greater convulsant activity than the parent drug. Szeto and colleagues,[189] Armstrong and Bersten,[5] and Hassan and associates[86] all have reported patients in renal failure in whom increased plasma ratios of norpethidine to pethidine were associated with excitatory signs. Hemodialysis provides a suitable method of treatment, with a plasma meperidine clearance of 50 mL/min and an average reduction in the normeperidine concentrations of 26% over 3 hours of dialysis.[86]

Other Intraoperative Opioids

The kinetics and dynamics of buprenorphine and oxycodone have been studied in patients undergoing renal transplantation. Hand and coworkers[83] found that renal impairment had little effect on parent drug kinetics of buprenorphine, but there were significant increases in the plasma concentrations of two metabolites (buprenorphine-3-glucuronide and norbuprenorphine). There was no evidence, however, that the latter resulted in any prolonged drug action.

Oxycodone disposition has been studied in healthy anesthetized patients and patients undergoing cadaver transplantation. Kirvela and coworkers[108] found a prolonged elimination half-life owing to a reduction in clearance and an increase in the volume of drug distribution. There also were higher plasma concentrations of the metabolite noroxycodone. The authors did not comment on any dynamic consequences of their findings, however.

Neuromuscular Relaxant Drugs

The neuromuscular blocking drugs are a group of ionized, water-soluble compounds that are freely filtered at the glomerulus. Most relaxants have low (<50%) plasma protein binding, and changes in plasma albumin concentrations (which may occur in patients with end-stage renal disease) are unlikely to affect the drugs' disposition. If the drug is normally excreted unchanged via the kidney, however, the kinetics and dynamics would be altered in patients with renal failure. Table 13-3 lists the extent of urinary excretion in the elimination of the various muscle relaxants.

Table 13–3 **Renal Excretion of Neuromuscular Blocking Drugs**

Quaternary Amines	
Suxamethonium	<10%
Gallamine	>95%
Benzylisoquinolinium Compounds	
Tubocurarine	31-45%
Methyltubocurarine	42-52%
Atracurium	10%
Doxacurium	25-30%
Mivacurium	<10%
Cisatracurium	?
Aminosteroid Compounds	
Pancuronium	35-50%
Vecuronium	15-20%
Pipercuronium	38%
Rocuronium	9%

Note: Expressed as a mean percentage (or range) of total drug elimination.

Depolarizing Neuromuscular Relaxants

Because potassium homeostasis is altered in patients with renal failure, concerns have been raised over the use of suxamethonium and the possibility of exaggerated hyperkalemic responses leading to adverse cardiac effects. Way and colleagues[200] showed the increase in potassium in patients on hemodialysis to be comparable with that seen in normal healthy subjects, however. Koide and Waud[117] observed no difficulties with the use of the drug as long as the plasma potassium was less than 5.5 mmol/L. Numerous case reports, case series, and controlled studies[191] suggest that suxamethonium can be used safely for rapid-sequence intubation as long as there is no associated uremic neuropathy or preoperative hyperkalemia. Repeated doses of suxamethonium are best avoided, however.

To minimize the increase in plasma potassium levels seen after suxamethonium, numerous pretreatments have been evaluated, including predosing with a nondepolarizing neuromuscular blocking agent, benzodiazepines (e.g., flunitrazepam, diazepam), or magnesium sulfate. Only the studies of Koide and Waud[117] and Radnay and coworkers[157] assessed the efficacy of these pretreatments in patients with renal failure. Koide and Waud[117] found that tubocurarine did not prevent the increase in potassium. Radnay and coworkers[157] showed that hexafluorenium prevented the increase in potassium; however, this latter compound is no longer available for clinical use.

There is a further aspect to the hyperkalemic response. In chronic renal failure (but *not* in acute renal failure), there are adaptive changes in the kidneys and the gut to prevent hyperkalemia. Despite the patient with chronic renal failure having a chronically increased extracellular potassium level (E_{K+}), the intracellular concentration (I_{K+}) also is increased. As a result, the ratio (I_{K+}) to (E_{K+}) is unaltered. Depolarization of the cardiac cell membrane with resulting cardiac arrhythmias would occur only with a change in the intracellular-to-extracellular potassium ratio. It is probably safe to use suxamethonium for intubation in the presence of a clinically increased potassium. In a patient with chronic renal failure with preoperative hyperkalemia (>6 mmol/L), there is less supportive evidence, however, because a small increase in the

potassium level may trigger an arrhythmia. Although nondepolarizing neuromuscular blocking drugs may prevent the onset of muscle fasciculations, they do not block the increase in plasma potassium concentrations.

For a rapid-sequence intubation in renal transplant recipients, *in the absence of hyperkalemia,* suxamethonium remains the drug of choice, although large doses of some nondepolarizing drugs (especially atracurium, cisatracurium, mivacurium, and rocuronium) offer an alternative in patients with hyperkalemia. A further issue with the use of suxamethonium relates to decreased activity of the enzyme pseudocholinesterase in patients being treated for renal failure by hemodialysis; however, this does not seem to be a significant problem with current hemodialysis techniques.

Nondepolarizing or Competitive Neuromuscular Relaxants

Nondepolarizing relaxants can be broadly divided into agents showing significant alteration in the kinetics and duration of effect in end-stage renal disease patients (and not useful in the anesthetic management of transplant recipients), and agents for which renal failure has little effect on the drug's dynamics.

DRUGS SHOWING SIGNIFICANT ALTERATIONS IN PHARMACODYNAMICS IN RENAL DISEASE

Many authors have reported kinetic and dynamic interactions between chronic renal failure and tubocurarine, d-methyl tubocurarine, gallamine, and pancuronium. The altered dynamics of these agents relates to significant renal excretion for their elimination, and these drugs should no longer be used for neuromuscular blockade in renal transplant recipients. Pipecuronium and doxacurium are newer neuromuscular blockers that are excreted mainly unchanged by the kidney, and renal failure causes a prolonged elimination half-life and reduced clearance.[23,24,27,39,68] With other relaxants now widely available, there is no place for any of these drugs as part of the anesthetic technique for renal transplantation.

DRUGS MOST SUITED FOR USE IN PATIENTS UNDERGOING RENAL TRANSPLANTATION

Atracurium. Initial clinical studies by Hunter and colleagues[97] found no difference in the duration of neuromuscular blockade from an initial dose of atracurium or from repeated doses when the drug was administered to patients with normal function compared with patients who were anephric. This finding was confirmed by the dynamic-kinetic studies of Fahey and associates[66] and De Bros and coworkers,[54] who showed that onset time, duration of action, recovery time (from 25% to 75% initial twitch height), and disposition kinetics were unaltered in patients with renal failure (Table 13-4). Another study by Hunter and colleagues[98] compared the properties of atracurium, vecuronium, and tubocurarine in healthy patients and in patients with renal failure. After bolus dosing, atracurium and vecuronium were little affected by renal failure, but tubocurarine was longer acting and less predictable, and inappropriate for use in these patients.

Atracurium may be administered by bolus dosing or continuous infusion to maintain neuromuscular blockade. Even after prolonged infusion, rapid recovery has been reported in patients with renal failure,[166] although Nguyen and colleagues[145] showed a prolonged recovery rate and longer time to 90% recovery of twitch height when administering atracurium by infusion to anephric patients anesthetized with nitrous oxide and increments of fentanyl. The breakdown of atracurium is by Hoffmann degradation and ester hydrolysis, although Fisher and colleagues[67] showed that 50% of total systemic clearance cannot be accounted for by either of these mechanisms.

An important metabolite of atracurium is laudanosine. Laudanosine is normally eliminated in the urine. When administered intravenously in high doses to animals, laudanosine has been reported to cause excitatory electroencephalogram activity. When given to nephrectomized cats, these electroencephalogram changes of nonepileptiform spike activity were seen only when the plasma concentrations were 8 to 10 times those observed in patients during continuous infusions of atracurium.[100] Ward and coworkers[197] investigated the relationship between renal function and plasma concentrations of laudanosine. After single doses of atracurium (0.3 mg/kg), there were no effects of renal failure on the disposition of atracurium or its two metabolites, laudanosine and the associated monoquaternary alcohol. Peak laudanosine concentrations were not significantly different in healthy patients and patients with renal failure.

Table 13–4 **Disposition of Neuromuscular Blocking Drugs in Patients with Chronic Renal Failure**

	Patients with Normal Renal Function			Patients with Impaired Renal Function		
	$T_{1/2}el$	Cl_p	V_{ss}	$T_{1/2}el$	Cl_p	V_{ss}

Rocuronium: Szenohradszky et al[188]	71	2.9	0.26	97	2.9	0.21
Cooper et al[41]	104	3.7	0.21	97	2.5*	0.21

*$P < .05$.
Cl_p, systemic clearance (mL/kg/min); $T_{1/2}el$, elimination half-life (min); V_{ss}, apparent volume of distribution at steady state (L/kg).
Note: Mean values are given.

Other studies by Fahey and colleagues[65,66] have observed higher plasma laudanosine concentrations in cadaver transplant recipients, however, compared with healthy anesthetized subjects after larger doses of atracurium. In both of these studies and in the study by LePage and associates,[121] peak plasma laudanosine concentrations were considerably lower than the concentrations associated with electroencephalogram excitation in the anesthetized dog.[29] Although elimination of laudanosine is principally via the kidney, there is some evidence in humans that other organs (e.g., the liver) may be involved in its elimination.

Vecuronium. Lynam and coworkers[129] studied the kinetics of 0.1 mg/kg of vecuronium in patients receiving cadaver renal allografts and a control group of healthy patients, where anesthesia was maintained with nitrous oxide in oxygen and 1% end-tidal isoflurane. There were no significant effects on the elimination half-life or systemic clearance of vecuronium, but the duration of neuromuscular blockade and recovery from blockade were significantly prolonged in the renal failure group. Several other studies also have suggested the accumulation of vecuronium in patients with renal failure.[12,34,122,184] Because of the clinical importance of any dynamic interaction with renal failure, Beauvoir and colleagues[11] conducted a meta-analysis of the available data. Based on six studies, they found renal failure to cause a significant increase in the duration of effect (measured as the time from injection to 25% recovery of twitch height), but no effect on the onset time, or the 25% to 75% recovery time. Part of the explanation for these dynamic effects may lie in the biotransformation of vecuronium. It is metabolized by hepatic hydrolysis to yield three desacetyl metabolites—3-desacetyl vecuronium, 17-desacetyl vecuronium, and 3,17-desacetyl vecuronium. The first of these is estimated to have the potency of about 80% of the parent drug, and there is good evidence that 3-desacetyl vecuronium accumulates in patients with renal failure.[177] A more recent study by Sakamoto and associates[167] has confirmed that the duration of action of vecuronium is prolonged in patients with end-stage renal disease mainly as a result of a higher sensitivity to the drug (rather than the result of kinetics alterations).

OTHER FACTORS AFFECTING DURATION OF NEUROMUSCULAR BLOCKADE

Potentiation of neuromuscular blockade may occur in patients with metabolic acidosis; the acidosis also opposes the reversal by neostigmine. In the uremic patient undergoing transplant surgery, potentiation of blockade also may occur secondary to hypokalemia, hypocalcemia, hypermagnesemia, parenteral or topical use of some aminoglycoside antibiotics, furosemide, mannitol, and methylprednisolone. Caution should be exercised to ensure complete return of neuromuscular function if multiple increments or infusions of the drug are used during prolonged surgery in anephric patients.

Newer Neuromuscular Blocking Drugs

There are three new neuromuscular blocking agents that show differing disposition profiles in patients with end-stage renal failure (see Table 13-4).

MIVACURIUM

Mivacurium is a short-acting benzylisoquinolinium that is metabolized by plasma esterases and presumably also in the liver. In healthy subjects, De Bros and colleagues[53] showed an elimination half-life of 17 minutes and a high clearance (54 mL/kg/min). Early studies suggested that the kinetics and duration of effect of mivacurium were not prolonged in renal failure.[40]

Similar to atracurium, mivacurium is formulated as a number of stereoisomers (cis-trans, 37%; trans-trans, 57%; and the less active cis-cis, 6%). Phillips and Hunter[155] showed a prolonged duration of action of mivacurium in renal failure patients compared with patients with normal renal function. In another study, Head-Rapson and colleagues[89] examined the kinetics and dynamics of the isomers in anesthetized patients with renal failure. Although clearance of the cis-cis isomer was significantly reduced in renal failure, the disposition of the other two isomers was not. The clearance of each isomer correlated significantly with plasma cholinesterase activity. The median infusion rate required to achieve a common level of neuromuscular blockade (T1/T0: 10%) was similar in patients with renal failure compared with healthy subjects.

CISATRACURIUM

Cisatracurium is one of the ten stereoisomers of atracurium and has the advantage of being three times more potent and releasing less histamine in animals. In contrast to the parent compound, its metabolism is mainly by Hoffmann degradation with no ester hydrolysis. Studies by Kisor and associates[113] confirm that the Hoffmann pathway accounts for about 77% of total body clearance, 23% of organ clearance, and 16% of renal clearance. The drug has an elimination half-life of 23 minutes and clearance in healthy subjects of 5.2 mL/kg/ min. The main metabolites are laudanosine and a monoquaternary acrylate.

Two more recent studies have examined the dynamics and disposition of cisatracurium in renal failure. Boyd and coworkers[16] found that at a dose of $2 \times ED_{95}$ (0.1 mg/kg), onset times were longer in the renal failure group, but recovery was not affected. The clearance of cisatracurium was decreased by 13%, and the half-life was longer (34.2 minutes versus 30 minutes). Although plasma concentrations of laudanosine were elevated in patients with renal failure, the peak values were about one tenth of the values seen after atracurium.[62] In the only study directly comparing these relaxants, Jirasiritham and colleagues[101] found no differences in the hemodynamic responses to anesthesia and surgery in renal failure patients receiving atracurium or cisatracurium as the neuromuscular blocking agent.

ROCURONIUM

Rocuronium has a rapid onset of effect and intermediate duration of action and may be an alternative to suxamethonium for rapid-sequence intubation. Being a steroid molecule, it is primarily metabolized in the liver, with only 9% of the injected dose being recovered unchanged in the urine. In a comparison of its kinetics and dynamics in healthy anesthetized subjects and patients undergoing cadaver renal transplantation, Szenohradszky and colleagues[188] found that renal failure altered drug distribution, but not systemic clearance. Cooper and colleagues[41] found a decreased clearance of the relaxant in patients with renal failure during isoflurane anesthesia.

Several studies have examined the dynamics of rocuronium in patients with chronic renal failure, with differing outcomes.

In an initial study with the drug, Khuenl-Brady and colleagues[106] found no differences in onset, duration of effect, or recovery after doses of 0.6 mg/kg and three maintenance doses of 0.15 mg/kg during isoflurane anesthesia. There also were no significant differences in drug dynamics in the study of Cooper and colleagues.[41] More recently, Robertson and colleagues[164,165] investigated the dynamics and kinetics of the relaxant during propofol infusion anesthesia. After a single dose of 0.6 mg/kg, renal failure had no effect on the onset of neuromuscular block, but was associated with a prolonged duration of effect. This finding can be explained by a decrease of 39% in drug clearance in renal failure patients, coupled with an 84% prolongation of the mean residence time. When administered in a smaller dose of 0.3 mg/kg, however, there were no kinetic or dynamic differences.

In a single-dose comparison of vecuronium, atracurium, cisatracurium, and rocuronium in healthy controls and in patients undergoing renal transplantation, there were no significant differences within patient groups of onset time or duration of action; however, the recovery index was slower in the renal patients for all four neuromuscular blocking drugs. There also was a prolonged duration of effect after repeat doses of rocuronium and vecuronium in the renal patients.[57] Despite the chemical similarity of rocuronium to vecuronium, and the observations of Della Rocca and associates,[57] rocuronium has a possible role in providing neuromuscular blockade for patients with renal impairment, although most anesthesiologists would currently favor atracurium or cisatracurium as the drug of choice.

Anticholinesterases

All anticholinesterases are excreted through the kidney by glomerular filtration and tubular secretion. The pharmacokinetics of neostigmine, pyridostigmine, and edrophonium have been studied in patients with chronic renal failure by Cronnelly and Morris.[47] Significant decreases in the clearance of anticholinesterases are seen in anephric patients, although pharmacokinetics parameters similar to those in patients with normal renal function can be shown in patients to whom the drugs are given approximately 1 hour after receiving a living related renal transplant (Table 13-5). Because a greater percentage (75%) of an intravenous dose is excreted by the kidney, the terminal half-life of pyridostigmine is more prolonged than that of neostigmine in patients with renal failure.

A more recent development to the reversal of neuromuscular blockade has been the introduction of ORG 25969 (Sugammadex).[73] This is a cyclodextrin molecule specially designed to bind rocuronium and bring about the reversal of neuromuscular blockade by a physicochemical interaction. To our knowledge, there are no available published data on its use in renal transplant recipients, but it could offer an important pharmacological advance in the conduct of renal transplant anesthesia.

Inhalational Anesthetic Agents

All volatile anesthetic agents are, to some extent, myocardial depressants and may reduce the cardiac output and blood flow to the transplanted kidney. Some agents (particularly enflurane and sevoflurane) are biotransformed in the liver, resulting in increased serum levels of inorganic fluoride. This ion can lead to the development of high output renal failure.

When used to provide anesthesia for patients undergoing living related donor renal transplantation, Wickstrom[202] observed that administration of 2.4 MAC-hour enflurane (mean duration 189 minutes) caused a peak fluoride concentration of 21 μmol/L (MAC-hour is the product of minimum alveolar concentration of a volatile anesthetic agent and time). In 1 of 10 patients, the serum fluoride concentration increased significantly, however, to 40 μmol/L. There also has been a case report of deterioration in renal transplant function when enflurane was given to provide anesthesia for vascular access surgery.[126] Enflurane should not be used to supplement anesthesia for renal transplantation. In contrast, its isomer isoflurane undergoes only limited biotransformation to inorganic fluoride and is one of the agents of choice for a balanced anesthetic technique.[76,135]

The two newer volatile agents (desflurane and sevoflurane) differ in their molecular stability and extent of biotransformation. Desflurane does not undergo breakdown either by the liver or by contact with soda lime, and after 1 MAC-hours anesthesia, the increase in inorganic fluoride is less than 1 μmol/L. Desflurane also has no deleterious effect on routine laboratory tests of renal function when given to patients with chronic renal disease.[63,125,207]

Sevoflurane is less stable, with about 3% of the absorbed dose undergoing hepatic biotransformation. After prolonged anesthesia of an average 13.4 hours to patients with normal renal function, peak serum fluoride concentrations of 42.5 μmol/L have been reported—with 5 of 10 patients exceeding the assumed nephrotoxic threshold of 50 μmol/L.[114]

Table 13–5 **Influence of Renal Disease on Disposition of Anticholinesterases**

	Subjects with Normal Renal Function			Anephric Patients			Living Related Donor Renal Transplants			Renal Fraction of Total Clearance (%)
	$T_{1/2}$el	Cl_p	V_{ss}	$T_{1/2}$el	Cl_p	V_{ss}	$T_{1/2}$el	Cl_p	V_{ss}	
Neostigmine	80	9	0.7	183*	3.4*	0.8	104	9.4	1	54
Pyridostigmine	112	8.6	1.1	379*	2.1*	1	83	10.8	1	76
Edrophonium	110	9.6	1.1	206*	2.7*	0.7	87	9.9	0.9	66

*$P < .05$ versus transplant patients and subjects with normal renal function.
Cl_p, systemic clearance (mL/kg/min); $T_{1/2}$el, elimination half-life (min); V_{ss}, apparent volume of distribution at steady state (L/kg).
Adapted from Cronnelly R, Morris RB: Antagonism of neuromuscular blockade. Br J Anaesth 54:183, 1982.

There were no cases of gross renal dysfunction, however. Similarly, Higuchi and colleagues[92] found no evidence of any impairment in urinary concentrating ability to antidiuretic hormone administration after 10.6 MAC-hours sevoflurane anesthesia despite a mean plasma fluoride concentration of 41.9 μmol/L, and 1 of 11 patients having a plasma fluoride concentration greater than 50 μmol/L.

Subsequent studies by Kharasch and colleagues[105] have shown that it is the increased systemic fluoride concentration that causes nephrotoxicity. Neither the peak concentration nor the duration of the fluoride concentration increase alone is sufficient, however, to predict the occurrence of renal damage. Rather the site of the fluoride production is important. For sevoflurane, this site is extrarenal. When administered to patients with end-stage renal disease, sevoflurane (1% to 2.5%) supplementing nitrous oxide–oxygen anesthesia caused higher postoperative levels of blood and urea creatinine and serum and urinary β_2-microglobulins.[146] There were no differences, however, between these patients and controls in serum fluoride levels, the rate of elimination, or AUC fluoride-time. The patients with renal failure, however, had lower urinary fluoride concentrations compared with the healthy controls. Similar data have been found in studies in which low-flow sevoflurane and isoflurane have been compared in patients with impaired renal function.[37,91]

In another study in patients with chronically impaired renal function, peak serum fluoride concentrations were significantly higher after sevoflurane administration compared with enflurane (25 μmol/L versus 13.3 μmol/L), but no permanent deterioration of preexisting renal insufficiency was observed.[38] Goldberg and associates[76] examined inorganic fluoride concentrations in patients receiving isoflurane or sevoflurane anesthesia. The latter group contained three patients in whom the fluoride concentration exceeded 50 μmol/L, and two who had increased postoperative plasma urea and creatinine concentrations at 24 hours postoperatively. There was no evidence that sevoflurane caused further deterioration of renal function.

Sevoflurane also is degraded to a vinyl metabolite (compound A) when administered by low flow with a carbon dioxide absorber containing either Baralyme or to a lesser extent soda lime. Reductions in anesthetic fresh gas flow and an increase in temperature would result in increased compound A concentrations. Although this metabolite is nephrotoxic in rats, there is no evidence to support nephrotoxicity in humans.[71,104,134] The safety of sevoflurane in patients with renal impairment is unclear. Finally, no renal toxicity has been reported after inhalation of desflurane.[63]

CHOICE OF ANESTHETIC TECHNIQUE AND OUTCOME FOR RENAL TRANSPLANTATION

Although use of a balanced anesthetic technique (opioid with volatile supplementation) is the method of choice for renal transplantation, some authors have described other approaches.

Regional Techniques for Transplantation

When Vandam and colleagues[193] described the use of regional anesthetic techniques for renal transplantation, it was to avoid the complications of general anesthesia in uremic patients; however, this is no longer a major problem with modern dialysis techniques. In a subsequent review of regional anesthesia, Linke and Merin[124] cited its advantages as the avoidance of neuromuscular blocking drugs and endotracheal intubation, the reduced likelihood of regurgitation and pulmonary inhalation by a patient with a full stomach, and the provision of a pain-free awake postoperative patient.

In chronic renal failure, the onset of sensory analgesia occurs faster after subarachnoid blockade because of the combined effects of the metabolic acidosis causing a greater degree of ionization and a reduction in the volume of the epidural space secondary to distention of the epidural and spinal veins by a hyperdynamic circulation. The duration of sensory and motor blockades was shorter (20%) in the patients with renal failure because the increased cardiac output in these patients resulted in a faster washout of the local anesthetic from its site of action.[151,156]

There is concern over the possibility of extradural hematoma formation in patients with a disordered coagulation system. Basta and Sloan[8] reported the first case of an epidural hematoma in a patient with chronic renal failure about 60 hours after catheter placement. Other possible complications include difficulty in handling major blood loss in a vasodilated patient, an unpredictable response of a hypertensive renal patient on drug therapies to vasopressors, the maintenance of an awake patient's well-being during a long procedure, and the medicolegal complexity of a postoperative peripheral neuropathy.

Comparison of Different General Anesthetic Techniques

Other approaches used for renal transplant anesthesia include neuroleptanesthesia[123] and total intravenous techniques (e.g., the combination of propofol and alfentanil,[112] and ketamine supplemented by infusions of fentanyl-droperidol, fentanyl-propofol, or remifentanil-propofol). Studies have compared the different volatile agents as supplementation and have compared total intravenous and regional anesthesia. All volatile agents cause a dose-related decrease in mean arterial pressure. When halothane, enflurane, and isoflurane have been used as volatile supplementation in patients undergoing living related donor renal transplantation, they have been shown to have no influence on postoperative renal function.[48] Administration of a fluid challenge of 1000 mL 0.154M sodium chloride resulted in similar increases of arterial and central venous pressures, regardless of the choice of anesthetic agent.[45,46]

Patients with impaired renal function may develop cardiac dysrhythmias secondary to alterations in plasma electrolyte concentrations. There is an additional risk of acute hemodynamic changes occurring during transplantation owing to the release of catecholamines and renin from the revascularized kidney.[69] The effects of endogenous catecholamines may result in the development of ventricular dysrhythmias. Neither isoflurane nor desflurane significantly sensitizes the myocardium to these amines, and isoflurane and desflurane are the volatile agents of choice as the supplement to a nitrous oxide in oxygen-opioid anesthetic for renal transplantation.

Outcome studies have compared epidural and nitrous oxide–isoflurane anesthesia,[2] isoflurane versus desflurane anesthesia,[125] fentanyl-isoflurane versus propofol-alfentanil[6] or propofol-remifentanil total intravenous techniques,[140]

and combined spinal-epidural versus general anesthesia.[81] None of these anesthetic techniques seems to affect the outcome of transplantation.

Other Anesthetic-Related Complications after Renal Transplantation

The major postoperative anesthetic complications are vomiting and pulmonary aspiration; cardiac arrhythmias, which can lead to cardiac arrest; pulmonary edema; hypotension and hypertension; and delayed respiratory depression. Cardiovascular complications in the transplant recipient are responsible for about 33% of all mortality[59]; about 50% of all patients have arterial hypertension. Although hypertension is usually a reflection of chronic rejection or excess renin release from the patient's native kidneys, rarer causes include the effects of the immunosuppressive drugs (particularly cyclosporine), recurrent glomerulonephritis, and transplant renal artery stenosis. Transplant patients also seem to be at greater risk of developing left ventricular hypertrophy if the treatment of hypertension requires two or more antihypertensive therapies.[85]

The post-transplant patient also may manifest diabetes mellitus; this occurs in 3% to 16% of all recipients, with 4% of these patients requiring insulin. Usually the onset of hyperglycemia occurs within the first 3 months of transplantation or following the first bolus dose of steroid for the treatment of kidney graft rejection. Predisposing factors include preoperative glucose intolerance and the presence of HLA B28.

With increasing awareness of the surgical risk factors present in renal transplant patients, careful perioperative monitoring has led to low rates of perioperative mortality (0.03% to 0.06%). Factors leading to increased perioperative risk in renal transplantation include recipient age greater than 60 years, coronary artery disease, and diabetes mellitus.[190]

STIMULUS TO EARLY ALLOGRAFT FUNCTION

Loop diuretics or mannitol, or both, may be used to promote a diuresis from the grafted kidney. Use of mannitol (the reduced form of the 6-carbon sugar mannose) has been criticized, but there is evidence to suggest that it may have a protective role as a free radical scavenger preventing free radical–induced reperfusion injury. Mannitol reduces the incidence of impaired renal function immediately after transplantation from 55% to 14%.[201] It also has been shown to improve renal blood flow by a greater percentage than can be accounted for by plasma volume expansion alone.[102] It is a small molecule that equilibrates slowly with the interstitial fluid compartment and so causes an increased circulating blood volume. Mannitol is freely filtered by the renal glomerulus and is not reabsorbed in the distal tubules. Because of its osmotic effect, sodium and water also are excreted; this may lead to increases in the serum potassium by 0.7 mmol/L.

Moote and Manninen[141] examined the influence of mannitol on serum electrolytes in patients undergoing renal transplantation. A dose of 50 g of mannitol (four times the dose used in Oxford) increased the central venous pressure and decreased the serum concentrations of sodium, chloride, and bicarbonate. The increase in potassium was small, but this may assume clinical importance in patients also receiving a blood transfusion. The thiazide diuretics and furosemide are not open to the same criticism, although their use should be coupled with preloading of the patients with isotonic (0.154M) saline.

Besides use of mannitol and diuretics to establish a diuresis, it is important to maintain an adequate circulating volume. Dawidson and colleagues[52] found that urine output is delayed after reperfusion in patients in whom the blood volume was less than 70 mL/kg. Rehydration requirements can be estimated from the central venous pressure, using normal saline as the initial volume expander. If more than 40 to 90 mL/kg is required, colloid solutions should be added. The administration of this fluid load also acts as a physiological stimulus to urine production. This stimulus is important because most analgesic and inhalation anesthetic agents increase circulating antidiuretic hormone levels.[9]

ANESTHESIA FOR LIVING RENAL TRANSPLANTATION

Renal transplantation increasingly involves living related or unrelated donation. This section considers physiological and anesthetic principles underlying laparoscopic nephrectomy in the donor and outlines our practices in Oxford for the recipient. (See also Chapter 8.)

Physiological Consequences of Laparoscopic Surgery

The general effects of carbon dioxide on the cardiovascular system have been described fully elsewhere[35]; they include the mechanical consequences of pneumoperitoneum, neurohumoral responses, systemic absorption of the carbon dioxide, and physiological effects of patient posture. Insufflation of carbon dioxide to create a pneomoperitoneum decreases renal blood flow,[170] leading to transient intraoperative kidney dysfunction; there is interest as to whether this leads to a greater incidence of delayed graft function compared with open surgery. Although a greater incidence of delayed graft function was found in a series of cases reported by London and colleagues,[128] this was not subsequently confirmed by Biancofiore and associates.[13]

The need for the Trendelenburg position, coupled with the increase in arterial carbon dioxide tensions, can result in increased cerebral blood flow, whereas the increased intra-abdominal pressure and central hemodynamic effects of the pneumoperitoneum tend to reduce cerebral blood flow through the reduction in cardiac output. Studies of the head-down posture in an animal model of laparoscopy caused increases in intracranial pressure, however, of 150%. An analysis of possible renal protective strategies has shown loop diuretics, mannitol, atrial natriuretic peptide analogues, and dopamine by infusion to have no positive effect. Fenoldopam may be useful, however. The only useful protective approach against renal damage is to ensure adequate circulatory volume and optimal renal blood flow.[173] The aim should be to keep intra-abdominal pressure low (<12 mm Hg), to ensure a positive fluid balance, and to maintain an adequate urinary output with mannitol and furosemide as needed.

Monitoring during Laparoscopic Nephrectomy

Monitoring should include electrocardiography, blood pressure by a noninvasive method, pulse oximetry, end-tidal anesthetic and carbon dioxide tensions, temperature, and urine output. Some authorities also advocate measurement of the central venous pressure in the donor patient to ensure normovolemia and avoid the risk of underperfusion of the donated kidney. The aim in the donor is to promote a diuresis, aiming for a urine flow of 300 to 500 mL/hr. Although this goal can be partially achieved with fluid loading, mannitol (in a dose of 1 to 2 g/kg) also should be used. In addition to promoting urine flow, mannitol aids the preservation of the donor renal tissue with conservation of renal function and protects the donor against cerebral swelling secondary to any increased cerebral blood flow. Additional doses of furosemide may be needed.

Postoperative Pain

Despite the minimally invasive approach (which usually involves a separate incision for the retrieval of the donor kidney), there is a requirement for initial use of strong analgesics. The provision of PCA may be a useful adjunct to local analgesia infiltration. Use of morphine or similar opioids may increase the incidence of postoperative nausea and vomiting, delay the return of normal function, and prolong hospital stay. Little evidence is available regarding the provision of epidural analgesia in the kidney donor. A more recent advance in the use of laparoscopic techniques has been the introduction of a "gasless laparoscopic assisted donor nephrectomy," which avoids the effects of high circulating carbon dioxide tensions.[199]

Anesthesia for the Transplant Recipient

The following practices have been used in Oxford since the 1980s and are based on the physiological and pharmacological principles outlined previously. We use the same strategy for patients receiving either a cadaver or a living related graft.

Premedication is important because many patients are anxious at the time of transplantation; suitable attenuation of this anxiety may be achieved with an orally administered benzodiazepine (usually temazepam, 10 to 20 mg). Intramuscular premedication is avoided because of the tendency of the uremic patient to bleeding disorders. Vagolytic drugs (e.g., atropine) are given intravenously at the time of induction of anesthesia if clinically indicated, such as when suxamethonium is used to facilitate intubation, or when a combination of an opioid plus one of the hemodynamically neutral muscle relaxants is administered. The avoidance of pronounced bradycardias is particularly important in patients receiving long-term β-adrenoceptor blockade for the treatment of ischemic heart disease and hypertension. β-Adrenoceptor blocking drugs, calcium channel blockers, and other antihypertensive and antianginal therapies are continued up to the morning of surgery.

The routine prophylactic administration of antacids may be advocated for patients with symptoms of esophageal reflux; a single dose of sodium citrate (30 mL) in the anesthetic room is appropriate. Histamine H_2-receptor antagonists (e.g., ranitidine 150 mg orally) or proton-pump inhibitors (e.g., omeprazole) are given with the premedication to reduce gastric hyperacidity. Phenothiazine antiemetics and metoclopramide should be administered with care because they may cause prolonged sedation and extrapyramidal side effects in patients with renal failure (see earlier).

Anesthesia is best induced with a sleep dose of propofol coupled with a loading dose of fentanyl, 3 to 6 μg/kg, or an infusion of remifentanil, 0.05 to 0.1 μg/kg/min. For patients with poor cardiac reserve, etomidate, 0.3 mg/kg, may be preferred. Using the combination of a hypnotic and an opioid, the anesthesiologist can minimize the hemodynamic response to induction of anesthesia, laryngoscopy, intubation, and surgical incision. Neuromuscular blockade is provided by atracurium or cisatracurium in doses of 0.6 mg/kg or 0.15 to 0.4 mg/kg. To maintain neuromuscular blockade, increments of either drug are given when indicated clinically with neuromuscular transmission monitored using a peripheral nerve stimulator. An alternative technique involves continuous infusion of either relaxant (atracurium, 6 to 8 μg/kg/min, or cisatracurium, 1 to 2 μg/kg/min). For the patient in whom there is the added problem of an inadequate period of fasting before surgery, suxamethonium, 1 to 1.5 mg/kg, should be used to aid intubation.

Maintenance of anesthesia is achieved with isoflurane to supplement nitrous oxide; this has the advantages of nonrenal elimination and may be given with high inspired oxygen concentrations in severely anemic patients. Alternatively, with a remifentanil infusion, an air-oxygen-isoflurane mixture may be used. The arterial blood carbon dioxide tension should be kept at normocapnia or mild hypocapnia, and monitored by end-tidal carbon dioxide sampling. Short periods of hypoventilation can lead to hemoglobin desaturation, whereas excess hyperventilation with low arterial carbon dioxide tensions causes a shift of the oxyhemoglobin dissociation curve to the left. Intraoperative analgesia can be provided by intravenous morphine (10 to 15 mg).

At the end of surgery, anesthesia is discontinued, and residual muscular paralysis is reversed with neostigmine. The muscarinic effects may be blocked by atropine or glycopyrrolate. Glycopyrrolate is preferred in patients with associated hypertensive or ischemic heart disease to avoid excessive tachycardia. An important interaction for the anesthesiologist to be aware of is that between cyclosporine and muscle relaxants. Sidi and colleagues[180] found a greater incidence of postoperative respiratory failure in transplant patients receiving cyclosporine as the immunosuppressant drug. After extubation, all transplant patients should receive oxygen for 12 to 24 hours postoperatively.

Monitoring during Anesthesia

The high incidence of ischemic and hypertensive heart disease in these patients makes it essential to monitor the ECG and blood pressure continuously during induction of anesthesia, the perioperative period, and the immediate postoperative period. Blood pressure should be measured noninvasively, with the cuff placed on the nonfistula arm. Because of improvements in the preoperative preparation of kidney transplant recipients, and because excessive blood loss is the exception rather than the rule, arterial cannulation is only rarely needed for the perioperative monitoring of blood pressure. The aim should be to maintain the systolic blood pressure close to the patient's normal blood pressure.

Measurement of the central venous pressure is as important as measurement of the blood pressure in patients undergoing renal transplantation. We use a triple-lumen catheter inserted under ultrasound guidance into the internal jugular or subclavian vein. Intraoperative fluids are given generally as Hartmann's solution rather than normal saline (0.154M sodium chloride) because the large volumes of the latter have been found to cause episodes of hyperkalemia and a hyperchloremic metabolic acidosis.[150] Unless the recipient becomes ketoacidotic, the increased bicarbonate concentration (from metabolism of the lactate) is not significant. Hydroxyethyl starch solutions are more useful than gelatins to achieve plasma expansion and result in a greater increase in the central venous pressure. Blood is given to maintain a hemoglobin concentration of approximately 10 g/dL. With this fluid strategy, we aim to increase the central venous pressure by 4 to 8 mm Hg by the time of revascularization. In practice, we aim for a central venous pressure of 10 to 15 mm Hg in patients with good left ventricular function and 12 mm Hg in patients in whom function is impaired and older patients (>55 years old).

Postoperative fluid requirements depend on early renal function, but should be aimed at keeping the central venous pressure at its intraoperative level. In our practice, this equates to a regimen of urine output plus 50 to 100 mL/hr. Replacement fluids are given as crystalloid (equal volumes of 5% dextrose and Hartmann's solution), supplemented by colloid in cases of a decrease in central venous pressure accompanied by arterial hypotension. Persistent hypotension in the presence of an adequate central venous pressure (6 to 10 mm Hg) normally responds to a vasoconstrictor agent, such as norepinephrine. The accurate assessment of fluid balance postoperatively may be difficult in a predialysis patient who still has native urine production; after living related transplantation, there may be a major response by the kidney to the high osmotic load of creatinine, urea, and other solutes with urine outputs of 40 L over the first 24 hours. Urine output tends to return to normal volumes by 24 to 48 hours. Because of this high fluid flux, the patient's temperature should be carefully monitored intraoperatively, and heat balance should be maintained by warming all infused fluids and the use of convection heaters (e.g., the Bair Hugger, Arizant Healthcare Inc; Eden Prairie, MN). Other causes of a massive diuresis include the onset of the diuretic phase of acute tubular necrosis, characterized by large volumes of dilute urine.

With increasing availability of blood gas analysis, and near-patient testing systems, measurement of electrolytes and hemoglobin during the operative procedure has become more routine. There have been reports of sudden increases of plasma potassium levels leading to arrhythmias and cardiac arrest.[93] Several factors may be responsible, such as the administration of mannitol[143] or stored blood, severe metabolic acidosis, and hyperkalemia or hyperglycemia.[77] The cause of hyperkalemia or hyperglycemia is unknown. Prevention of this complication assumes greater significance in diabetic patients undergoing renal transplantation (see later). If urine output is more than 300 mL/hr, the serum sodium and potassium levels should be checked frequently. If output is greater than 1000 mL/hr, potassium supplements (10 mmol/L) may be needed. The excretion of large fluid volumes also may lead to intravascular and intracellular volume depletion manifesting as tachycardia (either ventricular tachycardia or atrial fibrillation) or seizures.

In patients with poor renal output in the absence of dehydration, electrolytes should be checked every 6 hours, and accurate weight should be obtained every 24 hours. Dialysis should be avoided during the first 24 hours postoperatively, but it is indicated when there is massive weight gain, severe hypertension, fluid overload with pulmonary edema, or a severe metabolic acidosis or hyperkalemia.

There are no indications for the use of "renal doses" of dopamine in the transplant recipient. Studies fail to show any efficacy of dopamine by infusion for improving renal function. Inotropic doses may be useful, however, in patients with poor myocardial function.

The diabetic patient undergoing renal transplantation also should receive an infusion of glucose (5 g/hr). The blood glucose level is titrated to normoglycemia (4 to 8 mmol/L) with a separate infusion of soluble human insulin.

Postoperative Care

Because of the multiple pathologies exhibited by transplant patients, they should receive postoperative care in the intensive care unit, where controlled oxygen therapy and full monitoring can be provided. The correct positioning of the triple-lumen catheter must be checked by radiography in the recovery area. If controlled ventilation is needed, admission to the intensive care unit is required. Strict monitoring of fluid input and output is essential; there should be regular monitoring of the ECG, blood pressure, heart rate, central venous pressure, and oxygen saturation by pulse oximetry.

Analgesia in the Postoperative Period

Analgesia should be titrated according to patient demand. The choice of drugs (opioids and oral non-narcotic analgesics) must be considered carefully because accumulation of active metabolites of pethidine and morphine may occur in a patient with a nonfunctioning allograft. Excessive use of opioids may lead to delayed respiratory depression, sedation, and convulsions (all related to parent drug and active metabolite accumulation). PCA may aid the more efficient and safe titration of dosage to desired effect in the uremic patient, although there have been reports of excessive sedation and respiratory depression after use of PCA in end-stage renal disease patients.[44] In Oxford, as in many other units, a morphine or fentanyl PCA is used with a bolus dose of 1 to 2 mg of morphine administered with a lockout of 5 to 10 minutes, or a bolus dose of 20 μg of fentanyl and a 3- to 6-minute lockout. We do not administer a background infusion of opioid as part of the PCA.

Although only a few nonsteroidal anti-inflammatory drugs (NSAIDs) are eliminated unchanged via the kidney, there is evidence of reduced clearance of ketoprofen, fenoprofen, naproxen, and carprofen in renal failure as a result of probable deconjugation of acyl glucuronide metabolites. More importantly, NSAIDs also can cause reversible kidney damage with reduction of renal blood flow and glomerular filtration rate. They also can cause edema, interstitial nephritis, and papillary necrosis in the kidney. These effects are probably caused by the action of the NSAIDs on prostaglandin synthesis—the latter being integral for renal blood flow and glomerular filtration rate autoregulation. These drugs should be avoided in the post-transplant patient and in *all* patients with renal impairment.

Vascular and Peritoneal Access for Dialysis

Surgery for shunt insertion or fistula creation may be done under general or regional anesthesia. The anesthetic agent may be infiltrated locally, but for vascular access in the upper limb, anesthesia is best achieved by brachial plexus blockade. The associated sympathetic nerve block abolishes vasospasm and ensures vasodilation. The duration of brachial plexus anesthesia in end-stage renal disease patients is decreased, however, by 39%.[18] This decrease was thought to be the result of metabolic changes present in uremia (e.g., hyperkalemia) and the increase in cardiac output secondary to anemia. Two later publications failed to support these earlier data, however.[132,137] Bupivacaine disposition is unaltered after supraclavicular plexus blockade in uremic patients,[163] and there is no direct correlation between the shortening of anesthetic action and the severity of anemia or uremia. Although bupivacaine is the agent of choice for local anesthetic procedures, a report by Gould and Aldrete[78] described cardiotoxic effects of bupivacaine after its use in normal doses in a patient with end-stage renal disease.

Other drugs suitable for this group of patients include lidocaine, prilocaine, mepivacaine, ropivacaine, and levobupivacaine. Compared with bupivacaine, lidocaine, mepivacaine, and prilocaine have a faster onset of anesthesia but a shorter duration. Generally, the normal maximal doses for bupivacaine and other local anesthetic agents (Table 13-6) should be decreased by 25% in end-stage renal disease patients because any accompanying acidosis would have the effect of decreasing the central nervous system threshold to the toxic effects of local anesthesia.

The use of regional anesthesia in a patient with uremic neuropathy generally is contraindicated. Similarly, use of vasoconstrictors such as epinephrine to prolong local anesthetic action is best avoided because of the risk of cardiac arrhythmias after systemic absorption in the acidotic, hyperkalemic patient. Other limitations to the use of regional anesthesia are the presence of a bleeding tendency, patient acceptance, and the possible inadequate duration of analgesia. For more complex procedures (e.g., the insertion of arteriovenous grafts, thigh shunts, or continuous ambulatory peritoneal dialysis cannulation), general anesthesia usually is preferable.

ANESTHETIC MANAGEMENT OF DIABETIC PATIENTS UNDERGOING RENAL OR COMBINED KIDNEY-PANCREAS TRANSPLANTATION

The combined problems of diabetes and uremia are common because patients with juvenile-onset diabetes that developed before age 30 years have a 1:5 chance of renal complications. At present in the United Kingdom, about 10% of all renal transplants are in diabetic patients, but in the United States, the figure is more than 40%. Hence, an increasing number of units are being faced with uremic diabetic patients for transplantation. There also is a move toward the combined transplantation of kidney and pancreas in these patients. The problems presented for the anesthesiologist by the diabetic patient may be considered under the following headings:

1. Influence of uremia on carbohydrate metabolism
2. Preoperative assessment of the patient
3. Anesthetic and postoperative management
4. Management of kidney-pancreas transplantation

Influence of Uremia on Carbohydrate Metabolism

The influence of uremia on carbohydrate metabolism has been extensively reviewed by de Fronzo and coworkers.[55] The main defect seems to be a systemic insulin antagonism. Coupled with this hyperglycemic response, there is a glucose-induced hyperkalemia. Its exact cause is uncertain, although hypoaldosteronism and hyporeninism have been suggested.

Preoperative Assessment of the Patient

The preoperative assessment of the patient does not differ significantly from that of the nondiabetic patient undergoing renal transplantation apart from the additional factor of achieving optimal glycemic control before surgery is started. All patients with diabetes present an increased risk to the anesthesiologist, especially related to the complicating factors of hypertension and coronary artery disease.[22] This increased

Table 13–6 **Maximal Safe Doses of Local Anesthetic Agents***

	Plain Solution (mg)	With Added Epinephrine (1:200,000) (mg)	Relative Duration of Sensory Block (hr)
Lidocaine	300	500	1.5
Bupivacaine	175	250	8
Mepivacaine	300	500	1.5
Etidocaine	300	400	8
Prilocaine	400	600	1.5
Chloroprocaine	600	650	0.75
Procaine	500	600	1
Ropivacaine	250	—	1
L-Bupivacaine	175	—	1

*These doses are based on a 70-kg body weight. Doses should be decreased by 25% in acidotic patients to avoid signs of central nervous system toxicity (e.g., lightheadedness, dizziness, disorientation, euphoria, dysarthria, slurring of speech, progressing to twitching and generalized convulsions).

risk includes a greater need for intraoperative blood pressure support and aggressive treatment of any hypotension with vasoconstrictor drugs. In the diabetic patient with renal failure, there is an even higher risk of perioperative myocardial ischemia and infarction, both of which may be silent because of the accompanying autonomic neuropathy. Other potential complications are the increased risk of wound infection and a prethrombotic state compared with nondiabetic renal transplantation.[160]

Heino[90] observed an increased perioperative morbidity and mortality in diabetic patients undergoing renal transplantation compared with nondiabetic transplant recipients. In a follow-up of 413 patients, Heino[90] showed that diabetic patients with end-stage renal disease had a higher incidence of preoperative ischemic ST-T wave changes (62.2% versus 39.8% in nondiabetic uremic patients) and higher incidences of pulmonary congestion (14.5% versus 5.2%) and pleural effusions on chest radiography (10.1% versus 4.5%). There were, however, no differences in the frequency of perioperative complications, although the diabetic patients had a greater mortality during the first postoperative month.

Many diabetics presenting for transplantation are poorly controlled and show lability of the blood glucose concentration. Concurrent administration of thiazide diuretics, diazoxide, and β-adrenoceptor blocking drugs may complicate glucose homeostasis further. If the patient is normally maintained on continuous ambulatory peritoneal dialysis, it should be continued up to 1 hour before surgery. In general, the anesthesiologist should aim for a blood glucose concentration of 4 to 8 mmol/L.

Anesthetic Technique

After induction of anesthesia, uremic patients with diabetic neuropathy may show a greater systolic pressor response to intubation and other noxious stimuli.[110] This response is due to an increased sensitivity to circulating catecholamines and a loss of baroreceptor control. These same authors also have shown that diabetic patients exhibit greater Q-Tc dispersion,[111] with an associated increased risk of sudden cardiorespiratory arrest.[162] The measurement of Q-T dispersion by 24-hour Holter ECG monitoring does not seem, however, to be a sensitive method per se to detect the cardiac autonomic neuropathy in these patients.[111]

Because of the possible association of diabetes with gastroparesis and an increased gastric residual volume, all diabetic uremic patients should undergo a rapid-sequence intubation using suxamethonium, unless there is hyperkalemia.[161] Other suitable drugs include large doses of atracurium or cisatracurium, coupled with the application of cricoid pressure. The handling of opiates during anesthesia in a diabetic patient with end-stage renal disease has not been researched in depth; Koehntop and colleagues[115] found an increased clearance of alfentanil (6.4 mL/kg/min versus 4.1 mL/kg/min) in the diabetic patient compared with the nondiabetic uremic patient.

Other potential anesthetic problems in these patients include temporomandibular joint rigidity and difficulties in intubation caused by tissue glycosylation.[94,159,168] Although Hogan and associates[94] reported that 32% of diabetic patients undergoing renal or simultaneous kidney-pancreas transplantation had a difficult grade laryngoscopy, more recent data from the Mayo Clinic found an overall incidence of difficult laryngoscopy of 2.1% in a series of 725 patients.[198] This latter figure compared with a 1% incidence of difficulty in renal failure patients without diabetes mellitus. If there is any concern, the anesthesiologist should use suxamethonium as the relaxant of choice or use fiberoptic techniques to aid intubation.

Anesthesia for Kidney-Pancreas Transplantation

Simultaneous kidney-pancreas transplantation is increasingly being used for the management of diabetic end-stage renal disease. Patients have creatinine clearance less than 40 mL/min and are on dialysis or are very close to needing it. The present results indicate a 1-year graft survival of 85% and a patient survival at 1 year greater than 94%. Simultaneous kidney-pancreas surgery offers numerous challenges, however, including a prolonged operation (5 to 7 hours), careful metabolic control, and provision of effective analgesia without postoperative respiratory depression. Patients undergoing simultaneous kidney-pancreas transplantation are type 1 diabetics; there is no evidence to support simultaneous kidney-pancreas transplantation in patients with type 2 diabetes mellitus and insulin resistance. All patients have evidence of secondary diabetic complications (e.g., retinopathy, vasculopathy, neuropathy). Contraindications to simultaneous kidney-pancreas transplantation include untreatable coronary artery disease, irreversible pulmonary or hepatic dysfunction, and recent myocardial infarction or significant left ventricular dysfunction. Relative contraindications include age older than 55 years, symptomatic cerebrovascular or peripheral vascular disease, severe aortoiliac disease, and body mass index greater than 30.

Preoperative assessment should include a thorough investigation of the cardiovascular system including ECG, echocardiogram, and thallium stress scan. In the presence of coronary disease, the patient should undergo angiography with percutaneous coronary intervention or coronary artery bypass graft if appropriate. Other important factors include examination for autonomic failure, with evidence of cardiac denervation, gastroparesis, and orthostatic hypotension. Preoperative electrolytes usually show the serum potassium level to be 5 to 6 mmol/L; cancellation is not warranted unless the serum potassium level is significantly outside these limits. All cardiac medications should be continued preoperatively.

For the conduct of anesthesia, our own practice is to premedicate with the combination temazepam, metoclopramide, and ranitidine. We use general anesthesia based on a fentanyl- or remifentanil-isoflurane-air-oxygen technique. There is some evidence to advocate insertion of a thoracic epidural because this provides a reduced incidence of venous thromboembolism, a reduction of respiratory complications, and first-rate postoperative analgesia. We avoid high-dose epidural local anesthetic regimens until the patient is stable at the end of surgery because they can make assessment of the patient's volume status difficult. There are large fluid shifts in these patients, and any period of hypotension secondary to hypovolemia is worsened by peripheral vasodilation. The use of epidural opiates (diamorphine or fentanyl) may be a useful adjunct. There is no place for NSAIDs because of the risk of renal impairment in the new graft and

the risk of gastrointestinal and surgical bleeding. The choice of immunomodulation therapies varies among different centers.

Careful monitoring is crucial in these patients. Our choice includes two large peripheral lines, invasive blood pressure measurement (this allows us to follow the swings in blood pressure and facilitates regular blood gas sampling), central venous pressure (with maintenance of central venous pressure at 10 to 12 mm Hg; this may require large fluid volumes at declamping), peripheral and core temperature monitoring, perioperative clotting studies (and if concerned about the development of a coagulopathy, thromboelastogram studies should be undertaken), and monitoring of neuromuscular blockade. Fluid requirements are given as Hartmann's solution via a fluid warmer. The hemoglobin should be maintained at greater than 8 g/dL, with monitoring of the serum K^+ and blood glucose, especially at unclamping of kidney and pancreas. Glucose control is provided by an infusion of 50% dextrose (10 to 15 mL/hr) and a separate infusion of a short-acting insulin. Diabetic control also is influenced by intraoperatively administered steroids given for immunosuppression and the use of intraoperative mannitol. Reperfusion of the pancreatic graft also can lead to an *increase* in blood glucose levels, however, owing to the release into the circulation of graft preservation fluid that contains high glucose concentrations.

CONCLUSION

Although Strunin[187] reported an immediate perioperative mortality of 16% after renal transplantation, more recent series have recorded immediate mortality rates of 0.03% to 0.6%. With present-day anesthetic techniques, the incidence of delayed extubation (owing to inadequate ventilatory performance) also is low (<3% of patients).

There is no single correct technique for the anesthetic management of patients in end-stage renal failure. Effective and safe anesthesia for the renal transplantation patient depends on an understanding of the pathophysiology and biochemistry of uremia, and its effect on the pharmacokinetics and metabolism of the drugs used. As the criteria for accepting patients into renal transplantation programs broaden, the anesthesiologist is likely to be faced with increasing problems of the interaction of other intercurrent diseases and multiple drug therapies.

Chapter 14

Early Course of the Patient with a Kidney Transplant

Stuart J. Knechtle • John D. Pirsch

A successful long-term outcome for a new kidney transplant recipient depends on the early perioperative management and course after surgery. Important factors affecting long-term outcome include the occurrence of delayed graft function (DGF)[7,55]; episodes of acute rejection[7]; early surgical complications,[5] such as obstruction, urine leak, or vascular complications; and sepsis.[1] Toxicity from calcineurin inhibitors can lead to chronic transplant nephropathy later in the post-transplantation course.[36] Donor and recipient factors affect long-term outcome, particularly the use of expanded criteria donors[33] or highly sensitized recipients. The early management and amelioration of risk factors in the immediate postoperative period may lessen their long-term negative impact and improve outcome.

OVERVIEW

Perioperative Management

Management of the transplant recipient begins in the immediate preoperative period. An initial assessment of the recipient includes a careful assessment of pretransplant fluid status to determine the need for dialysis and a careful physical examination to exclude potential contraindications to transplantation, such as significant cardiac disease or vascular insufficiency, which could preclude successful surgery. Knowledge of the donor status also is helpful in the early postoperative management of the transplant recipient. With an ideal donor or a living related donor, the expected outcome is an immediately functioning transplant that may preclude post-transplant dialysis. Expanded criteria donors (donor age >60 years or age 50 to 59 years with death due to cerebrovascular accident, history of hypertension, or creatinine level >1.5 mg/dL) have a higher likelihood of DGF, which can lead to volume overload and the need for urgent dialysis.[12] Technical considerations include the need for vascular reconstruction, which may prolong surgery and contribute to postoperative DGF. Recipient factors also affect the early postoperative course. Significant risk factors for early post-transplant dysfunction include pretransplant sensitization, obesity, younger or older age, and anatomical considerations that complicate the surgery.

In the early perioperative period, attention to fluid and electrolyte balance is crucial. Careful monitoring of urine output is essential, and any decrease in urine flow must be evaluated carefully. A decrease in urine volume may be due to acute tubular necrosis, hypovolemia, urinary leak, ureteric obstruction or, most significantly, vascular thrombosis. Assessment of the patient's volume status with the measurement of central venous pressure may help eliminate hypovolemia as a cause of decreasing urine output. DGF can be ascertained further with a nuclear scan or duplex ultrasonography to assess perfusion of the graft and to exclude renal artery or vein thrombosis. Duplex ultrasonography also allows the diagnosis of a urinary complication.

Measures to decrease the likelihood of DGF often are used during the operative procedure and in the perioperative period. Maintenance of adequate blood pressure and fluid status may be accomplished with intravenous albumin[17] or crystalloid, the latter being preferable. Shorter cold ischemia or pulsatile perfusion of the donor organ also may decrease the likelihood of postoperative DGF. Some centers have used intra-arterial calcium channel blockers, such as verapamil, to improve renal blood flow.[16] It is common practice to administer mannitol (12.5 g) about 10 minutes before the kidney is reperfused, which helps to trigger an osmotic diuresis and might be protective. Oral calcium channel blockers have been used to decrease the incidence of DGF.[15] There is controversy about the early initiation of calcineurin inhibitors because of the potential for nephrotoxicity. Some centers delay the use of calcineurin inhibitors until there is

Table 14–1 Early Surgical and Medical Complications after Transplantation

Surgical/Mechanical	Medical
Obstruction	Acute rejection
Hematuria	Delayed graft function
Urinoma	Acute cyclosporine/ tacrolimus nephrotoxicity
Arterial stenosis	Prerenal/volume contraction
Arterial thrombosis	Drug toxicity
Renal vein thrombosis	Infection
Postoperative hemorrhage	Recurrent disease
Lymphocele	

established diuresis. If additional immunosuppression is desired, polyclonal or monoclonal anti–T cell antibodies may be used.

Graft Dysfunction

Early complications of renal transplantation may be mechanical/surgical or medical. Early medical problems are more common than post-transplant surgical problems (Table 14-1). The most common early post-transplant medical problem is DGF, which occurs in 20% of patients who received kidneys from ideal deceased donors and in nearly 40% of patients in whom the donors were older than age 55 years.[8] After or concomitant with DGF, acute rejection may become a significant clinical problem.[52,55,58] Other reasons for early medical complications include acute cyclosporine or tacrolimus nephrotoxicity, prerenal azotemia, other drug toxicity, infection, and early recurrent disease. An uncommon but serious post-transplantation medical problem is thrombotic microangiopathy, formerly called hemolytic-uremic syndrome. Thrombotic microangiopathy may be induced by rejection or as a secondary event from cyclosporine, tacrolimus, or sirolimus therapy.[39]

Mechanical problems usually are the result of complications of surgery or specific donor factors, such as multiple arteries, that lead to post-transplantation dysfunction. Mechanical/surgical factors include obstruction of the transplant, hematuria, urine leak or urinoma, and vascular problems such as renal artery or vein stenosis or thrombosis. Postoperative bleeding is another potential complication that may cause compression of the transplant because the transplant usually is placed in the retroperitoneal space. Post-transplant lymphoceles are another common cause of early transplant dysfunction. Lymph drainage from transected lymph vessels accumulates in the perivascular and periureteral space and can cause ureteral obstruction or lower extremity swelling from iliac vein compression.

SURGICAL COMPLICATIONS

Urinary Problems

Urinary Obstruction

After implantation of a living donor kidney transplant, urine output begins immediately or within minutes. (See Chapter 27 for a more complete discussion of urinary problems.) The same is not generally true of cadaver donor kidneys, in which urine output may not be apparent for 1 hour or more after implantation and may be sluggish or nonexistent for days if the kidney has been injured (DGF) by donor factors or preservation. If a kidney that was formerly making urine slows down or stops and does not respond to fluid administration, urinary obstruction has to be considered in the differential diagnosis. The initial evaluation is to check the patient's vital signs and central venous pressure to ensure adequate hydration and to check that the Foley catheter is functioning correctly. Obstruction of the Foley catheter by blood clots may occur easily and can be cleared by gentle irrigation. If these problems are not present, renal transplant ultrasound is the fastest, most accurate, and least expensive method to assess the renal pelvis for obstruction. Pelvicaliceal dilation seen by ultrasound implies distal obstruction. If the bladder is collapsed rather than full, the problem is likely to be ureteral obstruction. Treatment should be immediate decompression of the renal transplant pelvis by percutaneous insertion of a nephrostomy tube. Subsequently (usually 1 or 2 days later to allow blood and edema to clear after nephrostomy tube placement), a nephrogram can be obtained to evaluate the ureter for stenosis or obstruction. The diagnosis is confirmed by a decline in the serum creatinine level after decompression of the renal pelvis.

After the Foley catheter is removed, the most common cause of urinary obstruction is not ureteral stenosis, but rather bladder dysfunction. This cause is particularly common in diabetic patients with neurogenic bladders. Initial management is replacement of the Foley catheter and a trial of an α-blocker, such as doxazosin or terazosin. If bladder dysfunction persists after one or two such trials, it may be necessary to start intermittent self-catheterization. In rare instances in which bladder dysmotility is severe and urinary tract infections are common, it may be preferable to drain the transplant ureter into an ileal conduit to the anterior abdominal wall. Ideally, a patient with a neurogenic bladder should have been evaluated before transplantation with urodynamic studies, and a decision should have been made about management at that time (see Chapters 4 and 12).

During the first 1 or 2 weeks after transplantation, obstruction usually is due to a technical problem related to surgery (see Chapter 27). If a ureteral stent was placed at the time of surgery, it is highly unusual to have obstruction. Possible explanations for obstruction are a twisted ureter or anastomotic narrowing. Generally, obstructions appear several weeks postoperatively, after the stent has been removed, and occur most frequently at the anastomosis between ureter and bladder.[24] Usually, these obstructions can be crossed by a guidewire and dilated percutaneously by an interventional radiologist (Fig. 14-1). If the the nephrostogram shows a long (>2 cm) stricture, especially a proximal or midureteral stricture, it is likely that the problem is not amenable to balloon dilation and that surgical repair is necessary (Fig. 14-2). The operation of choice for a long stricture or one that has failed balloon dilation is ureteroureterostomy or ureteropyelostomy using the ipsilateral native ureter. The spatulated ends of the transplant and native ureters are anastomosed using running 5-0 absorbable suture. This anastomosis can be done over a 7F double-J stent, which is left in place for 4 to 6 weeks. If no ipsilateral ureter is available, it may be necessary to use the contralateral ureter. If neither the ipsilateral ureter nor the contralateral ureter is available, alternatives include bringing the bladder closer to the kidney using a psoas hitch or

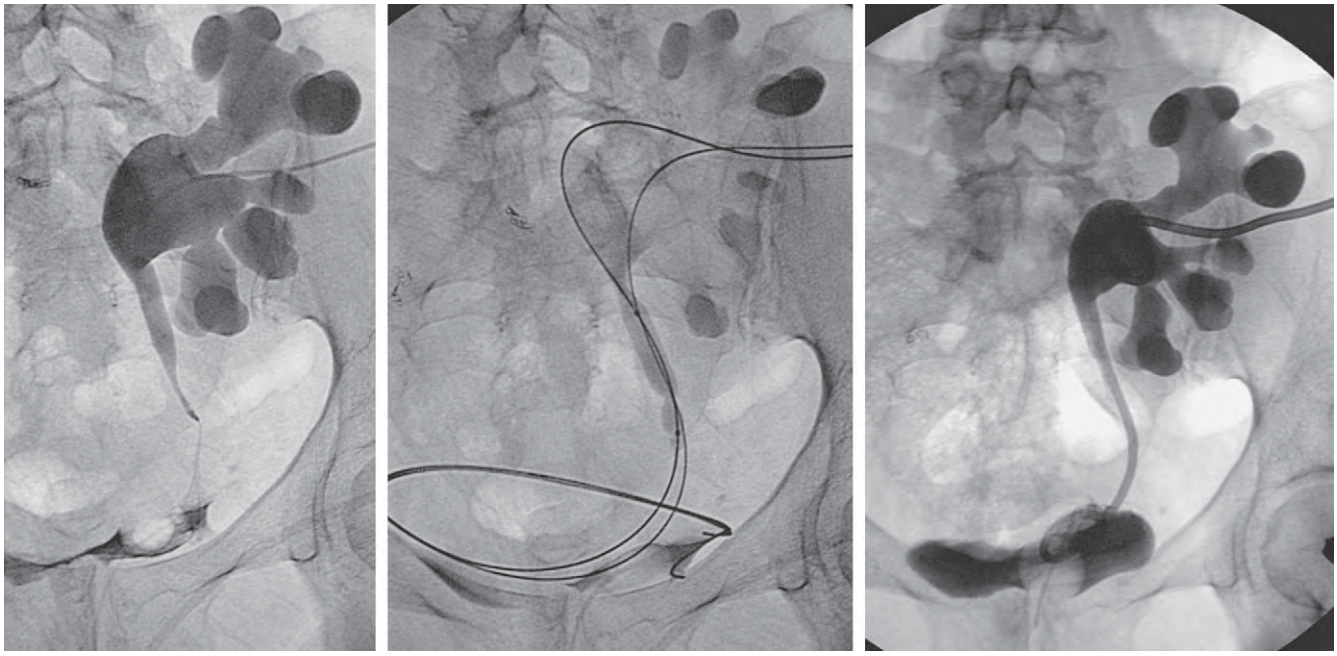

Figure 14–1 This patient presented with an elevated creatinine level. Ultrasound showed pelvicaliceal dilation. **A**, A percutaneous nephrostomy tube was placed, and the following day a nephrostogram was obtained. **B**, The midureteral stenosis was crossed successfully with a guidewire, and the ureter was dilated with a balloon (the waist of the dilated balloon corresponds to the stricture). **C**, Subsequently, a double-J stent was placed from the renal pelvis into the bladder across the dilated stricture.

fashioning a Boari flap,[18] but these measures are rarely necessary. Another method is endoureterotomy[20]; experience with this method is growing.[29]

Even if urinary obstruction is clinically silent (i.e., the patient is asymptomatic with a normal creatinine value), urinary obstruction manifested by dilation of the pelvis and calices on ultrasound should be treated because it ultimately leads to thinning of the renal cortex and loss of renal function. Urinary obstruction should be treated immediately to minimize damage to the transplanted kidney.

Bleeding into the Urinary System

Gross hematuria is common immediately postoperatively because of surgical manipulation of the bladder. The Leadbetter-Politano procedure for ureteroneocystostomy is associated with more hematuria compared with the extravesical approach typified by the Lich technique or the technique described by us (see Chapter 11).[28] The advantage of this technique is that it effectively prevents reflux and can be done with excellent long-term results. Occasionally, continuous bladder irrigation is necessary if gross hematuria is associated with clots, although intermittent manual irrigation usually is adequate. Obstruction of the bladder outlet by a blood clot is an emergency; vigilant nursing care is required to ensure that it does not occur. It is preferable not to distend the bladder in the immediate postoperative period to avoid disrupting the bladder sutures or causing a leak, and continuous bladder irrigation and cystoscopy ideally are avoided. Minor hematuria without clots is common in the first 1 or 2 days regardless of the surgical method of ureteroneocystostomy and does not require treatment; it resolves over time without specific treatment.

Urine Leak

A leak of urine from the transplanted kidney in the early postoperative period may be clinically obvious if the patient presents with abdominal pain, an increasing creatinine level, and a decrease in urine output. Urine in the peritoneal cavity causes peritonitis and pain. More commonly, assuming that the kidney was placed in the retroperitoneal position, a urinoma collects around the kidney and bladder and causes a bulge in the wound and pain with direct displacement of adjacent viscera, including the bladder. The diagnosis should be suspected if the serum creatinine level is increasing (or not decreasing appropriately). Adjunctive tests to help make the diagnosis of urine leak, if it is not obvious clinically, include a renal scan, which would show urine in the retroperitoneal space surrounding the bladder or around loops of bowel, or an ultrasound, which would show a fluid collection outside the bladder and which when aspirated has a high creatinine level. Urine leak generally is due to a surgical problem with the ureteroneocytostomy or ischemic necrosis of the distal ureter. This leak should be immediately repaired surgically because the risk of wound infection increases with delay in treating this complication.

Vascular Problems

Arterial Stenosis

Transplant renal artery stenosis may manifest in the early postoperative period by (1) fluid retention, (2) elevated creatinine levels, and (3) hypertension.[21,57] (See Chapters 26 and 28 for a more complete discussion of vascular problems.)

Figure 14–2 This intra-abdominal kidney transplant was found by ultrasound to be obstructed. A nephrostomy tube was placed, and a nephrostogram was obtained the following day. The kidney had rotated medially and twisted the ureter proximally. The patient was managed operatively by placing the kidney laterally in a retroperitoneal pocket and performing ureteroureterostomy using the ipsilateral native ureter.

Commonly, the patient does not tolerate cyclosporine or tacrolimus because these drugs exacerbate the already existing ischemia at the glomerular arteriolar level. The aforementioned triad of clinical findings need not all be present, and the diagnosis should be suspected for any one of the three clinical signs. Cytomegalovirus infection and DGF have been described as risk factors for transplant renal artery stenosis.[4] If the creatinine level is greater than 2 mg/dL, renal arteriography is best avoided because of the nephrotoxicity of the contrast dye. Magnetic resonance imaging angiography usually can give an accurate delineation of the arterial anatomy. Ultrasound also is safe, but not particularly discriminating, and is helpful only if jetting of flow is seen.

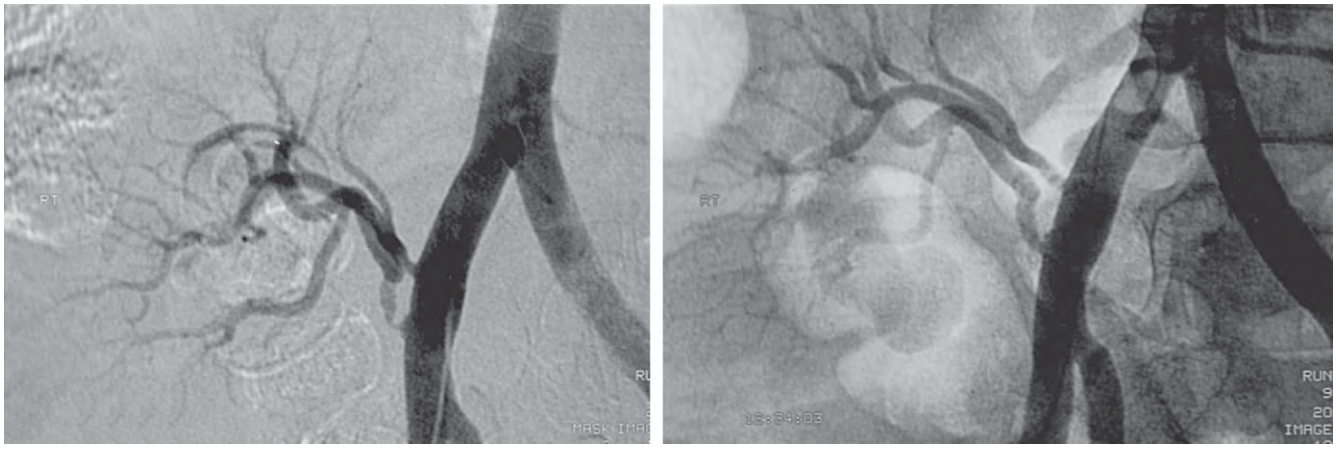
As the population of renal transplant recipients has become older and includes more diabetic patients and patients with vascular disease, transplant renal artery pseudostenosis has become increasingly common. Pseudostenosis refers to arterial stenosis in the iliac artery proximal to the implantation of the transplant renal artery. Although the anastomosis and renal artery may be completely normal, the problem is high renin output by the transplanted kidney, resulting from its hypoperfusion.

Treatment of transplant renal artery stenosis and pseudostenosis includes balloon dilation and surgery. Generally, ostial stenosis, long areas of stenosis, and stenosis in tortuous arteries difficult to access radiographically are not treated as successfully with balloon dilation as with surgery. Stenoses within smaller branches of the renal artery may be treatable only by angioplasty. Iliac artery disease causing pseudostenosis may be treated by angioplasty, but the risk is present of embolization or dissection causing thrombosis or further ischemia. Surgical options include bypass of the stenosis using autologous saphenous vein, a prosthetic graft, or an allogeneic arterial graft procured from a deceased donor. The risk of the procedure has to be weighed against the potential benefit of improving renal transplant blood flow. In addition to the serum creatinine determination, a biopsy may be useful to assess the quality of the renal parenchyma. In advanced chronic rejection with a creatinine value greater than 2.5 mg/dL for more than 1 month, it may not be prudent to repair such arteries. Figure 14-3 shows a renal artery stenosis in the lower pole artery that was managed successfully by balloon angioplasty.

Arterial Thrombosis

Renal transplant arterial thrombosis usually occurs early (within 30 days) in the post-transplant period,[43] but should be a rare event because it is generally due to a technical error at the time of surgery. It usually is related to an intimal injury to the donor kidney during procurement or to anastomotic narrowing or iliac artery injury during implantation. Kidneys from donors younger than 5 years old have been associated with a higher risk of thrombosis.[53] The kidney tolerates only 30 to 60 minutes of warm ischemia before it is irreversibly injured, making it difficult to diagnose and correct this problem before it is too late to salvage the kidney. The diagnosis should be suspected in a patient who has had a transplant hours to days before and has had a good urine output but who suddenly has a decrease in urine output to zero. A high degree of suspicion has to be present, and the patient should be returned to the operating room promptly. If the patient had urine output preoperatively from the native kidneys, the diagnosis is hard to make in a timely manner because urine output may continue after the renal transplant has thrombosed. The advantage of diagnostic ultrasound has to be weighed against the disadvantage of delaying a return to the operating room. Almost all kidney transplants with arterial thrombosis are lost because of ischemic injury.

In cases of more than one renal transplant artery in which arterial reconstruction is performed at implantation, there may be increased risk of thrombosis of one or more arteries. This increased risk particularly is a concern if there is a small accessory renal artery supplying the lower pole of the kidney and providing the ureteral blood supply. Thrombosis of a branch artery may manifest as an increase in serum creatinine levels associated with increased hypertension. Angiography shows partial thrombosis and loss of perfusion of a wedge-shaped section of renal parenchyma. The risk of this situation, in addition to potential long-term hypertension, is caliceal infarction and urine leak in the early postoperative period. Such kidneys, with partial infarction, generally can be salvaged. Urine leaks occurring through the outer cortex of the kidney after partial infarction may be managed by nephrostomy tube placement for urinary drainage and placement of another drain adjacent to the kidney to prevent urinoma. When the transplant ureter necroses as a result of



A B

Figure 14–3 This patient presented with fluid retention, hypertension, and an elevated creatinine level. **A**, An arteriogram showed that the artery to the lower pole arising from a common aortic patch was stenotic proximally. **B**, This stenosis was successfully treated with balloon angioplasty with resolution of the patient's symptoms.

arterial ischemia, alternative urinary drainage needs to be provided surgically; this would be managed most often by ureteropyelostomy using the ipsilateral native ureter.

Renal Vein Thrombosis

Renal vein thrombosis may occur when the donor renal vein was narrowed by repair of an injury or when the vein was twisted or compressed externally, but it may occur in the absence of a technical complication. The diagnosis is indicated by sudden onset of gross hematuria and decrease in urine output, associated with pain and swelling over the graft. Ultrasound shows absence of flow in the renal vein, diastolic reversal of flow in the renal artery (Fig. 14-4), and an enlarged kidney often with surrounding blood. Ultrasound can point to this diagnosis definitively. Only if it is immediately recognized and repaired can this problem be reversed. Immediate surgical repair of the vein and control of bleeding are required, and it is generally necessary to remove the kidney and revise the venous anastomosis. Bleeding from the swollen and cracked kidney surface usually can be controlled with hemostatic agents.

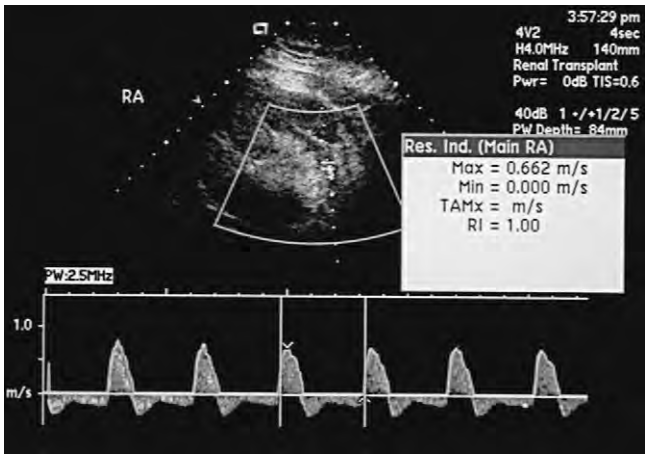


Figure 14–4 Ultrasound shows absence of flow in the renal vein and reversal of diastolic flow in the renal artery. This kidney was enlarged to 14 cm in length with a surrounding fluid collection that represented blood. These ultrasound findings were pathognomonic of transplant renal vein thrombosis. The condition was treated surgically with excision of the kidney, placement of a venous extension graft using donor iliac vein obtained from a third-party donor, and reimplantation of the kidney. Three weeks later, the patient had a normally functioning kidney transplant.

Postoperative Bleeding

As with all surgery, postoperative bleeding may complicate renal transplant outcomes. Bleeding generally occurs during the first 24 to 48 hours after transplantation and is diagnosed by a decreasing hematocrit, swelling over the graft with a bulging incision, or significant blood seepage from the incision. Most often, bleeding occurs in patients taking anticoagulation agents for other medical problems. Patients treated with clopidogrel for underlying cardiac disease are at significant risk for postoperative bleeding; this class of medications should be avoided or discontinued 1 week before renal transplantation if acceptable from a cardiac perspective.[19] If the hematoma is not clinically obvious, an ultrasound or computed tomographic scan can define its size and help determine whether or not surgical evacuation is appropriate. Treatment includes immediate surgery and blood transfusions as necessary.

REJECTION DURING THE EARLY POSTOPERATIVE PERIOD

Hyperacute Rejection

If a renal transplant is performed in the setting of ABO mismatch or a positive lymphocytotoxic crossmatch, the risk of hyperacute rejection is 85% (see Chapter 22). The incidence is not 100%, presumably because some antibodies have lower affinity or do not bind complement. There is no effective treatment for hyperacute rejection. It may be possible to prevent it by plasmapheresis to remove preformed antibodies, but variable results have been reported. Cases of blood type A_2 donors being transplanted to type O recipients have

been reported because type A_2 expresses less of the putative antigen, but this strategy also has increased risk of graft loss.[25] In almost all transplant centers, a crossmatch-negative, ABO-compatible recipient can be identified, or the kidney can be shipped to a center that has such a patient awaiting a kidney. A hyperacutely rejected kidney has no perfusion on renal scan (because of microvascular thrombosis) and needs to be removed.

Accelerated Vascular Rejection

Despite a negative T cell crossmatch test preoperatively, some patients may develop an early aggressive form of rejection, termed accelerated vascular rejection. This rejection is seen most often in sensitized patients with a high level of a panel-reactive antibody and in patients with a previous transplant. The time course of this type of rejection is typically within 2 to 5 days of the transplant procedure, and it tends to be poorly responsive to steroids and occasionally resistant to all forms of antirejection therapy. Histologically, such patients have fibrin deposition evident in the renal transplant biopsy specimen and endothelitis. Although successful prophylaxis of rejection has been described using intravenous immunoglobulin, rituximab, plasmapheresis, or thymoglobulin in highly sensitized patients,[26] when this form of rejection has started there is no standard treatment. We use plasmapheresis in this setting because of the likely contribution of the humoral immune response.

Acute Rejection

The most common form of immunological rejection in the early post-transplant period is acute cellular rejection, mediated predominantly by host lymphocytes responding to the allogeneic donor kidney. Acute rejection typically occurs 5 to 7 days after transplantation, but it can occur at virtually any time after this. The highest incidence of acute rejection is within the first 3 months, and overall rates of rejection vary from 5% to 50% within the first 6 months, depending on HLA matching and the immunosuppressive protocol. The clinical harbingers of acute rejection include an increasing creatinine level, weight gain, fever, and graft tenderness. Since the introduction of cyclosporine and tacrolimus, fever and graft tenderness are seldom present. The diagnostic "gold standard" is kidney biopsy, which can be performed safely under local anesthesia with light sedation. An 18-gauge biopsy needle is introduced under ultrasound guidance and removes a core of tissue that can be evaluated immediately for histological criteria of rejection (see Chapter 24). These criteria include tubulitis (invasion of tubules by lymphocytes) and arteritis.[48]

First-line treatment of acute cellular rejection is bolus steroid therapy with methylprednisolone sodium succinate (Solu-Medrol). Many regimens are used successfully, but a typical dose and duration are 500 mg intravenously, followed by 250 mg the following day, then a daily taper by 30-mg increments. Another commonly used regimen is three intravenous boluses of 0.5 g or 1 g of methylprednisolone 24 hours apart. About 85% to 90% of acute cellular rejection episodes are steroid responsive. If the patient's serum creatinine level has not begun to decrease by day 4 of therapy, alternative treatment must be considered, such as antilymphocytic globulin, alemtuzumab (Campath), or rituximab (anti-CD20) as lymphocytotoxic therapy. Antibody-depleting therapies may be associated, however, with an increase in infectious complications when used to treat rejection compared with when used for induction.[34] Rejection that does not respond to treatment with steroids or antibody therapy occurs in less than 5% of patients, although more frequently in sensitized patients or repeat transplants.

Patients who experience acute cellular rejection while taking cyclosporine or tacrolimus should have their calcineurin phosphatase inhibitor withheld during treatment of rejection because the increase in creatinine level makes them more susceptible to nephrotoxicity from these drugs, and there is generally no need for them to be taking cyclosporine while they are taking high-dose steroids or antilymphocyte therapy. This measure eliminates the possibility that a further increase of creatinine is due to cyclosporine or tacrolimus nephrotoxicity.

The impact of acute cellular rejection on graft survival depends on the response to treatment. Whether or not an early rejection episode predisposes the kidney to chronic rejection is controversial.

Graft Loss

During the early post-transplant period, if a renal transplant loses perfusion because of thrombosis or because of hyperacute, acute, or accelerated vascular rejection, it must be removed. Otherwise, the systemic toxicity of a necrotic kidney may cause fever, graft swelling or tenderness, and generalized malaise. Loss of perfusion can be assessed by nuclear scan or Doppler ultrasound. The technically easiest way to perform a transplant nephrectomy depends on how long the kidney has been in place. If nephrectomy is performed within 4 weeks, there are minimal adhesions, and the vessels are exposed easily for ligation and transplant nephrectomy. At later times, it is usually easiest to reopen the transplant incision and enter the subcapsular plane around the kidney. The kidney is dissected free in the subcapsular space, and a large vascular clamp is placed across the hilum. The kidney is amputated above the clamp, and 3-0 polypropylene (Prolene) is used to oversew the hilar vessels. The ureter also is oversewn (see Chapter 11).

MEDICAL COMPLICATIONS

Delayed Graft Function

DGF is the earliest and most frequent post-transplant complication. DGF is an important post-transplant complication because its occurrence has early and long-term consequences for allograft survival. The mechanism and cellular events that may cause DGF include donor factors, such as age, cause of death of the donor, and postischemic reperfusion injury with subsequent injury and activation of the immune system leading to an increased incidence of acute rejection.[31]

DGF is one of the main predictors of poor graft survival in cadaver donor renal transplantation. DGF typically is defined as the need for dialysis during the first week after transplantation. The incidence of DGF is significantly higher in cadaver versus living donor transplants and is less common in patients receiving first cadaver donor grafts than in patients undergoing repeat transplantation. An analysis of 107,787 cadaver donor kidney transplants reported to the

United Network for Organ Sharing Scientific Renal Transplant Registry between October 1987 and 2001 showed an incidence of approximately 23% for standard criteria donors versus 34% for expanded criteria donors.[9] An increase in DGF has been noted with advancing donor age. Young donors have a lower incidence of DGF (approximately 20%) compared with donors older than age 55 years (38%).[52] Prolonged cold ischemia time, at least 30 hours, does not seem to have a significant impact on the incidence of DGF, unless there is an episode of rejection. Although overall rejection rates have declined, recipients of expanded criteria donor kidneys are more likely to receive treatment for rejection, which may be a consequence of an increased incidence of DGF.[10]

The diagnosis of DGF is apparent during the first 24 hours after transplantation. Although some kidneys may make urine initially, a decline in urine output unresponsive to fluid challenge is the most common clinical scenario indicating DGF. The major differential diagnostic consideration in a patient with decreasing or absent urine output is an acute vascular or urological complication. Other conditions that can mimic DGF are antibody-mediated rejection[47] and recurrent focal glomerulosclerosis. This differential diagnosis can be determined easily with urgent ultrasound or radionuclide renal scanning. Typically, a transplant with DGF shows good renal perfusion and good parenchymal uptake of orthoiodohippurate (^{123}I OIH) or mercaptoacetyltriglycine (^{99m}Tc MAG 3) with poor or no renal excretion. Kidney transplant biopsy is the gold standard for diagnosis. When the diagnosis of DGF is established, careful attention to fluid status is paramount to decrease the frequency and necessity for dialysis. The usual time course of DGF is 10 to 14 days, and patients may require supportive dialysis therapy for management of fluid and electrolyte disturbances.

The major concern for transplant recipients with DGF is the potential for early acute rejection. Data are accumulating that the development of DGF may lead to activation of the immune system with release of cytokine and adhesion molecules (see Chapter 24).[23,31] This situation may lead to an anti–major histocompatibility complex (MHC)–directed alloimmune response, leading to an increased frequency of acute rejection. The diagnosis of rejection in patients with DGF may be hindered because the primary clinical monitoring tool is a decrease in serum creatinine levels. For this reason, some centers use antilymphocyte therapy, such as thymoglobulin or Atgam, to prevent early acute rejection in patients with DGF. Alternatively, frequent biopsies in patients with DGF have been proposed as a way to detect early acute rejection episodes. Graft half-lives in patients with DGF are shortened with or without acute rejection. Graft half-lives in standard criteria donor recipients with DGF average 8.8 years compared with 13 years for patients without DGF or rejection. Graft half-lives in expanded criteria donor kidneys are 7.7 years without DGF and 6 years with DGF.[9] Prevention of DGF and early recognition of rejection are important goals to help improve early and long-term graft survival.

Nephrotoxicity from Calcineurin Inhibitors

Early institution of calcineurin inhibitors (cyclosporine and tacrolimus) after transplantation is important to prevent acute rejection episodes. Because of the potential for additive nephrotoxicity, however, some centers avoid instituting calcineurin inhibitors until there is adequate function of the transplanted kidney. Most centers that delay the onset of calcineurin inhibitors use some form of sequential antibody induction therapy with humanized or chimeric interleukin-2 receptor inhibitors such as daclizumab or basiliximab, polyclonal antibodies such as thymoglobulin or Atgam, or a monoclonal antibody such as OKT3. Other centers begin administering calcineurin inhibitors early in the post-transplant course whether or not the allograft is functioning well or in DGF. Both of the calcineurin inhibitors, cyclosporine and tacrolimus, are effective in preventing acute rejection episodes, but they can lead to nephrotoxicity primarily by decreasing renal blood flow in the afferent arteriole, leading to tubular injury.[32,44] Because of variability of intestinal absorption in the early transplant period, underdosing and overdosing of these agents is common, which can lead to rejection episodes or cyclosporine nephrotoxicity, or both occurring in the same patient. Although there are many clinical parameters that have been advocated to differentiate calcineurin inhibitor nephrotoxicity from rejection, most clinical parameters are of insufficient sensitivity to predict confidently the cause of the transplant dysfunction. In patients with DGF, it may be more difficult to diagnose acute rejection or calcineurin nephrotoxicity reliably. Monitoring cyclosporine and tacrolimus levels is valuable in preventing significant increases in blood levels, which may lead to nephrotoxicity. Some centers routinely use a high-dose calcineurin inhibitor protocol to prevent rejection and accept a certain level of nephrotoxicity as a consequence.

The most reliable way of differentiating calcineurin nephrotoxicity from rejection is percutaneous renal allograft biopsy. Generally, biopsies can be performed 3 to 5 days after transplantation using real-time ultrasound imaging and automated biopsy needle devices. The histological hallmarks of calcineurin nephrotoxicity vary. Early functional nephrotoxicity is manifested most often by evidence of tubular injury. In patients with established calcineurin nephrotoxicity, reducing the dose or temporary discontinuation of cyclosporine or tacrolimus can lead to reversal of the renal injury.

The avoidance of subclinical or clinical episodes of nephrotoxicity may be important in terms of long-term allograft histology.[54] A study that examined 2-year biopsy specimens of tacrolimus-treated and cyclosporine-treated recipients showed that chronic transplant nephropathy and fibrosis strongly correlate with episodes of early clinical nephrotoxicity from these agents. This study led to a re-examination of calcineurin-sparing protocols, and clinical studies are now in progress.

Prerenal Azotemia and Volume Contraction

Prerenal azotemia or volume contraction often may lead to allograft deterioration during the immediate postoperative period. Excessive use of diuretics and uncontrolled blood glucose are two of the most common causes for the development of prerenal azotemia from volume contraction. Because most of these patients already are receiving calcineurin inhibitors, which decrease renal blood flow, the concomitant insult of volume contraction may lead to elevated blood urea nitrogen and serum creatinine levels, which may be difficult to distinguish from an episode of acute rejection. Careful attention to daily weights and intake

and output and assessment of orthostatic blood pressure changes can diagnose volume contraction as a contributing factor for renal allograft dysfunction. Volume repletion with intravenous or oral fluids is indicated.

Other Drug Toxicity

Transplant patients often have complex pharmacological regimens at the time of transplantation, which may include nephrotoxic medications or medications that may cause concomitant nephrotoxicity with calcineurin inhibitors.[30,56] Examples of the former include nonsteroidal anti-inflammatory drugs and nephrotoxic antibiotics such as amphotericin and aminoglycosides. Drugs that may interact with the metabolism of calcineurin inhibitors include calcium channel blockers such as diltiazem and verapamil, ketoconazole, erythromycin, and fluconazole. Tacrolimus and cyclosporine are metabolized in the cytochrome P-450-3A4 system, and all of these agents may increase the blood levels of tacrolimus or cyclosporine. Grapefruit juice also has been shown to increase the gastrointestinal absorption of cyclosporine (see Chapters 16 and 17).

Routine drug level monitoring is paramount when drugs that are metabolized in the cytochrome P-450-3A4 system are used. Adjustment in the daily dose of cyclosporine and tacrolimus to attain therapeutic blood levels may help prevent episodes of nephrotoxicity from the concomitant use of these agents. Avoidance of concomitant medications that interfere with drug metabolism is desirable. Selective serotonin reuptake inhibitor antidepressants are another class of pharmacological agents that need to be used with care. In particular, nefazodone and fluvoxamine are metabolized in the cytochrome P-450-3A4 system and may increase calcineurin blood levels.

Recurrent Disease

Most causes of renal failure do not recur in the transplanted kidney; when they do, it is usually later in the post-transplant course. (See also Chapters 4 and 24 for further discussion of recurrent disease.) Two diseases may occur in the immediate post-transplant period and lead to significant graft dysfunction or graft loss if not treated aggressively. Focal glomerulosclerosis is the most common glomerulonephritis that can recur in the immediate postoperative period.[2,3] Presumably, a serum factor is present that causes glomerular injury and massive early proteinuria.[50] It is uncommon but may occur immediately after transplantation. The diagnosis is established by the development of a nephrotic range of proteinuria in a patient with a pretransplant diagnosis of focal segmental glomerulosclerosis and is confirmed on biopsy. Electron microscopy shows diffuse foot process effacement, which is diagnostic in this setting. Various strategies have been used to treat recurrent focal segmental glomerulosclerosis, including high-dose calcineurin inhibitors, prednisone, and plasmapheresis. Currently, plasmapheresis seems to be most effective in the treatment of recurrent focal segmental glomerulosclerosis; however, some patients may have only a partial remission or may not respond to this modality.[3] The usual course of therapy is 9 to 10 plasmapheresis treatments over several weeks. In some cases, plasma exchange may need to be repeated if there is an initial response and subsequent relapse. If patients do not have any response, it is unlikely that additional plasmapheresis therapy will be effective.

The other recurrent disease of concern in the immediate postoperative period is thrombotic microangiopathy, which can result from recurrent disease, endothelial injury from calcineurin inhibitors, hypercoagulable disorders, or antibody-mediated rejection.[11] Thrombotic microangiopathy is multifactorial in origin. It is characterized clinically by a decrease in hematocrit or platelet count, or both, with evidence of a microangiopathic process on peripheral blood smear, increased lactate dehydrogenase levels, and transplant allograft dysfunction. Kidney biopsy specimens show fibrin clot in the small arterioles of the kidney. Thrombotic microangiopathy has been noted to be induced by tacrolimus or cyclosporine. Discontinuation of the calcineurin inhibitor and plasmapheresis[27] have been beneficial in some series. The use of anticoagulants and aspirin is of uncertain benefit.

Infection

In the immediate postoperative period, most infections are related to the surgical procedure and usually involve wound infection, bacteremia from a central line, urinary tract infection, or pneumonia.[49] (See Chapter 29 for a complete discussion of infection.) Prevention of these infections involves meticulous surgical technique, careful line care and use, removal of the Foley catheter as soon as possible, and early mobilization of the patient to prevent atelectasis or pneumonia. Most opportunistic infections do not occur until after the first 30 days. Of the opportunistic infections, cytomegalovirus is still common after transplantation, particularly in recipients who are seronegative for cytomegalovirus and who receive seropositive organs. Epstein-Barr virus infection may occur early after transplantation and usually is related to heightened immunosuppression in a previously seronegative patient. In the past, *Pneumocystis carinii* pneumonia was a frequent complication of transplantation; however, most centers now use routine prophylaxis with trimethoprim/sulfamethoxazole, which has nearly eliminated the occurrence of this infection in transplant patients. Other prophylactic strategies that have been used include intravenous ganciclovir in the immediate postoperative period followed by high-dose oral acyclovir or oral valganciclovir for at least 3 months.[41] The antiviral agents are effective at reducing the incidence and severity of cytomegalovirus infection (particularly oral ganciclovir); however, after stopping ganciclovir, cytomegalovirus may still occur. Other prophylactic agents include antifungal agents, such as fluconazole or clotrimazole troches, which can reduce the risk of mucosal *Candida* superinfection.

Highly resistant organisms have been detected with increasing frequency in transplant patients. Vancomycin-resistant *Enterococcus*[37,38,40] and *Candida*[35,42,46] infections are becoming significant causes of morbidity in hospitalized transplant patients. Risk factors for vancomycin-resistant *Enterococcus* include prolonged hospitalization in the intensive care unit, extensive surgical procedures, and intra-abdominal infection. Treatment options for this infection are limited. Quinupristin/dalfopristin (Synercid), linezolid (Zyvox), and daptomycin (Cubicin) may be useful for control of serious vancomycin-resistant *Enterococcus* infections. The increase in *Candida* infection seems to be due to the routine use of clotrimazole or fluconazole to prevent *Candida* infection. Intravenous antibiotic use predisposes patients to fungal infection after transplantation.

Table 14–2 **Advantages and Potential Side Effects of Antihypertensive Agents in Transplant Recipients**

Class	Advantages/Indications	Side Effects
Diuretics	Salt-sensitive hypertension	Hyperuricemia Volume depletion
β-Blockers	Large selection Selective agents preferred	Adverse effect on lipids Relative contraindication with asthma, CHF, diabetes, or peripheral vascular disease
α-Blockers	Useful with prostatic hypertrophy	Postural hypotension (first dose)
Central α-agonists	Clonidine useful in diabetic patients Clonidine available as transdermal patch	Dry mouth Rebound hypertension Fatigue
Calcium channel blockers	Improve renal blood flow May ameliorate cyclosporine nephrotoxicity	Drug interaction with cyclosporine (verapamil and diltiazem)
ACE inhibitors	Native kidney hypertension	May cause renal insufficiency Hyperkalemia
Angiotensin II receptor antagonists	Proteinuria	Anemia

ACE, angiotensin-converting enzyme; CHF, congestive heart failure.

When an infection has occurred, aggressive management is indicated. This management may include removal of central venous catheters or Foley catheters. Any intra-abdominal fluid collections should be aspirated and drained if found to be infected. Urinary tract infections should be treated promptly, preferably after the Foley catheter and ureteral stent have been removed.

Hypertension

Hypertension develops in nearly 80% of renal transplant patients after transplantation.[13,14,22,45,59] (See also Chapter 28.) In kidney transplant recipients, hypertension may be due to intrinsic problems with the allograft (DGF, rejection, cyclosporine nephrotoxicity, or donor allograft nephropathy) or due to extrinsic causes (hypertension from the native kidneys or familial hypertension). Because multiple causes may be present in the same patient, it often is difficult to ascertain the specific cause of hypertension after transplantation.

For some patients, hypertension is associated with immunosuppression. Cyclosporine, tacrolimus, and corticosteroids all may contribute to the development of hypertension. Cyclosporine and tacrolimus cause afferent arteriole vasoconstriction, which may stimulate the release of endothelin. Hypertension may ensue as a result of the activation of the renin-angiotensin system. Patients with significant hypertension should be treated aggressively. Most centers prefer the use of calcium channel blockers and β-blockers as first-line agents, although angiotensin-converting enzyme inhibitors or angiotensin II receptor antagonists are being used more frequently. The major issue with the use of angiotensin-converting enzyme inhibitors or angiotensin II receptor inhibitors is anemia, which can be a problem in patients treated with calcineurin inhibitors. Patients who do not respond readily to antihypertensive therapy or have new-onset hypertension need to be evaluated. Hypertension may be the result of renal artery or iliac artery stenosis, which may be compromising renal blood flow to the kidney and causing hypertension.[6,51] A patient with a bruit over the transplant with poorly controlled hypertension and fluid retention needs to be evaluated carefully for renal artery or iliac artery stenosis. Table 14-2 presents the advantages and potential side effects of antihypertensive agents in transplant recipients.

Management of Graft Dysfunction

The diagnosis and treatment of graft dysfunction are integral components of successful long-term management of the renal transplant recipient. Early diagnosis and directed therapy are crucial in the early post-transplant period to initiate appropriate therapy and avoid potential overimmunosuppression. Evaluation of graft dysfunction should start with a careful history to see if there is a potential for nephrotoxicity from drugs or if there is any likelihood of volume contraction contributing to the elevation of serum creatinine levels. A vigorous search for potential infection should follow, and if there is no obvious cause for deterioration in graft function, an ultrasound followed by a renal biopsy should be performed. If there is any clinical suspicion of renal artery or iliac artery stenosis, a magnetic resonance angiogram or arteriogram should be performed. The differentiation of calcineurin nephrotoxicity or rejection is ascertained most easily with percutaneous renal biopsy. Nephrotic range proteinuria in a patient whose original disease was focal segmental glomerulosclerosis or thrombotic microangiopathy should prompt an immediate biopsy for diagnosis and potential treatment with plasmapheresis.

SUMMARY

Optimization of outcomes after renal transplantation depends on rapid diagnosis and treatment of surgical and medical complications. In view of the invasiveness of the transplant procedure itself, the complexity of medical problems in this patient population, and the side effects of nonspecific immunosuppressive therapy, close attention to the problems outlined in this chapter is crucial to avoid graft loss and patient death. Because the frequency of complications is greatest during the early post-transplant period, this is the time when vigilance should be highest.

Chapter 15
Azathioprine and Steroids

Simon R. Knight • Peter J. Morris

Azathioprine and steroids were the backbone of immunosuppression in renal transplantation for many years and the only form of immunosuppression from the early 1960s to the early 1980s, when cyclosporine first became available. After the introduction of cyclosporine, azathioprine and steroids were used in combination with cyclosporine or often after cessation of cyclosporine in so-called conversion protocols (see Chapter 16). One might wonder whether in the sixth edition of this book there still needs to be a chapter on azathioprine and steroids, bearing in mind the introduction of mycophenolate and sirolimus, both of which are antiproliferative agents, but with different mechanisms of action. Mycophenolate has largely replaced azathioprine in developed countries as a standard therapy with a calcineurin inhibitor and steroids (see Chapters 16, 17, and 18). Azathioprine is an inexpensive agent, however, and it is expected to continue to have a role in transplantation not only in the Western world in combination with cyclosporine but also, in particular, in developing countries where the cost of immunosuppression is a major factor in determining immunosuppressive protocols.

Although steroids are expected to continue to have a place in the prevention and treatment of rejection, the introduction of more powerful immunosuppressive agents is allowing steroid-sparing protocols to be developed. As outlined later in this chapter, the complications of steroids are considerable, and a major aim of current immunosuppressive protocols and trials is to diminish the use of steroids or to avoid their use altogether.

Mercaptopurine was developed by Elion and Hitchings at Burroughs Wellcome as an anticancer agent in the 1950s.[30,31] Subsequently, mercaptopurine was shown to be an immunosuppressive agent by Schwartz and Dameshek[127,128]; it suppressed the humoral response to a foreign protein and prolonged the survival of skin allografts in rabbits. The key publication by Schwartz and Dameshek on drug-induced immunological tolerance was noted by Calne in the United Kingdom and Hume in the United States, and these investigators independently showed that mercaptopurine could delay or prevent rejection of renal allografts in dogs. In the original paper of Calne,[14] only two dogs survived the renal transplant operation for a short time, but when the dogs died from pneumonia at a little more than 1 month after transplantation, there was no histological evidence of rejection whatsoever, which was a unique finding at that time. Similar results in a much larger series of dog renal transplants in Hume's unit in Richmond, Virginia, were published at the same time.[153] Soon after that, Elion and colleagues[32,33] produced azathioprine, an imidazolyl derivative of mercaptopurine, and this drug seemed to be less toxic than mercaptopurine.[15] Azathioprine was first used in the clinic at the Peter Bent Brigham Hospital, Boston in 1961.[99,100] Soon thereafter, azathioprine was introduced into renal transplantation in a rapidly increasing number of renal transplant units throughout the world.

Steroids first were used to treat rejection in patients on azathioprine,[41] but then were added to azathioprine by Starzl and coworkers[137] to prevent rejection from the time of transplantation because rejection seemed inevitable. From the beginning of this so-called azathioprine era, arbitrarily large doses of steroids were given from the time of transplantation with a gradual reduction over 6 to 12 months to maintenance levels. The high doses of steroids used with azathioprine were responsible for most of the morbidity of transplantation (discussed later). It was not until the 1970s that a series of randomized trials and observational studies led slowly to the realization that low-dose steroids were as effective as high-dose steroids in preventing rejection and that there was a major reduction in steroid complications of transplantation with low-dose regimens. By the late 1970s, azathioprine and low-dose steroids, sometimes used together with an antilymphocyte serum or globulin for induction (particularly in North America), were the standard immunosuppressive therapy until the introduction of cyclosporine in the early 1980s.

AZATHIOPRINE

Mechanism of Action

Azathioprine and mercaptopurine are thiopurines, and azathioprine is an imidazolyl derivative of mercaptopurine.

Azathioprine is metabolized in the liver before becoming active. One metabolic pathway is through its conversion to mercaptopurine, the active metabolite of mercaptopurine being 6-thioinosinic acid. Azathioprine also is metabolized by other pathways independent of mercaptopurine. Azathioprine inhibits DNA and RNA synthesis by preventing interconversion among the precursors of purine synthesis and suppressing de novo purine synthesis. Azathioprine and mercaptopurine block lymphocyte proliferation in vitro and the production of interleukin-2, which is probably an important aspect of its antiproliferative activity.[5] Xanthine oxidase has an important role in the catabolism of mercaptopurine, and if allopurinol is used with azathioprine, it is mandatory to reduce the dosage of azathioprine significantly because the allopurinol inhibits the xanthine oxidase pathway.[33] This inhibition increases not only the immunosuppressive potency but also the major side effect of azathioprine—bone marrow depression. Although the metabolites are excreted in the urine, they are inactive, and no reduction in dosage is required in the presence of a nonfunctioning kidney.[4] Polymorphisms in the thiopurine S-methyltransferase enzyme, which catalyzes the S-methylation of mercaptopurine and azathioprine, may be associated with an increased likelihood of myelotoxicity and leukopenia.[34,81]

Dosage

Azathioprine is given as a single daily dose; if used with steroids alone, a suitable dose is 2.5 mg/kg/day. Careful monitoring of the leukocyte count is required, particularly in the early weeks after transplantation, when the dosage is reduced only in the presence of leukopenia. Although the dose of azathioprine may be reduced with time, a maintenance dose, particularly in the presence of low-dose steroids, should not be less than 2 mg/kg/day. An important multicenter randomized trial was done in Australia to test low-dose versus high-dose steroids used with azathioprine after transplantation. The trial failed to show that low-dose steroids were as effective as high-dose steroids (in contrast to earlier but smaller trials), until it was realized that the poorer outcome with low-dose steroids was confined to units using low-dose azathioprine (i.e., <2 mg/kg/day).[22] A more recent analysis of data from the Collaborative Transplant Study also suggested that long-term graft survival was related to the dose of azathioprine that patients were receiving for maintenance. Patients receiving azathioprine and steroids only, who were receiving greater than 1.5 mg/kg, had better graft survival than patients receiving a lower maintenance dose of azathioprine.[105]

When azathioprine is used with cyclosporine and steroids (triple therapy), lower doses are given. A fairly standard dose of azathioprine in a triple-therapy protocol is 1.5 mg/kg, or 100 mg/day (see Chapter 16). At this level, hematological toxicity is uncommon except in the presence of cytomegalovirus infection. There is some evidence in experimental models that azathioprine and cyclosporine are synergistic in terms of immunosuppression,[135] but there is no evidence of this in clinical studies.

In a randomized trial, low-risk patients received azathioprine and steroids or cyclosporine, azathioprine, and steroids. All patients received antilymphocytic globulin induction. Patient and graft survival were the same at 12-year follow-up, as was the incidence of rejection, but renal function was better in the patients not given cyclosporine.[46]

Side Effects

The major complication of azathioprine therapy is bone marrow aplasia most commonly evident as leukopenia, although in cases of more severe marrow depression, anemia and thrombocytopenia may be present. Regular monitoring of the leukocyte count is an important aspect of azathioprine therapy, and if the leukocyte count decreases to less than 3×10^9/L, the azathioprine dose should be reduced. Megaloblastic anemia has been described in association with the use of azathioprine. As already mentioned, if allopurinol is required for the prevention of gout, the azathioprine dose should be reduced to 25% of the previous dose.

Hepatotoxicity has been attributed to azathioprine for many years, and although undoubtedly azathioprine is associated with hepatic dysfunction, this is probably rare (see Chapter 30). Other causes of hepatic dysfunction in the presence of azathioprine need to be sought energetically before attributing it to azathioprine. Hair loss is a common side effect of azathioprine when used in therapeutic doses. Early observations attributed an increased incidence of squamous cell cancer in transplant patients to azathioprine. There does not seem to be any evidence, however, that squamous cell cancers have a greater incidence in patients treated with azathioprine and steroids compared with patients treated with other immunosuppressive protocols, such as cyclosporine and steroids. The major factor in the increased incidence of squamous cell cancer in immunosuppressed patients is the overall immunosuppressive load, rather than any specific drug activity (see Chapters 32 and 33).

Monitoring of Azathioprine Therapy

Blood levels of azathioprine or its metabolites are not routinely monitored in clinical practice. As already suggested, the leukocyte count is monitored, and the dose is adjusted if leukopenia arises. It has been noted, however, that leukopenia also can result from viral infection, leading to the suggestion that erythrocyte 6-thioguanine nucleotide levels may be a better indicator of azathioprine activity in transplant patients.[126]

Numerous genetic variations in the thiopurine methyltransferase gene have been identified, which have been related to azathioprine-induced myelotoxicity.[34,81] Genotyping for this polymorphism before starting azathioprine might allow the appropriate azathioprine dosage to be determined for an individual patient.[122]

Azathioprine and Mycophenolate Mofetil

Three classic randomized controlled trials comparing azathioprine or placebo with two doses of mycophenolate mofetil (MMF) in a triple-therapy protocol with cyclosporine (Sandimmune) and steroids were done in the early 1990s (see Chapter 18). These three trials showed a significant reduction in the incidence of acute rejection, although patient survival and graft survival were not different at 1 year. Gradually, azathioprine was replaced with MMF in most modern immunosuppressive protocols. In recent years, there has been some doubt cast on the superior efficacy of MMF over azathioprine, however, especially in the era of microemulsion formulations of cyclosporine. Remuzzi and colleagues[118] conducted a trial comparing azathioprine with

MMF, in which Neoral was used instead of Sandimmune, together with steroids. They found no difference in rejection rates or in graft survival. This result was attributed to the superior absorption of the Neoral formulation compared with Sandimmune. Remuzzi and colleagues[118] also pointed out that the cost of MMF was some 15 times more than azathioprine. Another cohort study from UK Transplant compared the long-term outcome of cadaver donor kidneys in which one kidney went to a recipient who received azathioprine and the paired kidney went to a patient given MMF.[130] In this paired kidney analysis, there was no difference in patient or graft survival, but increased rejection rates were noted in the MMF group.

Another small trial compared MMF with azathioprine in combination with tacrolimus and steroids and found no difference in outcome.[98] A large randomized trial comparing tacrolimus, MMF, and steroids with tacrolimus, azathioprine, and steroids or cyclosporine (Neoral), MMF, and steroids showed that at 3 years all three regimens were safe and efficacious, but the best overall results were with the tacrolimus, MMF, and steroid combination.[40] Finally, an analysis of 49,666 primary renal allograft recipients reported to the United States Renal Data System suggested that continued therapy with MMF was associated with a protective effect against declining renal function at 1 year compared with azathioprine.[96]

Cyclosporine Conversion to Azathioprine

Conversion of cyclosporine to azathioprine can be successfully achieved at 3 to 12 months after transplantation, with a resulting improvement in renal function, albeit with an increased risk of acute rejection; this is well documented in Chapter 16.

Azathioprine Conversion to Mycophenolate Mofetil

There have been numerous studies in patients with chronic allograft nephropathy receiving a calcineurin inhibitor with azathioprine and steroids in whom azathioprine has been switched to MMF, and the calcineurin inhibitor dosage has been either reduced or eliminated. Generally, most of these studies, but not all, showed either stabilization or an improvement in renal function.[38,86,138]

Tacrolimus and Azathioprine

Several studies of tacrolimus with or without azathioprine suggest that azathioprine does not add anything to the immunosuppressive potency provided by tacrolimus. One large randomized trial in Europe involving nearly 500 patients showed no difference in outcome at 3 years with regard to patient survival, graft survival, and acute or chronic rejection.[110] (See Chapter 17.)

STEROIDS

Mechanism of Action

Steroids are administered as prednisone or prednisolone. These agents are absorbed rapidly from the gut, and peak plasma concentrations occur 1 to 3 hours after administration. The mechanism of action of steroids is extremely complex and is still not understood fully.[21,35,119] Steroids are anti-inflammatory and immunosuppressive. It was first noted by Billingham and colleagues[9] that cortisone would produce a modest prolongation of the life of skin allografts in the rabbit. In the treatment of acute rejection, the anti-inflammatory activity probably produces the immediate response, whereas when used prophylactically the immunosuppressive activity is predominant. A small randomized trial comparing prednisolone with a nonsteroidal anti-inflammatory drug (ibuprofen) showed a higher rate of rejection in the patients receiving the nonsteroidal agent, suggesting that the major role of steroids in renal transplantation is not their anti-inflammatory effect.[79]

Steroids are metabolized in the liver, where prednisone is converted to prednisolone. Although it has been estimated that the bioavailability of prednisone is approximately 80% of that achieved by prednisolone, no evidence exists in practice that there is a difference in outcome between prednisone (used most commonly in the United States) or prednisolone (used most commonly in Europe).[13,37] The half-life of steroids is short—about 60 minutes for prednisone and 200 minutes for prednisolone. These half-lives are increased substantially in the presence of hepatic dysfunction and are shorter in the presence of drugs such as phenytoin and rifampicin that induce hepatic enzymes. There is no evidence that these interactions have produced significant problems in clinical practice. It also has been shown that the clearance of prednisolone is slower in patients receiving cyclosporine compared with patients receiving azathioprine.[108] A later study suggested, however, that cyclosporine did not influence the metabolism of methylprednisolone, but the authors noted a considerable variation of the metabolism of methylprednisolone among patients.[144] The time-dependent and dose-dependent induction of uridine diphosphate glucuronosyltransferase activity by steroids may increase the clearance of mycophenolic acid, reducing exposure to mycophenolate. Cattaneo and coworkers have shown that as steroids are tapered over the postoperative period, the mycophenolic acid area under the curve increases.[16] The pharmacokinetics of prednisolone during sirolimus therapy also have been studied, with some evidence for a minor interaction between sirolimus and prednisolone in some patients.[70]

Steroids do have a significant effect in vitro on T cell proliferation, blocking interleukin-2 production.[103] A variety of other actions may augment their immunosuppressive activity (e.g., preventing the induction of interleukin-1 and interleukin-6 genes in macrophages).[77,152] The anti-inflammatory activity perhaps is mediated by the inhibition of migration of monocytes to areas of inflammation,[35] and this same anti-inflammatory activity has a marked deleterious effect on wound healing.

Steroid Resistance

The sensitivity of individuals to steroid therapy varies. A study in healthy volunteers showed a wide interindividual variation in the inhibition of lymphocyte proliferation by steroids.[53] Steroid resistance is seen frequently in patients with inflammatory conditions and has been shown to correlate well with in vitro measurements of lymphocyte steroid sensitivity in patients with rheumatoid arthritis,[76] ulcerative colitis,[52] asthma,[20] and systemic lupus erythmatosus.[129]

In vitro studies of lymphocyte steroid sensitivity have shown a higher incidence of resistance in patients with chronic renal failure than in healthy volunteers (52.9% versus 3.8%).[72] In renal transplant recipients, Langhoff and colleagues[82] showed that pretransplant in vitro measurements of lymphocyte sensitivity are predictive of graft survival at 1 year in patients coadministered azathioprine, but less so in patients receiving cyclosporine. These results have been confirmed in vivo, with significantly higher sensitivity to methylprednisolone seen in patients with graft function at 6 months compared with patients with graft failure.[83] This difference in sensitivity is smaller in cyclosporine-treated patients than in patients receiving azathioprine, suggesting that the effect is partly offset by the use of cyclosporine. A more recent study from Hirano and colleagues[55] has shown an increased risk of acute allograft rejection after renal transplantation in patients with low pretransplant lymphocyte steroid sensitivity cotreated with cyclosporine and prednisolone. The variability in pretransplant lymphocyte response was higher with prednisolone than with methylprednisolone, suggesting a role for methylprednisolone in prednisolone-resistant recipients. Reduced lymphocyte prednisolone sensitivity correlates with impaired sensitivity to cyclosporine and tacrolimus, which may play a role in the high risk of allograft rejection in these patients.[72]

Numerous potential mechanisms for this resistance to steroids have been suggested.[123] Administration of glucocorticoid receptor (GR) agonists is capable of downregulating GR expression in human lymphocytes, although the mechanism for this homologous downregulation is poorly understood.[124] Studies have shown no correlation, however, between GR density or affinity and resistance to steroids, pointing to a postreceptor mechanism.[53,55]

Alternate splicing of human GR pre-mRNA generates two isoforms, hGRα and hGRβ; hGRβ is capable of acting as an inhibitor of hGRα-mediated transcription.[6] It has been suggested that differences in the ratio of the two isoforms may result in relative steroid resistance. Proinflammatory cytokines are capable of inducing hGRβ expression,[85,139] and increases in hGRβ-positive lymphocytes have been identified in many inflammatory conditions, including ulcerative colitis[57] and asthma.[50,85] More hGRβ-positive cells are seen in glucocorticoid-resistant than in glucocorticoid-sensitive individuals in these conditions.

The hGRα isoform is capable of suppressing the activity of the proinflammatory transcription factor nuclear factor κB (NFκB), and this suppression seems to be mutual.[95] NFκB activity is upregulated by several proinflammatory signals (e.g., tumor necrosis factor-α, lipopolysaccharide), providing a potential mechanism for the decreased steroid sensitivity seen in inflammatory conditions. Expression of the NFκB p65 subunit is increased in ulcerative colitis patients before treatment and is decreased by the administration of steroids in steroid-sensitive patients but not in steroid-resistant patients.[88]

More recent studies have concentrated on the role of interleukin-2 in glucocorticoid resistance. Interleukin-2 and anti-CD28 have been shown to reduce dexamethasone-mediated suppression of CD4 cell proliferation.[146] Interleukin-2 and CD28 signals are transduced via the mitogen-activated protein kinase and extracellular signal-regulated kinase pathway. Blockade of this signal transduction pathway abolishes the costimulation-induced resistance to dexamethasone. Inhibitors of this pathway may have a role to play in the therapy of steroid resistance. Steroid resistance is a complex phenomenon and must be relevant to the occurrence of so-called steroid-resistant rejection (discussed later).

Dosage

Steroids have been used since the introduction of azathioprine to prevent and to treat rejection. When used prophylactically, steroids were used initially in high doses (e.g., 100 mg/day), reducing to a maintenance dose of 20 mg/day over 6 to 9 months. As mentioned earlier, a maintenance dose of steroids in association with azathioprine requires a therapeutic dose of azathioprine in most instances—at least 2 mg/kg/day of azathioprine. McGeown and coworkers[94] consistently reported excellent graft survival from Belfast with a low incidence of steroid-related complications using a dose of prednisolone of 20 mg/day given orally as a single morning dose, with a further reduction occurring at 6 months to a baseline maintenance dose of 10 mg/day. Because most of the Belfast patients had bilateral nephrectomies, and all had more than 100 blood transfusions before transplantation, it was unclear whether the excellent results were related to the low dosage of steroids or to a transfusion effect, which was recognized widely as an important factor in improving graft outcome in the azathioprine era.

Initially, trials of low-dose versus high-dose steroids were performed in Oxford, then in many other centers, all of which showed not only that low-dose steroids were as effective as high-dose steroids in preventing rejection but also that there was a significant reduction in steroid-related complications in patients receiving low-dose steroids.[12,17,18,24,64,66,97,109,136] The results of these trials led quickly to the wide adoption of low-dose steroid regimens with azathioprine. In contrast, a study from Helsinki suggested that an initial high dose of methylprednisolone resulted in significantly better graft survival at 1 year.[51] The results of the large multicenter trial reported by d'Apice and associates,[22] already referred to, showed that low-dose steroids are only equally effective as high-dose steroids in preventing rejection if therapeutic doses of azathioprine are used (i.e., at least 2 mg/kg/day).

With the introduction of cyclosporine, steroids remained in use with or without azathioprine. Generally, low-dose steroid protocols were continued, although there was a tendency, particularly in North America, to go back toward higher steroid dosage regimens in the first few weeks after transplantation. This was a relatively transient practice, and now with modern immunosuppressive protocols, low-dose steroids are the norm, and discontinuation of steroids is becoming increasingly possible, not only after 1 year in the case of triple therapy (see Chapter 16) but also as early as 7 days after transplantation with more potent immunosuppressive protocols (see Chapters 17 and 20).

Whether steroids should be given as a single daily dose in the morning or in divided doses has not been resolved. Because of the short half-life of prednisone and prednisolone, divided doses may be more rational, but it could be argued that a single morning daily dose would be more appropriate taking into account the diurnal rhythm of glucocorticoid metabolism.[42,102] There is no clinical evidence that one or the other protocol is more effective or less likely to produce side effects.

For many years, maintenance dosages of prednisone or prednisolone of 10 mg/day were standard therapy in association with azathioprine. In patients with long-surviving grafts with good function, steroid dosages have been reduced to 5 or 6 mg/day. It is unlikely, however, that many patients who are taking azathioprine and steroids long term would be able to have their steroid dosage reduced to much less than 5 mg/day. Previous attempts to withdraw steroids have often led to the onset of rejection when dosages of less than 5 mg/day are reached; this is important to note because there are many long-surviving patients still taking azathioprine and steroids. When patients have been on steroids for many years, their adrenocortical function may not recover from the long-standing suppression as the steroid dose is reduced, and this may produce clinical features of adrenocortical insufficiency.[101]

Alternate-day steroid therapy for maintenance also has been used widely, especially in children in an attempt to reduce side effects, particularly growth retardation.[11,25,27,84,93,115] In children, alternate-day therapy may be associated with a greater incidence of rejection, but this is probably not the case in adults. A small randomized trial of alternate-day therapy failed to show any benefit over daily steroids, however.[93] Alternate-day therapy may lead to greater problems with respect to compliance, in contrast to a daily regimen of steroids. It has been and still is common practice to administer a bolus of methylprednisolone prophylactically during the transplant operation with the aim of increasing immunosuppression and perhaps preventing delayed graft function, but a randomized prospective trial of bolus methylprednisolone versus placebo at the time of surgery did not show any benefit of the high perioperative intravenous dose of methylprednisolone.[74] Nevertheless, it remains standard practice whatever the immunosuppressive regimen is to be.

Treatment of Acute Rejection

High-dose steroids are the first approach to the treatment of an acute rejection episode. In some units in the early days of azathioprine, especially at the Necker Hospital in Paris, steroids were not administered prophylactically to prevent rejection; they were administered only if rejection occurred. In the case of HLA-identical sibling transplants, many patients never required steroids, but in cadaver transplantation, most patients had rejection and had to be treated with steroids.[78] Using steroids prophylactically with azathioprine from the time of transplantation became the standard practice.

Early approaches to the treatment of an acute rejection episode involved either increasing the oral dosage of steroids to high levels (e.g., 200 mg/day for 3 days), with a rapid reduction over 10 days to the dosage levels of steroids being given before the acute rejection episode, or giving boluses of intravenous methylprednisolone (e.g., 0.5 to 1 g/day for 3 to 5 days). Probably both approaches are equally effective. In an early randomized prospective trial in Oxford, high intravenous doses were as effective as high oral doses in reversing rejection, but there was a definite suggestion that steroid-related complications were reduced in patients who received intravenous therapy.[43] In a randomized study in children, a high intravenous dosage of methylprednisolone (600 mg/m^2 daily for 3 days) was no more effective than low oral doses of prednisolone, reversing rejection in 70% as opposed to 72% of episodes.[107]

The most common form of high-dose intravenous therapy to treat acute rejection has been 1 g of methylprednisolone given intravenously as a single bolus daily for 3 days. The intravenous bolus should be administered slowly over 5 minutes because the sudden injection of the bolus can lead to cardiac arrhythmias.[143] It is probable that 1 g of methylprednisolone is a much greater dose than required; we have used 0.5 g of methylprednisolone daily intravenously for 3 days in Oxford for many years, whereas the Stockholm unit has used 0.25 g daily intravenously for 3 days. The lower intravenous doses do not seem to be associated with any greater incidence of steroid-resistant rejection, as originally suggested by a prospective trial of high-dose versus low-dose intravenous steroids to treat rejection.[75] Similarly, in a small double-blind, randomized trial, Stromstad and associates[140] failed to show any therapeutic benefit of a 30 mg/kg bolus over a 3 mg/kg bolus, and Lui and coworkers[89] failed to show any benefit of a bolus of 15 mg/kg body weight over a bolus of 3 mg/kg.

The concept of steroid-resistant rejection as a surrogate marker of inadequate immunosuppression has become part of the analysis of efficacy of all new immunosuppressive protocols. Treatment generally requires use of a lymphocyte-depleting agent. As discussed earlier, steroid resistance is a complex phenomenon, however, and has been studied extensively in autoimmune disorders. Perhaps not enough attention has been paid to this phenomenon in organ transplantation.

Side Effects

The side effects of continuous steroid therapy are numerous (Table 15-1). High-dose steroids were responsible for most complications of renal transplantation in the azathioprine era, especially as experience with azathioprine led to its use in lower doses. With the widespread use of low-dose steroids, the incidence of serious side effects has been reduced markedly, but side effects still are a problem. Efforts to develop protocols that allow the withdrawal of steroids or, ideally, avoid their use entirely have been carried out or are in progress with a variety of new immunosuppressive protocols. In a study of the cost of steroid side effects over 10 years in a cohort of 50 patients, the additional cost per patient attributable to a steroid complication was assessed at $5300 (U.S. dollars).[149]

Table 15–1 **Side Effects of Steroids after Renal Transplantation**

Cushingoid facies
Poor wound healing
Growth retardation
Diabetes
Hyperlipidemia
Bone disease
Obesity
Hypertension
Psychiatric disturbance
Cataracts
Pancreatitis
Skin changes
Peptic ulceration

Cushingoid Facies

Cushingoid facies used to be the hallmark of a renal transplant patient—a moon face, buffalo hump, acne, obese torso, and thin, easily bruised skin, all representing the cumulative effect of high-dose steroids. With lower dose steroids, cushingoid facies is seen much less often, although most patients show modest changes in their facies in the early months after transplantation, particularly in association with the brutalization of the face that may be associated with cyclosporine therapy. Most patients taking low-dose steroids, which are the normal practice now with cyclosporine, have relatively minimal facial changes related to steroids.

Wound Healing

The anti-inflammatory activity of steroids leads to poor wound healing. In the days of high-dose steroids, poor wound healing was a major problem, affecting the healing not only of the incision but also of the ureterovesical reconstruction. With low-dose steroids, poor wound healing is no longer a major problem, but nevertheless skin sutures are left in situ for at least 14 days.

Growth Retardation

Growth retardation is of particular concern in children after renal transplantation. A major advantage of cyclosporine is that it allows lower doses of steroids to be used in children, and growth retardation is less of a problem.[120] As discussed in Chapter 35, however, growth retardation in children requiring transplants is still a problem because retardation resulting from renal failure already is present, and protocols for immunosuppression that might allow catch-up growth are favored. Such a protocol requires the use of low-dose steroids or alternate-day steroids, or preferably no steroids. The use of growth hormone has had a significant impact on growth rates after transplantation.[36]

Diabetes

Glycosuria and insulin-dependent and non–insulin-dependent diabetes are common after transplantation. The occurrence of diabetes is related partly to steroid use,[67] but it has become more common with the concomitant use of cyclosporine and tacrolimus, both of which can induce diabetes independently of steroids. In the presence of these two agents, the use of steroids augments the potential for diabetes, and often patients who become diabetic on cyclosporine or tacrolimus have a regression of the diabetes when steroid therapy is discontinued.

Hyperlipidemia

Hypercholesterolemia and hypertriglyceridemia are associated with steroid use, as was evident in the azathioprine and steroid era. Hyperlipidemia has become a greater problem in the cyclosporine era because cyclosporine also leads to an increased incidence of hyperlipidemia (see Chapter 28).[26,73,92] Withdrawal of steroids leads to improvements in the lipid profile.[56,106,116]

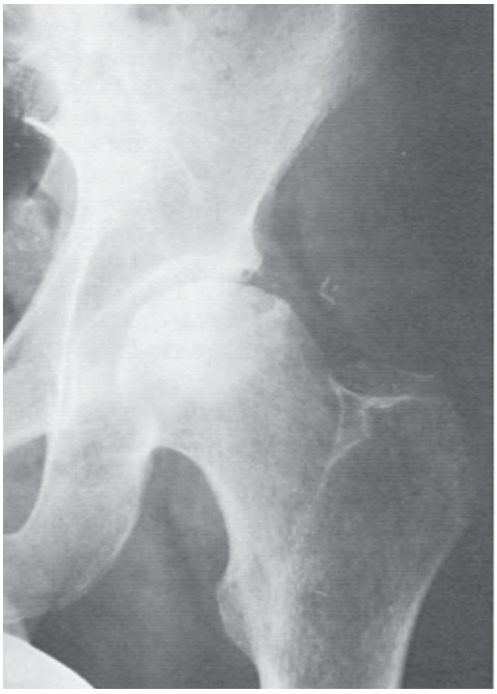
Bone Disease

Bone disease (osteopenia, osteoporosis) is a common and major problem after transplantation, especially in postmenopausal women.[1,47,48,58,69,151] This problem is not entirely due to steroids; more space is devoted to it here, however, because it is not discussed in detail elsewhere in this book. In the days of high-dose steroid therapy after transplantation, avascular necrosis of bones, particularly of the head of the femur, was common, occurring with an incidence of approximately 10% to 15% within 2 years of transplantation (Fig. 15-1). All of the evidence suggests that this incidence was due to a cumulative effect of steroid dosage. As low-dose steroid protocols were introduced, the incidence of avascular necrosis decreased dramatically. The cumulative dose of steroids received by a patient on a high-dose steroid regimen, as opposed to a low-dose regimen, is not that much higher after 6 months, however. Avascular necrosis of the hip should be treated by hip replacement early to enable full rehabilitation to occur. In patients requiring hip replacement, every attempt should be made to withdraw steroids if that seems feasible.

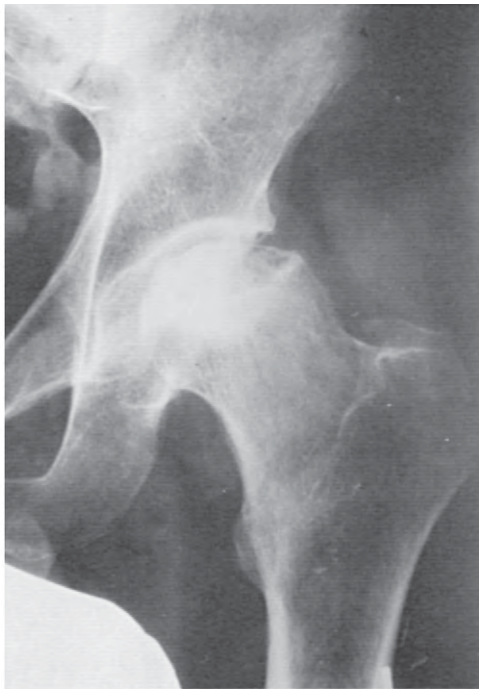
Osteoporosis is associated with steroid therapy. In randomized studies, Hollander and associates[56] and van den Ham and colleagues[147] showed that vertebral bone density was increased significantly in patients discontinuing steroids. Similar evidence was reported by Aroldi and coworkers[3] in a randomized study of three different immunosuppressive protocols and vertebral bone density. These investigators showed that lumbar bone density decreased significantly in patients receiving cyclosporine and steroids, but increased significantly in patients receiving cyclosporine alone without steroids. A more recent randomized controlled trial comparing a steroid-free regimen with a low-dose steroid regimen for 4 months after transplantation showed no important influence on bone density during the first year after renal transplantation.[142] The osteoporosis associated with steroids may be cumulative, as suggested by a study showing that patients on modern low-dose steroid regimens had only minimal loss of bone mineral density at 1 year after transplantation.[150]

Many patients who are to undergo renal transplantation have a degree of secondary hyperparathyroidism, and bone changes related to the hyperparathyroidism are enhanced by steroid therapy. Much more aggressive approaches to parathyroidectomy in patients with renal failure are being taken by most units now before transplantation. In post-transplantation patients with increased parathormone levels, early parathyroidectomy also should be considered.

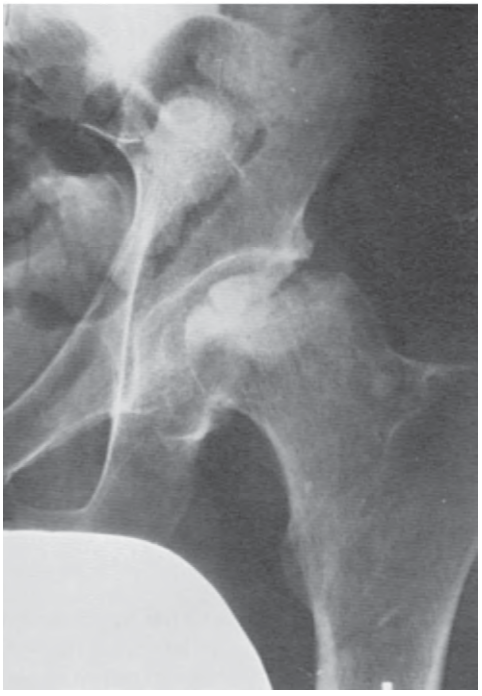
Although there are no firm data in transplant patients, it has been generally thought that women who are postmenopausal should receive hormone replacement therapy in an attempt to diminish the overall likelihood of significant bone disease. The Million Women Study suggests, however, that hormone replacement therapy increases the risk of breast and ovarian cancer, which would seem to contraindicate this approach today.[7,8] The use of protocols that would allow low-dose steroids to be used or steroids to be discontinued is particularly important in these women. Another study has suggested that use of deflazacort instead of prednisone is associated with a decreased loss of total skeleton and lumbar spine density and improving the lipid profile.[87] Data now suggest that vitamin D and calcium supplements or the use of bisphosphonates may prevent the loss of bone density in adult and pediatric kidney transplant recipients.[28,29,49,68,145] A randomized trial in postmenopausal nontransplanted women has shown a significant reduction in the risk of fractures following



A



B



C

Figure 15–1 **A-C**, The progression of avascular necrosis of the head of the femur. **A,** Normal radiograph on first complaint of pain 1 year post-transplantation, 5 months later (**B**), and 20 months later (**C**). At this time, a hip replacement was performed.

a once-yearly infusion of zoledronic acid.[10] A strong case can be made for the administration of bisphosphonates and vitamin D and calcium in renal transplant patients of middle age or older, especially in postmenopausal women. More randomized controlled trials are required in this area.

Obesity

Steroid therapy leads to a marked increase in appetite, and without any dietary restrictions after transplantation, all patients tend to gain weight, which is in addition to a weight increase resulting from salt and water retention. Many patients become obese (body mass index >30), and this adds to the risks of poor survival. Every attempt should be made to advise patients from the time of transplantation to restrict calorie intake carefully because after patients have gained weight in the presence of steroid therapy, it is extremely difficult for them to reduce their weight.

Hypertension

Hypertension after transplantation is common and is related partly to steroids, but in the cyclosporine era hypertension also is due to cyclosporine (see Chapter 28). In steroid withdrawal protocols, hypertension improves after steroids are discontinued.[116]

Psychiatric Disturbance

Psychiatric disturbance is evident in patients on steroids in two ways. In the early days after transplantation, particularly with the need for high-dose steroids to treat rejection, significant psychiatric mood changes may be observed. Later, when steroids are being withdrawn or reduced to low doses, psychiatric mood changes, especially depression, also may occur.

Cataracts

Steroid-related cataracts are common after renal transplantation, occurring in approximately 25% of patients.[132]

Pancreatitis

Acute pancreatitis occurs with a much greater incidence after renal transplantation than would be expected. Azathioprine and steroids have been associated with acute pancreatitis. The pancreatitis is probably related to overall immunosuppression and is often severe.[134] The clinical features of acute pancreatitis can be masked to some extent by steroids.

Skin Changes

Long-term steroids produce typical skin changes in renal transplant patients—the skin being thin, atrophic, easily bruised, and susceptible to knocks (see Chapter 32). A syndrome known as transplant leg is associated with long-term steroid use; this occurs when a patient bumps into a chair or a table (a trivial injury), and a flap of skin is stripped or elevated from the lower leg.

Peptic Ulceration

Although it is debatable whether steroids lead to development of peptic ulceration, most units use prophylactic H_2 antagonists or proton-pump inhibitors in the early months after transplantation, when steroid doses are at their highest. The advent of low-dose steroid therapy has been associated with a dramatic diminution in the incidence of peptic ulceration after transplantation.

Acute Abdomen

In all renal transplant patients who present with an acute abdomen, steroids may mask the symptoms noted by the patient. If this fact is not remembered, diagnosis of diverticulitis or a perforated peptic ulcer may be delayed, with disastrous results.

Steroid Withdrawal

As a result of the numerous complications associated with midterm and long-term steroid therapy in renal transplant patients, many attempts have been made to reduce the cumulative dose of steroids after transplantation and to withdraw steroids altogether. In the azathioprine era, reducing or withdrawing steroids was impossible, but with the advent of cyclosporine there was renewed interest in reducing the dosage of steroids and withdrawing steroids from immunosuppressive protocols. The availability of additional potent immunosuppressive agents, such as sirolimus, tacrolimus, and MMF, together with monoclonal antibodies used for induction, has allowed further steroid-sparing protocols to be developed.

Steroid Withdrawal in the Azathioprine Era

As discussed earlier, the side effects of steroids were improved by the use of alternate-day regimens. Attempts to withdraw steroids, mostly anecdotal, were generally associated with rejection, however. In patients receiving azathioprine and steroids, there seems to be a crucial dosage level, below which there are likely to be problems with rejection.[101] This crucial dosage level is possibly about 5 to 6 mg of prednisolone per day. In one study from Edinburgh, patients with long-term surviving grafts were receiving azathioprine and 10 mg of prednisolone per day, a protocol that allowed for a slow reduction in the prednisolone dosage; many patients developed rejection when the daily steroid dose was reduced to less than 6 mg/day. As a result, the study directed at weaning patients with long-surviving transplants off steroids was abandoned.[2] Today there still are many long-surviving patients on azathioprine and prednisolone. If such patients are stable, no attempt should be made to alter this regimen.

Steroid Withdrawal in the Cyclosporine Era

Controversy still exists as to whether cyclosporine is best used with or without steroids (see Chapter 16). It would seem that if a high dose of cyclosporine is used, monotherapy may be satisfactory in many patients, but with a greater risk of acute rejection often requiring the addition of steroids and perhaps with a greater risk of nephrotoxicity.[23,54,114,125] The use of steroids possibly allows the use of lower doses of cyclosporine, and steroids may decrease the incidence of nephrotoxicity in the early weeks after transplantation, but there is no firm evidence for either of these suggestions.[45]

The timing of steroid withdrawal has been shown to be a risk factor for the failure of withdrawal, with cessation of steroids before 6 months after transplantation increasing the risk of acute rejection.[62] An early meta-analysis from Hricik and colleagues[63] included seven randomized controlled trials of steroid avoidance or withdrawal in patients receiving cyclosporine-based protocols, six of which involved withdrawal in the first 3 months after transplantation. The results of this meta-analysis suggested that avoidance of steroids or early withdrawal increased the risk of acute rejection but did not affect patient or graft survival adversely. Only one of the studies included had a follow-up period of longer than 2 years. This was the Canadian Multicentre Cyclosporine Trial, which showed a superior longer term graft survival in the patients who continued taking steroids compared with patients in whom steroids were withdrawn at 3 months.[133] This finding emphasizes the importance of long-term follow-up in such studies.

Later withdrawal of steroids may improve the outcome from such protocols. In a large retrospective analysis of data from the Collaborative Transplant Study, Opelz[104] found that patients with a functioning graft at 1 year who had steroids withdrawn had better graft and patient survival thereafter than patients remaining on steroids. The initial criticism of this study was that patients still on steroids at 1 year represented those with poorer function as a result of

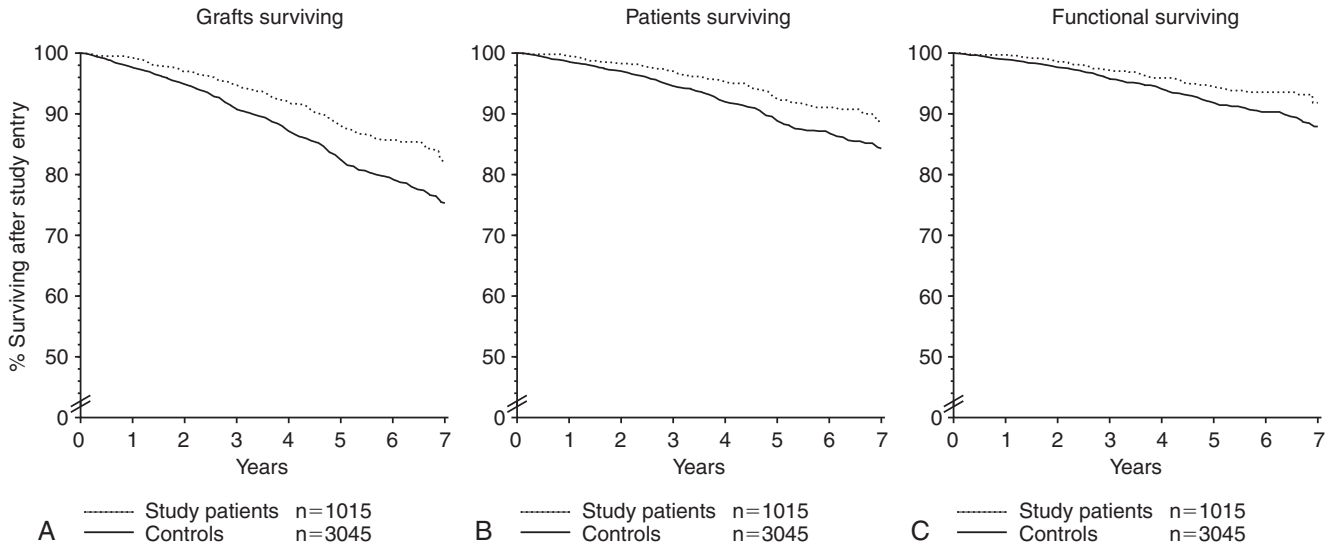


Figure 15–2 **A-C**, Seven-year graft (**A**), patient (**B**), and functional graft (**C**) survival in renal transplant recipients after steroid withdrawal (study patients) or steroid continuation (matched controls). (From Opelz G, Dohler B, Laux G: Long-term prospective study of steroid withdrawal in kidney and heart transplant recipients. Am J Transplant 5[4 Pt 1]:720-728, 2005.)

rejection episodes or delayed graft function, but a subsequent analysis examining outcome only in patients with satisfactory renal function at 1 year found the same results. A more recent prospective study from the same group has confirmed a benefit in graft and patient survival in renal and cardiac transplant patients in whom steroids are withdrawn more than 6 months after transplantation, with no increase in incidence of acute rejection (Fig. 15-2).[106] Benefits also were seen in cardiovascular parameters in the withdrawal group, with significantly fewer patients showing elevated cholesterol levels. Although the number of patients and length of follow-up in this study is impressive (7 years), a criticism is a lack of a randomized design, with the control cohort being retrospectively matched patients from the Collaborative Transplant Study registry.

Further, more recent data from randomized prospective trials support the suggestion that steroids may be withdrawn with a relative degree of safety and a low incidence of rejection in patients with stable graft function at about 1 year after transplantation. In a trial from Oxford, patients receiving triple therapy (cyclosporine, azathioprine, and steroids) with stable function at least 1 year after transplantation were randomly assigned to have steroids withdrawn over several months or continued at a maintenance level of 10 mg/day.[116] Although steroid withdrawal was successful in most patients, there was 10% deterioration in renal function at 1 year, with a further modest deterioration during the second year. Thereafter, renal function seemed to be stable (Fig. 15-3). This decrease in renal function, evidenced in the serum creatinine level and the creatinine clearance, was concerning, but there is no evidence that further deterioration of function was occurring in a longer follow-up of patients in the trial (unpublished observations). As already described in Opelz's observations, benefits were seen in terms of a decline in blood pressure (although not sustained in all patients) and a 1 mmol/L decrease in total cholesterol in the patients in the withdrawal group. The standard triple-therapy protocol (cyclosporine, azathioprine, and steroids) in Oxford thereafter included cessation of steroids at 1 year after transplantation.

Another randomized trial from Holland, with a protocol similar to the Oxford study, enrolled patients with stable renal function at 1 year or longer.[56] Steroids were withdrawn successfully in two thirds of patients, with acute rejection as the major cause of withdrawal failure. No grafts were lost from rejection, however, and significant benefits from withdrawal were seen with respect to hypertension, hypercholesterolemia, hyperglycemia, and appearance. The authors concluded that steroids could be withdrawn safely 1 year after transplantation provided that careful follow-up was maintained.

Favorable changes associated with steroid withdrawal have been documented by other groups, including cholesterol levels, glucose tolerance, and growth in children.[59-61,64,67] The risk of acute rejection and graft loss after steroid withdrawal in children is much greater than in adults, however, and despite the potential growth benefits it has not been recommended.[65,117,121,141]

Steroid Withdrawal with Newer Immunosuppressant Agents

In many transplant centers, azathioprine has now been replaced with MMF for use in conjunction with either cyclosporine or tacrolimus. A considerable amount of data, mostly from observational studies, suggest that tacrolimus is more steroid sparing than cyclosporine. In units using tacrolimus, many patients can have steroids withdrawn during the first year after transplantation. In one report from Pittsburgh, Shapiro and colleagues,[131] who had noted previously that steroids could be discontinued in 70% of renal transplant patients receiving tacrolimus, reported a further longer term follow-up of approximately 289 patients not receiving steroids. The patients in the steroid withdrawal group had impressive 1-year and 3-year graft survivals of 98% and 94% compared with 90 patients in whom steroids had not been withdrawn, who had 1-year and 3-year graft

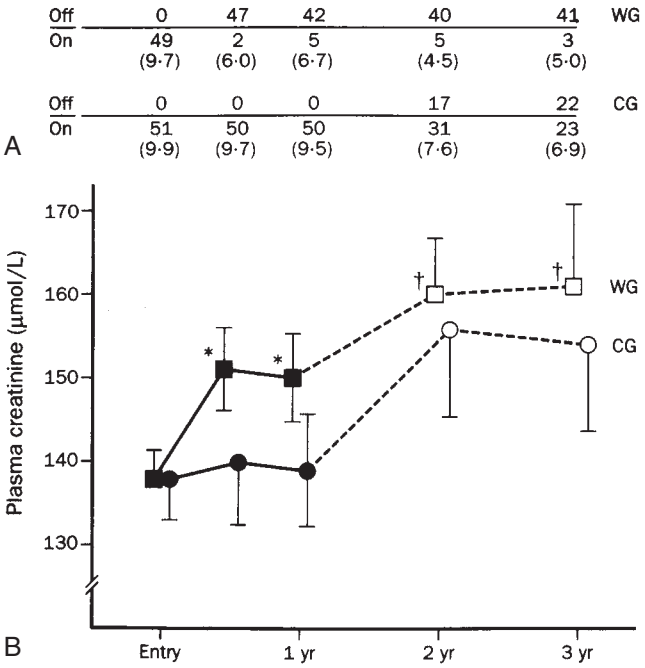

Figure 15–3 Changes in creatinine during the trial period and after 2 years of further follow-up. **A**, Numbers at the top are number of patients in each of the original groups who were not taking (off) or taking (on) prednisolone, together with the mean daily dose of prednisolone in the patients taking steroids. **B**, Mean plasma creatinine in each group at the trial end points (*solid symbols*) and subsequent follow-up (*open symbols*) for each group assigned by intention to treat (*squares*, withdrawal group; *circles*, control group). *Bars* indicate standard errors. Statistical comparison, with entry values by Student two-tailed paired *t*-test. **P* <.001. †*P* <.05. CG, control group; WG, withdrawal group. (From Ratcliffe PJ, Dudley CR, Higgins RM, et al: Randomised controlled trial of steroid withdrawal in renal transplant recipients receiving triple immunosuppression. Lancet 348:643-648, 1996.)

survivals of 77% and 50%. Although the authors stated that there was no difference between the two groups in terms of the proportion of living and cadaver donors, HLA matching, recipient sex, race, or sensitization, the patients in whom steroids were not withdrawn were generally patients who had delayed graft function or experienced acute rejection, both of which are factors having a significant deleterious impact on graft outcome (see Chapter 37). This type of observational study suggested that steroid withdrawal in renal transplant patients receiving tacrolimus-based immunosuppression is possible most of the time and is reasonably safe in short-term and medium-term follow-up after transplantation. Renal function remains stable in patients in whom steroids have been withdrawn, at least in the medium term. Another small, prospective, observational study of patients receiving tacrolimus, MMF, and steroids, in whom steroids were withdrawn at 1 week, showed an incidence of acute rejection of about 25%, but no grafts were lost.[44]

Following these encouraging observational studies, numerous randomized trials have now been performed investigating steroid withdrawal in patients receiving these newer immunosuppressive regimens. Pascual and colleagues[111] performed a meta-analysis of six such trials, four with MMF and cyclosporine and two with MMF and tacrolimus. Although the risk of acute rejection was increased slightly more than twofold when steroids were withdrawn, there was no significant difference in the incidence of graft failure. This meta-analysis did not differentiate the relative steroid-sparing potential of cyclosporine and tacrolimus. A more recent randomized trial from the European Tacrolimus/MMF Renal Transplantation Study Group randomly assigned immunologically low-risk patients who had undergone transplantation 3 months earlier to continue triple therapy (tacrolimus, MMF, and steroids), withdraw steroids, or withdraw MMF.[148] The incidence of acute rejection at 6 months was similar in all three groups, supporting the earlier observations that tacrolimus enables more effective steroid sparing than cyclosporine. Reductions in total cholesterol and low-density lipoprotein cholesterol were greater in the steroid-free group.

Patients from this study have now been followed for 3 years, with only 23.3% of patients randomly assigned to stop steroids having restarted steroid therapy at this time.[112] Graft and patient survival and the incidence of acute rejection were similar between groups at 3 years, and serum creatinine levels remained stable. The reduction in total cholesterol and low-density lipoprotein cholesterol seen at 6 months was maintained, with a lower mean systolic blood pressure. There was no difference seen in adverse events, such as malignancy, infection, and fractures. It would seem that in a tacrolimus and MMF–based regimen, steroids can be withdrawn without long-term detriment to graft function or survival and with a reduction in cardiovascular risk factors.

Pescovitz and colleagues[113] first noted that sirolimus may aid in the withdrawal of steroids from a calcineurin-based regimen. Further observational studies seem to support this, and the use of sirolimus may allow steroid withdrawal alongside reduction in the exposure to calcineurin inhibitors.[19,71,90,91]

The use of newer immunosuppressive agents, such as MMF and sirolimus, also may allow the safe withdrawal of steroids earlier than previously seen with cyclosporine-based regimens. Kumar and coworkers[80] reported a 3-year analysis of a large trial of 300 patients receiving basiliximab induction, a calcineurin inhibitor, and MMF or sirolimus in which patients were randomly assigned either to have steroids withdrawn on day 2 or to continue steroids. There was no difference in graft function, patient and graft survival, biopsy-proven acute rejection, or chronic allograft nephropathy. The incidence of new-onset diabetes was lower in the steroid-free group.

Gelens and colleagues[39] attempted to combine early steroid withdrawal with a calcineurin inhibitor–free maintenance regimen. Patients were randomly assigned to receive tacrolimus and sirolimus, tacrolimus and MMF, or daclizumab induction, sirolimus, and MMF. Steroids were withdrawn after 2 days in all patients. The trial was halted after an interim analysis showed an unacceptably high incidence of acute rejection in the calcineurin-free group. It would seem that even with modern immunosuppressant agents and antibody induction, it is impossible to combine the complete withdrawal of calcineurin inhibitors with steroid withdrawal.

Conclusions

In cyclosporine-based protocols such as triple therapy, early steroid withdrawal is associated with a significant increase in acute rejection. Late steroid withdrawal is feasible in these protocols in most patients with stable graft function with demonstrable metabolic benefits. The use of the newer immunosuppressant agents tacrolimus, MMF, and sirolimus has allowed further development of these steroid-sparing

protocols with the possibility of earlier steroid withdrawal. Although 3-year follow-up results from studies have now been reported, long-term follow-up of these protocols to at least 5 years is required in light of the results from the Canadian Multicentre Study.[133]

Chapter 16
Cyclosporine

Neil K. I. Russell • Simon R. Knight • Peter J. Morris

Cyclosporine is a powerful immunosuppressive drug and has proved to be a potent agent in a wide variety of experimental models of tissue transplantation and in clinical organ transplantation. When it became available in the early 1980s, it revolutionized kidney transplantation (as well as liver and heart transplantation) primarily by markedly reducing the loss of kidneys from acute irreversible rejection in the first 3 months after transplantation. A new spectrum of drug-specific side effects appeared, however, not the least of which was nephrotoxicity. Over the next 20 years, protocols designed to reduce the side effects while maintaining this potent new immunosuppression were developed and tested. The development of another potent calcineurin inhibitor, tacrolimus (see Chapter 17), in the 1990s with a slightly different spectrum of side effects has led gradually to the use of tacrolimus as a first-line immunosuppressive agent in an increasing number of renal and liver transplant units in the Western world. Because most young clinicians are less familiar with cyclosporine and in particular the history of its introduction to the clinic, which was an exciting development in transplantation, we have retained much of this material in this chapter because there is still much that can be learned in this current era of immunosuppression, and perhaps all that is new is not better.

Cyclosporine was first isolated from two strains of imperfect fungi (*Cylindrocarpon lucidum Booth* and *Trichoderma polysporum Rifai*) from soil samples by the Department of Microbiology at Sandoz (Basel, Switzerland) as an antifungal agent of limited activity.[88] The latter, from which cyclosporine now is produced, is known more correctly as *Tolypocladium inflatum Gams* and was shown by Borel and colleagues[33,34,36] to have potent immunosuppressive activity in a variety of in vitro and in vivo experiments. The drug has a molecular weight of 1200 kD and comprises 11 amino acids, one of which is unique, and most of which are hydrophobic. Cyclosporine is soluble only in lipids or organic solvents.

After Borel's initial description of the immunosuppressive properties of cyclosporine, it was shown to suppress rejection of vascularized organ allografts in rats, dogs, and rabbits[46,121,150,188] and skin allografts in rabbits.[120] Similar observations in various models of vascularized organ allografts in many species followed quickly.[226] Clinical trials of the drug in renal transplantation began in Cambridge in 1978[47]; by the early 1980s, cyclosporine was licensed for use in renal transplantation, first in Europe and then in the United States.

Cyclosporine-based protocols rapidly became standard therapy in renal transplantation, unless restricted by cost, and until more recently represented the conventional therapy against which new immunosuppressive agents were compared. Now tacrolimus is considered the first-choice calcineurin inhibitor in many units. Because cyclosporine made a significant impact not only in renal transplantation but also in liver and heart transplantation and because it is still widely used, especially in developing countries,

we review the early clinical experience in this chapter. For information regarding the early experimental work done with cyclosporine, the reader is referred to the 5th edition of this book.

MECHANISM OF ACTION

It was apparent from many early in vivo experiments that cyclosporine exerts its effect at an early stage after exposure of the recipient to a tissue allograft. This situation was illustrated in the rat renal allograft model (Table 16-1),[150,228] showing that cyclosporine is ineffective in this model if given after induction of the immune response has taken place or before the recipient animal has been exposed to the allogeneic histocompatibility antigens of the transplanted kidney.

In vitro experiments correlated well with these in vivo observations. In several species and in humans, cyclosporine has been shown to inhibit the proliferative response of lymphocytes to concanavalin A, phytohemagglutinin, and pokeweed mitogen in vitro.[35,42,198,200,353,357] If cyclosporine is added 48 hours after the addition of mitogen to a culture, there is no inhibition of proliferation, and the effect is reversed by washing the lymphocytes and re-exposing them to the mitogen.[357] Complete inhibition of the mixed lymphocyte reaction by cyclosporine has been shown in several species, including humans.[139,152,178,179,200,333] The generation of cytotoxic lymphocytes in the mixed lymphocyte reaction is prevented by cyclosporine, but when these lymphocytes are generated, cyclosporine has no effect on their cytotoxic activity.[40,139,140,152,179] Cyclosporine also has been shown to reduce markedly the generation of cytotoxic T lymphocytes in the blood of patients with renal transplants compared with patients receiving azathioprine and prednisolone.[180] Theoretically, cyclosporine might be expected to be less effective in preventing graft rejection in sensitized animals.[149] Although it does not inhibit the secondary mixed lymphocyte reaction response or the generation of cytotoxic T lymphocytes in such a secondary reaction,[139,200] it does inhibit interleukin (IL)-2 production significantly,[17,141] suggesting that cyclosporine could have some efficacy in sensitized recipients or in the treatment of ongoing rejection. Cyclosporine also has been shown to inhibit the induction of major histocompatibility complex (MHC) class II antigen expression in the transplanted kidney[224] and to a considerable extent in humans.[107] Cyclosporine not only inhibits the generation of cytotoxic T cells but also may reduce the antigenicity of the target organ.

The predominant action of cyclosporine is directed against $CD4^+$ T (T helper) lymphocytes.[33,35,42,51,117,168,194] This effect on the $CD4^+$ T cell prevents the production of lymphokines, especially IL-2,[40,196,198,256] which inhibits the further proliferation of $CD4^+$ T cells and the generation of cytotoxic T cells from the cytotoxic T cell precursor.

It was not until the late 1980s and early 1990s that the mechanism of action of cyclosporine was described at a molecular level within the cell.[289,290,302] Cyclosporine binds within the cytosol to cyclophilin, a *cis-trans*-peptidyl-prolyl isomerase that has an important role in folding proteins and peptides into their native conformation.[96] Cyclophilin has been found in a wide variety of cell types and organisms other than lymphocytes. The inhibition of this isomerase activity was thought initially to be responsible for the immunosuppressive activity of cyclosporine.[95,322] There is a family of cyclophilins to which cyclosporine binds, although most of the drug binds to cyclophilin A, a 12-kD molecule. It has been shown that mice who are deficient in cyclophilin A are resistant to the immunosuppressive effects of cyclosporine.[72] The cyclophilins belong to a larger family of immunophilins (proteins that bind immunosuppressive agents), FK-binding protein being another member of that family to which tacrolimus and rapamycin (sirolimus) bind. Tacrolimus and cyclosporine seem to have an identical mechanism of action that is quite different from that of rapamycin (see Chapters 17 and 19).

The complex of cyclosporine and cyclophilin is the immunosuppressive molecule, cyclosporine being a prodrug and not by itself immunosuppressive. This complex of the drug and its immunophilin binds to a calcium-dependent and calmodulin-dependent phosphatase, calcineurin.[104,209] Calcineurin plays a crucial role in the transduction of the calcium-dependent signal that leads to the activation of the enhancer region of the IL-2 gene[70,245] because it dephosphorylates the cytosolic form of the nuclear factor of activated T cells (NFATc), which is necessary for its translocation into the nucleus as NFATn, which activates the enhancer region of the IL-2 gene leading to its transcription.[119] Other transcription factors, such as NFIL-2 A and B, also are inhibited by cyclosporine.[221] This cyclosporine-immunophilin complex, which binds to calcineurin and blocks the dephosphorylation

Table 16–1 **Effects of Cyclosporine on Rejection of Dark Agouti Renal Allografts in Lewis Rats Depending on the Time of Administration***

Treatment Period (Days)	Dose of Cyclosporine (mg/kg)	No. Rats	Median Survival and Range (Days)
—	0	9	11 (10-11)
–14-–1	10	7	12 (10-13)
–2-0	10	6	12 (12-14)

of NFATc and its translocation into the nucleus, prevents the transcription of the IL-2 gene.[97,118] There is a second pathway of activation (the so-called second signal), however, mediated by CD28 with distinct signal pathways, including protein kinase C.[335] Activation of this pathway also leads to IL-2 production and IL-2 receptor expression, and this pathway is resistant to cyclosporine.[142]

Although the reduction of IL-2 production and IL-2 receptor expression and the resultant reduction of T cell activation is the main pathway by which cyclosporine induces immunosuppression, it has other mechanisms of action that are thought to contribute to its immunosuppressive effects. Cyclosporine enhances transforming growth factor (TGF)-β mRNA expression in normal human T cells and constrains new DNA synthesis through a TGF-β–dependent mechanism.[182,209] It increases the production of TGF-β by activated T cells,[5] and kidney transplant recipients being treated with cyclosporine have been found to have higher levels of circulating TGF-β than patients on other immunosuppressive agents.[68,219] TGF-β has been found to inhibit IL-2–dependent T cell proliferation and inhibit IL-2 receptor upregulation by IL-2[176] and suppress antigen-specific T cell proliferation.[332] It also has been shown to promote the expansion of regulatory T cells.[154] It has been suggested that TGF-β may have an immunoregulatory role and may be an immunosuppressive cytokine in its own right,[56,344] and more recently it has been suggested that TGF-β mediates in part the immunosuppressive properties of cyclosporine. As discussed later, TGF-β may play a role in the development of fibrosis, a characteristic feature of chronic rejection.[183]

The role of dendritic cells in antigen presentation is pivotal (see Chapter 2). More recent data suggest that dendritic cells are a target for cyclosporine and T cells, and this may play a role in the immunosuppressive properties of cyclosporine. Cyclosporine has been shown to alter the migratory abilities of dendritic cells[64] and to inhibit the maturation of circulating dendritic cells.[321] It also is thought that cyclosporine can alter the antigen presentation capabilities of dendritic cells and have an effect on their ability to activate T cells.[67,202,220]

Although cyclosporine generally has not been thought to inhibit the function of B lymphocytes,[34,42,117] there is some evidence to the contrary in humans[255,265] and mice.[38,184,194] O'Garra and colleagues[244] showed a cyclosporine-sensitive subpopulation of T cell–independent B lymphocytes in mice and showed that cyclosporine can inhibit the production of murine B cell–derived lymphokines. It has been shown that cyclosporine and tacrolimus can inhibit B cell activation when the stimulating factor triggers an increase in intracellular calcium.[356] Venkataraman and coworkers[339] suggested that cyclosporine may inhibit B cell function in the same manner as it inhibits T cell function, by inhibiting NFAT. They showed that NFAT also is present in B cells, and that it is inhibited within B cells by cyclosporine. See Chapter 2 for discussion of the role of B cells in rejection.

Unraveling the molecular mechanism of action of the calcineurin inhibitors (cyclosporine and tacrolimus) and the newer immunosuppressive agents, such as mycophenolate mofetil (MMF) and sirolimus, has led to a much more detailed understanding of the nature of signal transduction after the T cell receptor has recognized alloantigen. This understanding should allow drugs with more specific actions to be designed. This design also may be enhanced by the description of the three-dimensional structure of the cyclosporine-cyclophilin complex, which at a crystallographic level appears to be a pentamer with the two pentamers forming a sandwich with the cyclophilin pentamers on the outside and the cyclosporine molecules inside the sandwich.[263,327]

The major mechanism of action of cyclosporine is still thought to be due to inhibition of T cell activation as a result of the blocking of IL-2 production. It is now clear, however, that T cell inhibition is not the only pathway by which cyclosporine produces immunosuppression.

EARLY EXPERIENCE

Cyclosporine first was used in renal transplantation by Calne and colleagues[47,48] in Cambridge. Initially, it was used with other drugs, such as prednisolone or Asta 036.5122 (cytimum, an analogue of cyclophosphamide), but this proved a dangerous combination, with many patients dying of infection. For the first time, it became apparent that cyclosporine was nephrotoxic in humans; this was not a feature of the extensive experimental use of cyclosporine in animal models at that time, although it became apparent later.[23,354,355] Three lymphomas were seen in these early patients, which caused considerable alarm. A new policy was adopted at Cambridge whereby cyclosporine was used only in patients whose grafts were diuresing, and it was used alone, with high-dose methylprednisolone given to treat acute rejection. If more than 6 g of methylprednisolone was required, patients were converted to azathioprine and prednisolone. Following this policy, 60 cadaver grafts were performed in 59 patients, all but 1 of whom had been transfused previously. Actuarial graft survival at 1 year was 82%. Six deaths occurred, five from infection, and 10 patients were converted to azathioprine and prednisolone because rejection was not controlled with cyclosporine.[49] Many of these patients were not receiving steroids; many had never received any steroids.

This early experience in Cambridge prompted many controlled trials of cyclosporine—single-center trials in Minneapolis, Oxford, Pittsburgh, and Sydney; multicenter trials in Europe and Canada; and uncontrolled studies in Denver, Pittsburgh, Stockholm, and Boston. In the European multicenter trial, only patients who were given grafts that were diuresing 6 hours after surgery were randomly assigned to receive cyclosporine alone or conventional treatment with azathioprine and prednisolone, according to the custom of the unit. The trial was closed at the end of 1981 after 1 year, when slightly more than 200 patients had been entered. Actual survival at 1 year was 72% in the cyclosporine group and 52% in the control group,[13,14] although many patients were converted to azathioprine and steroids because of apparent rejection on cyclosporine. At 5 years, there was a marked difference (but not as great) in graft survival in favor of cyclosporine—55% versus 40% in the control group[50]—and at 10 years, the difference was 35% versus 29%, with stable renal function in the cyclosporine group, although at a higher serum creatinine level than in the control group (Fig. 16-1).[16] Many of the grafts considered to be in a process of rejection in this trial likely had nephrotoxicity in retrospect, an ever-present problem that is discussed later. Actual survival in the patients excluded from the trial and treated with conventional immunosuppression was similar to that of the control group within the trial.

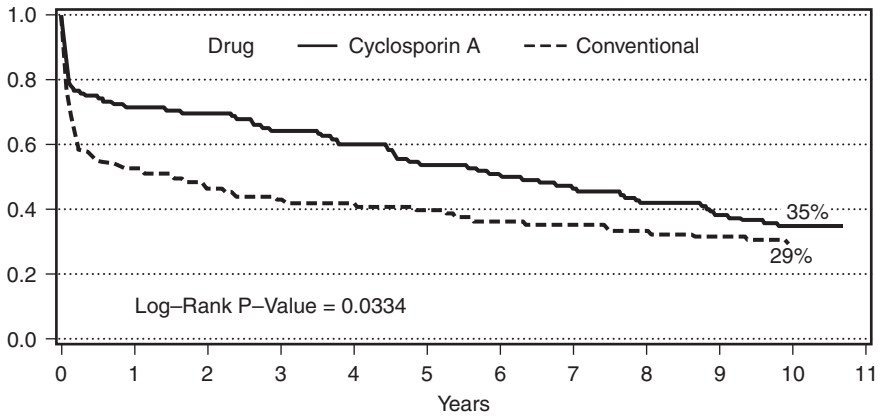

Figure 16–1 Graph showing actual graft survival with cyclosporine compared with azathioprine and steroids, one of the first randomized controlled trials of cyclosporine versus azathioprine and steroids.[16]

An excellent randomized multicenter trial was conducted in Canada, in which cyclosporine and prednisolone therapy was compared with standard therapy based on azathioprine and prednisolone in 209 cadaver renal allograft recipients.[54] In this first analysis, actuarial graft survival at 1 year was 84% in the cyclosporine group compared with 67% in patients receiving standard therapy, with patient survivals of 97% and 90%, respectively, in the two groups. At 3 years, graft survival was 69% in the cyclosporine-treated group and 58% in the control group, a less striking difference than in the initial analysis.[15] Patient survival was 90% in the cyclosporine group and 82% in the control group. A detrimental effect on graft survival was seen in cyclosporine-treated patients if they received kidneys that had been preserved for longer than 24 hours or if the surgical anastomosis time took longer than 45 minutes, suggesting that cyclosporine nephrotoxicity is more likely to occur in kidneys that have some ischemic damage.

In Minneapolis, all HLA-mismatched living or cadaver donor transplants were eligible for a trial in which cyclosporine plus prednisolone was compared with conventional therapy of azathioprine, steroids, and antilymphocyte globulin.[91,235,236] All patients had had a splenectomy and at least 5 U of blood before transplantation. The trial comprised 230 patients and included cadaver and living related transplants and diabetic and nondiabetic recipients. Overall graft survival rates at 2 years were 82% in the cyclosporine group and 77% in the control group, and patient survival was 88% and 91%, respectively. In the living related transplants, graft survival at 2 years was 87% in the cyclosporine group and 83% in the control group, whereas the 2-year graft survival figures in the cadaver transplants were 78% and 73%, respectively. These differences in survival were not significant, but the cumulative incidence of rejection episodes in the first year after transplantation in the cyclosporine group was half that in the control group, as was the incidence of infection.

Similarly, Starzl and colleagues,[313,314] first at Denver (where treatment was not standardized) and then at Pittsburgh, reported impressive results with cyclosporine and prednisolone (at a maintenance dose of 20 mg/day after a burst of high-dose prednisolone) in primary and secondary cadaver transplants. Graft survival was about 90% at 1 year in primary cadaver transplants. In 26 patients who received 27 cadaver second transplants, 1-year graft survival was 78%. After that initial experience, virtually all contraindications to the use of cyclosporine in renal transplantation were disregarded, and in 96 primary cadaver grafts, patient survival at 1 year was predicted as 90%, and graft survival was predicted as 80%.[314] Early anuria was not considered a contraindication to cyclosporine, which was sometimes considered to be the result of rejection or nephrotoxicity, or both, although it did cause diagnostic problems in the management of patients.

In the Sydney controlled trial of cyclosporine versus azathioprine, prednisolone, and antilymphocyte globulin, 60 patients receiving first cadaver grafts were entered, and graft survival of 70% at 1 year was similar in both groups. Persistent anuria after transplantation was a major problem in the cyclosporine group.[297] In the Oxford trials, all patients were started on cyclosporine, but were randomly assigned at 3 months either to azathioprine and prednisolone or to remain on cyclosporine. The objective was to reduce nephrotoxicity.[227,229] This approach is discussed later in this chapter.

This early experience with cyclosporine in prospective controlled trials and in uncontrolled observational studies indicated that cyclosporine was a major advance in immunosuppressive therapy, as was evident in the Collaborative Transplant Study, which had data from more than 200 transplant centers and several thousand renal transplants.[249] Many side effects had become evident, the major one being nephrotoxicity, and so subsequent protocols were designed to obtain the same improved immunosuppression achieved with cyclosporine, but with a reduction in side effects resulting from lower doses of cyclosporine (Table 16-2).

CYCLOSPORINE WITH OR WITHOUT STEROIDS

The initial use of cyclosporine in Europe was based on the experimental data and the early Cambridge experience, using a high dose of cyclosporine alone (monotherapy), whereas in North America cyclosporine was used with steroids. Gradually, most units added steroids to their cyclosporine protocols, but not with any convincing evidence that steroids were necessary. In the United States, there had been a tendency to use high-dose steroids, at least in the early weeks after transplantation. Four prospective controlled trials comparing cyclosporine alone with cyclosporine and steroids were performed.[83,123,160,210,316]

Table 16–2 **Cyclosporine-Based Protocols That Have Been Used or Are in Use in Renal Transplantation**

Cyclosporine (monotherapy)
Cyclosporine + prednisolone
Cyclosporine + azathioprine (dual therapy)
Cyclosporine + azathioprine + prednisolone (triple therapy)
ALG/OKT3 + azathioprine + prednisolone → cyclosporine + azathioprine + prednisolone (sequential therapy)
Cyclosporine + prednisolone → azathioprine + prednisolone (conversion therapy)
ALG/OKT3 + cyclosporine + azathioprine + prednisolone (quadruple therapy)
New Therapies
Cyclosporine + MMF + prednisolone
Cyclosporine + sirolimus/everolimus + prednisolone
Anti–IL-2R antibody + cyclosporine + MMF/azathioprine + prednisolone
Anti-CD52 antibody + cyclosporine + MMF ± prednisolone
Anti–IL-2R antibody + cyclosporine + CTLA-4 immunoglobulin + MMF + prednisolone
Cyclosporine conversion and reduction protocols*

*See section on cyclosporine reduction.
ALG, antilymphocyte globulin; IL, interleukin; MMF, mycophenolate mofetil.

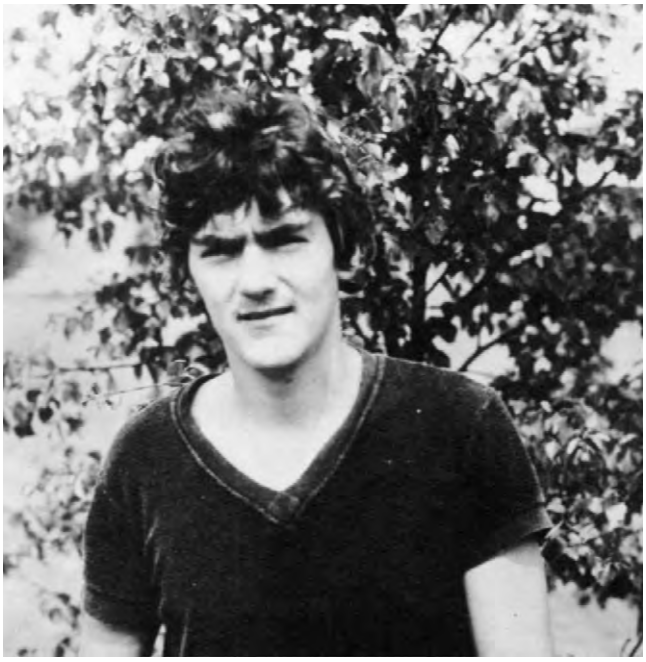

Figure 16–2 Patient in the cyclosporine era with the lack of cushingoid facies so typical of the azathioprine steroids era.

None was able to confirm an additive effect of steroids in terms of immunosuppression. Two groups found an increased incidence of infection with steroids, although Griffin and coworkers[123] suggested that steroids reduced the incidence of cyclosporine nephrotoxicity. Schmidt and colleagues,[287] in a morphological study of renal biopsy specimens 1 year after renal transplantation, found no difference in biopsy specimens from patients treated with cyclosporine and steroids compared with those treated with cyclosporine without steroids. In these studies, steroids were used for the treatment of rejection, and in many patients with recurrent rejection steroids were added to the cyclosporine regimen.

Many patients can be managed without steroids or weaned off steroids early, although the long-term outcome of the Canadian trial suggested that the withdrawal of steroids was associated with a poorer graft outcome.[304] Patients who have not had steroids present an entirely different facies to that which clinicians had become used to in the precyclosporine era (Fig. 16-2). The need for steroid maintenance therapy and the length of time for which such therapy is required after transplantation remain unresolved and are discussed in more detail in Chapter 15. Most patients are likely to need high-dose methylprednisolone for the treatment of acute rejection episodes. Most units have used steroids with cyclosporine from the time of transplantation. Two types of protocols were used. In North America, the tendency was to use high oral doses of prednisolone (e.g., 100 mg/day) from the time of transplantation, reducing rapidly to lower doses over the first 2 to 3 weeks, whereas in Europe, the trend was to use low doses from the time of transplantation (e.g., 20 to 30 mg/day), reducing to maintenance doses over the first 3 to 6 months. There is no evidence that one approach was better than the other, and on general principles the low-dose steroid protocol should be favored if steroids are to be used routinely with cyclosporine.

Cyclosporine alone has been used in the past at what would now be considered high doses (17.5 mg/kg/day), and many of the reported side effects of cyclosporine, most of which are dose related, can be attributed to these high doses. In subsequent years, cyclosporine doses gradually were reduced based on the maintenance of adequate trough blood levels (200 to 400 ng/mL in the early months and 100 to 200 ng/mL thereafter), and although this led to a reduction in nephrotoxicity and other side effects, it has not led to the disappearance of nephrotoxicity, which remains a major side effect. It is possible that the concurrent use of steroids with these lower doses of cyclosporine is important for adequate immunosuppression; that is the view held by most clinicians. The trials mentioned previously all used higher doses of cyclosporine. A randomized prospective trial comparing cyclosporine monotherapy with cyclosporine, azathioprine, and prednisolone triple therapy did not show any difference in graft survival, but more severe rejections were seen in the monotherapy group, which required more high-dose steroid rejection treatments. Cyclosporine nephrotoxicity also was more common in the monotherapy group, which was started on 15 mg/kg/day of cyclosporine, than in the triple-therapy group, which received 8 mg/kg/day.[324]

Cyclosporine is administered as a single daily dose or twice-daily dose with the older formulation (Sandimmune) or as two 12-hourly doses with the newer microemulsion formulation (Neoral). After administration of Sandimmune, trough levels (C_0) are reached at 12 to 18 hours, whereas with Neoral, which is much better absorbed and has an increased bioavailability, trough levels are achieved at 10 to 12 hours. Sandimmune can be given as a single daily dose, whereas Neoral probably needs to be given twice daily (every 12 hours). There is increasing concern that nephrotoxicity may be related more to high peak levels rather than high trough levels, and although there is no evidence that twice-daily doses

of Sandimmune produced better immunosuppression, it was suggested that there was a greater incidence of nephrotoxicity.[286] There is more recent evidence, however (discussed later), that low peak levels may predict rejection better than low trough levels.

TRIPLE THERAPY

In an attempt to maintain the improved immunosuppression provided by cyclosporine and to reduce the incidence of cyclosporine side effects, especially nephrotoxicity, triple therapy with low doses of cyclosporine, azathioprine, and steroids was introduced by several groups.[105,155,303,306] Data in experimental models suggested that azathioprine and cyclosporine might be synergistic in their immunosuppressive activity.[312]

The results of triple therapy by the late 1980s were excellent,[106,163] with 1-year first cadaver graft survival rates of about 80% reported in most instances and with many patients having no rejection. In the Oxford experience, 38% of patients with cadaver grafts had no clinical or histological rejection episodes in the first 3 months after transplantation.[163] There did not seem to be an increase in the incidence of infection despite the possible enhancement of immunosuppression achieved with the triple therapy. This form of triple therapy soon became the most commonly used immunosuppressive therapy in renal transplantation (as well as liver and cardiac transplantation), although today azathioprine has been replaced largely by MMF. Despite low doses of cyclosporine, renal function remained suboptimal and did not seem to be much improved over that seen in the Oxford unit in our earlier experience using high doses of cyclosporine alone. Although triple therapy is a potent immunosuppressive regimen, it did not seem to be any more effective than some of the other cyclosporine protocols described in this section.[129] Its ease of use made triple therapy an increasingly popular protocol in many units, with acceptable results that continue to improve despite the increased acceptance of older recipients with other comorbidities (Fig. 16-3).

An attempt to resolve the problem of efficacy was reported first from Milan[266,324] in a randomized controlled trial of triple therapy versus high-dose cyclosporine and steroids. Although patient and graft survival rates were similar in the two groups, there were more rejection episodes in the triple-therapy group but evidence of greater renal impairment and infection in the high-dose cyclosporine group. The second report was of a multicenter prospective trial from Australia comparing triple therapy with cyclosporine and prednisolone and with cyclosporine and azathioprine.[129] Approximately 140 patients were entered into each arm of the trial, which included nondiabetic transfused recipients of first cadaver grafts. Patient and graft survival rates were excellent in all three groups—91% and 85%, respectively, at 1 year. Of patients receiving cyclosporine and azathioprine, however, 36% required long-term prednisolone treatment to control rejection. The investigators suggested that optimal therapy might involve the initial use of cyclosporine plus one other agent, with the possible addition of a third if required.

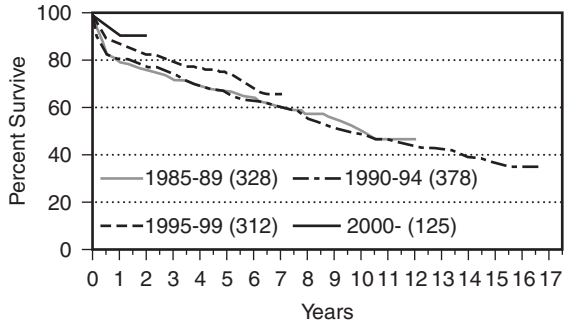

Figure 16–3 Graph showing cadaver donor graft survival in the cyclosporine era in the Oxford unit in 5-year cohorts from 1985. All patients received triple therapy (cyclosporine, azathioprine, and steroids).

Many units have explored the possibility of dropping one of the three drugs, most commonly steroids, after several months of triple therapy. It seems that this can be done safely in most patients. In a trial from Finland, patients on triple therapy were randomly assigned to drop one of the three drugs after 3 months.[133] The early experience of this trial suggested that any one of the three drugs can be discontinued safely with excellent graft survival being maintained in all three groups. Subsequently a randomized prospective trial of steroid withdrawal in patients on triple therapy with stable renal function after 1 year was reported from Oxford.[271] Complete steroid withdrawal was possible in most patients with significant improvement in cardiovascular risk factors (i.e., serum cholesterol and blood pressure) and in bone mineral metabolism. A modest reduction in graft function, of uncertain origin, was common, but was not progressive, at least in the medium term. Withdrawal of steroids in patients on triple therapy has been shown to improve significantly the management of patients with post-transplant diabetes mellitus.[153] It seems reasonable to attempt withdrawal of steroids in all patients on triple therapy who have stable renal function. Whether this steroid withdrawal can be done earlier than 1 year after transplantation is uncertain, but it may be possible (see Chapter 15).

As mentioned earlier, triple therapy can be undertaken with MMF replacing azathioprine, which results in a significant reduction in the incidence of acute rejection episodes in the first 6 months after transplantation.[17,309] This reduction in the incidence of acute rejection was not reflected by better graft survival. The ability of MMF to reduce acute rejection rates was reinforced by a study of the United States Renal Data System. When 47,693 patients were analyzed, it was shown that treatment with MMF reduces the incidence of acute rejections beyond 1 year post-transplantation compared with azathioprine. In a systematic review of MMF versus azathioprine published in 2004, the authors showed a reduced incidence of acute rejection at 6 and 12 months with MMF.[347] More recently, a randomized controlled trial comparing MMF with azathioprine when combined with the Neoral preparation of cyclosporine did not show any benefit with MMF, however, compared with azathioprine.[273] An analysis of the United Kingdom transplant database between 1999 and 2002 comparing paired kidneys in which one kidney went to a patient treated with cyclosporine and MMF and one went to a patient treated with cyclosporine and azathioprine showed no difference in graft or patient survival rate, but a significant reduction in acute rejections in the patients treated with azathioprine (44% versus 31%; $P < .01$).[295] There also is a significant cost implication with treating patients with MMF compared

with azathioprine. In the study by Remuzzi and colleagues,[273] the cost of 1 day of treatment with MMF was $15.30, whereas the cost of azathioprine for 1 day was $1.10. In the United Kingdom, the cost of 125 mg of azathioprine is £0.62 compared with £6.99 for 2 g of MMF (prices obtained from the British National Formulary).

QUADRUPLE THERAPY

Adding a prophylactic course of heterologous antilymphocyte globulin or OKT3 or, more recently, a monoclonal antibody against the IL-2 receptor (basiliximab or daclizumab) to triple therapy has been advocated by some groups, with delay of the administration of cyclosporine in patients with delayed primary function.[303] Although induction with an antilymphocyte agent is common practice in the United States, these are potent agents (antilymphocyte globulin or OKT3) associated with an increased risk of lymphoproliferative disease and infection and are not necessary in most patients receiving renal transplants.[251] Their use for induction in quadruple-therapy protocols possibly should be restricted to highly sensitized patients and patients with delayed graft function. The use of OKT3 as an induction agent has diminished, and OKT3 has been replaced for the most part by either thymoglobulin or other monoclonal antibodies such as basiliximab and daclizumab (anti–IL-2 receptor antibodies). The use of humanized or chimeric monoclonal antibodies against the IL-2 receptor has resulted in less rejection without an apparent increase in infection or lymphoproliferative disease (see Chapter 20),[237,341] and the tendency is to use these agents routinely as induction therapy. New, more potent monoclonal antibodies also are available, including the anti-CD52 monoclonal antibody, alemtuzumab, which produces a profound and lasting lymphopenia. It seems to be a good induction agent and may allow sparing of steroids or calcineurin inhibitors as suggested in a systematic review.[230] Rituximab, an anti-CD20 monoclonal antibody, also currently is being evaluated as an induction agent for use in sensitized patients (see Chapter 20 for more details).

SEQUENTIAL THERAPY

Sequential therapy has been used routinely by many units that previously gave antilymphocyte globulin or OKT3 with azathioprine and steroids.[24,93,192,298] Cyclosporine is not started until renal function has reached an acceptable level. The simplest approach used by the Basel group is to administer antilymphocyte globulin alone for the first 5 days before starting cyclosporine.[326] Generally, the more common approach is to give antilymphocyte globulin with low-dose azathioprine and prednisolone, starting cyclosporine after 7 or 14 days.[85,310] Although there is no firm evidence that this type of protocol is better than others, the graft survival figures from units using this approach were impressive at the time. In one prospective trial from Brussels, comparing sequential therapy using OKT3 with triple therapy, the graft survival rate was improved significantly—83% at 1 year in the OKT3-treated group versus 75% in the control group.[2] A subsequent report of a randomized prospective multicenter trial from the United States, in which sequential therapy using OKT3 for 14 days with the addition of cyclosporine on day 11 was compared with triple therapy, showed significantly fewer rejections in the OKT3 patients (51% versus 66%); 2-year patient and graft survival rates were 95% and 84%, respectively, in the OKT3 group and 94% and 75%, respectively, in the triple-therapy group.[241] Although no increased morbidity was associated with OKT3 in this trial, the routine use of antilymphocyte globulin or OKT3 induction therapy in low-risk renal transplant recipients seems to expose patients to more potent immunosuppression than generally is required and is not justified in most patients. More recently, a trial of sequential therapy using an anti–IL-2 receptor antibody for induction, with patients being randomly assigned to start cyclosporine therapy early, day 0, or late, day 6, showed that there was no difference in acute rejection or renal function or incidence of delayed graft function between the two groups, and there was no difference in patient or graft survival.[172]

CYCLOSPORINE IN HIGH-RISK PATIENTS

High-risk patients include a miscellaneous group of patients who may be at high risk for immunological or medical reasons. The following groups probably represent the patients who have benefited most from the use of cyclosporine.

1. Older patients. Cyclosporine has allowed transplantation to be offered to patients older than age 55 years with end-stage renal failure, patients who would have been excluded from transplantation by most units in the azathioprine-prednisolone era because the risks of the procedure and immunosuppression were considered unacceptable. In that earlier era, however, the Stockholm group[252] had shown that transplantation represented the most satisfactory solution to end-stage renal failure in the elderly patient. Similar data were reported from Dallas using cyclosporine immunosuppression.[338] Similarly in Oxford, using triple-therapy immunosuppression, renal transplantation was shown to be a safe procedure in most patients older than age 55. Although loss of grafts from rejection is rare in this older group, graft survival is lower because of a greater death rate with a functioning graft, usually as a result of cardiovascular disease. In Oxford, in patients younger than age 55, patient and graft survival are 96% and 87%, respectively, at 1 year compared with 84% and 74%, respectively, in patients older than age 55. At 5 years, the corresponding figures are 90% and 74%, respectively, in the younger cohort and 68% and 56%, respectively, in the older cohort. The pharmacokinetics of cyclosporine in elderly patients do not seem to be different, the main problem being interaction with other medications that are eliminated by the same metabolic mechanisms, such as cytochrome P-450 and P-glycoprotein.[191] Because elderly patients require less immunosuppression, attention should be paid to reducing cyclosporine levels to the lowest acceptable level. It is important in this group to withdraw steroids as early as possible, not later than 9 to 12 months after transplantation and probably earlier.
2. Very young patients. As described in detail in Chapter 35, cyclosporine has made transplantation an acceptable approach to renal failure in infants and young children.

3. Diabetic patients. Patients with diabetes have done much better after renal transplantation with cyclosporine protocols than previously. Cadaver renal transplantation has now become the treatment of choice for diabetics with chronic renal failure and in many instances is accompanied by a pancreas transplant (see Chapter 34).
4. Sensitized patients. Sensitized patients, particularly patients having a second graft, show much improved graft survival rates with cyclosporine protocols than seen before with azathioprine and prednisolone.[41,314] This improvement has been particularly evident at Oxford, most likely owing to the sophisticated analysis of the antibody status of sensitized recipients and the crossmatch between donor and recipient, rather than cyclosporine (see Chapter 10).

LIVING RELATED TRANSPLANTS

HLA-Identical Transplants

Although cyclosporine has had an impact on living related transplantation, its use for HLA-identical transplants is controversial because patient and graft survival are excellent with azathioprine and steroids, and most patients can be weaned off steroids after about 1 year. Flechner and coworkers[100] always had considered cyclosporine as the preferred therapy in these patients, however. A thought-provoking analysis of renal transplantation between HLA-identical siblings treated with azathioprine and prednisone or cyclosporine and prednisone has been reported from New York.[319] Patient and graft survival rates were 100% and 97%, respectively, in the cyclosporine group at 1 year compared with 91% and 85%, respectively, in the azathioprine group. Although renal function remained stable in the azathioprine group, there was a progressive deterioration in renal function in the cyclosporine group, a cause for considerable concern. At the Cleveland Clinic, a group treated with azathioprine and prednisone was compared with a group treated with cyclosporine and prednisone. Five-year patient survival was 100% versus 96%, and graft survival was 92% versus 83%. A nonsignificant increase in the serum creatinine level was noted in the cyclosporine patients (1.7 mg/dL) compared with azathioprine patients (1.3 mg/dL).[114] The question of whether cyclosporine is required for immunosuppression in HLA-identical living related transplants remains unresolved. A case can be made for the use of azathioprine and steroids or conversion from cyclosporine to azathioprine or MMF at 3 months in HLA-identical sibling transplants.

Non–HLA-Identical Transplants

The use of donor-specific transfusions in the early 1980s in patients with non–HLA-identical transplants led to a dramatic improvement in graft survival, approaching that of HLA-identical siblings.[284] Many patients become sensitized against the donor as a result of the transfusions, however, even with the concurrent administration of azathioprine.[8] Kahan[169] and Groth[125] first advocated that donor-specific transfusions be abandoned because equally good results in this group could be obtained with cyclosporine.[98] The concurrent use of cyclosporine with donor-specific transfusions was explored by Hillis and associates[146] and Cheigh and coworkers.[63] There were still some instances of sensitization, and it was unclear that results of the subsequent transplants were superior to the results of transplants in patients given donor-specific transfusions alone. The use of cyclosporine without donor-specific transfusions before transplantation simplifies the whole procedure and became the protocol followed by the Oxford unit for non–HLA-identical living related transplants for many years. Nevertheless, the long-term outcome of the non–HLA-identical transplants pretreated with donor-specific blood under azathioprine cover remains impressive in the St. Louis experience.[9] The role of prior donor-specific transfusion in this type of transplant is unresolved, but today there are other reasons for avoiding blood transfusions, and deliberate transfusions in nontransfused recipients are avoided in most units today.

LIVING UNRELATED TRANSPLANTS

The improved results that were obtained with cyclosporine have led many groups to embark on living unrelated transplants between highly motivated donors and recipients, usually spouses. The results of the Madison unit have been excellent. A protocol of donor-specific transfusions under azathioprine cover was followed by quadruple therapy with delayed administration of cyclosporine after transplantation.[22] A smaller study from Norway without donor-specific transfusions but using cyclosporine, either with prednisolone or azathioprine and prednisolone, also reported good early results for living unrelated transplantations.[308]

These early results have led to an increasing number of living unrelated transplants throughout the world, mostly with spouse donors. Registry results from the United Network for Organ Sharing and from the Collaborative Transplant Study have confirmed the excellent outcome of these transplants, results being equivalent to that of one haplotype–disparate living related transplants.[250,325] With living unrelated transplants, outcome still is related to the degree of fortuitous matching between donor and recipient.[250] The use of paired donations for ABO-incompatible or highly sensitized recipients is becoming more common, although this presents considerable logistic problems (see Chapter 22).

CONVERSION TO CYCLOSPORINE

Conversion to cyclosporine from azathioprine and steroids may be considered for side effects of azathioprine and steroid therapy in an ever-decreasing cohort of long surviving patients or for steroid-resistant acute or chronic rejection. In a phase I study at Oxford, nine patients with long-standing stable renal function were converted to cyclosporine because of steroid side effects. Although the early experience was encouraging,[330] the longer term follow-up was unsatisfactory: Only four patients remained on cyclosporine. Although the steroid side effects resolved, other problems arose: Two kidneys were lost, two patients died of sepsis, renal function declined in all grafts, and one patient developed recurrent squamous cell carcinoma of the skin; hypertrichosis and gout were less serious problems. A more favorable experience was reported after conversion to cyclosporine for steroid side effects from Basel and Odense,[137,326] but follow-up in these patients was short, which may be relevant, considering the initial favorable impression of conversion at Oxford. Although conversion of

long-term renal allograft recipients to cyclosporine for steroid side effects does not place the graft at risk for rejection, problems may occur from cyclosporine nephrotoxicity and other side effects. Before adopting this approach in patients with severe steroid side effects, one should be aware of the potential problems, and only patients with excellent renal function should be considered as candidates for conversion. Otherwise, conversion to MMF may be a more satisfactory path to follow.

Conversion to cyclosporine from tacrolimus may be considered when patients have side effects associated with tacrolimus. In their systematic review comparing cyclosporine with tacrolimus, Webster and colleagues[352] showed that post-transplant diabetes is more commonly associated with tacrolimus. In kidney transplant patients who have developed post-transplant diabetes with tacrolimus therapy, the conversion to cyclosporine has been shown to improve glucose metabolism and in some cases resolve the diabetes.[37,247] Conversion from tacrolimus to cyclosporine is not associated with increased risk of rejection during conversion.[144]

CYCLOSPORINE COST REDUCTION

Numerous studies have investigated the use of drugs to slow the metabolism of cyclosporine to reduce the dose and the cost of immunosuppression. Such strategies are of particular relevance to the care of transplant patients in developing countries or uninsured transplant patients in some areas of the Western world.

Cyclosporine is metabolized by isoenzymes of the cytochrome P-450 system. Ketoconazole, a broad-spectrum antifungal agent, inhibits this enzyme system in vitro and in vivo. Cyclosporine toxicity has been reported in the presence of ketoconazole owing to high blood or serum levels of the drug.[79,92,115] First and colleagues[94] at Cincinnati first proposed that ketoconazole might be used to decrease the dose of cyclosporine required for adequate blood levels, reducing the cost of the drug. Using a ketoconazole dose of 200 mg/day, retrospective and prospective studies support a reduction in the cyclosporine dose of 60% to 85%, with an associated cost reduction of 60% to 79%.[55,112] There was no associated increase in acute rejection episodes or hepatotoxicity. These findings were replicated in a more recent randomized controlled trial administering 100 mg/day of ketoconazole, with a dose reduction of 65% after 10 years.[90] This latter study also reported a significant decrease in chronic allograft nephrotoxicity, with no difference in metabolic complications. A further randomized trial showed a cost reduction of 42% using a smaller ketoconazole dose of 50 mg/day.[1]

One caveat to this application of ketoconazole is that all of the aforementioned studies monitored cyclosporine using trough levels. More recent, albeit small, studies have suggested that the use of ketoconazole alters the pharmacodynamic profile of cyclosporine microemulsion, meaning that newer 2-hour (C_2) monitoring strategies may be invalid.[87,340,361] Analysis of cyclosporine pharmacokinetic profiles has shown a flattening of the absorption curve with increased variability and longer elimination half-life with the addition of ketoconazole. In this situation, the trough level and the level at 4 hours after dosing are better predictors of area under the curve (AUC) than C_2. A small retrospective study from Chile has suggested that the use of ketoconazole in conjunction with C_2 monitoring may increase the risk of hepatotoxicity.[340]

Numerous trials have investigated the use of other metabolic inhibitors in reducing the cost of cyclosporine treatment.[217] These include other antifungal preparations such as fluconazole and itraconazole, calcium channel blockers, and the macrolide antibiotics. The dose reduction achieved with these drugs is generally less than with ketoconazole, with reductions of 20% to 50% seen with coadministration of diltiazem. It also has been suggested that addition of diltiazem or verapamil can improve clinical outcomes, with reductions in the severity of rejection episodes and improvements in renal function.[66,82,211]

CYCLOSPORINE FORMULATIONS

Sandimmune

The original, oil-based formulation of cyclosporine (Sandimmune; Novartis Basel, Switzerland) was introduced in 1983. Although a significant advance in immunosuppressive therapy, this formulation had numerous problems. Absorption was slow and showed a great deal of intrapatient and interpatient variability, making dosing difficult and increasing the risk of chronic rejection.[171,189]

Neoral

In 1995, Neoral (Sandimmune Neoral; Novartis Basel, Switzerland), a microemulsion formulation of cyclosporine, was approved for use by the Food and Drug Administration. This new formulation improved bioavailability with more rapid absorption and less variability in de novo and stable transplant patients.[189,190] Since its introduction, numerous randomized and nonrandomized studies have been performed to ascertain whether this new formulation improved clinical outcomes in transplant recipients. Shah and colleagues[294] collected the results of these trials in a thorough meta-analysis. Rates of graft loss and renal function do not differ when the two formulations are compared. The investigators found that in de novo renal, liver, and cardiac transplant recipients, acute rejection rates are lower in patients treated with Neoral. In stable patients, no difference in acute rejection rates is seen. Generally, adverse event rates are similar between the two formulations, with an increase in adverse events in Sandimmune-treated de novo liver recipients. When only randomized controlled trials were considered, lower rejection rates were seen in de novo and stable patients treated with Neoral. The tradeoff was an increase in adverse events seen in these stable patients in randomized, blinded trials.

More recently, longer term outcomes have been reported. Goel and colleagues[116] showed in a retrospective analysis that graft and patient survivals do not differ at 5 years. Although chronic rejection rates and renal function do not differ, use of Neoral leads to significantly more patients free of acute rejection at 5 years. Another longer term study has suggested that the increase in bioavailability of the microemulsion formulation of cyclosporine may lead to increased rates of Kaposi's sarcoma.[58] A review of pharmacoeconomic studies from Europe and Canada in renal and liver transplant patients has suggested that the overall costs of treating patients with the microemulsion formulation is

marginally less than the original formulation, but this does not reach statistical significance.[74]

Generic Formulations

In recent years, numerous generic microemulsion formulations have been approved for use, and many others are in use in developing countries (e.g., India). Although these have been shown to be bioequivalent in healthy male volunteers, questions have arisen as to how appropriate such testing is in the field of transplantation. Transplanted patients have considerable differences in drug absorption and availability compared with healthy individuals, meaning that testing bioavailability of these drugs in healthy individuals may be invalid.[162,267]

Pharmacological studies of generic formulations in transplant recipients give conflicting results. Many studies have shown bioequivalence between Neoral and various generic formulations in stable renal patients.[81,143,218,278] Despite such suggestions of equivalence, Qazi and coworkers[269] showed that when switching from Neoral to the generic formulation Gengraf, nearly 20% of patients required dosage changes to maintain trough blood levels.

Numerous studies also have assessed the clinical outcomes in patients treated with generic formulations, with varied results. Sharma and associates[296] prospectively treated 37 de novo renal transplant recipients with either Neoral or the ArpimuneME (RPG Life Sciences, Mumbai, India) formulation, showing equivalent clinical outcomes at 6 months. Taber and colleagues[320] showed increased rates of acute rejection with the use of Gengraf in a retrospective review of de novo renal recipients. An analysis of data from the Collaborative Transplant Study shows significantly worse 1-year survival in patients treated with generic formulations,[73] but this has not been confirmed by Opelz in more recent data (Opelz, personal communication, 2007). Generic cyclosporine also is used widely in developing countries with no obvious deleterious effects (see Chapter 36).

When a switch to the use of generic cyclosporine formulations is being considered, patients must be closely monitored for the need for dosage adjustments. More prospective clinical data are required to confirm the impact of such formulations on long-term clinical outcomes.

CYCLOSPORINE VERSUS TACROLIMUS

Tacrolimus, a calcineurin inhibitor similar to cyclosporine, was introduced into transplantation in the early 1990s. There have been numerous clinical trials to try to determine whether tacrolimus is a better immunosuppressive agent than cyclosporine and to ascertain if the side-effect profiles are comparable. It is beyond the scope of this chapter to review all of the trials comparing cyclosporine with tacrolimus (see Chapter 17). The Cochrane Renal group produced a thorough systematic review and meta-analysis on this subject in 2005 that showed tacrolimus may provide significant improvements in graft survival and acute rejection rates over cyclosporine.[352] It was shown that graft loss with tacrolimus is reduced by 44% at 6 months and 29% at 3 years compared with cyclosporine. The data available for 5 years showed no significant benefit, however, in terms of graft survival with tacrolimus. Tacrolimus seemed to reduce acute rejection rates beyond 3 months and the rate of steroid-resistant acute rejections. Tacrolimus also was shown to be less nephrotoxic than cyclosporine as determined by serum creatinine levels. Tacrolimus did pose a significantly greater risk, however, with respect to post-transplant diabetes, with an incidence twice that of cyclosporine.

CYCLOSPORINE SPARING

During the early experience with cyclosporine in Cambridge, the side effect of nephrotoxicity was discovered.[47] This side effect had not been seen in the early animal models. The knowledge of this side effect and the resultant concern for the long-term effects on kidney grafts resulted in the cyclosporine-sparing protocols being introduced early after the introduction of cyclosporine. The first such protocol was developed in Oxford, where patients in a small phase I trial were randomly assigned to treatment with cyclosporine alone with conversion to azathioprine and prednisolone at 3 months or to the conventional treatment at that time of azathioprine and prednisolone.[227] There were 35 patients entered into the trial; 21 were randomly assigned to the conversion protocol, and 14 were assigned to the conventional treatment. The results of this study showed that the treatment with cyclosporine and conversion to azathioprine and prednisolone was satisfactory and that the renal function of those who were converted showed improvement after conversion from cyclosporine. A second, larger randomized trial from the same center produced similar results with good long-term graft survival, but there was a 25% incidence of acute rejection episodes after conversion, all of which responded to treatment or conversion back to cyclosporine.[229]

Other centers have adopted similar protocols of conversion to azathioprine. Some long-term results of these trials have been published more recently. Bakker and coworkers[19] published 15-year results of a randomized trial with conversion from cyclosporine and prednisolone to azathioprine and prednisolone at 3 months. There was no difference in patient survival over the 15 years, but there was worse graft survival in the patients remaining on cyclosporine, and the risk of chronic allograft nephropathy was greater in that group; patients who were converted to azathioprine had better renal function and required less antihypertensive medication.

Gallagher and colleagues[108] also published 15-year follow-up data on an Australian trial in which patients were randomly assigned to one of three arms: azathioprine and prednisolone, cyclosporine and prednisolone, or initial treatment with cyclosporine alone followed by conversion to azathioprine and prednisolone at 3 months. Their study showed no difference in patient survival or graft survival between the groups, but there was a benefit in graft function seen in the group converted to azathioprine.

A similar trial in Glasgow, in which patients were converted from cyclosporine and prednisolone to azathioprine and prednisolone at 1 year or continued on cyclosporine and prednisolone, showed that there was no difference in graft or patient survival at 15 years.[165] Graft function was improved in the conversion group at 2, 5, and 10 years, but by 15 years the improvement in renal function in the azathioprine group was no longer significant. The investigators also showed that conversion to azathioprine carried an increased risk of rejection; this was not seen or reported in the other trials, except from Oxford.

Although these trials seemed to have satisfactory short-term and long-term results, conversion protocols never became standard practice. More recently, sirolimus and MMF have been used to replace cyclosporine in patients with evidence of worsening graft function.[89,351] Both trials showed that conversion from cyclosporine to sirolimus[351] or MMF[89] can improve graft function without a resultant increase in acute rejection or graft survival in the short-term.

Other protocols have been considered in an attempt to reduce the nephrotoxic effects of cyclosporine. The protocols fall into four main categories: (1) replacement of cyclosporine by another agent (as mentioned earlier), (2) withdrawal of cyclosporine without addition of another immunosuppressive agent, (3) cyclosporine-free protocols (i.e., the patient never receives any cyclosporine at any point), and (4) reduction of the cyclosporine dose compared with normal.

The large Rapamune Maintenance Regimen (RMR) study, which looked at withdrawal of cyclosporine at 3 months from treatment with cyclosporine, sirolimus, and prednisolone, reported 4-year results that showed the withdrawal of cyclosporine resulted in graft survival of 91.5% at 4 years compared with 84.2% in the cyclosporine continuation arm ($P = .024$) and significantly better renal function with cyclosporine withdrawal.[246] No difference in acute rejection rates was seen. In a meta-analysis of calcineurin inhibitor (cyclosporine or tacrolimus) withdrawal from sirolimus-based therapy, Mulay and coworkers[232] looked at six trials, including the RMR trial, and found no benefit to graft survival with calcineurin inhibitor withdrawal. There was a significant increase, however, in acute rejection rate with calcineurin inhibitor withdrawal, although better renal function was seen with calcineurin inhibitor withdrawal.

Withdrawal protocols also have been used in regimens with MMF.[3,134,288,307] These trials all have a follow-up of at least 1 year and show no change in graft or patient survival between the cyclosporine continuation arm and the cyclosporine withdrawal arm. All four trials showed an increase in acute rejection rates in the cyclosporine withdrawal arm, but only two of the trials showed a benefit in renal function with cyclosporine withdrawal.[134,288]

Kasiske and associates[174] published a meta-analysis of trials of cyclosporine withdrawal from protocols with azathioprine. This meta-analysis showed a picture similar to the more recent meta-analysis by Mulay and coworkers,[232] mentioned previously. There was a significant increase in acute rejections in the cyclosporine withdrawal arm, but no difference in graft or patient survival. The meta-analysis did not comment on graft function.

Removing the risk of cyclosporine nephrotoxicity completely by using cyclosporine-free immunosuppressive regimens has been tried by using sirolimus instead of cyclosporine along with prednisolone and MMF or azathioprine.[101,126,193] These three trials showed similar results in that there was no difference in patient or graft survival or acute rejection rates, but the cyclosporine-free arms had better renal function. Different side-effect profiles were encountered with sirolimus, including poor wound healing, thrombocytopenia, hypercholesterolemia, and hypertriglyceridemia.

Another approach to reducing the nephrotoxic effects of cyclosporine, while maintaining its immunosuppressive properties, is to reduce the doses of cyclosporine used. Cyclosporine reduction has been tried in regimens containing conventional immunosuppressive agents such as azathioprine and MMF and in more novel protocols with the use of newer induction agents, such as alemtuzumab.

Cyclosporine reduction 1 year after transplantation in combination with azathioprine and prednisolone resulted in no change in graft or patient survival compared with full-dose cyclosporine, but there was a reduced rate of cancers, at the expense of an increase in acute rejection at 6 years after transplantation.[80] A similar study with cyclosporine reduction from the time of transplantation showed no difference in graft or patient survival or renal function at 7 years after transplantation, but the article did not report acute rejection rates; no difference in cancer incidence was seen.[225] Cyclosporine reduction in combination with MMF and prednisolone was shown to be effective in a study in which cyclosporine was reduced by 50% at 1 year after transplantation. Six-month results show a benefit in renal function over full-dose cyclosporine without any increase in acute rejection rate or change in graft survival.[259]

Alemtuzumab, a powerful lymphocytic monoclonal antibody, also has been used for induction to try to reduce exposure to cyclosporine. In a small randomized study, 20 patients who received alemtuzumab and low-dose cyclosporine monotherapy were compared with 10 control patients who received conventional triple therapy. At 6 months, there was no difference in acute rejection or graft and patient survival, but approximately 80% of patients with a functioning graft who received alemtuzumab were no longer taking steroids.[337]

There seems to be a general trend in most trials to try to reduce the nephrotoxic side effects of cyclosporine by reducing the patient's exposure to the drug in that often an improvement in renal function is observed, but reduction also may be associated with an increase in the incidence of acute rejection. This is a dilemma in that renal function at 1 year and acute rejection rates have been shown to be surrogate markers of long-term graft survival.[131] Does the improvement in renal function outweigh the increased risk of rejection? If one looks at the long-term results on conversion of cyclosporine to azathioprine from Glasgow,[165] although the study showed an improvement in renal function when converting to azathioprine, it also showed an increase in the incidence of acute rejection. There was no detrimental effect on long-term graft survival, however, by converting to azathioprine. One could conclude that the benefit of improved renal function outweighs the increased risk of acute rejection with regard to long-term graft survival. In these early trials, the dose of cyclosporine was higher than is currently used in triple-therapy regimens. A very strong case can be made for cyclosporine (or tacrolimus) conversion protocols, with the expectation that renal function will improve. A conversion protocol should be considered, however, only if regular and frequent follow-up is possible for at least 6 months after conversion.

MONITORING OF CYCLOSPORINE

Close monitoring of cyclosporine is essential to control the tradeoff between immunosuppression and the nephrotoxicity associated with long-term use. Cyclosporine levels are particularly valuable in the first 2 weeks after transplantation for detecting patients who are not absorbing the drug

adequately, and later on for detecting lack of compliance or adherence. Many drugs interact with cyclosporine, and measuring cyclosporine levels is valuable in monitoring these interactions (see Table 16-5).

Trough Monitoring

Traditionally, cyclosporine levels have been monitored at their trough, before administering the next dose (C_0 levels) (Fig. 16-4). Table 16-3 shows commonly used target levels. Although C_0 monitoring is convenient, allowing a relatively wide time window in which samples can be taken, there are questions as to how effective it is. The most accurate method of monitoring cyclosporine levels is calculating the AUC using multiple blood samples to give an estimate of total drug exposure. For the original and microemulsion formulations of cyclosporine, C_0 levels are shown to correlate poorly with AUC.[122,156,212] The relationship between C_0 levels and nephrotoxicity is not linear,[148,170] and C_0 levels correlate poorly with episodes of acute rejection.[212]

Area under the Curve

The inability of C_0 levels to predict important clinical outcomes accurately has fueled interest in finding a more effective monitoring strategy. Although an AUC measurement for the 12 hours following a dose correlates well with clinical outcomes, it is largely impractical outside of the research setting, requiring blood samples at multiple time points.[207,291] The microemulsion formulation of cyclosporine has the advantage of more rapid, more consistent absorption, which allows accurate monitoring with fewer blood samples. Gaspari and colleagues[111] showed a good correlation with the full AUC using samples taken at 1, 5, 8, and 11 hours, but 0, 1, and 3 hours also correlated well. Mahalati and others[177,212,213] showed that most variability in Neoral absorption occurs in the first 4 hours after administration, leading to the suggestion of a monitoring strategy measuring AUC for the first 4 hours after dosing ($AUC_{0\text{-}4h}$). Although $AUC_{0\text{-}4h}$ correlates well with clinical outcomes, it still requires multiple blood samples, making it impractical for everyday use. The ideal strategy is a single time point surrogate that correlates well with AUC and clinical outcomes, and a blood sample 2 hours after the ingestion of Neoral (C_2) is considered as the ideal surrogate marker.

Two-Hour Monitoring

The role of C_2 monitoring in organ transplantation has been systematically reviewed[186]; only the highlights of this review with respect to renal transplantation are presented here. Results from the International Neoral Renal Transplantation Study Group show that a blood sample taken 2 hours after intake of Neoral (C_2) is the most accurate one-point predictor for $AUC_{0\text{-}4h}$ and shows less variability than either C_0 or C_1. In clinical studies, retrospective analysis shows C_2 levels to correlate well with acute rejection in de novo renal transplant patients.[177,262] The Canadian Neoral Renal Transplant Study Group showed in retrospective analysis a significantly lower acute rejection rate in patients in whom C_2 levels were maintained at greater than 1500 μg/L in the 2 weeks after transplantation.[177] Dose adjustments in this study were based on trough levels.

The evidence from prospective studies with dose adjustment according to C_2 levels is less convincing. Commonly used target ranges in these studies are shown in Table 16-3. A group from Helsinki randomly assigned de novo renal transplant recipients to either C_0 or C_2 monitoring for the first 3 weeks after transplantation.[195] There was no significant difference in the rates of acute rejection between groups. Patients monitored by C_2 levels had difficulty reaching target levels, and the mean cyclosporine dose was 56% higher over the first 20 days. Although this difference in dose did not cause impairment in renal function over the short period of this study, over a longer time course this higher dose may have detrimental effects. A further randomized study from China contradicts these results, showing a significantly higher acute rejection rate in C_0 monitored patients.[348] The authors do not specify the C_0 target range or mean levels, however, and it is possible that a difference in target ranges could account for these differences. Many nonrandomized studies have failed to show a beneficial effect on

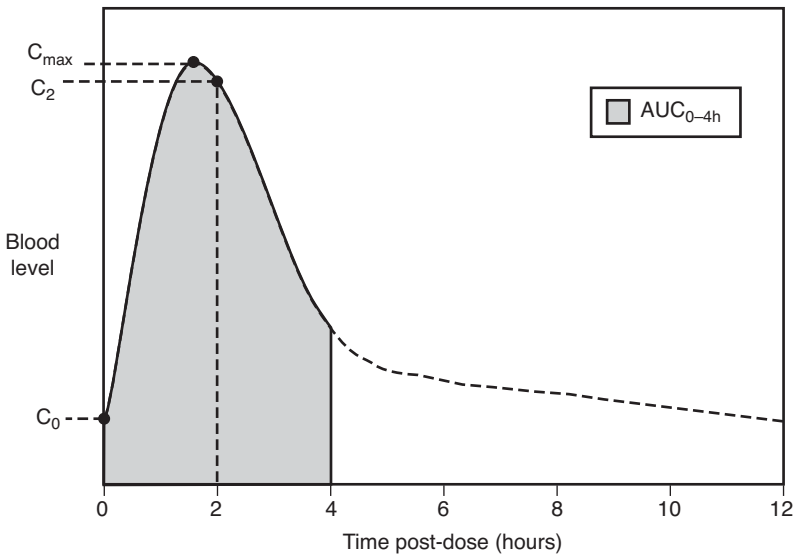

Figure 16–4 Cyclosporine absorption curve. C_0, trough (predose) level; C_2, 2-hour postdose level; C_{max}, maximal blood level; $AUC_{0\text{-}4h}$, area under the concentration-time curve from 0 to 4 hours.

Table 16–3 Commonly Used Cyclosporine Target Ranges from Prospective Trials*

	Time Post-Transplant (mo)		
	0-1	1-6	6-12
Target C_0 level (μg/L)	200-300	150-250	100-200
Target C_2 level (μg/L)	1500-1800	1000-1500	600-1000

*Guidelines based on prospective trials in published literature. Actual target range depends on concurrent immunosuppression.

acute rejection rates,[28,130,214,268,285] and some studies support the finding from the Helsinki study that the mean cyclosporine dose in the early period in C_2 monitored patients is significantly higher than the dose in patients monitored by C_0.[28,214,285] Most of these nonrandomized studies show no difference in renal function between groups.

Less evidence is available in stable renal transplant recipients. The only randomized trial to date involved patients more than 3 months post-transplantation, who were randomly assigned to continue monitoring by C_0 levels or switched to C_2 monitoring. Although there was no difference in acute rejection rates between the cohorts, the switch to C_2 monitoring allowed a dose reduction in 34% of patients compared with reductions in 14.3% of patients monitored by C_0. Observations from before and after studies in which cohorts of stable patients are switched from C_0 to C_2 monitoring support these findings of significant cyclosporine dose reductions with no increase in acute rejection rates.[69,71,305] Despite the dose reductions, none of these studies show an improvement in renal function during follow-up periods of 40 months.

When considering the role of C_2 monitoring in patient management, logistical aspects must be addressed. Blood samples for C_2 levels are taken during a more dynamic phase of cyclosporine absorption than samples for trough levels, making accurate timing of sampling essential. Consensus guidelines suggest that there is a 15-minute "window of opportunity" before and after the 2-hour point in which samples should be taken.[204] More recent evidence suggests that this window may be 10 minutes to give an acceptable (±20%) error around the true value.[279] Although such strict timing requirements may be adhered to in the context of a clinical trial, it is likely that problems will arise in the setting of a busy outpatient clinic.

Indirect evidence suggests an advantage of C_2 monitoring over trough levels. Retrospective analysis shows that the risk of acute rejection is reduced in patients in whom a certain threshold for C_2 is exceeded.[177] In prospective studies, these advantages are not substantiated. In the Helsinki study, 45% of C_2 monitored patients failed to reach the target levels by day 5 post-transplantation compared with 2.5% of C_0 monitored patients.[195] This difficulty in reaching target levels may partially explain why the theoretical benefit of C_2 monitoring in the early post-transplant period is not borne out. It can be argued that if such difficulty is met trying to reach target levels in the controlled environment of a clinical trial, it would be even more difficult to implement such a strategy in a nontrial population. For this reason, more prospective evidence, particularly in the early postoperative period, is required before adoption of C_2 monitoring can be recommended. For the moment, trough levels (C_0) remain the standard despite the inherent poor correlation with outcomes.

Cyclosporine Assays

Regardless of the sampling points used, the laboratory measurement of cyclosporine has been the subject of much interest over the years.[161] The reference "gold standard" is often regarded as high-performance liquid chromatography because of its specificity and ability to separate the parent compound from metabolites. High-performance liquid chromatography can lead to poor precision with difficulty identifying low plasma concentrations of the drug, however, and does not have a short enough turnaround time for the busy transplant clinic.[207]

Many nonspecific and specific immunoassays are available (Table 16-4). Although the nonspecific assays show a poor relationship to clinical events, the specific assays are much more clinically useful[207] and tend to be the most commonly used. Novartis, the manufacturer of Neoral, recommends high-performance liquid chromatography as the reference method but reports the specific immunoassays as sensitive, convenient, and reproducible alternatives (Neoral product literature).

Even the newer specific immunoassays have drawbacks. There is still cross-reactivity of the antibodies used in these assays with inactive metabolites of cyclosporine leading to overestimation of blood levels, the magnitude of which cannot be easily predicted.[315] The immunoassays have limited analytical ranges with an inability to detect potentially significant low levels of cyclosporine, while requiring dilution for the measurement of high blood concentrations adding a potential source of error. For this reason, the laboratory in Oxford has now adopted the use of a rapid liquid chromatography–mass spectrometry method to enable the accurate and rapid detection of cyclosporine blood levels over a wide concentration range. This method gives good agreement with the existing enzyme multiplied immunoassay technique.[175]

DRUG INTERACTIONS

Cyclosporine is metabolized almost entirely in the liver, mostly through the cytochrome P-450 system. Most of the drug is excreted in the bile, with only trace amounts being

Table 16–4 Assays Available for Monitoring of Cyclosporine

High-performance liquid chromatography
Rapid liquid chromatography–tandem mass spectrometry
Nonspecific polyclonal immunoassays

Specific monoclonal immunoassays
  Abbott TDx (Abbott Laboratories, Abbott Park, Ill., USA)
  Abbott AxSYM (Abbott Laboratories, Abbott Park, Ill., USA)
  DiaSorin Cylo-Trac-SP (RIA) (Diasorin S.p.A., Vercelli, Italy)
  ADIVA Centaur (Siemens Healthcare Diagnostics, Inc., Tarrytown, NY, USA)

excreted in the urine. Drugs that induce hepatic enzymes, such as rifampicin, increase the rate of metabolism of cyclosporine and decrease blood levels of the parent compound. Other drugs that are potentially nephrotoxic, such as gentamicin, have an additive effect with cyclosporine on nephrotoxicity. It is important to be aware of known drug interactions and to keep in mind the possibility of other, but as yet unconfirmed, interactions. The measurement of levels is important in detecting such interactions and in the monitoring of levels at which drugs with known interactions have to be used. Table 16-5 lists well-known interactions. All known interactions are noted, and the relevant citations to the literature are given in the "Sandimmune Drug Interactions and Neoral Drug Interactions," available from the Novartis Medical Information Department (Basel, Switzerland); these are continually updated and are available on the Internet.

Other drugs or dietary products that can affect cyclosporine levels include atorvastatin, which has been shown to increase cyclosporine trough concentration by 25%,[274] and grapefruit juice, which can increase cyclosporine AUC by 37%.[29] Lopinavir and ritonavir (antiretroviral protease inhibitors) have been shown to increase levels of cyclosporine such that doses could be reduced to 5% to 20% of the initial dose to maintain AUC concentrations.[342] Isoniazid has been shown to decrease cyclosporine levels,[76] as has more recently vitamin C and vitamin E supplementation.[30,84]

Cyclosporine itself alters the plasma levels of other drugs. It can increase the levels of methotrexate and reduce the clearance of digoxin, colchicine, prednisolone, and 3-hydroxy-3-methylglutaryl-coenzyme A reductase inhibitors.

Table 16–5 **Drugs That Interact with Cyclosporine**

Drugs That May Potentiate Renal Dysfunction
Amphotericin B
Cimetidine
Ciprofloxacin

SIDE EFFECTS OF CYCLOSPORINE

Renal Effects

Nephrotoxicity is the most worrying side effect of cyclosporine (and similarly tacrolimus) and is of particular concern in renal transplantation, in which it has to be distinguished from acute or chronic rejection as a cause of deteriorating renal function. In the early rat and dog models of transplantation, nephrotoxicity was not noted. Nephrotoxicity became evident soon after initial clinical use,[47] however, and the investigators advocated the use of cyclosporine only in patients whose kidneys were diuresing after transplantation.[49] Nephrotoxicity subsequently was shown in animal models using larger doses and more sophisticated evaluation of renal function, and some morphological changes attributed to nephrotoxicity in humans were observed.[354,355]

Three clinical types of nephrotoxicity are observed with cyclosporine. The first occurs immediately after transplantation, usually in a kidney already damaged by ischemia and perhaps associated with the use of intravenous cyclosporine. The nephrotoxic effect of cyclosporine in experimental models of ischemia of the kidney has been controversial in that one of the first attempts to show this interaction in dogs failed to do so.[151] Since then, the susceptibility of the ischemic kidney to damage by cyclosporine has been well documented in rat models.[65,158,173] In humans, the incidence of delayed function after renal transplantation has tended to be higher in patients treated with cyclosporine than in patients given azathioprine and steroids,[14,297] although there is no general agreement about this.[99] The implications of the possible additive effects of cyclosporine nephrotoxicity on an ischemic kidney are important because they suggest that protocols that delay the administration of cyclosporine until adequate renal function is established are more appropriate. Because intravenous cyclosporine is rarely used now, however, this type of toxicity is not seen as commonly as the acute and chronic cyclosporine nephrotoxicity seen with oral cyclosporine.

Acute Cyclosporine Nephrotoxicity

The second type of nephrotoxicity is seen any time after the first 2 or 3 weeks and is associated with deteriorating renal function, usually but not always associated with high trough blood levels of cyclosporine, and responds to a reduction in cyclosporine dosage. This type of nephrotoxicity has to be differentiated from an acute rejection episode. As pointed out in Chapter 14, this differentiation often is difficult because the florid signs of acute rejection previously seen in patients taking azathioprine and prednisolone (i.e., fever, graft tenderness and swelling, oliguria, and rapidly increasing serum creatinine levels) are much less evident in patients treated with cyclosporine. Although high blood trough levels

often are associated with nephrotoxicity and low levels are associated with rejection, there are numerous exceptions to this.[148] If the serum creatinine level has increased to greater than 300 μmol/L, it suggests rejection, and treatment for rejection should be started (e.g., 0.5 g of methylprednisolone intravenously daily for 3 days) while awaiting the results of the obligatory graft biopsy; this should be followed by an improvement in renal function.[103] At lower levels of serum creatinine, without any other clinical evidence of rejection, a significant reduction in the dose of cyclosporine (e.g., by 30%) should be implemented, and an improvement in renal function should follow rapidly if true nephrotoxicity is present; if not, a biopsy should be performed.

Percutaneous biopsy or fine-needle aspiration of the kidney can be valuable in helping to make the correct diagnosis; at Oxford, both approaches have been used in cases of acute renal dysfunction in which the distinction between rejection and nephrotoxicity is unclear. The development of an automated percutaneous needle biopsy technique has made frequent biopsies quick, easy, and safe. There are no definite morphological changes in biopsy specimens that implicate cyclosporine nephrotoxicity; the diagnosis still tends to be one of exclusion.[78,239] A simple technique for measuring the intrarenal pressure has been described by Salaman and Griffin[280]; they claimed it distinguishes rejection (pressures >40 mm Hg) from nephrotoxicity (pressures <40 mm Hg) with a high degree of accuracy.[281] With the simplicity of ultrasound-guided biopsy today, however, this technique no longer has a place, as is also the case with fine-needle aspiration biopsy. This type of nephrotoxicity recovers rapidly with a cyclosporine dosage reduction or conversion to azathioprine, MMF, and prednisolone.[61]

Cyclosporine-induced acute nephrotoxicity is caused by functional changes that result in a reduction in renal blood flow, an increase in renal vascular resistance, and a decrease in glomerular filtration rate.[261] The metabolites of cyclosporine have a similar effect.[276] These changes are reversible on reduction or withdrawal of cyclosporine, resulting in improvement in renal function usually within 1 week. The mechanisms involved that result in the changes to the renal vasculature that cause the nephrotoxicity are likely multifactorial and interdependent. They include an increase in the vasoactive substance endothelin I, the activation of the renin-angiotensin system resulting in increased levels of angiotensin II, and a decrease in the synthesis of nitric oxide (NO).

The vasoactive peptide, endothelin, potentially may contribute to the hemodynamic alterations caused by cyclosporine.[261] Endothelin release is increased from smooth muscle cells in culture on exposure to cyclosporine and in patients on cyclosporine who have received bone marrow transplants.[132] This increase in endothelin subsequently has been shown in kidney transplant recipients[59] and heart transplant recipients.[203] The fact that the use of endothelin receptor blockers in animals has been shown to reduce cyclosporine-mediated vasoconstriction of afferent arterioles[197] and that endothelin receptors are upregulated in rats with cyclosporine-induced nephrotoxicity[260] suggests that endothelin may have a role in acute cyclosporine nephrotoxicity.

The renin-angiotensin system is believed to play an important role in acute nephrotoxicity because it has been shown experimentally that cyclosporine increases plasma renin activity[201,233] and that cyclosporine causes hyperplasia of the juxtaglomerular apparatus, where renin is synthesized.[201,240] Increased levels of renin also have been shown in non–renal transplant patients treated with cyclosporine.[166] An increase in renin alters renal hemodynamics, resulting in a decrease in renal function. The blockade of the renin-angiotensin system by angiotensin-converting enzyme inhibitors and angiotensin II receptor blockers has provided some evidence of improved renal hemodynamics in the presence of cyclosporine.[43,52,277,299]

NO is a powerful vasodilator, and it has been implicated in acute cyclosporine nephrotoxicity, although there seems to be some confusion as to its role. There is some debate as to whether cyclosporine increases or decreases NO production. It has been shown in healthy volunteers to increase NO production, but in recipients of renal transplants it has been shown that basal and stimulated levels of NO are reduced,[231] and in rat models cyclosporine has been shown to increase, reduce, and not alter NO production.[44] The effect of NO on blood vessels also has been tested, and it has been shown that cyclosporine reduces endogenous epithelium-dependent vasodilation mediated by NO.[39,109,215] Cyclosporine has been shown not only to enhance endothelial NO synthetase activity, causing an increase in NO production, but also to decrease acetylcholine-induced NO production.[238,318]

The role of NO is unclear; it is likely multifactorial, and whether NO is causative in cyclosporine-induced nephrotoxicity, or the changes in NO production are an effect of cyclosporine nephrotoxicity is unknown. It is suggested that changes in NO production may have a causative role to play because blocking NO production can induce similar histopathological changes as seen in cyclosporine administration.[31,32] Also, promoting NO production by the administration of L-arginine, a substrate for NO synthetase, protects against the effects of NO blockade and the changes seen with cyclosporine administration.[10,359] This protection has been shown experimentally, but L-arginine has not been proved to show any protective effect in clinical trials.[187]

Other factors that may have a role in acute nephrotoxicity are the increase in thromboxane, the production of free radicals, and the increase in sympathetic tone, all of which may be attributed to cyclosporine.[44,45,53,57] Another possible uncommon manifestation of acute cyclosporine nephrotoxicity is a hemolytic-uremic syndrome–like condition that occurs in the first week after transplantation. A biopsy specimen shows striking arteriolopathy and thrombosis. Despite the striking nature of the histological findings, a return of renal function was noted with cessation of cyclosporine or the use of streptokinase and heparin.[181,272,310]

Chronic Cyclosporine Nephrotoxicity

Chronic cyclosporine nephrotoxicity is a condition in which there is a slow, steady deterioration in renal function, and the histology of the kidney may reveal severe interstitial fibrosis (see Chapter 25). This type of nephrotoxicity shows some improvement in renal function with a decrease in the cyclosporine dosage, but this improvement tends to be short-lived. It is likely that many of the changes observed result from chronic immunological damage on which some element of cyclosporine nephrotoxicity is superimposed. That chronic changes of cyclosporine nephrotoxicity do occur is unquestioned in view of the striking morphological changes of interstitial fibrosis and tubular atrophy observed in the native kidneys of patients with uveitis treated

with cyclosporine.[257] After cardiac transplantation, this steady deterioration in renal function of patients receiving cyclosporine resulted in some patients requiring hemodialysis[234]; this remains a problem in cardiac transplantation and is seen also in liver transplant patients. Chronic nephrotoxicity probably is a cumulative effect of initial ischemic damage to the kidney in association with high early doses of cyclosporine. A hypothesis was put forward by Salomon,[282,283] however, in which he postulates that the deterioration of renal function in patients on cyclosporine was not due to cyclosporine nephrotoxicity but represented chronic rejection resulting from underimmunosuppression as doses of cyclosporine are reduced with time. There is no evidence to support this hypothesis, intriguing as it was at the time.

TGF-β type 1 has been suggested to play a role in chronic cyclosporine nephrotoxicity. TGF-β type 1 is a prosclerotic cytokine. Detectable levels have been found in the plasma of transplant recipients but not in healthy controls or patients with membranous nephropathy. There was no difference in levels among patients with differing renal function, time since transplantation, or cyclosporine trough levels.[75] In isolated human renal proximal tubular cells, increasing concentrations of cyclosporine caused an increase in the production by the tubular cells of TGF-β and platelet-derived growth factor, both fibrogenic cytokines.[159] In a study of renal biopsy specimens, TGF-β content correlated with cyclosporine toxicity, as opposed to acute tubular necrosis. TGF-β also was expressed in biopsy specimens from patients with acute rejection, however, with more expression in patients with more severe rejection.[258] Another study on renal biopsy specimens showed that nonrejected kidneys lacked TGF-β expression, whereas biopsy specimens from kidneys with acute rejection, chronic allograft nephropathy, or acute cyclosporine toxicity showed high levels of TGF-β expression.[254]

In rats receiving cyclosporine on a low-sodium diet, a model for cyclosporine toxicity that gives similar histological appearances to those of chronic cyclosporine toxicity in humans, mRNA expression of TGF-β was increased. Peripheral renin activity also was increased.[300] Human mesangial cells and renal fibroblasts in culture also produced more collagen III on exposure to cyclosporine.[113] Cyclosporine also has been shown to increase the expression of TGF-β and its receptors in mesangial cells and the production of fibronectin and plasminogen activator inhibitor by mesangial cells.[343]

Studies have shown that some of the changes seen in chronic cyclosporine nephrotoxicity can be prevented by the use of anti–TGF-β antibodies,[157,208] strengthening the argument for cyclosporine-induced increase in TGF-β having a role in the development of chronic cyclosporine nephrotoxicity. It is uncertain, however, what therapeutic benefit would result from reducing TGF-β because, as has been previously mentioned in this chapter (and in Chapter 2), TGF-β also may have a positive role to play in immunomodulation and preventing acute rejection.

As mentioned earlier in the rat model of chronic cyclosporine nephrotoxicity, renin is increased as well as TGF-β. There is evidence to support the fact that the renin-angiotensin system also may play a part in chronic cyclosporine nephrotoxicity. Cyclosporine has been shown to stimulate the renin-angiotensin system in many studies.[43,110,222] The increase in activation of the renin-angiotensin system has been linked with the morphological changes that occur in chronic cyclosporine nephrotoxicity by experimental studies in which angiotensin II receptor blockers have been shown to reduce these changes.[264,300,360]

The current mechanism by which cyclosporine stimulates the renin-angiotensin system is unknown. It is generally accepted that it increases renin release from the juxtaglomerular apparatus and that the mechanism is probably multifactorial.[199,205] Other mechanisms that are thought to be involved in chronic cyclosporine nephrotoxicity are the decrease in renal NO production caused by cyclosporine; the upregulation of osteopontin by cyclosporine, which is a chemotactic factor for macrophages resulting in macrophage infiltration and fibrosis; the induction of apoptosis of some renal cells by cyclosporine; and the activation of nuclear factor κB and activator protein 1 (AP-1), which are transcription factors thought to have a role in chronic nephrotoxicity.[57,205]

Hepatic Effects

Hepatotoxicity has been observed in patients receiving cyclosporine after renal, cardiac, and bone marrow transplantation (see Chapter 30).[136,185,253] Generally, this hepatotoxicity has not been more than a temporary elevation of liver enzymes on function tests that regressed on dosage reduction. These biochemical changes are uncommon with the lower doses of cyclosporine used today. No histological changes have been described in association with these biochemical changes, but high doses of cyclosporine in rats produce ultrastructural changes and a deterioration in liver function.[331] Cyclosporine may be contraindicated in patients with abnormal liver function tests before renal transplantation because there is a risk of the development of frank cirrhosis in such patients.[145] Because cyclosporine is metabolized in the liver, depressed liver function may alter blood levels of the drug, and careful attention must be paid to cyclosporine levels in such patients.

Neoplastic Effects

An apparent increased incidence of lymphomas in the early patients with a renal allograft receiving cyclosporine caused considerable alarm.[26,27,328] As time has passed, however, this increased incidence of lymphoma in renal and cardiac allograft recipients is no greater than that expected in recipients treated with azathioprine and steroid therapy. Most patients who developed lymphomas received other drugs as well, such as prednisolone and antilymphocyte agents, suggesting that the occurrence of lymphoma is due to excessive immunosuppression, rather than specifically to cyclosporine. The pathogenesis and incidence of lymphomas are described in detail in Chapter 33. Skin cancer, a major complication after transplantation in countries such as Australia with heavy sun exposure, appears just as commonly with cyclosporine immunosuppression, and this too is described in detail in Chapters 32 and 33. It has been observed that cyclosporine produces striking morphological changes in vitro, including increased cell motility, and in vivo, enhancing tumor growth in immunodeficient SCID-beige mice. These effects seem to be mediated by TGF-β. Cyclosporine potentially can promote tumor progression independent of its effect on the immune response.[147]

More recently, the protumor effects of cyclosporine have been linked to its promotion of tumor angiogenesis by a vascular endothelial growth factor–dependent mechanism.[128] It has been shown that cyclosporine can increase vascular endothelial growth factor.[301] Cyclosporine also may promote tumor growth independent of its effect on the immune system because it has been shown to increase IL-6 in Epstein-Barr virus–infected B cells, and IL-6 is capable of promoting B cell growth and possible progression to post-transplantation lymphoproliferative disorder.[323,345] The DNA repair capabilities of cells also may be disrupted by cyclosporine, with it affecting DNA repair in a dose-dependent fashion.[138]

In contrast, there is some evidence that cyclosporine has antitumor activity. It was previously suggested that cyclosporine may inhibit drug resistance in cancer cells,[334] and more recently it has been used in combination with cytotoxic drugs to reverse the tumor resistance to those drugs.[206]

Dermatological Effects

Dermatological problems, of which hypertrichosis is the most worrisome, are discussed in detail in Chapter 32. In children, facial dysmorphism may be striking. This feature is not evident in children receiving azathioprine and steroids.[77]

Gastrointestinal Effects

The development of a gelatin capsule for cyclosporine was welcomed by most patients. The capsules are large and difficult to swallow, however, and some patients prefer to take the liquid form. Cyclosporine in the liquid form is unpleasant to take and is not disguised adequately even when taken with flavored drinks, such as orange juice or chocolate milk. The unpalatability of cyclosporine causes nausea and anorexia in some patients, particularly with large doses, but in general this is less of a problem with current low doses.

Metabolic Effects

Hyperkalemia is common in patients taking cyclosporine[4,102] and is reversible with reduction of the dose or cessation of the drug.[62] The mechanism is unclear, but the decreased potassium excretion may be due to decreased serum aldosterone levels[4,20] or to a primary tubular defect.[20]

Renal handling of uric acid is affected by the use of cyclosporine, leading to higher serum urate levels in cyclosporine-treated patients after correction for elevated serum creatinine levels.[61] The high urate levels return to normal slowly over several weeks after discontinuing the drug and probably reflect a tubular defect associated with cyclosporine nephrotoxicity. Gout occasionally occurs as a by-product of the hyperuricemia, and urate levels may need to be reduced with allopurinol, remembering that the leukocyte count needs to be monitored carefully if the patient is taking azathioprine and cyclosporine.

Hypomagnesemia is due to an increased magnesium clearance in patients taking cyclosporine and usually is associated with high blood levels of the drug.[6,167] Hypomagnesemia reflects another manifestation of cyclosporine nephrotoxicity. Convulsions, which may be another manifestation of cyclosporine toxicity (as discussed in the next section and in Chapter 31), have been attributed to hypomagnesemia.

Glycosuria may occur in patients taking cyclosporine and is often associated with an increased blood glucose level. Glycosuria is a manifestation of nephrotoxicity,[60] but hyperglycemia may reflect a toxic effect of cyclosporine on beta cells of the islets of Langerhans. This condition seems to be reversible. There is evidence in rats that cyclosporine produces glucose intolerance, probably through the inhibition of insulin secretion.[358]

Neurological Effects

A variety of neurological complications have been reported with the use of cyclosporine, including tremor, convulsions, various paresthesias of the limbs, mania, and depression.[18,21,124,329,346] These complications are discussed in detail in Chapter 31. Although neurological syndromes are not always clearly caused by cyclosporine, there is sufficient evidence that such syndromes can be attributed to cyclosporine toxicity in many instances because they seem to be associated with high serum and blood levels. The syndrome is reversible with dosage reduction. These problems have become infrequent with current low doses of cyclosporine. Some evidence suggests that cyclosporine-induced hypomagnesemia may be the cause of these neurological complications, especially the convulsions, as already mentioned.

Cardiovascular Effects

Hypertension and hyperlipidemia are associated with the use of cyclosporine and are discussed in detail in Chapter 28. Cyclosporine seems to have complex effects on intravascular coagulation, and there have been reports of an increased incidence of renal artery and vein thrombosis[14,164,223,275] and an increase in the incidence of deep venous thrombosis,[336] which was not confirmed at Oxford (see Chapter 26).[7] Although it is tempting to attribute these complications, including microangiopathy and hemolytic-uremic syndrome, to the effect of cyclosporine on the arachidonic acid metabolic pathway as discussed earlier, the evidence is too uncertain to draw any firm conclusions. Raynaud's phenomenon seems to be another uncommon complication of cyclosporine therapy,[86] and one such case has occurred at Oxford.

Dental Effects

Gingival hypertrophy (see Fig. 32-3) is associated with poor dental hygiene and high doses of cyclosporine[293] and is discussed in detail in Chapter 32.

Hematological Effects

ABO autoimmune hemolytic anemia may occur after renal transplantation when a blood group O kidney is placed in a blood group A or B recipient. Several such cases have been reported,[25,216,242] although ABO autoimmune hemolytic anemia is more common after liver transplantation.[270] The occurrence of this complication, a form of graft-versus-host reaction, reflects the better immunosuppression achieved with cyclosporine.

Genotoxicity and Breast-Feeding

Experimental animal and human data so far indicate that cyclosporine is unlikely to be genotoxic.[248] In studies reported so far, there has been no increase in congenital anomalies or genetic disease. Monitoring should be continued, however, to increase the sample size.

Cyclosporine concentrations in breast milk were similar to concentrations in blood, but they were below detection limits in breast-fed infants. No change in creatinine levels of the infants occurred over 12 months of continued breast-feeding.[243]

Skeletal Effects

Although the major culprit for osteopenia after kidney transplantation is the use of steroids in immunosuppression protocols, it may be that cyclosporine also contributes to the loss of bone mass. Animal studies have shown that cyclosporine has adverse effects on bone and mineral metabolism, with a resulting loss in bone volume, although most clinical studies do not show these toxic effects of cyclosporine on bone, including studies in which cyclosporine is used without steroids.[135,311]

Antiviral Effects

Cyclosporine may possess anti–human immunodeficiency virus (HIV) and anti–hepatitis C virus (HCV) properties. It has been shown that cyclophilin A (the intracellular protein with which cyclosporine binds) is involved in the maturation and replication of HIV-1, and that by cyclosporine binding to cyclophilin A this process can be altered.[317] The use of cyclosporine in HIV-1-infected individuals has been shown to increase the CD4 count and to reverse HIV-associated lymphadenopathy.[11] The effect on CD4 T cells may be due to the ability of cyclosporine to prevent HIV-related activation–induced T cell apoptosis.[127] Cyclosporine also seems to slow the progression of HIV infection to AIDS. In a review of cases of transplant patients who contracted HIV either through their transplant or through blood transfusions at the time of transplant, the 5-year cumulative incidence of AIDS was 31% in patients who were taking cyclosporine compared with 90% ($P = .001$) in patients who were not taking cyclosporine.[292]

Cyclosporine also seems to have the ability to alter HCV viral replication through a mechanism similar to that of HIV. Cyclophilin B is a cellular replication cofactor of the HCV genome, and by binding cyclophilin B, cyclosporine shows anti-HCV properties.[349,350]

CONCLUSION

Cyclosporine, the first calcineurin inhibitor, represented a major advance in immunosuppression when it became available in the early 1980s, the first new immunosuppressive drug since the advent of azathioprine 2 decades earlier. The striking effect of cyclosporine was the reduction in the rate of acute irreversible rejection in the first 3 months after transplantation, with a resultant increase in 1-year graft survival by 15% to 20% compared with that achieved previously with azathioprine and steroids. However, side effects, mostly dose related, soon became evident, the most serious of which was nephrotoxicity. As a result, the decline in graft survival after 1 year was not altered, the major benefits being obtained in that first year—actually in the first few months—after transplantation. In recent years, considerable efforts have been directed at protocols that allow cyclosporine sparing or withdrawal to diminish the nephrotoxicity and other side effects. Nevertheless, calcineurin inhibitors have a major role in renal transplantation and are likely to remain in use for some time.

Chapter 17

Tacrolimus in Renal Transplantation

Amit Basu • Ron Shapiro

Tacrolimus is an immunosuppressive agent that has improved clinical outcomes in liver and kidney transplant recipients.[39] The phase III trials leading to Food and Drug Administration (FDA) approval of tacrolimus (in 1994) were conducted first in liver rather than in kidney transplant recipients, in contrast to other immunosuppressive agents. Subsequent clinical trials in kidney transplantation led to FDA approval for kidney transplantation in 1997. By 2003, 67% of all new kidney transplant recipients and 89% of all new liver transplant recipients were receiving tacrolimus as maintenance immunosuppressive therapy before discharge[116]; these percentages have continued to increase over time.

Tacrolimus (FK506, Prograf) was isolated in 1984 from the fermentation broth of *Streptomyces tsukubaensis*, a soil organism found at the foot of Mount Tsukuba near Tokyo. This compound was developed by researchers at the Chiba University of Japan. In the first clinical (rescue) trial, tacrolimus was administered to patients who were taking standard immunosuppressive therapy but who faced retransplantation because of ongoing organ rejection, or who had undesirable drug toxicities.[39] The initial clinical trial of tacrolimus as a primary immunosuppressive agent for the prophylaxis of rejection in liver transplant recipients began in the spring of 1990 at the University of Pittsburgh.[125] This work led eventually to multicenter randomized trials in liver and kidney transplantation.[86,99] Patients treated with tacrolimus had significantly fewer and less severe episodes of acute rejection than did patients given cyclosporine therapy. Tacrolimus also has shown efficacy as a rescue agent and as a primary maintenance immunosuppressive agent in heart, lung, pancreas, and small bowel transplantation[44,58,76,89,104,123] and was approved for heart transplantation in 2006.

MECHANISM OF ACTION

Tacrolimus inhibits T lymphocyte activation by binding to FK BP-12, an intracellular protein. A complex is then formed of tacrolimus–FK BP-12, calcium, calmodulin, and calcineurin, which inhibits the phosphatase activity of calcineurin. This complex prevents the dephosphorylation and subsequent translocation of the nuclear factor of activated T cells (NF-AT), a nuclear component that initiates gene transcription for the formation of interleukin-2 (Fig. 17-1). As a result, T lymphocyte activation is inhibited.[39] Tacrolimus is 10 to 100 times more potent than cyclosporine in its immunosuppressive effects.[100] Tacrolimus inhibits nitric oxide synthetase activation; it also inhibits apoptosis and potentiates the action of corticosteroids in the inhibition of apoptosis (see Chapter 16).[65,90]

PHARMACOKINETIC PROPERTIES

The pharmacokinetic characteristics of tacrolimus show high interindividual and intraindividual variability, and the drug has a narrow therapeutic index; therapeutic drug monitoring is necessary to optimize treatment. Because 90% of the drug is partitioned in the cellular components of blood, whole blood concentrations correlate better with drug exposure (area under the curve) than do plasma concentrations.[23]

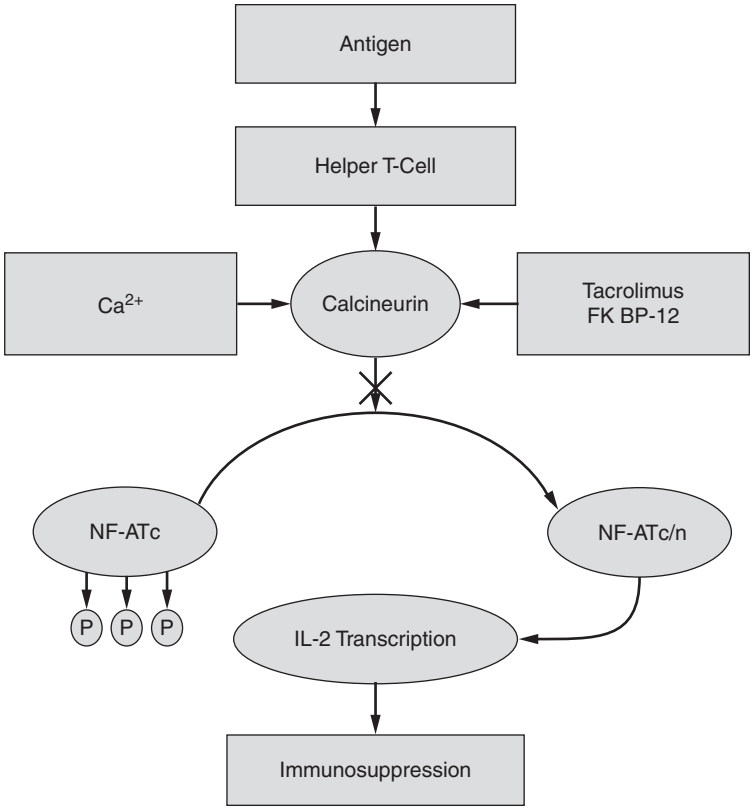

Figure 17–1 Mechanism of action of tacrolimus. A complex is formed of tacrolimus–FK BP-12, calcium, calmodulin, and calcineurin, which inhibits the phosphatase activity of calcineurin. This prevents the dephosphorylation and subsequent translocation of nuclear factor of activated T cells (NF-AT), a nuclear component that initiates gene transcription for the formation of IL-2. C, Cytoplasm; n, nucleus, P, phosphate. (From Fung JJ: Tacrolimus and transplantation: a decade in review. Transplantation 77:S41, 2004.)

Therapeutic drug monitoring of tacrolimus can be achieved using whole-blood trough concentrations to individualize dose requirements and reduce drug-related toxicity.[12]

ABSORPTION AND DISTRIBUTION

Tacrolimus is rapidly, but incompletely, absorbed in the gastrointestinal tract, and peak tacrolimus concentrations in whole blood are attained 1 to 2 hours after oral administration.[131] Tacrolimus has low oral bioavailability (average 25%; range 4% to 93%).[131] The mean oral bioavailability of tacrolimus is comparable in adult (25%) and pediatric (31%) transplant recipients. The rate and extent of absorption of tacrolimus is reduced in the presence of food, with the peak concentration in whole blood compared with the fasting state decreased by approximately 50% to 75%, and the area under the curve decreased by 25% to 40% when the drug is taken after a meal.[100] Tacrolimus is highly bound to erythrocytes, in a concentration-dependent manner, with reduced ratios at higher drug concentrations related to binding saturation. Plasma protein binding may be 99%, with most of the drug bound to α_1-acid glycoprotein and albumin. Tacrolimus is widely distributed in most tissues, including the lungs, spleen, heart, kidney, pancreas, brain, muscle, and liver; tacrolimus crosses the placenta, with umbilical cord plasma concentrations one third of those in maternal plasma.[100,131] Tacrolimus also is present in breast milk, but at extremely low levels (<2.5 ng/mL).

METABOLISM AND ELIMINATION

Tacrolimus is metabolized extensively in the liver and, to a much lesser extent, in the intestinal mucosa, with metabolism mediated at both sites by cytochrome P-450 (CYP) 3A4 isoenzymes.[100,131] Tacrolimus is converted by hydroxylation and demethylation to at least 15 metabolites, with the main metabolite being 13-*O*-dimethyl-tacrolimus. The mean clearance after intravenous administration of tacrolimus is as follows: 0.040 L/hr/kg in healthy volunteers, 0.083 L/hr/kg in adult kidney transplant patients, 0.053 L/hr/kg in adult liver transplant patients, and 0.051 L/hr/kg in adult heart transplant patients. When administered orally, fecal elimination accounts for 92.6 ± 3.07% and urinary elimination accounts for 2.3 ± 1.1% of the administered dose in healthy volunteers.[5]

The main drugs that interact with tacrolimus when administered simultaneously are either inducers or inhibitors of CYP3A4. Although CYP3A4 inhibitors potentially increase whole-blood tacrolimus concentrations, CYP3A4 inducers decrease tacrolimus concentrations (Table 17-1; see Chapter 16).

SPECIAL PATIENT POPULATIONS

Three percent of patients require higher dosages (>0.4 mg/kg/day) to reach therapeutic tacrolimus concentrations; this is a reflection of the low bioavailability and, to a lesser extent, the high clearance of the drug.[131] In a nonblinded, parallel-group study, the bioavailability of tacrolimus was significantly (P=.01) lower in African-American (11.9%) and Latin-American (14.4%) patients than in white patients (18.8%).[82] A retrospective study in renal transplant recipients showed that African-American recipients required higher dosages of tacrolimus on a milligram-per-kilogram basis.[131]

Children typically require higher tacrolimus dosages on a milligram-per-kilogram basis than adult patients, most

Table 17–1 **Drug Interactions Associated with Tacrolimus**

Drugs Increasing Tacrolimus Concentration (Cytochrome P-450 3A4 Inhibitors)
Calcium channel blockers—diltiazem, nicardipine, nifedipine, verapamil
Imidazole antifungal agents—clotrimazole, fluconazole, itraconazole, ketoconazole
Macrolide antibiotics—clarithromycin, erythromycin
Prokinetic agents—cisapride, metoclopramide
Other drugs—bromocriptine, cimetidine, corticosteroids, danazol, protease inhibitors
Grapefruit juice
Drugs Decreasing Tacrolimus Concentration (Cytochrome P-450 3A4 Inducers)
Anticonvulsants—carbamazepine, phenobarbital, phenytoin
Rifabutin/rifampicin, isoniazid
St. John's wort

likely reflecting the higher mean total body clearance and volume of distribution in children. Clinically relevant differences do not exist between adults and children, however, in terms of the time taken to reach maximal blood concentrations (2.1 hours in children versus 2 hours in adults), bioavailability (31% versus 25%), and mean terminal elimination half-life (11.5 hours versus 12 hours).[108] The mean clearance of tacrolimus in patients with renal dysfunction was similar to that in normal volunteers; tacrolimus pharmacokinetics after a single intravenous administration was similar in seven patients not receiving dialysis and five receiving dialysis.[5]

The mean clearance of tacrolimus in patients with mild hepatic dysfunction (mean Pugh score of 6.2) was not substantially different from that in normal volunteers after a single intravenous and oral dose. The mean clearance was substantially lower in patients with severe hepatic dysfunction (mean Pugh score >10), regardless of the route of administration.[5]

CLINICAL STUDIES IN KIDNEY TRANSPLANTATION

Rescue Therapy in Adults

The efficacy of tacrolimus in kidney transplantation was first shown in recipients with refractory rejection. Tacrolimus showed remarkable efficacy in the therapy of refractory rejection[74]; the first article on tacrolimus rescue was by Jordan and colleagues,[64] and the first multicenter trial was reported by Woodle and coworkers.[147] Refractory rejection episodes in cyclosporine-treated patients could be reversed by replacing cyclosporine with tacrolimus as the maintenance immunosuppressive agent. In contrast to antilymphocyte antibody preparations (e.g., OKT3 and polyclonal antibody preparations) that induce long-term suppression of T cell responses, the immunosuppressive effects of tacrolimus could be titrated on a daily basis by following drug levels.[74]

An early large experience with tacrolimus in treating refractory acute renal allograft rejection in 77 patients receiving cyclosporine-based immunosuppressive therapy was reported from Pittsburgh.[64] Several conclusions were drawn from this study, as follows: (1) Tacrolimus provided effective therapy for acute renal allograft rejection, (2) tacrolimus often provided effective therapy for vascular rejection in kidney transplants, and (3) the success of tacrolimus therapy for refractory acute renal allograft rejection was related to the severity and duration of rejection.

The 5-year follow-up of the Pittsburgh experience showed good long-term renal allograft function in patients undergoing tacrolimus rescue therapy.[62,63] A total of 169 patients were converted from cyclosporine to tacrolimus for refractory rejection, with a 74% success rate and a mean serum creatinine value of 2.3 ± 1.1 mg/dL (202 μmol/L). Of the patients receiving dialysis at the time of tacrolimus initiation, 46% were salvaged, with a mean serum creatinine level of 2.2 ± 0.4 mg/dL (189 μmol/L). Corticosteroid withdrawal was achieved in 22% of patients after conversion to tacrolimus, and the mean prednisone dose was reduced from 28 ± 1.1 mg/day to 8.5 ± 4.1 mg/day.

A prospective, randomized, multicenter comparative trial has confirmed the efficacy of tacrolimus-based rescue therapy in patients with acute renal transplant rejection.[31] Rescue therapy with tacrolimus-based regimens reduced the incidence of recurrent acute rejection to 8.8% versus 34.1% ($P = .002$) in patients who remained on cyclosporine-based immunosuppression. Three-month Kaplan-Meier estimates for freedom from a second biopsy-proven acute rejection were 89.1% versus 61.4% ($P = .002$) in the tacrolimus-rescue and the cyclosporine-continuation groups, respectively. Freedom from treatment failure was 72.6% versus 43% ($P = .005$), with treatment failure being defined as graft loss, second acute rejection, or withdrawal from treatment.

In a large European study on tacrolimus conversion for cyclosporine-induced toxicities, 73% of patients with cyclosporine-induced gingival hyperplasia ($n = 32$) showed significant resolution of hyperplasia, and recipients with cyclosporine-induced hypertrichosis ($n = 116$) showed marked improvement. The mean serum low-density lipoprotein (LDL) level decreased from 138 mg/dL to 120 mg/dL, and the high-density lipoprotein levels remained unchanged in patients with cyclosporine-induced hyperlipidemia ($n = 78$). Finally, hypertension had markedly or completely resolved in 25% of patients ($n = 75$).[101]

Antibody-Mediated Rejection

Antibody-mediated rejection often occurs within the first 2 weeks after transplantation and is associated with oliguria, graft tenderness, fever, leukocytosis, and circulating antidonor antibodies. Before the introduction of tacrolimus, combinations of bolus corticosteroids, plasmapheresis, and antilymphocyte antibody preparations were used to treat acute humoral rejection, with inconsistent and unsatisfactory response rates. Tacrolimus-based regimens were developed for acute humoral rejection in renal transplant recipients, based on clinical experiences with tacrolimus in treating liver and heart transplants with acute humoral rejection.[98,144,145] Experimental evidence also supported the potential of tacrolimus in limiting antibody responses.[137,138]

Tacrolimus-based regimens for treating acute humoral rejection are based on the removal of circulating antibody at the time of the rejection episode (by plasmapheresis), suppressing the formation of new antidonor antibody

with high-dose tacrolimus, and monitoring kidney allograft histology with protocol biopsies. Tacrolimus-based regimens were shown to reverse antibody-mediated rejection in renal allograft recipients.[143,146] In one series, all four patients had aggressive rejection episodes confirmed by immunohistopathology. These rejections were treated successfully with daily plasmapheresis for 5 days and high-dose tacrolimus (initial target levels 20 to 25 ng/mL) that resulted in reversal of rejection and allowed long-term graft survival. This regimen was not associated with life-threatening opportunistic infections or post-transplant diabetes mellitus (PTDM), despite high tacrolimus trough levels. The efficacy of tacrolimus in acute humoral rejection preceded the use of plasmapheresis and intravenous immunoglobulin regimens in the management of humoral rejection and highly sensitized patients (see Chapter 22).[143,146,148]

Maintenance Immunosuppression

The outcomes of kidney transplantation have improved with the advent of powerful immunosuppressive agents such as tacrolimus and the use of tacrolimus as part of highly effective immunosuppressive regimens. Several studies have addressed short-term outcomes of immunosuppression, including rates of acute rejection and patient and graft survival. Studies also have addressed medium-term outcomes with tacrolimus-based immunosuppression, including 5-year patient and graft survival, renal function, cardiovascular events, and post-transplant diabetes mellitus.

Comparison of Tacrolimus-Based and Cyclosporine-Based Regimens

The phase III U.S. multicenter clinical trial compared the efficacy and safety of tacrolimus with that of the original formulation of cyclosporine.[99] At 1 year post-transplantation, 30.7% of tacrolimus-treated patients had experienced acute rejection compared with 46.4% of cyclosporine-treated patients ($P = .001$). The incidence of moderate-to-severe rejection was 10.8% in the tacrolimus-treated group compared with 26.5% in the cyclosporine-treated group. Intent-to-treat analysis revealed that the 1-year patient survival was 95.6% and 96.6% for the tacrolimus-treated and cyclosporine-treated patients, respectively (P = nonsignificant [NS]). The 1-year graft survival rate was 91.2% and 87.9% for the tacrolimus-treated and cyclosporine-treated patients, respectively (P = NS). The intent-to-treat analysis showed no significant differences in 5-year patient or graft survival between the tacrolimus-treated and the cyclosporine-treated patients. When crossover because of rejection was counted as graft failure, a statistically significant increase in graft survival was found in the tacrolimus group at 5 years (63.8% versus 53.8%; $P = .014$).[132] There also was a significant difference in the serum creatinine level between the tacrolimus-treated and cyclosporine-treated patients and in the number of patients who had a serum creatinine value greater than 1.5 mg/dL (tacrolimus 40.4% versus cyclosporine 62%; $P = .0017$). The patients treated with tacrolimus had a lower incidence of hirsutism and gingival hyperplasia, but a higher incidence of alopecia than patients treated with cyclosporine.

Racial differences also were evaluated for acute rejection in the U.S. phase III multicenter clinical trial.[96] Among African-Americans, 23.2% of patients in the tacrolimus-treated group developed acute rejection compared with 47.9% of patients in the cyclosporine-treated group ($P = .012$). When crossover because of rejection was counted as graft failure, there was a significant increase in the 5-year graft survival in African-American patients in the tacrolimus-treated group (65.4% versus 42.6%; $P = .013$) compared with the cyclosporine-treated group.[133]

The U.S. multicenter study that compared the efficacy and tolerability of tacrolimus versus cyclosporine also revealed that significantly fewer kidney transplant recipients required antihypertensive treatment in the tacrolimus-treated group compared with the cyclosporine-treated group.[59] In this 3-year multicenter comparative study, tacrolimus was associated with a significantly lower incidence of hypercholesterolemia than was cyclosporine (24% versus 38%; $P = .007$), and the need for lipid-lowering agents was significantly lower in the tacrolimus-treated patients (14% versus 38%; $P < .001$).[59] The projected graft half-life evaluated by the European Multicenter Renal Transplant Study also favored tacrolimus over cyclosporine (15.8 years versus 10.8 years).[85]

All adult kidney transplants from 1995 to 2000 reported to United Network for Organ Sharing/Organ Procurement and Transplantation Network were analyzed by discharge immunosuppression.[13] The 1-, 3-, and 5-year adjusted actuarial graft survival rates with the tacrolimus-based regimens were 91.8%, 81.1%, and 69.8%, and for the cyclosporine-based regimens, these rates were 90.3%, 79.9%, and 67.5% ($P < .0001$).

A single-center report studied the effects of immunosuppression on African-American recipients undergoing kidney transplantation between 1995 and 2001.[37] The 1-year and 5-year graft survival rates for African-Americans were 89% and 79% with tacrolimus-based therapy and 85% and 60% with cyclosporine-based therapy ($P = .006$).

Cadaver donors reported to the Scientific Registry of Transplant Recipients Database between 1995 and 2002 were included in a study analyzing paired kidneys in which one kidney was allocated to a patient who was treated with cyclosporine microemulsion and the other kidney was allocated to a patient receiving tacrolimus therapy.[67] There was no difference in 5-year patient or graft survival. Renal function was superior in the tacrolimus-treated group at all time points. The 6-month inverse creatinine levels were significantly worse in the microemulsion cyclosporine arm compared with the tacrolimus arm ($P < .0001$).

In normal, healthy subjects, treatment with cyclosporine increased baseline creatinine level and blood pressure and reduced renal plasma flow and glomerular filtration rate in otherwise normal kidneys. In contrast, treating normal human subjects with tacrolimus did not influence renal hemodynamic parameters, and the mean arterial blood pressure remained unchanged.[72]

A multicenter trial evaluated the effect of tacrolimus as secondary intervention in patients being treated with cyclosporine for 3 or more months after transplantation who had one of the following risk factors for chronic renal allograft failure: serum creatinine 2 mg/dL or greater for men and 1.7 mg/dL or greater for women, or a greater than 30% increase in the nadir post-transplant serum creatinine level.

The trial randomly assigned 197 patients to convert to tacrolimus or remain on cyclosporine.[136] At 24 months, 56.8% of the patients in the tacrolimus-treated group and 87.5% in the cyclosporine-treated group had a serum creatinine level 2 mg/dL or greater ($P = .002$). Significantly fewer patients who were converted from cyclosporine to tacrolimus experienced a cardiovascular event compared with patients who continued treatment with cyclosporine (5.6% versus 24.3%; $P = .002$). Median serum cholesterol and LDL cholesterol levels were significantly lower in the tacrolimus-treated group compared with the cyclosporine-treated group. Therapeutic intervention with tacrolimus resulted in improved renal function, better lipid profiles, and fewer cardiovascular events in patients who were at risk for developing chronic renal allograft failure.[136]

Patients who have an acute rejection episode and hypercholesterolemia have a more than twofold greater risk of graft loss.[133] These combined risk factors were significantly different between treatment arms (tacrolimus 4.7% versus cyclosporine 17.4%; $P = .0008$). In another study, tacrolimus therapy was associated with a significantly reduced requirement for medications to control hypertension and hyperlipidemia. A 6-month study of 560 patients in the European Tacrolimus versus Cyclosporine Microemulsion Renal Transplantation Study Group showed that patients treated with cyclosporine had significantly higher rates of hypertension (23.2% versus 15.7%; $P = .032$) and hypercholesterolemia (8.9% versus 4.2%; $P = .037$) compared with the tacrolimus-treated group.[84]

Blood pressure and lipid profiles were measured in stable renal transplant recipients during initial treatment with cyclosporine and again after 4 weeks of treatment with tacrolimus.[81] Antihypertensive drugs were stopped at least 3 weeks before the study. After patients were switched to tacrolimus, the mean daytime blood pressure decreased from 149 ± 12 mm Hg/95 ± 8 mm Hg to 138 ± 13 mm Hg/87 ± 9 mm Hg ($P < .001$). Total and LDL cholesterol levels also decreased from 6.1 ± 0.7 mmol/L and 3.84 ± 0.79 mmol/L to 5.1 ± 0.8 mmol/L and 2.98 ± 0.75 mmol/L ($P < .001$).[81]

A randomized, prospective study was done to compare the clinical and economic outcomes of tacrolimus versus cyclosporine in a regimen consisting of antithymocyte globulin (ATG) (Thymoglobulin) induction, an antimetabolite, and prednisone.[51] At 1 year, acute rejection, patient survival, graft survival, and the rate of cytomegalovirus infection were similar. Creatinine levels were lower in the tacrolimus-treated group compared with the cyclosporine-treated group. The requirement for dyslipidemia treatment was statistically similar at 12 months after transplant (30% tacrolimus versus 35% cyclosporine). Total 12-month medication costs were similar ($17,723 ± $11,647 tacrolimus versus $16,515 ± $10,189 cyclosporine).[51]

A clinical study conducted in the early 1990s that compared treatment with cyclosporine versus tacrolimus found that significantly more patients who received tacrolimus-based immunosuppression developed PTDM.[132] A more recent study that compared treatment with tacrolimus versus cyclosporine found a similar incidence of PTDM for both regimens, however.[128] The decrease in insulin secretion caused by treatment with tacrolimus was dose-dependent and reversible. PTDM was reversible when tacrolimus blood levels were reduced (see Chapter 16).

Comparison of Tacrolimus/Azathioprine and Tacrolimus/Mycophenolate Mofetil Regimens

A randomized, prospective three-arm study compared the impact of immunosuppressive protocols using tacrolimus/azathioprine ($n = 76$), cyclosporine microemulsion/mycophenolate mofetil (MMF) ($n = 75$), and tacrolimus/MMF ($n = 72$).[60] At 1 year, although there were no significant differences in overall rejection rates, there were significant differences in the total number of patients who required antilymphocyte antibody treatment (4.2% in the tacrolimus/MMF arm compared with 10.7% in the cyclosporine/MMF arm and 11.8% in the tacrolimus/azathioprine arm; $P = .05$). There were no significant differences among the three groups in patient or graft survival at 1, 2, and 3 years.[2,41,60] In patients with delayed graft function, there was a trend toward improved graft survival in the tacrolimus-based treatment group at 1 year. This trend became significant when the tacrolimus/MMF arm was compared with the cyclosporine/MMF arm at 2 and 3 years. At 3 years, the serum creatinine level was significantly lower in the tacrolimus-treated patients than in the cyclosporine-treated patients.[41]

Comparison of Tacrolimus/Mycophenolate Mofetil and Tacrolimus/Sirolimus Regimens

Long-term post-transplant renal function is influenced by the incidence of acute rejection episodes, chronic allograft nephropathy, age of the kidney donor, and the use of calcineurin inhibitors.[132] Analysis of registry data examining the rate of change of creatinine clearance for patients who received kidney transplants between 1990 and 2000 showed that renal function improved in transplants performed after 1997. A more stable creatinine clearance was associated with tacrolimus versus cyclosporine therapy and with MMF versus azathioprine therapy.[43]

A randomized study comparing the combination of sirolimus or MMF with tacrolimus-based immunosuppression showed no significant differences in the incidence of biopsy-confirmed acute rejection (13% tacrolimus/sirolimus [$n = 185$] versus 11.4% tacrolimus/MMF [$n = 176$]; $P = .64$).[42] Graft survival and patient survival were not significantly different between the groups at 6 months after transplantation. Significantly more recipients discontinued treatment with sirolimus (21.1% versus 10.8%; $P = .0008$). Renal function was significantly better in the tacrolimus/MMF group (serum creatinine 1.44 ± 0.45 mg/dL versus 1.77 ± 1.42 mg/dL; $P = .018$). The combination of tacrolimus and MMF was superior to tacrolimus and sirolimus in terms of improved renal function and a lower risk of hypertension and hyperlipidemia.[42]

The incidence of acute rejection was significantly higher in the cyclosporine/sirolimus arm (21% versus 4% for tacrolimus/sirolimus and 4% for tacrolimus/MMF; $P = .013$) in a randomized trial comparing these three regimens in renal transplantation.[91] At 12 months after transplantation, the mean serum creatinine level was 1.48 mg/dL in the tacrolimus/sirolimus treatment group, 1.29 mg/dL in the tacrolimus/MMF treatment group, and 1.69 mg/dL in the cyclosporine/sirolimus treatment group ($P < .05$).

Analysis at 3 years showed similar patient and graft survival rates among the three groups. There was a trend toward better graft function, fewer endocrine disorders, and fewer acute rejection episodes in the tacrolimus/MMF group versus the tacrolimus/sirolimus or cyclosporine/sirolimus groups.[25]

Several publications have reported on the comparison of the efficacy of tacrolimus and MMF with that of tacrolimus and sirolimus. The course of 97 kidney transplant patients treated with sirolimus and reduced-dose tacrolimus was reviewed. The outcomes of 19 patients who were converted to a tacrolimus/MMF protocol for various nonrenal side effects were compared with 78 patients who remained on a tacrolimus/sirolimus protocol. Tacrolimus levels were increased in patients who were converted. Conversions from tacrolimus/sirolimus to tacrolimus/MMF led to improved renal function, however, despite increased tacrolimus exposure after conversion.[6]

A prospective study compared the safety and efficacy of steroid avoidance in tacrolimus/MMF ($n = 75$) and tacrolimus/sirolimus ($n = 75$) in kidney transplantation. The primary end point was acute rejection. Surveillance biopsies were done to analyze subclinical acute rejection and chronic allograft nephropathy. Clinical acute rejection and subclinical acute rejection were treated with methylprednisolone.[75] Two-year patient and graft survival, renal function, and adverse effects were monitored. Steroid avoidance under tacrolimus-based immunosuppression with MMF or sirolimus provided equivalent 2-year patient and graft survival, with a low incidence of acute rejection and new-onset diabetes mellitus. Subclinical acute rejection and chronic allograft nephropathy were lower in the tacrolimus/sirolimus group than in the tacrolimus/MMF group.

These optimistic findings were countered by an analysis of 44,915 adult renal transplants in the Scientific Renal Transplant Registry from 2000 to 2004. A total of 3524 (7.8%) patients received a baseline immunosuppressive regimen of tacrolimus/sirolimus, with an inferior overall survival ($P < .001$) and death-censored graft survival ($P < .001$) compared with tacrolimus/MMF ($n = 27{,}007$). In multivariate Cox models, the adjusted hazard ratio for overall graft loss with tacrolimus/sirolimus was 1.47 and with cyclosporine/sirolimus was 1.38 relative to tacrolimus/MMF. These effects were most apparent in high-risk transplants. Six-month acute rejection rates were low and did not differ among groups.[88] These data have to be interpreted in the context of the limitations of any retrospective database analysis.

The efficacy of combining tacrolimus and two different dosages of sirolimus was compared with a tacrolimus/MMF regimen.[135] In addition to tacrolimus, 325 patients received 2 mg/day of sirolimus (tacrolimus-sirolimus 2 mg), 325 patients received 0.5 mg/day of sirolimus (tacrolimus-sirolimus 0.5 mg), and 327 patients received 1 g/day of MMF (tacrolimus-MMF). Steroid dosing was identical in all groups. The incidence of biopsy-proven acute rejection was lower in the tacrolimus-sirolimus 2 mg group compared with the tacrolimus-sirolimus 0.5 mg and tacrolimus-MMF groups. Graft and patient survival were similar among the three groups. Combining 2 mg/day of sirolimus with tacrolimus resulted in reduced rates of acute rejection, but a greater incidence of adverse events, including hyperlipidemia, hypertension, lymphoceles, and new-onset diabetes mellitus.

Comparison of Tacrolimus-Based Dual versus Triple Immunosuppression Therapy

Dual immunosuppression therapy refers to the use of tacrolimus with a second agent, such as a corticosteroid. Triple immunosuppression therapy refers to the use of tacrolimus and a corticosteroid with a third agent, such as azathioprine or MMF.

Dual therapy with tacrolimus-based immunosuppression provided similar efficacy to tacrolimus-based triple therapy for 36 months.[17,22,40,97,109,119] At 12 months, patient survival rates in the dual-therapy groups were ≥96% compared with ≥94% with triple therapy, with graft survival rates of ≥90% (dual-therapy groups) and ≥91% (triple-therapy groups). Three-year follow-up data are available from the Italian and Spanish trial, and graft survival was 87% in dual-therapy and triple-therapy groups. A similar percentage of patients experienced an acute rejection episode with dual-therapy or triple-therapy tacrolimus-based immunosuppressive regimens. Most of these episodes occurred in the first year after transplantation, with a 10-fold to 15-fold reduction in the incidence of rejection over the next 2 years.[40,97] In one study, the addition of MMF to tacrolimus plus corticosteroid therapy significantly ($P = .007$) reduced the incidence of rejection at 9 months.[119]

A prospective, randomized trial was performed to compare FK506/prednisone with FK506/azathioprine/prednisone from August 1, 1991, to October 11, 1992. With a mean follow-up of 9 ± 4 months, the 1-year actuarial patient survival in the two-drug group was 95%, and for the three-drug group it was 91% (P = NS). One-year actuarial graft survival in the two-drug group was 90%, whereas in the three-drug group it was 82% (P = NS).[113] In another prospective, randomized trial reported from the same center, the combination of tacrolimus and prednisone was compared with tacrolimus, MMF, and prednisone in renal transplant recipients.[114] The combination of tacrolimus, steroids, and MMF was associated with excellent patient and graft survival and a lower incidence of rejection than occurred with the combination of tacrolimus and steroids.

Role of Tacrolimus and Corticosteroids in the Development of Hypertension and Hyperglycemia

Steroid dosing may play an important part in the development of complications after transplantation (see Chapter 15). In one study, patients were evaluated 4 months after kidney transplantation; twice as many patients treated with tacrolimus and high-dose prednisone developed hypertension compared with patients treated with tacrolimus and low-dose prednisone (63% versus 32%; $P < .05$).[30]

Corticosteroids may promote the development of PTDM by inducing insulin resistance, decreasing insulin receptor number and affinity, impairing endogenous glucose production, and impairing glucose uptake by muscle.[107] Reducing or withdrawing corticosteroids reduces hyperglycemia and can reduce the incidence of PTDM; however, it also can increase the risk of acute rejection.[55]

A study was done to assess the relative role of tacrolimus and corticosteroids in the development of glucose metabolic disorders.[10] Corticosteroid withdrawal in patients receiving tacrolimus-based immunosuppression led to a 22% decrease

in fasting C-peptide levels ($P = .0009$). Fasting insulin levels and the insulin-to-glucose ratio decreased (P = NS). Steroid withdrawal also led to a reduction in lipid levels. Tacrolimus trough level reduction from 9.5 ng/mL to 6.4 ng/mL resulted in a 36% increase in pancreatic beta cell secretion ($P = .04$), and insulin secretion increased by a similar rate. Hemoglobin A_{1c} improved from 5.9% to 5.3% ($P = .002$), although lipid levels did not change after trough level reduction.[10] Corticosteroid withdrawal resulted in a decrease in insulin resistance and a reduction in lipid levels; reduction of tacrolimus trough levels also improved glucose metabolism.

Early Corticosteroid Withdrawal Regimens

The safety of early corticosteroid withdrawal (see Chapter 15) was evaluated by a prospective, randomized, multicenter, double-blind study of early (7 days post-transplantation) corticosteroid cessation versus long-term maintenance of corticosteroids along with tacrolimus, MMF, and antibody induction in primary renal transplant patients.[142] Patient and graft survivals at 1 year were 98% and 96%, respectively. Biopsy-proven acute rejection occurred in 9.8% of patients, and 4% were treated empirically for rejection. Interim analysis suggested that early withdrawal of corticosteroids was safe, resulting in excellent patient and graft survival, low acute rejection rates, and no graft loss to rejection.[142]

A prospective, randomized study was done to determine the ideal long-term maintenance immunosuppressive regimen after discontinuation of prednisone on day 5.[66] Patients were randomly assigned to receive cyclosporine/MMF ($n = 85$), low-dose sirolimus/high-dose tacrolimus ($n = 72$), or high-dose sirolimus/low-dose tacrolimus ($n = 82$). No significant differences in patient or graft survival, acute rejection, or serum creatinine were noted; four patients developed PTDM (all in the tacrolimus-sirolimus groups). The incidence of wound complications was greater in the tacrolimus-sirolimus arms ($P = .02$), but the incidence decreased when the sirolimus loading dose was stopped.

A randomized, prospective trial of early steroid withdrawal versus low-dose steroids was performed in renal transplant recipients.[77] Serial protocol biopsies were done to assess efficacy and safety. Sixty patients were randomly assigned into two groups: Control patients ($n = 28$) received low doses of prednisone throughout, and study patients ($n = 32$) were withdrawn from steroids 7 days post-transplant. Immunosuppression consisted of rabbit ATG induction therapy, tacrolimus and MMF. Protocol biopsies were performed at 1, 6, and 12 months. Renal function was well maintained and was equivalent in both groups. The immunosuppressive combination of rabbit ATG, tacrolimus, and MMF prevented subclinical rejection and the need for high doses of steroids after transplantation. Serial protocol biopsy specimens showed increased allograft fibrosis over time in both groups, however, which was significant at 1 year in the steroid-withdrawal group.

In another study, 101 patients underwent renal transplantation with tacrolimus, MMF, and 7 days of corticosteroids.[11] Anti-CD25 monoclonal antibody was administered to 25 patients at higher immunological risk. After a median follow-up of 51 months (range 36 to 62 months), patient survival was 97%, and graft survival was 91%. The incidence of acute rejection at 12 months was 19%. Only three further episodes of rejection occurred beyond 12 months. Graft function was stable during the study, with a mean estimated creatinine clearance of 57 mL/min at the end of follow-up. This steroid avoidance regimen was associated with excellent medium-term patient and graft outcomes and a low incidence of side effects.

Corticosteroid-Free Immunosuppression Regimens

A 6-month, open-label, multicenter, parallel-group study included 538 renal patients randomly assigned (1:1) to a daclizumab/tacrolimus/MMF regimen ($n = 260$) or a tacrolimus/MMF/corticosteroid regimen ($n = 278$).[104] The incidence of biopsy-proven acute rejection was 16.5% in both treatment groups; the incidence of biopsy-proven corticosteroid-resistant acute rejection was 4.3% and 5% in the tacrolimus/MMF/corticosteroids and daclizumab/tacrolimus/MMF groups (P = NS). The median serum creatinine level at 6 months and overall safety profile were similar with both regimens. Compared with the tacrolimus/MMF/steroid regimen, a significantly lower incidence of new-onset insulin-dependent diabetes mellitus (5.4% versus 0.4%; $P = .003$) was found with the steroid-free regimen. Mean total cholesterol concentrations increased from baseline in the tacrolimus/MMF/corticosteroids group by 0.19 mmol/L; in the daclizumab/tacrolimus/MMF group, cholesterol concentrations decreased by 0.19 mmol/L.[104]

A single-center, nonrandomized, retrospective sequential study was used to evaluate outcomes in kidney transplant recipients given either alemtuzumab (Campath) ($n = 123$) or basiliximab ($n = 155$) in combination with a prednisone-free maintenance protocol using tacrolimus and MMF.[69] There was no significant difference in the 3-year graft and patient survival rates between the two groups. A lower rate of early (<3 months) rejection was observed in the alemtuzumab (4.1%) versus the basiliximab (11.6%) group, but rejection rates for both groups were equivalent at 1 year. Patient and graft survival and rejection rates were nearly identical between whites and African-Americans receiving alemtuzumab. The quality of renal function and the incidence of infectious complications were similar between the alemtuzumab and basiliximab groups.

Recipient pretreatment by lymphoid depletion using ATG or alemtuzumab combined with minimal post-transplant immunosuppression was used as an innovative approach to the management of kidney transplant recipients.[110] This treatment algorithm was derived from the notion that rejection and tolerance are stages of the same continuum.[120] The usually dominant host-versus-graft response can be reduced to a more easily deletable range by pretreatment with polyclonal ATG or the humanized monoclonal antibody, alemtuzumab. The aim of minimal post-transplant immunosuppression is to reduce further the clonal response with enough treatment to prevent irreversible immune damage to the graft, but not such heavy treatment that donor-specific clonal exhaustion-deletion is precluded (Fig. 17-2).[110]

Based on the aforementioned principles, 150 unselected renal transplant recipients with a mean age of 51 ± 15 years were pretreated with 5 mg/kg of rabbit ATG in the hours before transplantation, with two boluses of intravenous methylprednisolone to prevent cytokine reactions.[112] Minimal post-transplant immunosuppression was with

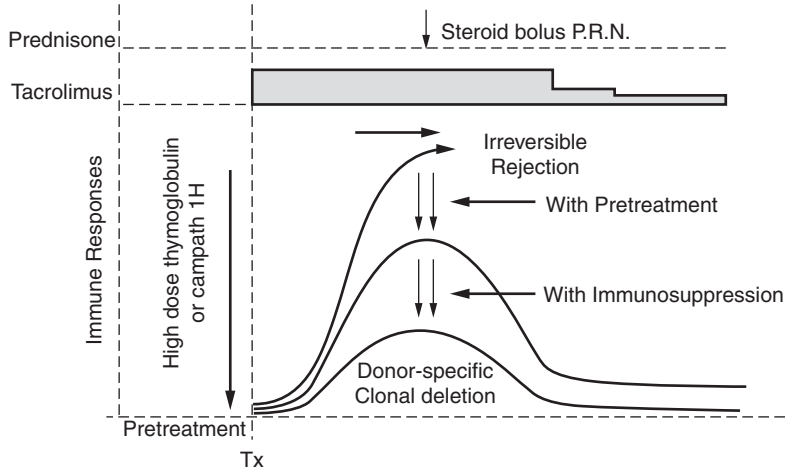

Figure 17–2 Mechanism of tolerogenic immunosuppression. Conversion of rejection (*arrows on the curve "irreversible rejection"*) to an immune response that can be exhausted and deleted by combination of pretreatment with high-dose antithymocyte globulin (Thymoglobulin) or alemtuzumab (Campath) and minimalistic post-transplant immunosuppression with tacrolimus. (From Starzl TE, Murase N, Abu-Elmagd K, et al: Tolerogenic immunosuppression for organ transplantation. Lancet 361:1502-1510, 2003.)

tacrolimus monotherapy to which steroids or other agents were added only for the treatment of rejection. Four months after transplantation, patients were consolidated to once-daily tacrolimus monotherapy; 2 or more months later, spaced weaning was carried out in stable patients. One-year patient and graft survivals were 97% and 92%, respectively. The incidence of early acute rejection was 37%; however, only 7% required prolonged treatment with agents other than tacrolimus. With a follow-up of 6 to 21 months, 94 (63%) of the 150 patients were receiving spaced doses of tacrolimus ranging from every other day to once a week.

The results in ATG-pretreated patients (n = 101) or alemtuzumab-pretreated patients (n = 90) were compared with the results in 152 conventionally immunosuppressed recipients in the immediately preceding era.[110] Spaced weaning was attempted in more than 90% of the kidney transplant recipients after pretreatment with either lymphoid-depleting agent. Although there was a much higher rate of acute rejection in the ATG-pretreated recipients than in the alemtuzumab-pretreated recipients, patient and graft survivals in both lymphoid depletion groups were at least equivalent to the survivals of historical control patients. Kidney transplantation after lymphoid depletion was readily accomplished under minimal immunosuppression, with less dependence on late maintenance immunosuppression, fewer viral complications, and less post-transplant diabetes. Alemtuzumab was the more effective agent for pretreatment.[110]

Two corticosteroid-free, tacrolimus-based regimens were compared with standard triple therapy in a 6-month, phase III, open-label, parallel-group multicenter study.[134] Four hundred fifty-one patients were randomly assigned (1:1:1) to receive tacrolimus/MMF/corticosteroids, tacrolimus/MMF, or tacrolimus monotherapy with basiliximab induction. The incidences of biopsy-proven acute rejection were 8.2% (triple therapy), 30.5% (tacrolimus/MMF), and 26.1% (basiliximab/tacrolimus) ($P < .001$). The incidences of corticosteroid-resistant acute rejection were similar among the groups (P = NS). Graft and patient survival rates were similar among the groups. Overall safety profiles were similar: Differences were noted for anemia (24.5% versus 12.6% versus 14.5%), diarrhea (12.9% versus 17.9% versus 5.9%), and leukopenia (7.5% versus 18.5% versus 5.9%) for the triple therapy, tacrolimus/MMF, and basiliximab/tacrolimus groups. Both corticosteroid-free regimens were equally effective in preventing acute rejection, with the basiliximab/tacrolimus regimen offering some safety benefits.[134]

A randomized clinical trial was done using three different induction agents in 90 first renal transplant recipients from cadaver donors: Group A received ATG, group B received alemtuzumab, and group C received daclizumab.[24] Maintenance immunosuppression included tacrolimus and MMF in all three arms, and methylprednisolone in groups A and C. Targeted trough levels of tacrolimus were 8 to 10 ng/mL in groups A and C, and the MMF dose was 1 g twice daily. The target tacrolimus trough levels in group B were 4 to 7 ng/mL to reduce nephrotoxicity, with 500 mg twice daily MMF and no steroid maintenance. At 15 months post-transplantation, no differences were noted among the groups in terms of patient and graft survival. Acute rejection at 1 year was equivalent in all three groups. In group B, there was slightly worse renal function at 1 month, but no difference at 1 year. Group B patients had more leukopenia, but a greater percentage of T regulatory cells and number of Fox-P3 RNA copies by flow cytometry and semiquantitative polymerase chain reaction analysis. In group B, 80% of patients remained steroid-free 1 year postoperatively with lower tacrolimus trough levels and no other adverse events.[24] At 18 months, although there were no differences in the incidences of acute rejection or infectious complications among the three groups, there was statistically worse graft survival, worse kidney function, and a higher incidence of chronic allograft nephropathy in the alemtuzumab group. The alemtuzumab group received less MMF because of a higher incidence of neutropenia, and the authors speculate that this may have accounted for the disparity in outcomes among the three groups.[27]

Comparison of Corticosteroid-Sparing Regimens Using Tacrolimus-Based and Cyclosporine-Based Immunosuppression

Studies of corticosteroid-sparing protocols in patients treated with cyclosporine and MMF showed acute rejection rates to be unacceptably high among African-American recipients.[1] A study examining corticosteroid withdrawal in 52 stable renal transplant recipients treated with tacrolimus and MMF showed a 98% patient survival and 92.3% graft survival.[14] The tacrolimus-based regimen was thought to

promote compliance by facilitating steroid withdrawal and reducing cosmetic complications (see Chapter 15).

Tacrolimus Avoidance Regimens

A prospective, randomized trial was performed in which 132 live donor renal allotransplant recipients were divided into two groups. Steroids and basiliximab induction were given to every patient.[50] Group A patients received tacrolimus/sirolimus as maintenance immunosuppression, whereas group B patients received MMF and sirolimus. No difference was noted in 1-year patient or graft survival between the two groups. The incidence of biopsy-proven acute rejection was slightly less in group B (P = NS). In addition, significantly better renal function was noted in group B patients 2 years after transplantation. One-year protocol biopsy specimens showed no significant differences in the chronic allograft damage index between groups.

A prospective, randomized trial in renal transplantation compared sirolimus/MMF/prednisone (n = 81) with tacrolimus/MMF/prednisone (n = 84). The mean follow-up was 33 months. There was no difference in patient survival, graft survival, or the incidence of clinical acute rejection between the two groups. There also was no difference in the mean glomerular filtration rate measured by iothalamate clearance between the tacrolimus and sirolimus groups at 1 or 2 years.[79] At 1 year, chronicity using the Banff schema showed no difference in interstitial, tubular, or glomerular changes, but fewer chronic vascular changes in the sirolimus group. This study suggests that many of the promises of calcineurin inhibitor–free immunosuppression have perhaps not been achieved with short-term follow-up. The question of improved safety and efficacy in the longer term with calcineurin inhibitor–free immunosuppression has to be subjected to longer term follow-up of the aforementioned study and similar studies.[87]

Many previous studies of complete calcineurin inhibitor avoidance have used cyclosporine as the comparator drug. In one study, the mean corrected iothalamate clearance was 60.6 mL/min/1.73 m^2 in sirolimus-treated patients, and the mean iothalamate clearance for cyclosporine-treated patients at 2 years was 49.2 mL/min/1.73 m^2.[36] The iothalamate clearances in the sirolimus versus tacrolimus study[79] were comparable to the mean corrected iothalamate clearance of 60.6 mL/min/1.73 m^2 at 2 years in the sirolimus-treated patients in the study reported by Flechner and colleagues.[36] The major difference between the results of the two studies[36,79] is that the tacrolimus-treated patients had better renal function at 2 years compared with the cyclosporine-treated patients.

A pilot study was done in 22 renal transplant recipients using alemtuzumab induction and maintenance immunosuppression with MMF (500 mg twice daily) and sirolimus (concentration controlled at 8 to 12 ng/mL). The results of this study showed reasonable composite end points, with most recipients calcineurin inhibitor–free and steroid-free at 1 year.[35] A higher than expected rate of acute rejection, leukopenia, and possibly pulmonary toxicity was noted, however. It is possible that an initial period of calcineurin inhibitor use could be considered in this steroid avoidance regimen.[35] It would be premature today to administer calcineurin inhibitor–avoidance protocols to most kidney transplant recipients (see Chapter 19).[141]

Pediatric Renal Transplantation (see Chapter 35)

The efficacy of tacrolimus as an immunosuppressive agent in pediatric renal transplantation has been shown in single-center experiences and in multicenter trials. A retrospective cohort study of 986 pediatric renal transplant recipients in the North American Pediatric Renal Transplant Cooperative Study (NAPRTCS) database (index renal transplant 1997 through 2000), who were treated with either cyclosporine/MMF/steroids (n = 766) or tacrolimus/MMF/steroids (n = 220), was performed to examine differences in outcome between these two groups.[95] In this analysis, tacrolimus and cyclosporine, in combination with MMF and steroids, were associated with similar rejection rates and graft survival in pediatric renal transplant recipients. Tacrolimus was associated with improved graft function at 1 year and 2 years after transplantation.

A 6-month, randomized, prospective, open, parallel group study with an open extension phase was conducted in 18 centers from nine European countries to compare the efficacy and safety of tacrolimus with cyclosporine in pediatric renal transplant recipients.[34] The study randomly assigned (1:1) 196 pediatric patients (<18 years old) to receive either tacrolimus (n = 103) or cyclosporine microemulsion (n = 93), administered concomitantly with azathioprine and corticosteroids. The primary end point was incidence and time to first acute rejection. At 1 year, tacrolimus therapy resulted in a significantly lower incidence of acute rejection (36.9%) compared with cyclosporine (59.1%; P = .003). At 4 years, patient survival was similar, but graft survival significantly favored tacrolimus over cyclosporine (86% versus 69%; P = .025). At 1, 2, 3, and 4 years, the mean glomerular filtration rate was significantly better in the tacrolimus group than in the cyclosporine group. Three patients in each arm developed post-transplant lymphoproliferative disorder, and the incidence of diabetes mellitus was similar in the two groups. Tacrolimus was significantly more effective than cyclosporine in preventing acute rejection in pediatric renal transplant recipients. Renal function and graft survival also were superior with tacrolimus.[34] This study represents the only randomized trial in pediatric renal transplantation to show significantly improved graft survival with tacrolimus compared with cyclosporine.

The effect of corticosteroids on the epiphyseal growth plates is well recognized and results in irreversible growth stunting. Experience with steroid withdrawal in pediatric kidney transplant recipients receiving cyclosporine has shown limited success. Late rejection episodes and graft dysfunction occurred in 68.8% of pediatric kidney transplant recipients after steroid withdrawal under primary immunosuppression with cyclosporine.[103] Experience with corticosteroid withdrawal under tacrolimus therapy in pediatric patients has been associated with favorable outcomes. Two thirds of the pediatric kidney transplant recipients were withdrawn successfully from corticosteroids, with a low incidence of graft dysfunction or acute rejection (23%).[115] Many of these patients had remarkable catch-up growth.

Changes in kidney function, mixed lymphocyte culture, cell-mediated lympholysis, cytotoxic antibodies, lymphocyte populations, and cytokine response were studied in 14 pediatric renal transplant recipients with chronic rejection who were converted to tacrolimus. Serum creatinine levels

decreased, creatinine clearance increased, and urinary protein excretion decreased after 6 months, and these values were maintained after 2 years under tacrolimus treatment.[32]

In adult renal transplant recipients, coadministration of tacrolimus and sirolimus resulted in reduced exposure to tacrolimus at sirolimus doses of 2 mg/day. Eight pediatric renal transplant recipients (median age at transplant 2 years; range 1.2 to 12.9 years) were converted to tacrolimus-based and sirolimus-based immunosuppression as rescue therapy. All patients had biopsy-proven chronic allograft nephropathy. After the addition of sirolimus, the median dose required to keep tacrolimus blood trough concentrations within the target range increased by 71.2% (range 21.9% to 245.4%), and the dose-normalized tacrolimus exposure (area under the curve) decreased to 67.1%. Adding sirolimus to tacrolimus-based immunosuppression in young pediatric renal transplant recipients resulted in a significant decrease in tacrolimus exposure.[33]

Heavy post-transplant immunosuppression can contribute to long-term immunosuppression dependence by subverting tolerogenic mechanisms. Two therapeutic principles were employed to achieve a degree of acquired tolerance: (1) pretransplant lymphoid depletion and (2) minimal post-transplant immunosuppression with tacrolimus monotherapy.[111] Lymphoid depletion in 17 unselected pediatric recipients of live ($n = 14$) or cadaver donor kidneys ($n = 3$) was carried out with ATG ($n = 8$) or alemtuzumab ($n = 9$). Tacrolimus was started after transplantation with eventual lengthening of intervals between doses (spaced weaning). After 16 to 31 months' follow-up (mean 22 months), patient and graft survivals were 100% and 94%, respectively. The only graft loss occurred in a nonweaned, noncompliant recipient. In the other 16 recipients, the mean serum creatinine level was 0.85 ± 0.35 mg/dL, and the calculated creatinine clearance was 90.8 ± 22.1 mL/min/1.73 m^2. All 16 patients were on monotherapy (15 tacrolimus, 1 sirolimus), whereas 14 were dosed every other day or three times per week. This strategy of lymphoid depletion and minimal post-transplant immunosuppression seemed safe and effective for pediatric kidney recipients, although more follow-up is needed to establish its long-term efficiency.

CLINICAL STUDIES IN KIDNEY-PANCREAS TRANSPLANTATION (see Chapter 34)

The increase in the number of pancreas transplants has been made possible by technical improvements and improved immunosuppressive regimens. Treatment with tacrolimus-based immunosuppression has been associated with lower rejection rates, higher graft survival rates, and less nephrotoxicity compared with treatment with cyclosporine.[47,52]

Simultaneous Pancreas-Kidney (SPK) Transplantation

In an analysis of 1194 pancreas transplantations performed at the University of Minnesota, the results were divided into five time periods ("eras") based on the technique and immunosuppressive regimen used.[121] In era II, the immunosuppressive regimen consisted of Minnesota antilymphocytic globulin (MALG) or muromonab-CD3 (OKT3) for induction and a combination of cyclosporine, azathioprine, and prednisone for maintenance. Duct management in eras II and III was by bladder drainage. In era III, tacrolimus was used for pancreas transplantation as soon as it was approved by the FDA in 1994. Induction was with equine antithymocyte globulin (Atgam), and OKT3 was used for treatment of rejection episodes. When MMF was approved a year later, it was added to the maintenance immunosuppressive regimen. In era IV, which began in March 1998, daclizumab, alone or in combination with the polyclonal anti–T cell antibody (Atgam or ATG), was added to the induction regimen. Enteric drainage was the principal exocrine drainage technique. In patients with primary simultaneous pancreas-kidney (SPK) transplantation, pancreas and kidney graft survival rates were significantly higher in eras III and IV than in era II. In eras III and IV combined, 1-year patient, pancreas, and kidney survival rates were 92%, 79%, and 88%, respectively; at 5 years, the corresponding figures were 88%, 73%, and 81%, respectively.[121]

The rate of acute rejection in SPK transplantation has been decreasing over the past decade at the University of Miami Medical Center, from nearly 100% to less than 10% in the first year after transplantation.[15] In a prospective, randomized trial, 42 SPK recipients received ATG and daclizumab induction, with tacrolimus and steroids as baseline immunosuppression. Twenty-two patients were randomly assigned to receive MMF, and 20 patients received sirolimus in addition to tacrolimus and steroids. Actuarial patient, kidney, and pancreas allograft survivals were 100%, 100%, and 95%, respectively, at 6 months in the sirolimus group and 100%, 100%, and 100%, respectively, in the MMF group. The incidence of acute rejection was less than 10% and was limited to instances in which recipient immunosuppression was reduced.[15]

A prospective study of combined tacrolimus, MMF, and steroids without antibody induction was done on 17 SPK transplant patients at Miami. Low-dose intravenous tacrolimus was used as induction therapy. Clinical and biopsy-proven rejection occurred in four (23%) patients. Patients who developed rejection had low tacrolimus levels or had had discontinuation of MMF because of leukopenia, gastroparesis, or gastrointestinal side effects.[26] All rejection episodes responded to steroids.

Immunosuppression for SPK transplantation at Northwestern University was divided into four eras over an 8.5-year period.[70] In era I (March 1993 to February 1997), three immunosuppression combinations were used: cyclosporine/azathioprine/steroids ($n = 28$), cyclosporine/MMF/steroids ($n = 8$), or tacrolimus/MMF/steroids ($n = 10$); bladder drainage was used. In era II (July 1995 to February 1998), the combination of tacrolimus, MMF, and corticosteroids was used, with bladder drainage. In era III, combinations of tacrolimus (12-hour trough concentrations 10 to 12 ng/mL) and MMF (3 g/day) were used along with corticosteroids for maintenance immunosuppression; enteric drainage was used. In era IV, steroids were eliminated within 6 days of transplantation, and tacrolimus was combined with either MMF ($n = 20$) or sirolimus ($n = 38$); enteric drainage was used.

In eras I and II, all recipients received induction therapy with Atgam for 7 to 14 days after transplantation. In era III, for induction therapy, 17 patients were randomly assigned to a noninduction therapy arm, and 37 patients were randomly assigned to an anti–interleukin-2 receptor monoclonal antibody (daclizumab, $n = 35$; basiliximab, $n = 2$).

Induction therapy in era IV consisted of rabbit ATG, 1 mg/kg intraoperatively and on postoperative days 1, 2, 4, 6, 8, 10, 12, and 14. One-year actuarial patient survival rates in eras III and IV were 96.3% and 100%, respectively; 1-year actuarial kidney survival rates in eras III and IV were 94.4% and 97.7%, respectively, and the 1-year actuarial pancreas survival rates were 88.9% and 100%, respectively. The 1-year rejection-free rate was 87.1% for era III and 96.6% for era IV. Compared with era I, kidney function significantly improved over the three eras. Rapid elimination of corticosteroids was successful in all recipients in era IV, with higher patient and graft survival rates than in the previous three eras. Rejection rates decreased further in era IV. The Northwestern group concluded that corticosteroids could be rapidly eliminated prospectively in all recipients without a decrease in graft survival rates or an increase in the rate of rejection.[70]

The combination of tacrolimus, MMF, and steroids with ATG induction was associated with an incidence of acute rejection of 33% compared with an incidence of 73% using ATG induction followed by cyclosporine, azathioprine, and steroids, in a randomized trial reported from Ruhr University, Germany.[140] The incidence of cytomegalovirus and malignancies was not higher using tacrolimus/MMF compared with the cyclosporine/azathioprine regimen, with 5 years' follow-up.

A multicenter trial was done to assess the effect of antibody induction in SPK transplant recipients receiving tacrolimus, MMF, and corticosteroids.[16] The trial randomly assigned 174 SPK transplant recipients to induction ($n = 87$) or noninduction ($n = 87$), and the recipients were followed for 3 years. Induction agents included T cell depleting or interleukin-2 receptor antibodies. At 3 years, actual patient (94.3% and 89.7%) and pancreas (75.9% and 75.9%) survival rates were similar in the induction and noninduction groups. Actual kidney survival was significantly better in the induction group compared with the noninduction group at 3 years (92% versus 82%; $P = .04$).[16]

The EuroSPK Study Group, which compared tacrolimus and cyclosporine in primary SPK transplantation, enrolled 205 patients.[78] After antilymphocyte globulin induction, patients were randomly assigned to receive either tacrolimus or cyclosporine microemulsion together with MMF and steroids. At 1 year after transplantation, patient and kidney survival rates were excellent in both treatment groups. There was a significant difference in pancreas graft survival: 94.2% for tacrolimus and 73.9% for cyclosporine ($P = .00048$). There were significantly fewer grade 2 and grade 3 rejections with tacrolimus-based therapy. The EuroSPK group also presented data showing that 34 patients were switched from cyclosporine to tacrolimus, but only 6 patients receiving tacrolimus required conversion to alternative therapy during the course of the study.[9] The mean doses of MMF at 1 year also were lower in the tacrolimus group (1.36 g/day versus 1.67 g/day; $P = .007$).

Steroid Withdrawal and Steroid-Free Protocols

Reduction of steroid use is extremely desirable in pancreas transplantation because long-term steroid use is associated with hypertension, hyperlipidemia, and glucose intolerance.[56] Complete steroid withdrawal was achieved in 58 (47%) of 124 patients transplanted at the University of Pittsburgh, with a mean time to steroid withdrawal of 15.2 ± 8 months.[61] Patient, pancreas, and kidney survival rates at 1 year were 100%, 100%, and 98%, respectively, (off steroids) versus 97%, 91%, and 96%, respectively, (on steroids, all P = NS). The cumulative risk of rejection was 74% for patients off steroids versus 76% for patients on steroids (these patients had not received antibody induction). The mean glycosylated hemoglobin levels were 5.2 ± 0.9% (off steroids) and 6.2 ± 2.1% (on steroids; $P = .02$). The Pittsburgh group concluded that steroid withdrawal could be achieved in pancreas transplant patients under tacrolimus-based immunosuppression and was associated with excellent patient and graft survival.[61] More recently, the Pittsburgh group has used alemtuzumab preconditioning with tacrolimus monotherapy in pancreas recipients,[124] with promising early results.

Based on experimental studies, it was found that preconditioning with a depleting antibody and low-dose post-transplant immunosuppression could lead to partial tolerance.[18] T lymphocyte depletion strategies using alemtuzumab[19] or ATG[120] administered as preconditioning agents are based on this principle. Fourteen patients received pancreatic allografts at the University of Pittsburgh, which were transplanted alone ($n = 4$) or with kidneys from the same donor ($n = 10$). Two of the 4 pancreas-alone recipients and 6 of the 10 pancreas-kidney recipients also had donor-specific bone marrow cell infusion.[120] The immunosuppressive regimen consisted of pretreatment with 5 mg/kg of ATG over several hours preceding transplantation; participants also received 1 to 2 g of intravenous methylprednisolone concomitantly to minimize cytokine release. Twice-daily monotherapy with tacrolimus was begun the day after transplantation, with a target trough concentration level of 10 ng/mL. Other agents, including prednisone, sirolimus, or muromonab-CD3, were added as necessary for control of rejection and for as brief a period as possible. At 4 months, patients receiving tacrolimus monotherapy were considered for consolidation to once-daily tacrolimus and eventual spaced weaning. Patient survival was 100% and pancreas graft survival was 86%, with 13 to 18 months' follow-up. Five of 12 patients with functioning pancreas grafts were receiving spaced doses of tacrolimus monotherapy ranging from every other day ($n = 1$), to three times a week ($n = 2$), and once a week ($n = 2$).[120]

The Minnesota Group reported a prospective trial of steroid withdrawal in pancreas transplantation.[48] Recipients with functioning grafts ≥6 and ≤36 months after SPK transplantation or pancreas after kidney (PAK) transplantation were enrolled. All patients received triple therapy for maintenance immunosuppression using tacrolimus and MMF, with the following inclusion criteria: (1) low maintenance steroid dose 0.075 mg/kg/day, (2) MMF dosed ≥750 mg orally twice a day, and (3) tacrolimus levels ≥8 ng/mL. Fifty-five patients (29 SPK, 26 PAK) were randomly assigned to remain on steroids or to steroid withdrawal after 4 to 8 weeks. The median follow-up was 27 months in the SPK category and 26 months in the PAK category, and from randomization, 10 months in both categories. Steroid withdrawal 6 months after a successful pancreas transplant was not associated with a decrease in patient or graft survival, and it was not associated with an increase in the incidence of rejection or in the rate of graft loss from rejection. There was a better quality of life and a reduction in serum cholesterol levels in the steroid withdrawal group.[48]

Rapid corticosteroid elimination was carried out in 40 SPK recipients from Northwestern University in Chicago.[71] ATG was used for induction; maintenance immunosuppression was with tacrolimus/MMF in 20 patients and tacrolimus/sirolimus in 20 patients. Patient and graft survival rates and rejection rates were compared with historical controls ($n = 86$). One-year actuarial patient, kidney, and pancreas survival rates in the rapid corticosteroid elimination group were 100%, 100%, and 100%, respectively, and in the historical control group rates were 97%, 93%, and 97%, respectively. The 1-year rejection-free survival rate was 97% in the rapid corticosteroid elimination recipients versus 80% in the historical controls. Serum creatinine levels remained stable in all groups at 6 and 12 months after transplantation.[71]

Steroid-free immunosuppression has been used with excellent short-term results in low-risk pancreas-kidney transplantation recipients at the University of California at San Francisco.[38] Forty patients underwent pancreas-kidney transplantation from November 2000 to July 2002. ATG induction was combined with MMF, tacrolimus, and sirolimus for maintenance immunosuppression. Steroids were used as pretreatment only, given with ATG and discontinued by the end of the first postoperative week. Patient, kidney, and pancreas survival rates were 95%, 92.5%, and 87.5%, respectively. Biopsy-proven pancreas rejection rates at 1 and 3 months after transplantation were 2.5%, and kidney rejection rates at 1 and 3 months were 2.5%.[38]

Pancreas after Kidney Transplantation

According to data from the International Pancreas Transplant Registry, the current, nearly uniform use of tacrolimus/MMF in PAK transplantation makes a comparison with other regimens difficult, although graft survival rates have been significantly better than in the preceding era, when cyclosporine/azathioprine was used.[45] In the overall analysis of tacrolimus/MMF-treated primary PAK transplant recipients, graft survival rates did not differ significantly whether or not antibody induction was given, although they tended to be numerically higher in PAK recipients given depleting or nondepleting antibody than in recipients not given antibody induction. In the PAK category, the relative risk of pancreas graft failure was reduced by the use of tacrolimus/MMF for immunosuppression.[45]

Between July 1, 1978, and April 30, 2002, 406 PAK transplants were performed at the University of Minnesota.[46] Immunosuppression was divided into eras. In era III, tacrolimus was used in combination with prednisone and initially azathioprine. MMF replaced azathioprine when it was approved by the FDA. Polyclonal antibody induction therapy with Atgam was used in 99%, and monoclonal antibody (OKT3) was used in 1% of patients; the median duration of antibody therapy was 5 days. In era IV, tacrolimus, MMF, and prednisone were the principal maintenance immunosuppressive agents. Daclizumab was used for induction either alone (21%) or in combination (79%) with a polyclonal antibody (Atgam or ATG). The median duration of antibody therapy was 3 days. Overall patient survival rates (cadaver and living donor) at 1 and 3 years were 97% and 90%, respectively, and at 1 year in era IV overall survival was 96%. Overall pancreas graft survival rates (cadaver and living donor) at 1 and 3 years in era III were 78% and 60%, respectively, and in era IV, at 1 year overall graft survival was 77%. Of technically successful transplants, pancreas graft loss rates to rejection in era III at 1 and 3 years were 10% and 19%, respectively; in era IV, at 1 year, it was 9%. PAK transplants now can be performed almost as successfully as SPK transplants; the introduction of tacrolimus and MMF in the mid-1990s contributed to this development.

Using tacrolimus-based and MMF-based immunosuppression, only 20% of recipients experiencing rejection episodes ultimately lost their pancreas graft to irreversible rejection. In eras III and IV, when tacrolimus was being used, there no longer existed a difference in outcome between primary transplants and second transplants. With the use of tacrolimus, the advantage of living donor PAK transplants over cadaver donor PAK transplants no longer existed.[46]

SIDE EFFECTS AND TOLERABILITY OF TACROLIMUS

The side-effect profile of tacrolimus is similar to that of cyclosporine (Table 17-2; see Chapter 16). The physiological effects, including reduction in renal blood flow and glomerular filtration, are similar between tacrolimus and cyclosporine. The pathological manifestations of tacrolimus and cyclosporine toxicity are similar in that they include tubular vacuolization and arteriolar nodular hyalinosis that are indistinguishable. Microvascular changes involving arterioles or glomerular capillaries sometimes predominate, displaying a wide spectrum of severity from apoptosis and vacuolization of smooth muscle cells to thrombotic microangiopathy.

A review of 21 patients with tacrolimus-associated thrombotic microangiopathy was published[126]; 17 of these occurred in kidney transplant recipients, whereas 2 cases occurred in liver transplant recipients and 1 each in heart and bone marrow transplant recipients. The mean time from transplantation to the onset of thrombotic microangiopathy was 9.3 ± 7.9 months. Clinical presentation varied from an absence of signs and symptoms of hemolysis to florid hemolytic anemia, thrombocytopenia, and azotemia. Renal biopsy specimens were obtained from the patients

Table 17–2 **Adverse Effects Associated with Tacrolimus Therapy**

Nephrotoxicity
Reduced renal blood flow, glomerular perfusion
Tubular and vascular toxicity
Neurotoxicity
Headaches, tremors, seizures, peripheral neuropathy, paresthesias
Metabolic disturbances
Hyperkalemic, hyperchloremic acidosis
Hypomagnesemia

Hyperuricemia
Hypercholesterolemia
Hypertension
Gastrointestinal disturbances
Diarrhea
Anorexia, nausea, and vomiting
Epigastric cramping
Cosmetic
Alopecia

with a kidney transplant and showed acute thrombi within the glomerular capillaries or arterioles, or both. Tacrolimus causes tissue ischemia by reducing the renal plasma flow and glomerular filtration rate, leading to endothelial cell injury. There are large circulating polymers of von Willebrand's factor in thrombotic microangiopathy, which increases the tendency for platelets to adhere to and aggregate on the subendothelium, resulting in thrombi and fibrin deposition. Treatment consists of reducing the dose of tacrolimus and substitution with cyclosporine or sirolimus. Other treatment modalities have included plasmapheresis, fresh frozen plasma exchange, and anticoagulation.[126]

Adverse events dictate the optimal dosage regimen of the drug. Decreasing the dosage of tacrolimus generally reduces its toxic effects, although some adverse effects are idiosyncratic and do not respond to such measures.[108] Tacrolimus treatment is associated with a higher incidence of diarrhea, disturbances in glucose metabolism, and some types of neurotoxicity but a lower incidence of hypertension and hypercholesterolemia than cyclosporine. Tacrolimus is only rarely associated with the cyclosporine-specific adverse effects of hirsutism, gum hyperplasia, and gingivitis, but it may cause alopecia and pruritus.

In a trial in renal transplant recipients, significantly fewer (all $P < .05$) tacrolimus recipients (compared with cyclosporine microemulsion recipients) experienced new-onset or worsening hypertension (15.7% versus 23.2%), urinary tract disorders (4.9% versus 9.2%), hypercholesterolemia (4.2% versus 8.9%), hyperbilirubinemia (0.3% versus 3.3%), gastrointestinal hemorrhage (0.3% versus 2.6%), cholestatic jaundice (0.3% versus 2.6%), hirsutism (0% versus 4.4%), and gum hyperplasia (0% versus 4.1%).[84] Tremor (12.2% versus 4.1% of patients), hypomagnesemia (6.6% versus 1.5%), thrombosis (4.5% versus 1.5%, mainly affecting the dialysis access vessels), and gastritis (3.1% versus 0.4%) were significantly (all $P < .05$) more common in the tacrolimus group.

Because tacrolimus and cyclosporine cause acute and chronic nephrotoxicity, concomitant use of these two agents is contraindicated. Nephrotoxicity related to tacrolimus treatment is dose related and responds to dosage reduction.[117] Mean or median serum creatinine levels in renal transplant recipients were lower in tacrolimus-treated patients, with 5 years' follow-up, than in patients treated with cyclosporine microemulsion (or standard formulation).[49,133] Administration of other nephrotoxic agents simultaneously can exacerbate the adverse effects of tacrolimus. Examples of such agents include aminoglycosides, angiotensin-converting enzyme inhibitors, angiotensin receptor antagonists, amphotericin, and nonsteroidal anti-inflammatory drugs.

Cardiovascular Adverse Effects

Hyperlipidemia occurs commonly after transplantation and is a risk factor for cardiovascular disease. Immunosuppression with tacrolimus-based regimens is associated with better lipid profiles than is immunosuppression with cyclosporine-based regimens.[4,83]

Analysis of the United States Renal Data System database showed that fewer tacrolimus (than cyclosporine) recipients had at least one new-onset hyperlipidemia code during the first year of treatment (11% versus 16%; $P = .0001$); a multivariate analysis showed that the risk of new-onset hypertension after transplantation was reduced by 35% under tacrolimus-based immunosuppression.[106] The 5-year follow-up results from a U.S. randomized trial indicated that significantly fewer tacrolimus than cyclosporine recipients were receiving antihypertensive treatment (80.9% versus 91.3%; $P < .05$).[133]

Concentric increases in left ventricular posterior wall and interventricular septum thickness can occur with tacrolimus immunosuppression in 0.1% of patients.[28] This condition is reversible after dosage reduction or discontinuation of the drug.

Post-Transplant Diabetes Mellitus

PTDM is a serious adverse effect of tacrolimus treatment; the complications of diabetes mellitus can result in decreased patient and graft survival.[93] PTDM is defined as insulin use for more than 30 consecutive days in the absence of preexisting diabetes. The incidence of PTDM was significantly higher among tacrolimus-treated patients than cyclosporine-treated patients (9.8% versus 2.7%), according to a more recent meta-analysis.[53] In corticosteroid minimization trials, the 6-month incidence of PTDM (use of insulin >30 days) in the corticosteroid-free arm ranged from 0.4% to 1.4%.[21,73] Tacrolimus target trough levels have tended to be lower and more rapidly tapered in recent years; this also has led to a decrease in the incidence of PTDM.[92] The introduction of MMF and sirolimus and the use of combinations of these agents with tacrolimus has led to a reduction in acute rejection rates and a reduction in corticosteroid treatment for acute rejection episodes in the first year after transplantation; this also has resulted in a reduced incidence of PTDM in recent years.

A study from Cleveland compared the outcomes of 56 African-American adult primary kidney transplant recipients treated with corticosteroids, sirolimus, and tacrolimus, targeted to low trough blood levels, with 65 white patients treated with steroids, MMF, and tacrolimus, targeted to higher blood levels. There were no significant differences in the actuarial 2-year patient, graft, and rejection-free graft survival rates between the two groups. PTDM occurred in 36% of the African-American patients, however, despite similar doses of corticosteroids and lower trough levels of tacrolimus, compared with 15% of white patients ($P = .024$).[54]

Recipient-related risk factors for PTDM include an underlying glucose metabolic disorder (e.g., family history of diabetes mellitus, older recipient age, nonwhite ethnicity, sedentary lifestyle, higher body mass index) and hepatitis C virus positivity. Transplantation-related risk factors include acute rejection during first post-transplant year, high doses of corticosteroids, and high tacrolimus trough levels.

The risk of developing PTDM is highest in the first few months after transplantation, after which the incidence increases more slowly. The European multicenter trial found a 6-month PTDM incidence of 4.5% and an additional incidence of 0.4% from months 7 through 12.[84]

Many patients with PTDM can have reversal of diabetes mellitus, with eventual discontinuation of insulin. In the European trial, the 1-year cumulative incidence of PTDM with tacrolimus was 8.3%, whereas the prevalence at 1 year was 5.5%.[86] In a U.S. trial combining tacrolimus with MMF and corticosteroids, the 1-year incidence was 6.5%, and the 1-year prevalence was 2.2%.[60]

High levels of FK BP-12 are present in pancreatic beta cells, and this is associated with a decrease in insulin mRNA transcription and reduced insulin production in rats.[122] In the clinical setting, tacrolimus affects insulin secretion but does not affect insulin resistance. In addition, PTDM is probably not a separate entity but a consequence of an underlying glucose metabolic disorder that is uncovered by immunosuppression.[105] The effects of tacrolimus on insulin release are reversible, and after the early post-transplant period, tacrolimus and cyclosporine are equivalent in terms of their effect on glucose metabolism.[129]

Compared with cyclosporine-treated patients, the relative risk for developing PTDM in tacrolimus-treated patients was 1.53 ($P < .001$).[68] Compared with cyclosporine-treated patients, tacrolimus therapy was associated with a reduced risk of death (relative risk 0.65; $P < .001$) and graft failure (relative risk 0.70; $P < .001$). Under tacrolimus-based immunosuppression, the positive effects of lower blood pressure, less hypercholesterolemia, better renal function, and lower fibrinogen[7] offset the negative effect of PTDM.

The main principles in the management of PTDM are as follows:[130] Therapeutic trough levels of tacrolimus are maintained in month 1—between 15 ng/mL and 20 ng/mL in the first 2 weeks and between 10 ng/mL and 15 ng/mL in the latter 2 weeks. Trough levels of tacrolimus are reduced to 4 to 7 ng/mL by month 3. Corticosteroid cessation is begun as soon as possible. Corticosteroids are to be reduced to 10 mg/day at month 1, after which they should be withdrawn. In patients who are at high risk for rejection, corticosteroids are administered at 5 mg/day. The aforementioned measures led to the resolution of PTDM in most instances. In cases in which impaired glycemic control does not resolve, the degree of insulin resistance should be determined. Underlying infection or obesity should be treated when appropriate. Use of the thiazolidinediones should be considered.[8] In patients with low insulin output, insulin treatment or conversion to calcineurin-free immunosuppression is recommended. Evidence from a meta-analysis suggests that targeting tacrolimus concentrations to less than 10 ng/mL minimizes graft loss and reduces the risk of diabetes mellitus without increasing the risk of acute rejection.[139]

Malignancies (see Chapters 32 and 33)

The use of immunosuppressive agents increases the risk of malignancies developing, the most common being malignancies of the skin and lymphoma. All agents increase these risks, and the risk is related to the intensity and duration of treatment. Epstein-Barr virus–related post-transplant lymphoproliferative disorder is associated with immunosuppressive treatment, with a lower risk in adults than in children. In the European Multicenter Renal Study, the incidence of post-transplant lymphoproliferative disorder at 1-year follow-up was 1% in the tacrolimus group and 0.7% in the cyclosporine microemulsion group.[86] The incidence of post-transplant lymphoproliferative disorder in pediatric renal transplant patients with tacrolimus immunosuppression was 0.96% based on an analysis of the NAPRTCS database.[29]

Other Side Effects

Tacrolimus-treated patients are more likely to have alopecia, tremor, headache, insomnia, dyspepsia, vomiting, diarrhea, and hypomagnesemia than cyclosporine-treated patients.[139] Cyclosporine-treated patients are more likely to have constipation, hirsutism, and gingival hyperplasia.

Special Patient Populations

In a large, randomized multicenter trial involving pediatric renal transplant recipients (children and adolescents), the most common (3% of patients) adverse events associated with tacrolimus-based primary immunosuppression were hypertension, infections, hypomagnesemia, increased mean serum creatinine, diarrhea, PTDM, and tremor.[127] Significantly more tacrolimus recipients experienced hypomagnesemia ($P = .001$) and diarrhea ($P < .05$) than did cyclosporine recipients, and significantly fewer tacrolimus recipients experienced hypertrichosis ($P = .005$), flu syndrome ($P < .05$), and gum hyperplasia ($P < .05$).

The risks of tacrolimus during pregnancy are similar to the risks associated with cyclosporine. Data from the U.S. National Transplantation Pregnancy Registry were used to compare outcomes in 19 tacrolimus recipients (24 pregnancies) with outcomes in 56 cyclosporine microemulsion recipients (71 pregnancies). Seventy-one percent of pregnancies resulted in live births in the tacrolimus group versus 80% of pregnancies in the cyclosporine microemulsion group; the mean gestational age was lower in the tacrolimus group than the cyclosporine group (32.9 weeks versus 35.8 weeks; $P = .0035$).[3] There were no other statistically significant differences in outcomes.

A single-center analysis was performed on 13 kidney transplant recipients and 2 SPK recipients who became pregnant under tacrolimus-based immunosuppression.[57] The 13 mothers after kidney transplantation delivered 19 infants, whereas the 2 mothers after SPK transplantation delivered 3 infants. All mothers survived the pregnancy. One infant was stillborn. Forty-one percent of the infants were either preterm or premature, and 27% of the infants were delivered by cesarean section. Toxemia of pregnancy or preeclampsia was seen in 23% of these pregnancies. None of the mothers experienced rejection during their pregnancy.

CONCLUSION

The studies discussed in this chapter have consolidated the place of tacrolimus as an important agent for primary immunosuppression in adult and pediatric kidney and in adult kidney-pancreas transplantation. The key comparator for tacrolimus is cyclosporine microemulsion. Treating kidney transplant recipients with tacrolimus results in a 44% reduction in graft loss (censored for death) compared with cyclosporine-treated patients in the first 6 months after kidney transplantation.[139] On the basis of meta-analyses of data from randomized trials, treating 100 recipients at low risk (e.g., adult, well-matched, first transplants) with tacrolimus instead of cyclosporine would avoid 6 cases of acute rejection; this number increases to 17 cases if high-risk recipients are considered (e.g., sensitized recipients, second or third transplants, children). In contrast, treating with tacrolimus would lead to excess harm in an extra five recipients by causing them to develop insulin-dependent diabetes.[139] Both of the calcineurin inhibitors are nephrotoxic, and this can contribute to chronic allograft nephropathy

directly via drug toxicity or indirectly via hypertension and dyslipidemia.[20,80,94,118]

Tacrolimus is associated with less hypertension and less hypercholesterolemia than cyclosporine. Tacrolimus use has steadily increased, and it is now used in more than 67% of kidney recipients. Despite its side effects, the superior immunosuppressive efficacy of tacrolimus has led to its preferential use in kidney and kidney-pancreas recipients.

Chapter 18

Mycophenolate Mofetil

Barry D. Kahan

Mycophenolic acid (MPA), a fermentation product of *Penicillium brevicompactum* and related fungi,[48] has been known to be an inhibitor of nucleic acid synthesis for 100 years.[40] The development of the drug for transplantation was based on the findings that inherited deletions in this pathway result in immunodeficiencies; children lacking adenosine deaminase show combined T cell and B cell deficits.[45] In contrast, subjects with absence of hypoxanthine-guanine phosphoribosyl transferase display essentially normal immune function,[4] showing that, in contrast to the de novo synthesis pathway, the purine salvage pathway is not preeminent for lymphocyte function. These observations suggested the potential utility of inhibition of nucleotide synthesis for immunosuppression,[37] a hypothesis that was confirmed by the activity of the relatively nonselective mercapto-analogue azathioprine. Despite its profound capacity to block lymphocyte proliferation by inhibition of inosine monophosphate dehydrogenase (IMPDH),[37] MPA shows only marginal antitumor effects[83] and modest antibiotic activity toward a variety of organisms, including gram-positive bacteria, *Candida albicans, Leishmania*, and other intracellular protozoans, as previously reviewed.[84] To augment the oral bioavailability of MPA, the mofetil analogue (mycophenolate mofetil [MMF]) was formulated as an ester product.[81]

MECHANISM OF ACTION

MPA acts as a rapid, reversible, noncompetitive inhibitor of IMPDH, a rate-limiting enzyme in the de novo synthesis of guanine (Fig. 18-1).[37] This effect arrests new DNA synthesis in proliferating cells at the G_1/S interface; guanosine triphosphate (GTP) levels decrease to 10% of those in unstimulated T cells.[3] Addition of guanosine or deoxyguanosine reverses the inhibition, documenting the IMPDH target. Of its two isozymes, IMPDH type II, which is fourfold more sensitive to MPA,[23] shows the greatest increase in stimulated lymphocytes, the cell type that is particularly sensitive to the drug.

Guanine and adenine nucleotides produce coordinated feedback inhibition of 5-phosphoribosyl-1-pyrophosphate (PRPP) synthetase in most human cells. A decrease in guanine potentially would override the IMPDH block; however, guanosine monophosphate seems to be necessary to activate PRPP in lymphocytes.[5] The adenosine triphosphate (ATP) content is reduced to levels less than 50% of unstimulated cells.[113] This effect markedly dampens the activity of ATP-dependent enzymes, including tyrosine kinases that mediate signal transduction. Rescue of ATP pools by salvage via hypoxanthine or by de novo synthesis via inosine monophosphate is impaired because catalysis by adenylsuccinate synthetase is GTP-dependent.[83] There is no increase in cytosine triphosphate (CTP) because CTP synthetase also is a GTP-dependent enzyme. The deficiency in CTP is homeostatically countered by upregulated synthesis of uridine nucleotides, producing an imbalance in pyrimidine pools. MPA affects pyrimidine and purine pools.

The action at the G_1/S interface is selective. Neither the production of interleukin-2 nor the expression of its receptor is affected, showing a lack of influence on signal 1 of lymphocyte activation (Fig. 18-2). MPA decreases neither the cytoplasmic intermediates of extracellular signal-related kinase 1 nor signal transducer and activators of transcription,[114] suggesting preservation of signal 3. MPA has been claimed to

Figure 18–1 Purine synthetic pathways showing site of inhibition by mycophenolic acid (MPA). ATP, adenosine triphosphate; DP, diphosphate; HGPRTase, hypoxanthine-guanine phosphoribosyl transferase; IMPDH, inosine monophosphate dehydrogenase; MP, monophosphate; PRPP, phosphoribosyl pyrophosphate; TP, triphosphate. exert a modest proapoptotic effect, however, on lymphocytes responding to antigenic stimulation.[30] The primary antiproliferative action not only inhibits mixed lymphocyte responses but also retards induction of cytotoxic T cells.[37] Similarly, MPA seems to mitigate primary and ongoing B cell responses, presumably as a result of blockade of cell division.[51] Among patients in the U.S. pivotal trial, those who received MMF displayed a far lower incidence of production of xenoantibody toward rabbit antithymocyte globulin than the azathioprine cohort.[71] MPA treatment has been reported to blunt the synthesis of natural xenoantibodies after plasma exchange and splenectomy in rats.[38] Among the other elements of the immune response, the drug suppresses the maturation and allostimulation functions of dendritic cells in vitro.[31]

A distinct mechanism of drug action may relate to the need for GTP to activate fucose and mannose transfer as dolichol phosphate–linked oligosaccharides preparatory to glycoprotein synthesis. This effect is particularly relevant to transplantation because it would diminish the expression of adhesion molecules. α1,3-Fucosylated oligosaccharide ligands of L-selectin and vascular cell adhesion molecule-1 and intercellular adhesion molecule-1 glycoproteins depend on GTP-sugar intermediates. This effect was proposed in a preliminary report,[5] which inferred that MPA-treated cells displayed reduced glycoprotein assembly based on an indirect index that suggested inhibited expression and limited incorporation of mannose into these macromolecules. Using an in vitro model, endothelial cells from rat donors treated with 20 mg/kg/day or 60 mg/kg/day of MMF showed reduced expression of mannose-containing glycoproteins and moderate protection of their cardiac allografts after storage for 2 hours at room temperature.[148] Theoretically, a deficiency of bound guanine nucleotides also could exert independent actions to disrupt cell membrane physiology. In aggregate, these effects, on the one hand, would interfere with leukocyte binding to the endothelium, but, on the other hand, would promote tumor cell metastasis.[17]

Although lymphocytes seem to be 10-fold more sensitive to the drug than other elements, vascular smooth muscle cells,[93] mesangial cells,[57] and myofibroblasts[12] also have been reported to display dampened proliferation, using in vitro and in vivo rodent models of chronic rejection, chronic allograft nephropathy, and atherosclerosis. In a subhuman primate model of orthotopic aortic allografts, intravascular ultrasound documented that four of six hosts showed dose-dependent inhibition of the progression of intimal volume changes owing to ongoing vasculopathy.[95] The effects were potentiated when MMF was combined with sirolimus,[64] although at least within synthetic vascular grafts, the effects of MMF to reduce intimal hyperplasia exceeded those of sirolimus.[158] The efficacy of MMF was confirmed using aortic allografts in another subhuman primate model[72] and in a rodent chronic rejection system.[11] Coadministration of MMF and sirolimus seemed to reduce transforming growth factor (TGF)-β_1 mRNA and protein levels, which stimulate the synthesis of extracellular matrix protein and inhibit extracellular matrix degradation.[132] TGF-β_1 is a presumed vector of long-term cyclosporine nephropathy. Coadministration of MMF decreased TGF-β despite the propensity of baseline sirolimus treatment to increase it.[131] Additional potential actions of MPA on endothelium in vitro include inhibition of nitric oxide synthase upregulation after combined stimulation with interferon-γ and tumor necrosis factor-α[128] and inhibition of prostaglandin E_2 release after activation by allogeneic cells, interferon-γ, or interleukin-1.[18]

MPA inhibits the proliferation of multiple cell types by direct effects on guanosine synthesis and indirect effects on the generation of other nucleotides. Therapeutic benefits on T cell and B cell adaptive immune responses may be augmented or counterbalanced (based on the tissue) by antiproliferative effects on other rapidly dividing cells. Postulated effects on glycoprotein synthesis or assembly await robust experimental and clinical data.

PHARMACOKINETICS

Drug Measurement

The MPA parent compound is readily measured in plasma by high-performance liquid chromatography owing to its high predose concentrations (C_0).[58] The parent drug (MMF) is not detected in plasma. In contrast, the widely available automated enzyme multiplier immunoassay technique[94] yields 15% to 20% higher results because its antibody reagent cross-reacts with the acyl-MPAG metabolite(Fig. 18-3), which has immunosuppressive and toxic effects.[151] In addition, this metabolite accumulates greatly in renal failure. Because of these properties, some workers have suggested that the enzyme multiplier immunoassay technique may be preferable, although it is currently not approved by the Food and Drug Administration (FDA) for clinical purposes.

Bioavailability

Orally delivered MMF is rapidly and almost completely absorbed in the stomach and upper intestine. Drug absorption as assessed by area under the curve (AUC) is not significantly altered by coadministered food, although the maximal concentration (C_{max}) is 40% lower in simultaneously fed renal transplant recipients (CellCept package insert). The time to maximal concentration (T_{max}) of less than 1 hour (CellCept package insert) is independent of hepatic or renal function. The T_{max} is slightly delayed, however, in the period immediately after transplantation (1.31 ± 0.76 hours) and in diabetic patients (1.59 ± 0.67 hours). In contrast, by 3 months, it is 0.90 ± 0.24 hours.

MMF is quickly metabolized to MPA, yielding 94% bioavailability. Over the range of 100 to 3000 mg/day, the MPA area under the concentration-time curve for 24 hours ($AUC_{0\text{-}24}$) is proportionate to dose.[21] The volume of distribution of MPA is about 4 L/kg in normal volunteers.

Metabolism

MPA is rapidly metabolized to an inactive glucuronide (MPAG) via one or more isoforms of the *UGT1* gene family of uridine diphosphate–glucuronosyl transferases in the gastrointestinal tract, liver, and possibly kidney. Two minor metabolites also are formed—the acyl glucuronide and the phenolic glucoside (see Fig. 18-3).

Clearance

The apparent elimination half-life of MPA in healthy volunteers is 17.9 hours—a clearance of 11.6 L/hr.[8] At 8 to 12 hours

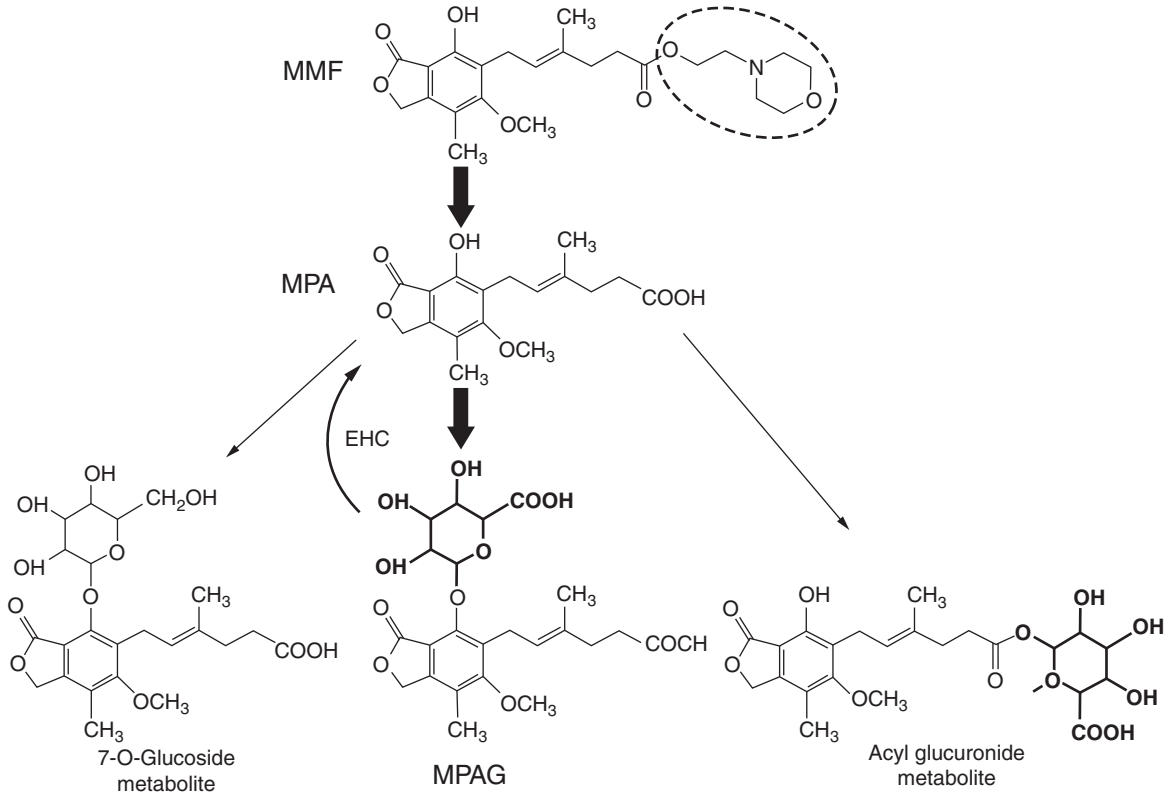

Figure 18–3 Metabolism of parent component mycophenolate mofetil (MMF) to mycophenolic acid (MPA) by cleavage of mofetil group (encircled) with primary metabolism to its glucuronide (MPAG), which may undergo enterohepatic recycling (EHC), and secondary acyl glucuronide and 7-O-glucoside metabolites. (Adapted from Shaw LM, Korecka M, Venkataramanan R, et al: Mycophenolic acid pharmacodynamics and pharmacokinetics provide a basis for rational monitoring strategies. Am J Transplant 3:534, 2003.)

after oral drug administration, 37% of patients (range 10% to 61%) display a secondary peak in plasma MPA concentrations representing enterohepatic recirculation. The additional peak results from excreted MPAG in bile undergoing deglucuronidation by intestinal bacteria with subsequent reabsorption of MPA.[21]

MPAG is the major urinary excretion product (93% of the radioactive parent compound); urinary excretion of MPA is negligible (<1%). Fecal excretion accounts for 6%. Neither hemodialysis nor peritoneal dialysis significantly affects MPA plasma concentrations, although in multiple-dose studies either dialysis method may remove some MPAG. With renal dysfunction, there is a moderate increase in plasma MPA and a marked accumulation of MPAG. MPA binds tightly and extensively (97%), but reversibly, to serum albumin, decreasing its ability to inhibit IMPDH.[101] The free fraction, constituting 1% to 3% of the total amount in the blood of stable patients, is cleared by biliary and renal routes. Hypoalbuminemia is associated with increased free MPA and greater MPA clearance. Renal dysfunction also increases the MPA free fraction because it decreases the binding of acidic drugs; in contrast, hepatic oxidative impairment produces no effect. Estimates of free MPA in ultrafiltrate samples have not been shown to offer any advantage over measurements of total MPA to predict therapeutic versus adverse reactions[8,77] except in the presence of impaired early renal function, wherein there are increased concentrations of MPAG and other metabolites.[130]

After the first few months following transplantation, drug clearance declines,[55] presumably reflecting MPA saturation of tissues. This decline may partially explain the 40% higher drug concentrations at these times compared with the concentrations observed within the first 40 days after transplantation. The increased levels are not consistently maintained after transplantation, however.

Drug-Drug Interactions

Recipients treated with cyclosporine in combination with MMF display lower MPA concentrations than do patients who either are not receiving cyclosporine or have been discontinued from the drug.[52] The reduction seems to be due to decreased biliary excretion of MPAG resulting from inhibition of multidrug resistance–associated protein-2, which is present in the canalicular membrane of hepatocytes.[73] Drug levels decreased by 40% also have been observed after coadministration of cholestyramine, which reduces the AUC of MPA, not by affecting the T_{max} but rather by affecting the absorption phase after 6 hours. Similarly, antibiotic therapy disrupting the gastrointestinal flora may interfere with deglucuronidation and enterohepatic recirculation, decreasing drug levels (CellCept package insert). Conversely, unexpectedly lower cyclosporine levels at 2 hours after oral delivery have been observed among pediatric patients concomitantly receiving MMF, possibly resulting from the diarrheal side effects of MPA.[106]

In contrast, coadministration with tacrolimus tends to increase MPA levels, primarily owing to the lack of the cyclosporine inhibitory effects, but also possibly to the inhibition of the uridine diphosphate–glucuronosyl transferase

that generates MPAG.[166] Sirolimus has neither positive nor negative effects, but the MPA levels are higher than levels observed with cyclosporine.[74] Finally, the steroid component of most regimens increases MPAG by inducing hepatic glucuronosyl transferase.[24,25] Because acyclovir and ganciclovir compete with MPAG for tubular secretion, they increase drug concentrations slightly, particularly among patients experiencing renal impairment.

PHASE I, II, AND III CLINICAL TRIALS ON PROPHYLAXIS OF ACUTE REJECTION EPISODES

Early dose-finding studies suggested beneficial therapeutic effects of MMF de novo at doses of 2 to 3 g/day in combination with cyclosporine[32] and in the treatment settings of an ongoing[138] or a steroid-resistant acute renal rejection episode.[137] Among the three pivotal trials in patients on a baseline cyclosporine-prednisone regimen, the European Mycophenolate Mofetil Study compared 2 g/day and 3 g/day doses of MMF versus placebo with no induction therapy.[98,112] The rates of biopsy-proven acute rejection episodes reported within 6 months were 17% and 13.8% versus 46.4%, respectively (Table 18-1). The U.S. Renal Transplant Study, which stipulated antithymocyte globulin antibody induction for all patients and included an azathioprine control arm, yielded corresponding acute rejection rates of 19.8%, 17.5%, and 38%, respectively.[136] The Tricontinental Study, which did not include antibody induction, but used an azathioprine comparator, yielded rates of 19.7% and 15.9% versus 35.5%, respectively.[146] All three pivotal trials documented the benefit of MMF compared with azathioprine (or placebo) to approximately halve the incidence of acute allograft rejection episodes within 6 months with equal graft and patient survivals at 12 months.

A 12-month analysis of combined data from the three studies, which included 1493 randomized subjects, confirmed the benefit of MMF on acute rejection episodes—19.8% and 16.5% versus 40.8%, yielding a relative risk ratio of 0.46.[56] Despite this benefit, however, the incidences of graft loss and death were 9.6%, 10.8%, and 12.4% (P = not significant), respectively. Longer term follow-up failed to suggest a benefit of MMF versus azathioprine or placebo in the U.S. Renal Transplant Study or Tricontinental Study, although

data from the European trial revealed that the 2-g, but not the 3-g, dose of MMF reduced death-censored graft loss compared with placebo—8.7%, 12.8%, and 16%, respectively ($P = .03$).

An analysis of the outcomes of 66,774 renal recipients in the U.S. Renal Transplant Registry suggested that prescription of MMF yielded significantly better 4-year patient and graft survivals. The risk of late acute rejection episodes was reduced by 65%,[88] and the risk of chronic allograft nephropathy was reduced by 27%.[87,103] Owing to the incomplete database in this Registry, the authors had to assume a random distribution of all other nonreported factors that affect these outcomes, an assumption that has not yet been tested in multivariate fashion. This problem with Registry data markedly dilutes the observation. Further support for concern about the Registry conclusion is the observation that despite apparently widespread use of MMF, U.S.-wide renal allograft survivals have not improved, suggesting that any potential benefit has been counterbalanced by alterations in other immunosuppressants, increased recipient and donor ages, increased waiting times on dialysis, and emergence of BK viral nephropathy.

Because of the high cost of MMF relative to azathioprine, pharmacoeconomic analyses are of particular importance to determine whether the acquisition expense offsets the savings associated with a lower incidence and severity of rejection episodes. Although information from single-center analyses has been comprehensively reviewed,[163] the data from the randomized pivotal trials seem more relevant. An analysis of data from 1003 among the 1493 trial patients performed from the perspective of the French health insurance payers[82] suggested that the lower health care costs over the first 6 months of MMF treatment were substantially offset by the acquisition expense. An analysis of the U.S. multicenter trial[124] revealed similar costs and benefit for the azathioprine and the 2-g MMF cohorts, but a higher expense for the 3-g MMF dose. If one examined graft survival cost-effectiveness, the MMF combination was most effective at 1 year, but not at 10 years. At the later time, azathioprine or MMF regimens including antithymocyte globulin induction were most effective, suggesting that MMF may not be as useful in the longer term.[123] The economic implications of the Tricontinental Study for Canada were evaluated by comparing the 2-g dose of MMF with the azathioprine cohort, including drug acquisition costs. There was only a slight difference in the first year. Subsequently, the incremental costs per graft-year gained were $Can 14,268, and, per quality-adjusted life-year, $50,717, amounts that offset the acquisition fee.[68] A United States Renal Data System (USRDS) cost analysis, including an examination of the earlier-described limited database using multivariate regression tools, suggested that at 6.4 years, the average costs to Medicare with respect to graft loss were the same for MMF and azathioprine.[123] The benefit apparent at 4 years had eroded by 6.4 years.

De novo treatment with MMF augments the immunosuppressive effects of cyclosporine and steroid during the first 6 months. Thereafter, maintenance therapy with MMF is expensive. To date, the benefits have not been shown to outweigh the costs, although, as described subsequently, substantial reductions in the doses of concomitant medications in the immunosuppressive matrix may engender savings and improved outcomes. Longer term pharmacoeconomic analyses of various treatments by cooperative-group protocols with complete databases should resolve these cost-effectiveness issues.

TOXICITIES

The initial clinical trials of MMF suggested a lack of nephrotoxicity, neurotoxicity, or hepatotoxicity. The myelotoxicity and gastrointestinal side effects were reportedly "modest."[138] There was a consistent risk of an increased incidence of invasive cytomegalovirus (CMV) infections. To evaluate toxicity requires controlled clinical trials, however, recognizing that these studies tend to enroll patients in a more optimal condition than patients encountered in general transplant practice. In the pivotal trials, adverse events accounted for withdrawal of 14.7% of subjects in the MMF 3 g/day dose, 8.7% from MMF 2 g/day dose, and 5.2% from the comparator cohorts.

Gastrointestinal Adverse Reactions

The constellations of gastrointestinal symptoms are the most commonly reported adverse effects of MMF therapy, including diarrhea, indigestion with nausea and vomiting, abdominal pain, and gastroesophageal reflux. In the renal transplant setting, diarrhea can be due to a variety of causes other than immunosuppressant therapy, including preexisting diabetic or uremic conditions, intercurrent infectious diseases, and concurrent antibiotic treatment. The overall incidences of any gastrointestinal complaint were 52.5% and 45.5% versus 41.6% for the MMF 3-g and 2-g doses versus the azathioprine arms, respectively. Because diarrhea is the most frequently reported complication, colonic biopsies often have been performed; the biopsy specimens have shown apoptosis of intestinal gland epithelial cells[105] and atrophy of the intestinal villi, which in one patient was documented to disappear a few months after MMF withdrawal.[34]

Diarrhea that is persistent and not accompanied by fever may be associated with an erosive enterocolitis causing malabsorption of nutrients. Presumably reflecting the immunosuppressed state, 60% of 26 cases of diarrhea were due to an infectious origin—CMV, *Campylobacter*, or bacterial overgrowth,[84] or in another report, microsporidiosis.[54] In the other 40%, enterocolitis was characterized by faster colonic transit, crypt distortion, and focal inflammation, attributed in one study to a toxic action of the acyl MPAG metabolite on absorptive cells, leading to a predominance of goblet cells.[133] A review has suggested the potential gastrointestinal toxicity of *N*-(2-hydroxyethyl) morpholine, which is a de-esterification product of MMF that has local irritative effects on gastric mucosal cells.[68] Generally, the occurrence of these side effects more frequently has been linked to the MMF dose rather than to the plasma concentration of parent compound or its metabolites. The syndromes respond to MMF dose reduction. Although the presence of diarrhea, if anything, may reduce cyclosporine levels, it tends to enhance tacrolimus concentrations markedly.[147]

For the cohorts of MMF 2-g dose ($n = 336$), MMF 3-g dose ($n = 330$), or azathioprine ($n = 326$), the incidences of diarrhea were 31%, 36%, and 21%, respectively; of constipation, they were 23%, 19%, and 22%, respectively; of nausea, they were 20%, 24%, and 25% respectively; of dyspepsia,

they were 18%, 14%, and 14%, respectively; of vomiting, they were 13%, 14%, and 9% respectively; and for nausea, vomiting, and diarrhea the incidences were 10%, 10%, and 11%, respectively (CellCept package insert). Patients with preexisting gastrointestinal illnesses were excluded from participation in the pivotal trials. It is difficult to define precisely and categorize all gastrointestinal effects because they are of variable degree and may be delayed in onset. Although gastrointestinal effects are not life-threatening, they may seriously affect the quality of life.

An alternative, enteric-coated form of MPA—mycophenolate sodium (EC-MPS)—has been developed to mitigate the gastrointestinal toxicities. Compared with MMF, EC-MPS showed equivalent efficacy in animal models and in humans,[122] but only similar safety when administered de novo in randomized fashion or on conversion of stable patients.[19,20] Subsets of patients who displayed gastrointestinal intolerance on MMF administration required fewer dose changes of EC-MPS, however, and showed an apparently reduced symptom burden, better functioning, and improved health-related quality of life.[26] Although renal transplant patients, particularly patients experiencing these symptoms, seem to be able to be safely converted from MMF to EC-MPS, the clinician should be aware that the FDA U.S. Prescribing Information does not regard the two formulations as proved to be equivalent.

Myelosuppression

In addition to immunosuppressive drugs, the multiple causes of anemia in renal transplant patients include poor allograft function, iron deficiency, viral infections, and treatment with agents affecting angiotensin. An MMF dose-dependent occurrence of anemia was reported in a prospective pivotal trial. Patients receiving 3-g or 2-g doses of MMF versus placebo-treated control subjects showed 25.5% and 23.8% versus 13.3% incidences, respectively, of anemia or leukopenia.[98] In other pivotal trials, the bone marrow toxicity seemed to be slightly less frequent with MMF than with azathioprine.[136,146] This result may not solely reflect relative myelosuppression because the azathioprine dose is generally chosen to be the greatest one tolerable, which would predispose this cohort to cytopenia.

MMF dose and MPA predose (C_0) plasma concentrations have been correlated with decreased hemoglobin values among stable renal transplant recipients.[149] A more recent study suggested an even better correlation of anemia, however, with MPA metabolites—MPAG and acyl MPAG—than with MPA itself.[75,76] Compared with another antiproliferative agent, 87 sirolimus-treated renal allograft recipients in a single-center study experienced a greater incidence, severity, and resistance to treatment of anemia at 6 and 12 months after transplantation than did 127 patients on an MMF regimen. Similarly, sirolimus-treated patients displayed fewer instances of post-transplant erythrocytosis[10] and worse renal function.[9] These findings reinforce the major danger of combinations of sirolimus and MMF—profound anemia that is resistant to erythropoietin treatment.

Similar to other agents that interfere with cell division, MMF may produce leukopenia, which in some cases may be associated with markedly abnormal neutrophil morphology.[13] MPA plasma concentrations and particularly free MPA $AUC_{0\text{-}12hr}$ have been shown to be significantly related to severe infections and leukopenia.[59,160,161] The leukopenia has been associated with stomatitis,[44] particularly when combined with a sirolimus-based regimen, another hazard of this combination regimen.[152] In one case, failure of improvement after administration of granulocyte stimulation factor suggested to the authors that MMF produced a direct antiproliferative effect on the oral mucosa, which is subject to recurrent abrasions and to direct exposure to the orally administered MMF.[6] Similarly, the drug showed teratogenic effects at subclinical doses in animal studies,[33] suggesting caution in its use in pregnant women (U.S. FDA category C), although a successful outcome has been reported involving renal transplantation in the first trimester of pregnancy under a tacrolimus/MMF/steroid regimen.[110]

Infections

Compared with azathioprine, MMF therapy has been associated with greater incidences and severity of tissue-invasive CMV, herpes simplex and zoster, and BK virus infections. These effects may reflect its potency to impair the immune response, particularly when prescribed in combination with tacrolimus. BK infection rates of 10% have been reported from several centers and are held to be responsible for the emerging significance of this entity in renal transplant practice. Some workers have argued that MMF should be continued even during treatment of CMV disease because of its effects on critical viral enzymes. The primary antibiotics for treatment of CMV—acyclovir and related drugs—are metabolized to monophosphates and then triphosphates, which are incorporated into replicating viral DNA, irreversibly inactivating viral DNA polymerase. MPA has been suggested not only to enhance this phosphorylation of acyclovir but also to deplete the 2-deoxy-guanosine pool, inhibiting viral DNA polymerase.[100] These potential beneficial effects must be counterbalanced, however, against the hazards of unaltered immunosuppression and the general impression of a greater prevalence and severity of infection among patients treated with this drug.

MMF therapy has been reported to produce a significant increase in hepatitis C virus viremia among patients receiving concomitant cyclosporine.[120] In contrast, inception MMF seems to show no significant effect on hepatitis B virus viremia despite in vitro studies that suggested that it inhibited viral replication.[85] In contrast, an anti–*Pneumocystis carinii* effect has been noted among transplant recipients who do not require ongoing antibiotic prophylaxis.[104]

Neoplastic Diseases

Three pivotal trials involving almost 1500 patients followed for at least 1 year reported a numerical but nonsignificant increase in the incidence of lymphoma among the MMF arm compared with the placebo or azathioprine groups.[56] A large, prospective, observational cohort study that investigated this question failed to reveal an increased risk of lymphoma or malignancy associated with MMF compared with the other immunosuppressant regimens available at that time.[117] In contradistinction to the antilymphoma activity of sirolimus, however, MMF does not retard neoplastic cell division. Conversion from MMF to sirolimus is probably indicated for patients who are experiencing or are at risk for

neoplastic disease in conjunction with a regimen of minimal immunosuppression.[67]

Pulmonary Toxicity

In the refractory rejection study,[144] 5.2% of patients had to interrupt the drug because of noninfectious respiratory side effects. In a single-center experience, within 3 months after transplantation, 11.1% of deceased donor recipients experienced a nonproductive cough on administration of MMF in combination with cyclosporine and steroids.[36] In addition to cough, dyspnea and abundant sputum production, seemingly representing a bronchiectasis-like condition, have been reported to be associated with MMF treatment.[118] The findings have been attributed to impaired leukocyte recruitment leading to reduced pulmonary clearance of microorganisms. Conversion to alternative immunosuppressants seems to resolve the symptoms.

Another constellation of adverse reactions related to pulmonary fibrosis was reported in at least three cases by independent investigators. The disorder apparently is not associated with infection. Whether this condition is specific for MMF or typical of antiproliferative agents as a class is unclear. Severe diffuse pulmonary fibrosis has been known to be a reaction to drugs, including azathioprine as reported in the 1980s,[14] and sirolimus.[65]

Experimental Animal Models

Rats treated with MMF show reduced intestinal mucosal protection against invasive bacterial or toxic agents. The antiproliferative effects of MMF have been cited as the cause of impaired healing of left-sided colon anastomoses in rats,[165] a finding that has not been confirmed in humans, possibly because most surgeons would withdraw the drug in this clinical situation.

MMF treatment of Wistar rats (40 mg/kg × 21 days), using a dose equivalent to that which produces a high incidence of gastrointestinal side effects in humans, led to downregulation of four genes expressed in the liver, jejunum, ileum, and colon—polymeric immunoglobulin receptor (pIgR), major α-hemoglobin, CCAAT/enhancer protein (C/EBP-α), and catalase. PIgR, which mediates IgA and IgM transport into bodily fluids, may be a cause of diarrhea because downregulation of its expression would be expected to enhance host vulnerability to exogenous pathogens. The diminished catalase level suggests altered resistance to oxidative stress, which is known to play a role in the formation of gastric lesions and chronic ileitis and generally to predispose to gut cell apoptosis. The reduced C/EBP-α would exacerbate effects on the catalase gene because it plays an important role in the promoter region for the expression of this enzyme. Finally, the reduced expression of α-hemoglobin presumably reflects the systemic anemic state.[134] A report described the benefits of an herbal gastrointestinal relaxant to mitigate the diarrheal effects of MMF combined with the antibacterial levofloxacin: There was decreased fecal water content and bacterial flora.[159]

The appearance of gastrointestinal or myelosuppressive adverse effects generally demands progressive MMF dose reduction, seeking to determine the maximal amount acceptable to a given individual. Patients tolerating only modest, presumably subtherapeutic, doses of MMF may benefit from conversion to EC-MPS. The morbidity of the infectious and neoplastic complications depends on the aggregate intensity of the immunosuppressive regimen relative to the immunocompetence of the individual patient.

THERAPEUTIC DRUG MONITORING

Although fixed doses of MMF generally have been used in clinical therapy, there is a rationale to implement therapeutic drug monitoring for this drug.[15] Considerable interpatient pharmacokinetic variability of MMF has been documented to be due to differences in hepatic/renal functions, concurrent drug administration, and the presence of diarrhea but not to ethnicity[129] or gender.[111] At least some patients show a poor relationship between drug dose and measured C_0 plasma concentrations,[24] suggesting the benefit of AUC estimates. Finally, most available studies suggest that a concentration metric may be more useful to diagnose a rejection episode, and that the dose may correlate with adverse reactions.

Pharmacokinetic Therapeutic Drug Monitoring

A correlation between MPA AUC and the risk of early rejection has been reported to show a sensitivity of 83% and a specificity of 64%.[70,142,150] Combined with full exposure to cyclosporine, the apparent optimal MPA AUC is 30 to 60 mg/hr/L, and the most useful value of the less robust metric of the predose concentration (C_0) is 1 to 3.5 mg/L. Using a receiver operating characteristic analysis, the cutoff points for optimal benefit with MPA were AUC ($P = .001$) and C_0 ($P = .02$) values each 20% lower than those reported in previous studies.[109] Because full AUC monitoring with at least seven samples is impractical on a routine basis, abbreviated sampling strategies have been proposed (e.g., concentrations predose and at 0.67 and 2 hours after dosing). This estimate shows an r^2 correlation coefficient of 0.75, which is acceptable[42]; however, it is not sufficiently robust for routine clinical application. The most likely use of concentration monitoring is early after transplantation when absorption may be slow and incomplete, and clearance more rapid than at 3 months.

There seems to be a better relationship between adverse reactions and MMF dose rather than MPA concentrations (C_0, C_{max}, or AUC). Some investigators have claimed MPA AUC to correlate with hematologic and infectious side effects,[8] whereas others have noted predose C_0 values to be associated with anemia[24] or hematologic and gastrointestinal side effects.[133] The acyl-MPAG content has been proposed as a surrogate metric of gastrointestinal and anemic side effects.[75-77,133]

MMF has achieved a respectable position in the immunosuppressive armamentarium using uniform dosing regimens adjusted based on individual patient tolerance. Only extremely large clinical trials that show the utility of pharmacokinetic therapeutic drug monitoring are likely to change this general practice.

Pharmacodynamic Therapeutic Drug Monitoring

Global estimates of antiproliferative activity of immunosuppressants used since the azathioprine era have been, as expected, employed to assess MMF effects.[102] So many other

factors affect the proliferative activity of peripheral blood cells in this setting that their clinical utility is modest. IMPDH assays are technically demanding and difficult to reproduce; in addition, the whole blood matrix may not reflect the activated lymphocytes, which are the cells of interest. Estimates of IMPDH activity in isolated peripheral blood mononuclear cells, clearly the preferable matrix to whole blood, display considerable interindividual variability. The time course of IMPDH inhibition, as measured by the production of xanthine monophosphate by isolated mononuclear cells, parallels the MPA plasma concentration.[19,20] An alternative assay proposes measurement of inhibition of CEM cell proliferation by patient serum because this cell line is unaffected by calcineurin antagonists or steroids.[91] Patients who showed lower IMPDH levels before transplantation, suggesting a genetically determined susceptibility to the drug, more frequently underwent dosage reductions within 6 months.[114] It is unclear, however, whether levels or fluctuations in IMPDH activity can be used to predict acute rejection episodes or a tendency to drug toxicity.

Can pretransplant estimates of IMPDH activity be used to tailor MMF doses, or is there a relationship between MPA pharmacokinetic parameters and IMPDH inhibition? In the absence of a currently confirmed, robust benefit of MMF on long-term graft survival, and in view of the probably variable dose-concentration-effect relationships, one viable avenue to reform the drug regimen and achieve durable therapeutic benefits may be a rigorous pharmacokinetic and pharmacodynamic therapeutic drug monitoring approach.

IMMUNOSUPPRESSIVE DRUG COMBINATIONS WITH MYCOPHENOLATE MOFETIL

Cyclosporine (see Chapter 16)

Because the pivotal trials used the less effective oil-based form of cyclosporine, a European study employing the superior microemulsion cyclosporine formulation (Neoral) is of particular interest. This study showed only modest, insignificant reductions in acute rejection episodes with MMF compared with azathioprine, questioning the value of the highly significant 10-fold to 15-fold cost differential.[115] A European Collaborative Group described similar results among patients converted from MMF to azathioprine at 3 months compared with subjects maintained on MMF in combination with the microemulsion formulation of cyclosporine and steroids.[121] These findings in patients probably at low immunological risk should be extrapolated cautiously to other situations.

Because clinical trials generally are conducted within populations of ideal risk candidates to minimize the contributions of other factors, such as age and ethnicity, a variety of derivative analyses have been performed in these populations. Two reports have shown opposite outcomes of renal transplants among patients older than 55 years, a population putatively at reduced risk of rejection. One group[63] noted worse patient survival with MMF than with azathioprine, whereas other workers observed a significantly better outcome with MMF.[140] Critics have ascribed the findings in the latter study to the lower, probably subtherapeutic, doses of azathioprine that were prescribed for the control cohort.

A subgroup analysis of putatively higher immunological risk patients enrolled in the U.S. pivotal trial shows that the benefit for African-American versus white recipients was restricted to the MMF 3-g dose compared with the MMF 2-g dose or azathioprine cohorts—there were acute rejection rates of 12%, 32%, and 48%, respectively.[99] These findings were independently confirmed: MMF produced greater reduction in rejection risk among African-American (relative risk 0.88) than white (relative risk 0.35) recipients.[126]

MMF may have putative benefits to mitigate chronic allograft nephropathy. Despite full exposure to cyclosporine/steroid, the addition of MMF seemed to be associated with a lower incidence of chronic nephropathy than the cyclosporine/ azathioprine/prednisone cohort.[27] Patients in the USRDS registry who were maintained on MMF for at least 2 years were reported to show a 34% reduced risk of worsening renal function.[87,103] A Spanish study suggested that even when cyclosporine was not reduced,[50] MMF displayed a benefit for patients with chronic allograft nephropathy at 6 years' mean follow-up. Patients with established chronic nephropathy are unlikely to respond to MMF addition, however, without alteration of the overall regimen.[47]

Tacrolimus (see Chapter 17)

A single-center study evaluating the combination of MMF and tacrolimus plus steroids versus only the last two agents showed a decreased risk of an acute rejection episode from 44% to 27% at about 1 year.[27-29] A subsequent multicenter trial[92] reported the benefit of the MMF 2 g/day dose to reduce the incidence of acute rejection episodes compared with MMF 1 g/day dose or azathioprine treatment—8.6%, 32.2%, or 32.2%, respectively. The low acute rejection rate with the 2-g MMF dose suggested to the authors that a combination with tacrolimus produced superior results to cyclosporine. The incidences of opportunistic infections and malignances at 1 year seemed to be similar across the groups. In contrast, another study failed to show a significant benefit of tacrolimus versus cyclosporine in combination with MMF on the incidence of acute rejection episodes, graft survival, or patient survival at 2 years among the 223 enrolled North American subjects.[62] A follow-up investigation by the United Network for Organ Sharing registry of living donor renal transplantations performed in 1998 and 1999 reported in 2003 that at 2 years, there was a significantly greater risk of graft failure with the tacrolimus/MMF than with the cyclosporine/MMF combination.[22]

A single-center report described tacrolimus as obtaining superior results in combination with MMF rather than sirolimus,[27] findings that were confirmed using a steroid-free regimen.[89] This observation was confirmed in a randomized, multicenter clinical trial comparing patients treated with MMF (n = 176) versus sirolimus (n = 185) in association with tacrolimus and steroids. The MMF cohort displayed better renal function, less hypertension, and reduced hyperlipidemia.[49,89] Among patients on a tacrolimus-based regimen, improvements in renal function were observed in 19 patients converted from sirolimus to MMF compared with 78 recipients remaining on sirolimus.[9]

Sirolimus (see Chapter 19)

Based on a primate study suggesting a supra-additive antirejection effect[157] and a rat study supporting prophylaxis of chronic renal allograft rejection,[11] the combination of MMF

and sirolimus seemed to be useful, even though they are both antiproliferative agents. An initial clinical study suggested that the combination of MMF plus sirolimus was at least as effective to prevent acute renal allograft rejection as MMF plus cyclosporine.[74] Because the actual incidence of treated acute rejections was greater than 30% in both arms of this study, the addition of basiliximab to the regimen was investigated as a means to enhance the immunosuppression. The initially favorable results at a single center[39] were not confirmed in a multicenter trial, which had to be prematurely terminated because of a high incidence of acute rejection episodes. The two antiproliferative agents show overlapping toxicities—anemia and diarrhea—and prohibitively high acquisition costs of each component of the regimen. These problems argue against prescription of MMF/sirolimus except for special situations, such as delayed renal graft function or possibly documented calcineurin inhibitor–induced vasculopathy in a patient at high immunological risk.

Antibodies (see Chapter 20)

The two anti–interleukin-2 receptor monoclonal antibodies—humanized daclizumab and chimeric basiliximab—have been tested in conjunction with calcineurin inhibitor/MMF/steroid protocols. In a randomized trial, addition of basiliximab to a regimen of cyclosporine/MMF/steroid produced a trend toward a reduced incidence of acute rejection episodes without augmented toxicity.[80] In conjunction with cyclosporine/MMF/steroid, even a two-dose regimen of daclizumab seems to reduce the acute rejection rate. Compared with a historical control group who received OKT3 induction therapy, the 305 renal recipients treated with tacrolimus/MMF/steroids plus five doses of daclizumab displayed a lower acute rejection rate (2% versus 7%; $P = .01$) and fewer infections, but there was no difference in patient or graft survival.[28] The regimen of daclizumab/tacrolimus (C_0 8 to 12 ng/mL)/MMF (1 g twice a day)/steroids yielded similar results in putatively high-risk African-American renal recipients and in patients of other ethnicities.[29]

The sole administration of the humanized anti-CD52 monoclonal antibody at a dose of 0.3 mg/kg produces profound depletion of T lymphocytes and, to a lesser extent, B lymphocytes. Despite these effects, it is inadequate immunosuppression as monotherapy for renal transplantation, however. The reagent did display beneficial effects in 44 recipients when combined with MMF (500 mg twice a day) and tacrolimus (C_0 5 to 7 ng/mL) but no steroid, although these patients experienced severe leukopenia.[28]

USE OF MYCOPHENOLATE MOFETIL TO POTENTIATE, MINIMIZE, OR AVOID PRESCRIPTION OF OTHER IMMUNOSUPPRESSANTS

Reversal of Acute Rejection Episodes

To reverse acute rejection episodes among 150 subjects treated with cyclosporine/steroid, MMF was reported to achieve a 45% benefit compared with a steroid regimen including five daily intravenous boluses followed by a tapered oral steroid dosing, which was more effective than azathioprine/steroids.[96] Despite a promising initial result, a 3-year analysis of the outcomes of 221 patients failed to confirm any benefit of MMF in this setting.[137] A multicenter study suggested that inception of MMF may be useful to ameliorate steroid-resistant acute rejection episodes.[137]

Reduction in Calcineurin Inhibitor Exposure

The use of MMF to achieve cyclosporine or tacrolimus dosage reduction has been generally accepted as a means to moderate immunosuppression and decrease drug-related nephrotoxicity after 6 months post-transplantation. This maneuver resulted in improved serum creatinine values.[2,108] A controlled trial documented the benefit of a 50% reduction versus no reduction in cyclosporine C_0 in terms of improved creatinine clearance, uric acid, blood pressure, and triglyceride values.[35] Another publication observed that low MMF doses (500 to 1000 mg/day) were sufficient to facilitate calcineurin inhibitor reduction with consequent improvement in renal function and decreased TGF-β levels.[60] Under the cover of MMF coadministration after 3 months, modest-to-moderate reductions in calcineurin inhibitor exposure (cyclosporine C_0 100 to 150 ng/mL; tacrolimus C_0 5 to 7 ng/mL) seem to be generally well tolerated by patients who have been previously free of rejection episodes.

Withdrawal of Calcineurin Inhibitor after Transplantation

Some studies have sought to eliminate cyclosporine from the maintenance regimen to avert chronic nephrotoxicity. One multicenter study of patients with deteriorating renal function at a mean of 6 years after transplantation documented significantly improved renal function at 6 and 12 months after stepwise withdrawal of cyclosporine.[141] A single-center randomized prospective study initiated at a mean 7 years post-transplantation compared 20 patients in an MMF/calcineurin inhibitor continuation arm with 19 patients in an MMF/calcineurin inhibitor withdrawal arm, showing improved renal function and blood pressure without an episode of acute rejection.[135] Discontinuation of cyclosporine at 1 year after transplantation resulted in a significant improvement in mean serum creatinine values at 8 months thereafter for the azathioprine and the MMF cohorts, although the latter group experienced fewer acute rejection episodes.[135] Replacement of cyclosporine with MMF after 6 months was successful in 15 of 17 patients who tolerated the drug, and renal function improved.[126]

A multicenter study compared the 1-year outcomes of withdrawal at 3 months of either cyclosporine ($n = 44$) or MMF ($n = 40$) from a three-drug regimen including steroid therapy.[125] Withdrawal of cyclosporine was associated with better creatinine clearances, decreased blood pressures, and more favorable lipid profiles despite a twofold increase in acute rejection episodes. Although 5-year data are needed before one can judge the benefits versus hazards of calcineurin inhibitor withdrawal, provisionally one may conclude that the maneuver is relatively safe in stable patients at low immunological risk, offering benefits on creatinine and lipid levels.

De novo Avoidance of Calcineurin Antagonists

Although the initial multicenter trials documented the efficacy of MMF in combination with full doses of cyclosporine, the

adverse effect of progressive nephrotoxicity associated with calcineurin inhibitor therapy has led to studies to avoid cyclosporine de novo. Using a five-injection daclizumab induction protocol and an MMF/steroid maintenance regimen in 98 low-risk recipients of cadaver and living donor kidneys, acute rejection episodes were observed in 53% of recipients within 12 months, requiring institution of calcineurin antagonists.[155] A smaller study confined to recipients of living donor kidneys failed to observe a substantial benefit.[145] In contrast, a single-center report described 12 patients older than 50 years who received grafts from elderly donors who were successfully treated de novo with MMF and steroids and an induction regimen of rabbit antithymocyte globulin.[164]

For avoidance of calcineurin antagonists, MMF has been employed with steroids in conjunction with sirolimus,[74] basiliximab/sirolimus,[39] or LEA29 (Belatacept)/basiliximab,[156] yielding vastly different acute rejection rates during the first 6 months. Even when there was an early effect, however, the durability of the immunosuppressive protection is doubtful. In a Spanish study, 65% of MMF-treated patients remained on an avoidance regimen at 12 months, but only 36% were free of these drugs at 60 months.[53] Although a large randomized trial of the basiliximab/sirolimus/MMF/ prednisone regimen has been discontinued because of an excessive occurrence of acute rejection episodes, two pivotal studies of the LEA29/basiliximab/MMF/prednisone combination are ongoing. The use of sirolimus in addition to MMF as the base for de novo immunosuppressive therapy has been widely employed, although one retrospective analysis of the U.S. Renal Data System noted an increased incidence of delayed graft function with this regimen.[127] However it was unclear how patients were selected for the SRL-MMF combinations; it is likely that they were at increased risk for DGF based on extended donor criteria or operative findings.

Steroid Avoidance or Withdrawal

A large multicenter trial of steroid withdrawal at 3 months after transplantation using a cyclosporine/MMF/prednisone regimen documented an increased risk of rejection episodes resulting in early termination of the study.[107] In contrast, steroid withdrawal beginning at 3 months after transplantation showed no significant difference in rejection rates versus continued steroid therapy among European patients prescribed MMF/tacrolimus[139] or MMF/cyclosporine with antibody induction.[153] Although the superior results of the latter trial may be attributed to prescription of more potent baseline therapy, it is more likely due to the fact that the European cohorts generally show a low immunological risk compared with African-Americans, who displayed most of the failures in the original trial. An analysis of multiple studies in low-risk patients suggested a benefit of MMF to permit steroid withdrawal after 1 year.[79]

Early withdrawal at day 5 post-transplantation in conjunction with antithymocyte globulin induction treatment combined with an MMF/cyclosporine regimen yielded acceptable results at 3 years in a single-arm, single-center analysis.[69] A controlled trial of early withdrawal versus persistent therapy confirmed the safety of the approach using basiliximab as opposed to antithymocyte globulin induction.[154] There were no significant differences between the outcomes of withdrawal at 3 days versus 4 months using a daclizumab/MMF/cyclosporine regimen.[143]

Complete steroid avoidance has been reported in 100 renal recipients in conjunction with antithymocyte globulin induction plus cyclosporine/azathioprine. The cohort displayed a 13% incidence of acute rejection episodes and an 82% rate of graft survival at 4 years.[16] Similar findings were obtained using daclizumab induction with tacrolimus/MMF maintenance therapy: 89% of patients were steroid-free at 6 months.[119]

There seems to be less evidence for a unique benefit of steroids within the immunosuppressive matrix. Adjusting other therapeutic components readily compensates for their avoidance or for their early withdrawal.

Discontinuation of Cyclosporine and Prednisone

After a prolonged period of quiescence, withdrawal of cyclosporine and prednisone from a combination with MMF has been described in a pilot trial.[61,86] On the one hand, there was a 10.9% risk of acute rejection episodes; on the other hand, the maneuver resulted in improved serum creatinine and lipid levels within 1 year. Similar findings have been reported in a multicenter study.[116] At present, there is no longer term follow-up of patients on MMF monotherapy, however, beyond an anecdotal comment in a review.[79]

SUMMARY

Although MMF has been widely accepted as a component of de novo and maintenance therapy in renal transplantation, the drug has the potential for use in other settings of inflammatory disorders. MMF may mitigate the development of anti-HLA antibodies among transfused chronic kidney disease patients. In a parallel setting, administration of MMF (at concentrations therapeutic for heart transplant recipients) reduced the amounts and shortened the persistence of anti–HLA antibody responses by children receiving allografts for repair of congenital heart defects. MMF may have a role in suppressing the production of anti–blood type antibodies after renal transplantation across the ABO blood barrier.[69]

Far broader applications of MMF would be in autoimmune kidney diseases. Because many of these entities are either resistant to or relapse on initial treatment, intense salvage therapy is frequently necessary. The conventional regimen of intravenous cyclophosphamide and steroid boluses is associated with concomitant adverse effects of infertility, alopecia, bladder problems, and infections. Among the autoimmune diseases, systemic lupus erythematosus (SLE) is the one most often reported to display beneficial effects after MMF treatment. Based on results in a murine model[154] and single-center reports,[16,119,143] a multicenter, randomized U.S. trial is under way to compare MMF with a regimen of intravenous boluses of steroid and cyclophosphamide in 140 lupus nephritis patients with biopsy-proven diffuse proliferative disease. At 6 months, there were fewer treatment failures in the MMF arm.[78] If these findings are confirmed on extended follow-up, it may be useful to examine whether MMF benefits other renal diseases of putatively autoimmune etiology, as reviewed more recently.[78]

MMF has become a component of many immunosuppressive regimens in renal transplantation because of its ease

Table 18–2 **Potential Algorithms of Induction Regimens Using Mycophenolate Mofetil: 7- to 14-Day Treatments**

of oral administration (1- to 3-g doses daily) without mandatory monitoring of plasma concentrations. Because MMF seems to be an agent of moderate potency—less potent than calcineurin inhibitors or sirolimus (but more potent than azathioprine or steroids)—it has been used successfully more often in association with other immunosuppressants, particularly agents that do not produce overlapping side effects of gastrointestinal disturbances, anemia, or leukopenia. The increased incidence or severity of viral infections observed with regimens including MMF seems to relate largely to the coadministered immunosuppressants.

Table 18-2 shows some possible regimens for induction immunosuppression that include MMF. The regimens are classified according to the risk status of the host and of the donor graft. High immunological responders benefit from rabbit antithymocyte globulin treatment. In the event of likely, or of documented, delayed or slow graft function—high donor risk—sirolimus comedication should be considered to achieve adequate immunosuppression, despite the potential problems with wound healing. For recipients of kidneys at low risk of dysfunction, reduced doses of calcineurin antagonists are preferable to mitigate their nephrotoxicity. The low-immunological-risk patient is frequently induced with an anti–interleukin-2R monoclonal antibody, accompanied in the high donor risk situation with sirolimus or in the low donor risk setting with a low dose of calcineurin antagonist.

In the maintenance phase, inception or intensification of the MMF regimen may facilitate a reduction in or elimination of the more potent coadministered agents. Among weak immune responders free of rejection after transplantation, there is the potential for steroid withdrawal, with modest exposures to calcineurin antagonist or sirolimus, depending on the renal function (Table 18-3). MMF monotherapy may represent a useful option in special cases, including elderly recipients, patients free of rejection for years, HLA-identical matches, or subjects intolerant of any other drug.

The high immunological responder presents a greater challenge because of the need to maintain a robust level of immunosuppression. Calcineurin antagonists remain the central agent in this setting; although steroids are normally continued, they have been withdrawn particularly in patients experiencing post-transplant diabetes mellitus, osteopenia, or another profound side effect. Patients with impaired renal function usually associated with chronic allograft nephropathy are frequently intolerant of calcineurin antagonists, however. Inception of sirolimus therapy early in the course when the creatinine increase does not exceed 3.5 mg/dL represents a potential, albeit as yet unproved, strategy to stabilize or possibly ameliorate dysfunction.

Several areas remain to be explored further. First, more efficient methods of therapeutic drug monitoring than AUC to estimate parent compound or metabolite concentrations need to be developed and correlated with

Table 18–3 **Potential Algorithms for Maintenance Immunosuppressive Regimens Using Mycophenolate Mofetil**

pharmacodynamic assays. Second, multicenter studies need to be performed to yield quantitative clinical data on the outcomes of various MMF-based drug combinations that are tailored to provide optimal effects at minimal exposures in various patient cohorts, including the elderly, the mixed ethnic, and retransplantations. Finally, long-term, randomized, biopsy-based trials must be designed to show the potential of MMF for protective effects against the progression of chronic allograft nephropathy. Applications of 21st century molecular tools in the clinical setting are likely to improve the already excellent renal allograft outcomes obtained with MMF.

Chapter 19

mTOR Inhibitors: Sirolimus and Everolimus

Christopher J. E. Watson • J. Andrew Bradley

Sirolimus and everolimus are closely related members of a relatively new class of potent immunosuppressive agents that impair T cell proliferation by inhibiting the mammalian Target of Rapamycin (mTOR). Sirolimus and its newer analogue everolimus have undergone extensive clinical evaluation during which they have shown potency as immunosuppressive agents after kidney and other types of solid organ transplantation. Much has been learned about their efficacy in preventing acute rejection and their side effects. Because sirolimus and everolimus are similar in their mode of action and clinical efficacy, it is convenient to consider them collectively under the term mTOR inhibitors. This consideration inevitably biases discussion toward sirolimus rather than its newer alternative everolimus, however, because most of the published literature on mTOR inhibitors in renal transplantation relates to sirolimus. Despite the many similarities of sirolimus and everolimus, significant clinical differences between the two agents may emerge.

DISCOVERY

Sirolimus (AY-22989, rapamycin, Rapamune) is a fermentation product of *Streptomyces hygroscopicus*, a microorganism first isolated from soil samples taken from Easter Island, known locally as *Rapa Nui*.[53] The geographical origin of the microorganism led the Ayerst company (now incorporated into the Wyeth company) to name the drug rapamycin. It was first investigated for its potential as an antifungal agent[7,125,140] and was found to inhibit tumor cell growth[41,57] and to reduce lymphocyte proliferation.[97] Sirolimus was evaluated further as an immunosuppressive agent in animal models of transplantation, but was noted to cause a lethal vasculitis in the dog renal transplant model,[16] hitherto considered to be one of the most reliable preclinical models for evaluating immunosuppressive agents. Interestingly in the light of subsequent clinical findings, the same authors also found a high incidence of interstitial pneumonitis in pigs after kidney transplantation.[16] The findings of drug-induced vasculitis delayed further clinical evaluation of sirolimus. Tacrolimus, which shares a marked structural similarity with sirolimus (Fig. 19-1), also causes a vasculitis in the dog,[24] but when used in humans in 1989 there was no sign of such toxicity.[133] The promising early clinical results with tacrolimus helped lead to a resumption in the clinical evaluation of sirolimus.

As the potential of sirolimus as a clinical immunosuppressive agent became apparent, other companies looked for similar compounds. Everolimus (RAD001, SDZRAD, Certican) was synthesized by chemists at Novartis, who made a 2-hydroxyethyl chain substitution at position 40 of the sirolimus structure (see Fig. 19-1) and created a molecule with improved oral availability.[123]

MECHANISM OF ACTION

After entering into cells, mTOR inhibitors bind to one of a family of immunophilins called FK506-binding

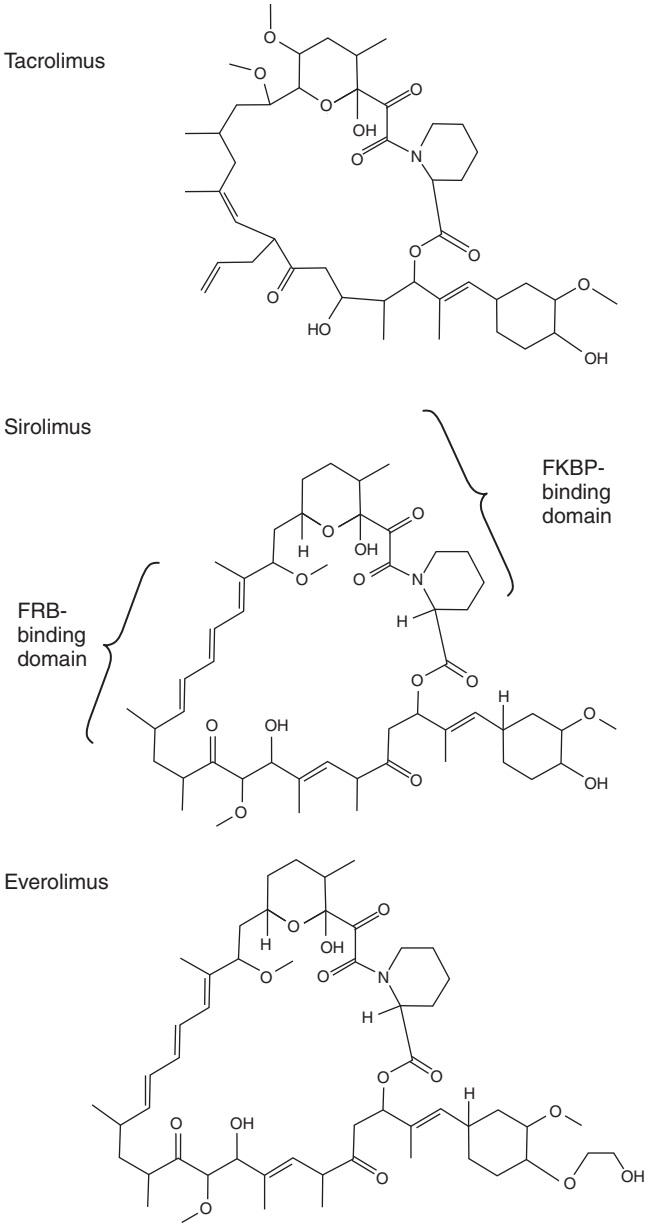

Figure 19–1 Structure of tacrolimus, sirolimus, and everolimus. Sirolimus and everolimus are macrocyclic lactones with structural similarity to tacrolimus (FK506, Prograf). Everolimus has a 2-hydroxyethyl chain substitution at position 40 of the sirolimus structure. All three molecules have a common area that binds to a family of intracellular carrier proteins, the FK506 binding proteins (FKBPs), in particular the 12-kD protein FKBP12.

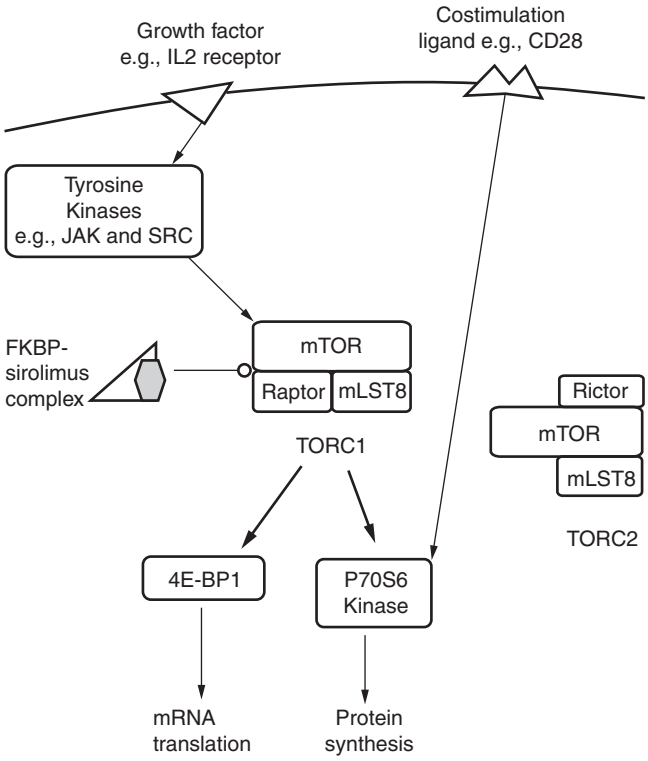

Figure 19–2 Highly simplified schematic representation of the mechanism of action of mTOR inhibitors. The mTOR inhibitors sirolimus and everolimus form an intracellular complex with FKBP12, and this complex inhibits the function of the TORC1 complex, possibly by preventing association of Raptor. TORC1 is important for cell proliferation in response to growth factor stimulation and regulates the S6K1 response to stimulation via the CD28 ligand in T cells. mTOR also forms the TORC2 complex, which is resistant to sirolimus and everolimus and is involved in cytoskeleton control.

proteins (FKBPs), particularly the 12-kD FKBP12 (Fig. 19-2). Immunophilins are protein chaperones with peptidylprolyl cis/trans isomerase activity. FKBPs are cytosolic proteins present in abundance in the cytoplasm.[46] The sirolimus-FKBP12 or everolimus-FKBP12 complexes with mTOR, previously known variously as FKBP-rapamycin associated protein, the Rapamycin and FK506 Target, and the sirolimus effector protein.[55] mTOR is a serine-threonine kinase that acts as a scaffold for the binding of other proteins and is a key component of the cell cycle regulatory signaling pathway.

Two mTOR complexes (TORC1 and TORC2) have been recognized, with different proteins binding to the TOR scaffold; only TORC1 is sensitive to sirolimus.[59,150] In mammals, TORC1 is involved in regulation of cell growth. TORC1 comprises mTOR, mLST8 (also known as GβL), and Raptor, and this complex controls activation of a p70 S6 kinase (S6K1), which is involved in regulating protein synthesis and mRNA translation, and eukaryotic initiation factor 4E binding protein 1, which also is necessary for translation and protein synthesis.[43,78,114] mTOR seems to be the catalytic subunit of the TORC1 complex, whereas Raptor is involved in substrate recognition. The role of TORC2 in mammalian cells is not clearly elucidated, but it is resistant to sirolimus and comprises mTOR, mLST8, and Rictor. It is probably involved in regulation of cell morphology and the cytoskeleton.

In mammalian cells, regulation of TORC1 signaling occurs in response to growth factors, cytokines, nutrients (especially amino acids), energy status (e.g., adenosine monophosphate-to-adenosine triphosphate ratio), and stress (e.g., hypoxia)—all factors that would be expected to regulate cell growth and proliferation. In lymphoid cells, the important signals originate from the cell surface and are generated by cytokine-receptor binding, such as the binding of interleukin-2 to the interleukin-2 receptor complex, or ligand binding to coreceptors such as CD28. When cell surface receptors are stimulated, kinases such as janus kinase 3 are activated, and the ensuing signaling cascade results in activation of TORC1. In the same way that calcineurin is

a rate-limiting step in gene transcription after activation of the T cell receptor complex, TORC1 is the rate-limiting step in the proliferative response to cytokine and coreceptor binding.

Sirolimus binds to the FKBP-rapamycin binding (FRB) domain on mTOR,[22] and binding to FRB is enhanced 2000-fold when sirolimus is complexed with FKBP12.[9] How binding of sirolimus to the FRB domain affects mTOR is unclear, but it may block binding of regulatory proteins such as Raptor, part of the TORC1 complex.[113] Blockade of mTOR results in inactivation of S6K1 and 4EBP and inhibition of CD28-mediated downregulation of IκBα, a regulatory protein that mediates upregulation of interleukin-2 transcription.[79] The result is cell cycle arrest in late G_1 phase.[138] In addition to its effects on lymphocytes, sirolimus may have a direct inhibitory effect on dendritic cells, inducing apoptosis through interaction with growth factor signaling.[105,149] It also may impair neutrophil responses by inhibiting neutrophil migration in response to chemoattractants.[50] Finally, sirolimus also inhibits cytokine-stimulated and growth factor–stimulated proliferation of smooth muscle cells, fibroblasts, and tumors in vitro and in animal tumor models.[3,19,41,57,98] These effects are of potential clinical importance in the context of chronic allograft nephropathy, in which arterial smooth muscle and fibroblast proliferation are major pathological features.

PHARMACOKINETICS

Sirolimus

Sirolimus is marketed in tablet form and as an oral solution. After absorption, it is extensively bound to blood cells, particularly erythrocytes, and less than 5% of the drug remains free in the plasma, where it is associated with the nonlipoprotein fraction.[151] It has a long half-life of about 60 hours in renal transplant patients (tacrolimus has a half-life of 18 to 20 hours), with rapid absorption time to maximal concentration at 1 to 2 hours) and exposure that is proportional to dose, but with a large intersubject coefficient of variance [CV] = 52%) and significant intrasubject variability (CV = 26%).[42,88] The pharmacokinetic profile of the tablet formulation and liquid formulations of sirolimus are similar apart from a lower maximal concentration with tablets.[70] With both formulations, the total drug exposure (area under the concentration-time curve [AUC]) correlates well with maximal concentration and trough concentration. Similar to cyclosporine and tacrolimus, the pharmacokinetics of sirolimus differ in different ethnic groups, with reduced oral bioavailability in African-Americans.[31]

Everolimus

Everolimus is more water-soluble than sirolimus, and this increases its bioavailability. In studies of single doses of everolimus capsules in renal transplant recipients, the drug was shown to have a much shorter half-life than sirolimus (16 to 19 hours), a rapid absorption (maximal concentration reached within 3 hours), and a good correlation between trough and AUC.[64] Similar to sirolimus, there is significant intersubject (85%) and intrasubject (41%) variability in AUC.[75] As with sirolimus, ethnicity affects everolimus pharmacokinetics, with a higher dose requirement in African-American patients.[74] Administration of everolimus does not seem to affect cyclosporine pharmacokinetics.[12,75]

Pharmacogenetics

Metabolism of sirolimus is by the cytochrome P-450 (CYP) 3A group of enzymes, particularly CYP3A4 and, to a lesser degree, CYP3A5. Polymorphisms of these enzymes are common and owing to linkage disequilibrium (the genes lie adjacent on chromosome 7q21) may occur together. Polymorphisms of CYP3A enzymes are associated with loss of function and seem to result in lower drug concentration-to-dose ratios in patients expressing the least common genotypes.[5,83] This genetic variability is an argument against fixed-dose administration of mTOR inhibitors and favors instead concentration-controlled dosing.

Drug Interactions

Similar to most immunosuppressive agents, and as noted previously, sirolimus and everolimus are metabolized primarily by CYP3A4, and their metabolism is altered by drugs that affect this enzyme pathway. Important among these are the calcineurin inhibitors, particularly cyclosporine, which can increase the concentration of sirolimus with a reciprocal increase in cyclosporine concentration; these effects are not observed in single-dose studies, but are apparent after multiple doses. This drug interaction is particularly noticeable when the time interval between sirolimus and cyclosporine ingestion varies, with cyclosporine markedly increasing the bioavailability of sirolimus.[152] It is important that patients receiving sirolimus and cyclosporine adhere to a standard pattern of medication and do not vary the interval between taking the two agents. Conversely, sirolimus reduces the exposure to tacrolimus when the two drugs are coadministered.[8] Other groups of drugs with important interactions with the CYP pathway are the antimicrobials (especially fluconazole and erythromycin) and the 3-hydroxy-3-methylglutaryl-coenzyme A reductase inhibitors (statins), both of which are widely used in renal transplant recipients.

mTOR inhibitors also differ from cyclosporine in the way they interact with the other immunosuppressive agents. Patients taking sirolimus have a much higher exposure to mycophenolic acid, the active constituent of mycophenolate mofetil (MMF), than do patients taking cyclosporine and MMF.[11,38] It has been suggested that patients receiving 1 g twice daily of MMF while taking cyclosporine should have the dose of MMF reduced to 750 mg twice daily when they convert to sirolimus to maintain the same exposure to mycophenolic acid. A similar drug interaction is recognized with tacrolimus. Sirolimus also has been observed to cause a reduced exposure (lower AUC) to prednisolone compared with cyclosporine.[61]

USE OF mTOR INHIBITORS

mTOR inhibitors have been evaluated for use in renal transplantation as an addition to calcineurin inhibitor–based therapy and as a substitute for calcineurin inhibitors. mTOR inhibitors also have been used as de novo treatment from the time of renal transplantation, as a later addition to calcineurin inhibitors to enhance immunosuppression in response to acute rejection, and as a substitute for calcineurin

inhibitors to treat calcineurin inhibitor toxicity in the maintenance phase.

Early in vitro and in vivo studies suggested that mTOR inhibitors and calcineurin inhibitors when used together had a synergistic immunosuppressive effect.[62,71,135] Initially, it was envisaged that mTOR inhibitors might be best used along with calcineurin inhibitors to exploit this synergistic immunosuppressive effect, optimizing immunosuppression and minimizing agent-specific side effects. Evidence from rodent studies suggested, however, that sirolimus may exacerbate cyclosporine nephrotoxicity,[4] a finding that was subsequently confirmed in clinical studies.[66] Most of the initial work with sirolimus was done in conjunction with cyclosporine rather than tacrolimus because it was believed that competition for the FKBP12 immunophilin would preclude the coadministration of tacrolimus and sirolimus. It has become evident, however, that there is an abundance of FKBP12 in the cytoplasm, and in vitro studies suggest that less than 5% of the available FKBP needs to be bound to cause half-maximal immunosuppression.[33] Tacrolimus and sirolimus can be administered simultaneously at therapeutic doses in humans without significant competition for FKBP12.[143]

De novo Therapy with mTOR Inhibitors in the Absence of Calcineurin Inhibitors

Sirolimus has been investigated in numerous studies where it was the principal immunosuppressant. The first such studies were phase II trials conducted in Europe that examined sirolimus when used in a concentration-controlled manner, rather than when given at a fixed dose. When sirolimus was administered as a component of triple therapy with azathioprine and prednisolone, it was associated with a similar incidence of acute rejection to that observed in patients on the Sandimmune preparation of cyclosporine (41% versus 38% at 12 months).[51] A follow-up study substituted azathioprine with MMF and showed no significant difference in the incidence of acute rejection between sirolimus and cyclosporine, although there were numerically more acute rejection episodes in the sirolimus arm (27.5% versus 18.5%).[76] Patient and graft survival were similar in the two study groups, although the studies were insufficiently powered to detect small differences. Pooled data from both studies showed significantly higher glomerular filtration rates in patients receiving sirolimus.[106] These two early studies provided the first detailed insight into the toxicity profile of sirolimus in humans, and suggested side effects different from those associated with calcineurin inhibitors (Table 19-1).

Subsequent studies further explored the use of sirolimus with MMF, together with anti-CD25 monoclonal antibody induction therapy. Early data suggested that the combination of sirolimus and MMF was superior to a cyclosporine-based regimen.[44] A more recent randomized trial comparing sirolimus and tacrolimus (each given along with MMF and prednisolone) showed the two regimens to be comparable in terms of acute rejection rate and graft function.[82] A registry analysis suggested, however, that renal allograft recipients treated with a combination of sirolimus and MMF had a higher acute rejection rate and reduced allograft survival compared with recipients receiving alternative immunosuppressive regimens.[129] Later reports from two large-scale trials (ORION[129] and SYMPHONY[37a]) suggest that the combination of sirolimus and MMF is inferior to low-dose tacrolimus and MMF–based triple therapy. Finally, a systematic review of randomized trials in which mTOR inhibitors were used in place of calcineurin inhibitors as initial therapy after kidney transplantation (eight different trials with a total of 750 participants) revealed that there was no difference in the incidence of acute rejection at 1 year, but the level of serum creatinine (a possible surrogate end point for long-term graft survival) was lower in patients receiving mTOR inhibitors.[147]

De novo Combination Therapy with mTOR Inhibitors and Calcineurin Inhibitors

One of the first studies of sirolimus in renal transplantation to be performed was a dose-ranging study that combined different doses of sirolimus (given as a fixed dose) in conjunction with high-dose or low-dose Sandimmune cyclosporine (concentration controlled).[63] All groups received steroids but no azathioprine or MMF. Small numbers of patients in the study and an unequal distribution of African Americans between the six study groups meant that the results were difficult to interpret. Nevertheless, the study showed that the combination of sirolimus and cyclosporine was more potent than cyclosporine alone in the prevention of acute rejection and that half-dose cyclosporine and sirolimus was as efficacious as full-dose cyclosporine and sirolimus. The higher incidence of acute rejection seen in African Americans in this study also was observed in subsequent studies.[65] The other important finding to emerge from this study was a high incidence of *Pneumocystis* pneumonia in sirolimus-treated patients, mostly in patients from one center where routine prophylaxis against *Pneumocystis jirovecii* was not given.

Two large phase III studies of sirolimus followed shortly afterward, one conducted in the United States[65] and the second worldwide (Table 19-2).[89] Similar to the earlier studies, these studies used a fixed dose of sirolimus (2 mg/day or 5 mg/day) in combination with concentration-controlled cyclosporine. In the U.S. study, the two different doses of sirolimus were compared with azathioprine, and all groups received steroids but no induction therapy.[65] Only patients with functioning renal allografts were recruited, in contrast to the global study in which function of the graft was not a prerequisite for enrollment.[89] The other major difference between the U.S. and the global study was that the comparator in the global study was placebo rather than azathioprine. Both studies showed a clear benefit in terms of reduction in the acute rejection rate for patients receiving sirolimus, an effect that was more marked in patients receiving a higher dose of sirolimus. There was a difference in acute rejection rates, patient survival, and graft survival in the U.S. study compared with the global study in all treatment arms, which likely reflects the different enrollment requirements, with only recipients with functioning grafts being entered into the U.S. study.

These two pivotal studies in the development of sirolimus are the largest such studies to date and reveal much about how best to use sirolimus and its drawbacks. There was a high incidence of lymphocele formation (12% to 15% versus 3% in the azathioprine control in U.S. study) and wound infection compared with the control arm. Of particular

Table 19–1 Adverse Effects of Sirolimus Identified in Phase II Studies of Sirolimus Compared with Cyclosporine

	Sirolimus (*n* = 41 + 40)	Cyclosporine + Azathioprine (*n* = 42)	Cyclosporine + MMF (*n* = 38)
Metabolic

§P <.001 relative to the placebo arm.
Aza, azathioprine; SRL, sirolimus.
Note: Acute rejection incidence and creatinine clearance (Nankivell formula) are 6-month values; graft and patient survivals are 12-month values.
From MacDonald A; for the Rapamune Global Study Group: A worldwide, phase III, randomized, controlled, safety and efficacy study of a sirolimus/cyclosporine regimen for prevention of acute rejection in recipients of primary mismatched renal allografts. Transplantation 71: 271, 2001.

importance was the observation that the renal function of patients on a combination of sirolimus and cyclosporine was worse than that of patients on cyclosporine alone, with a 12-month calculated creatinine clearance of 67.5 mL in the azathioprine control group compared with 62 mL/min and 55.5 mL/min in the 2-mg and 5-mg sirolimus groups ($P < .05$ and $P < .001$ compared with the azathioprine group). A similar effect was seen in the global study. The reason for the reduction in glomerular filtration rate in patients receiving sirolimus and cyclosporine is not well understood, but it is a concern because renal function in the shorter term is a surrogate for long-term graft survival.

The immunosuppressive synergy between cyclosporine and sirolimus in these studies was analyzed by median effect analysis of the pooled data.[66] This analysis showed that administration of sirolimus permitted a 2.2-fold reduction in cyclosporine exposure, and reciprocally cyclosporine permits a 5-fold reduction in sirolimus dose to achieve the same immunosuppressive efficacy. Experimental data also suggest that synergism accounts for the increased nephrotoxicity,[115] although this has not been proved clinically.

Sirolimus also has been evaluated in combination with tacrolimus after an initial report suggesting that the theoretical misgivings about the combination are not seen in clinical practice.[99] At the time of this writing, publication of two large-scale trials evaluating the combined use of sirolimus and tacrolimus are awaited. Other evidence suggests that there may be little to recommend the combination compared with tacrolimus plus MMF,[23,142] and registry data suggest poorer outcome in terms of graft survival for the sirolimus/tacrolimus combination.[103] One criticism of the clinical studies published to date is their use of fixed dose administration of sirolimus, in light of evidence that concentration-controlled dosing is more appropriate.

Everolimus also has been evaluated as an adjunct to cyclosporine in renal transplantation, again in fixed dose combinations. Phase III studies indicated that the combination of either 1.5 mg/day or 3 mg/day of everolimus was better than MMF in the prevention of acute renal allograft rejection when combined with cyclosporine and steroids after kidney transplantation, although the higher dose of everolimus was less well tolerated.[141] As with the combination of sirolimus and calcineurin inhibitors, the combination of everolimus with cyclosporine was associated with poorer renal function (creatinine clearance 52.9 mL/min on 1.5 mg, 49.3 on 3 mg, and 56.9 on MMF at 12 months; $P < .05$). These findings were echoed in a second phase III study.[86] Although mTOR inhibitors provide powerful immunosuppression when combined with calcineurin inhibitors, the increased nephrotoxicity observed suggests that this therapeutic combination might best be reserved for use in the early post-transplant period for patients at particularly high risk of rejection, or for patients who have steroid-resistant rejection.

Maintenance Therapy with mTOR Inhibitors

Although available data suggest that mTOR inhibitors are as efficacious in terms of immunosuppressive potency as calcineurin inhibitors when used as the principal immunosuppressive agent, their use immediately after renal transplantation may be undesirable because of their effects on wound healing and lymphocele formation. Because mTOR inhibitors when used in the absence of calcineurin inhibitors are not nephrotoxic, however, they are potentially attractive agents for use in the maintenance phase of the post-transplant course, especially in patients with calcineurin inhibitor–associated problems, including chronic allograft nephropathy. The first major study to examine the efficacy of mTOR inhibitors in this context used sirolimus combined with cyclosporine and steroids as initial therapy, with the cyclosporine being stopped at 3 months in half of the patients. Sirolimus was shown to provide sufficient immunosuppression during the maintenance phase, with a superior calculated creatinine clearance compared with patients remaining on sirolimus and cyclosporine. Although the acute rejection rate was slightly higher in the no-cyclosporine group, this did not translate into poorer renal function.[60] Longer follow-up confirmed the sustained benefit of sirolimus maintenance therapy.[77,112] This study had no standard control group, and the subsequent finding of enhanced nephrotoxicity when calcineurin inhibitors are combined with sirolimus casts a shadow over the results.[65,89]

Smaller studies also suggest a benefit of sirolimus over calcineurin inhibitors as maintenance therapy after renal transplantation. A dual-center randomized controlled trial from our own unit suggested that conversion to sirolimus in patients with impaired graft function results in a rapid improvement in measured glomerular filtration rate at 3 months, which was sustained to 2 years, whereas patients who remained on calcineurin inhibitors experienced deteriorating graft function.[145] Because of concerns about triggering acute rejection during the conversion from calcineurin inhibitors to sirolimus, some investigators have used a period of overlap of immunosuppression,[29] or covered the transition period with additional agents such as basiliximab,[137] but in patients who are greater than 6 months post-transplantation, it is unlikely that such manipulation is necessary.

Late conversion to sirolimus is associated with three dominant side effects that might limit its usefulness as a maintenance agent, in addition to the other side effects that are well recognized with sirolimus (see later). First, more than half of patients in some studies experience a rash, either an acneiform rash or a dermatitis-like rash affecting the hands and, in particular, the fingers. Second, the period of conversion to sirolimus is associated with the development of mouth ulcers, an occurrence that resolves within 4 weeks in most patients. If mouth ulcers do not resolve, herpes simplex should be considered. Finally, patients with suboptimal renal function, particularly patients with proteinuria, are prone to the development of marked proteinuria after conversion.[28,85] Whether this proteinuria reflects the increased glomerular filtration or difference in tubular response to protein is unclear,[122,136] although blockade of the angiotensin system may be useful to limit this phenomenon.

Despite the potential drawbacks in terms of side effects, evidence is accumulating that conversion from calcineurin inhibitors to mTOR inhibitors may be worthwhile in patients with chronic allograft nephropathy and, at least in the short term, may lead to improved graft function.[30] The optimal time for conversion in such patients is unclear, but early rather than late conversion is probably best, before the structural changes associated with chronic allograft nephropathy become extensive. Switching to mTOR inhibitors in patients who are experiencing other side effects

from calcineurin inhibitors, such as neurotoxicity and diabetes, also seems to be a reasonable option. Conversion from calcineurin inhibitors to mTOR inhibitors for patients who develop hemolytic-uremic syndrome also could be considered, although sirolimus itself has been identified as a cause of this condition.[10,121] Because mTOR inhibitors lead to an increased urinary excretion of uric acid, a further possible indication for use of mTOR inhibitors is in the management of severe gout in patients taking calcineurin inhibitors.

mTOR INHIBITORS AND MALIGNANCY

mTOR Inhibitors as Antitumor Agents

As noted earlier, mTOR inhibitors not only inhibit lymphocyte proliferation but also prevent tumor cell growth. The inhibitory effect of sirolimus on the in vitro growth of tumor cell lines and its inhibitory effect on transplanted tumors in rodent models have long been known, but the clinical potential of mTOR inhibitors as an important novel class of anticancer agents has been appreciated only more recently.[36] Although intuitively, the detrimental effects of immunosuppression after mTOR inhibition might be expected to outweigh any beneficial effect on limiting tumor cell growth in patients with malignancy, it seems that the anticancer activity of mTOR inhibitors is the dominant clinical effect in such patients. There is now intense interest in oncology in evaluating the role of mTOR inhibitors as therapeutic agents.

Many sirolimus derivatives have now been developed specifically for their use as antitumor agents. Temsirolimus (CC1-779), a sirolimus derivative formulated for intravenous administration, has now been used in many phase I/II clinical trials, either as monotherapy or as a component of combination chemotherapy in patients with a range of malignancies, including advanced renal cell carcinoma, breast cancer, prostatic cancer, pancreatic cancer, glioblastoma, and lymphoma. Although sometimes associated with serious side effects, there is evidence for potential clinical benefit, and currently phase III trials of mTOR inhibitors are under way in patients with renal cell carcinoma and patients with advanced or metastatic breast cancer.

mTOR Inhibitors and Post-Transplantation Malignancy

Because patients after renal transplantation are at increased risk of developing most types of malignancy, particularly lymphoma and skin cancer, the anticancer effects of mTOR inhibitors are of major relevance. Several more recent reports suggest that maintenance immunosuppression with mTOR inhibitors after renal transplantation may be associated with a reduced risk of post-transplant malignancy. A relatively low incidence of malignancy in patients receiving sirolimus-based maintenance immunosuppression has been reported from a center with extensive experience of mTOR inhibitor use.[67] A multivariate analysis of post-transplant malignancies in 33,249 renal allograft recipients in the United States revealed that the incidence rates of any type of post-transplant malignancy were 0.6% in patients taking mTOR inhibitors, 0.6% for patients taking mTOR inhibitors plus calcineurin inhibitors, and 1.8% for patients taking calcineurin inhibitors alone.[69] Similarly, the incidence of post-transplant malignancy in adults randomly assigned to remain on sirolimus and calcineurin inhibitors was found to be greater than that in subjects randomly assigned to early calcineurin inhibitor withdrawal and an increased dose of sirolimus.[18] Although these studies are encouraging, further long-term data on the potential for mTOR inhibitors to reduce the development of malignancy after renal transplantation are needed before firm conclusions can be drawn.

mTOR Inhibitors and Post-Transplantation Lymphoproliferative Disorder

Everolimus and sirolimus have been shown to inhibit markedly the growth of human post-transplantation lymphoproliferative disorder–derived cell lines and Epstein-Barr virus–transformed B lymphocytes in vitro and in vivo.[94,95,110] A renal transplant recipient in whom disseminated post-transplantation lymphoproliferative disorder resolved completely after conversion of immunosuppression to sirolimus also has been reported.[25] Sirolimus was not found to modify the risk of developing post-transplantation lymphoproliferative disorder, however, in an analysis of 25,127 patients (344 of whom developed post-transplantation lymphoproliferative disorder) who underwent renal transplantation in the United States.[15]

mTOR Inhibitors and Kaposi's Sarcoma

mTOR inhibitors may have a useful role in the treatment of renal transplant recipients who develop Kaposi's sarcoma associated with herpesvirus-8, especially if the disease is confined to the skin. In a study of 15 patients who developed cutaneous Kaposi's sarcoma after renal transplantation while taking cyclosporine, switching them to sirolimus led to complete, histologically confirmed remission in all patients for the duration of the study (6 months) with preservation of graft function.[132] Response varies, however, and may depend on the severity of disease. A retrospective analysis in which 14 renal transplant recipients with Kaposi's sarcoma (including several with visceral or advanced disease) were switched from calcineurin inhibitors to sirolimus showed that the switch was generally well tolerated. Complete remission was seen in two patients, and a partial response was seen in a further eight, although three of the partial responders with advanced disease relapsed after several months.[84] Further studies are needed to evaluate the role of mTOR inhibitors in treatment of Kaposi's sarcoma and to determine the optimal treatment schedule for patients with more advanced disease.

SAFETY AND SIDE EFFECTS OF mTOR INHIBITORS

It was not until the phase II studies of sirolimus by Groth and Kreis and their colleagues[51,76] that the sirolimus-specific side effects became clear because until then and in most of the subsequent studies sirolimus (and everolimus) was used in conjunction with calcineurin inhibitors. Table 19-1 shows the principal side effects found in these studies. In contrast to calcineurin inhibitors, it is notable that although mTOR inhibitors may cause a range of agent-specific side effects, these do not include nephrotoxicity, neurotoxicity, hypertension, or gingival hyperplasia.

Infection

The incidence and pattern of infections reported in patients receiving mTOR inhibitors is broadly similar to patients receiving calcineurin inhibitor–based immunosuppression. Neither the U.S. study nor the global studies of de novo sirolimus use (see Table 19-2) identified any particular problem with infection over and above that observed in the comparator groups, although the global study noted an increase in the incidence of mucosal lesions attributed (but without virological confirmation) to herpes simplex virus.[65,90] A meta-analysis of mTOR inhibitor use as primary immunosuppression after kidney transplantation confirmed the overall safety of mTOR inhibitors in terms of infection and noted that when mTOR inhibitors were substituted for antimetabolites, there was a reduction in the incidence of cytomegalovirus infection.[146] Some studies have suggested that the incidence of pneumonia may be greater in patients receiving mTOR inhibitors, but the evidence for this remains inconclusive and confounded by the occurrence of drug-induced pneumonitis.

Lipids

One of the most concerning long-term problems associated with mTOR inhibitors is their metabolic effect on lipid metabolism. Two thirds of patients may develop increased triglyceride levels, and half develop increased serum cholesterol levels. Fifty-three percent of sirolimus-treated patients required lipid-lowering agents compared with 24% in the cyclosporine groups combined. The full significance of the increased lipids associated with mTOR inhibitors is unclear, but it is a long-term concern. Lipids are implicated in the development of cardiovascular disease and in the genesis of chronic rejection.[100] What is unclear is whether these risks pertain in the presence of sirolimus. There is limited evidence in animal models that sirolimus inhibits graft vasculopathy,[58] an observation that has been confirmed with everolimus using intravascular ultrasound in heart transplant recipients.[37] Sirolimus also seems to be able to prevent the accelerated vascular disease seen in cholesterol-fed, apolipoprotein E–deficient mice despite a high cholesterol level.[40] Its effect on stabilizing the endothelial cell wall also underlies its beneficial effect when incorporated into intravascular stents. The occurrence of lipid abnormalities seems to be, at least in part, genetically determined with polymorphisms in apolipoprotein A implicated in at least one study.[96]

Pneumonitis

Although lipid abnormalities might be the most common side effect seen with mTOR inhibitor therapy, pneumonitis is the most feared. Pneumonitis may occur at any time after initiation of sirolimus treatment and manifests as progressive dyspnea, dry cough, fatigue, and fever,[21,54] and may progress to pulmonary failure. Imaging reveals bilateral pulmonary infiltrates (Fig. 19-3), and pulmonary function tests may show a restrictive pattern. Open lung biopsies have revealed granulomata in some cases, but not in others. The effect is reversible with discontinuation of sirolimus.

The true incidence of sirolimus-associated pneumonitis is unclear, and it is probably underrecognized and underreported. The first reports of sirolimus-associated pneumonitis were in 2000,[108,148] and these were followed by a disclosure from the U.S. Food and Drug Administration of 31 other cases of interstitial pneumonitis associated with sirolimus use.[128] Earlier studies had reported an increased incidence of pneumonia (see Table 19-1),[51] however, and one of the first studies reported an excess of *Pneumocystis* pneumonia[63]; it is possible that some of these were sirolimus-induced pneumonitis. Ten years previously, the complication had been noted as the principal cause of death in pigs undergoing renal transplantation with sirolimus.[16]

The etiology of sirolimus-associated pneumonitis is unclear. Reports suggest that it is more common in patients switching from a calcineurin inhibitor to sirolimus or having a calcineurin inhibitor withdrawn from a sirolimus/calcineurin inhibitor combination, and having high drug concentrations.[21,49,128] A mortality of 12% was noted in the Food and Drug Administration report, although early recognition of the problem, with immediate discontinuation of sirolimus, should reduce the mortality from this complication. One report suggests that conversion from sirolimus to everolimus is associated with recovery,[117] whereas another report also implicates the related antitumor drug temsirolimus in causing pneumonitis[34]; both observations would suggest that it is not mTOR blockade per se that is responsible for the complication, but that the lipophilic nature of sirolimus and temsirolimus also is important in its cause.

Hemolytic-Uremic Syndrome (Thrombotic Microangiopathy)

One of the main attractions of mTOR inhibitor therapy is its perceived lack of nephrotoxicity. Although sirolimus does not cause the typical changes associated with calcineurin inhibitor therapy, it is not entirely devoid of adverse effects on the kidney. The most dangerous of these is its association with hemolytic-uremic syndrome (thrombotic microangiopathy). Hemolytic-uremic syndrome was identified as a problem in patients taking cyclosporine and sirolimus,[80,118] but subsequent reports highlight it to be associated with sirolimus in the absence of calcineurin inhibitors.[10,121] It also occurs in the native kidneys of non–renal transplant recipients,[52] as is reported with everolimus, suggesting that it is a property of mTOR as a group.[86]

Proteinuria

Proteinuria is now recognized as a common manifestation of sirolimus toxicity in patients converted for renal impairment and has been noted in patients taking everolimus.[86] It is most common in patients who already have a degree of proteinuria at the time of conversion,[120] and it seems to be a direct sirolimus effect that occurs in adults and children.[14,85] The absence of proteinuria seems to be the best indicator of improvement in renal function after conversion.[13,28] The cause of the proteinuria is unclear. In one study of four patients who developed proteinuria, biopsy specimens revealed glomerulonephritis (membranoproliferative glomerulonephritis in one, membranous glomerulonephritis in another, and IgA nephropathy in the last two).[32] The proteinuria resolved when the patients were converted back to calcineurin inhibitors and the sirolimus was stopped. In a separate study involving patients who had liver transplants

but developed renal impairment, no proteinuria was seen on conversion to sirolimus, suggesting that preexisting renal damage may be necessary before proteinuria manifests.[27] Proteinuria has been observed in patients undergoing islet transplantation and receiving sirolimus, however, in whom underlying diabetic nephropathy may have been contributory.[126]

Some authors have suggested that proteinuria may arise from the removal of arteriolar vasoconstriction afforded by calcineurin inhibitors, but such a mechanism cannot account for the observation that proteinuria occurs in patients treated from the outset on a sirolimus-based, calcineurin inhibitor–free protocol.[134] Other authors have suggested that an increased intraglomerular pressure might be causative,[122] whereas still others have suggested that a reduction in tubular protein reabsorption is responsible.[136]

Delayed Recovery from Ischemia-Reperfusion Injury

Delayed recovery of normal kidney function (delayed graft function) is a common manifestation of ischemia-reperfusion injury, most notable with kidneys donated after cardiac death, where warm ischemia and cold ischemia contribute to renal injury. Reduced exposure to calcineurin inhibitors in the early postoperative stage has been common practice in many transplant units, so the advent of a "non-nephrotoxic" agent, such as sirolimus, was an attractive alternative. Early experimental work in rats showed delayed recovery from ischemia-reperfusion injury,[48] and this has subsequently been observed in the clinic in small retrospective studies[101] and registry analyses.[127] The mechanism behind this observation presumably relates to the inhibition of cell proliferation

Figure 19–4 Sirolimus-induced erythema and limb edema. Acute erythema and swelling in the limbs associated with sirolimus. The symptoms resolved after administration of steroids.

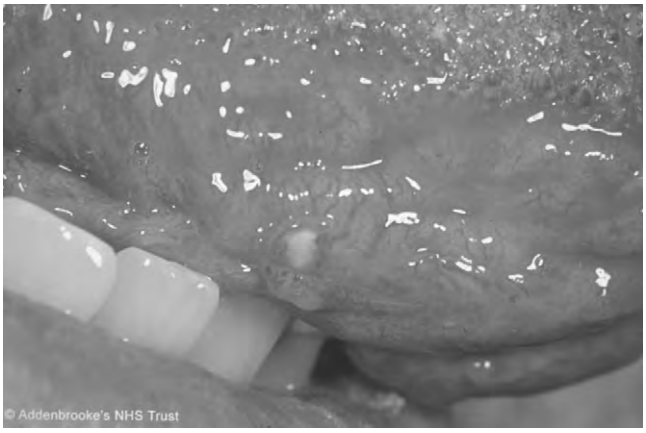

Figure 19–5 Sirolimus-induced oral ulceration. Solitary aphthous-type ulcer on the undersurface of the tongue occurring several days after late (>6 months) conversion from calcineurin inhibitor to sirolimus. Such lesions are often multiple and painful and can be distressing for the patient. They usually resolve rapidly after adjustment of sirolimus to the lower end of the target range of 5 to 10 ng/mL.

affecting tubular repair.[87] Although sirolimus is associated with a higher incidence of delayed graft function and prolonged recovery of function, the renal function in the long-term does not seem to suffer.[102,130]

Peripheral Edema

Although not widely recognized, the occurrence of edema in patients taking sirolimus and everolimus is well described. Most edema affects the lower limb[1] and may be unilateral (Fig. 19-4) or bilateral; it is not necessarily ipsilateral to the kidney transplant. Angioedema affecting the eyelids and tongue also has been described.[47,104,131,144] It typically resolves on discontinuation of the mTOR inhibitors. The cause of this complication is unknown.

Wound Healing and Lymphocele Formation

One of the most concerning complications of mTOR inhibitors is the potentially detrimental effect they have on the operative site. mTOR inhibitors not only impair wound healing but also are associated with a high incidence of lymphoceles after renal transplantation, although this seems partly center specific, suggesting a technical component, such as whether lymphatics were deliberately divided or ligated, or both. Wound problems include fluid collections around the graft and under the skin, superficial infections, and late hernias.[26] Anastomotic healing has not been reported as a problem after clinical renal transplantation, but poor healing of the airway anastomosis has been cited after lung transplantation,[35,72] and there is some evidence in the pig that ureteric anastomoses are not as strong.[68] The problems observed with wounds may relate to mTOR inhibition resulting in lack of fibroblast response to fibroblast growth factor and lack of neovascularization of wounds owing to blockade of vascular endothelial growth factor.

Mouth Ulcers

Oral ulceration (mucositis) manifesting as painful gingival or buccal mucosa leading to pain on eating is a well-documented and troublesome side effect of mTOR inhibitors (Fig. 19-5). The ulcers are usually small but multiple, and in many cases are probably related to herpes simplex virus infection. In the global phase III study of de novo treatment with rapamycin, ulceration of the oral mucosa was observed in 19% of patients randomly assigned to 5 mg/day of sirolimus, 10% of patients randomly assigned to 2 mg/day of sirolimus and 9% of patients in the placebo group.[90] The lesions all were mild and resolved spontaneously without discontinuation of sirolimus.[90]

Mouth ulcers also are common in patients converted to mTOR inhibitors. As is the case in de novo treatment, such ulcers usually resolve spontaneously, but they can be problematic. In one prospective randomized study in which renal transplant recipients were converted at 1 year from a steroid-free regimen of tacrolimus and MMF to sirolimus and MMF, oral ulceration occurred in 9 of 15 converted patients. The mucosal lesions healed within 2 weeks of discontinuing sirolimus, but the problem led to premature cessation of the study.[139] The authors postulated that the high incidence of oral ulceration may have been attributable to overimmunosuppression during conversion, the use of oral emulsion of sirolimus rather than tablets, and the lack of corticosteroids.[139] In a randomized study of conversion from calcineurin inhibitors to sirolimus after renal transplantation, aphthous-type mouth ulcers occurred in one third of patients during the first 2 weeks after conversion, although all resolved with adjustment of sirolimus to the lower end of the target range of 5 to 15 ng/mL.[145] The association between sirolimus and mucosal ulceration may be attributable predominantly to the detrimental effect of mTOR inhibitors on wound healing, rather than any direct effect in initiating ulcer formation.

Figure 19–6 Sirolimus-induced rash. After conversion from calcineurin inhibitor to sirolimus, patients commonly develop skin problems that may take the form of a dermatitis-like rash affecting the hands and, in particular, the fingers.

Rash

As already noted, rash is a common complication of mTOR inhibitor therapy and most commonly takes the form of an inflammatory acneiform eruption[92] or a dermatitis-like rash affecting the hands and, in particular, the fingers (Fig. 19-6). This rash was apparent in both of the early multicenter randomized trials of de novo sirolimus treatment after renal transplantation. In the U.S. study, an acneiform rash was observed in 25% of recipients on 2 mg/day, 19% of recipients on 5 mg/day, and 11% in the azathioprine control group.[65] In the global phase III study, rash was observed in 14% of patients randomly assigned to 5 mg/day of sirolimus, 4% of patients randomly assigned to 2 mg/day of sirolimus, and 5% of patients in the placebo group.[90]

In studies in which an in-depth dermatological analysis has been undertaken, the incidence of dermatological side effects is considerably higher. A cross-sectional study of cutaneous adverse events in renal transplant recipients receiving long-term, sirolimus-based immunosuppression reported the presence of an acne-like eruption in 46%, scalp folliculitis in 26%, and hidradenitis suppurativa in 12% of patients.[91] In the absence of a control group, it is difficult to attribute side effects exclusively to mTOR inhibitors, but such studies indicate the high frequency of dermatological complications associated with mTOR inhibitors. Although rashes are usually mild, they may be a reason for discontinuing mTOR inhibitors. In the randomized trial of late conversion to sirolimus in our center, 68% of converted patients developed a rash, particularly acne, and 2 of the 19 converted patients discontinued sirolimus because of this.[145] The pathophysiology of rash in patients taking mTOR inhibitors is unclear, but may be attributable to the effect of mTOR inhibitors on the epidermal growth factor receptor, which is important in the differentiation and development of the hair follicle.[92]

Anemia, Thrombocytopenia, and Leukopenia

Anemia, thrombocytopenia, and leukopenia all are well-recognized side effects of use of mTOR inhibitors. Although thrombocytopenia attracted the most attention in early studies, anemia has emerged as the most significant clinical problem. Anemia is a common complication during the first 6 months after renal transplantation regardless of the immunosuppressive regimen,[2] but the incidence is increased with use of mTOR inhibitors. In the global study of primary use of sirolimus in renal allograft recipients, anemia was observed in 16% of recipients taking 2 mg/day and 27% of recipients taking 5 mg/day of sirolimus. The incidence of anemia in the 5 mg/day group was significantly higher than that in the placebo group (13%) receiving cyclosporine and steroids.[90] mTOR inhibitor dosage adjustment may be required, and in some patients administration of erythropoietin may be necessary.

Anemia after renal transplantation most often results from iron deficiency and defective erythropoietin production, but the mechanisms responsible for mTOR inhibitor–induced anemia are unclear. Sirolimus blocks the in vitro response of bone marrow cells to several hematopoietic cytokines, including granulocyte colony-stimulating factor, interleukin-3, and kit ligand.[116] Although mTOR inhibitor–induced suppression of nonerythroid bone marrow cells contributes to leukopenia and thrombocytopenia, the extent to which mTOR inhibitor–induced suppression of erythrocyte production leads to anemia is uncertain. A more recent study observed that sirolimus reduced hemoglobin levels but did not reduce the erythrocyte count in renal transplant recipients, arguing against a direct antiproliferative effect on erythroid bone marrow.[93] Instead, it was suggested that sirolimus had a direct effect on iron homeostasis.[93]

Thrombocytopenia was identified as a side effect of sirolimus in the global and U.S. phase III randomized trials of de novo sirolimus and seemed to be dose related.[65,90] In both studies, a few patients randomly assigned to the higher dose (5 mg/day) of sirolimus (6 of 208 [2.8%] in the global study and 3 of 274 [1.1%] in the U.S. study) had to have sirolimus discontinued because of thrombocytopenia, although none of the patients experienced severe thrombocytopenia or were reported to have had related hemorrhage. mTOR inhibitors may reduce circulating platelets as part of their inhibitory effect on hematopoietic cytokines. In addition, sirolimus has been shown to promote agonist-induced platelet aggregation in vitro,[6] and conceivably if increased platelet aggregation occurs in vivo, it may promote increased removal of platelets by the spleen.

Although it is now well recognized that mTOR inhibitors may lead to a decrease in the platelet count, this is not usually of clinical significance and is rarely a barrier to continued administration of mTOR inhibitors. Thrombocytopenia most often occurs within the first month of starting sirolimus, and its occurrence correlates with whole-blood trough levels of sirolimus that exceed 16 ng/mL. If the platelet count falls significantly, it usually responds well to dosage reduction without the need to withdraw mTOR inhibitors.[56] Finally, mTOR inhibitors may produce mild leukopenia, which is usually transient and dose related.

Gastrointestinal Symptoms

Gastrointestinal side effects include abdominal pain, nausea, and vomiting, but the most common symptom is diarrhea, which is usually mild, is dose related, and does not require mTOR inhibitor withdrawal. In the pivotal phase III studies

of de novo sirolimus use, mild diarrhea was observed in 27% to 32% of patients receiving 5 mg/day of sirolimus, 16% to 20% of patients receiving 2 mg/day of sirolimus, and 11% to 13% of patients in the control groups.[65,90] Mild diarrhea may be particularly common in patients receiving a combination of mTOR inhibitors and MMF.[76] The high incidence of diarrhea sometimes reported in patients receiving sirolimus and MMF may be related to pharmacokinetic interaction between the two agents[20]; concentration-controlled administration of MMF markedly reduces gastrointestinal symptoms.[45]

Thrombosis

Sirolimus, similar to calcineurin inhibitors, has been shown to increase platelet aggregation in vitro,[6] and it has been suggested that sirolimus, when used in combination with calcineurin inhibitors, may increase the risk of hepatic artery thrombosis after liver transplantation. Although there is no published trial evidence that mTOR inhibitors are associated with an increased risk of thromboembolic events after renal transplantation, it is recognized in the data sheets for sirolimus that thromboembolic events may be associated with its use. In a retrospective single-center analysis of deep vein thrombosis, graft thrombosis, and pulmonary embolism in renal transplant recipients, the addition of sirolimus in recipients taking cyclosporine did not increase the risk of postoperative thrombotic events.[81] A strong correlation between the development of deep vein thrombosis and lymphocele was observed, however, in patients receiving sirolimus,[81] and the increased risk of deep vein thrombosis in patients developing lymphocele should be kept in mind.

Renal Tubular Effects: Hypokalemia and Hypophosphatemia

mTOR inhibitors may contribute to hypokalemia after renal transplantation, and in the phase II and III trials of primary treatment with sirolimus, values of serum potassium less than the normal range were recorded during the first 3 months in about half of all patients.[106] Hypokalemia is usually mild, and only about 10% of patients required a period of potassium supplementation, which readily corrected the problem.[106] Hypokalemia may be partially related to the dose of mTOR inhibitors given and seems to be due to mTOR inhibitor–induced alterations in tubular function leading to increased tubular secretion of potassium.[107]

Hypophosphatemia also is common in the first few weeks after renal transplantation and is multifactorial in etiology. Although reduced serum phosphate levels may observed more often during the first 3 months in patients receiving mTOR inhibitors, this is rarely a clinically significant issue, and values return to normal with time or dosage adjustment.[106] The mechanisms underlying mTOR inhibitor–associated hypophosphatemia are not completely understood, but mTOR inhibitors may impair renal tubular phosphate reabsorption, prolonging the phosphate leak.[124]

Bone Effects

Arthralgia was identified as a side effect of mTOR inhibitors in the global phase III study of the sirolimus. It was observed in 27% of recipients on the higher dose (5 mg/day) of sirolimus compared with 16% and 13% of recipients on low-dose sirolimus or placebo.[89] Similar to the calcineurin inhibitor–induced pain syndrome, bone pain associated with sirolimus affects weight-bearing areas, particularly the feet, ankles, and knees, although the pain may be unrelated to weight bearing. It is generally bilateral and symmetrical. The problem is much less common when lower doses of mTOR inhibitors are used, and symptoms may improve after dosage reduction or respond to treatment with bisphosphonates or alfacalcidol. mTOR inhibitor–induced bone pain and calcineurin inhibitor–induced pain syndrome are likely due to a combination of increased adipocyte volume, reduced intraosseous perfusion, and marrow edema giving rise to a "bone compartment syndrome."[39] The diagnosis usually can be confirmed by radionuclide bone scan (Fig. 19-7) or magnetic resonance imaging scan that reveals hyperemia and marrow edema.

Osteoporosis and bone loss are common after renal transplantation, and there is evidence from preclinical and early clinical studies that mTOR inhibitors may have bone-sparing properties compared with calcineurin inhibitors. Although sirolimus is associated with bone remodeling, it does not result in a loss of trabecular bone volume in rat studies, in contrast to calcineurin inhibitors.[119] Similarly, everolimus inhibits osteoclast activity in vitro and reduces bone loss in an oophorectomized rat model.[73] Markers of bone turnover (serum osteocalcin and urinary N-telopeptides) also are significantly lower in renal transplant recipients taking de novo sirolimus compared with recipients taking cyclosporine.[17] Such studies suggest a possible advantage of mTOR inhibitors over calcineurin inhibitors, but more extensive clinical studies with extended follow-up are needed to confirm these early indications.

Liver Function Abnormalities

Sirolimus tends to cause increased levels of transaminases (alanine aminotransferase and aspartate aminotransferase) and lactate dehydrogenase. Whether this is clinically significant is unclear. There is a single case report of hepatotoxicity in a renal transplant recipient[111] and a series of 10 liver transplant recipients in whom sirolimus was thought to be responsible for abnormal liver function tests, with 2 of the patients having liver biopsy specimens with eosinophilia and sinusoidal congestion.[109] This latter group of 10 patients underwent transplantation for hepatitis C, which had reinfected their grafts, making a clear association with sirolimus difficult.

Amenorrhea

In a study of conversion from calcineurin inhibitors to sirolimus, it was noted that all three female patients younger than 40 years of age who were switched to sirolimus developed amenorrhea for a variable length of time and then resumed irregular menses.[145] Whether this finding is due to an effect of mTOR inhibitors on the hypothalamic-pituitary-gonadal axis or to a direct effect on the endometrium is unclear.

SUMMARY AND CONCLUSION

mTOR inhibitors have been undergoing clinical evaluation as immunosuppressive agents in renal transplantation for more than a decade, and much has been learned about their

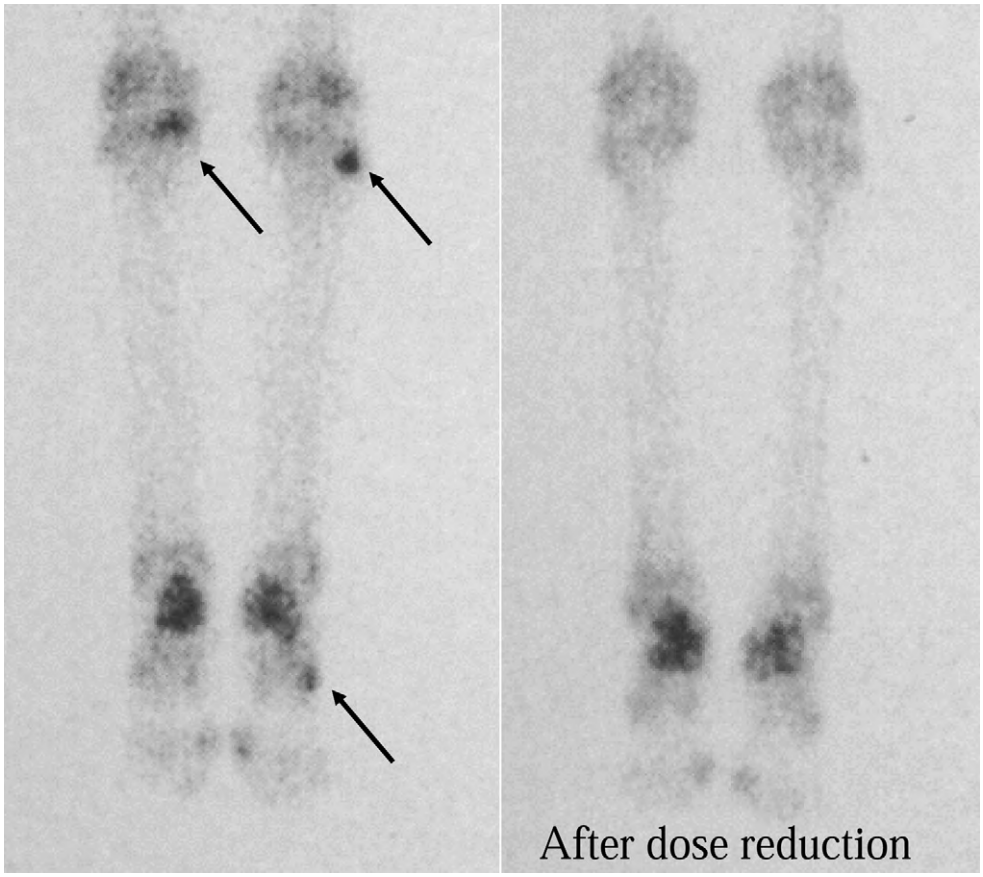

Figure 19–7 Radionuclide bone scan in a patient with sirolimus-induced bone pain. The patient complained of pain affecting the feet, ankles, and knees. The diagnosis was confirmed by radioisotope scanning that revealed areas of increased uptake in the knees and at the ankles (*arrows in left panel*). After sirolimus dosage reduction, the symptoms resolved, and the bone scan returned to normal (*right panel*).

efficacy and side effects. Sirolimus and more recently everolimus have been shown to be effective agents for preventing acute renal allograft rejection and preserving glomerular filtration rate, but their clinical niche remains to be clearly defined. The safety profile of mTOR inhibitors in terms of post-transplant infection is satisfactory and broadly comparable with that of patients receiving standard calcineurin inhibitor–based therapy.

The agent-specific side-effect profile of mTOR inhibitors also is now well established and has relatively little overlap with that of calcineurin inhibitors, making mTOR inhibitors an attractive alternative for patients who cannot tolerate calcineurin inhibitors. mTOR inhibitors are not nephrotoxic when given in the absence of calcineurin inhibitors, and there is some evidence that they may limit chronic allograft nephropathy. The problems of lymphocele formation and impaired wound healing seen with sirolimus argue against the immediate use of mTOR inhibitors after renal transplantation, however, and the adverse effect of mTOR inhibitors on the lipid profile and the significant, but ill-defined risk of life-threatening pneumonitis are significant concerns with long-term use.

The optimal timing for the introduction of mTOR inhibitors after renal transplantation needs to be determined, and ways to better manage the troublesome mucosal and dermatological complications that are commonly seen after conversion to mTOR inhibitors need to be found. Most importantly, long-term studies are needed to determine whether the early benefits observed with mTOR inhibitors in terms of preservation of renal function translate into improved long-term graft survival and protection from chronic allograft nephropathy. There is also a need to determine the extent to which any such benefits outweigh the long-term side effects of mTOR inhibitors, particularly their adverse effect on the lipid profile. Confirmation of the anticancer properties of mTOR inhibitors in renal transplant recipients also is awaited, but initial data are encouraging.

Chapter 20

Antibodies and Fusion Proteins

Allan D. Kirk

Renal transplantation is the preferred treatment for most end-stage renal diseases. The success of transplantation has been counterbalanced, however, by its dependence on immunosuppressive drugs with their related infectious, metabolic, and malignant complications. Consequently, a common goal throughout the history of clinical transplantation has been the minimization and individualization of immunosuppressive therapy. Typically, drugs with highly specific mechanisms of action have been preferred over drugs with broad effects, and the search for increasingly specific drugs has provided a major impetus for the development of immunosuppressive therapies in general, and of antibodies and fusion proteins in particular.

Antibodies and other glycoprotein cell surface receptors are defined by their ability to bind to a particular ligand with unambiguous specificity. Although they may mediate diverse effects through associated downstream signaling pathways, their function is characterized by fidelity to distinct binding motifs. This trait has been long recognized as having great potential for targeted therapeutic use with minimal unintended effects, and organ transplantation historically has been a preferred testing ground for receptor-based therapeutics, such as monoclonal antibodies (MAbs), polyclonal antibody preparations, and engineered glycoprotein receptor-antibody hybrids known as fusion proteins, collectively known as biologics. The initial success of biologics in transplantation has more recently led to an explosion in the number developed for clinical use.[232] In addition to transplant-related indications, biologics have been developed for the treatment of many oncologic and autoimmune conditions, and there are now at least 200 preparations in some level of clinical or preclinical development.[231] Importantly, although renal allograft rejection was the original indication for MAb therapy,[63] most modern development has been spurred by indications serving larger population bases. In addition to using agents developed for transplantation, clinicians are increasingly adopting therapies from other immunologically relevant indications. This so-called off-label use is now increasingly common and is becoming a primary means of biologics development for transplantation.

This chapter provides an overview of antibody-based and receptor-based therapies for kidney transplantation. Drugs developed and approved for use in transplantation are described; drugs with relevant actions that have been developed for other indications but evaluated in transplantation also are described. Investigational agents that have been tested clinically are reviewed.

HISTORICAL PERSPECTIVE

The early experiences in renal transplantation were marked by very high rates of rejection and complications related to the effects of the two available immunosuppressants of the day, glucocorticosteroids and azathioprine; this, combined with the recognition that lymphocytes were the predominant effectors in rejection, stimulated interest in alternative lymphocyte-directed strategies. By the mid-1960s, several investigators had shown that animals injected with lymphocytes would produce sera containing lymphocyte-specific antibodies, which could be used to reduce the lymphocyte counts when injected into other experimental animals. This technology gave rise to the initial lymphocyte depletion trials using antilymphocyte antibody preparations—antilymphocyte serum, antilymphocyte globulin, and antithymocyte globulin.[26,62,72,269] These agents were collectively called polyclonal preparations because they were composed of antibodies with many, largely undefined, specificities. Their ability to prevent and reverse rejection, particularly in patients refractory to the drugs of the day, led to their increasing use over the ensuing decade.[64]

The increased use of polyclonals made many of their limitations apparent. The imprecise in vivo methods for producing polyclonal antibodies resulted in preparations with promiscuous binding to many nonlymphocyte cell types. Although each antibody in the preparation bound to a single target, collectively, the preparation bound to a broad array of cell surface molecules. Cross-reactivity with many hematopoietic cells made anemia, neutropenia, and thrombocytopenia dose limiting. The method of production also led to wide batch-to-batch variability. The clinical effect of the agent varied considerably, making it difficult to establish prospectively proper dosages and estimate the magnitude of anticipatable side effects. In addition, because the preparations were made in animals, usually rabbits or horses, they contained proteins that were antigenic to humans.[201,281] They had the potential to induce a neutralizing antibody response and evoke adverse effects, such as serum sickness or anaphylaxis.[222] Finally, some lymphocyte cell surface receptors, when bound by antibody, would induce cell activation, leading to a release of anaphylatoxins and cytokines, producing a syndrome of flu-like and, in extreme cases, septic-like symptoms subsequently termed cytokine release syndrome.

In the 1970s, Kohler and Milstein[159] presented a landmark development in the field of protein therapeutics—a means of producing antibody preparations with a single, genetically defined monoclonal specificity. The development of MAbs addressed many of the shortcomings associated with polyclonal preparations, particularly specificity and variability. The first such preparation approved for clinical use was muromonab (OKT3), a MAb of mouse origin specific for human cluster of differentiation (CD) 3 (described later).[63] OKT3 rapidly and specifically cleared T cells from the peripheral circulation and was shown to be a very effective treatment for allograft rejection.[63,87,209,217,235] Although many of the problems associated with the diffuse nature of polyclonal antibodies were addressed, some were not. The immune response against heterologous animal proteins and the cytokine release syndrome remained. OKT3's heightened specificity for the T cell receptor (TCR) not only produced more reliable T cell clearance but also more reliable T cell activation and cytokine release. The antimouse antibody response also limited prolonged dosing in a subset of patients.[131]

With the genetic engineering advances of the 1980s, the production of MAbs became much more efficient, theoretically allowing any surface molecules to be targeted. Effort was redirected from pan–T cell depletion toward fine targeting of relevant T cell subsets and blockade of functions unique to effector T cell activation. An example was the high-affinity interleukin (IL)-2 receptor, CD25 (described later), expressed predominantly on activated T cells. Additionally, methods of genetic engineering were developed to allow DNA encoding for binding sites from heterologous proteins to be grafted onto genetic sequences encoding the monomorphic scaffold of human antibodies to create chimeric or humanized MAbs.[31,132,191] These techniques also allowed for unique fusion proteins to be created combining the Fc portions of antibodies with nonantibody receptors and ligands, and allowing for cell surface molecules to be created in a soluble form with prolonged half-lives.

The humanization of antibodies and the use of human-derived receptors has practically eliminated the problem of antibody clearance and opened the possibility for prolonged treatment regimens. More recently, the production of fully human antihuman antibodies has become a practical reality.[313] Techniques including phage display mutagenesis and the transgenic production of mice containing human immunoglobulin genes that respond to immunization with human antibody now offer the promise of highly specific, nonimmunogenic, well-tolerated protein reagents. Human and humanized biologics are now making possible prolonged therapy with highly specific therapeutic agents.

Multiple surface molecules have been targeted by biologics investigationally, and several are now accepted as clinical therapies in transplantation and other indications. Biologic therapy is being increasingly adopted into standard practice, with 70% of kidney transplants performed in the United States now using prophylactic antibody therapy of some sort.[1,250] Despite this general trend, however, it has not been established whether this strategy is necessary in all cases. Although antibody induction reduces acute rejection rates in the first year after transplantation, the lasting effects of induction remain incompletely defined.[278,279] The modern era is now characterized by the availability of many promising agents and the challenge of understanding their most appropriate clinical use.

ANTIBODY STRUCTURE AND FUNCTION

The clinical effects of MAbs in transplantation relate closely to the physiological effects and structural characteristics of antibodies in general. Antibodies are one of two common glycoprotein antigen receptors that result from somatic gene rearrangements in specialized lymphocytes, the other being TCRs.[98,127] Five different heavy chain loci (μ, γ, α, ε, and δ) and two light chain loci (κ and λ), each with variable, diversity, or junctional (V, D, or J) and constant (C) regions, are brought together randomly by the recombination associated gene (RAG)-1 and RAG-2 apparatus to form a functional antigen receptor with highly variable binding ability. Antibodies have a basic structure of two identical heavy chains and two identical light chains (Fig. 20-1). The heavy chain usage defines the immunoglobulin type as being IgM, IgG, IgA, IgE, or IgD. This structure forms two identical antigen-binding sites brought together on a common region known as the Fc portion of the antibody. Although all of these subtypes have therapeutic potential, IgG antibodies have been the most commonly used clinically. IgG molecules are the most common result of peripheral immunization and are structurally easier to produce and manipulate.

Physiologically, antibodies exist as surface molecules on B cells, facilitating their antigen-specific activation and, importantly, are secreted into the serum to bind to and neutralize circulating antigens. Heterologous nonhuman antibodies are sufficiently similar to their human counterparts to facilitate most physiological effector functions when used in humans. Antibodies produced by mice, rabbits, and horses can be used in humans and still evoke biologically important effects. There is no animal that is a priori superior, however, and all heterologous antibodies have the potential to induce a neutralizing antibody response.

Antibodies can have a broad range of effects when they bind (Fig. 20-2). They can mimic the native ligand of a molecule and lead to signal transduction, or they can bind to the molecule in such a way as to prevent it from binding to its intended ligand.[289,315] Antibodies can be either activating or

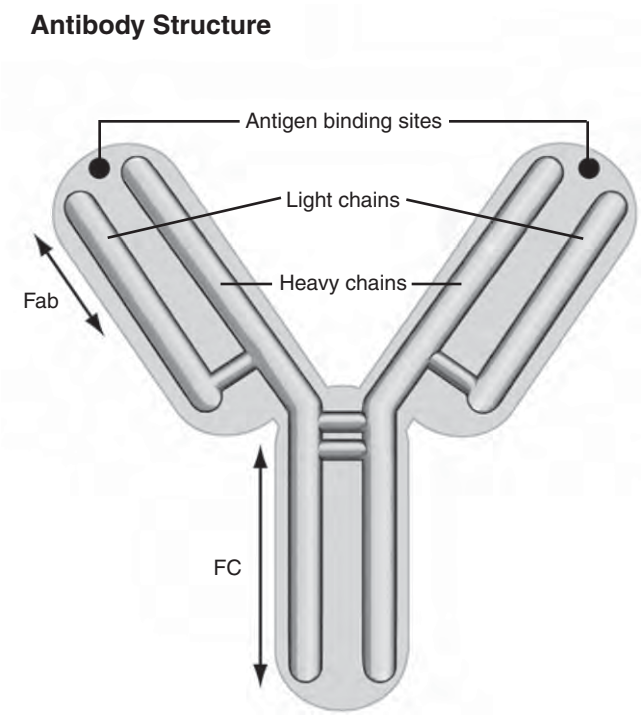

Figure 20–1 General antibody structure. The prototypic structure of an IgG molecule is shown.

inhibiting, and the predominant effect can be determined only through empirical in vivo analysis. Antibodies can bind to cells in such a way as to have no appreciable effect.[133] Antibody binding cannot be equated with functional significance. In some cases, a combined effect occurs whereby the antibody activates the targeted molecule but induces surface molecule internalization, effectively clearing the molecule from the cell surface and inhibiting its subsequent function.[144] This transient activation effect can lead to a burst of target cell activity (e.g., cytokine release), resulting in undesirable side effects, or can simply lead to surface modulation of the targeted molecule. Antibodies cannot target molecules that are not present on the cell surface. Although they can influence intracellular pathways, they cannot bind intracellular molecules directly.

Antibodies also activate the classical complement cascade and in doing so can induce complement-mediated lysis of a targeted cell. In addition, many phagocytic cells have receptors for the constant Fc region of antibodies and preferentially engulf cells coated with antibody through a process known as antibody-dependent cellular cytotoxicity (ADCC). Both of these activities facilitate the most noticeable effect of antibody therapies—target cell depletion. Depletion is only the most obvious effect of antibody therapy, however, and should not be assumed to be the most relevant or desired. Additionally, these effects depend on their antigen binding region and their nonvariable Fc region for effectiveness.[89] The importance of Fc segment effects is shown by nonspecific antibody infusion, which can mediate important effects presumably by neutralizing complement or saturating Fc receptors.[43,226]

It has become apparent that the maturation state of the targeted cells also can influence the response to antibody treatments. Specifically, cells that have matured into a memory phenotype have some degree of resistance to antibody-mediated depletion.[214] The mechanisms involved in depletion resistance remain to be defined, but memory cells differ from naive cells in many potentially relevant ways, including enhanced antiapoptotic and complement regulatory gene expression. The ultimate effect of antibody therapy may vary not only with the antibody preparation but also with the phenotype of the targeted cell and even the immune history of the recipient.

All of these effects can alter the function of molecules and cells, giving antibodies broad therapeutic potential. This array of effects makes antibody development difficult, however. Minor changes in antibody structure can radically alter their effects, and at present it is impossible to predict an antibody's properties on a structural basis alone. Certain IgG isotypes support complement and ADCC functions better than others, but generally an antibody must be tested in vivo to determine which of its many potential effects would be dominant.[103]

GENERAL CLINICAL CONSIDERATIONS FOR THE USE OF ANTIBODY PREPARATIONS

Immunosuppressive regimens used for organ transplantation can be generally characterized as induction, maintenance, or rescue therapies. Induction immunosuppression is intense treatment designed to inhibit immune responsiveness at the time of transplantation. It is usually potent to the point that its prolonged use is prohibitively toxic. Maintenance immunosuppression is of lesser potency, but is tolerable for long-term use and forms the basis of most immunosuppressive regimens. Rescue therapy is similar to induction in that it is intense, effective, and chronically intolerable, but differs in that it is used to reverse established rejection. Immunosuppressive medications can conceivably fall into any or all of these categorizations based on the dose and route used. Biologics currently are primarily indicated as rescue agents and are used in approximately 20% of all acute rejection episodes.[308] Their use as induction agents is growing; 50% to 70% of patients undergoing kidney transplantation now receive biologic induction.[1,250]

Antibody preparations also have been generally classified as depleting or nondepleting based on whether or not they deplete cells expressing the targeted antigen. Generally, T cell–depleting antibody preparations are primarily indicated for the treatment of refractory (e.g., steroid resistant) acute cellular rejections, acute rejections occurring in high-risk settings (e.g., marginal kidneys), and particularly aggressive vascular (e.g., Banff grade 2 or 3) rejections. Depleting antibodies also are being increasingly used as induction agents, although this is often an off-label use. Nondepleting antibody preparations and fusion proteins have been most commonly studied as induction agents and typically have less efficacy in rescue indications. Maintenance applications of biologics remain investigational.

Many depleting and nondepleting antibody preparations have been studied in randomized trials and have been proven efficacious in reducing the rate of acute rejection when used as an induction agent combined with standard maintenance regimens and compared with bolus methylprednisolone induction. Few prospective studies compare the prominent agents, however, and no agent has distinguished itself as clearly superior in all clinical circumstances. Most trials

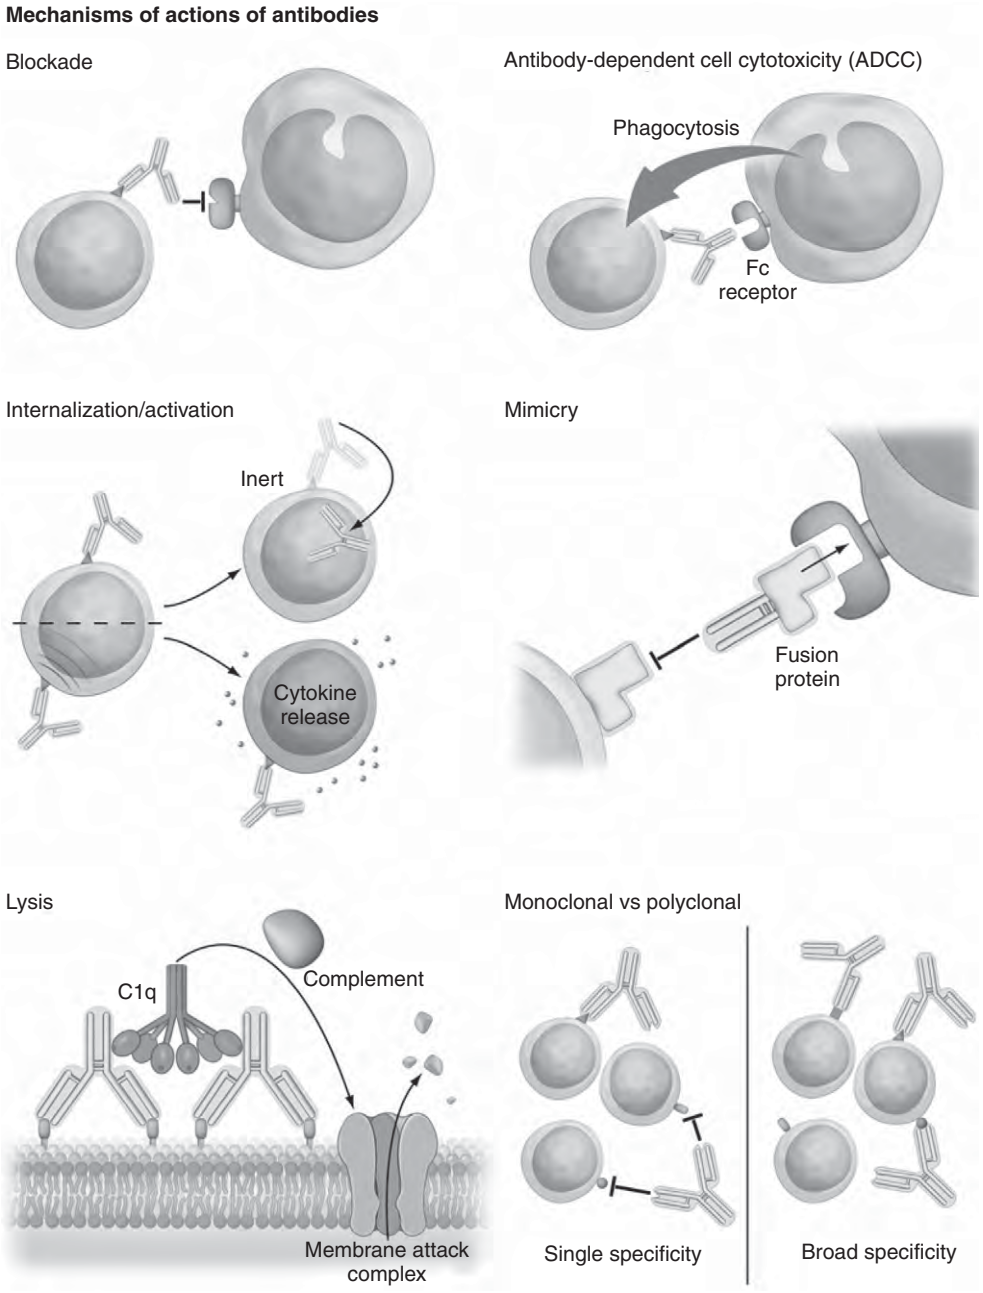

Figure 20–2 Mechanisms of action for antibody and fusion protein function. Antibodies can work via many mechanisms as depicted here and described in more detail in the text.

have used the surrogate end point of acute rejection, rather than more definitive outcome measures, such as patient or graft survival.

When considered as a whole, biologics have been convincingly shown to be more effective than steroids in reversing acute rejection.[308] When used as induction agents, they reduce the incidence of acute rejection in the first 6 months of transplantation in kidney recipients, particularly recipients who are sensitized, compared with the historical standard of bolus methylprednisolone induction and maintenance with cyclosporine, azathioprine, and prednisone.[278,279] Despite these benefits, there is no evidence that biologics alter long-term patient or graft survival in the era of modern immunosuppression.[278,279,308] Long-term analysis suggests that a measurable effect in kidney transplantation disappears after 5 years. This analysis may indicate that the side effects of maintenance therapy or comorbidities supersede early graft outcome and are the dominant determinants of outcome over time.

Antibody preparation use does not generally influence the rate of technical complications[128] but seems to reduce the risk of graft thrombosis in children.[259] Several induction strategies, in particular polyclonal antibodies and OKT3, have been shown, however, to increase measurably the risk of post-transplantation lymphoproliferative disease (PTLD) and death from malignancy when combined with conventional maintenance immunosuppression.[53,178,186,215,216] PTLD is a product of the intensity of the overall immunosuppressive therapy in combination with the recipient's preexisting immunity to the causative agent, Epstein-Barr virus.

Specifically, the expected PTLD rate is 0.5% in patients who do not receive antibody induction or who receive CD25-specific therapy. OKT3 induction carries a significantly higher rate of 0.85%, as does polyclonal depletion at 0.81%, particularly in recipients newly exposed to Epstein-Barr virus at transplantation.[53]

Other early complications, including cardiovascular and infectious deaths, correlate with antibody use, but the interpretation of this relationship is confounded by the preferential use of antibodies in high-risk patients.[37,186] Viral infection is a substantial concern, however, when using potent antibody therapy, particularly agents associated with T cell depletion. When used for induction or rescue, antibody preparations should be accompanied by broad prophylaxis against opportunistic infection. Antiviral therapy, such as ganciclovir or acyclovir,[15,118,291] should be initiated and continued for at least 3 months. The choice of agent is based on the pretransplant status of the donor and recipient. Oral candidiasis prophylaxis with nystatin or clotrimazole and *Pneumocystis* therapy with trimethoprim/sulfamethoxazole also should be maintained for several months. Individual clinical risks often dictate substantially longer periods of prophylaxis. Each antibody preparation has a unique side-effect profile and indication, which are discussed subsequently.

The use of antibody preparations for maintenance therapy had been limited until more recently by the immune response formed against the antibody itself. Recombinant humanized or chimeric antibodies and fusion proteins have essentially eliminated this as a concern, however. It is likely that future development of these molecules will investigate the role of antibodies in sustained preventive therapy.

POLYCLONAL ANTIBODY PREPARATIONS

Heterologous antibody preparations can be derived from many animals immunized with human tissues or cells (e.g., human lymphocytes). When reinfused into humans, these antibodies bind to antigens expressed on the original immunogen, where they mediate the effects discussed earlier. Given that these preparations are produced through whole-cell immunization, the resulting preparations contain a vast array of antibodies binding many epitopes expressed on the immunogen cells—some intended, and some not. Because each animal produces a unique immune response to an antigen, clinical-grade preparations are generally the result of pooled responses from many animals. For practical reasons, most polyclonal preparations are derived from rabbit or horse immunizations.

Ideally, a single renewable cell type equivalent to the effector cell in rejection could be used as a reproducible immunogen free from elements such as stromal tissue and neutrophils. No such cell has been developed, however. Commercially available polyclonal preparations continue to be made using heterogeneous cell populations or tissues such as thymus obtained from cadaver donors or surgical specimens. After immunization, the immunized animals are bled to obtain hyperimmune serum. The serum is typically absorbed against platelets, erythrocytes, and selected proteins to remove antibodies that could result in undesirable effects such as thrombocytopenia. Historically, hyperimmune serum was administered without additional purification, but now all commercially available products are purified to obtain only IgG isotypes. Even so, polyclonal antibody preparations are not fractionated to separate relevant from irrelevant antibodies preexistent from the environmental immune responses of the immunized animals. Greater than 90% of antibodies found in polyclonal preparations are likely not involved in therapeutically relevant antigen binding.[29,30,229,258]

Many groups have prepared polyclonal antibody preparations for their own institutional use, and this practice gave rise to a highly variable literature with little standardization or objective comparisons between products.[123,271,273,286] More recently, three dominant commercial polyclonal preparations have emerged: two rabbit-derived antibody preparations, antithymocyte globulin–rabbit (ATG-R, Thymoglobulin, or ATG-Meriux) and antithymocyte globulin–Fresenius (ATG-F), and one horse-derived product (ATGAM). Of these, Thymoglobulin is used most commonly in North America, with both rabbit preparations used in Europe.[1,250]

As discussed earlier, antibodies can mediate many effects when they bind to their target antigen, and a significant factor determining their effect is the antigenic specificity of the preparation. By their very nature, polyclonal preparations are composed of a wide variety of antibodies, and complete characterization has remained elusive.[29,30,229] Detected specificities include many T cell molecules involved in antigen recognition (CD3, CD4, CD8, and TCR), adhesion (CD2, lymphocyte function antigen [LFA]-1, and intracellular adhesion molecule [ICAM]-1), and costimulation (CD28, CD40, CD80, CD86, and CD154), and non–T cell molecules (CD16 and CD20) and class I and class II major histocompatibility complex (MHC) molecules (Fig. 20-3). Although all of these targets hypothetically can influence an immune response, and when studied individually, they do, it is unclear which of these specificities are crucial to the ultimate therapeutic effect. This broad reactivity with adhesion molecules and other receptors upregulated on activated endothelium has led many authors to advocate the preferential use of polyclonal antibody preparations in situations, such as prolonged ischemic times, where endothelial activation and ischemia-reperfusion injury is anticipated.[19,47]

Most polyclonal antibodies have prolonged serum half-lives of several weeks.[36,230] Nondepleted cells have been shown to be coated with heterologous antibody for months, suggesting that these preparations could influence the function of lymphocytes long after treatment has stopped. Lymphocyte subsets are abnormal for years after therapy, with particularly low $CD4^+$ T cell counts.[195] It also is reasonable to assume that antibodies targeting differing specificities would have variable effective half-lives based on the rates of surface molecule recycling, the affinity of the binding interaction, and the mechanism of action. Stimulating antibodies may have effects whenever they are bound, whereas inhibitory compounds could mediate an effect only when the natural ligand being antagonized is present. Polyclonal preparations likely have mechanisms of action that vary by batch, circumstance of use, and degradation state. It is unlikely that any single generalized mechanism exists. For the purposes of following the clinical effect, bulk T cell depletion is used as a general estimate of antibody potency, and polyclonal antibody preparations are considered depletional agents.

SPECIFIC CLINICAL APPLICATIONS OF POLYCLONAL ANTIBODY PREPARATIONS

Polyclonal antibody preparations have been used in transplantation to achieve immunosuppression since the 1960s.[269] They are used as induction and rescue therapies, but the immune response to the proteins has precluded attempts to use them as maintenance drugs. As discussed previously, no single mechanism of action has been established, and they likely mediate their antirejection properties through depletion and other effects, including costimulation blockade, adhesion molecule modulation, and B cell depletion.[29,30,221,229]

Induction

Historically, polyclonal antibody preparations were used to bolster the effect of steroids and azathioprine in an attempt to reduce the unacceptably high rejection rates typical of the 1960s and 1970s. Generally, a 2- to 3-week course of a polyclonal antibody delayed the onset of acute rejection and reduced the requirement for high-dose steroids in the early postoperative period without significantly altering long-term survival.[62,63,126,273,309] After the introduction of cyclosporine, the use of polyclonal antibody induction fell from favor with the realization that this potent combination was associated with increased infectious and malignant morbidity.[185,211] With improved viral prophylaxis, a better understanding of the infectious etiology of PTLD, and more standardized commercial polyclonal products, there has been a marked resurgence of interest in polyclonal antibody induction.[1,250]

Most modern trials have evaluated polyclonal antibodies added to an otherwise rigorous maintenance regimen (typically triple immunosuppressive therapy). This intense regimen has statistically reduced acute rejection rates, but has reciprocated with increased infectious morbidity without changing long-term outcome.[49,193] This increased infectious risk may be acceptable in selected higher risk patient populations, such as recipients of donation after cardiac death donors, recipients of extended criteria donation, and patients with a high risk of rejection such as retransplant recipients and recipients with delayed graft function,[19,44,45,47,99,255,271] particularly when avoidance of prolonged calcineurin inhibitors is desired.[78,248,262]

More recent trials have attempted to address the increased infectious risk by pairing aggressive polyclonal induction with substantially reduced maintenance therapy. Two pilot studies have shown that ATG-R induction facilitates reduced maintenance immunosuppression in highly selected, closely followed patients, leading to graft and patient survivals comparable to the current standard.[270,277] These studies have emphasized administration before reperfusion, theoretically to take maximal advantage of anti–adhesion molecule effects, and relatively high-dose therapy, to limit the proinflammatory effects of reperfusion and to achieve rapid and lasting T cell depletion. Although these studies indicate that such an approach is possible, it remains to be seen if it can be generalized to noninvestigational settings.

Rescue

Although polyclonal antibodies remain controversial for induction, their use for the treatment of steroid-refractory rejection is an established indication. Many polyclonal preparations have shown their utility in this setting, spanning several decades of associated maintenance regimens. The first randomized trial showing that antilymphocyte serum was superior to high-dose steroids for the treatment of established rejection was reported in 1979.[253] In the context of azathioprine and prednisone maintenance

immunosuppression, antilymphocyte serum reversed rejection faster than bolus glucocorticosteroids, reduced the rate of recurrent rejection, and led to improved survival at 1 year.[199] Most rejection episodes occurring in the cyclosporine era and beyond respond to bolus steroids. Polyclonal agents have been indicated as a second-line therapy for steroid-resistant acute cellular rejection.[21,95,183,234] Recurrent rejection can be treated with repeated courses of polyclonal antibodies in situations where antirabbit (or antihorse) antibodies have not been formed.[27,179]

Of the currently available polyclonal preparations, ATG-R is used most commonly for rescue. It has been shown to be superior to ATGAM in terms of reversal of steroid-resistant rejection and persistence of a rejection-free state.[95] This difference has not been shown, however, to influence patient or graft survival.

Non–T cell–specific polyclonal antibody preparations also reverse established cellular acute rejection. Although not typically considered alongside T cell–depleting polyclonal antibody preparations, high-dose human IgG fractions (intravenous immunoglobulin) are polyclonal antibodies of random specificity pooled from human donors. Because they are not derived from animals, are not the products of heterologous immunization, and do not target a specific cell type, most of the adverse effects associated with polyclonal antibodies are not applicable. Nevertheless, high-dose human IgG fractions have been shown to reverse rejection despite the absence of any T cell–depleting abilities. Although a course of polyclonal anti–T cell antibody typically consists of 5 to 20 mg/kg given over several days, intravenous immunoglobulin is infused at much higher doses, 500 to 1000 mg/kg over 1 to 3 days, and at this dose has been shown to reverse established rejection with the same overall reversal rate as OKT3.[43] At least at high dose, nonspecific antibody infusion can modulate immune responses, perhaps through Fc receptor binding and resultant downregulatory effects of Fc receptor–expressing antigen-presenting cells (APCs).[143]

Administration and Adverse Effects

The polyclonal preparations used in modern clinical practice are generally given through a large-caliber central vein to avoid thrombophlebitis. In experienced hands, a dialysis fistula can be accessed for this purpose. More recent reports have suggested that polyclonal antibodies can be administered peripherally when diluted and formulated with heparin, hydrocortisone, or bicarbonate solutions.[227,314] An in-line filter is recommended to prevent infusion of precipitates that may develop during storage. The protein content should not exceed 4 mg/mL, and dextrose-containing solutions should be avoided because they induce protein precipitation.

Given the weeks-long half-lives of polyclonal antibodies, divided doses are not required for steady-state levels. The tolerability of these compounds is markedly improved, however, by spaced dosing. The rate of infusion is associated with the severity of side effects, and the course of therapy is generally over several days, with individual doses given over 4 to 6 hours. This time course depends on the dose used and is most applicable to the standard doses of ATG-R and ATG-F (1.5 mg/kg/dose for a total of 7.5 to 10 mg/kg) or ATGAM (15 mg/kg/dose for a total of 75 to 100 mg/kg). More recent investigational induction studies have employed substantially higher doses given over 12 to 24 hours or, alternatively, while the patient is anesthetized.[99,270,277] With a growing emphasis being placed on reduced length of stay after transplantation, larger infusions over fewer days are being employed.

Generally, rabbit-derived polyclonal preparations seem to be significantly better tolerated and more efficacious than ATGAM when used in a quadruple regimen for renal transplantation.[32,110] The most common acute symptoms associated with polyclonal antibody use are the result of transient cytokine release. Chills and fevers occur in at least 20% of patients and are generally treatable by premedication with methylprednisolone, antipyretics, and antihistamines. The use of polyclonal antibodies, particularly in the treatment of rejection, has been associated with an increase in the reactivation and development of primary viral disease caused by cytomegalovirus, herpes simplex virus, Epstein-Barr virus, and varicella.[2,101] It is likely, however, that this is not a class-specific association, but rather an indication of more intensive immunosuppression in general.

Dosage adjustment is warranted to counter leukopenia and thrombocytopenia. Peripheral cell counts drawn immediately after infusion tend to exaggerate cytopenic effects, and most side effects are promptly remedied by time. T cell counts or, more easily, absolute lymphocyte counts can be monitored to ensure that the preparation is achieving its desired effect. Absolute lymphocyte counts less than 100 cells/μL are typical. Attempts to tailor therapy to a specific peripheral cell count have been made to limit the use of these costly preparations. Rejection can occur and persist with very low T cell counts, however, and there is little evidence that dose variation by cell count alters efficacy.

As discussed earlier, polyclonal antibody preparations evoke a humoral immune response to themselves.[201,222,281] This response can be detected by enzyme-linked immunosorbent assay–based assays for antirabbit or antihorse antibody, but these tests typically are unavailable in most clinical settings. Failure to achieve significant T cell depletion suggests the presence of these antibodies. Serum sickness and anaphylaxis also can occur.[222] Preemptive skin testing is not practiced often because these tests have not correlated well with clinical outcome.[25,33] Rather, slow infusion rates should be employed during the initial exposure. Antianimal antibodies are most likely to occur in individuals with prior exposure to the preparation involved, but also can exist in individuals with significant prior exposure to the animals themselves.

The most common adverse symptoms related to polyclonal antibodies are fever, urticaria, rash, and headache. These are most likely related to the release of pyrogenic cytokines, such as tumor necrosis factor (TNF)-α, IL-1, and IL-6, which results from activating antibody binding to targeted cell surface receptors and subsequent cell lysis.[51,75,295] Infrequently, pulmonary edema and severe hypertension or hypotension can result in death. As the number of target cells decreases with repeated dosing, this response typically abates. The most concerning response is within the first 24 hours of the first dose, and patients should be monitored closely during this period. The response is limited considerably by methylprednisolone premedication. The rash associated with polyclonal antibody administration conversely tends to occur late in the treatment or at times after the last dose. It is generally self-limiting and requires only symptomatic treatment for urticaria. Antiendothelial antibodies in

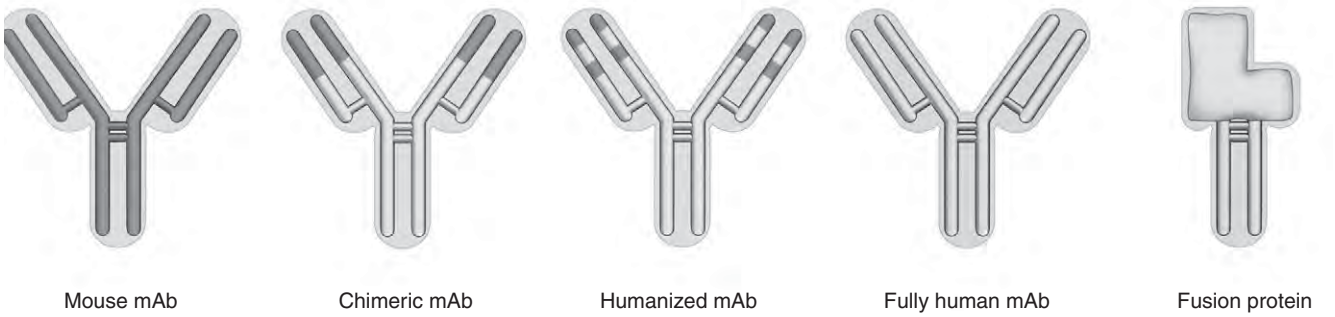

Figure 20–4 Types of monoclonal antibodies and fusion proteins. Dark areas represent portions of the molecule of nonhuman origin, and light areas represent human proteins.

polyclonal antibodies have been suggested to bind to donor endothelia and activate complement, inducing humoral rejection in some patients.[58]

MONOCLONAL ANTIBODY PREPARATIONS

MAb preparations differ from polyclonal preparations in that all antibody molecules are derived from a single genetic template and are identical. Batch-to-batch variation is eliminated, allowing the mechanism of action and half-life to be extrapolated based on a single ligand receptor interaction (although this still can be influenced by many individualized circumstances). This preparation narrows the scope of effect, however, making the use of these drugs more dependent on precise knowledge of the pathology involved.

Historically, MAbs are the product of clonally immortalized B cell hybridomas. More recently, genetically engineered mammalian cells have been the source. Use of other production methods, including viral and prokaryotic, or even plant cells, is being investigated.[9] As the production cell becomes increasingly distant from human, the resultant antibodies have increasingly aberrant glycosylation, which can radically alter their efficacy.[89] Regardless of the production cell, the resultant antibody can be purified of any extraneous proteins or other antibodies and used as an infused drug.

The most common method for deriving a MAb typically has been to immunize a mouse with a cell or cell fraction containing the antigen desired. Splenocytes are isolated from the immunized animal, and fused with an immortalized cell, producing many diverse antibody-producing cells. These cells are cloned (grown from single cell suspensions), and the supernatant from each clone is tested for reactivity against the desired antigen. A single robust clone with the desired antibody production characteristics is chosen and grown either in vitro or in a carrier animal. The supernatant from the clone is purified for therapeutic use. Because many MAbs are made by mouse B cells, they are mouse antibodies. Similar to animal-derived polyclonal antibodies, they can be cleared from the circulation by an antibody-directed immune response.[50] This immune response can cause anaphylaxis and neutralize the effect of the MAb in subsequent administrations.[246]

To improve the efficiency of antibody production and eliminate animal-derived protein epitopes, the gene fragment encoding the binding site of murine antibodies can be isolated and engineered onto the gene that encodes for nonpolymorphic regions of a human antibody, such as IgG1.[31,113,191] The resultant hybrid antibody gene can be transfected into a high expressing eukaryotic cell line and grown in vitro to produce antibodies that are predominantly human antibody, yet still bind to a specific human epitope (Fig. 20-4). These hybrid antibodies can be considered chimeric, if the entirety of the murine antibody binding site is used in the construct, or humanized, if the only murine portion is the specific complementary determining regions of the parent antibody.[132] Generally, chimeric antibodies preserve the specificity of the original antibody better, whereas humanized antibodies have less chance of evoking a neutralizing response.[83] Practically speaking, both are effective strategies that avoid the problem of antibody clearance.

The entire IgG gene has been transgenically expressed in a mouse.[313] This animal, when immunized, makes human, not mouse, antibody, which can be prepared for monoclonal production. This method is likely to be more efficient for producing truly human antihuman antibodies without the need to engineer each antibody individually.

When approved for clinical use, MAbs must be named based on their structural characteristics (Table 20-1). The generic name of a MAb gives the practitioner a reasonable understanding of the origins and specificity of the MAb.

MONOCLONAL ANTIBODIES IN CURRENT CLINICAL TRANSPLANTATION PRACTICE

Because each MAb has a singular specificity, each agent available for general clinical use is considered individually (see Fig. 20-3). Most MAbs are defined based on their targeted cell surface protein, and these generally are classified based on the CD nomenclature. A numerical CD designation does not define an antigen, but rather defines a molecule or group of molecules. MAbs that bind to the same CD molecule can bind to the same or different epitopes and have similar or different effects.

Table 20–1 **Nomenclature for Monoclonal Antibodies**

Prefix	Target		Source		Suffix
Varies based on preference of developer	-vi(r)-	Viral	-u-	Human	-mab
	-ba(c)-	Bacterial	-o-	Mouse	
	-li(m)-	Immune	-a-	Rat

	-go(t)-	Testicular tumor			
	-go(v)-	Ovarian tumor			
	-pr(o)-	Prostate tumor			
	-tu(m)-	Miscellaneous tumor			

Muromonab (OKT3; Murine Anti-CD3)

The TCR is linked to a transmembrane complex of proteins collectively known as CD3. The CD3 complex conveys an activating signal to the nucleus via a calcineurin-dependent pathway and serves as the fundamental signal in antigen-specific T cell activation. CD3 is present on essentially all T cells, defining the cell type. The TCR signal is generally known as signal 1 because it is primarily required for T cell activation and defines the antigen specificity of the T cell. Given that T cells are a crucial mediator of acute cellular rejection, CD3 was one of the first molecules to be targeted with MAbs, and OKT3 (muromonab) was the first MAb to gain clinical approval for therapeutic use in humans.[209]

Although the molecular target of OKT3 is singular and precise, its effects are many. The mechanism by which OKT3 mediates its immunosuppressive effect remains ill-defined. OKT3 is an IgG2a mouse antibody that binds to the ε component of human CD3. On binding, the antibody mediates complement-dependent cell lysis and ADCC and in doing so rapidly clears T cells from the peripheral circulation.[295] This binding event also leads to pan–T cell activation before their elimination, resulting in systemic cytokine release. The result is a marked cytokine release syndrome that is responsible for most of the adverse effects associated with the drug (see later).

When antigen binds to the TCR, TCR-CD3 internalization occurs; physiologically, this ensures that antigen binding is reflective of antigen burden and avoids activation mediated by continuous binding of a low-prevalence antigen. Similarly, OKT3 binding to CD3 leads to TCR-CD3 internalization.[51] T cells that are not cleared are often rendered void of surface TCR. These T cells that fail to express the TCR are incapable of receiving a primary antigen signal and are immunologically inert.

Bulk T cell clearance likely is not the primary mechanism of action of OKT3. Clinical rejection can occur with exceptionally low T cell counts achieved by other means, and stable graft function can occur with large T cell infiltrates within the graft itself.[124,151] Although the peripheral circulation is rapidly cleared by OKT3, many T cells can be found in the periphery and in the allograft itself.[144] A substantial amount of the rapid T cell clearance from the circulation is likely related to lymphocyte marginalization perhaps induced by the cytokines released and by the methylprednisolone that is given with OKT3. The overall effect of OKT3 is likely an aggregate effect of interrupted TCR binding, TCR internalization, cytokine-mediated regulatory changes, disrupted trafficking, and cell depletion. OKT3 has proven efficacy as an induction and a rescue agent. Its immunogenicity has prevented its use as a maintenance agent, and the drug is effective only in combination with other immunosuppressive compounds.[297]

Induction

Initial trials with OKT3 have shown that this MAb is an efficacious induction agent in kidney transplantation,[76,188,205] but only when combined with otherwise effective maintenance immunosuppression.[297] OKT3 cannot prevent rejection beyond the period of its actual infusion without additional maintenance therapy. Its usefulness as an induction agent is most pronounced in sensitized patients[208] and patients with delayed graft function, in whom it facilitates the delay of calcineurin inhibitor administration and the resultant nephrotoxicity.[22,136] It reduces the number of acute rejection episodes and the time to first rejection episode. In more recent literature, OKT3 has been shown to reduce acute rejection episodes compared with cyclosporine, azathioprine, or mycophenolate mofetil and steroids without changing patient or graft survival,[3,115,206] but to be equivalent to intravenous cyclosporine induction in children.[20] Despite its early prominence, use of OKT3 as an induction agent has dramatically declined in recent years, primarily as a result of its side-effect profile.

Because OKT3 is an entirely mouse-derived antibody, its use leads to the development of an antibody response directed against OKT3 in a significant percentage of patients. The development of antimouse antibodies varies based on the concomitant immunosuppression given, but is seen in at least 30% of patients.

Rescue

The primary modern indication for OKT3 is for the treatment of biopsy-proven, steroid-refractory, acute cellular rejection. In this indication, the side-effect profile is justifiable, and the efficacy of OKT3 is undeniable.[63,80,209,283,284] OKT3 is successful in providing sustained reversal of approximately 80% of

these vigorous rejections. It is effective even in the presence of prior aggressive lymphocyte depletion, suggesting that its mechanism of action is not primarily a result of bulk T cell depletion.[69,151,217] The incidence of steroid-refractory rejection, defined as failure to respond to 3 consecutive days of bolus methylprednisolone (e.g., 500 mg daily), has declined considerably with improved maintenance immunosuppressive agents, as has the incidence of rejection in general. The need for OKT3 has been reduced to only a few transplant recipients.

It is appropriate to consider OKT3 in patients with biopsy-proven acute rejection who have failed 3 days of therapy with high-dose methylprednisolone or some other vigorous rescue agent. Excessive delay beyond this time increases the complications of rescue therapy.[282] Additional indications for OKT3 include rejection associated with vasculitis (Banff grade 2 or 3 rejection) and rejections in clinical situations in which the organ is unlikely to tolerate prolonged immune attack.[137] Because misdiagnosis also can be responsible for apparent steroid resistance, a renal biopsy is indicated before the administration of OKT3 to confirm that acute cellular rejection is the cause of the renal dysfunction.

Administration and Adverse Effects

OKT3 targets T cells. It does not induce the pancytopenia typical of polyclonal antibody preparations. Its propensity to activate T cells induces a sometimes serious cytokine release syndrome, however, which is dependent on the number of T cells affected.[51,96] During the first dose, most T cells in the body are involved, many of which are in a highly activated state when rejection is ongoing. Cytokine release is worse at the first infusion, particularly for rescue indications. The effect abates with T cell clearance and after 3 days is usually negligible. Although many cytokines are likely involved in this syndrome, TNF-α is a dominant player because its sequestration can markedly attenuate the symptoms.[48,86]

Cytokine release can result in fever, nausea, vomiting, rigors, and general malaise reminiscent of severe flu-like symptoms.[285] It increases vascular permeability and can precipitate severe pulmonary edema. Patients with severe fluid overload owing to renal dysfunction should undergo dialysis before the first infusion. Occasionally, OKT3 can induce aseptic meningitis,[182] which in its most severe form can induce transtentorial herniation and death. Allograft thrombosis also has been reported.[3] Use of OKT3 increases the risk of PTLD, particularly in Epstein-Barr virus–naive recipients of kidneys from Epstein-Barr virus immune individuals.[53,285]

OKT3 generally is given as a peripheral infusion of 5 to 10 mg/dose. A central line is not required. Patients should be premedicated with methylprednisolone, acetaminophen, and diphenhydramine 1 to 2 hours before the initial infusion.[52,254] It is advisable to infuse the first dose over 1 to 2 hours to minimize the initial cytokine release. As the side effects abate with subsequent doses, the drug can be given over 5 minutes without adverse events. Patients should be monitored closely at the time of the initial infusion in an inpatient setting equipped to deal with cardiopulmonary arrest. Daily dosing is continued for 10 to 14 days, targeting a total dose of 70 mg. As OKT3 eliminates the TCR signal transduction pathway, calcineurin inhibitors can be safely discontinued or reduced substantially during therapy; this eliminates concomitant calcineurin inhibitor toxicity and facilitates more rapid return to normal renal function.[79,284] As the treatment course reaches an end, calcineurin inhibitor levels can be optimized for subsequent maintenance therapy to avoid rebound.

Human antimouse antibodies are formed in response to OKT3 administration in approximately one third of patients, depending partly on the concomitant immunosuppression used during therapy.[59,246] These antibodies should be documented in the event that subsequent OKT3 administration is contemplated, and reuse of the drug should be preceded by a test for antimouse antibody immunity.[169] Antibodies can be directed against the mouse IgG in general, or specifically against the OKT3 idiotype.[50,82,169] Measurement of CD3-expressing cells by flow cytometry during therapy ensures that the drug is effectively clearing T cells. Clinical presence of a pronounced cytokine release is substantial evidence, however, of a clinical effect. OKT3 is not used as a maintenance agent because of its side-effect profile and its immune clearance with time.

Interleukin-2 Receptor (CD25)-Specific Monoclonal Antibodies

The receptor for IL-2 is composed of three chains (α, β, and γ), of which the α and γ chains are constitutively expressed, and the β chain is induced with activation. The presence of the β chain, now designated as CD25, indicates prior T cell activation and identifies cells that have undergone some degree of effector maturation. CD25 has been targeted to suppress activated cells, while sparing resting cells.

There are two commercially available anti-CD25 antibodies, both of which have been engineered to avoid antimurine antibody responses. Daclizumab is a humanized anti-CD25 IgG1, and basiliximab is a chimeric mouse-human anti-CD25 IgG1. Both agents avoid immune clearance and can be used for prolonged periods without inducing a neutralizing antibody.[8,161,298] CD25 was the first molecule to be targeted successfully with a humanized MAb in transplantation.[155] These agents also avoid the serum sickness associated with mouse-derived, rabbit-derived, or horse-derived proteins.

Anti-CD25 antibodies are thought to work primarily through steric hindrance of IL-2 binding to CD25 and deprive T cells of this cytokine during early activation. There is little evidence for a depletional effect, or if there is one, it is limited to a few cells. More recently, it has become clear that CD25 induction is involved not only in the activation of cytotoxic T cells but also in the activation of cells with potentially salutary effects on the allograft, such as T regulatory cells.[275] T cells that have been previously activated and are responding in an anamnestic response are less dependent on IL-2 for proliferation. Heterologous responses (cross-reactive responses between a previously encountered pathogen and an alloantigen) or memory alloimmune responses seem not to be affected significantly by CD25 interruption. Given this biology primarily focused on naive T cell early activation, CD25-directed antibodies have found a role in induction, but have no role in the treatment of established rejection. Although there has been anecdotal experience using these antibodies for maintenance immunosuppression in the setting of calcineurin inhibitor toxicity with recurrent rejection, no study has formally evaluated this approach.

Induction

Many anti-CD25 antibodies, including anti-Tac,[155] 33B3.1,[264] LO-Tact-1,[119] and BT563,[296] have been tested in humans and been shown to delay modestly or reduce the onset of acute rejection when used with conventional maintenance immunosuppression. The experimental rodent antibodies have been generally abandoned in favor of the humanized/chimerized antibodies.

Daclizumab and basiliximab have been shown to reduce modestly the incidence of acute cellular rejection compared with methylprednisolone induction when used in triple or double immunosuppressive regimens, with exceptional patient tolerability in kidney and extrarenal transplantation.[23,117,135,197,198,200,249,299] Studies comparing basiliximab with polyclonal antibodies in regimens using cyclosporine, mycophenolate mofetil, and steroids have shown comparable outcomes.[168,194,261] The magnitude of the antirejection effect seen with anti-CD25 therapy depends to some extent on the intensity of the maintenance regimen, with earlier trials using cyclosporine-based and azathioprine-based regimens showing a 25% reduction and later trials in the tacrolimus/mycophenolate mofetil era showing a more modest 10% improvement. Anti-CD25 induction also has been used successfully in steroid-free regimens in kidney transplantation.[28,237] The use of anti-CD25 has not been shown, however, to facilitate more aggressive maintenance reduction regimens, such as monotherapy or calcineurin avoidance.[212,300]

Administration and Adverse Effects

Although the efficacy of anti-CD25 therapies is modest, the safety profile is highly favorable.[23,117,135,197,198,200,249,261,299] Binding of anti-CD25 antibodies does not mediate T cell activation, and no perceptible cytokine release occurs. Clinical trials generally have shown no increase in infectious complications or delayed wound healing. The risk of PTLD with anti-CD25 induction is similar to that when no induction agent is employed.[53]

Alemtuzumab (Humanized Anti-CD52)

Given the reduction in rejection achieved with prolonged polyclonal antibody–mediated T cell depletion, the ease of administration and consistency of MAbs, and the benefits of humanization, clinicians have sought agents with a combination of these traits. The CD52-specific humanized MAb alemtuzumab has emerged as a promising candidate.[177,306]

Alemtuzumab (Campath-1H) is a humanized IgG1 derivative of a rat antihuman CD52.[306] CD52 is a nonmodulating, glycosylphosphatidylinositol-anchored membrane protein of unknown function found in high density on most T cells, B cells, and monocytes.[108] CD52 is not found on hematopoietic precursor cells and does not seem to be an adhesion molecule; it is not necessary for T cell activation. Several versions of the nonhumanized anti-CD52 predecessors of alemtuzumab have been studied and been shown to be effective in mediating rapid T cell depletion and reversing steroid-resistant rejection. The humanized form has been studied in several indications and is currently approved for the treatment of lymphogenous malignancies.

Although not approved for use in solid organ transplantation, alemtuzumab has been used off-label as an induction agent.[250,251] Its mechanism of action seems to be predominantly related to bulk T cell depletion, with lesser depletion of B cells and monocytes. It rapidly depletes CD52-expressing lymphocytes centrally and peripherally in renal transplant recipients.[151] The use of alemtuzumab as a rescue drug is burgeoning, and there has been anecdotal investigation in this drug as a maintenance therapy.

Induction

In preliminary, uncontrolled studies, alemtuzumab has been shown to facilitate reduced maintenance immunosuppressive requirements without an apparent increase in infectious or malignant complications in kidney and extrarenal transplantation compared with historical controls.* Specifically, alemtuzumab has been used to achieve perioperative depletion in combination with triple immunosuppression and early steroid weaning; steroid-free regimens with calcineurin inhibitors and mycophenolate mofetil maintenance; and with monotherapy regimens of cyclosporine, tacrolimus, or sirolimus. Graft and patient survivals have been comparable to contemporaneously reported registry data, although the incidence of reversible rejection has predictably increased with decreases in concomitant maintenance therapy. Although the efficacy of alemtuzumab as an induction agent has been encouraging to date, prospective comparison with other regimens is just beginning.

More recent studies investigating alemtuzumab induction have shown that although it depletes all T cell subsets, it has a modest selectivity for naive cell types.[214] Nondepleted T cells exhibit a memory phenotype and seem to be most susceptible to calcineurin inhibitors. Maintenance regimens including calcineurin inhibitors seem to do best in alemtuzumab-based maintenance reduction strategies. The rapid and profound depletion has allowed for a delay in the initiation of therapeutic calcineurin inhibitor levels, however, and has made this an attractive option for patients with delayed graft function.[158]

Although alemtuzumab depletes B cells, its effect on T cells is more profound and lasting. It does not clear plasma cells. Some investigators have associated alemtuzumab administration with an increase in antibody-mediated rejection or at least post-transplant development of donor-specific alloantibody.[38] Whether this association is related to the effects of the antibody or the reductionist maintenance regimens used with alemtuzumab remains to be determined.

Rescue

The rodent antihuman CD52 predecessors of alemtuzumab, Campath-1M and Campath-1G, were originally tested as rescue agents.[90-92,107] In the original studies using anti-CD52 for steroid-resistant rejection, the antibodies were used with triple immunosuppression and steroid bolus therapy, leading to a prohibitively immunosuppressive regimen with excess infectious morbidity and mortality. With the success of alemtuzumab as an induction agent, there has been a resurgence of interest in its use as a rescue agent. Several anecdotal reports have recently emerged.[14,68] Additional study is required to define its role in this setting, although its predilection for naive cells may limit its efficacy after sensitization.

*References 13, 39, 40, 106, 139, 140, 151, 152, 157, 158, 184, 251, 280, 294.

Administration and Adverse Effects

Alemtuzumab can be administered through a peripheral intravenous catheter and can be dosed as a 30-mg flat dose or at 0.3 mg/kg dose over 3 hours. Almost total elimination of peripheral $CD3^+$ T cells can be expected within 1 hour of the first infusion, although secondary lymphoid depletion requires 48 hours and at least two doses.[151,214] Higher doses have not been shown to be of additional benefit in transplantation.

The rapid depletion characteristic of alemtuzumab is associated with a cytokine release phenomenon similar to, but less severe than, that seen with polyclonal antibodies or OKT3. Administration should be preceded by a bolus of methylprednisolone, diphenhydramine, and acetaminophen. The first dose should be given in a setting capable of dealing with hypotension, anaphylaxis, and other sequelae of cytokine release. Neutralizing antibodies have not been described for alemtuzumab.

Early trials investigating alemtuzumab as a therapy for multiple sclerosis suggested an association between its use and the development of autoimmune thyroiditis.[57] Specifically, patients with multiple sclerosis receiving high-dose investigational therapy with alemtuzumab had a significantly increased risk of hyperthyroidism developing 1 to 3 years after therapy. It has been hypothesized that T cell depletion, particularly depletion that selectively spares activated cells, could disrupt T cell regulation and unmask autoreactive clones. This effect could be most evident in individuals with low-level adjuvant maintenance immunosuppression, as was the case in the multiple sclerosis trials. There has been a case report of autoimmune thyroiditis in an alemtuzumab-treated renal transplant patient, leaving the potential for autoimmune disease as an unresolved matter of concern.[153]

Rituximab (Humanized Anti-CD20)

Rituximab is a chimeric MAb specific for CD20. CD20 is a cell surface glycoprotein involved in B cell activation and maturation whose natural ligand is unknown.[73] Similar to alemtuzumab, it has been developed and approved for use in lymphogenous malignancies, particularly $CD20^+$ B cell lymphomas and PTLD.[105] Given its specificity for B cells (and despite its lack of specificity for antibody-producing plasma cells), rituximab has been suggested to be a therapy for antibody-mediated rejection and rejections involving vasculitis.[17,18] Rituximab also has been used in regimens designed to facilitate transplantation in sensitized individuals, such as ABO-incompatible donor recipient pairs or transplants across a positive crossmatch following antibody removal.[263,293] At present, the role of rituximab in transplantation is largely investigational; however, similar to alemtuzumab, its off-label use is increasing considerably.

The mechanism of action of rituximab is presumed to be depletional, primarily through induced apoptosis.[74] Treatment with this antibody rapidly and specifically clears $CD20^+$ cells from the circulation. The role of $CD20^+$ cells in alloimmune responses is currently incompletely defined. Although these cells are precursors to antibody-producing plasma cells, they do not produce antibody without further maturation. Their role in acute antibody production is not well established, and it is unlikely that they have a direct effector cell role in rejection. Several authors have documented $CD20^+$ infiltrates as a marker for particularly recalcitrant acute rejection.[121,243] These cells are known to have APC function and it has been postulated that they serve to facilitate intragraft antigen presentation. Currently, rituximab is being used in induction and rescue indications.

Induction

The use of rituximab as an induction agent has been limited to patients with known donor-specific sensitization. In particular, rituximab has been suggested to be a surrogate for recipient splenectomy in patients undergoing donor desensitization with plasmapheresis or intravenous immunoglobulin infusion, or both.[263,293] It has not been prospectively studied, but rituximab seems to have some effect in reducing the rebound of alloantibody in these complex patients.

Rescue

Several reports have emerged suggesting that rituximab has a role in the treatment of vascular rejection (Banff classification 2 and 3) and in reversing emerging alloantibody formation.[17,18] This would be presumed to be relevant for allograft infiltrates shown to contain $CD20^+$ cells, although specific guidelines for the use of rituximab remain forthcoming. As with its use as an induction therapy, use of rituximab as a rescue agent remains investigational.

Rituximab's most important indication in organ transplantation is not as a rescue agent for rejection, but rather as a primary treatment for PTLD.[276] Although immunosuppression reduction is the primary therapeutic maneuver in PTLD, rituximab has emerged as an effective and well-tolerated maneuver to be interjected between immunosuppressive withdrawal and more aggressive chemotherapy.

Administration and Adverse Effects

Rituximab can be administered through a peripheral vein and is associated with few overt side effects. As with all proteins, anaphylaxis can occur, and initial doses should be given in a monitored environment. When used as a treatment for PTLD, it is typically given at a dose of 375 mg/M^2. Dosing as an immunosuppressant has empirically followed this regimen. Rituximab persists in the circulation for weeks to months, and a single dose effectively eliminates $CD20^+$ cells for a similarly prolonged period. The presence of rituximab in the serum artificially produces a pan-positive B cell crossmatch by complement dependent cytotoxicity and flow techniques. Characterization of alloantibody after the use of rituximab requires alloantigen-specific methods, such as solid-phase bead array assays.

Humax-CD20 is a new, fully human form of CD20-specific antibody.[16] It is currently in phase II clinical trials for rheumatoid arthritis and chronic lymphocytic leukemia. Although it is not used in transplantation to date, its application is anticipated.

FUSION PROTEINS

Fusion proteins are molecules that have been engineered from a single receptor targeting a ligand of interest fused to another protein that provides another salutary property. In transplantation, this secondary molecule is typically the Fc portion of an IgG molecule that gives the receptor an antibody-like half-life.[138,165,174] Fusion proteins also can involve the fusion of a specific toxin to a MAb to facilitate

epitope-directed drug delivery.[156] Fusion proteins are similar to MAbs because they have a single homogeneous specificity and can be composed of human or humanized components, limiting their immune clearance and opening their use for prolonged administration. There are no fusion proteins approved for use in transplantation at present. There are notable examples, however, of transplant-relevant fusion proteins in late stage development that are discussed subsequently.

Monoclonal Antibodies and Fusion Proteins in Clinical Transplantation Investigation

The promise of MAb therapy has led to the development of a rapidly expanding number of antibodies and fusion proteins targeting a wide variety of surface molecules. Several of these agents have shown efficacy in large animal transplant models and in early clinical transplant trials. Even more have been developed for autoimmune indications, such as psoriasis and rheumatoid arthritis, but their immunomodulating effects have clear potential in transplant indications. The following agents have been studied in early phase clinical transplant trials or have received approval for clinical use in nontransplant indications and have preclinical trials suggesting efficacy in transplantation. These agents are discussed based on their targeted ligand. All new antibodies under clinical development are now humanized or fully human.[232]

CD2-Specific Approaches

CD2, also known as LFA-2, is an adhesion molecule expressed on T cells and natural killer cells that binds to CD58 (LFA-3) on APCs and facilitates TCR binding and signal transduction. It has been targeted by the rat IgG2b anti-CD2 MAb, BTI-322, and more recently by siplizumab (also known as MEDI-507), a humanized IgG1 version of BTI-322. BTI-322 was investigated initially as an induction and rescue agent for cadaver donor renal and hepatic allografts and for graft-versus-host disease, and was shown to have biological activity and to give results consistent with the standard therapies available at the time.[173,192,224,267]

Clinical trials in psoriasis using siplizumab began in 1999 and were met with an unexpected propensity toward agent immunogenicity.[161] This agent has been used in nonhuman primate transplant tolerance trials with success in mixed chimerism–directed approaches[141] and has been used clinically as part of a nonmyeloablative conditioning regimen to achieve mixed hematopoietic chimerism.[266] Siplizumab currently is being investigated in phase I trials for T lymphocytic malignancies.[56]

Alefacept is a human fusion protein of the CD2 ligand (CD58, LFA-3) with IgG1 that has been shown to inhibit T cell proliferation. Its administration also has been shown to have a relative selective depleting effect on effector memory T cells, the same cells that have been relatively spared by other depleting MAbs and polyclonal preparations.[100,244] It has gained increased attention more recently in experimental transplantation. Alefacept is currently approved for the treatment of plaque-like psoriasis. Preclinical trials in nonhuman primate transplantation have shown that alefacept has minimal effect on graft survival when used alone, but that it does extend graft survival when used with adjuvant therapies.[84] Its use as a combination therapy remains to be completely explored.

CD3-Specific Antibodies

Targeting CD3 is a proven strategy as shown by the success of OKT3. Significant effort has been directed toward modernizing the anti-CD3 approach to avoid the many side effects associated with CD3 activation. Several CD3-specific antibodies, including huOKT3γ1, aglycosyl CD3, and visilizumab (HuM291), have been humanized and otherwise engineered to eliminate their undesirable activating properties and immunogenicity.[93,207,317] Phase I studies have indicated that modified versions of a CD3-specific antibody can achieve T cell depletion without the confounding problems of cytokine release or an antibody neutralization. Phase II trials using visilizumab in marrow transplantation have shown initial efficacy against graft-versus-host disease,[42] and huOKT3γ1 has shown promise as a prophylactic agent in new-onset diabetes mellitus.[116] These studies have shown that the side effects related to OKT3 use are not inherent in CD3-directed therapies, opening the door for more refined targeting of this receptor complex. Currently, huOKT3γ1 is in a single clinical study in islet transplantation. Visilizumab is in phase III trials for ulcerative colitis.[56]

CD4-Specific Antibodies

CD4 is a cell surface glycoprotein that binds to a monomorphic region of MHC class II molecules and in doing so stabilizes the interaction between the TCR and MHC class II. It is expressed on approximately two thirds of peripheral T cells and has partially defined several functional T cell subsets, including helper T cells and T regulatory cells. CD4 also is expressed by peripheral monocytes and other APCs, where its function is poorly characterized. It likely plays a crucial role in facilitating cell-to-cell communication among lymphoid cells, and it has lesser effects on physiological effector functions. Given its central role in cellular immune responses, CD4 has long been a target for immune manipulation, and several antibodies have been tested in transplantation. Generally, the efficacy has been exceptional in defined rodent models and modest in more clinically relevant settings; this may relate to the growing recognition that $CD4^+$ T cells have a potential role in tempering immune responses.[6,275,305]

Many studies have shown that anti-CD4 antibody induction dramatically inhibits the development of acute rejection in rodents, particularly when combined with supplementary donor antigen, such as donor-specific transfusion.[176,239,256,316] Given that the distribution of MHC class II molecules differs substantially between rodents and humans, however, these studies have not been predictive of the anticipated effect in humans. Depleting[81,218,240] and nondepleting[10,65,71,170,203,311] antibodies have shown an effect in experimental models suggesting that cell elimination, disruption of cell-cell communication, or signal transduction through CD4 may be mechanistically relevant. Two humanized anti-CD4 preparations have shown significant prolongation of nonhuman primate renal allograft survival.[65,218]

Initial clinical transplantation trials using anti-CD4 MAbs employed murine-derived antibodies, including OKT4A, BL4, MT151, and B-F5.[70,81,166] Predictably, these agents were subject to immune clearance, but nevertheless were shown to lead to $CD4^+$ T cell clearance. Regardless, patients experienced

rejection rates of 50%, and the agents were not sufficiently efficacious to warrant further development. Subsequent trials investigating the humanized OKT4A[61] and the chimeric cM-T412[187] have been evaluated in conjunction with cyclosporine-based maintenance therapy in kidney and heart transplant recipients.[235] In both cases, the antibody was well tolerated, and treated patients had low rates of rejection, suggesting that this approach is promising. Antibody responses toward the remnant murine portions of the MAb were surprisingly frequent, however. $CD4^+$ T cell depletion was not achieved using OKT4A, but was common with cM-T412.

The mouse antihuman CD4 MAb, Max.16H5, has been tested in pilot fashion as a clinical rescue agent.[233] Max.16H5 depleted $CD4^+$ T cells and was associated with reversal of rejection in most treated patients. Neutralizing antibodies were not detected. No trials investigating humanized anti-CD4 MAbs have been reported for rescue therapy.

Many human or humanized CD4-specific MAbs, including HuMax-CD4, TNX355, and 4162W94,[54,164,260] have been evaluated in phase I, II, and III trials for nontransplant indications, such as psoriasis and rheumatoid arthritis. These studies have shown that CD4-specific antibodies can influence immune responses and that their use is relatively safe in humans. Currently, there are no active anti-CD4 MAb trials registered in transplantation.[56]

Costimulation-based Therapies

Interest in the costimulation pathways as targets for immune manipulation has exploded in recent years.[111] Generally, these agents interfere with pathways that act to influence the outcome of antigen binding to the TCR. Costimulatory molecules can exert positive or negative influences on the efficiency of antigen presentation and recognition and alter the threshold for activation of naive T lymphocytes without having a primary activating or inhibitory function. Costimulatory molecule manipulation influences only cells with ongoing TCR activation and should have effects only on cells actively undergoing antigen recognition; this has been thought to allow for antigen-specific immune manipulation.

The most studied costimulatory receptor on T cells is CD28. It has two known ligands, CD80 (B7-1) and CD86 (B7-2), both of which are expressed on APCs. CD28 is constitutively expressed on most T cells and on ligation reduces the threshold for TCR activation.[134] CD152 (cytotoxic T lymphocyte–associated antigen 4 [CTLA4]) is an induced molecule expressed on T cell activation that is structurally similar to CD28 and competitively binds CD80 and CD86, transmitting an inhibitory signal that acts to terminate the immune response.[307] CD28 and CD152 serve reciprocal roles, both stimulated by the B7 molecules and facilitating (CD28) or quelling (CD152) a T cell response.

An additional receptor ligand pair that has gained considerable attention involves CD40 and CD154. CD154, also known as CD40-ligand, is expressed on activated T cells and other cells, including platelets.[11,102,114,150] CD40 is expressed on APCs. Although the specific effect of CD154 on T cells is incompletely defined, CD40 has a major influence on APC activation. CD40 ligation leads to marked APC activation, including increased expression of the B7 molecules and MHC, and stimulatory cytokine production greatly facilitating antigen presentation.[46] CD154 expressed by activated platelets greatly augments alloimmune responses and can serve as the sole source of CD154 responsible for rejection.[319] CD154 exists as a large inducible reservoir that can be triggered by platelet activation and augment antigen presentation at the time of a traumatic injury, including a transplant procedure. Many other costimulatory molecules have been investigated, but none has yet been exploited as a target for clinical manipulation.[55]

Costimulatory molecules can be targeted with blocking MAbs to inhibit their stimulatory effects. Because it is difficult to determine prospectively whether a MAb is stimulatory or inhibitory in vivo, and because costimulatory molecules have stimulatory and inhibitory effects, it has been challenging to find therapeutically reliable agents. Because CD152 and CD154 are upregulated on activated T cells, these costimulatory molecules also may serve as targets for selective elimination of activated effector cells.[189]

Although most experimental use of MAbs directed against costimulatory molecules has focused on tolerance induction (elimination of a need for any maintenance therapy), the clinical focus has been on pairing costimulation-directed biologics with maintenance minimization strategies, particularly calcineurin-sparing approaches. Agents interfering with the CD28/B7 and the CD40/CD154 pathways have reached clinical trials, with the B7-specific agents being developed the most (discussed in depth subsequently). Two humanized MAbs specific for CD154, hu5c8 and IDEC-131, have been shown in nonhuman primates to prevent acute rejection for months to years without additional immunosuppression and have been paired with sirolimus monotherapy and donor-specific transfusion to lead to operational tolerance in some cases.[146,147,220,318] Early human trials with hu5c8 were hindered by unimpressive efficacy and concerns for thromboembolic risk.[142,148]

CD154-specific therapies have not been studied clinically in recent years, and most preclinical attention has turned toward intervention with CD40 as opposed to CD154.[5] Nevertheless, investigational interest in CD154 manipulation remains intense.

A cocktail of two humanized MAbs specific for the B7 molecules CD80 and CD86 has been shown to facilitate prolonged renal allograft survival in nonhuman primates.[149] These antibodies reached clinical trials in organ transplantation and were shown to have initial safety in humans. Their development has not been pursued. A similar approach has been exploited with the fusion protein belatacept (see later).[165]

Although there are many costimulation molecules that have been targeted in rodents with dramatic results, no MAbs have been successfully transitioned to the clinic. This situation likely relates to the fundamental role that costimulation molecules have in general immunity and immune homeostasis. In addition to the thromboembolic concerns, marked adverse reactions have been associated with costimulation-directed MAbs. Severe autoimmune enteritis and vasculitis have been triggered by a humanized antibody directed against CTLA4, showing that CTLA4 signaling and its resultant negative T cell regulation is vital to preserving a balance with the activating effects of CD28 signaling.[122] Similarly, severe septic-like responses have been reported after the administration of TGN1412, a CD28-specific MAb tested in phase I trials.[274] There seems to be a fundamental balance between the two B7-specific T cell molecules CD28 and CD152 that is required to avoid dysregulated autoimmunity.

Greater success has been achieved with agents that target the B7 molecules CD80 and CD86, providing inhibition of potential CD28 and CD152 signals; this has been achieved through the use of B7-specific fusion proteins.

B7-Directed Fusion Proteins

Two costimulation-based therapies that are immediately relevant to renal transplantation are fusion proteins combining the extracellular domain of CD152 (CTLA4), a costimulatory receptor that binds to the costimulatory molecules CD80 and CD86 (collectively known as the B7 molecules), and the Fc portion of IgG1.[165,174] It is crucial to recognize that CTLA4 fusion proteins do not bind to CTLA4, but rather bind with high affinity to the B7 molecules CD80 and CD86. In doing so, they inhibit CD28 and CD152 signaling, rather than having the unopposed CD28 or CD152 signaling that has been associated with adverse events. Although, theoretically, inhibiting both could lead to immunosuppression through inhibition of CD28/B7 interactions or immunostimulation through prevention of CD152/B7 interactions, in practice the effect seems to be immunosuppressive.

Abatacept is a direct fusion of the extracellular domain of CTLA4 to the Fc portion of IgG1 and has been studied extensively preclinically under the name CTLA4-Ig. Rodent studies have shown that administration of CTLA4-Ig can prevent allograft rejection.[172,292] Abatacept has been shown to delay modestly the onset of acute rejection up to 30 days when used in nonhuman primate models of renal transplantation.[146] Although not dramatic, this is similar to the efficacy of clinically used polyclonal antibodies and anti-CD25 therapies in primate models. Currently, abatacept is approved for use in the treatment of rheumatoid arthritis, but has not been developed further in transplantation.[97,190]

Belatacept is a second-generation form of abatacept that has been investigated preclinically under the name LEA29Y. It has been mutated to contain two amino acid substitutions (L104E and A29Y) to give slower dissociation rates for its binding to CD86 and CD80. It has been shown to prolong the onset of acute rejection in nonhuman primates and to synergize with basiliximab and other clinically available immunosuppressants. Given its superior performance in preclinical models relative to abatacept, belatacept has been developed in clinical renal transplantation. In a phase II study, belatacept was used in lieu of cyclosporine in combination with mycophenolate mofetil and prednisone and was shown to give similar acute rejection rates with improved renal function at 1 year and a lower incidence of effects typically attributed to cyclosporine.[302] Based on these promising results, phase III trials in renal transplantation have begun. This agent is likely to become the first costimulation blockade agent developed for transplantation and to make possible many mechanistically novel therapeutic approaches toward tolerance induction.

Belatacept is currently being developed with a specific intention to be used to facilitate calcineurin inhibitor avoidance in renal transplantation.[165,302] It is being specifically envisioned not only as an induction agent but also as the first biologic to be intended for use as maintenance immunosuppression. Given its tolerability and apparent efficacy in phase II trials, belatacept represents an amalgam of antibody-relevant technologies that have been combined to create a nondepletional, nonactivating, human protein construct that can be administered without inducing a neutralizing response.

Tumor Necrosis Factor-α–based Approaches

Sequestration of cytokines using MAbs has long been contemplated as a therapeutic strategy in many inflammatory diseases. Although many cytokine-specific agents have been developed, only TNF-α–specific agents have gained widespread clinical use. TNF-α is a cytokine produced by many immune cells that is ubiquitously present in most inflammatory responses and has numerous general proinflammatory effects, including increased chemotaxis, vascular permeability, and fever. It has been considered as an attractive target for many inflammatory aspects of transplantation, including depletion-associated cytokine release syndrome, ischemia-reperfusion injury, and rejection. Three TNF-α–specific agents are currently approved for nontransplant conditions, and their use in transplantation is emerging.

Infliximab is a chimeric IgG1 MAb that binds to cell-bound and circulating TNF-α, sequestering it from the TNF receptor and inhibiting TNF-dependent proinflammatory effects. It has been developed for the treatment of numerous autoimmune disorders, including rheumatoid arthritis (its primary approved clinical use), psoriasis, Crohn's disease, and ulcerative colitis.[257,312] It has been used in pilot studies of many transplant indications, including renal, bone marrow, intestinal, and islet transplantation with suggestive success. Its predominant therapeutic effect in transplantation seems to be to limit paracrine cytokine-mediated activation within the graft and to mute the clinical sequelae of rejection without altering the overall infiltrate of inciting allosensitization.[67,94,213]

Etanercept is a soluble recombinant TNF receptor–IgG fusion protein that acts to absorb soluble TNF-α and limit its availability in the circulation. It is approved for the treatment of rheumatoid arthritis and has been increasingly evaluated for a role in the treatment of graft-versus-host disease.[130] Use of etanercept in solid organ transplantation has not been reported. Similarly, adalimumab is a TNF-α–specific MAb that has been approved for the treatment of psoriatic arthritis.[312] Golimumab is a fully human TNF-α–specific MAb that is in phase II trials for rheumatoid arthritis. No reports have been made of use of these agents in transplantation, although there are more than 20 trials in autoimmune indications.[56]

PSGL1 (CD162)

PSGL1-Ig is a fusion protein combining the extracellular domains of P-selectin glycoprotein ligand-1 (CD162) with the Fc portion of IgG1. CD162 is a ligand for P-selectin, E-selectin, and L-selectin, all of which have been shown to facilitate leukocyte and platelet adhesion. Because cell adhesion has been implicated as a primary event in reperfusion injury and in allorecognition, this drug has been contemplated as a therapy to limit the impact of events occurring during initial implantation. Treatment with PSGL1-Ig has been shown to attenuate ischemia-reperfusion injury, most prominently in rodent models of hepatic warm ischemia.[41,85,88] This agent is currently in a phase I/II evaluation in kidney transplantation to determine its efficacy in preventing reperfusion injury.[56]

Other Experimental Antibodies and Fusion Proteins

Almost all surface molecules expressed by leukocytes have been considered for therapeutic targeting. Many have been formally investigated in early clinical trials without sufficient promise to warrant additional clinical development. Others have significant promise in advanced preclinical settings but have yet to be tested in humans. Knowledge of these agents is useful for a complete understanding of the field.

Targeting CD5

CD5 is an adhesion molecule that is constitutively expressed on T cells and a subset of B cells.[228] It binds to CD72 and is thought to regulate the intensity of antigen receptor signal transduction. Its primary function may be costimulatory or inhibitory, but mounting evidence suggests that it has a role in self-tolerance. XomaZyme-CD5 Plus (XomaZyme H65) is a ricin-conjugated CD5-specific MAb that has been evaluated in clinical trials to prevent graft-versus-host disease after bone marrow transplantation, without apparent efficacy.[181] As the biology of this molecule is better understood, its re-evaluation as a therapeutic target may be warranted.

Targeting CD6

The human CD6 is a cell surface glycoprotein expressed by T cells and a subset of B cells. It has been shown to act as a costimulatory molecule and can stimulate T cells when cross-linked with CD28.[210] Anti-CD6 MAbs inhibit the interaction of CD6 with its ligand, activated leukocyte cell adhesion molecule.[268] Anti-T12, an anti-CD6 MAb, has been evaluated clinically, but has not shown consistent efficacy.[154] More recently, an anti-CD6 has been used ex vivo to T cell deplete bone marrow before its use in marrow transplantation.[242]

Targeting CD7

CD7 is a cell surface costimulatory molecule expressed on human T and natural killer cells and on cells in the early stages of T, B, and myeloid cell differentiation.[247,272] Its expression is augmented on activated alloimmune-responsive T cells. CD7 has been thought to be an attractive target for MAbs, offering the possibility of alloimmune-activated T cell–specific depletion.

SDZCHH380 is a chimeric mouse antihuman CD7 IgG1 that has been studied in initial clinical renal transplant trials.[167] SDZCHH380 induction was prospectively compared with OKT3 induction with comparable results. At 4 years, SDZCHH380-treated patients had good allograft function and did not develop neutralizing antibodies.[252] Additional development has not been reported.

Targeting CD8

CD8 is a glycoprotein present on approximately one third of T cells in lieu of CD4. Similar to CD4, it binds to a monomorphic region MHC, although it binds to class I rather than class II antigens. CD8 defines cytotoxic effector cells and perhaps a subset of regulatory cells. It facilitates binding between the TCR and class I molecules and is important in protective immune lysis of virally infected parenchymal cells. $CD8^+$ T cells are known to infiltrate allografts and to participate in allograft rejection.[236] Despite this demonstrated role in rejection, CD8 has not been successfully targeted in transplantation, perhaps because $CD8^+$ T cells are recruited late in an alloimmune response and have less regulatory control over immune responses than $CD4^+$ T cells. The CD8-specific MAb anti-Leu2a has been shown to deplete peripheral blood $CD8^+$ cells in humans; however, when tested as a rescue agent, it had limited effects in reversing renal allograft rejection.[310] More recently, 76-2-11, a mouse anti-swine CD8-specific MAb, has been shown to delay the onset of cardiac allograft vasculopathy in a miniature swine model of cardiac transplantation, suggesting that there may be a limited role for this approach.[7] Additionally, ex vivo depletion of $CD8^+$ T cells with anti-Leu2a has been investigated as a means of reducing graft-versus-host disease with promising preliminary results.[204] Anti-CD8 induction has not been investigated clinically in solid organ transplantation.

Targeting CD45

CD45 is a transmembrane protein tyrosine phosphatase expressed on T cells. It is physically associated with the TCR and facilitates the signal transduction function of CD3 through interactions with the zeta and zeta-associated protein-70 components of CD3.[175] CD45 exists in several isoforms (CD45RA, CD45RB, and CD45RO) that result from RNA spliced variants, and these are differentially expressed on T cells with varying degrees of maturity and activation. Of these, CD45RB has been most aggressively targeted as T cells expressing high amounts of this isoform skewing toward an aggressive T helper type 1 phenotype. CD45RB-specific MAbs have been shown to induce transplant tolerance in some rodent models and to prolong the survival of nonhuman primate renal allografts significantly.[175] Several antibodies have entered phase I trials for lymphocytic leukemia,[56] and at least one humanized anti-CD45RB is anticipated to enter early-phase clinical trials in renal transplantation.[301] ChA6, a chimeric MAb binding CD45RB and CD45RO (an isotype found on memory T cells), has been shown to prevent islet allograft rejection in mice by deleting memory T cells and being permissive for the persistence of protolerant regulatory T cells.[104]

Targeting Cell Adhesion

Given the fundamental requirement for adhesion molecules in most inflammatory responses, there has been long-standing interest in blocking adhesion interactions to prevent lymphocyte infiltration. As discussed previously, polyclonal antibodies are thought to bind to and inhibit some adhesion molecules. Several MAbs have been developed to target adhesion pathways. Among the most prominent is the LFA-1/ICAM-1 pathway. LFA-1 (CD11a/CD18) is expressed on mature T cells and binds to ICAM-1 (CD54) expressed on APCs and endothelial cells.[180,238,265] The pathway greatly facilitates initial lymphocyte recruitment at sites of injury and inflammation.[196] Adhesion pathways have been studied in several preclinical settings, including rodents[129,225] and nonhuman primates,[24,66,138] with survival being markedly prolonged in rodents and prolonged 30 days in primates.

Enlimomab, a murine anti-CD54 MAb, was successfully tested in a phase I trial involving high-risk deceased donor kidneys[112] and subsequently evaluated in a placebo-controlled phase II study combined with conventional triple-drug maintenance therapy.[241] No significant difference was detected between the treated and the placebo groups, and further development was not pursued. Similarly, odulimomab,

a murine anti-LFA-1 MAb, was studied as an induction agent compared with R-ATG in renal transplantation, with no significant difference being found between the groups.[125] A single rescue trial using the anti-LFA-1 murine MAb 25-3 failed to show efficacy.[171]

Efalizumab (Raptiva) is a recombinant humanized MAb that binds to human CD11a and inhibits the LFA-1/ICAM-1 interaction.[77,202] Efalizumab has been tested in phase I studies for renal transplantation and is currently in one clinical trial for islet transplantation to improve initial engraftment and function.[56] It is now approved by the Food and Drug Administration for treatment of mild-to-moderate psoriasis.

Targeting the T Cell Receptor

T cells bind their cognate antigen through their heterodimeric glycoprotein TCR. There are two general forms, an α/β form, expressed on 95% of peripheral T cells and responsible for specifying most alloimmune responses, and a γ/δ form, which is involved in innate immune responses and appears late in allograft rejection.[145] The TCR is a result of somatic gene rearrangement similar to that seen in antibody formation, and the specificity of each T cell can be defined by its individual TCR. Rejections based on specific TCR/MHC interactions select for specific TCR types showing that each MHC mismatch is recognized by a few clones, rather than by the entire T cell repertoire.[109] Although this finding fostered initial enthusiasm for targeting antigen-specific T cells through custom MAbs specific for a given TCR, this approach has been deemed impractical given the vast number of TCRs generated during T cell maturation and their variable cross-reactivity with variable MHC polymorphisms. Nevertheless, the success of targeting TCR-associated proteins such as CD3 has generated some interest in targeting monomorphic portions of the TCR directly. More recently, the realization that TCR signaling is required for T cell apoptosis and regulation has made preservation of the TCR a competing strategy.

T10B9, also known as Medi-500, is a murine IgM specific for a monomorphic determinant on α/β and γ/δ TCRs. It is effective in mediating T cell depletion in vitro and in vivo[34] and has been studied as a rescue and induction agent in renal and cardiac transplantation.[303,304] In both trials, the antibody-mediated T cell depletion was well tolerated. Its efficacy as a rescue agent seemed to be similar to that of OKT3, and the cardiac trial suggested efficacy as an induction agent. Nevertheless, the agent has not been developed further in organ transplantation, likely as a result of comparably effective humanized MAbs. T10B9 has been studied as a conditioning agent of bone marrow transplantation,[288] and a phase III trial using T10B9 as an ex vivo depletional agent for bone marrow transplantation has been completed.[56]

Targeting Complement

Proteins of the complement cascade have long been known to be crucial in mediating antibody-associated cytotoxicity.[60] Many approaches have been contemplated to achieve complement elimination in the setting of antibody presensitization, including plasmapheresis and intravenous immunoglobulin administration. More recently, it has been shown that complement, specifically that produced locally within the kidney itself, is a contributing factor facilitating peripheral T cell maturation and rejection.[219] Polymorphisms in complement expression have been shown to influence the incidence of rejection and renal allograft survival in ways not previously recognized.[35]

Two complement-specific agents have been used clinically and have been shown to be biologically active with promise for application in transplantation. Eculizumab is a humanized MAb specific for C5a, a key initiation factor in complement membrane attack complex formation. It has been shown to be a potentially effective therapy for paroxysmal nocturnal hemoglobinuria and is currently in phase III trials for this indication.[56,120] TP-10 (soluble complement receptor type 3) is a recombinant soluble protein that binds and inactivates the central activating component of the complement cascade, C3. It has been used in numerous preclinical settings and shown to be effective in preventing humoral xenograft rejection in a pig-to-nonhuman primate model.[223] It is currently being investigated in a clinical trial for its role in preventing cardiopulmonary bypass–related complications.[56]

Immunotoxins

Antibodies that have been joined either chemically or genetically with a specific cytotoxic agent (e.g., ricin or diphtheria toxin) have been termed immunotoxins.[163] These compounds have the specificity of MAbs but can exert a cytotoxic effect beyond that related to complement or ADCC. Many immunotoxins are now being investigated as tumor-specific cytotoxic agents for malignancies and have been shown to have potent antitumor effects. Two CD25-specific immunotoxins currently in clinical trials for lymphoblastic leukemia, LMB-2 and RFT5.dgA, have shown the ability to clear $CD25^+$ cells effectively from the circulation.[12,56,162] These agents could be envisioned to perform in a means analogous to the CD25-specific MAbs currently available, with a more potent depletional effect rather than acting predominantly through steric inhibition of CD25. Similarly, a CD22-specific immunotoxin is in trials for $CD22^+$ lymphoblastic leukemia and might be envisioned as an agent similar to other B cell–specific MAbs such as rituximab.[56,245]

Although immunotoxins have not been clinically tested in transplantation, ample preclinical data suggest that they have great therapeutic potential. Specifically, a macaque CD3-specific diphtheria immunotoxin, FN18-CRM9, has been used in nonhuman primate renal transplantation with remarkable success.[156,287] Treatment with FN18-CRM9 induces a rapid 3-log–fold depletion of T cells in the peripheral circulation and in the secondary lymphoid organs. Rhesus monkeys so treated before transplantation experience markedly prolonged allograft survival with no other maintenance immunosuppression, and a significant proportion survive for years after T cell repopulation. Although most of these animals eventually develop chronic allograft nephropathy,[290] the induction effect is impressive, and it has served as the conceptual inspiration for many clinical trials using T cell depletion.[39,151,157] Because most adults have antibodies against diphtheria toxin, this approach has not been successfully transferred to a human-specific MAb. Nevertheless, this is a promising approach for future development.

CONCLUSION

Antibodies are now established as valuable agents for the treatment and prevention of allograft rejection.

Currently, several polyclonal and monoclonal anti–T cell antibodies have proven roles in the treatment of steroid-resistant acute rejection. The last decade has seen increasing justification for the use of antibodies as induction agents. Antibody induction has been shown to be an effective means of achieving very low rates of acute rejection in renal transplantation. The trials performed to date have shown, however, that antibodies produce a modest benefit over regimens with calcineurin inhibitors, antiproliferative agents, and steroids, or that they are associated with increased morbidity. Nevertheless, it is appropriate to consider antibody induction as emerging from an adolescence of sorts, and less morbid target strategies and reduced maintenance regimens are expected to improve the side-effect profile of antibody induction schemes.

The optimal use of antibody induction is still being determined, but it is increasingly clear that the benefits derived from antibodies will be determined by their appropriate application. Modern immunosuppressive regimens should be individualized, specifically pairing induction agents based on their mechanism of action to a specific clinical need, and combining them with complementary maintenance therapies.

The future of transplantation continues to be cloaked by a need for more specific therapies with broader therapeutic indices. Antibodies are highly specific and have proved to be safe and effective drugs whose side effects are generally confined to the specific effects of the target antigen bound. Although the early hopes of clinicians have been slow to materialize, the technology associated with antibody design, construction, and production have consistently improved to yield a diverse array of agents to be tested and added to the transplant armamentarium. The future is likely to see almost exclusive use of humanized or human antibodies and fusion proteins as opposed to xenogeneic protein constructs. Past problems of antigenicity and severe cytokine release effects are surmountable, and as the targeted antigens become more rationally selected based on growing understanding of biology, antibodies and fusion proteins are expected to continue to establish themselves as crucial agents not only for induction and rescue but also, importantly, for maintenance therapy. Trials are beginning to explore this facet of antibody and fusion protein administration. Additionally, the use of antibody combinations may become an attractive way of manipulating the immune response. Transplant clinicians will need to become increasingly aware of immune therapies developed for autoimmune and malignant indications.
